We also conduct multimodal experiments where we combine linguistic and acoustic features using either early fusion by concatenating all the feature vectors, or late fusion by aggregating the outputs of each classifier using a rule-based score level fusion that assigns a weight of 0.8 to the linguistic classifier, and 0.2 to the acoustic classifier.[10]

Overall, the results show performance gains when using late fusion as compared to early fusion. While the late fusion model does not outperform the best linguistic model in terms of accuracy and high empathy F-score, the multimodal late fusion classifier has significantly better F-score performance in the classification of low empathy encounters, thus suggesting potential benefits of fus-

ing acoustic and linguistic cues during the prediction of counselor empathy.

8 Conclusions

In this paper, we presented an extensive analysis of counselors and clients behaviors during MI encounters, and found significant differences in the way counselors and clients behave during high and low empathy encounters. We specifically explored the engagement, coordination, and discourse of counselors during MI interventions. Our main findings include:

Engagement: Empathic counselors show more engagement during the conversation by a) showing levels of verbal interaction consistent with their client, and b) reducing their relative talking time with clients.

Coordination: Empathic counselors match the linguistic style of their clients across the session, but maintain control of the conversation by coordinating less at immediate conversation turn-level.

Conversation content: Empathic counselors use reflective language and talk about behavior change, while less empathic counselors persuade more and focus on client resistance toward change.

The results of these analyses were used to build accurate counselor empathy classifiers that rely on linguistic and acoustic cues, with accuracies of up to 80%.

In the future, we plan to build upon the acquired knowledge and the developed classifiers to create automatic tools that provide accurate evaluative feedback of counseling practice.

Leveraging Knowledge Bases in LSTMs for Improving Machine Reading

Abstract

This paper focuses on how to take advantage of external knowledge bases (KBs) to improve recurrent neural networks for machine reading. Traditional methods that exploit knowledge from KBs encode knowledge as discrete indicator features. Not only do these features generalize poorly, but they require task-specific feature engineering to achieve good performance. We propose KBLSTM, a novel neural model that leverages continuous representations of KBs to enhance the learning of recurrent neural networks for machine reading. To effectively integrate background knowledge with information from the currently processed text, our model employs an attention mechanism with a sentinel to adaptively decide whether to attend to background knowledge and which information from KBs is useful. Experimental results show that our model achieves accuracies that surpass the previous state-of-the-art results for both entity extraction and event extraction on the widely used ACE2005 dataset.

1 Introduction

Recurrent neural networks (RNNs), a neural architecture that can operate over text sequentially, have shown great success in addressing a wide range of natural language processing problems, such as parsing (Dyer et al., 2015), named entity recognition (Lample et al., 2016), and semantic role labeling (Zhou and Xu, 2015)). These neural networks are typically trained end-to-end where the input is only text or a sequence of words and a lot of background knowledge is disregarded.

The importance of background knowledge in natural language understanding has long been recognized (Minsky, 1988; Fillmore, 1976). Earlier NLP systems mostly exploited restricted linguistic knowledge such as manually-encoded morphological and syntactic patterns. With the advanced development of knowledge base construction, large amounts of semantic knowledge become available, ranging from manually annotated semantic networks like WordNet [1] to semi-automatically or automatically constructed knowledge graphs like DBPedia [2] and NELL [3]. While traditional approaches have exploited the use of these knowledge bases (KBs) in NLP tasks (Ratinov and Roth, 2009; Rahman and Ng, 2011; Nakashole and Mitchell, 2015), they require a lot of task-specific engineering to achieve good performance.

One way to leverage KBs in recurrent neural networks is by augmenting the dense representations of the networks with the symbolic features derived from KBs. This is not ideal as the symbolic features have poor generalization ability. In addition, they can be highly sparse, e.g., using WordNet synsets can easily produce millions of indicator features, leading to high computational cost. Furthermore, the usefulness of knowledge features varies across contexts, as general KBs involve polysemy, e.g., "Clinton" can refer to a person or a town. Incorporating KBs irrespective of the textual context could mislead the machine reading process.

Can we train a recurrent neural network that learns to adaptively leverage knowledge from KBs to improve machine reading? In this paper, we propose KBLSTM, an extension to bidirec-

tional Long Short-Term Memory neural networks (BiLSTMs) (Hochreiter and Schmidhuber, 1997; Graves et al., 2005) that is capable of leveraging symbolic knowledge from KBs as it processes each word in the text. At each time step, the model retrieves KB concepts that are potentially related to the current word. Then, an attention mechanism is employed to dynamically model their semantic relevance to the reading context. Furthermore, we introduce a sentinel component in BiLSTMs that allows flexibility in deciding whether to attend to background knowledge or not. This is crucial because in some cases the text context should override the context-independent background knowledge available in general KBs.

In this work, we leverage two general, readily available knowledge bases: WordNet (WordNet, 2010) and NELL (Mitchell et al., 2015). WordNet is a manually created lexical database that organizes a large number of English words into sets of synonyms (i.e. synsets) and records conceptual relations (e.g., hypernym, part_of) among them. NELL is an automatically constructed web-based knowledge base that stores beliefs about entities. It is organized based on an ontology of hundreds of semantic categories (e.g., person, fruit, sport) and relations (e.g., personPlaysInstrument). We learn distributed representations (i.e., embeddings) of WordNet and NELL concepts using knowledge graph embedding methods. We then integrate these learned embeddings with the state vectors of the BiLSTM network to enable knowledge-aware predictions.

We evaluate the proposed model on two core information extraction tasks: entity extraction and event extraction. For entity extraction, the model needs to recognize all mentions of entities such as person, organization, location, and other things from text. For event extraction, the model is required to identify event mentions or event triggers[4] that express certain types of events, e.g., elections, attacks, and travels. Both tasks are challenging and often require the combination of background knowledge and the text context for accurate prediction. For example, in the sentence "Maigret left viewers in tears.", knowing that "Maigret" can refer to a TV show can greatly help disambiguate its meaning. However, knowledge bases may hurt performance if used blindly. For example, in the sentence "Santiago is charged with murder.", methods that rely heavily on KBs are likely to interpret "Santiago" as a location due to the popular use of Santiago as a city. Similarly for events, the same word can trigger different types of events, for example, "release" can be used to describe different events ranging from book publishing to parole. It is important for machine learning models to learn to decide which knowledge from KBs is relevant given the context.

Extensive experiments demonstrate that our KBLSTM models effectively leverage background knowledge from KBs in training BiLSTM networks for machine reading. They achieve significant improvement on both entity and event extraction compared to traditional feature-based methods and LSTM networks that disregard knowledge in KBs, resulting in new state-of-the-art results for entity extraction and event extraction on the widely used ACE2005 dataset.

2 Related Work

Essential to RNNs' success on natural language processing is the use of Long Short-Term Memory neural networks (Hochreiter and Schmidhuber, 1997) (LSTMs) or Gated Recurrent Unit (Cho et al., 2014) (GRU) as they are able to handle long-term dependencies by adaptively memorizing values for either long or short durations. Their bidirectional variants BiLSTM (Graves et al., 2005) or BiGRU further allow the incorporation of both past and future information. Such ability has been shown to be generally helpful in various NLP tasks such as named entity recognition (Huang et al., 2015; Chiu and Nichols, 2016; Ma and Hovy, 2016), semantic role labeling (Zhou and Xu, 2015), and reading comprehension (Hermann et al., 2015; Chen et al., 2016). In this work, we also employ the BiLSTM architecture.

In parallel to the development for text processing, neural networks have been successfully used to learn distributed representations of structured knowledge from large KBs (Bordes et al., 2011, 2013; Socher et al., 2013; Yang et al., 2015; Guu et al., 2015). Embedding the symbolic representations into continuous space not only makes KBs more easy to use in statistical learning approaches, but also offers strong generalization ability. Many attempts have been made on connecting distributed representations of KBs with text in the

[4] An event also consists of participants whose types depend on the event triggers. In this work, we focus on predicting event triggers and leave the prediction of event participants for future work.

context of knowledge base completion (Lao et al., 2011; Gardner et al., 2014; Toutanova et al., 2015), relation extraction (Weston et al., 2013; Chang et al., 2014; Riedel et al., 2013), and question answering (Miller et al., 2016). However, these approaches model text using shallow representations such as subject/relation/object triples or bag of words. More recently, Ahn et al. (2016) proposed a neural knowledge language model that leverages knowledge bases in RNN language models, which allows for better representations of words for language modeling. Unlike their work, we leverage knowledge bases in LSTMs and applies it to information extraction.

The architecture of our KBLSTM model draws on the development of attention mechanisms that are widely employed in tasks such as machine translation (Bahdanau et al., 2015) and image captioning (Xu et al., 2015). Attention allows the neural networks to dynamically attend to salient features of the input. With a similar motivation, we employ attention in KBLSTMs to allow for dynamic attention to the relevant knowledge given the text context. Our model is also closely related to a recent model of caption generation introduced by Lu et al. (2017), where a visual sentinel is introduced to allow the decoder to decide whether to attend to image information when generating the next word. In our model, we introduce a sentinel to control the tradeoff between background knowledge and information from the text.

3 Method

In this section, we present our KBLSTM model. We first describe several basic recurrent neural network frameworks for machine reading, including basic RNNs, LSTMs, and bidirectional LSTMs (Sec. § 3.1). We then introduce our extension to bidirectional LSTMs that allows for the incorporation of KB information at each time step of reading (Sec. § 3.2). The KB information is encoded using continuous representations (i.e., embeddings) which are learned using knowledge embedding methods (Sec. § 3.3).

3.1 RNNs, LSTMs, and Bidirectional LSTMs

RNNs are a class of neural networks that take a sequence of inputs and compute a hidden state vector at each time step based on the current input and the entire history of inputs. The hidden state vector can be computed recursively using the following equation (Elman, 1990):

$$\mathbf{h}_t = F(\mathbf{W}\mathbf{h}_{t-1} + \mathbf{U}\mathbf{x}_t)$$

where $\mathbf{x}_t$ is the input at time step t, $\mathbf{h}_t$ is the hidden state at time step t, $\mathbf{U}$ and $\mathbf{W}$ are weight matrices, and F is a nonlinear function such as tanh or ReLu. Depending on the applications, RNNs can produce outputs based on the hidden state of each time step or just the last time step.

A Long Short-Term Memory network (Hochreiter and Schmidhuber, 1997) (LSTM) is a variant of RNNs which was design to better handle cases where the output at time t depends on much earlier inputs. It has a memory cell and three gating units: an input gate that controls what information to add to the current memory, a forget gate which controls what information to remove from the previous memory, and an output gate which controls what information to output from the current memory. Each gate is implemented as a logistic function σ that takes as input the previous hidden state and the current input, and outputs values between 0 and 1. Multiplication with these values controls the flow of information into or out of the memory. In equations, the updates at each time step t are:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_i\mathbf{h}_{t-1} + \mathbf{U}_i\mathbf{x}_t) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_f\mathbf{h}_{t-1} + \mathbf{U}_f\mathbf{x}_t) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_o\mathbf{h}_{t-1} + \mathbf{U}_o\mathbf{x}_t) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot tanh(\mathbf{W}_c\mathbf{h}_{t-1} + \mathbf{U}_c\mathbf{x}_t) \\
\mathbf{h}_t &= \mathbf{o}_t \odot tanh(\mathbf{c}_t)
\end{aligned}$$

where $\mathbf{i}_t$ is the input gate, $\mathbf{f}_t$ is the forget gate, $\mathbf{o}_t$ is the output gate, $\mathbf{c}_t$ is the memory cell, and $\mathbf{h}_t$ is the hidden state. $\odot$ denotes element-wise multiplication. $\mathbf{W}_i, \mathbf{U}_i, \mathbf{W}_f, \mathbf{U}_f, \mathbf{W}_o, \mathbf{U}_o, \mathbf{W}_c, \mathbf{U}_c$ are weight matrices to be learned.

Bidirectional LSTMs (Graves et al., 2005) (BiLSTMs) are essentially a combination of two LSTMs in two directions: one operates in the forward direction and the other operates in the backward direction. This leads to two hidden states $\overrightarrow{\mathbf{h}_t}$ and $\overleftarrow{\mathbf{h}_t}$ at time step t, which can be viewed as a summary of the past and the future respectively. Their concatenation $\mathbf{h}_t = [\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}]$ provides a whole summary of the information about the input around time step t. Such property is attractive in NLP tasks, since information of both previous words and future words can be helpful for interpreting the meaning of the current word.

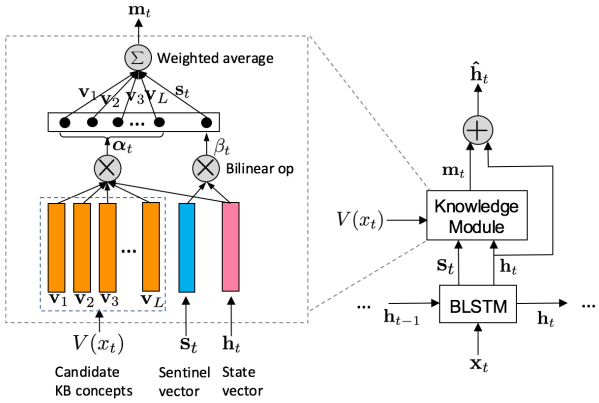

Figure 1: Architecture of the KBLSTM model. As each time step t, the knowledge module retrieves a set of candidate KB concepts $V(x_t)$ that are related to the current input x_t, and then computes a knowledge state vector $\mathbf{m}_t$ that integrates the embeddings of the candidate KB concepts $\mathbf{v}_1, \mathbf{v}_2, ..., \mathbf{v}_L$ and the current context vector $\mathbf{s}_t$. See Section § 3.2 for details.

3.2 Knowledge-aware Bidirectional LSTMs

Our model (referred to as KBLSTM) extends BiLSTMs to allow flexibility in incorporating symbolic knowledge from KBs. Instead of encoding knowledge as discrete features, we encode it using continuous representations. Concretely, we learn embeddings of concepts in KBs using a knowledge graph embedding method. (We will describe the details in Section § 3.3). The KBLSTM model then retrieves the embeddings of candidate concepts that are related to the current word being processed and integrates them into its state vector to make knowledge-aware predictions. Figure 1 depicts the architecture of our model.

The core of our model is the knowledge module, which is responsible for transferring background knowledge into the BiLSTMs. The knowledge at time step t consists of candidate KB concepts $V(x_t)$ for input x_t. (We will describe how to obtain the candidate KB concepts from NELL and WordNet in Section § 3.3). Each candidate KB concept $i \in V(x_t)$ is associated with a vector embedding $\mathbf{v}_i$. We compute an attention weight α_{ti} for concept vector $\mathbf{v}_i$ via a bilinear operator, which reflects how relevant or important concept i is to the current reading context $\mathbf{h}_t$:

$$\alpha_{ti} \propto \exp(\mathbf{v}_i^T \mathbf{W}_v \mathbf{h}_t) \quad (1)$$

where $\mathbf{W}_v$ is a parameter matrix to be learned.

Note that the candidate concepts in some cases are misleading. For example, a KB may store the fact that "Santiago" is a city but miss the fact that it can also refer to a person. Incorporating such knowledge in the sentence "Santiago is charged with murder." could be misleading. To address this issue, we introduce a knowledge sentinel that records the information of the current context and use a mixture model to allow for better tradeoff between the impact of background knowledge and information from the context. Specifically, we compute a sentinel vector $\mathbf{s}_t$ as:

$$\mathbf{b}_t = \sigma(\mathbf{W}_b \mathbf{h}_{t-1} + \mathbf{U}_b \mathbf{x}_t) \quad (2)$$

$$\mathbf{s}_t = \mathbf{b}_t \odot tanh(\mathbf{c}_t) \quad (3)$$

where $\mathbf{W}_b$ and $\mathbf{U}_b$ are weight parameters to be learned. The weight on the local context is computed as:

$$\beta_t \propto \exp(\mathbf{s}_t^T \mathbf{W}_s \mathbf{h}_t) \quad (4)$$

where $\mathbf{W}_s$ is a parameter matrix to be learned. The mixture model is defined as:

$$\mathbf{m}_t = \sum_{i \in V(x_t)} \alpha_{ti} \mathbf{v}_i + \beta_t \mathbf{s}_t \quad (5)$$

where $\sum_{i \in V(x_t)} \alpha_{ti} + \beta_t = 1$. $\mathbf{m}_t$ can be viewed as a knowledge state vector that encodes external KB information with respect to the input at time t. We combine it with the state vector $\mathbf{h}_t$ of BiLSTMs to obtain a knowledge-aware state vector $\hat{\mathbf{h}}_t$:

$$\hat{\mathbf{h}}_t = \mathbf{h}_t + \mathbf{m}_t \quad (6)$$

If $V(x_t) = \emptyset$, we set $\mathbf{m}_t = 0$. $\hat{\mathbf{h}}_t$ can be used for predictions in the same way as the original state vector $\mathbf{h}_t$ (see Section § 4 for details).

3.3 Embedding Knowledge Base Concepts

Now we describe how to learn embeddings of concepts in KBs. We consider two KBs: WordNet and NELL, which are both knowledge graphs that can be stored in the form of RDF[5] triples. Each triple consists of a subject entity, a relation, and an object entity. Examples of triples in WordNet are (*location*, *hypernym_of*, *city*), and (*door*, *has_part*, *lock*), where both the subject and object entities are synsets in WordNet. Examples of triples in NELL are (*New York*, *located_in*, *United States*)

[5] https://www.w3.org/TR/rdf11-concepts/

and (*New York*, *is_a*, *city*), where the subject entity is a noun phrase that can refer to a real-world entity and the object entity can be either a noun phrase entity or a concept category.

In this work, we refer to the synsets in WordNet and the concept categories in NELL as *KB concepts*. They are the key components of the ontologies and provide generally useful information for language understanding. As our KBLSTM model reads through each word in a sentence, it retrieves knowledge from NELL by searching for entities with the current word and collecting the related concept categories as candidate concepts; and it retrieves knowledge from WordNet by treating the synsets of the current word as candidate concepts.

We employ a knowledge graph embedding approach to learn the representations of the candidate concepts. Denote a KB triple as (e_1, r, e_2), we want to learn embeddings of the subject entity e_1, the object entity e_2, and the relation r, so that the relevance of the triple can be measured by a scoring function based on the embeddings. We employ the BILINEAR model described in (Yang et al., 2015).[6] It computes the score of a triple (e_1, r, e_2) via a bilinear function: $S_{(e_1,r,e_2)} = \mathbf{v}_{e_1}^T \mathbf{M}_r \mathbf{v}_{e_2}$, where $\mathbf{v}_{e_1}$ and $\mathbf{v}_{e_2}$ are vector embeddings for e_1 and e_2 respectively, and $\mathbf{M}_r$ is a relation-specific embedding matrix. We train the embeddings using the max-margin ranking objective:

$$\sum_{q=(e_1,r,e_2)\in\mathcal{T}} \sum_{q'=(e_1,r,e_2')\in\mathcal{T}'} \max\{0, 1 - S_q + S_{q'}\} \tag{7}$$

where $\mathcal{T}$ denotes the set of triples in the KB and $\mathcal{T}'$ denotes the "negative" triples that are not observed in the KB.

For WordNet, we train the concept embeddings using the preprocessed data provided by (Bordes et al., 2013), which contains 151,442 triples with 40,943 synsets and 18 relations. We use the same data splits for training, development, and testing. During training, we use AdaGrad (Duchi et al., 2011) to optimize objective 7 with an initial learning rate of 0.05 and a mini-batch size of 100. At each gradient step, we sample 10 negative object entities with respect to the positive triple. Our implementation of the BILINEAR model achieves top-10 accuracy of 91% for predicting missing object entities on the WordNet test set, which is comparable with previous work (Yang et al., 2015).

For NELL, we train the concept embeddings using a subset of the NELL data[7]. We filter noun phrases with annotation confidence less than 0.9 in order to remove erroneous labels introduced during the automatic construction of NELL (Wijaya, 2016). This results in 180,107 noun phrases and 258 concept categories in total. We randomly split 80% of the data for training, 10% for development and 10% for testing. For each training example, we enumerate all the unobserved concept categories as negative labels. Instead of treating each entity as a unit, we represent it as an average of its constituting word vectors concatenated with its head word vector. The word vectors are initialized with pre-trained paraphrastic embeddings (Wieting et al., 2015) and fine-tuned during training. Using the same optimization parameters as before, the BILINEAR model achieves 88% top-1 accuracy for predicting concept categories of given noun phrases on the test set.

4 Experiments

4.1 Entity Extraction

We first apply our model to entity extraction, a task that is typically addressed by assigning each word/token BIO labels ($Begin$, $Inside$, and $Outside$) (Ratinov and Roth, 2009) indicating the token's position within an entity mention as well as its entity type.

To allow tagging over phrases instead of words, we address entity extraction in two steps. The first step detects mention chunks, and the second step assigns entity type labels to mention chunks (including an O type indicating *other* types). In the first stage, we train a BiLSTM network with a conditional random field objective (Huang et al., 2015) using gold-standard BIO labels regardless of entity types, and only predict each token's position within an entity mention. This produces a sequence of chunks for each sentence. In the second stage, we train another supervised BiLSTM model to predict type labels for the previously extracted chunks. Each chunk is treated as a unit input to the BiLSTMs and the input vector is computed by averaging the input vectors of individual words within the chunk concatenated with its head word vector. The BiLSTMs can be trained

[6] We also experimented with TransE (Bordes et al., 2013) and NTN (Socher et al., 2013), and found that they perform significantly worse than the Bilinear method, especially on predicting the "is_a" facts in NELL.

[7] http://rtw.ml.cmu.edu/rtw/resources

with a softmax objective that minimizes the cross-entropy loss for each individual chunk. It computes the probability of the correct type for each chunk:

$$p_{y_t} = \frac{\exp(\mathbf{w}_{y_t}^T \mathbf{h}_t)}{\sum_{y'_t} \exp(\mathbf{w}_{y'_t}^T \mathbf{h}_t)} \quad (8)$$

The BiLSTMs can also be trained with a CRF objective (referred to as BiLSTM-CRF) that minimizes the negative log-likelihood for the entire sequence. It computes the probability of the correct types for a sequence of chunks:

$$p_{\mathbf{y}} = \frac{\exp(g(\mathbf{x}, \mathbf{y}))}{\sum_{\mathbf{y}'} \exp(g(\mathbf{x}, \mathbf{y}'))} \quad (9)$$

where $g(\mathbf{x}, \mathbf{y}) = \sum_{t=1}^{l} P_{t,y_t} + \sum_{t=0}^{l} A_{y_t,y_{t+1}}$, $P_{t,y_t} = \mathbf{w}_{y_t}^T \mathbf{h}_t$ is the score of assigning the t-th chunk with tag y_t and $A_{y_t,y_{t+1}}$ is the score of transitioning from tag y_t to y_{t+1}. By replacing $\mathbf{h}_t$ in Eq. 8 and Eq. 9 with the knowledge-aware state vector $\hat{\mathbf{h}}_t$ (Eq. 6), we can compute the objective for KBLSTM and KBLSTM-CRF respectively.

4.1.1 Implementation Details

We evaluate our models on the ACE2005 corpus (LDC, 2005) and the OntoNotes 5.0 corpus (Hovy et al., 2006) for entity extraction. Both datasets consist of text from a variety of sources such as newswire, broadcast conversations, and web text. We use the same data splits and task settings for ACE2005 as in Li et al. (2014) and for OntoNotes 5.0 as in Durrett and Klein (2014).

At each time step, our models take as input a word vector and a capitalization feature (Chiu and Nichols, 2016). We initialize the word vectors using pretrained paraphrastic embeddings (Wieting et al., 2015), as we find that they significantly outperforms randomly initialized embeddings. The word embeddings are fine-tuned during training. For the KBLSTM models, we obtain the embeddings of KB concepts from NELL and WordNet as described in Section § 3.3. These embeddings are kept fix during training.

We implement all the models using Theano on a single GPU. We update the model parameters on every training example using Adam with default settings (Kingma and Ba, 2014) and apply dropout to the input layer of the BiLSTM with a rate of 0.5. The word embedding dimension is set to 300 and the hidden vector dimension is set to 100. We train models on ACE2005 for about 5 epochs and on OntoNotes 5.0 for about 10 epochs with early stopping based on development results.

For each experiment, we report the average results over 10 random runs. We also apply the Wilcoxon rank sum test to compare our models with the baseline models.

Model	P	R	F1

Table 1: Entity extraction results on the ACE2005 test set with gold-standard mention boundaries.

4.1.2 Results

We compare our KBLSTM and KBLSTM-CRF models with the following baselines: BiLSTM, a vanilla BiLSTM network trained using the same input, and BiLSTM-Fea, a BiLSTM network that combines its hidden state vector with discrete KB features (i.e., indicators of candidate KB concepts) to produce the final state vector. We also include their variants BiLSTM-CRF and BiLSTM-Fea-CRF, which are trained using the CRF objective instead of the standard softmax objective.

We first report results on entity extraction with gold-standard boundaries for multi-word mentions. This allows us to focus on the performance of entity type prediction without considering mention boundary errors and the noise they introduce in retrieving candidate KB concepts. Table 1 shows the results.[8] We find that the CRF objective generally outperforms the softmax objective. Our KBLSTM-CRF model significantly improves over its counterpart BiLSTM-Fea-CRF. This demonstrates the effectiveness of KBLSTM architecture in leveraging KB information.

Table 2 breaks down the results of the KBLSTM-CRF and the BiLSTM-Fea-CRF using different KB settings. We find that the KBLSTM-CRF outperforms the BiLSTM-Fea-CRF in all the settings and that incorporating both KBs leads to the best performance.

Next, we evaluate our models on entity extraction with predicted mention boundaries. We first train a BiLSTM-CRF to perform mention

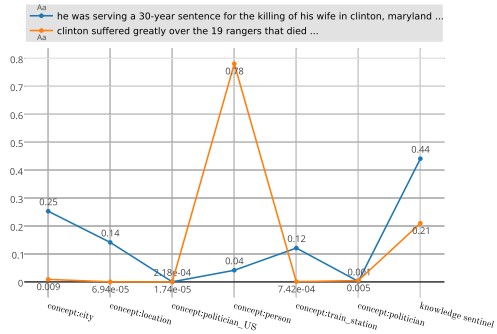
chunking using the same setting as described in Section 4.1.1. We then treat the predicted chunks as units for entity type labeling. Table 3 reports the full entity extraction results on the ACE2005 test set. We compare our models with the state-of-the-art feature-based linear models Li et al. (2014), Yang and Mitchell (2016), and the recently proposed sequence- and tree-structured LSTMs (Miwa and Bansal, 2016). Interestingly, we find that using BiLSTM-CRF without any KB information already gives strong performance compared to previous work. The KBLSTM-CRF model demonstrates the best performance among all the models and achieves the new state-of-the-art performance on the ACE2005 dataset.

We also report the entity extraction results on the OntoNotes 5.0 test set in Table 4. We compare our models with the existing feature-based models Ratinov and Roth (2009) and Durrett and Klein (2014), which both employ heavy feature engineering to bring in external knowledge. BiLSTM-CNN (Chiu and Nichols, 2016) employs a hybrid BiLSTM and Convolutional neural network (CNN) architecture and incorporates rich lexicon features derived from SENNA and DBPedia. Our KBLSTM-CRF model shows competitive results compared to their results. It also presents significant improvements compared to the BiLSTM and BiLSTM-Fea models. Note that the benefit of adding KB information is smaller on OntoNotes compared to ACE2005. We believe that there are two main reasons. One is that NELL has a lower coverage of entity mentions in OntoNotes than in ACE2005 (57% vs. 65%). Second, OntoNotes has a significantly larger amount of training data, which allows for more accurate models without much help from external resources.

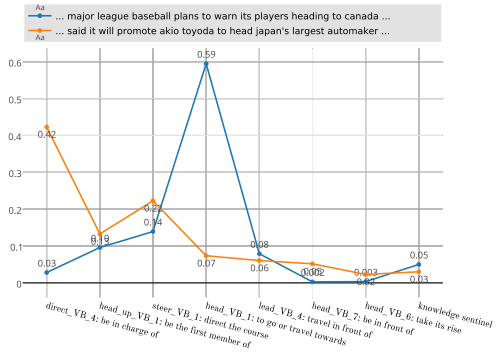
4.2 Event Extraction

We now apply our model to the task of event extraction. Event extraction is concerned with detecting *event triggers*, i.e., a word that expresses the occurrence of a pre-defined type of event. Event triggers are mostly verbs and eventive nouns but can occasionally be adjectives and other content words. Therefore, the task is typically addressed as a classification problem where the goal is to label each word in a sentence with an event type or an O type if it does not express any of the defined events. It is straightforward to apply the BiLSTM architecture to event extraction. Similarly to the models for entity extraction, we can train the BiLSTM network with both the softmax objective and the CRF objective.

We evaluate our models on the portion ACE2005 corpus that has event annotations. We use the same data split and experimental setting as in Li et al. (2013). The training procedure is the same as in Section 4.1.1, and we train all the models for about 5 epochs. For the KBLSTM models, we integrate the learned embeddings of WordNet synsets during training.



(a) The X-axis represents relevant NELL concepts for the entity mention **clinton**. The Y-axis represents the concept weights and the knowledge sentinel weight.



(b) The X-axis represents relevant WordNet concepts for the event trigger **head**. The Y-axis represents the concept weights and the knowledge sentinel weight.

Figure 2: Visualization of the attention weights for KB features learned by KBLSTM-CRF. Higher weights imply higher importance.

Model	P	R	F1

BiLSTM	71.3	59.3	64.7
BiLSTM-CRF	64.2	66.6	65.4
BiLSTM-Fea	68.4	62.7	65.5
BiLSTM-Fea-CRF	65.5	66.7	66.1
KBLSTM	70.1	67.3	68.7
KBLSTM-CRF	71.6	67.8	**69.7***

Table 5: event extraction results on the ACE2005 test set.

4.2.1 Results

We compare our models with the prior state-of-the-art approaches for event extraction, including neural and non-neural ones: JOINTBEAM refers to the joint beam search approach with local and global features (Li et al., 2013); JOINTENTITYEVENT refers to the graphical model for joint entity and event extraction (Yang and Mitchell, 2016); DMCNN is the dynamic multi-pooling CNNs in Chen et al. (2015); and JRNN is an RNN model with memory introduced by Nguyen et al. (2016). The first block in Table 5 shows the results of the feature-based linear models (taken from Yang and Mitchell (2016)). The second block shows the previously reported results for the neural models. Note that they both make use of gold-standard entity annotations. The third block shows the results of our models. We can see that our KBLSTM models significantly outperform the BiLSTM and BiLSTM-Fea models, which again confirms their effectiveness in leveraging KB information. The KBLSTM-CRF model achieves the best performance and outperforms the previous state-of-the-art methods without having access to any gold-standard entities.

4.3 Model Analysis

In order to better understand our model, we visualize the learned attention weights $\boldsymbol{\alpha}$ for KB concepts and the sentinel weight β that measures the tradeoff between knowledge and context. Figure 2a visualizes these weights for the entity mention "clinton". In the first sentence, "clinton" refers to a LOCATION while in the second sentence, "clinton" refers to a PERSON. Our model learns to attend to different word senses for 'clinton' (KB concepts associated with 'clinton') in different sentences. Note that the weight on the knowledge sentinel is higher in the first sentence. This is because the local text alone is indicative of the entity type for "clinton": the word "in" is more likely to be followed by a location than a person. We find that BiLSTM-Fea-CRF models often make wrong predictions on examples like this due to its inflexibility in modeling knowledge relevance with respect to context. Figure 2b shows the learned weights for the event trigger word "head" in two sentences, one expresses a TRAVEL event while the other expresses a STARTPOSITION event. Again, we find that our model is capable of attending to relevant WordNet synsets and more accurately disambiguate event types.

5 Conclusion

In this paper, we introduce the KBLSTM network architecture as one approach to incorporating background KBs for improving recurrent neural networks for machine reading. This architecture employs an adaptive attention mechanism with a sentinel that allows for learning an appropriate tradeoff for blending knowledge from the KBs with information from the currently processed text, as well as selecting among relevant KB concepts for each word (e.g., to select the correct semantic categories for "clinton" as a town or person in figure 2a). Experimental results show that our model achieves state-of-the-art performance on standard benchmarks for both entity extraction and event extraction.

We see many additional opportunities to integrate background knowledge with training of neural network models for language processing. Though our model is evaluated on entity extraction and event extraction, it can be useful for other machine reading tasks. Our model can also be extended to integrate knowledge from a richer set of KBs in order to capture the diverse variety and depth of background knowledge required for accurate and deep language understanding.

Abstract

What prerequisite knowledge should students achieve a level of mastery before moving forward to learn subsequent coursewares? We study the extent to which the prerequisite relation between knowledge concepts in Massive Open Online Courses (MOOCs) can be inferred automatically. In particular, what kinds of information can be leveraged to uncover the potential prerequisite relation between knowledge concepts. We first propose a representation learning-based method for learning latent representations of course concepts, and then investigate how different features capture the prerequisite relations between concepts. Our experiments on three datasets form Coursera show that the proposed method achieves significant improvements (+5.9-48.0% by F1-score) comparing with existing methods.

1 Introduction

Mastery learning was first formally proposed by Benjamin Bloom in 1968 (Bloom, 1981), suggesting that students must achieve a level of mastery (e.g., 90% on a knowledge test) in prerequisite knowledge before moving forward to learn subsequent knowledge concepts. From then on, prerequisite relations between knowledge concepts become a cornerstone for designing curriculum in schools and universities. Prerequisite relations essentially can be considered as the dependency among knowledge concepts. It is crucial for people to learn, organize, apply, and generate knowledge (Laurence and Margolis, 1999). Figure 1 shows a real example from Coursera. The student wants to learn "Conditional Random Field" (in video18 of CS229). The prerequisite knowledge might be "Hidden Markov Model" (in video25 of CS224), whose prerequisite knowledge is "Maximum Likelihood" (in video12 of Math112).

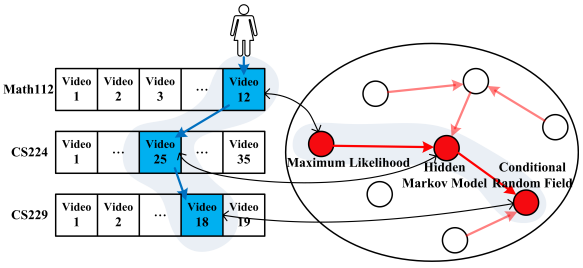

Figure 1: An example of prerequisite relations in MOOCs

Organizing the knowledge structure with prerequisite relations in education improves tasks such as curriculum planning (Yang et al., 2015), automatic reading list generation (Jardine, 2014), and improving education quality (Rouly et al., 2015). For example, as shown in Figure 1, with explicit prerequisite relations among concepts (in red), a coherent and reasonable learning sequence can be recommended to the student (in blue). Before, the prerequisite relationships were provided by teachers or teaching assistants (Novak, 1990); however in the era of MOOCs, it is becoming *infeasible* as the teachers would find that they are facing with hundreds of thousands of students with various background. Meanwhile, the rapid growth of Massive Open Online Courses has offered thousands of courses, and students are free to choose any course from the thousands of candidates. Therefore, there is a clear need for methods to automatically dig out the prerequisite relationships among knowledge concepts from the large course space, so that the students from different background can easily explore the knowledge space and better design their personalized learning schedule.

There are a few efforts aiming to automatically detect prerequisite relations for knowledge base. For example, Talukdar and Cohen (2012) proposed a method for inferring prerequisite relationships between entities in Wikipedia and Liang et al. (2015) presented a more general approach

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1447–1456
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1133

to predict prerequisite relationships. A few other works intend to extract prerequisite relationships from textbooks (Yosef et al., 2011; Wang et al., 2016). However, it is far from sufficient to directly apply these methods to the MOOC environments due to the following reasons. First, the focus of most previous attempts has been on prerequisite inference of Wikipedia concepts (either Wikipedia articles or Wikipedia concepts in textbooks). Many course concepts are not included in Wikipedia (Schweitzer, 2008; Okoli et al., 2014). We can leverage Wikipedia, in particular the existing entity relationships in Wikipedia, but cannot only rely on Wikipedia for detecting prerequisite relations in MOOCs. Second, with the thousands of courses from different universities and also very different disciplinaries, the MOOC scenario is much more complicated — there are not only inter-course concept relationships, but also intra-course and even intra-disciplinary relationships. Moreover, user interactions with the MOOC system might be also helpful to identify the prerequisite relations. How to fully leverage the different information to obtain a better performance for inferring prerequisite relations in MOOCs is a challenging issue.

In this paper, we attempt to figure out what kinds of information in MOOCs can be used to uncover the prerequisite relations among concepts. Specifically, we consider it from three aspects, including course concept semantics, course video context and course structure. First, semantic relatedness plays an important role in prerequisite relations between concepts. If two concepts have very different semantic meanings (e.g., "matrix" and "anthropology"), it is unlikely that they have prerequisite relations. However, statistical features in MOOCs do not provide sufficient information for capturing the concept semantics because of the short length of course videos in MOOCs, we propose an embedding-based method to incorporate external knowledge from Wikipedia to learn semantic representations of concepts in MOOCs. Based on it, we propose one **semantic feature** to calculate the semantic relatedness between concepts. Second, motivated by the *reference distance* (RefD) (Liang et al., 2015), we propose three new **contextual features**, i.e., Video Reference Distance, Sentence Reference Distance and Wikipedia Reference Distance, to infer prerequisite relations in MOOCs based on context information from different aspects, which are more general and informative than RefD and overcome its sparsity problem. Third, we examine different distributional patterns for concepts in MOOCs, including appearing position, distributional asymmetry, video coverage and survival time. We further propose three **structural features** to utilize these patterns to help prerequisite inference in MOOCs.

To evaluate the proposed method, we construct three datasets, each of which consists of multiple real courses in a specific domain from Coursera [1], the largest MOOC platform in the world. We also compare our method with the representative works of prerequisite learning and make a deep analysis of the feature contribution proposed in the paper. The experimental results show that our method achieves the state-of-the-art results in the prerequisite relation discovery in MOOCs. In summary, our contributions include: a) the first attempt, to the best of our knowledge, to detect prerequisite relations among concepts in MOOCs; b) proposal of a set of novel features that utilize contextual, structural and semantic information in MOOCs to identify prerequisite relations; c) design of three useful datasets based on real courses of Coursera to evaluate our method.

2 Problem Formulation

In this section, we first give some necessary definitions and then formulate the problem of prerequisite relation learning in MOOCs.

A **MOOC corpus** is composed by n courses in the same subject area, denoted as $\mathcal{D} = \{\mathcal{C}_1, \cdots, \mathcal{C}_i, \cdots, \mathcal{C}_n\}$, where $\mathcal{C}_i$ is one course. Each course $\mathcal{C}$ can be further represented as a video sequence $\mathcal{C} = (\mathcal{V}_1, \cdots, \mathcal{V}_i, \cdots, \mathcal{V}_{|\mathcal{C}|})$, where $\mathcal{V}_i$ denotes the i-th teaching video of course $\mathcal{C}$. Finally, we view each video $\mathcal{V}$ as a document of its video texts (video subtitles or speech script), i.e., $\mathcal{V} = (s_1 \cdots s_i \cdots s_{|\mathcal{V}|})$, where s_i is the i-th sentence of the video texts.

Course concepts are subjects taught in the course, i.e., the concepts not only mentioned but also discussed and taught in the course. Let us denote the course concept set of $\mathcal{D}$ as $\mathcal{K} = \mathcal{K}_1 \cup \cdots \cup \mathcal{K}_n$, where $\mathcal{K}_i$ is the set of course concepts in $\mathcal{C}_i$.

Prerequisite relation learning in MOOCs is formally defined as follows. Given a MOOC corpus $\mathcal{D}$ and its corresponding course concepts

[1] https://www.coursera.org/

$\mathcal{K}$, the objective is to learn a function $\mathcal{P} : \mathcal{K}^2 \rightarrow \{0, 1\}$ that maps a concept pair $\langle a, b\rangle$, where $a, b \in \mathcal{K}$, to a binary class that predicts whether a is a prerequisite concept of b.

In order to learn this mapping, we need to answer two crucial questions. How could we represent a course concept? What information regarding a concept pair is helpful to capture their prerequisite relation? We first propose an embedding-based method to learn appropriate semantic representations for each course concept in $\mathcal{K}$. Based on the learned representations, we propose 7 novel features to capture whether a concept pair has prerequisite relation. These features utilize different aspects of information and can be classified into 1 semantic feature, 3 contextual features and 3 structural features. In the following section, we first describe the semantic representations in detail, and then formally introduce our proposed features.

3 Method

3.1 Concept Representation & Semantic Relatedness

We first learn appropriate representations for course concepts. Given the course concepts $\mathcal{K}$ as input, we utilize a *Wikipedia corpus* to learn semantic representations for concepts in $\mathcal{K}$. A Wikipedia corpus $\mathcal{W}$ is a set of Wikipedia articles and can be represented as a sequence of words $\mathcal{W} = \langle w_1 \cdots w_i \cdots w_m \rangle$, where w_i denotes a word and m is the length of the word sequence. Our method consists of two steps: (1) entity annotation, and (2) representation learning.

Entity Annotation. We first automatically annotate the entities in $\mathcal{W}$ to obtain an **entity set** $\mathcal{E}$ and an **entity-annotated Wikipedia corpus** $\mathcal{W}' = \langle x_1 \cdots x_i \cdots x_{m'} \rangle$, where x_i corresponds to a word $w \in \mathcal{W}$ or an entity $e \in \mathcal{E}$. Note that $m' < m$ because multiple adjacent words could be labeled as one entity. Many entity linking tools are available for entity annotation, e.g. TAGME (Ferragina and Scaiella, 2010), AIDA (Yosef et al., 2011) and TremenRank (Cao et al., 2015). However, the rich hyperlinks created by Wiki editors provide a more natural way. In our experiments, we simply use the hyperlinks in Wikipedia articles as annotated entities.

Representation Learning. We then learn word embeddings (Mikolov et al., 2013b,a) on $\mathcal{W}'$ to obtain low-dimensional, real-valued vector representations for entities in $\mathcal{E}$ and words in $\mathcal{W}$. Let us denote v_e and v_w as the vector of $e \in \mathcal{E}$ and $w \in \mathcal{W}$, respectively. For a course concept $a \in \mathcal{K}$, suppose a is a N-gram term $\langle g_1 \cdots g_N \rangle$ and $g_1, \cdots, g_N \in \mathcal{W}$, we obtain its semantic representations v_a as follows.

$$v_a = \begin{cases} v_e, & \text{if } a \equiv e \text{ and } e \in \mathcal{E} \\ v_{g_1} + \cdots + v_{g_N}, & \text{otherwise} \end{cases} \quad (1)$$

It means that if a is a Wikipedia entity, we can directly obtain its semantic representations; otherwise, we obtain its vector via the vector addition of its individual word vectors. In this way, a has no corresponding vector only if any of its constituent word is absence in the whole Wikipedia corpus. This case is unusual because a large online encyclopedia corpus can easily cover almost all individual words of the vocabulary. Our experimental results verify that over 98% of the course concepts have vector representations.

Feature 1: *Semantic Relatedness*

For a given concept pair $\langle a, b\rangle$, the **semantic relatedness** between a and b, denoted as $\omega(a, b)$, is our first feature (the only semantic feature). With learned semantic representations, semantic relatedness of two concepts can be easily reflected by their distance in the vector space. We define $\omega(a, b) \in [0, 1]$ as the normalized cosine distance between v_a and v_b, as follows.

$$\omega(a, b) = \frac{1}{2}(1 + \frac{v_a \cdot v_b}{\|v_a\| \cdot \|v_b\|}) \quad (2)$$

3.2 Contextual Features

Context information in course videos provides important clues to infer prerequisite relations. In videos where concept A is taught, if the teacher also mentions concept B for a lot but not vice versa, then B is more likely to be a prerequisite of A than A of B. For example, "gradient descent" is a prerequisite concept of "back propagation". In teaching videos of "back propagation", the concept "gradient descent" is frequently mentioned when illustrating the optimization detail of back propagation. On the contrary, however, "back propagation" is unlikely to be mentioned when teaching "gradient descent". A similar observation also exists in Wikipedia, based on which Liang et al. (2015) proposed an indicator, namely *reference distance* (RefD), to infer prerequisite relations among Wikipedia articles. However, RefD is computed based on the link structure of Wikipedia, thus is only feasible for Wikipedia

concepts and is not applicable in plain text. We overcome the above shortcomings of RefD to propose three novel features, which utilize different aspects of context information—course videos, video sentences and Wikipedia articles—to infer prerequisite relations in MOOCs.

Feature 2: ***Video Reference Distance***

Given a concept pair $\langle a, b\rangle$ where $a, b \in \mathcal{K}$, we propose the **video reference weight** (Vrw) to quantify how b is referred by videos of a, defined as follows.

$$Vrw\left(a,b\right)=\frac{\sum\limits_{\mathcal{C}\in\mathcal{D}}\sum\limits_{\mathcal{V}\in\mathcal{C}}f\left(a,\mathcal{V}\right)\cdot r\left(\mathcal{V},b\right)}{\sum\limits_{\mathcal{C}\in\mathcal{D}}\sum\limits_{\mathcal{V}\in\mathcal{C}}f\left(a,\mathcal{V}\right)} \tag{3}$$

where $f\left(a,\mathcal{V}\right)$ indicates the term frequency of concept a in video $\mathcal{V}$, which reflects how important is concept a to this video. $r\left(\mathcal{V},b\right) \in \{0,1\}$ denotes whether concept b appears in video $\mathcal{V}$. Intuitively, if b appears in more important videos of a, $Vrw\left(a,b\right)$ tends to be larger, and the range of $Vrw\left(a,b\right)$ is between 0 and 1. Then, the **video reference distance** (Vrd) is defined as the difference of Vrw between two concepts, as follows.

$$Vrd\left(a,b\right)=Vrw\left(b,a\right)-Vrw\left(a,b\right) \tag{4}$$

In practice, this feature may be too sparse if the MOOC corpus is small. For an arbitrary concept pair, they may have no co-occurrence in all course videos. We expend the video reference distance to a more general version by considering the semantic relatedness among concepts. Besides the conditions in which A refers to B, we also consider the cases in which A-related concepts refer to B. We first define the **generalized video reference weight** ($GVrw$) as follows.

$$GVrw\left(a,b\right)=\frac{\sum_{i=1}^{M}Vrw\left(a_i,b\right)\cdot\omega\left(a_i,b\right)}{\sum_{i=1}^{M}\omega\left(a_i,b\right)} \tag{5}$$

where $a_1,\cdots,a_M \in \mathcal{K}$ are the top-M most similar concepts of a, measured by the semantic relatedness function $\omega(\cdot,\cdot)$ in feature 1. $GVrw$ is the weighted average of $Vrw\left(a_i,b\right)$, indicating how b is referred by a-related concepts in their corresponding videos. Note that $a_1 = a$, thus $GVrw\left(a,b\right) \equiv Vrw\left(a,b\right)$ when $M = 1$. Similarly, we define the **generalized video reference distance** ($GVrd$) as follows.

$$GVrd\left(a,b\right)=GVrw\left(b,a\right)-GVrw\left(a,b\right) \tag{6}$$

Intuitively, if most of b-related concepts refer to a but not vice versa, then a is likely to be a prerequisite of b. For example, it is plausible for the related concepts of "gradient descent", e.g., "steepest descent" and "Newton's method", to mention "matrix" but clearly not vice versa.

Feature 3: ***Sentence Reference Distance***

Sentence reference distance is similar to feature 2, but stands on the sentence level. Following the same design pattern of feature 2, we define the **sentence reference weight** (Srw) and **sentence reference distance** (Srd) as follows.

$$Srw\left(a,b\right)=\frac{\sum\limits_{\mathcal{C}\in\mathcal{D}}\sum\limits_{\mathcal{V}\in\mathcal{C}}\sum\limits_{s\in\mathcal{V}}r(s,a)\cdot r(s,b)}{\sum\limits_{\mathcal{C}\in\mathcal{D}}\sum\limits_{\mathcal{V}\in\mathcal{C}}\sum\limits_{s\in\mathcal{V}}r(s,a)} \tag{7}$$

$$Srd\left(a,b\right)=Srw\left(b,a\right)-Srw\left(a,b\right) \tag{8}$$

where $r\left(s,a\right) \in \{0,1\}$ is an indicator of whether concept a appears in sentence s. $Srw(a,b)$ calculates the ratio of B appearing in the sentences of a. We also define **generalized sentence reference weight** ($GSrw$) and **generalized sentence reference distance** ($GSrd$) as follows.

$$GSrw\left(a,b\right)=\frac{\sum_{i=1}^{M}Srw\left(a_i,b\right)\cdot\omega\left(a_i,b\right)}{\sum_{i=1}^{M}\omega\left(a_i,b\right)} \tag{9}$$

$$GSrd\left(a,b\right)=GSrw\left(b,a\right)-GSrw\left(a,b\right) \tag{10}$$

Feature 4: ***Wikipedia Reference Distance***

Contextual information of Wikipedia is also useful for detecting prerequisite relations. As mention before, RefD is not general enough to be applied in our settings, because it is limited to Wikipedia concepts. Therefore, we improve this indicator to a more general one, which is also suitable for non-wiki concepts.

Specifically, for a concept $a \in \mathcal{K}$, let us denote the top-M most related wiki entities of a as $\mathcal{R}_a = \langle e_1,\cdots,e_M\rangle$, where $e_1,\cdots,e_M \in \mathcal{E}$. Because concepts in $\mathcal{K}$ and entities in $\mathcal{E}$ are jointly embedded in the same vector space in Section 3.1, we can easily obtain $\mathcal{R}_a$ with the semantic relatedness metric $\omega(\cdot,\cdot)$ in Feature 1. We then define the **wikipedia reference weight** (Wrw) as follows.

$$Wrw\left(a,b\right)=\frac{\sum\limits_{e\in\mathcal{R}_a}Erw\left(e,b\right)\cdot\omega\left(e,a\right)}{\sum\limits_{e\in\mathcal{R}_a}\omega\left(e,a\right)} \tag{11}$$

where $Erw(e,a)$ is a binary indicator, in which $Erw(e,a) = 1$ if the Wikipedia article of e refers to any entity in $\mathcal{R}_a$, and $Erw(e,a) = 0$ otherwise. $Wrw\left(a,b\right)$ measures how frequently that a-related wiki entities refer to b-related wiki entities. Finally, **wikipedia reference distance** (Wrd) is

defined as the difference of Wrw between a and b, i.e., $Wrd(a,b) = Wrw(b,a) - Wrw(a,b)$.

3.3 Structural Features

Since course concepts are usually introduced based on their learning dependencies, the structure of MOOC courses also significantly contribute to prerequisite relation inference in MOOCs. However, structure-based features for prerequisite detection have not been well-studied in previous works. In this section, we investigate different structural information, including appearing positions of concepts, learning dependencies of videos and complexity levels of concepts, to propose three novel features to infer prerequisite relations in MOOCs. Before introducing these features, let us define two useful notations as follows. $\mathcal{C}(a)$ are the courses in which a is a course concept, i.e., $\mathcal{C}(a) = \{\mathcal{C}_i | \mathcal{C}_i \in \mathcal{D}, a \in \mathcal{K}_i\}$. $\mathcal{I}(\mathcal{C}, a)$ are the video indexes that contain concept a in course $\mathcal{C}$. For example, if a appears in the first and the 4-th video of $\mathcal{C}$, then $\mathcal{I}(\mathcal{C}, a) = \{1, 4\}$.

Feature 5: *Average Position Distance*

In a course, for a specific concept, its prerequisite concepts tend to be introduced before this concept and its subsequent concepts tend to be introduced after this concept. Based on this observation, for a concept pair $\langle a, b\rangle$, we calculate the distance of the average appearing position of a and b as one feature, namely **average position distance** (Apd). If $\mathcal{C}(a) \cap \mathcal{C}(b) \neq \emptyset$, $Apd(a,b)$ is formally defined as follows.

$$Apd(a,b) = \frac{\sum_{\mathcal{C} \in \mathcal{C}(a) \cap \mathcal{C}(b)} \left| \frac{\sum_{i \in \mathcal{I}(\mathcal{C},a)} i}{|\mathcal{I}(\mathcal{C},a)|} - \frac{\sum_{j \in \mathcal{I}(\mathcal{C},b)} j}{|\mathcal{I}(\mathcal{C},b)|} \right|}{|\mathcal{C}(a) \cap \mathcal{C}(b)|} \tag{12}$$

If $\mathcal{C}(a) \cap \mathcal{C}(b) = \emptyset$, we set $Apd(a,b) = 0$.

Feature 6: *Distributional Asymmetry Distance*

We also use the learning dependency of course videos to help infer learning dependency of course concepts. Based on our observation, the chance that a prerequisite concept is frequently mentioned in its subsequent videos is larger than that a subsequent concept is talked about in its prerequisite videos. Specifically, if video $\mathcal{V}_a$ is a precursor video of $\mathcal{V}_b$, and a is a prerequisite concept of b, then it is likely that $f(b, \mathcal{V}_a) < f(a, \mathcal{V}_b)$, where $f(a, \mathcal{V})$ denotes the term frequency of a in video $\mathcal{V}$. We thus define another feature, namely **distributional asymmetry distance** (Dad), to calculate the extent that a given concept pair satisfies this distributional asymmetry pattern. Formally, in course $\mathcal{C}$, for a given concept pair $\langle a, b\rangle$, we first define $\mathcal{S}(\mathcal{C}) = \{(i,j) | i \in \mathcal{I}(\mathcal{C}, a), j \in \mathcal{I}(\mathcal{C}, b), i < j\}$, i.e., all possible video pairs of $\langle a, b\rangle$ that have sequential relation. Then, the distributional asymmetry distance of $\langle a, b\rangle$ is formally defined as follows.

$$Dad(a,b) = \frac{\sum_{\mathcal{C} \in \mathcal{C}(a) \cap \mathcal{C}(b)} \frac{\sum_{(i,j) \in \mathcal{S}(\mathcal{C})} f(a, \mathcal{V}_i^{\mathcal{C}}) - f(b, \mathcal{V}_j^{\mathcal{C}})}{|\mathcal{S}(\mathcal{C})|}}{|\mathcal{C}(a) \cap \mathcal{C}(b)|} \tag{13}$$

where $\mathcal{V}_i^{\mathcal{C}}$ denotes the i-th video of course $\mathcal{C}$. If $\mathcal{C}(a) \cap \mathcal{C}(b) = \emptyset$, we set $Dad(a,b) = 0$.

Feature 7: *Complexity Level Distance*

Two related concepts with prerequisite relationship tend to have a difference in their complexity level, meaning that one concept is basic while another one is advanced. For example, "data set" and "training set" have learning dependencies and the latter concept is more advanced than the former one. However, "test set" and "training set" have no such relation when their complexity levels are similar. Complexity level of a course concept is implicit in its distribution in courses. Specifically, we observe that, for a concept in MOOCs, if it covers more videos in a course or it survives longer time in a course, then it is more likely to be a basic concept rather than an advanced one. We then formally define the **average video coverage** (avc) and the **average survival time** (ast) of a concept a as follows.

$$avc(a) = \frac{1}{|\mathcal{C}(a)|} \sum_{\mathcal{C} \in \mathcal{C}(a)} \frac{|\mathcal{I}(\mathcal{C}, a)|}{|\mathcal{C}|} \tag{14}$$

$$ast(a) = \frac{1}{|\mathcal{C}(a)|} \sum_{\mathcal{C} \in \mathcal{C}(a)} \frac{max(\mathcal{I}(\mathcal{C}, a)) - min(\mathcal{I}(\mathcal{C}, a)) + 1}{|\mathcal{C}|} \tag{15}$$

where $max/min(\mathcal{I}(\mathcal{C}, a))$ obtains the video index where a appears the last/first time in course $\mathcal{C}$. Based on the above equations, we define the **complexity level distance** (Cld) between concept a and b as follows.

$$Cld(a,b) = avc(a) \cdot ast(a) - avc(b) \cdot ast(b) \tag{16}$$

4 Experiments

4.1 Data Sets

In order to validate the efficiency of our features, we conducted experiments on three MOOC corpus with different domains: "Machine Learning" **(ML)**, "Data Structure and Algorithms" **(DSA)**, and "Calculus" **(CAL)**. To the best of our knowledge, there is no public data set for mining

Dataset	#courses	#videos	#concepts	#pairs		κ
				$-$	$+$	
ML	5	548	244	5,676	1,735	0.63
DSA	8	449	201	3,877	1,148	0.65
CAL	7	359	128	1,411	621	0.59

Table 1: Dataset Statistics

prerequisite relations in MOOCs. We created the experimental data sets through a three-stage process.

First, for each chosen domain, we select its relevant courses from Coursera, one of the leading MOOC platforms, and download all course materials using *coursera-dl* [2], a widely-used tool for automatically downloading Coursera.org videos. For example, for ML, we select 5 related courses [3] from 5 different universities and obtain a total of 548 course videos. Then, we manually label course concepts for each course: (1) Extract candidate concepts from documents of video subtitles following the method of Parameswaran et al. (2010). (2) Label the candidates as "course concept" or "not course concept" and obtain a set of course concepts for this course.

Finally, we manually annotate the prerequisite relations among the labeled course concepts. If the number of course concepts is n, the number of all possible pairs to be checked could reach $n \times (n-1)/2$, which requires arduous human labeling work. Therefore, for each dataset, we randomly select 25 percent of all possible pairs for evaluation. For each course concept pair $\langle a, b \rangle$, three human annotators majoring in the corresponding domain were asked to label them as "a is b's prerequisite", "b is a's prerequisite" or "no prerequisite relationship" using their own knowledge background and additional textbook resources. We take a majority vote of the annotators to create final labels and access the inter-annotator agreement using the average of pairwise κ statistics (Landis and Koch, 1981) between all pairs of the three annotators.

The statistics of the three datasets are listed in Table 1, where *#courses* and *#videos* are the total number of courses and videos in each dataset and *#concepts* is the number of labeled course concepts. The *#pairs* denotes the number of labeled concept pairs for evaluation, in which '$+$' denotes the number of positive instances, i.e. pairs who have prerequisite relations, and '$-$' denotes the number of negative instances.

[2]https://github.com/coursera-dl/coursera-dl

[3]These courses are: "Machine Learning (Stanford)", "Machine Learning (Washington)", "Practical Machine Learning (JHU)", "Machine Learning With Big Data (UCSD)" and "Neural Networks for Machine Learning (UofT)"

Classifier		ML		DSA		CAL

Table 2: Classification results of the proposed method(%).

4.2 Evaluation Results

For each dataset, we apply 5-fold cross validation to evaluate the performance of the proposed method, i.e., testing our method on one fold while training the classifier using the other 4 folds. Usually, there are much fewer positive instances than negative instances, so we balance the training set by oversampling the positive instances (Yosef et al., 2011; Talukdar and Cohen, 2012). In our experiments, we employ 4 different binary classifiers, including NaïveBayes (*NB*), Logistic Regression (*LR*), SVM with linear kernel (*SVM*) and Random Forest (*RF*). We use precision (P), recall (R), and F1-score (F_1) to evaluate the prerequisite classification results. The experimental results are presented in Table 2.

Contextual features are shaped by the parameter M, i.e., the number of related concepts being considered. In our experiments, we tried different settings of M and report the results when M=1 and M=10 in Table 2. As for the semantic representation, we use the latest publicly available Wikipedia dump [4] and apply the skip-gram model (Mikolov et al., 2013b) to train word embeddings using the Python library gensim [5] with default parameters.

As shown in Table 2, the evaluation results varies by different classifiers. It turns out that NaïveBayes performs the worst. This seems to be caused by the fact that the independence assumption is not satisfied for our features; for

[4]https://dumps.wikimedia.org/enwiki/20170120/

[5]http://radimrehurek.com/gensim/

example, Feature 2 and Feature 3 both utilize the local context information, only with different granularity, thus are quite co-related. Random Forest beats others, with best F_1 across all three datasets. Its average F_1 outperforms SVM, NB and LR by 7.0%, 11.1% and 8.3%, respectively (M=10). The reason is as follows. Instead of a simple descriptive feature, each of our proposed feature determines whether a concept pair has prerequisite relation from a specific aspect; its function is similar to an independent weak classifier. Therefore, rather than using a linear combination of features for classification (e.g., SVM and LR), a boosting model (e.g., Random Forest) is more suitable for this task. The performance is slightly better when M=10 for all classifiers, with +0.20% for SVM, +0.53% for NB, +0.73% for LR and +3.63% for RF, with respect to the average F_1. The results verify the effectiveness of considering related concepts in contextual features. We use RF and set M=10 in the following experiments.

4.3 Comparison with Baselines

We further compare our approach with three representative methods for prerequisite inference.

4.3.1 Baseline Approaches

Hyponym Pattern Method (HPM). Prerequisite relationships often exists between hyponym-hypernym concept pairs (e.g., "Machine Learning" and "Supervised Learning"). As a baseline, we adopt the 10 lexico-syntactic patterns used by Wang et al. (2016) to extract hyponym relationships between concepts. If a concept pair matches at least one of these patterns in the MOOC corpus, we judge them to have prerequisite relations.

Reference Distance (RD) We also employ the RefD proposed by Liang et al. (2015) as one of our baselines. However, this method is only appliable to Wikipedia concepts. To make it comparable with our method, for each of our datasets, we construct a subset of it by picking out the concept pairs $\langle a, b\rangle$ in which a and b are both Wikipedia concepts. For example, we find 49% of course concepts in ML have their corresponding Wikipedia articles and 28% percent of concept pairs in ML meet the above condition. We use the new datasets constructed from ML, DSA and CAL, namely **W-ML**, **W-DSA**, and **W-CAL**, to compare our method with RefD.

Supervised Relationship Identification (SRI) Wang et al. (2016) has employed several features to infer prerequisite relations of Wikipedia concepts in textbooks, including 3 Textbook features and 6 Wikipedia features. Based on these features, they performed a binary classification using SVM to identify prerequisite relationships and has achieved state-of-the-art results. Because the Wikipedia features can only be applied to Wikipedia concepts, in order to make a comparison, we create two versions of their method: (1) **T-SRI**: only textbook features are used to train the classifier and (2) **F-SRI**: the original version, all features are used. We compare the performance of our method with T-SRI on ML, DSA and CAL datasets; we also compare our method with F-SRI on W-ML, W-DSA and W-CAL datasets.

Method		ML	DSA	CAL	W-ML	W-DSA	W-CAL
HPM	P	67.3	71.4	69.5	**79.9**	72.3	73.5
	R	18.4	14.8	16.5	25.5	27.3	23.3
	F_1	29.0	24.5	26.7	38.6	39.6	35.4
RD	P	–	–	–	73.4	**77.8**	**74.4**
	R	–	–	–	42.8	44.8	43.1
	F_1	–	–	–	54.1	56.8	54.6
T-SRI	P	61.4	62.3	62.5	58.1	60.1	62.7
	R	62.9	64.6	65.5	67.6	65.3	67.9
	F_1	62.1	63.4	64.0	62.5	62.6	65.2
F-SRI	P	–	–	–	64.3	64.3	64.8
	R	–	–	–	62.1	65.6	65.2
	F_1	–	–	–	63.2	64.9	65.0
MOOC	P	**71.4**	**72.7**	**70.3**	72.8	68.4	71.4
	R	**73.8**	**72.3**	**71.9**	**71.3**	**72.0**	**70.8**
	F_1	**72.6**	**72.5**	**71.1**	**72.0**	**70.2**	**71.1**

Table 3: Comparison with baselines(%).

4.3.2 Performance Comparison

In Table 3 we summarize the comparing results of different methods across different datasets ("MOOC" refers to our method). We find that our method outperforms baseline methods across all six datasets [6]. For example, the F_1 of our method on ML outperforms T-SRI and HPM by 10.5% and 43.6%, respectively. Specifically, we have the following observations. First, HPM achieves relatively high precision but low recall. This is because when A "is a" B, a prerequisite relation often exists from B to A, but clearly not vise versa. Second, T-SRI has certain effectiveness for learning prerequisite relations, with F_1 ranging from 62.1 to 65.2%. However, T-SRI only considers relatively simple features, such as the sequential and co-occurrence among concepts. With more

[6]The improvements are all statistically significant tested with bootstrap re-sampling with 95% confidence.

comprehensive feature engineering, the F_1 of our method significantly outperforms T-SRI (+10.5% on ML, +9.1% on DSA and +7.1% on CAL). Third, incorporating Wikipedia-based features (F-SRI) achieves certain promotion in performance (+0.93% comparing with T-SRI in average F_1).

4.4 Feature Contribution Analysis

In order to get an insight into the importance of each feature in our method, we perform a contribution analysis with different features. Here, we run our approach 10 times on the ML dataset. In each of the first 7 times, one feature is removed; in each of the rest 3 times, one group of features are removed, e.g., removing contextual features means removing $Gvrd$, $Gsrd$ and Wrd at the same time. We record the decrease of F1-score for each setting. Table 4 lists the evaluation results after ignoring different features.

According to the decrement of F1-scores, we find that all the proposed features are useful in predicting prerequisite relations. Especially, we observe that Cld (Feature 7), decreasing our best F1-score by 7.4%, plays the most important role. This suggests that most concepts do exist difference in complexity level. For two concepts, the difference of their coverage and survival times in courses are important for prerequisite relation detection. On the contrary, with 1.9% decrease, Sr (Feature 1) is relatively less important. We may easily find two concepts which have related semantic meanings (e.g., "test set" and "training set") but have no prerequisite relationship. However, semantic relatedness is critical for the contextual features because it overcomes the problem of the sparsity of context in calculation. We experience a decrease of 5.4% when we further do not consider related concepts in contextual features, i.e., set M=1. As for the feature group contribution, we observe that Structural Features, with a decrease of 9.2%, has a greater impact than the other two groups. This is as expected because it includes Cld. Among the three structural features, Apd makes relatively less contribution. The reason is that sometimes the professor may frequently mention a prerequisite concept after introducing a subsequent concept orally, for helping students better understand the concept.

5 Related Works

To the best of our knowledge, there has been no previous work on mining prerequisite relations among concepts in MOOCs. Some researchers have been engaged in detecting other type of prerequisite relations. For example, Yang et al. (2015) proposed to induce prerequisite relations among courses to support curriculum planning. Liu et al. (2011) studied learning-dependency between knowledge units, a special text fragment containing concepts, using a classification-based method. In the area of education, researchers have tried to find general prerequisite structures from students' test performance (Vuong et al., 2011; Scheines et al., 2014; Huang et al., 2015). Different from them, we focus on more fine-grained prerequisite relations, i.e., the prerequisite relations among course concepts.

Among the few related works of mining prerequisite relations among concepts, Liang et al. (2015) and Talukdar and Cohen (Talukdar and Cohen, 2012) studied prerequisite relationships between Wikipedia articles. They assumed that hyperlinks between Wikipedia pages indicate a prerequisite relationship and design several useful features. Based on these Wikipedia features plus some textbook features, Wang et al. (Wang et al., 2016) proposed a method to construct a concept map from textbooks, which jointly learns the key concepts and their prerequisite relations. However, the investigation of only Wikipedia concepts is also the bottleneck of their studies. In our work, we propose more general features to infer prerequisite relations among concepts, regardless of whether the concept is in Wikipedia or not. Liang et al. (2017) propose an optimization based framework to discover concept prerequisite relations from course dependencies. Gordon et al. (2016) utilize cross-entropy to learn concept dependencies in scientific corpus. Besides local statistical information, our method also utilize external knowledge to enrich concept semantics, which is more informativeness.

	Ignored Feature(s)	P	R	F_1
Single	Sr	69.6	72.9	71.2(**-1.4**)
	GVrd	68.8	71.4	70.1(-2.5)
	GSrd	67.9	71.4	69.6(-3.0)
	Wrd	70.1	72.1	71.1(-1.5)
	Apd	69.7	70.8	70.2(-2.4)
	Dad	69.2	69.5	69.4(-3.2)
	Cld	64.9	65.6	65.2(**-7.4**)
Group	Semantic	69.6	72.9	71.2(**-1.4**)
	Contextual	66.4	68.9	67.6(-5.0)
	Structural	63.7	64.2	63.4(**-9.2**)

Table 4: Contribution analysis of different features(%).

Our work is also related to the study of automatic relation extraction. Different research lines have been proposed around this topic, including hypernym-hyponym relation extraction (Ritter et al., 2009; Wei et al., 2012), entity relation extraction (Zhou et al., 2006; Fan et al., 2014; Lin et al., 2015) and open relation extraction (Fader et al., 2011). However, previous works mainly focus on factual relations, the extraction of cognitive relations (e.g. prerequisite relations) has not been well studied yet.

6 Conclusions and Future Work

We conducted a new investigation on automatically inferring prerequisite relations among concepts in MOOCs. We precisely define the problem and propose several useful features from different aspects, i.e., contextual, structural and semantic features. Moreover, we apply an embedding-based method that jointly learns the semantic representations of Wikipedia concepts and MOOC concepts to help implement the features. Experimental results on online courses with different domains validate the effectiveness of the proposed method. Promising future directions would be to investigate how to utilize user interaction in MOOCs for better prerequisite learning, as well as how deep learning models can be used to automatically learn useful features to help infer prerequisite relations.

Abstract

Most work on segmenting text does so on the basis of topic changes, but it can be of interest to segment by other, stylistically expressed characteristics such as change of authorship or native language. We propose a Bayesian unsupervised text segmentation approach to the latter. While baseline models achieve essentially random segmentation on our task, indicating its difficulty, a Bayesian model that incorporates appropriately compact language models and alternating asymmetric priors can achieve scores on the standard metrics around halfway to perfect segmentation.

1 Introduction

Most work on automatically segmenting text has been on the basis of topic: segment boundaries correspond to topic changes (Hearst, 1997). There are various contexts, however, in which it is of interest to identify changes in other characteristics; for example, there has been work on identifying changes in authorship (Koppel et al., 2011) and poetic voice (Brooke et al., 2012). In this paper we investigate text segmentation on the basis of change in the native language of the writer.

Two illustrative contexts where this task might be of interest are patchwriting detection and literary analysis. Patchwriting is the heavy use of text from a different source with some modification and insertion of additional words and sentences to form a new text. Pecorari (2003) notes that this is a kind of textual plagiarism, but is a strategy for learning to write in an appropriate language and style, rather than for deception. Keck (2006), Gilmore et al. (2010) and Vieyra et al. (2013) found that non-native speakers, not surprisingly in situations of imperfect mastery of a language, are strongly over-represented in this kind of textual plagiarism. In these cases the boundaries between the writer's original text and (near-)copied native text are often quite apparent to the reader, as in this short example from Li and Casanave (2012) (copied text italicised): "Nevertheless, doubtfulness can be cleared reasonably by the experiments conducted upon the 'split-brain patients', *in whom intra-hemispheric communication is no longer possible*. To illustrate, *one experiment has the patient sit at a table with a* non-transparent *screen blocking the objects behind*, who is then asked to *reach* the objects with different hand respectively." Because patchwriting can indicate imperfect comprehension of the source (Jamieson and Howard, 2013), identifying it and supporting novice writers to improve it has become a focus of programmes like the Citation Project.[1]

For the second, perhaps more speculative context of literary analysis, consider Joseph Conrad, known for having written a number of famous English-language novels, such as *Heart of Darkness*; he was born in Poland and moved to England at the age of 21. His writings have been the subject of much manual analysis, with one particular direction of such research being the identification of likely influences on his English writing, including his native Polish language and the French he learnt before English. Morzinski (1994), for instance, notes aspects of his writing that exhibit Polish-like syntax, verb inflection, or other linguistic characteristics (*e.g.* "Several had still their staves in their hands" where the awkwardly placed adverb *still* is typical of Polish). These appear both in isolated sentences and in larger chunks of text, and part of

Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1134

an analysis can involve identifying these chunks.

This raises the question: Can NLP and computational models identify the points in a text where native language changes? Treating this as an unsupervised text segmentation problem, we present the first Bayesian model of text segmentation based on authorial characteristics, applied to native language.

2 Related Work

Topic Segmentation The most widely-researched text segmentation task has as its goal to divide a text into topically coherent segments. *Lexical cohesion* (Halliday and Hasan, 1976) is an important concept here: the principle that text is not formed by a random set of words and sentences but rather logically ordered sets of related words that together form a topic. In addition to the semantic relation between words, other methods such as back-references and conjunctions also help achieve cohesion. Based on this, Morris and Hirst (1991) proposed the use of *lexical chains*, sequences of related words (defined via thesaurus), to break up a text into topical segments: breaks in lexical chains indicate breaks in topic. The *TextTiling* algorithm (Hearst, 1994, 1997) took a related approach, defining a function over lexical frequency and distribution information to determine topic boundaries, and assuming that each topic has its own vocabulary and that large shifts in this vocabulary usage correspond to topic shifts.

There have been many approaches since that time. A key one, which is the basis for our own work, is the unsupervised Bayesian technique BAYESSEG of Eisenstein and Barzilay (2008), based on a generative model that assumes that each segment has its own language model. Under this assumption the task can be framed as predicting boundaries at points which maximize the probability of a text being generated by a given language model. Their method is based on lexical cohesion — expressed in this context as topic segments having compact and consistent lexical distributions — and implements this within a probabilistic framework by modelling words within each segment as draws from a multinomial language model associated with that segment.

Much other subsequent work either uses this as a baseline, or extends it in some way: Jeong and Titov (2010), for example, who propose a model for joint discourse segmentation and alignment for documents with parallel structures, such as a text with commentaries or presenting alternative views on the same topic; or Du et al. (2013), who use hierarchical topic structure to improve the linear segmentation.

Bible Authorship Koppel et al. (2011) consider the task of decomposing a document into its authorial components based on their stylistic properties and propose an unsupervised method for doing so. The authors use as their data two biblical books, Jeremiah and Ezekiel, that are generally believed to be single-authored: their task was to segment a single artificial text constructed by interleaving chapters of the two books. Their most successful method used work in biblical scholarship on lexical choice: they give as an example the case that in Hebrew there are seven synonyms for the word *fear*, and that different authors may choose consistently from among them. Then, having constructed their own synsets using available biblical resources and annotations, they represent texts by vectors of synonyms and apply a modified cosine similarity measure to compare and cluster these vectors. While the general task is relevant to this paper, the particular notion of synonymy here means the approach is specific to this problem, although their approach is extended to other kinds of text in Akiva and Koppel (2013). Aldebei et al. (2015) proposed a new approach motivated by this work, similarly clustering sentences, then using a Naive Bayes classifier with modified prior probabilities to classify sentences.

Poetry Voice Detection Brooke et al. (2012) perform stylistic segmentation of a well-known poem, *The Waste Land* by T.S. Eliot. This poem is renowned for the great number of voices that appear throughout the text and has been the subject of much literary analysis (Bedient and Eliot, 1986; Cooper, 1987). These distinct voices, conceived of as representing different characters, have differing tones, lexis and grammatical styles (*e.g.* reflecting the level of formality). The transitions between the voices are not explicitly marked in the poem and the task here is to predict the breaks where these voice changes occur. The authors argue that the use of generative models is not feasible for this task, noting: "Generative models, which use a bag-of-words assumption, have a very different problem: in their standard form, they can capture only lexical cohesion, which is not the (primary) focus of stylistic analysis."

They instead present a method based on a curve that captures stylistic change, similar to the TextTiling approach but generalised to use a range of features. The local maxima in this change curve represent potential breaks in the text. The features are both internal to the poem (*e.g.* word length, syllable count, POS tag) as well as external (*e.g.* average unigram counts in the 1T Corpus or sentiment polarity from a lexicon). Results on an artificially constructed mixed-style poem achieve a P_k of 0.25. Brooke et al. (2013) extend this by considering clustering following an initial segmentation.

Native Language Identification (NLI) NLI casts the detecting of native language (L1) influence in writing in a non-native (L2) language as a classification task: the framing of the task in this way comes from Koppel et al. (2005). There has been much activity on it in the last few years, with Tetreault et al. (2012) providing a comprehensive analysis of features that had been used up until that point, and a shared task in 2013 (Tetreault et al., 2013) that attracted 29 entrants. The shared task introduced a new, now-standard dataset, TOEFL11, and work has continued on improving classification results, *e.g.* by Bykh and Meurers (2014) and Ionescu et al. (2014).

In addition to work on the classification task itself, there have also been investigations of the features used, and how they might be employed elsewhere. Malmasi and Cahill (2015) examine the effectiveness of individual feature types used in the shared task and the diversity of those features. Of relevance to the present paper, simple part-of-speech n-grams alone are fairly effective, with classification accuracies of between about 40% and 65%; higher-order n-grams are more effective than lower, and the more fine-grained CLAWS2 tagset more effective than the Penn Treebank tagset. An area for application of these features is in Second Language Acquisition (SLA), as a data-driven approach to finding L1-related characteristics that might be a result of cross-linguistic influence and consequently a possible starting for an SLA hypothesis (Ellis, 2008); Swanson and Charniak (2013) and Malmasi and Dras (2014) propose methods for this.

Tying It Together Contra Brooke et al. (2012), we show that it is possible to develop effective generative models for segmentation on stylistic factors, of the sort used for topic segmentation. To apply it specifically to segmentation based on a writer's L1, we draw on work in NLI.

3 Experimental Setup

We investigate the task of L1-based segmentation in three stages:

1. Can we define any models that do better than random, in a best case scenario? For this best case scenario, we determine results over a devset with the best prior found by a grid search, for a single language pair likely to be relatively easily distinguishable. Note that as this is *unsupervised* segmentation, it is a devset in the sense that it is used to find the best prior, and also in a sense that some models as described in §4 use information from a related NLI task on the underlying data.

2. If the above is true, do the results also hold for test data, using priors derived from the devset?

3. Further, do the results also hold for all language pairs available in our dataset, not just a single easily distinguishable pair?

We first describe the evaluation data — artificial texts generated from learner essays, similar to the artificially constructed texts of previously described work on Bible authorship and poetry segmentation — and evaluation metrics, followed in §4 by the definitions of our Bayesian models.

3.1 Source Data

We use as the source of data the TOEFL11 dataset used for the NLI shared task (Blanchard et al., 2013) noted in §2. The data consists of 12100 essays by writers with 11 different L1s, taken from TOEFL tests where the test-taker is given a *prompt*[2] as the topic for the essay. The corpus is balanced across L1s and prompts (which allows us to verify that segmentation isn't occurring on the basis of topic), and is split into standard training, dev and test sets.

3.2 Document Generation

As the main task is to segment texts by the author's L1, we want to ensure that we are not segmenting by topic and thus use texts written by authors from different L1 backgrounds on the same topic (prompt). We will also create one dataset to verify that segmentation by topic works in this domain; for this we use texts written by authors from the same L1 background on different topics.

For our L1-varying datasets, we construct composite documents to be segmented as alternat-

[2]For example, prompt P7 is: "Do you agree or disagree with the following statement? It is more important for students to understand ideas and concepts than it is for them to learn facts. Use reasons and examples to support your answer."

ing segments drawn from TOEFL11 from two different L1s holding the topic (prompt) constant, broadly following a standard approach (Brooke et al., 2012, for example) (see Appendix A.1 for details). We follow the same process for our topic-varying datasets, but hold the L1 constant while alternating the topic (prompt). For our single pair of L1s, we choose German and Italian. German is the class with the highest NLI accuracy in the TOEFL11 corpus across the shared task results and Italian also performs very well. Additionally, there is very little confusion between the two; a binary NLI classifier we trained on the language pair achieved 97% accuracy. For our all-pairs results, given the 11 languages in the TOEFL11 corpus, we have 55 sets of documents of alternating L1s (one of which is German–Italian).

We generate four distinct types of datasets for our experiments using the above methodology. The documents in these datasets, as described below, differ in the parameters used to select the essays for each segment and what type of tokens are used. Tokens (words) can be represented in their original form and used for performing segmentation. Alternatively, using an insight from Wong et al. (2012), we can represent the documents at a level other than lexical: the text could consist of the POS tags corresponding to all of the tokens, or n-grams over those POS tags. The POS representation is motivated by the usefulness of POS-based features for capturing L1-based stylistic differences as noted in §2. Our method for encoding n-grams is described in Appendix A.2.

TOPICSEG-TOKENS This data is generated by keeping the L1 class constant and alternating segments between two topics. We chose Italian for the L1 class and essays from the prompts "P7" and "P8" are used. The dataset, constructed from TOEFL11-TRAIN and TOEFL11-DEV, contains a total of 53 artificial documents, and will be used to verify that topic segmentation as discussed in Eisenstein and Barzilay (2008) functions as expected for data from this domain: that is, that topic change is detectable.

TOPICSEG-PTB Here the tokens in each text are replaced with their POS tags or n-grams over those tags, and the segmentation is performed over this data. In this dataset the tags are obtained via the Stanford Tagger and use the Penn Treebank (PTB) tagset. The same source data (TOEFL11-TRAIN and TOEFL11-DEV), L1 and topics as TOPICSEG-TOKENS are used for a total of 53 documents. This dataset will be used to investigate, *inter alia*, whether segmentation over these stylistically related features could take advantage of topic cues. We would expect not.

L1SEG-PTB This dataset is used for segmentation based on native language, also using (n-grams over) the PTB POS tags. We choose a specific topic and then retrieve all essays from the corpus that match this; here we chose prompt "P7", since it had the largest number of essays for our chosen single L1 pair, German–Italian. For the dataset constructed from TOEFL11-TRAIN and TOEFL11-DEV (which we will refer to as L1SEG-PTB-GI-DEV), this resulted in 57 documents. Documents that are composites of two L1s are then generated as described above. For investigating questions 2 and 3 above, we similarly have datasets constructed from the the smaller TOEFL11-TEST data (L1SEG-PTB-GI-TEST), which consist of 5 documents of 5 segments each for the single L1 pair, and from all language pairs (L1SEG-PTB-ALL-DEV, L1SEG-PTB-ALL-TEST). We would expect that these datasets should not be segmentable by topic, as all the segments are on the same topic; the segments should however, differ in stylistic characteristics related to the L1.

L1SEG-CLAWS2 This dataset is generated using the same methodology as L1SEG-PTB, with the exception that the essays are tagged using the RASP tagger which uses the more fine-grained CLAWS2 tagset, noting that the CLAWS2 tagset performed better in the NLI classification task (Malmasi and Cahill, 2015).

3.3 Evaluation

We use the standard P_k (Beeferman et al., 1999) and WindowDiff (WD) (Pevzner and Hearst, 2002) metrics, which (broadly speaking) select sentences using a moving window of size k and determines whether these sentences correctly or incorrectly fall into the same or different reference segmentations. P_k and WD scores range between 0 and 1, with a lower score indicating better performance, and 0 a perfect segmentation. It has been noted that some "degenerate" algorithms — such as placing boundaries randomly or at every possible position — can score 0.5 (Pevzner and Hearst, 2002). WD scores are typically similar to P_k, correcting for differential penalties between false positive boundaries and false negatives implicit in P_k. P_k and WD scores reported in §5 are

averages across all documents in a dataset. Formal definitions are given in Appendix A.3.

4 Segmentation Models

For all of our segmentation we use as a starting point the unsupervised Bayesian method of Eisenstein and Barzilay (2008); see §2.[3] We recap the important technical definitions here.

In Equation 1 of their work they define the observation likelihood as,

$$p(\mathbf{X} \mid \mathbf{z}, \Theta) = \prod_{t}^{T} p(\mathbf{x}_t \mid \theta_{z_t}), \quad (1)$$

where $\mathbf{X}$ is the set of all T sentences, $\mathbf{z}$ is the vector of segment assignments for each sentence, $\mathbf{x}_t$ is the bag of words drawn from the language model and Θ is the set of all K language models $\Theta_1 \ldots \Theta_K$. As is standard in segmentation work, K is assumed to be fixed and known (Malioutov and Barzilay, 2006); it is set to the actual number of segments. The authors also impose an additional constraint, that z_t must be equal to either z_{t-1} (the previous sentence's segment) or $z_{t-1}+1$ (the next segment), in order to ensure a linear segmentation.

This segmentation model has two parameters: the set of language models Θ and the segment assignment indexes $\mathbf{z}$. The authors note that since this task is only concerned with the segment assignments, searching in the space of language models is not desirable. They offer two alternatives to overcome this: (1) taking point estimates of the language models, which is considered to be theoretically unsatisfying and (2) marginalizing them out, which yields better performance. Equation 7 of Eisenstein and Barzilay (2008), reproduced here, shows how they marginalize over the language models, supposing that each language model is drawn from a symmetric Dirichlet prior (*i.e.* $\theta_j \sim \mathrm{Dir}(\theta_0)$):

$$p(\mathbf{X} \mid \mathbf{z}, \theta_0) = \prod_{j}^{K} p_{dcm}(\{\mathbf{x}_t : z_t = j\} \mid \theta_0) \quad (2)$$

The Dirichlet compound multinomial distribution p_{dcm} expresses the expectation over all the multinomial language models, when conditioned on the symmetric Dirichlet prior θ_0:

$$p_{dcm}(\{\mathbf{x}_t : z_t = j\} \mid \theta_0) = \frac{\Gamma(W\theta_0)}{\Gamma(N_j + W\theta_o)} \prod_{i}^{W} \frac{\Gamma(n_{j,i} + \theta_0)}{\Gamma(\theta_0)} \quad (3)$$

where W is the number of words in the vocabulary and $N_j = \sum_i^W n_{j,i}$, the total number of words in the segment j. They then observe that the optimal segmentation maximizes the joint probability

$$p(\mathbf{X}, \mathbf{z} \mid \theta_0) = p(\mathbf{X} \mid \mathbf{z}, \theta_0) p(\mathbf{z})$$

and assume a uniform $p(\mathbf{z})$ over valid segmentations with no probability mass assigned to invalid segmentations. The hyperparameter θ_0 can be chosen, or can be learned via an Expectation-Maximization process.

Inference Eisenstein and Barzilay (2008) defined two methods of inference, a dynamic programming (DP) one and one using Metropolis-Hastings (MH). Only MH is applicable where shifting a boundary will affect the probability of every segment, not just adjacent segments, as in their model incorporating cue phrases. Where this is not the case, they use DP inference. Their DP inference algorithm is suitable for all of our models, so we also use that.

Priors For our priors, we carry out a grid search on the devsets (that is, the datasets derived from TOEFL11-TRAIN and TOEFL11-DEV) in the interval $[0.1, 3.0]$, partitioned into 30 evenly spaced values; this includes both weak and strong priors.[4]

4.1 TOPICSEG

Our first model is exactly the one proposed by Eisenstein and Barzilay (2008) described above. The aim here is to look at how we perform at segmenting learner essays by topic in order to confirm that topic segmentation works for this domain and these types of topics. We apply this model to the TOPICSEG-TOKENS and TOPICSEG-PTB datasets where the texts have the same L1 and boundaries are placed between essays of differing topics (prompts).

4.2 L1SEG

Our second model modifies that of Eisenstein and Barzilay (2008) by revising the generative story.

[3] An open-source implementation of the method, called BAYESSEG, is made available by the authors at `http://groups.csail.mit.edu/rbg/code/bayesseg/`

[4] The Eisenstein and Barzilay (2008) code does implement an EM method for finding priors in the symmetric case, but we found that perhaps surprisingly the grid search almost always found better ones.

Where they assume a standard generative model over words with constraints on topic change between sentences, we make minor modifications to adapt the model for our task. The standard generative story (Blei, 2012) — an account of how a model generates the observed data — usually generates words in a two-stage process: (1) For each document, randomly choose a distribution of topics. (2) For each word in the document: (a) Assign a topic from those chosen in step 1. (b) Randomly choose a word from that topic's vocabulary.

Here we modify this story to be over part-of-speech data instead of lexical items. By using this representation (which as noted in §2 is useful for NLI classification) we aim to segment our texts based on the L1 of the author for each segment. For this model we only make use of the L1SEG-PTB-GI-DEV dataset.[5]

4.3 L1SEG-COMP

It is not obvious that the same properties that produce compact distributions in standard lexical chains would also be the case for POS data, particularly if extended to POS n-grams which can result in a very large number of potential tokens. In this regard Eisenstein and Barzilay (2008) note: "To obtain a high likelihood, the language models associated with each segment should concentrate their probability mass on a compact subset of words. Language models that spread their probability mass over a broad set of words will induce a lower likelihood. This is consistent with the principle of lexical cohesion."

Eisenstein and Barzilay (2008) discuss this within the context of topic segmentation.[6] However, it is unclear if this would also would happen for POS tags; there is no syntactic analogue for the sort of lexical chains important in topic segmentation. It may then turn out that using all POS tags or n-grams over them as in the previous model would not achieve a strong performance. We thus use knowledge from the NLI classification task to help.

Discarding Non-Discriminative Features One approach that could possibly overcome these limitations is the removal of features from the input space that have been found to be non-discriminative in NLI classification. This would allow us to encode POS sequence information via n-grams while also keeping the model's vocabulary sufficiently small. Doing this requires the use of extrinsic information for filtering the n-grams. The use of such extrinsic information has proven to be useful for other similar tasks such as the poetry style change segmentation work of Brooke et al. (2012), as noted in §2.

We perform this filtering using the discriminative feature lists derived from the NLI classification task using the system and method described in Malmasi and Dras (2014), also noted in §2. We extract the top 300 most discriminative POS n-gram features for each L1 from TOEFL11-TRAIN and TOEFL11-DEV, resulting in two lists of 600 POS bigrams and trigrams; these are thus independent of our test datasets. (We illustrate a text with respect to these discriminative features in Appendix A.4.) Note that discriminative n-grams can overlap with each other within the same class and also between two classes. We resolve such conflicts by using the weights of the features from the classification task as described in Malmasi and Dras (2014) and choosing the feature with the higher weight.

4.4 L1SEG-ASYMP

Looking at the distribution of discriminative features in our documents, one idea is that incorporating knowledge about which features are associated with which L1 could potentially help improve the results. One approach to do this is the use of asymmetric priors. We note that features associated with an L1 often dominate in a segment. Accordingly, priors can represent evidence external to the data that some some aspect should be weighted more strongly: for us, this is evidence from the NLI classification task. The segmentation models discussed so far only make use of a symmetric prior but later work mentions that it would be possible to modify this to use an asymmetric prior (Eisenstein, 2009).

Given that priors are effective for incorporating external information, recent work has highlighted the importance of optimizing over such priors, and in particular, the use of asymmetric priors. Key work on this is by Wallach et al. (2009) on LDA, who report that "an asymmetric Dirichlet prior over the document-topic distributions has substantial advantages over a symmetric prior",

[5] We also looked at including words. The results of these models were always worse, and we do not discuss them in this paper.

[6] For example, a topic segment related to the previously mentioned essay prompt P7 might concentrate its probability mass on the following set of words: {`education`, `learning`, `understanding`, `fact`, `theory`, `idea`, `concept`, `knowledge`}.

with prior values being determined through hyperparameter optimization. Such methods have since been applied in other tasks such as sentiment analysis (Lin and He, 2009; Lin et al., 2012) to achieve substantial improvements. For sentiment analysis, Lin and He (2009) incorporate external information from a subjectivity lexicon. In applying LDA, instead of using a uniform Dirichlet prior for the document–sentiment distribution, they use asymmetric priors for positive and negative sentiment, determined empirically.

For our task, we assign a prior to each of two languages in a document, one corresponding to $\mathrm{L1}_a$ and the other to $\mathrm{L1}_b$. Given this, we can assume that segments will alternate between $\mathrm{L1}_a$ and $\mathrm{L1}_b$. And instead of a single θ_0, we have two asymmetric priors that we call θ_a, θ_b corresponding to $\mathrm{L1}_a$ and $\mathrm{L1}_b$ respectively. This will require reworking the definition of p_{dcm} in Equation 3. First adapting Equation 2,

$$p(\mathbf{X} \mid \mathbf{z}, \theta_a, \theta_b) = \prod_{\{j_o\}} p_{dcm}(\{\mathbf{x}_t : z_t = j_o\} \mid \theta_a) \cdot \prod_{\{j_e\}} p_{dcm}(\{\mathbf{x}_t : z_t = j_e\} \mid \theta_b), \quad (4)$$

with $\{j_o\} = \{j \mid j \mod 2 = 1, 1 \leq j \leq K\}$ the set of indices over odd segments and $\{j_e\} = \{j \mid j \mod 2 = 0, 1 \leq j \leq K\}$ the set over evens. K is the (usual) total number of segments. Then

$$p_{dcm}(\{\mathbf{x}_t : z_t = j_o\} \mid \theta_a) = \frac{\Gamma(\sum_k^W \theta_a[k])}{\Gamma(N_{j_o} + \sum_k^W \theta_a[k])} \prod_i^W \frac{\Gamma(n_{j,i} + \theta_a[i])}{\Gamma(\theta_a[i])} \quad (5)$$

W is now more generally the number of items in our vocabulary (whether words or POS n-grams). A notational addition here is $\theta_a[k]$ which refers to the $\mathrm{L1}_a$ prior for the kth word or POS n-gram. There is an analogous p_{dcm} for θ_b.

The next issue is how to construct the θ_a and θ_b. The simplest scenario would require a single constant value for all elements in one L1 and another for all elements in the other L1. Specifically, using $\mathrm{discrim}(\mathrm{L1}_x)$ to denote "the ranked list of discriminative n-grams for $\mathrm{L1}_x$", we define

$$\theta_a[i] = \begin{cases} c_1 & \text{if } \theta_a[i] \in \mathrm{discrim}(\mathrm{L1}_a) \\ c_2 & \text{if } \theta_a[i] \in \mathrm{discrim}(\mathrm{L1}_b) \end{cases}$$

and analogously for $\theta_b[i]$. We would expect that $c_1 > c_2$ (*i.e.* the prior is stronger for elements that come from the appropriate ranked list of discriminative features), but these values will be learned.

In principle we would calculate versions of $p(\mathbf{X} \mid \mathbf{z}, \theta_a, \theta_b)$ twice: once where we assign θ_a to segment 1, and the second time where we assign θ_b. We'd then compare the two $p(\mathbf{X} \mid \mathbf{z}, \theta_a, \theta_b)$, and see which one fits better. In this work, however, we will fix the initial L1: segment 1 corresponds to $\mathrm{L1}_a$ and consequently has prior θ_a.[7]

5 Results

5.1 Segmenting by Topic

We begin by testing the TOPICSEG model to ensure that the Bayesian segmentation methodology can achieve reasonable results for segmenting learner essays by topic. The results on the TOPICSEG-TOKENS dataset (Table 1) show that content words are very effective at segmenting the writings by topic, achieving $\mathrm{P_k}$ values in the range 0.19–0.21. These values are similar to those reported for segmenting *Wall Street Journal* text (Beeferman et al., 1999). On the other hand, using the PTB POS tag version of the data in the TOPICSEG-PTB dataset results in very poor segmentation results, with $\mathrm{P_k}$ values around 0.45. This is essentially the same as the performance of degenerate algorithms (noted in §3.3) of 0.5. This demonstrates that, as expected, POS unigrams do not provide enough information for topic segmentation; it is not possible to construct even an approximation to lexical chains using them.

5.2 L1-based Segmentation

Having verified that the Bayesian segmentation approach is effective for topic segmentation on this data, we now turn to the L1SEG model for segmenting by the native language.

From the results in Table 1 we see very poor performance with a $\mathrm{P_k}$ value of 0.466 for segmenting the texts in L1SEG-PTB-GI-DEV using the unigrams as is. This was a somewhat unexpected result given than we know POS unigram distributions are able to capture differences between L1-groups (Malmasi and Cahill, 2015), albeit with limited accuracy. Moreover, neither bigram nor trigram encodings, which perform better at NLI, resulted in any improvement in our results.

[7] This requires an extension of the BAYESSEG software to support asymmetric priors. We will make this extended version of the code available under the same conditions as BAYESSEG. Please contact the first or second author for this.

Model	Dataset	Prior(s)	P_k	WD

5.3 Incorporating Discriminative Features

Filtering the bigrams results in some minor improvements over the best results from the L1Seg model. However, there are substantial improvements when using the filtered POS trigrams, with a P_k value of 0.393. We did not test unigrams as they were the weakest NLI feature of the three.

This improvement is, we believe, because the Bayesian modelling of lexical cohesion over the input tokens requires that each segment concentrates its probability mass on a compact subset of words. In the context of the n-gram tokenization method tested in the previous section, the L1Seg model with n-grams would most likely exacerbate the issue by substantially increasing the number of tokens in the language model: while the unigrams do not capture enough information to distinguish non-lexical shifts, the n-grams provide too many features.

We also see that using the CLAWS2 tagset outperforms the PTB tagset. The results achieved for bigrams are much higher, while the trigram results are also better, with $P_k = 0.370$. NLI experiments using different POS tagsets have established that more fine-grained tagsets (*i.e.* those with more tag categories) provide greater classification accuracy when used as n-gram features for classification.[8] Results here comport with the previous findings.

As one of the two best models, we run it on the held-out test data, using the best priors found from the grid search on the devset data (Table 2); we find the P_k and WD values are comparable (and in fact slightly better), so the model still works if the filtering uses discriminative NLI features from the devset. Looking at results across all 55 L1 pairs (Table 3), we also see similar mean P_k and WD values with only a small standard deviation, indicating the approach works just as well across all language pairs. Priors here are all also weak, in the range $[0.1, 0.9]$.

In sum, the results here demonstrate the importance of inducing a compact distribution, which we did here by reducing the vocabulary size by stripping non-informative features.

5.4 Applying Two Asymmetric Priors

Our final model, L1Seg-AsymP, assesses whether setting different priors for each L1 can improve performance. Our grid search over two priors gives 900 possible prior combinations. These combinations also include cases where θ_a and θ_b are symmetric, which is equivalent to the L1Seg-Comp model. We observe (Table 1) that

[8] In §2 we noted the comparison of PTB and CLAWS2 tagsets in Malmasi and Cahill (2015); also, Gyawali et al. (2013) compared Penn Treebank and Universal POS tagsets and found that the more fine-grained PTB ones did better.

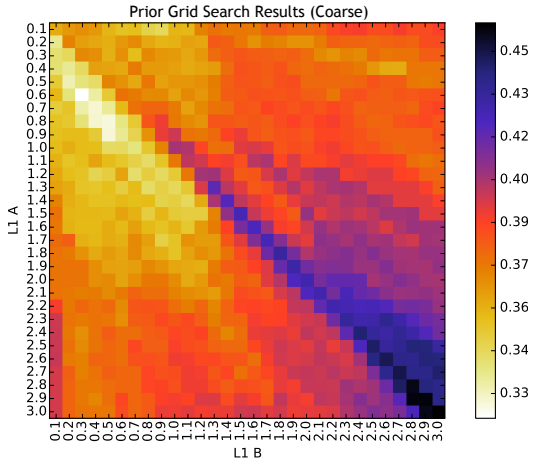

Figure 1: Heatmap over asymmetric priors on L1SEG-CLAWS2-ALL-DEV

the prior pair of $(0.6, 0.3)$ achieves a P_k value of 0.321, a substantial improvement over the previous best result of 0.370. Inspecting priors (see Figure 1 for a heatmap over priors) shows that the best results are in the region of weak priors for both values, which is consistent with the emphasis on compactness since weak priors result in more compact models (noted by *e.g.* Wang and Blei (2009)). Moreover, they are away from the diagonal, *i.e.* the L1SEG-COMP model will not produce the best results. A more fine-grained grid search, focusing on the range that provided the best results in the coarse search, can improve the results further still: over the interval $[0.3, 0.9]$, partitioned into 60 evenly spaced values, finds a prior pair of $(0.64, 0.32)$ that provides a slight improvement of the P_k value to 0.316.

As with L1SEG-COMP, we also evaluate this on the same held-out test set (Table 2). Applying the best asymmetric prior from the devset grid search, this improves to 0.266. Again, results across all 55 L1 pairs (Table 3) show the same pattern, and much as for L1SEG-COMP, priors are all weak or neutral (range $[0.1, 1.0]$). These results thus demonstrate that setting an asymmetric prior gives the best performance on this task.

6 Conclusion and Future Work

Applying the approach to our two illustrative applications of §1, patchwriting and literary analysis, would require development of relevant corpora. In both cases the distinction would be between native writing and writing that shows characteristics of a non-native speaker, rather than between two non-native L1s. There isn't yet a topic-balanced corpus like TOEFL11 which includes native speaker writing for evaluation, although we expect (given recent results on distinguishing native from non-native text in Malmasi and Dras (2015)) that the techniques should carry over. For the literary analysis, as well, to bridge the gap between work like Morzinski (1994) and a computational application, it remains to be seen how precise an annotation is possible for this task. Additionally, the granularity of segmentation may need to be finer than sentence-level, as suggested by the examples in §1; this level of granularity hasn't previously been tackled in unsupervised segmentation.

In terms of possible developments for the models presented for the task here, previous NLI work has shown that other, syntactic features can be useful for capturing L1-based differences. The incorporation of these features for this segmentation task could be a potentially fruitful avenue for future work. We have taken a fairly straightforward approach which modifies the generative story. A more sophisticated approach would be to incorporate features into the unsupervised model. One such example is the work of Berg-Kirkpatrick et al. (2010) which demonstrates that each component multinomial of a generative model can be turned into a miniature logistic regression model with the use of a modified EM algorithm. Their results showed that the feature-enhanced unsupervised models which incorporate linguistically-motivated features achieve substantial improvements for tasks such as POS induction and word segmentation. We note also that the models are potentially applicable to other stylistic segmentation tasks beyond L1 influence.

As far as this initial work is concerned we have shown that, framed as a segmentation task, it is possible to identify units of text that differ stylistically in their L1 influence. We demonstrated that it is possible to define a generative story and associated Bayesian models for stylistic segmentation, and further that segmentation results improve substantially by compacting the n-gram distributions, achieved by incorporating knowledge about discriminative features extracted from NLI models. Our best results come from a model that uses alternating asymmetric priors for each L1, with the priors selected using a grid search and then evaluated on a held-out test set.

The authors thank John Pate for very helpful discussions in the early stages of the paper, and the three anonymous referees for useful suggestions.

A Details on Dataset Generation and Evaluation

A.1 Document Generation

For our L1-varying datasets, we construct composite documents to be segmented as alternating segments drawn from TOEFL11 from two different L1s. Broadly following a standard approach (Brooke et al., 2012, for example), to generate such a document, we randomly draw TOEFL11 essays — each of which constitutes a segment — from the appropriate L1s and concatenate them, alternating the L1 class after each segment. This is repeated until the maximum number of segments per document, s, is reached. We generate multiple composite documents until all TOEFL11 have been used. In this work we use datasets generated with $s = 5$.[9] We follow the same process for our topic-varying datasets, but hold the L1 constant while alternating the topic (prompt).

A.2 Encoding n-gram information

Lau et al. (2013) investigated the importance of n-grams within topic models over lexical items. They note that in topic modelling each token receives a topic label and that the words in a collocation — *e.g. stock market*, *White House* or *health care* — may receive different topic assignments despite forming a single semantic unit. They found that identifying collocations (via a t-test) and preprocessing the text to turn these into single tokens provides a notable improvement over a unigram bag of words.

We implement a similar preprocessing step that converts each sentence within each document to a set of bigrams or trigrams using a sliding window, where each n-gram is represented by a single token. So, for example, the trigram `DT JJ NN` becomes a single token: `DT-JJ-NN`.

A.3 Evaluation: Metric Definitions

Given two segmentations r (reference) and h (hypothesis) for a corpus of N sentences,

[9] This is the average number of segments per chapter in the written text used by Eisenstein and Barzilay (2008). However, we have also successfully replicated our results using $s = 7, 9$.

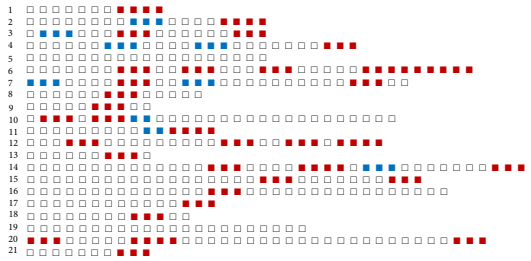

Figure 2: A visualization of sentences from a single segment. Each row represents a sentence and each token is represented by a square. Token trigrams considered discriminative for either of our two L1 classes are shown in blue or red, with the rest being considered non-discriminative.

$$P_D(r,h) = \sum_{1 \le i \le j \le N} D(i,j)(\delta_r(i,j) \bar{\oplus} \delta_h(i,j)) \quad (6)$$

where $\delta_r(i,j)$ is an indicator function specifying whether i and j lie in the same reference segment, $\delta_h(i,j)$ similarly for a hypothesised segment, $\bar{\oplus}$ is the XNOR function, and D is a distance probability distribution over the set of possible distances between sentences. For P_k, this D is defined by a fixed window of size k which contains all the probability mass, and k is set to be half the average reference segment length. The WD definition is:

$$WD(r,h) = \frac{1}{N-k} \sum_{i=1}^{N-k} (|b(r_i, r_{i+k}) - b(h_i, h_{i+k})| > 0) \quad (7)$$

where $b(r_i, r_j)$ represents the number of boundaries between positions i and j in the reference text (similarly, the hypothesis text).

A.4 Visualisation of Discriminative Features

Figure 2 shows a visualization of the discriminative features of a single segment where each row represents a sentence and each token is represented by a square. Tokens that are part of a trigram which is considered discriminative for either of our two L1 classes are shown in blue or red. Note that discriminative n-grams can overlap with each other within the same class (*e.g.* on lines 1 and 2 where two overlapping trigrams form a group of four consecutive tokens) and also between two classes (*e.g.* on lines 10 and 11).

Abstract

The state-of-the-art named entity recognition (NER) systems are supervised machine learning models that require large amounts of manually annotated data to achieve high accuracy. However, annotating NER data by human is expensive and time-consuming, and can be quite difficult for a new language. In this paper, we present two weakly supervised approaches for cross-lingual NER with no human annotation in a target language. The first approach is to create automatically labeled NER data for a target language via annotation projection on comparable corpora, where we develop a heuristic scheme that effectively selects good-quality projection-labeled data from noisy data. The second approach is to project distributed representations of words (word embeddings) from a target language to a source language, so that the source-language NER system can be applied to the target language without re-training. We also design two co-decoding schemes that effectively combine the outputs of the two projection-based approaches. We evaluate the performance of the proposed approaches on both in-house and open NER data for several target languages. The results show that the combined systems outperform three other weakly supervised approaches on the CoNLL data.

1 Introduction

Named entity recognition (NER) is a fundamental information extraction task that automatically detects named entities in text and classifies them into pre-defined entity types such as PERSON, ORGANIZATION, GPE (GeoPolitical Entities), EVENT, LOCATION, TIME, DATE, etc. NER provides essential inputs for many information extraction applications, including relation extraction, entity linking, question answering and text mining. Building fast and accurate NER systems is a crucial step towards enabling large-scale automated information extraction and knowledge discovery on the huge volumes of electronic documents existing today.

The state-of-the-art NER systems are supervised machine learning models (Nadeau and Sekine, 2007), including maximum entropy Markov models (MEMMs) (McCallum et al., 2000), conditional random fields (CRFs) (Lafferty et al., 2001) and neural networks (Collobert et al., 2011; Lample et al., 2016). To achieve high accuracy, a NER system needs to be trained with a large amount of manually annotated data, and is often supplied with language-specific resources (e.g., gazetteers, word clusters, etc.). Annotating NER data by human is rather expensive and time-consuming, and can be quite difficult for a new language. This creates a big challenge in building NER systems of multiple languages for supporting multilingual information extraction applications.

The difficulty of acquiring supervised annotation raises the following question: given a well-trained NER system in a source language (e.g., English), how can one go about extending it to a new language with decent performance and no human annotation in the target language? There are mainly two types of approaches for building weakly supervised cross-lingual NER systems.

The first type of approaches create weakly labeled NER training data in a target language. One way to create weakly labeled data is through annotation projection on aligned parallel corpora or translations between a source language and a target language, e.g., (Yarowsky et al., 2001; Zitouni and Florian, 2008; Ehrmann et al., 2011). Another way is to utilize the text and structure of

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1470–1480
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1135

Wikipedia to generate weakly labeled multilingual training annotations, e.g., (Richman and Schone, 2008; Nothman et al., 2013; Al-Rfou et al., 2015).

The second type of approaches are based on direct model transfer, e.g., (Täckström et al., 2012; Tsai et al., 2016). The basic idea is to train a single NER system in the source language with language independent features, so the system can be applied to other languages using those universal features.

In this paper, we make the following contributions to weakly supervised cross-lingual NER with no human annotation in the target languages. First, for the *annotation projection* approach, we develop a heuristic, language-independent data selection scheme that seeks to select good-quality projection-labeled NER data from comparable corpora. Experimental results show that the data selection scheme can significantly improve the accuracy of the target-language NER system when the alignment quality is low and the projection-labeled data are noisy.

Second, we propose a new approach for direct NER model transfer based on *representation projection*. It projects word representations in vector space (word embeddings) from a target language to a source language, to create a universal representation of the words in different languages. Under this approach, the NER system trained for the source language can be directly applied to the target language without the need for re-training.

Finally, we design two *co-decoding* schemes that combine the outputs (views) of the two projection-based systems to produce an output that is more accurate than the outputs of individual systems. We evaluate the performance of the proposed approaches on both in-house and open NER data sets for a number of target languages. The results show that the combined systems outperform the state-of-the-art cross-lingual NER approaches proposed in Täckström et al. (2012), Nothman et al. (2013) and Tsai et al. (2016) on the CoNLL NER test data (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003).

We organize the paper as follows. In Section 2 we introduce three NER models that are used in the paper. In Section 3 we present an annotation projection approach with effective data selection. In Section 4 we propose a representation projection approach for direct NER model transfer. In Section 5 we describe two co-decoding schemes that effectively combine the outputs of two projection-based approaches. In Section 6 we evaluate the performance of the proposed approaches. We describe related work in Section 7 and conclude the paper in Section 8.

2 NER Models

The NER task can be formulated as a sequence labeling problem: given a sequence of words $x_1, ..., x_n$, we want to infer the NER tag l_i for each word x_i, $1 \leq i \leq n$. In this section we introduce three NER models that are used in the paper.

2.1 CRFs and MEMMs

Conditional random fields (CRFs) are a class of discriminative probabilistic graphical models that provide powerful tools for labeling sequential data (Lafferty et al., 2001). CRFs learn a conditional probability model $p_\lambda(\mathbf{l}|\mathbf{x})$ from a set of labeled training data, where $\mathbf{x} = (\mathbf{x}_1, ..., \mathbf{x}_n)$ is a random sequence of input words, $\mathbf{l} = (\mathbf{l}_1, ..., \mathbf{l}_n)$ is the sequence of label variables (NER tags) for $\mathbf{x}$, and $\mathbf{l}$ has certain Markov properties conditioned on $\mathbf{x}$. Specifically, a general-order CRF with order o assumes that label variable $\mathbf{l}_i$ is dependent on a fixed number o of previous label variables $\mathbf{l}_{i-1}, ..., \mathbf{l}_{i-o}$, with the following conditional distribution:

$$p_\lambda(\mathbf{l}|\mathbf{x}) = \frac{e^{\sum_{i=1}^{n}\sum_{k=1}^{K}\lambda_k f_k(\mathbf{l}_i, \mathbf{l}_{i-1}, ..., \mathbf{l}_{i-o}, \mathbf{x})}}{Z_\lambda(\mathbf{x})} \quad (1)$$

where f_k's are feature functions, λ_k's are weights of the feature functions (parameters to learn), and $Z_\lambda(\mathbf{x})$ is a normalization constant. When $o = 1$, we have a first-order CRF which is also known as a linear-chain CRF.

Given a set of labeled training data $\mathcal{D} = (\mathbf{x}^{(j)}, \mathbf{l}^{(j)})_{j=1,...,N}$, we seek to find an optimal set of parameters λ^* that maximize the conditional log-likelihood of the data:

$$\lambda^* = \arg\max_\lambda \sum_{j=1}^{N} \log p_\lambda(\mathbf{l}^{(j)}|\mathbf{x}^{(j)}) \quad (2)$$

Once we obtain λ^*, we can use the trained model $p_{\lambda^*}(\mathbf{l}|\mathbf{x})$ to decode the most likely label sequence $\mathbf{l}^*$ for any new input sequence of words $\mathbf{x}$ (via the Viterbi algorithm for example):

$$\mathbf{l}^* = \arg\max_{\mathbf{l}} p_{\lambda^*}(\mathbf{l}|\mathbf{x}) \quad (3)$$

A related conditional probability model, called *maximum entropy Markov model* (MEMM) (McCallum et al., 2000), assumes that $\mathbf{l}$ is a Markov

chain conditioned on $\mathbf{x}$:

$$p_\lambda(\mathbf{l}|\mathbf{x}) = \prod_{i=1}^{n} p_\lambda(\mathbf{l}_i|\mathbf{l}_{i-1},...,\mathbf{l}_{i-o},\mathbf{x}) = \prod_{i=1}^{n} \frac{e^{\sum_{k=1}^{K}\lambda_k f_k(\mathbf{l}_i,\mathbf{l}_{i-1},...,\mathbf{l}_{i-o},\mathbf{x})}}{Z_\lambda(\mathbf{l}_{i-1},...,\mathbf{l}_{i-o},\mathbf{x})} \quad (4)$$

The main difference between CRFs and MEMMs is that CRFs normalize the conditional distribution over the whole sequence as in (1), while MEMMs normalize the conditional distribution per token as in (4). As a result, CRFs can better handle the label bias problem (Lafferty et al., 2001). This benefit, however, comes at a price. The training time of order-o CRFs grows exponentially ($O(M^{o+1})$) with the number of output labels M, which is typically slow even for moderate-size training data if M is large. In contrast, the training time of order-o MEMMs is linear ($O(M)$) with respect to M independent of o, so it can handle larger training data with higher order of dependency. We have implemented both a linear-chain CRF model and a general-order MEMM model.

2.2 Neural Networks

With the increasing popularity of distributed (vector) representations of words, neural network models have recently been applied to tackle many NLP tasks including NER (Collobert et al., 2011; Lample et al., 2016).

We have implemented a feedforward neural network model which maximizes the log-likelihood of the training data similar to that of (Collobert et al., 2011). We adopt a locally normalized model (the conditional distribution is normalized per token as in MEMMs) and introduce context dependency by conditioning on the previously assigned tags. We use a target word and its surrounding context as features. We do not use other common features such as gazetteers or character-level representations as such features might not be readily available or might not transfer to other languages.

We have deployed two neural network architectures. The first one (called NN1) uses the word embedding of a word as the input. The second one (called NN2) adds a smoothing prototype layer that computes the cosine similarity between a word embedding and a fixed set of prototype vectors (learned during training) and returns a weighted average of these prototype vectors as the input. In our experiments we find that with the smoothing layer, NN2 tends to have a more balanced precision and recall than NN1. Both networks have one hidden layer, with sigmoid and softmax activation functions on the hidden and output layers respectively. The two neural network models are depicted in Figure 1.

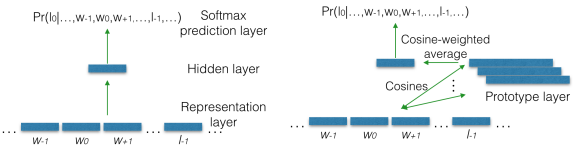

Figure 1: Architecture of the two neural network models: left-NN1, right-NN2.

3 Annotation Projection Approach

The existing annotation projection approaches require parallel corpora or translations between a source language and a target language with alignment information. In this paper, we develop a heuristic, language-independent data selection scheme that seeks to select good-quality projection-labeled data from noisy comparable corpora. We use English as the source language.

Suppose we have comparable[1] sentence pairs $(\mathbf{X},\mathbf{Y})$ between English and a target language, where $\mathbf{X}$ includes N English sentences $\mathbf{x}^{(1)},...,\mathbf{x}^{(N)}$, $\mathbf{Y}$ includes N target-language sentences $\mathbf{y}^{(1)},...,\mathbf{y}^{(N)}$, and $\mathbf{y}^{(j)}$ is aligned to $\mathbf{x}^{(j)}$ via an alignment model, $1 \le j \le N$. We use a sentence pair $(\mathbf{x},\mathbf{y})$ as an example to illustrate how the annotation projection procedure works, where $\mathbf{x} = (x_1, x_2, ..., x_s)$ is an English sentence, and $\mathbf{y} = (y_1, y_2, ..., y_t)$ is a target-language sentence that is aligned to $\mathbf{x}$.

Annotation Projection Procedure

1. Apply the English NER system on the English sentence $\mathbf{x}$ to generate the NER tags $\mathbf{l} = (l_1, l_2, ..., l_s)$ for $\mathbf{x}$.

2. Project the NER tags to the target-language sentence $\mathbf{y}$ using the alignment information. Specifically, if a sequence of English words $(x_i, ..., x_{i+p})$ is aligned to a sequence of target-language words $(y_j, ..., y_{j+q})$, and $(x_i, ..., x_{i+p})$ is recognized (by the English NER system) as an entity with NER tag l,

[1] Ideally, the sentences would be translations of each other, but we only require possibly parallel sentences.

then $(y_j, ..., y_{j+q})$ is labeled with l[2].
Let $\mathbf{l}' = (l'_1, l'_2, ..., l'_t)$ be the projected NER tags for the target-language sentence $\mathbf{y}$.

We can apply the annotation projection procedure on all the sentence pairs $(\mathbf{X}, \mathbf{Y})$, to generate projected NER tags $\mathbf{L}'$ for the target-language sentences $\mathbf{Y}$. ($\mathbf{Y}$, $\mathbf{L}'$) are automatically labeled NER data with no human annotation in the target language. One can use those projection-labeled data to train an NER system in the target language. The quality of such weakly labeled NER data, and consequently the accuracy of the target-language NER system, depend on both 1) the accuracy of the English NER system, and 2) the alignment accuracy of the sentence pairs.

Since we don't require actual translations, but only comparable data, the downside is that if some of the data are not actually parallel and if we use all for weakly supervised learning, the accuracy of the target-language NER system might be adversely affected. We are therefore motivated to design effective data selection schemes that can select good-quality projection-labeled data from noisy data, to improve the accuracy of the annotation projection approach for cross-lingual NER.

3.1 Data Selection Scheme

We first design a metric to measure the annotation quality of a projection-labeled sentence in the target language. We construct a frequency table T which includes all the entities in the projection-labeled target-language sentences. For each entity e, T also includes the projected NER tags for e and the relative frequency (empirical probability) $\hat{P}(l|e)$ that entity e is labeled with tag l. Table 1 shows a snapshot of the frequency table where the target language is Portuguese.

We use $\hat{P}(l|e)$ to measure the reliability of labeling entity e with tag l in the target language. The intuition is that if an entity e is labeled by a tag l with higher frequency than other tags in the projection-labeled data, it is more likely that the annotation is correct. For example, if the joint accuracy of the source NER system and alignment system is greater than 0.5, then the correct tag of a random entity will have a higher relative frequency than other tags in a large enough sample.

Based on the frequency scores, we calculate the quality score of a projection-labeled target-language sentence $\mathbf{y}$ by averaging the frequency scores of the projected entities in the sentence:

$$q(\mathbf{y}) = \frac{\Sigma_{e \in \mathbf{y}} \hat{P}(l'(e)|e)}{n(\mathbf{y})} \quad (5)$$

where $l'(e)$ is the projected NER tag for e, and $n(\mathbf{y})$ is the total number of entities in sentence $\mathbf{y}$.

We use $q(\mathbf{y})$ to measure the annotation quality of sentence $\mathbf{y}$, and $n(\mathbf{y})$ to measure the amount of annotation information contained in sentence $\mathbf{y}$. We design a *heuristic data selection scheme* which selects projection-labeled sentences in the target language that satisfy the following condition:

$$q(\mathbf{y}) \geq q;\ n(\mathbf{y}) \geq n \quad (6)$$

where q is a quality score threshold and n is an entity number threshold. We can tune the two parameters to make tradeoffs among the annotation quality of the selected sentences, the annotation information contained in the selected sentences, and the total number of sentence selected.

One way to select the threshold parameters q and n is via a development set - either a small set of human-annotated data or a sample of the projection-labeled data. We select the threshold parameters via *coordinate search* using the development set: we first fix $n = 3$ and search the best $\hat{q}$ in $[0, 0.9]$ with a step size of 0.1; we then fix $q = \hat{q}$ and select the best $\hat{n}$ in $[1, 5]$ with a step size of 1.

Entity Name	NER Tag	Frequency
Estados Unidos	GPE	0.853
Estados Unidos	ORGANIZATION	0.143
Estados Unidos	PEOPLE	0.001
Estados Unidos	PRODUCT	0.001
Estados Unidos	TITLEWORK	0.001
Estados Unidos	EVENT	0.001

Table 1: A snapshot of the frequency table where the target language is Portuguese. *Estados Unidos* means *United States*. The correct NER tag for Estados Unidos is GPE which has the highest relative frequency in the weakly labeled data.

3.2 Accuracy Improvements

We evaluate the effectiveness of the data selection scheme via experiments on 4 target languages: Japanese, Korean, German and Portuguese. We use comparable corpora between English and each target language (ranging from 2M to 6M tokens) with alignment information. For each target language, we also have a set of manually annotated NER data (ranging from 30K to 45K tokens)

[2]If the IOB (Inside, Outside, Beginning) tagging format is used, then $(y_j, y_{j+1}, ..., y_{j+q})$ is labeled with (B-l, I-l,...,I-l).

Language	(q, n)	Training Size	F_1 Score
Japanese	(0, 0)	4.9M	41.2
	(0.7, 4)	1.3M	53.4
Korean	(0, 0)	4.5M	25.0
	(0.4, 2)	1.5M	38.7
German	(0, 0)	5.2M	67.2
	(0.4, 4)	2.6M	67.5
Portuguese	(0, 0)	2.1M	61.5
	(0.1, 4)	1.5M	62.7

Table 2: Performance comparison of weakly supervised NER systems trained without data selection ($(q, n) = (0, 0)$) and with data selection ($(\hat{q}, \hat{n})$ determined by coordinate search).

which are served as the test data for evaluating the target-language NER system.

The source (English) NER system is a linear-chain CRF model which achieves an accuracy of 88.9 F_1 score on an independent NER test set. The alignment systems between English and the target languages are maximum entropy models (Ittycheriah and Roukos, 2005), with an accuracy of 69.4/62.0/76.1/88.0 F_1 score on independent Japanese/Korean/German/Portuguese alignment test sets.

For each target language, we randomly select 5% of the projection-labeled data as the development set and the remaining 95% as the training set. We compare an NER system trained with all the projection-labeled training data with no data selection (i.e., $(q, n) = (0, 0)$) and an NER system trained with projection-labeled data selected by the data selection scheme where the development set is used to select the threshold parameters q and n via coordinate search. Both NER systems are 2nd-order MEMM models[3] which use the same template of features.

The results are shown in Table 2. For different target languages, we use the same source (English) NER system for annotation projection, so the differences in the accuracy improvements are mainly due to the alignment quality of the comparable corpora between English and different target languages. When the alignment quality is low (e.g., as for Japanese and Korean) and hence the projection-labeled NER data are quite noisy, the proposed data selection scheme is very effective in selecting good-quality projection-labeled data and the improvement is big: +12.2 F_1 score for Japanese and +13.7 F_1 score for Korean. Using a stratified shuffling test (Noreen, 1989), for a significance level of 0.05, data-selection is statistically significantly better than no-selection for Japanese, Korean and Portuguese.

[3]In our experiments, CRFs cannot handle training data with a few million words, since our NER system has over 50 entity types, and the training time of CRFs grows at least quadratically in the number of entity types.

4 Representation Projection Approach

In this paper, we propose a new approach for direct NER model transfer based on representation projection. Under this approach, we train a single English NER system that uses only word embeddings as input representations. We create mapping functions which can map words in any language into English and we simply use the English NER system to decode. In particular, by mapping all languages into English, we are using one universal NER system and we do not need to re-train the system when a new language is added.

4.1 Monolingual Word Embeddings

We first build vector representations of words (word embeddings) for a language using monolingual data. We use a variant of the Continuous Bag-of-Words (CBOW) word2vec model (Mikolov et al., 2013a), which concatenates the context words surrounding a target word instead of adding them (similarly to (Ling et al., 2015)). Additionally, we employ weights $w = \frac{1}{dist(x,x_c)}$ that decay with the distance of a context word x_c to a target word x. Tests on word similarity benchmarks show this variant leads to small improvements over the standard CBOW model.

We train 300-dimensional word embeddings for English. Following (Mikolov et al., 2013b), we use larger dimensional embeddings for the target languages, namely 800. We train word2vec for 1 epoch for English/Spanish and 5 epochs for the rest of the languages for which we have less data.

4.2 Cross-Lingual Representation Projection

We learn cross-lingual word embedding mappings, similarly to (Mikolov et al., 2013b). For a target language f, we first extract a small training dictionary from a phrase table that includes word-to-word alignments between English and the target language f. The dictionary contains English and target-language word pairs with weights: $(x_i, y_i, w_i)_{i=1,...,n}$, where x_i is an English word, y_i is a target-language word, and the weight $w_i = \hat{P}(x_i|y_i)$ is the relative frequency of x_i given y_i as extracted from the phrase table.

Suppose we have monolingual word embeddings for English and the target language f. Let $\mathbf{u_i} \in \mathcal{R}^{d_1}$ be the vector representation for English word x_i, $\mathbf{v_i} \in \mathcal{R}^{d_2}$ be the vector representation for target-language word y_i. We find a linear mapping $\mathbf{M}_{f \to e}$ by solving the following weighted least squares problem where the dictionary is used as the training data:

$$\mathbf{M}_{f \to e} = \arg\min_{\mathbf{M}} \sum_{i=1}^{n} w_i ||\mathbf{u_i} - \mathbf{M}\mathbf{v_i}||^2 \quad (7)$$

In (7) we generalize the formulation in (Mikolov et al., 2013b) by adding frequency weights to the word pairs, so that more frequent pairs are of higher importance. Using $\mathbf{M}_{f \to e}$, for any new word in f with vector representation $\mathbf{v}$, we can project it into the English vector space as the vector $\mathbf{M}_{f \to e}\mathbf{v}$.

The training dictionary plays a key role in finding an effective cross-lingual embedding mapping. To control the size of the dictionary, we only include word pairs with a minimum frequency threshold. We set the threshold to obtain approximately 5K to 6K unique word pairs for a target language, as our experiments show that larger-size dictionaries might harm the performance of representation projection for direct NER model transfer.

4.3 Direct NER Model Transfer

The source (English) NER system is a neural network model (with architecture NN1 or NN2) that uses only word embedding features (embeddings of a word and its surrounding context) in the English vector space. Model transfer is achieved simply by projecting the target language word embeddings into the English vector space and decoding these using the English NER system.

More specifically, given the word embeddings of a sequence of words in a target language f, $(\mathbf{v}_1, ..., \mathbf{v}_t)$, we project them into the English vector space by applying the linear mapping $\mathbf{M}_{f \to e}$: $(\mathbf{M}_{f \to e}\mathbf{v}_1, ..., \mathbf{M}_{f \to e}\mathbf{v}_t)$. The English NER system is then applied on the projected input to produce NER tags. Words not in the target-language vocabulary are projected into their English embeddings if they are found in the English vocabulary, or into an NER-trained UNK vector otherwise.

5 Co-Decoding

Given two weakly supervised NER systems which are trained with different data using different models (MEMM model for annotation projection and neural network model for representation projection), we would like to design a *co-decoding* scheme that can combine the outputs (views) of the two systems to produce an output that is more accurate than the outputs of individual systems.

Since both systems are statistical models and can produce confidence scores (probabilities), a natural co-decoding scheme is to compare the confidence scores of the NER tags generated by the two systems and select the tags with higher confidences scores. However, confidence scores of two weakly supervised systems may not be directly comparable, especially when comparing O tags with non-O tags (i.e., entity tags). We consider an *exclude-O confidence-based co-decoding scheme* which we find to be more effective empirically. It is similar to the pure confidence-based scheme, with the only difference that it always prefers a non-O tag of one system to an O tag of the other system, regardless of their confidence scores.

In our experiments we find that the annotation projection system tends to have a high precision and low recall, i.e., it detects fewer entities, but for the detected entities the accuracy is high. The representation projection system tends to have a more balanced precision and recall. Based on this observation, we develop the following *rank-based co-decoding scheme* that gives higher priority to the high-precision annotation projection system:

1. The combined output includes all the entities detected by the annotation projection system.

2. It then adds all the entities detected by the representation projection system that do not conflict[4] with entities detected by the annotation projection system (to improve recall).

Note that an entity X detected by the representation projection system does not conflict with the annotation projection system if the annotation projection system produces O tags for the entire span of X. For example, suppose the output tag sequence of annotation projection is (B-PER,O,O,O,O), of representation projection is (B-ORG,I-ORG,O,B-LOC,I-LOC), then the combined output under the rank-based scheme will be (B-PER,O,O,B-LOC,I-LOC).

[4]Two entities detected by two different systems conflict with each other if either 1) the two entities have different spans but overlap with each other; or 2) the two entities have the same span but with different NER tags.

6 Experiments

In this section, we evaluate the performance of the proposed approaches for cross-lingual NER, including the 2 projection-based approaches and the 2 co-decoding schemes for combining them:
(1) The annotation projection (AP) approach with heuristic data selection;
(2) The representation projection approach (with two neural network architectures NN1 and NN2);
(3) The exclude-O confidence-based co-decoding scheme;
(4) The rank-based co-decoding scheme.

6.1 NER Data Sets

We have used various NER data sets for evaluation. The first group includes in-house human-annotated newswire NER data for four languages: Japanese, Korean, German and Portuguese, annotated with over 50 entity types. The main motivation of deploying such a fine-grained entity type set is to build cognitive question answering applications on top of the NER systems. The entity type set has been engineered to cover many of the frequent entity types that are targeted by naturally-phrased questions. The sizes of the test data sets are ranging from 30K to 45K tokens.

The second group includes open human-annotated newswire NER data for Spanish, Dutch and German from the CoNLL NER data sets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003). The CoNLL data have 4 entity types: PER (persons), ORG (organizations), LOC (locations) and MISC (miscellaneous entities). The sizes of the development/test data sets are ranging from 35K to 70K tokens. The development data are used for tuning the parameters of learning methods.

6.2 Evaluation for In-House NER Data

In Table 3, we show the results of different approaches for the in-house NER data. For annotation projection, the source (English) NER system is a linear-chain CRF model trained with 328K tokens of human-annotated English newswire data. The target-language NER systems are 2nd-order MEMM models trained with 1.3M, 1.5M, 2.6M and 1.5M tokens of projection-labeled data for Japanese, Korean, German and Portuguese, respectively. The projection-labeled data are selected using the heuristic data selection scheme (see Table 2). For representation projection, the source (English) NER systems are neural network models with architectures NN1 and NN2 (see Figure 1), both trained with 328K tokens of human-annotated English newswire data.

The results show that the annotation projection (AP) approach has a relatively high precision and low recall. For representation projection, neural network model NN2 (with a smoothing layer) is better than NN1, and NN2 tends to have a more balanced precision and recall. The rank-based co-decoding scheme is more effective for combining the two projection-based approaches. In particular, the rank-based scheme that combines AP and NN2 achieves the highest F_1 score among all the weakly supervised approaches for Korean, German and Portuguese (second highest F_1 score for Japanese), and it improves over the best of the two

projection-based systems by 2.2 to 7.4 F_1 score.

We also provide the performance of *supervised learning* where the NER system is trained with human-annotated data in the target language (with size shown in the bracket). While the performance of the weakly supervised systems is not as good as supervised learning, it is important to build weakly supervised systems with decent performance when supervised annotation is unavailable. Even if supervised annotation is feasible, the weakly supervised systems can be used to pre-annotate the data, and we observed that pre-annotation can improve the annotation speed by 40%-60%, which greatly reduces the annotation cost.

6.3 Evaluation for CoNLL NER Data

For the CoNLL data, the source (English) NER system for annotation projection is a linear-chain CRF model trained with the CoNLL English training data (203K tokens), and the target-language NER systems are 2nd-order MEMM models trained with 1.3M, 7.0M and 1.2M tokens of projection-labeled data for Spanish, Dutch and German, respectively. The projection-labeled data are selected using the heuristic data selection scheme, where the threshold parameters q and n are determined via coordinate search based on the CoNLL development sets. Compared with no data selection, the data selection scheme improves the annotation projection approach by 2.7/2.0/2.7 F_1 score on the Spanish/Dutch/German development data. In addition to standard NER features such as n-gram word features, word type features, prefix and suffix features, the target-language NER systems also use the multilingual Wikipedia entity type mappings developed in (Ni and Florian, 2016) to generate dictionary features and as decoding constraints, which improve the annotation projection approach by 3.0/5.4/7.9 F_1 score on the Spanish/Dutch/German development data.

For representation projection, the source (English) NER systems are neural network models (NN1 and NN2) trained with the CoNLL English training data. Compared with the standard CBOW word2vec model, the concatenated variant improves the representation projection approach (NN1) by 8.9/11.4/6.8 F_1 score on the Spanish/Dutch/German development data, as well as by 2.0 F_1 score on English. In addition, the frequency-weighted cross-lingual word embedding projection (7) improves the representation projection approach (NN1) by 2.2/6.3/3.7 F_1 score on the Spanish/Dutch/German development data, compared with using uniform weights on the same data. We do observe, however, that using uniform weights when keeping only the most frequent translation of a word instead of all word pairs above a threshold in the training dictionary, leads to performance similar to that of the frequency-weighted projection.

In Table 4 we show the results for the CoNLL development data. For representation projection, NN1 is better than NN2. Both the annotation projection approach and NN1 tend to have a high precision. In this case, the exclude-O confidence-based co-decoding scheme that combines AP and NN1 achieves the highest F_1 score for Spanish and Dutch (second highest F_1 score for German), and improves over the best of the two projection-based systems by 1.5 to 3.4 F_1 score.

In Table 5 we compare our top systems (confidence or rank-based co-decoding of AP and NN1, determined by the development data) with the best results of the cross-lingual NER approaches proposed in Täckström et al. (2012), Nothman et al. (2013) and Tsai et al. (2016) on the CoNLL test data. Our systems outperform the previous state-of-the-art approaches, closing more of the gap to

supervised learning.

7 Related Work

The traditional annotation projection approaches (Yarowsky et al., 2001; Zitouni and Florian, 2008; Ehrmann et al., 2011) project NER tags across language pairs using parallel corpora or translations. Wang and Manning (2014) proposed a variant of annotation projection which projects expectations of tags and uses them as constraints to train a model based on generalized expectation criteria. Annotation projection has also been applied to several other cross-lingual NLP tasks, including word sense disambiguation (Diab and Resnik, 2002), part-of-speech (POS) tagging (Yarowsky et al., 2001) and dependency parsing (Rasooli and Collins, 2015).

Wikipedia has been exploited to generate weakly labeled multilingual NER training data. The basic idea is to first categorize Wikipedia pages into entity types, either based on manually constructed rules that utilize the category information of Wikipedia (Richman and Schone, 2008) or Freebase attributes (Al-Rfou et al., 2015), or via a classifier trained with manually labeled Wikipedia pages (Nothman et al., 2013). Heuristic rules are then developed in these works to automatically label the Wikipedia text with NER tags. Ni and Florian (2016) built high-accuracy, high-coverage multilingual Wikipedia entity type mappings using weakly labeled data and applied those mappings as decoding constrains or dictionary features to improve multilingual NER systems.

For direct NER model transfer, Täckström et al. (2012) built cross-lingual word clusters using monolingual data in source/target languages and aligned parallel data between source and target languages. The cross-lingual word clusters were then used to generate universal features. Tsai et al. (2016) applied the cross-lingual wikifier developed in (Tsai and Roth, 2016) and multilingual Wikipedia dump to generate language-independent labels (FreeBase types and Wikipedia categories) for n-grams in a document, and those labels were used as universal features.

Different ways of obtaining cross-lingual embeddings have been proposed in the literature. One approach builds monolingual representations separately and then brings them to the same space typically using a seed dictionary (Mikolov et al., 2013b; Faruqui and Dyer, 2014). Another line of work builds inter-lingual representations simultaneously, often by generating mixed language corpora using the supervision at hand (aligned sentences, documents, etc.) (Vulić and Moens, 2015; Gouws et al., 2015). We opt for the first solution in this paper because of its flexibility: we can map all languages to English rather than requiring separate embeddings for each language pair. Additionally we are able to easily add a new language without any constraints on the type of data needed. Note that although we do not specifically create inter-lingual representations, by training mappings to the common language, English, we are able to map words in different languages to a common space. Similar approaches for cross-lingual model transfer have been applied to other NLP tasks such as document classification (Klementiev et al., 2012), dependency parsing (Guo et al., 2015) and POS tagging (Gouws and Søgaard, 2015).

8 Conclusion

In this paper, we developed two weakly supervised approaches for cross-lingual NER based on effective annotation and representation projection. We also designed two co-decoding schemes that combine the two projection-based systems in an intelligent way. Experimental results show that the combined systems outperform three state-of-the-art cross-lingual NER approaches, providing a strong baseline for building cross-lingual NER systems with no human annotation in target languages.

Abstract

We introduce a composite deep neural network architecture for supervised and language independent context sensitive lemmatization. The proposed method considers the task as to identify the correct edit tree representing the transformation between a word-lemma pair. To find the lemma of a surface word, we exploit two successive bidirectional gated recurrent structures - the first one is used to extract the character level dependencies and the next one captures the contextual information of the given word. The key advantages of our model compared to the state-of-the-art lemmatizers such as Lemming and Morfette are - (i) it is independent of human decided features (ii) except the gold lemma, no other expensive morphological attribute is required for joint learning. We evaluate the lemmatizer on nine languages - Bengali, Catalan, Dutch, Hindi, Hungarian, Italian, Latin, Romanian and Spanish. It is found that except Bengali, the proposed method outperforms Lemming and Morfette on the other languages. To train the model on Bengali, we develop a gold lemma annotated dataset[1] (having $1,702$ sentences with a total of $20,257$ word tokens), which is an additional contribution of this work.

1 Introduction

Lemmatization is the process to determine the root/dictionary form of a surface word. Morphologically rich languages suffer due to the existence of various inflectional and derivational variations of a root depending on several linguistic properties such as honorificity, parts of speech (POS), person, tense etc. Lemmas map the related word forms to lexical resources thus identifying them as the members of the same group and providing their semantic and syntactic information. Stemming is a way similar to lemmatization producing the common portion of variants but it has several limitations - (i) there is no guarantee of a stem to be a legitimate word form (ii) words are considered in isolation. Hence, for context sensitive languages i.e. where same inflected word form may come from different sources and can only be disambiguated by considering its neighbouring information, there lemmatization defines the foremost task to handle diverse text processing problems (e.g. sense disambiguation, parsing, translation).

The key contributions of this work are as follows. We address context sensitive lemmatization introducing a two-stage bidirectional gated recurrent neural network (BGRNN) architecture. Our model is a supervised one that needs lemma tagged continuous text to learn. Its two most important advantages compared to the state-of-the-art supervised models (Chrupala et al., 2008; Toutanova and Cherry, 2009; Gesmundo and Samardzic, 2012; Müller et al., 2015) are - (i) we do not need to define hand-crafted features such as the word form, presence of special characters, character alignments, surrounding words etc. (ii) parts of speech and other morphological attributes of the surface words are not required for joint learning. Additionally, unknown word forms are also taken care of as the transformation between word-lemma pair is learnt, not the lemma itself. We exploit two steps learning in our method. At first, characters in the words are passed sequentially through a BGRNN to get a syntactic embedding of each word and then the outputs are

[1]The dataset and the code of model architecture are released with the paper. They are also available in http://www.isical.ac.in/~utpal/resources.php

https://doi.org/10.18653/v1/P17-1136

combined with the corresponding semantic embeddings. Finally, mapping between the combined embeddings to word-lemma transformations are learnt using another BGRNN.

For the present work, we assess our model on nine languages having diverse morphological variations. Out of them, two (Bengali and Hindi) belong to the Indic languages family and the rests (Catalan, Dutch, Hungarian, Italian, Latin, Romanian and Spanish) are taken from the European languages. To evaluate the proposed model on Bengali, a lemma annotated continuous text has been developed. As so far there is no such standard large dataset for supervised lemmatization in Bengali, the prepared one would surely contribute to the respective NLP research community. For the remaining languages, standard datasets are used for experimentation. Experimental results reveal that our method outperforms Lemming (Müller et al., 2015) and Morfette (Chrupala et al., 2008) on all the languages except Bengali.

1.1 Related Works

Efforts on developing lemmatizers can be divided into two principle categories (i) rule/heuristics based approaches (Koskenniemi, 1984; Plisson et al., 2004) which are usually not portable to different languages and (ii) learning based methods (Chrupala et al., 2008; Toutanova and Cherry, 2009; Gesmundo and Samardzic, 2012; Müller et al., 2015; Nicolai and Kondrak, 2016) requiring prior training dataset to learn the morphological patterns. Again, the later methods can be further classified depending on whether context of the current word is considered or not. Lemmatization without context (Cotterell et al., 2016; Nicolai and Kondrak, 2016) is closer to stemming and not the focus of the present work. It is noteworthy here that the supervised lemmatization methods do not try to classify the lemma of a given word form as it is infeasible due to having a large number of lemmas in a language. Rather, learning the transformation between word-lemma pair is more generalized and it can handle the unknown word forms too. Several representations of word-lemma transformation have been introduced so far such as shortest edit script (SES), label set, edit tree by Chrupala et al. (2008), Gesmundo and Samardzic (2012) and Müller et al. (2015) respectively. Following Müller et al. (2015), we consider lemmatization as the edit tree classification problem. Toutanova and Cherry (2009); Müller et al. (2015) also showed that joint learning of lemmas with other morphological attributes is mutually beneficial but obtaining the gold annotated datasets is very expensive. In contrast, our model needs only lemma annotated continuous text (not POS and other tags) to learn the word morphology.

Since our experiments include the Indic languages also, it would not be an overstatement to say that there have been little efforts on lemmatization so far (Faridee et al., 2009; Loponen and Järvelin, 2010; Paul et al., 2013; Bhattacharyya et al., 2014). The works by Faridee et al. (2009); Paul et al. (2013) are language specific rule based for Bengali and Hindi respectively. (Loponen and Järvelin, 2010)'s primary objective was to improve the retrieval performance. Bhattacharyya et al. (2014) proposed a heuristics based lemmatizer using WordNet but they did not consider context of the target word which is an important basis to lemmatize Indic languages. Chakrabarty and Garain (2016) developed an unsupervised language independent lemmatizer and evaluated it on Bengali. They consider the contextual information but the major disadvantage of their method is dependency on dictionary as well as POS information. Very recently, a supervised neural lemmatization model has been introduced by Chakrabarty et al. (2016). They treat the problem as lemma transduction rather than classification. The particular root in the dictionary is chosen as the lemma with which the transduced vector possesses maximum cosine similarity. Hence, their approach fails when the correct lemma of a word is not present in the dictionary. Besides, the lemmatization accuracy obtained by the respective method is not very significant. Apart from the mentioned works, there is no such commendable effort so far.

Rest of this paper is organized as follows. In section 2, we describe the proposed lemmatization method. Experimental setup and the results are presented in section 3. Finally, in section 4 we conclude the paper.

2 The Proposed Method

As stated earlier in section 1.1, we represent the mapping between a word to its lemma using edit tree (Chrupała, 2008; Müller et al., 2015). An edit tree embeds all the necessary edit operations within it i.e. insertions, deletions and substitutions of strings required throughout the transformation

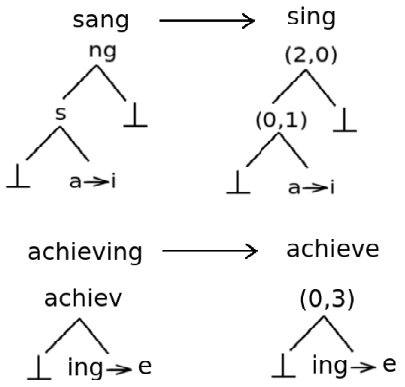

Figure 1: Edit trees for the word-lemma pairs 'sang-sing' and 'achieving-achieve'.

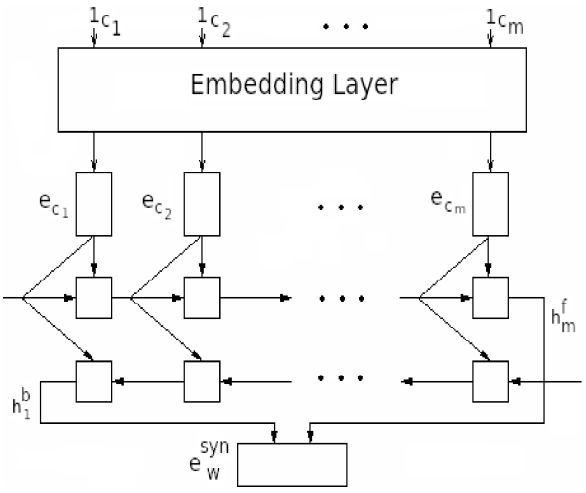

Figure 2: Syntactic vector composition for a word.

process. Figure 1 depicts two edit trees that map the inflected English words *'sang'* and *'achieving'* to their respective lemmas *'sing'* and *'achieve'*. For generalization, edit trees encode only the substitutions and the length of prefixes and suffixes of the longest common substrings. Initially, all unique edit trees are extracted from the associated surface word-lemma pairs present in the training set. The extracted trees refer to the class labels in our model. So, for a test word, the goal is to classify the correct edit tree which, applied on the word, returns the lemma.

Next, we will describe the architecture of the proposed neural lemmatization model. It is evident that for morphologically rich languages, both syntactic and semantic knowledge help in lemmatizing a surface word. Now a days, it is a common practice to embed the functional properties of words into vector representations. Despite the word vectors prove very effectual in semantic processing tasks, they are modelled using the distributional similarity obtained from a raw corpus. Morphological regularities, local and non-local dependencies in character sequences that play deciding roles to find the lemmas, are not taken into account where each word has its own vector interpretation. We address this issue by incorporating two different embeddings into our model. Semantic embedding is achieved using word2vec (Mikolov et al., 2013a,b), which has been empirically found highly successful. To devise the syntactic embedding of a word, we follow the work of Ling et al. (2015) that uses compositional character to word model using bidirectional long-short term memory (BLSTM) network. In our experiments, different gated recurrent cells such as LSTM (Graves, 2013) and GRU (Cho et al., 2014), are explored. The next subsection describes the module to construct the syntactic vectors by feeding the character sequences into BGRNN architecture.

2.1 Forming Syntactic Embeddings

Our goal is to build syntactic embeddings of words that capture the similarities in morphological level. Given an input word w, the target is to obtain a d dimensional vector representing the syntactic structure of w. The procedure is illustrated in Figure 2. At first, an alphabet of characters is defined as C. We represent w as a sequence of characters $c_1, \ldots, c_m$ where m is the word length and each character c_i is defined as a one hot encoded vector $\mathbf{1}_{c_i}$, having one at the index of c_i in the alphabet C. An embedding layer is defined as $\mathbf{E}_c \in \mathbb{R}^{d_c \times |C|}$, that projects each one hot encoded character vector to a d_c dimensional embedded vector. For a character c_i, its projected vector $\mathbf{e}_{c_i}$ is obtained from the embedding layer $\mathbf{E}_c$, using this relation $\mathbf{e}_{c_i} = \mathbf{E}_c \cdot \mathbf{1}_{c_i}$ where '$\cdot$' is the matrix multiplication operation.

Given a sequence of vectors $\mathbf{x}_1, \ldots, \mathbf{x}_m$ as input, a LSTM cell computes the state sequence $\mathbf{h}_1, \ldots, \mathbf{h}_m$ using the following equations:

$$\mathbf{f}_t = \sigma(\mathbf{W}_f \mathbf{x}_t + \mathbf{U}_f \mathbf{h}_{t-1} + \mathbf{V}_f \mathbf{c}_{t-1} + \mathbf{b}_f)$$
$$\mathbf{i}_t = \sigma(\mathbf{W}_i \mathbf{x}_t + \mathbf{U}_i \mathbf{h}_{t-1} + \mathbf{V}_i \mathbf{c}_{t-1} + \mathbf{b}_i)$$
$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot tanh(\mathbf{W}_c \mathbf{x}_t + \mathbf{U}_c \mathbf{h}_{t-1} + \mathbf{b}_c)$$
$$\mathbf{o}_t = \sigma(\mathbf{W}_o \mathbf{x}_t + \mathbf{U}_o \mathbf{h}_{t-1} + \mathbf{V}_o \mathbf{c}_t + \mathbf{b}_o)$$
$$\mathbf{h}_t = \mathbf{o}_t \odot tanh(\mathbf{c}_t),$$

Whereas, the updation rules for GRU are as follows

$$\mathbf{z}_t = \sigma(\mathbf{W}_z\mathbf{x}_t + \mathbf{U}_z\mathbf{h}_{t-1} + \mathbf{b}_z)$$
$$\mathbf{r}_t = \sigma(\mathbf{W}_r\mathbf{x}_t + \mathbf{U}_r\mathbf{h}_{t-1} + \mathbf{b}_r)$$
$$\mathbf{h}_t = (\mathbf{1} - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot tanh(\mathbf{W}_h\mathbf{x}_t + \mathbf{U}_h(\mathbf{r}_t \odot \mathbf{h}_{t-1}) + \mathbf{b}_h),$$

σ denotes the sigmoid function and $\odot$ stands for the element-wise (Hadamard) product. Unlike the simple recurrent unit, LSTM uses an extra memory cell $\mathbf{c}_t$ that is controlled by three gates - input ($\mathbf{i}_t$), forget ($\mathbf{f}_t$) and output ($\mathbf{o}_t$). $\mathbf{i}_t$ controls the amount of new memory content added to the memory cell, $\mathbf{f}_t$ regulates the degree to which the existing memory is forgotten and $\mathbf{o}_t$ finally adjusts the memory content exposure. **W**, **U**, **V** (weight matrices), **b** (bias) are the parameters.

Without having a memory cell like LSTM, a GRU uses two gates namely update ($\mathbf{z}_t$) and reset ($\mathbf{r}_t$). The gate, $\mathbf{z}_t$ decides the amount of update needed for activation and $\mathbf{r}_t$ is used to ignore the previous hidden states (when close to 0, it forgets the earlier computation). So, for a sequence of projected characters $\mathbf{e}_{c_1}, \ldots, \mathbf{e}_{c_m}$, the forward and the backward networks produce the state sequences $\mathbf{h}_1^f, \ldots, \mathbf{h}_m^f$ and $\mathbf{h}_m^b, \ldots, \mathbf{h}_1^b$ respectively. Finally, we obtain the syntactic embedding of w, denoted as $\mathbf{e}_w^{syn}$, by concatenating the final states of these two sequences.

$$\mathbf{e}_w^{syn} = [\mathbf{h}_1^b, \mathbf{h}_m^f]$$

2.2 Model

We present the sketch of the final integrated model in Figure 3. For a word w, let $\mathbf{e}_w^{sem}$ denotes its semantic embedding obtained using word2vec. Both the vectors, $\mathbf{e}_w^{syn}$ and $\mathbf{e}_w^{sem}$ are concatenated together to shape the composite representation $\mathbf{e}_w^{com}$ which carries the morphological and distributional information within it. Firstly, for all the words present in the training set, their composite vectors are generated. Next, they are fed sentence-wise into the next level of BGRNN to train the model for the edit tree classification task. This second level bidirectional network accounts the local context in both forward and backward directions, which is essential for lemmatization in context sensitive languages. Let, $\mathbf{e}_{w_1}^{com}, \ldots, \mathbf{e}_{w_n}^{com}$ be the input sequence of composite vectors to the BGRNN model, representing a sentence having n words $w_1, \ldots, w_n$. For the i^{th} vector $\mathbf{e}_{w_i}^{com}$, $\mathbf{h}_i^f$ and

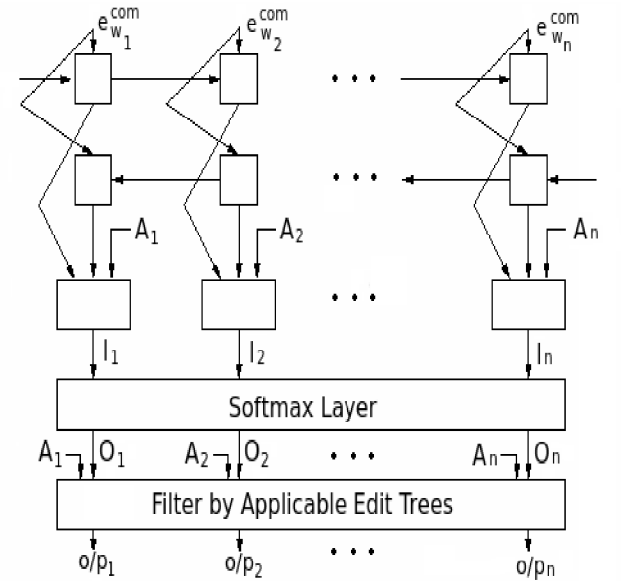

Figure 3: Second level BGRNN model for edit tree classification.

$\mathbf{h}_i^b$ denote the forward and backward states respectively carrying the informations of $w_1, \ldots, w_i$ and $w_i, \ldots, w_n$.

2.2.1 Incorporating Applicable Edit Trees Information

One aspect that we did not look into so far, is that for a word all unique edit trees extracted from the training set are not applicable as this would lead to incompatible substitutions. For example, the edit tree for the word-lemma pair 'sang-sing' depicted in Figure 1, cannot be applied on the word 'achieving'. This information is prior before training the model i.e. for any arbitrary word, we can sort out the subset of unique edit trees from the training samples in advance, which are applicable on it. In general, if all the unique edit trees in the training data are set as the class labels, the model will learn to distribute the probability mass over all the classes which is a clear-cut bottleneck. In order to alleviate this problem, we take a novel strategy so that for individual words in the input sequence, the model will learn, to which classes, the output probability should be apportioned.

Let $T = \{t_1, \ldots, t_k\}$ be the set of distinct edit trees found in the training set. For the word w_i in the input sequence $w_1, \ldots, w_n$, we define its applicable edit trees vector as $\mathbf{A}_i = (a_i^1, \ldots, a_i^k)$ where $\forall j \in \{1, \ldots, k\}$, $a_i^j = 1$ if t_j is applicable for w_i, otherwise 0. Hence, $\mathbf{A}_i$ holds the information regarding the set of edit trees to concentrate

upon, while processing the word w_i. We combine $\mathbf{A}_i$ together with $\mathbf{h}_i^f$ and $\mathbf{h}_i^b$ for the final classification task as following,

$$\mathbf{l}_i = softplus(\mathbf{L}^f \mathbf{h}_i^f + \mathbf{L}^b \mathbf{h}_i^b + \mathbf{L}^a \mathbf{A}_i + \mathbf{b}_l),$$

where 'softplus' denotes the activation function $f(x) = ln(1 + e^x)$ and $\mathbf{L}^f, \mathbf{L}^b, \mathbf{L}^a$ and $\mathbf{b}_l$ are the parameters trained by the network. At the end, $\mathbf{l}_i$ is passed through the softmax layer to get the output labels for w_i.

To pick the correct edit tree from the output of the softmax layer, we exploit the prior information $\mathbf{A}_i$. Instead of choosing the class that gets the maximum probability, we select the maximum over the classes corresponding to the applicable edit trees. The idea is expressed as follows. Let $\mathbf{O}_i = (o_i^1, \ldots, o_i^k)$ be the output of the softmax layer. Instead of opting for the maximum over $o_i^1, \ldots, o_i^k$ as the class label, the highest probable class out of those corresponding to the applicable edit trees, is picked up. That is, the particular edit tree $t_j \in T$ is considered as the right candidate for w_i, where

$$j = \text{argmax}_{j' \in \{1,\ldots,k\} \wedge a_i^{j'}=1} \, o_i^{j'}$$

In this way, we cancel out the non-applicable classes and focus only on the plausible candidates.

3 Experimentation

Out of the nine reference languages, initially we choose four of them (Bengali, Hindi, Latin and Spanish) for in-depth analysis. We conduct an exhaustive set of experiments - such as determining the direct lemmatization accuracy, accuracy obtained without using applicable edit trees in training, measuring the model's performance on the unseen words etc. on these four languages. Later we consider five more languages (Catalan, Dutch, Hungarian, Italian and Romanian) mostly for testing the generalization ability of the proposed method. For these additional languages, we present only the lemmatization accuracy in section 3.2.

Datasets: As Bengali is a low-resourced language, a relatively large lemma annotated dataset is prepared for the present work using Tagore's short stories collection[2] and randomly selected news articles from miscellaneous domains. One linguist took around 2 months to complete the annotation which was checked by another person and differences were sorted out. Out of the 91 short stories of Tagore, we calculate the value of (# tokens / # distinct tokens) for each story. Based on this value (lower is better), top 11 stories are selected. The news articles[3] are crafted from the following domains: animal, archaeology, business, country, education, food, health, politics, psychology, science and travelogue. In Hindi, we combine the COLING'12 shared task data for dependency parsing and Hindi WSD health and tourism corpora[4] (Khapra et al., 2010) together[5]. For Latin, the data is taken from the PROIEL treebank (Haug and Jøhndal, 2008) and for Spanish, we merge the training and development datasets of CoNLL'09 (Hajič et al., 2009) shared task on syntactic and semantic dependencies. The dataset statistics are given in Table 1. We assess the lemmatization performance by measuring the direct accuracy which is the ratio of the number of correctly lemmatized words to the total number of input words. The experiments are performed using 4 fold cross validation technique i.e. the datasets are equi-partitioned into 4 parts at sentence level and then each part is tested exactly once using the model trained on the remaining 3 parts. Finally, we report the average accuracy over 4 fold.

	# Sentences	# Word Tokens
Bengali	1,702	20,257
Hindi	36,143	819,264
Latin	15,002	165,634
Spanish	15,984	477,810

Table 1: Dataset statistics of the 4 languages.

Induction of Edit Tree Set: Initially, distinct edit trees are induced from the word-lemma pairs present in the training set. Next, the words in the training data are annotated with their corresponding edit trees. Training is accomplished on this edit tree tagged text. Figure 4 plots the growth of the edit tree set against the number of word-lemma samples in the four languages. With the increase of samples, the size of edit tree set gradually converges revealing the fact that most of the frequent transformation patterns (both regular and irregular) are covered by the induction process. From

[3] http://www.anandabazar.com/

[4] http://www.cfilt.iitb.ac.in/wsd/annotated_corpus/

[5] We also release the Hindi dataset with this paper as it is a combination of two different datasets.

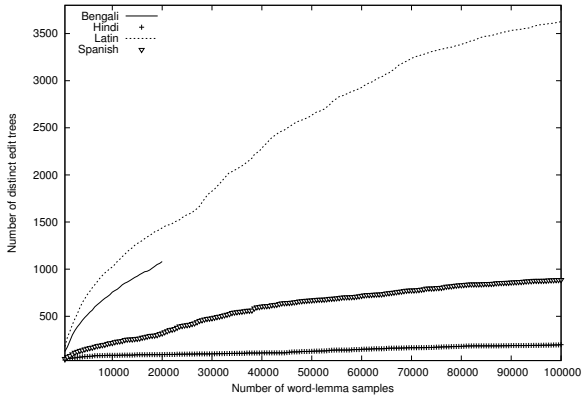

Figure 4: Increase of the edit tree set size with the number of word-lemma samples.

Figure 4, morphological richness can be compared across the languages. When convergence happens quickly i.e. at relatively less number of samples, it evidences that the language is less complex. Among the four reference languages, Latin stands out as the most intricate, followed by Bengali, Spanish and Hindi.

Semantic Embeddings: We obtain the distributional word vectors for Bengali and Hindi by training the word2vec model on FIRE Bengali and Hindi news corpora[6]. Following the work by Mikolov et al. (2013a), continuous-bag-of-words architecture with negative sampling is used to get 200 dimensional word vectors. For Latin and Spanish, we use the embeddings released by Bamman and Smith (2012)[7] and Cardellino (2016)[8] respectively.

Syntactic Representation: We acquire the statistics of word length versus frequency from the datasets and find out that irrespective of the languages, longer words (have more than 20-25 characters) are few in numbers. Based on this finding, each word is limited to a sequence of 25 characters. Smaller words are padded null characters at the end and for the longer words, excess characters are truncated out. So, each word is represented as a 25 length array of one hot encoded vectors which is given input to the embedding layer that works as a look up table producing an equal length array of embedded vectors. Initialization of the embedding layer is done randomly and the embedded vector dimension is set to 10. Eventually, the output of the embedding layer is passed to the first level BGRNN for learning the syntactic representation.

Hyper Parameters: There are several hyper parameters in our model such as the number of neurons in the hidden layer ($\mathbf{h}_t$) of both first and second level BGRNN, learning mode, number of epochs to train the models, optimization algorithm, dropout rate etc. We experiment with different settings of these parameters and report where optimum results are achieved. For both the bidirectional networks, number of hidden layer neurons is set to 64. Online learning is applied for updation of the weights. Number of epochs varies across languages to converge the training. It is maximum for Bengali (around 80 epochs), followed by Latin, Spanish and Hindi taking around 50, 35 and 15 respectively. Throughout the experiments, we set the dropout rate as 0.2 to prevent over-fitting. Different optimization algorithms like AdaDelta (Zeiler, 2012), Adam (Kingma and Ba, 2014), RMSProp (Dauphin et al., 2015) are explored. Out of them, Adam yields the best result. We use the categorical cross-entropy as the loss function in our model.

Baselines: We compare our method with Lemming[9] and Morfette[10]. Both the model jointly learns lemma and other morphological tags in context. Lemming uses a 2nd-order linear-chain CRF to predict the lemmas whereas, the current version of Morfette is based on structured perceptron learning. As POS information is a compulsory requirement of these two models, the Bengali data is manually POS annotated. For the other languages, the tags were already available. Although this comparison is partially biased as the proposed method does not need POS information, but the experimental results show the effectiveness of our model. There is an option in Lemming and Morfette to provide an exhaustive set of root words which is used to exploit the dictionary features i.e. to verify if a candidate lemma is a valid form or not. To make the comparisons consistent, we do not exploit any external dictionary in our experiments.

3.1 Results

The lemmatization results are presented in Table 2. We explore our proposed model with two types of gated recurrent cells - LSTM and GRU. As there

Table 3: Lemmatization accuracy (in %) without using applicable edit trees in training.

are two successive bidirectional networks - the first one for building the syntactic embedding and the next one for the edit tree classification, so basically we deal with two different models BLSTM-BLSTM and BGRU-BGRU. Table 2 shows the comparison results of these models with Lemming and Morfette. In all cases, the average accuracy over 4 fold cross validation on the datasets is reported. For an entry 'x/y' in Table 2, x denotes the accuracy without output classes restriction, i.e. taking the maximum over all edit tree classes present in the training set, whereas y refers to the accuracy when output is restricted in only the applicable edit tree classes of the input word. Except for Bengali, the proposed models outperform the baselines for the other three languages. In Hindi, BLSTM-BLSTM gives the best result (94.90%). For Latin and Spanish, the highest accuracy is achieved by BGRU-BGRU (89.59% and 98.11% respectively). In the Bengali dataset, Lemming produces the optimum result (91.69%) beating its closest performer BLSTM-BLSTM by 0.55%. It is to note that the training set size in Bengali is smallest compared to the other languages (on average, 16,712 tokens in each of the 4 folds). Overall, BLSTM-BLSTM and BGRU-BGRU perform equally good. For Bengali and Hindi, the former model is better and for Latin and Spanish, the later yields more accuracy. Throughout the experiments, restricting the output over applicable classes improves the performance significantly. The maximum improvements we get are: 0.30% in Bengali using BLSTM-BLSTM (from 90.84% to 91.14%), 0.06% in Hindi using BGRU-BGRU (from 94.44% to 94.50%), 0.19% in Latin using BGRU-BGRU (from 89.40% to 89.59%) and 0.06% in Spanish using BLSTM-BLSTM (from 97.85% to 97.91%). To compare between the two baselines, Lemming consistently performs better than Morfette (the maximum difference between their accuracies is 1.40% in Latin).

Bengali	Hindi	Latin	Spanish
27.17	5.25	15.74	7.54

Table 4: Proportion of unknown word forms (in %) present in the test sets.

Effect of Training without Applicable Edit Trees: We also explore the impact of applicable edit trees in training. To see the effect, we train our model without giving the applicable edit trees information as input. In the model design, the equation for the final classification task is changed as follows,

$$\mathbf{l}_i = softplus(\mathbf{L}^f \mathbf{h}_i^f + \mathbf{L}^b \mathbf{h}_i^b + \mathbf{b}_l),$$

The results are presented in Table 3. Except for Spanish, BLSTM-BLSTM outperforms BGRU-BGRU in all the other languages. As compared with the results in Table 2, for every model, training without applicable edit trees degrades the lemmatization performance. In all cases, BGRU-BGRU model gets more affected than BLSTM-BLSTM. Language-wise, the drops in its accuracy are: 1.94% in Bengali (from 90.84% to 88.90%), 0.46% in Hindi (from 94.50% to 94.04%), 2.72% in Latin (from 89.59% to 86.87%) and 0.38% in Spanish (from 98.11% to 97.73%).

One important finding to note in Table 3 is that irrespective of any particular language and model used, the amount of increase in accuracy due to the output restriction on the applicable classes is much more than that observed in Table 2. For instance, in Table 2 the accuracy improvement for Bengali using BLSTM-BLSTM is 0.30% (from 90.84% to 91.14%), whereas in Table 3 the corresponding value is 3.06% (from 86.46% to 89.52%). These outcomes signify the fact that training with the ap-

	Bengali	Hindi	Latin	Spanish
BLSTM-BLSTM	56.16/66.26	87.42/88.41	49.80/56.05	86.22/87.97
BGRU-BGRU	59.45/66.84	87.19/88.26	50.24/55.35	86.74/88.49

Table 6: Lemmatization accuracy (in %) on unseen words without using applicable edit trees in training.

plicable edit trees already learns to dispense the output probability to the legitimate classes over which, output restriction cannot yield much enhancement.

Results for Unseen Word Forms: Next, we discuss about the lemmatization performance on those words which were absent in the training set. Table 4 shows the proportion of unseen forms averaged over 4 folds on the datasets. In Table 5, we present the accuracy obtained by our models and the baselines. For Bengali and Hindi, Lemming produces the best results (74.10% and 90.35%). For Latin and Spanish, BLSTM-BLSTM and BGRU-BGRU obtain the highest accuracy (61.63% and 92.25%) respectively. In Spanish, our model gets the maximum improvement over the baselines. BGRU-BGRU beats Lemming with 33.36% margin (on average, out of 9,011 unseen forms, 3,005 more tokens are correctly lemmatized). Similar to the results in Table 2, the results in Table 5 evidences that restricting the output in applicable classes enhances the lemmatization performance. The maximum accuracy improvements due to the output restriction are: 1.04% in Bengali (from 71.06% to 72.10%), 0.38% in Hindi (from 87.80% to 88.18%) using BLSTM-BLSTM and 0.87% in Latin (from 60.65% to 61.52%), 0.77% in Spanish (from 91.48% to 92.25%) using BGRU-BGRU.

Further, we investigate the performance of our models trained without the applicable edit trees information, on the unseen word forms. The results are given in Table 6. As expected, for every model, the accuracy drops compared to the results shown in Table 5. The only exception that we find out is in the entry for Hindi with BLSTM-BLSTM. Though without restricting the output, the accuracy in Table 5 (87.80%) is higher than the corresponding value in Table 6 (87.42%), but after output restriction, the performance changes (88.18% in Table 5, 88.41% in Table 6) which reveals that only selecting the maximum probable class over the applicable ones would be a better option for the unseen word forms in Hindi.

	Sem. Embedding	Syn. Embedding
Bengali	90.76/91.02	86.61/86.82
Hindi	94.86/94.86	91.24/91.25
Latin	88.90/89.09	85.31/85.49
Spanish	97.95/98	96.07/96.10

Table 7: Results (in %) obtained using semantic and syntactic embeddings separately.

	# Sentences	# Word Tokens
Catalan	14,832	474,069
Dutch	13,050	197,925
Hungarian	1,351	31,584
Italian	13,402	282,611
Romanian	8,795	202,187

Table 8: Dataset statistics of the 5 additional languages.

Effects of Semantic and Syntactic Embeddings in Isolation: To understand the impact of the combined word vectors on the model's performance, we measure the accuracy experimenting with each one of them separately. While using the semantic embedding, only distributional word vectors are used for edit tree classification. On the other hand, to test the effect of the syntactic embedding exclusively, output from the character level recurrent network is fed to the second level BGRNN. We present the results in Table 7. For Bengali and Hindi, experiments are carried out with the BLSTM-BLSTM model as it gives better results for these languages compared to BGRU-BGRU (given in Table 2). Similarly for Latin and Spanish, the results obtained from BGRU-BGRU are reported. From the outcome of these experiments, use of semantic vec-

	Catalan	Dutch	Hungarian	Italian	Romanian
BLSTM-BLSTM	97.93/**97.95**	93.20/**93.44**	91.03/**91.46**	96.06/**96.09**	94.25/**94.32**
Lemming	89.80	86.95	87.95	92.51	93.34
Morfette	89.46	86.62	86.52	92.02	94.13

Table 9: Lemmatization accuracy (in %) for the 5 languages.

tor proves to be more effective than the character level embedding. However, to capture the distributional properties of words efficiently, a huge corpus is needed which may not be available for low resourced languages. In that case, making use of syntactic embedding is a good alternative. Nonetheless, use of both types of embedding together improves the result.

3.2 Experimental Results for Another Five Languages

As mentioned earlier, five additional languages (Catalan, Dutch, Hungarian, Italian and Romanian) are considered to test the generalization ability of the method. The datasets are taken from the UD Treebanks[11] (Nivre et al., 2017). For each language, we merge the training and development data together and perform 4 fold cross validation on it to measure the average accuracy. The dataset statistics are shown in Table 8. For experimentation, we use the pre-trained semantic embeddings released by (Bojanowski et al., 2016). Only BLSTM-BLSTM model is explored and it is compared with Lemming and Morfette. The hyper parameters are kept same as described previously except for the number of epochs needed for training across the languages. We present the results in Table 9. For all the languages, BLSTM-BLSTM outperforms Lemming and Morfette. The maximum improvement over the baselines we get is for Catalan (beats Lemming and Morfette by 8.15% and 8.49% respectively). Similar to the results in Table 2, restricting the output over applicable classes yields consistent performance improvement.

4 Conclusion

This article presents a neural network based context sensitive lemmatization method which is language independent and supervised in nature. The proposed model learns the transformation patterns between word-lemma pairs and hence, can handle the unknown word forms too. Additionally, it does not rely on human defined features and various morphological tags except the gold lemma annotated continuous text. We explore different variations of the model architecture by changing the type of recurrent units. For evaluation, nine languages are taken as the references. Except Bengali, the proposed method outperforms the state-of-the-art models (Lemming and Morfette) on all the other languages. For Bengali, it produces the second best performance (91.14% using BLSTM-BLSTM). We measure the accuracy on the partial data (keeping the data size comparable to the Bengali dataset) for Hindi, Latin and Spanish to check the effect of the data amount on the performance. For Hindi, the change in accuracy is insignificant but for Latin and Spanish, accuracy drops by 3.50% and 6% respectively. The time requirement of the proposed method is also analyzed. Training time depends on several parameters such as size of the data, number of epochs required for convergence, configuration of the system used etc. In our work, we use the 'keras' software keeping 'theano' as backend. The codes were run on a single GPU (Nvidia GeForce GTX 960, 2GB memory). Once trained, the model takes negligible time to predict the appropriate edit trees for test words (e.g. 844 and 930 words/second for Bengali and Hindi respectively). We develop a Bengali lemmatization dataset which is definitely a notable contribution to the language resources. From the present study, one important finding comes out that for the unseen words, the lemmatization accuracy drops by a large margin in Bengali and Spanish, which may be the area of further research work. Apart from it, we intend to propose a neural architecture that accomplishes the joint learning of lemmas with other morphological attributes.

Abstract

Fixed-vocabulary language models fail to account for one of the most characteristic statistical facts of natural language: the frequent creation and reuse of new word types. Although character-level language models offer a partial solution in that they can create word types not attested in the training corpus, they do not capture the "bursty" distribution of such words. In this paper, we augment a hierarchical LSTM language model that generates sequences of word tokens character by character with a caching mechanism that learns to reuse previously generated words. To validate our model we construct a new open-vocabulary language modeling corpus (the Multilingual Wikipedia Corpus; MWC) from comparable Wikipedia articles in 7 typologically diverse languages and demonstrate the effectiveness of our model across this range of languages.

1 Introduction

Language modeling is an important problem in natural language processing with many practical applications (translation, speech recognition, spelling autocorrection, etc.). Recent advances in neural networks provide strong representational power to language models with distributed representations and unbounded dependencies based on recurrent networks (RNNs). However, most language models operate by generating words by sampling from a closed vocabulary which is composed of the most frequent words in a corpus. Rare tokens are typically replaced by a special token, called the unknown word token, ⟨UNK⟩. Although fixed-vocabulary language models have some important practical applications and are appealing models for study, they fail to capture two empirical facts about the distribution of words in natural languages. First, vocabularies keep growing as the number of documents in a corpus grows: new words are constantly being created (Heaps, 1978). Second, rare and newly created words often occur in "bursts", i.e., once a new or rare word has been used once in a document, it is often repeated (Church and Gale, 1995; Church, 2000).

The open-vocabulary problem can be solved by dispensing with word-level models in favor of models that predict sentences as sequences of characters (Sutskever et al., 2011; Chung et al., 2017). Character-based models are quite successful at learning what (new) word forms look like (e.g., they learn a language's orthographic conventions that tell us that *sustinated* is a plausible English word and *bzoxqir* is not) and, when based on models that learn long-range dependencies such as RNNs, they can also be good models of how words fit together to form sentences.

However, existing character-sequence models have no explicit mechanism for modeling the fact that once a rare word is used, it is likely to be used again. In this paper, we propose an extension to character-level language models that enables them to reuse previously generated tokens (§2). Our starting point is a hierarchical LSTM that has been previously used for modeling sentences (word by word) in a conversation (Sordoni et al., 2015), except here we model words (character by character) in a sentence. To this model, we add a caching mechanism similar to recent proposals for caching that have been advocated for closed-vocabulary models (Merity et al., 2017; Grave et al., 2017). As word tokens are generated, they are placed in an LRU cache, and, at each time step the model decides whether to copy a previously generated word from the cache or to generate it from scratch, character by character. The decision of whether

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1492–1502
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1137

to use the cache or not is a latent variable that is marginalised during learning and inference. In summary, our model has three properties: it creates new words, it accounts for their burstiness using a cache, and, being based on LSTM s over word representations, it can model long range dependencies.

To evaluate our model, we perform ablation experiments with variants of our model without the cache or hierarchical structure. In addition to standard English data sets (PTB and WikiText-2), we introduce a new multilingual data set: the Multilingual Wikipedia Corpus (MWC), which is constructed from comparable articles from Wikipedia in 7 typologically diverse languages (§3) and show the effectiveness of our model in all languages (§4). By looking at the posterior probabilities of the generation mechanism (language model vs. cache) on held-out data, we find that the cache is used to generate "bursty" word types such as proper names, while numbers and generic content words are generated preferentially from the language model (§5).

2 Model

In this section, we describe our hierarchical character language model with a word cache. As is typical for RNN language models, our model uses the chain rule to decompose the problem into incremental predictions of the next word conditioned on the history:

$$p(\boldsymbol{w}) = \prod_{t=1}^{|\boldsymbol{w}|} p(w_t \mid \boldsymbol{w}_{<t}).$$

We make two modifications to the traditional RNN language model, which we describe in turn. First, we begin with a cache-less model we call the hierarchical character language model (HCLM; §2.1) which generates words as a sequence of characters and constructs a "word embedding" by encoding a character sequence with an LSTM (Ling et al., 2015). However, like conventional closed-vocabulary, word-based models, it is based on an LSTM that conditions on words represented by fixed-length vectors.[1]

The HCLM has no mechanism to reuse words that it has previously generated, so new forms will only be repeated with very low probability. However, since the HCLM is not merely generating sentences as a sequence of characters, but also segmenting them into words, we may add a word-based cache to which we add words keyed by the hidden state being used to generate them (§2.2). This cache mechanism is similar to the model proposed by Merity et al. (2017).

Notation. Our model assigns probabilities to sequences of words $\boldsymbol{w} = w_1, \ldots, w_{|\boldsymbol{w}|}$, where $|\boldsymbol{w}|$ is the length, and where each word w_i is represented by a sequence of characters $\boldsymbol{c}_i = c_{i,1}, \ldots, c_{i,|\boldsymbol{c}_i|}$ of length $|\boldsymbol{c}_i|$.

2.1 Hierarchical Character-level Language Model (HCLM)

This hierarchical model satisfies our linguistic intuition that written language has (at least) two different units, characters and words.

The HCLM consists of four components, three LSTMs (Hochreiter and Schmidhuber, 1997): a character encoder, a word-level context encoder, and a character decoder (denoted LSTM_{enc}, LSTM_{ctx}, and LSTM_{dec}, respectively), and a softmax output layer over the character vocabulary. Fig. 1 illustrates an unrolled HCLM.

Suppose the model reads word w_{t-1} and predicts the next word w_t. First, the model reads the character sequence representing the word $w_{t-1} = c_{t-1,1}, \ldots, c_{t-1,|\boldsymbol{c}_{t-1}|}$ where $|\boldsymbol{c}_{t-1}|$ is the length of the word generated at time $t-1$ in characters. Each character is represented as a vector $\mathbf{v}_{c_{t-1,1}}, \ldots, \mathbf{v}_{c_{t-1,|\boldsymbol{c}_{t-1}|}}$ and fed into the encoder LSTM_{enc} . The final hidden state of the encoder LSTM_{enc} is used as the vector representation of the previously generated word w_{t-1},

$$\mathbf{h}_t^{enc} = \text{LSTM}_{enc}(\mathbf{v}_{c_{t-1,1}}, \ldots, \mathbf{v}_{c_{t-1,|\boldsymbol{c}_t|}}).$$

Then all the vector representations of words $(\mathbf{v}_{w_1}, \ldots, \mathbf{v}_{w_{|\boldsymbol{w}|}})$ are processed with a context LSTM_{ctx} . Each of the hidden states of the context LSTM_{ctx} are considered representations of the history of the word sequence.

$$\mathbf{h}_t^{ctx} = \text{LSTM}_{ctx}(\mathbf{h}_1^{enc}, \ldots, \mathbf{h}_t^{enc})$$

Finally, the initial state of the decoder LSTM is set to be $\mathbf{h}_t^{ctx}$ and the decoder LSTM reads a vector representation of the start symbol $\mathbf{v}_{\langle \text{S} \rangle}$ and generates the next word w_{t+1} character by character. To predict the j-th character in w_t, the decoder

[1] The HCLM is an adaptation of the hierarchical recurrent encoder-decoder of Sordoni et al. (2015) which was used to model dialog as a sequence of actions sentences which are themselves sequences of words. The original model was proposed to compose words into query sequences but we use it to compose characters into word sequences.

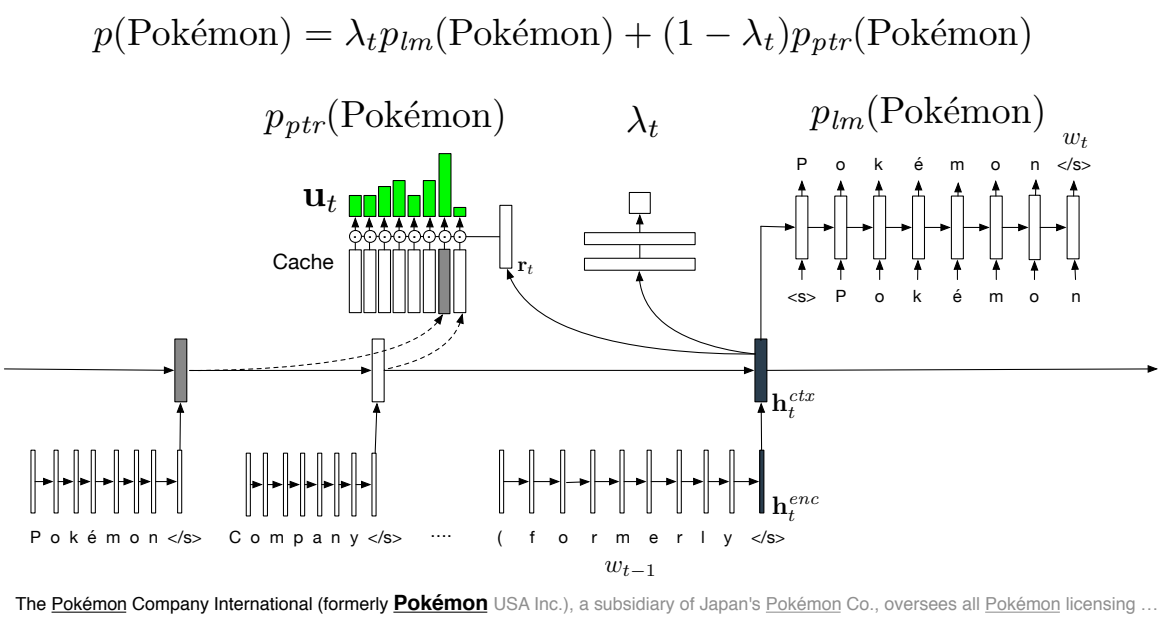

Figure 1: Description of Hierarchical Character Language Model with Cache.

LSTM reads vector representations of the previous characters in the word, conditioned on the context vector $\mathbf{h}_t^{ctx}$ and a start symbol.

$$\mathbf{h}_{t,j}^{dec} = \text{LSTM}_{dec}(\mathbf{v}_{c_{t,1}}, \ldots, \mathbf{v}_{c_{t,j-1}}, \mathbf{h}_t^{ctx}, \mathbf{v}_{\langle s \rangle}).$$

The character generation probability is defined by a softmax layer for the corresponding hidden representation of the decoder LSTM .

$$p(c_{t,j} \mid \boldsymbol{w}_{<t}, \boldsymbol{c}_{t,<j}) = \text{softmax}(\mathbf{W}_{dec}\mathbf{h}_{t,j}^{dec} + \mathbf{b}_{dec})$$

Thus, a word generation probability from HCLM is defined as follows.

$$p_{lm}(w_t \mid \boldsymbol{w}_{<t}) = \prod_{j=1}^{|\boldsymbol{c}_t|} p(c_{t,j} \mid \boldsymbol{w}_{<t}, \boldsymbol{c}_{t,<j})$$

2.2 Continuous cache component

The cache component is an external memory structure which store K elements of recent history. Similarly to the memory structure used in Grave et al. (2017), a word is added to a key-value memory after each generation of w_t. The key at position $i \in [1, K]$ is $\mathbf{k}_i$ and its value m_i. The memory slot is chosen as follows: if the w_t exists already in the memory, its key is updated (discussed below). Otherwise, if the memory is not full, an empty slot is chosen or the least recently used slot is overwritten. When writing a new word to memory, the key is the RNN representation that was used to generate the word ($\mathbf{h}_t$) and the value is the word itself (w_t). In the case when the word already exists in the cache at some position i, the $\mathbf{k}_i$ is updated to be the arithmetic average of $\mathbf{h}_t$ and the existing $\mathbf{k}_i$.

To define the copy probability from the cache at time t, a distribution over copy sites is defined using the attention mechanism of Bahdanau et al. (2015). To do so, we construct a query vector ($\mathbf{r}_t$) from the RNN's current hidden state $\mathbf{h}_t$,

$$\mathbf{r}_t = \tanh(\mathbf{W}_q\mathbf{h}_t + \mathbf{b}_q),$$

then, for each element i of the cache, a 'copy score,' $u_{i,t}$ is computed,

$$u_{i,t} = \mathbf{v}^T \tanh(\mathbf{W}_u\mathbf{k}_i + \mathbf{r}_t).$$

Finally, the probability of generating a word via the copying mechanism is:

$$p_{mem}(i \mid \mathbf{h}_t) = \text{softmax}_i(\mathbf{u}_t)$$
$$p_{ptr}(w_t \mid \mathbf{h}_t) = p_{mem}(i \mid \mathbf{h}_t)[m_i = w_t],$$

where $[m_i = w_t]$ is 1 if the ith value in memory is w_t and 0 otherwise. Since p_{mem} defines a distribution of slots in the cache, p_{ptr} translates it into word space.

2.3 Character-level Neural Cache Language Model

The word probability $p(w_t \mid \boldsymbol{w}_{<t})$ is defined as a mixture of the following two probabilities. The first

one is a language model probability, $p_{lm}(w_t \mid \boldsymbol{w}_{<t})$ and the other is pointer probability , $p_{ptr}(w_t \mid \boldsymbol{w}_{<t})$. The final probability $p(w_t \mid \boldsymbol{w}_{<t})$ is

$$\lambda_t p_{lm}(w_t \mid \boldsymbol{w}_{<t}) + (1 - \lambda_t) p_{ptr}(w_t \mid \boldsymbol{w}_{<t}),$$

where λ_t is computed by a multi-layer perceptron with two non-linear transformations using $\mathbf{h}_t$ as its input, followed by a transformation by the logistic sigmoid function:

$$\gamma_t = \text{MLP}(\mathbf{h}_t), \qquad \lambda_t = \frac{1}{1 - e^{-\gamma_t}}.$$

We remark that Grave et al. (2017) use a clever trick to estimate the probability, λ_t of drawing from the LM by augmenting their (closed) vocabulary with a special symbol indicating that a copy should be used. This enables word types that are highly predictive in context to compete with the probability of a copy event. However, since we are working with an open vocabulary, this strategy is unavailable in our model, so we use the MLP formulation.

2.4 Training objective

The model parameters as well as the character projection parameters are jointly trained by maximizing the following log likelihood of the observed characters in the training corpus,

$$\mathcal{L} = -\sum \log p(w_t \mid \boldsymbol{w}_{<t}).$$

3 Datasets

We evaluate our model on a range of datasets, employing preexisting benchmarks for comparison to previous published results, and a new multilingual corpus which specifically tests our model's performance across a range of typological settings.

3.1 Penn Tree Bank (PTB)

We evaluate our model on the Penn Tree Bank. For fair comparison with previous works, we followed the standard preprocessing method used by Mikolov et al. (2010). In the standard preprocessing, tokenization is applied, words are lowercased, and punctuation is removed. Also, less frequent words are replaced by unknown an token (UNK),[2] constraining the word vocabulary size to be 10k. Because of this preprocessing, we do not expect this dataset to benefit from the modeling innovations we have introduced in the paper. Fig.1 summarizes the corpus statistics.

[2]When the unknown token is used in character-level model, it is treated as if it were a normal word (i.e. UNK is the sequence U, N, and K). This is somewhat surprising modeling choice, but it has become conventional (Chung et al., 2017).

	Train	Dev	Test
Character types	50	50	48
Word types	10000	6022	6049
OOV rate	-	**0.00%**	**0.00%**
Word tokens	0.9M	0.1M	0.1M
Characters	5.1M	0.4M	0.4M

Table 1: PTB Corpus Statistics.

3.2 WikiText-2

Merity et al. (2017) proposed the WikiText-2 Corpus as a new benchmark dataset.[3] They pointed out that the preprocessed PTB is unrealistic for real language use in terms of word distribution. Since the vocabulary size is fixed to 10k, the word frequency does not exhibit a long tail. The wikiText-2 corpus is constructed from 720 articles. They provided two versions. The version for word level language modeling was preprocessed by discarding infrequent words. But, for character-level models, they provided raw documents without any removal of word or character types or lowercasing, but with tokenization. We make one change to this corpus: since Wikipedia articles make extensive use of characters from other languages; we replaced character types that occur fewer than 25 times were replaced with a dummy character (this plays the role of the ⟨UNK⟩ token in the character vocabulary). Tab. 2 summarizes the corpus statistics.

	Train	Dev	Test
Character types	255	128	138
Word types	76137	19813	21109
OOV rate	-	4.79%	5.87%
Word tokens	2.1M	0.2M	0.2M
Characters	10.9M	1.1M	1.3M

Table 2: WikiText-2 Corpus Statistics.

3.3 Multilingual Wikipedia Corpus (MWC)

Languages differ in what word formation processes they have. For character-level modeling it is therefore interesting to compare a model's performance

[3]http://metamind.io/research/the-wikitext-long-term-dependency-language-modeling-dataset/

across languages. Since there is at present no standard multilingual language modeling dataset, we created a new dataset, the Multilingual Wikipedia Corpus (MWC), a corpus of the same Wikipedia articles in 7 languages which manifest a range of morphological typologies. The MWC contains English (EN), French (FR), Spanish (ES), German (DE), Russian (RU), Czech (CS), and Finnish (FI).

To attempt to control for topic divergences across languages, every language's data consists of the same articles. Although these are only comparable (rather than true translations), this ensures that the corpus has a stable topic profile across languages.[4]

Construction & Preprocessing We constructed the MWC similarly to the WikiText-2 corpus. Articles were selected from Wikipedia in the 7 target languages. To keep the topic distribution to be approximately the same across the corpora, we extracted articles about entities which explained in all the languages. We extracted articles which exist in all languages and each consist of more than 1,000 words, for a total of 797 articles. These cross-lingual articles are, of course, not usually translations, but they tend to be comparable. This filtering ensures that the topic profile in each language is similar. Each language corpus is approximately the same size as the WikiText-2 corpus.

Wikipedia markup was removed with WikiExtractor,[5] to obtain plain text. We used the same thresholds to remove rare characters in the WikiText-2 corpus. No tokenization or other normalization (e.g., lowercasing) was done.

Statistics After the preprocessing described above, we randomly sampled 360 articles. The articles are split into 300, 30, 30 sets and the first 300 articles are used for training and the rest are used for dev and test respectively. Table 3 summarizes the corpus statistics.

Additionally, we show in Fig. 2 the distribution of frequencies of OOV word types (relative to the training set) in the dev+test portions of the corpus, which shows a power-law distribution, which is expected for the burstiness of rare words found in prior work. Curves look similar for all languages (see Appendix A).

[4]The Multilingual Wikipedia Corpus (MWC) is available for download from http://k-kawakami.com/research/mwc

[5]https://github.com/attardi/wikiextractor

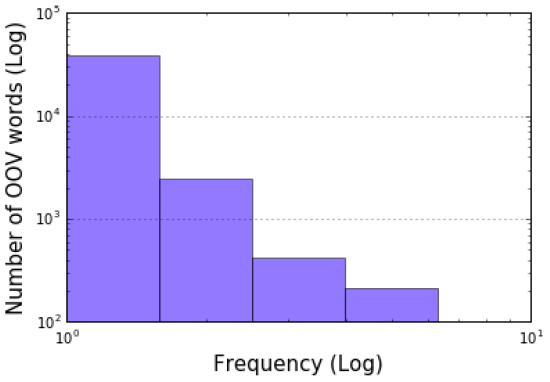

Figure 2: Histogram of OOV word frequencies in the dev+test part of the MWC Corpus (EN).

4 Experiments

We now turn to a series of experiments to show the value of our hierarchical character-level cache language model. For each dataset we trained the model with LSTM units. To compare our results with a strong baseline, we also train a model without the cache.

Model Configuration For HCLM and HCLM with cache models, We used 600 dimensions for the character embeddings and the LSTMs have 600 hidden units for all the experiments. This keeps the model complexity to be approximately the same as previous works which used an LSTM with 1000 dimension. Our baseline LSTM have 1000 dimensions for embeddings and reccurence weights.

For the cache model, we used cache size 100 in every experiment. All the parameters including character projection parameters are randomly sampled from uniform distribution from -0.08 to 0.08. The initial hidden and memory state of LSTM_{enc} and LSTM_{ctx} are initialized with zero. Mini-batches of size 25 are used for PTB experiments and 10 for WikiText-2, due to memory limitations. The sequences were truncated with 35 words. Then the words are decomposed to characters and fed into the model. A Dropout rate of 0.5 was used for all but the recurrent connections.

Learning The models were trained with the Adam update rule (Kingma and Ba, 2015) with a learning rate of 0.002. The maximum norm of the gradients was clipped at 10.

Evaluation We evaluated our models with bits-per-character (bpc) a standard evaluation metric

	Char. Types			Word Types			OOV rate		Tokens			Characters

Table 3: Summary of MWC Corpus.

for character-level language models. Following the definition in Graves (2013), bits-per-character is the average value of $-\log_2 p(w_t \mid \boldsymbol{w}_{<t})$ over the whole test set,

$$bpc = -\frac{1}{|\boldsymbol{c}|} \log_2 p(\boldsymbol{w}),$$

where $|\boldsymbol{c}|$ is the length of the corpus in characters.

4.1 Results

PTB Tab. 4 summarizes results on the PTB dataset.[6] Our baseline HCLM model achieved 1.276 bpc which is better performance than the LSTM with Zoneout regularization (Krueger et al., 2017). And HCLM with cache outperformed the baseline model with 1.247 bpc and achieved competitive results with state-of-the-art models with regularization on recurrence weights, which was not used in our experiments.

Expressed in terms of per-word perplexity (i.e., rather than normalizing by the length of the corpus in characters, we normalize by words and exponentiate), the test perplexity on HCLM with cache is 94.79. The performance of the unregularized 2-layer LSTM with 1000 hidden units on word-level PTB dataset is 114.5 and the same model with dropout achieved 87.0. Considering the fact that our character-level models are dealing with an open vocabulary without unknown tokens, the results are promising.

WikiText-2 Tab. 5 summarizes results on the WikiText-2 dataset. Our baseline, LSTM achieved 1.803 bpc and HCLM model achieved 1.670 bpc. The HCLM with cache outperformed the baseline models and achieved 1.500 bpc. The word level perplexity is 227.30, which is quite high compared to the reported word level baseline result 100.9 with LSTM with ZoneOut and Variational Dropout regularization (Merity et al., 2017). However, the character-level model is dealing with 76,136 types in training set and 5.87% OOV rate where the word level models only use 33,278 types without OOV in test set. The improvement rate over the HCLM baseline is 10.2% which is much higher than the improvement rate obtained in the PTB experiment.

[6]Models designated with a * have more layers and more parameters.

Table 5: Results on WikiText-2 Corpus .

Multilingual Wikipedia Corpus (MWC) Tab. 6 summarizes results on the MWC dataset. Similarly to WikiText-2 experiments, LSTM

is strong baseline. We observe that the cache mechanism improve performance in every languages. In English, HCLM with cache achieved 1.538 bpc where the baseline is 1.622 bpc. It is 5.2% improvement. For other languages, the improvement rates were 2.7%, 3.2%, 3.7%, 2.5%, 4.7%, 2.7% in FR, DE, ES, CS, FI, RU respectively. The best improvement rate was obtained in Finnish.

5 Analysis

In this section, we analyse the behavior of proposed model qualitatively. To analyse the model, we compute the following posterior probability which tell whether the model used the cache given a word and its preceding context. Let z_t be a random variable that says whether to use the cache or the LM to generate the word at time t. We would like to know, given the text $\boldsymbol{w}$, whether the cache was used at time t. This can be computed as follows:

$$p(z_t \mid \boldsymbol{w}) = \frac{p(z_t, w_t \mid \mathbf{h}_t, \text{cache}_t)}{p(w_t \mid \mathbf{h}_t, \text{cache}_t)} = \frac{(1-\lambda_t) p_{ptr}(w_t \mid \mathbf{h}_t, \text{cache}_t)}{p(w_t \mid \mathbf{h}_t, \text{cache}_t)},$$

where cache_t is the state of the cache at time t. We report the average posterior probability of cache generation excluding the first occurrence of w, $\overline{p(z \mid w)}$.

Tab. 7 shows the words in the WikiText-2 test set that occur more than 1 time that are most/least likely to be generated from cache and character language model (words that occur only one time cannot be cache-generated). We see that the model uses the cache for proper nouns: *Lesnar*, *Gore*, etc., as well as very frequent words which always stored somewhere in the cache such as single-token punctuation, *the*, and *of*. In contrast, the model uses the language model to generate numbers (which tend not to be repeated): *300*, *770* and basic content words: *sounds*, *however*, *unable*, etc. This pattern is similar to the pattern found in empirical distribution of frequencies of rare words observed in prior wors (Church and Gale, 1995; Church, 2000), which suggests our model is learning to use the cache to account for bursts of rare words.

To look more closely at rare words, we also investigate how the model handles words that occurred between 2 and 100 times in the test set, but fewer than 5 times in the training set. Fig. 3 is a scatter plot of $\overline{p(z \mid w)}$ vs the empirical frequency in the test set. As expected, more frequently repeated words types are increasingly likely to be drawn from the cache, but less frequent words show a range of cache generation probabilities.

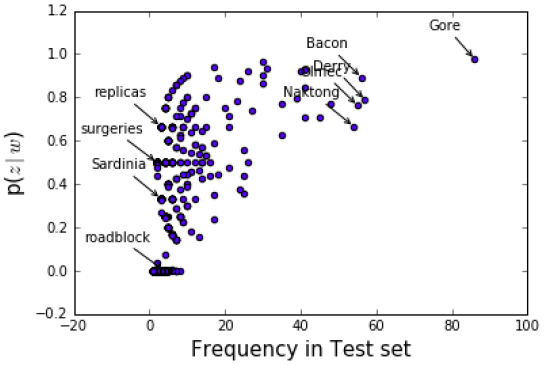

Figure 3: Average $p(z \mid w)$ of OOV words in test set vs. term frequency in the test set for words not obsered in the training set. The model prefers to copy frequently reused words from cache component, which tend to names (upper right) while character level generation is used for infrequent open class words (bottom left).

Tab. 8 shows word types with the highest and lowest average $p(z \mid w)$ that occur fewer than 5 times in the training corpus. The pattern here is similar to the unfiltered list: proper nouns are extremely likely to have been cache-generated, whereas numbers and generic (albeit infrequent) content words are less likely to have been.

6 Discussion

Our results show that the HCLM outperforms a basic LSTM. With the addition of the caching mechanism, the HCLM becomes consistently more powerful than both the baseline HCLM and the LSTM. This is true even on the PTB, which has no rare or OOV words in its test set (because of preprocessing), by caching repetitive common words such as *the*. In true open-vocabulary settings (i.e., WikiText-2 and MWC), the improvements are much more pronounced, as expected.

Computational complexity. In comparison with word-level models, our model has to read and generate each word character by character, and it also requires a softmax over the entire memory at every time step. However, the computation is still linear in terms of the length of the sequence, and the softmax over the memory cells and character

Table 8: Same as Table 7, except filtering for word types that occur fewer than 5 times in the training set. The cache component is used as expected even on rare words: proper nouns are extremely likely to have been cache-generated, whereas numbers and generic content words are less likely to have been; this indicates both the effectiveness of the prior at determining whether to use the cache and the burstiness of proper nouns.

vocabulary are much smaller than word-level vocabulary. On the other hand, since the recurrent states are updated once per character (rather than per word) in our model, the distribution of operations is quite different. Depending on the hardware support for these operations (repeated updates of recurrent states vs. softmaxes), our model may be faster or slower. However, our model will have fewer parameters than a word-based model since most of the parameters in such models live in the word projection layers, and we use LSTMs in place of these.

Non-English languages. For non-English languages, the pattern is largely similar for non-English languages. This is not surprising since morphological processes may generate forms that are related to existing forms, but these still have slight variations. Thus, they must be generated by the language model component (rather than from the cache). Still, the cache demonstrates consistent value in these languages.

Finally, our analysis of the cache on English does show that it is being used to model word reuse, particularly of proper names, but also of frequent words. While empirical analysis of rare word distributions predicts that names would be reused, the fact that cache is used to model frequent words suggests that effective models of language should have a means to generate common words as units. Finally, our model disfavors copying numbers from the cache, even when they are available. This suggests that it has learnt that numbers are not generally repeated (in contrast to names).

7 Related Work

Caching language models were proposed to account for burstiness by Kuhn and De Mori (1990), and recently, this idea has been incorporated to augment neural language models with a caching mechanism (Merity et al., 2017; Grave et al., 2017).

Open vocabulary neural language models have been widely explored (Sutskever et al., 2011; Mikolov et al., 2012; Graves, 2013, *inter alia*). Attempts to make them more aware of word-level dynamics, using models similar to our hierarchical formulation, have also been proposed (Chung et al., 2017).

The only models that are open vocabulary language modeling together with a caching mechanism are the nonparametric Bayesian language models based on hierarchical Pitman–Yor processes which generate a lexicon of word types using a character model, and then generate a text using these (Teh, 2006; Goldwater et al., 2009; Chahuneau et al., 2013). These, however, do not use distributed representations on RNNs to capture long-range dependencies.

8 Conclusion

In this paper, we proposed a character-level language model with an adaptive cache which selectively assign word probability from past history or character-level decoding. And we empirically show that our model efficiently model the word sequences and achieved better perplexity in every standard dataset. To further validate the performance of our model on different languages, we collected multilingual wikipedia corpus for 7 typologically diverse languages. We also show that our model performs better than character-level models by modeling burstiness of words in local context.

The model proposed in this paper assumes the observation of word segmentation. Thus, the model is not directly applicable to languages, such as Chinese and Japanese, where word segments are not explicitly observable. We will investigate a model which can marginalise word segmentation as latent variables in the future work.

Abstract

Bandit structured prediction describes a stochastic optimization framework where learning is performed from partial feedback. This feedback is received in the form of a task loss evaluation to a predicted output structure, without having access to gold standard structures. We advance this framework by lifting linear bandit learning to neural sequence-to-sequence learning problems using attention-based recurrent neural networks. Furthermore, we show how to incorporate control variates into our learning algorithms for variance reduction and improved generalization. We present an evaluation on a neural machine translation task that shows improvements of up to 5.89 BLEU points for domain adaptation from simulated bandit feedback.

1 Introduction

Many NLP tasks involve learning to predict a structured output such as a sequence, a tree or a graph. Sequence-to-sequence learning with neural networks has recently become a popular approach that allows tackling structured prediction as a mapping problem between variable-length sequences, e.g., from foreign language sentences into target-language sentences (Sutskever et al., 2014), or from natural language input sentences into linearized versions of syntactic (Vinyals et al., 2015) or semantic parses (Jia and Liang, 2016). A known bottleneck in structured prediction is the requirement of large amounts of gold-standard structures for supervised learning of model parameters, especially for data-hungry neural network models. Sokolov et al. (2016a,b) presented a framework for stochastic structured prediction under bandit feedback that alleviates the need for labeled output structures in learning: Following an online learning protocol, on each iteration the learner receives an input, predicts an output structure, and receives partial feedback in form of a task loss evaluation of the predicted structure.[1] They "banditize" several objective functions for linear structured predictions, and evaluate the resulting algorithms with simulated bandit feedback on various NLP tasks.

We show how to lift linear structured prediction under bandit feedback to non-linear models for sequence-to-sequence learning with attention-based recurrent neural networks (Bahdanau et al., 2015). Our framework is applicable to sequence-to-sequence learning from various types of weak feedback. For example, extracting learning signals from the execution of structured outputs against databases has been established in the communities of semantic parsing and grounded language learning since more than a decade (Zettlemoyer and Collins, 2005; Clarke et al., 2010; Liang et al., 2011). Our work can build the basis for neural semantic parsing from weak feedback.

In this paper, we focus on the application of machine translation via neural sequence-to-sequence learning. The standard procedure of training neural machine translation (NMT) models is to compare their output to human-generated translations and to infer model updates from this comparison. However, the creation of reference translations or post-edits requires professional expertise of users. Our framework allows NMT models to learn from feedback that is weaker than human references or post-edits. One could imagine a scenario of personalized machine translation where translations have to be adapted to the user's specific purpose and domain. The feedback required by our methods can be provided by laymen users or can even

[1] The name "bandit feedback" is inherited from the problem of maximizing the reward for a sequence of pulls of arms of so-called "one-armed bandit" slot machines.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1503–1513
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1138

be implicit, e.g., inferred from user interactions with the translated content on a web page.

Starting from the work of Sokolov et al. (2016a,b), we lift their objectives to neural sequence-to-sequence learning. We evaluate the resulting algorithms on the task of French-to-English translation domain adaptation where a seed model trained on Europarl data is adapted to the NewsCommentary and the TED talks domain with simulated weak feedback. By learning from this feedback, we find 4.08 BLEU points improvements on NewsCommentary, and 5.89 BLEU points improvement on TED. Furthermore, we show how control variates can be integrated in our algorithms, yielding faster learning and improved generalization in our experiments.

2 Related Work

NMT models are most commonly trained under a word-level maximum likelihood objective. Even though this objective has successfully been applied to many sequence-to-sequence learning tasks, the resulting models suffer from exposure bias, since they learn to generate output words based on the history of given reference words, not on their own predictions. Ranzato et al. (2016) apply techniques from reinforcement learning (Sutton and Barto, 1998; Sutton et al., 2000) and imitation learning (Schaal, 1999; Ross et al., 2011; Daumé et al., 2009) to learn from feedback to the model's own predictions. Furthermore, they address the mismatch between word-level loss and sequence-level evaluation metric by using a mixture of the REINFORCE (Williams, 1992) algorithm and the standard maximum likelihood training to directly optimize a sequence-level loss. Similarly, Shen et al. (2016) lift minimum risk training (Och, 2003; Smith and Eisner, 2006; Gimpel and Smith, 2010; Yuille and He, 2012; He and Deng, 2012) from linear models for machine translation to NMT. These works are closely related to ours in that they use the technique of score function gradient estimators (Fu, 2006; Schulman et al., 2015) for stochastic learning. However, the learning environment of Shen et al. (2016) is different from ours in that they approximate the true gradient of the risk objective in a full information setting by sampling a subset of translations and computing the expectation over their rewards. In our bandit setting, feedback to only a single sample per sentence is available, making the learning problem much harder. The approach by Ranzato et al. (2016) approximates the expectation with single samples, but still requires reference translations which are unavailable in the bandit setting.

To our knowledge, the only work on training NMT from weak feedback is the work by He et al. (2016). They propose a dual-learning mechanism where two translation models are jointly trained on monolingual data. The feedback in this case is a reward signal from language models and a reconstruction error. This is attractive because the feedback can automatically be generated from monolingual data and does not require any human references. However, we are interested in using estimates of human feedback on translation quality to directly adapt the model to the users' needs.

Our approach follows most closely the work of Sokolov et al. (2016a,b). They introduce bandit learning objectives for structured prediction and apply them to various NLP tasks, including machine translation with linear models. Their approach can be seen as an instantiation of reinforcement learning to one-state Markov decision processes under linear policy models. In this paper, we transfer their algorithms to non-linear sequence-to-sequence learning. Sokolov et al. (2016a) showed applications of linear bandit learning to tasks such as multiclass-classification, OCR, and chunking, where learning can be done from scratch. We focus on lifting their linear machine translation experiments to the more complex NMT that requires a warm start for training. This is done by training a seed model on one domain and adapting it to a new domain based on bandit feedback only. For this task we build on the work of Freitag and Al-Onaizan (2016), who investigate strategies to find the best of both worlds: models that adapt well to the new domain without deteriorating on the old domain. In contrast to previous approaches to domain adaptation for NMT, we do not require in-domain parallel data, but consult direct feedback to the translations generated for the new domain.

3 Neural Machine Translation

Neural models for machine translation are based on a sequence-to-sequence learning architecture consisting of an encoder and a decoder (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015). An encoder Recurrent Neural Network (RNN) reads in the source sentence and a decoder

RNN generates the target sentence conditioned on the encoded source.

The input to the encoder is a sequence of vectors $\mathbf{x} = (x_1, \ldots, x_{T_x})$ representing a sequence of source words of length T_x. In the approach of Sutskever et al. (2014), they are encoded into a single vector $c = q(\{h_1, \ldots, h_{T_x}\})$, where $h_t = f(x_t, h_{t-1})$ is the hidden state of the RNN at time t. Several choices are possible for the non-linear functions f and q: Here we are using a Gated Recurrent Unit (GRU) (Chung et al., 2014) for f, and for q an attention mechanism that defines the context vector as a weighted sum over encoder hidden states (Bahdanau et al., 2015; Luong et al., 2015a).

The decoder RNN predicts the next target word y_t at time t given the context vector c and the previous target words $\mathbf{y}_{<t} = \{y_1, \ldots, y_{t-1}\}$ from a probability distribution over the target vocabulary V. This distribution is the result of a softmax transformation of the decoder outputs $\mathbf{o} = \{o_1, \ldots, o_{T_y}\}$, such that

$$p_\theta(y_t = w_i | \mathbf{y}_{<t}, c) = \frac{\exp(o_{w_i})}{\sum_{v=1}^{V} \exp(o_{w_v})}.$$

The probability of a full sequence of outputs $\mathbf{y} = (y_1, \ldots, y_{T_y})$ of length T_y is defined as the product of the conditional word probabilities:

$$p_\theta(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T_y} p_\theta(y_t | \mathbf{y}_{<t}, c).$$

Since this encoder-decoder architecture is fully differentiable, it can be trained with gradient descent methods. Given a parallel training set of S source sentences and their reference translations $D = \{(\mathbf{x}^{(s)}, \mathbf{y}^{(s)})\}_{s=1}^{S}$, we can define a word-level Maximum Likelihood Estimation (MLE) objective, which aims to find the parameters

$$\hat{\theta}^{\text{MLE}} = \arg\max_\theta L^{\text{MLE}}(\theta)$$

of the following loss function:

$$\begin{aligned} L^{\text{MLE}}(\theta) &= \sum_{s=1}^{S} \log p_\theta(\mathbf{y}^{(s)} | \mathbf{x}^{(s)}) \\ &= \sum_{s=1}^{S} \sum_{t=1}^{T_y} \log p_\theta(y_t | \mathbf{x}^{(s)}, \mathbf{y}^{(s)}_{<t}). \end{aligned}$$

This loss function is non-convex for the case of neural networks. Clever initialization strategies, adaptive learning rates and momentum techniques are required to find good local maxima and to speed up convergence (Sutskever et al., 2013). Another trick of the trade is to ensemble several models with different random initializations to improve over single models (Luong et al., 2015a).

At test time, we face a search problem to find the sequence of target words with the highest probability. Beam search reduces the search error in comparison to greedy search, but also exponentially increases decoding time.

Algorithm 1 Neural Bandit Structured Prediction

Input: Sequence of learning rates γ_k
Output: Optimal parameters $\hat{\theta}$

Initialize θ_0
for $k = 0, \ldots, K$ **do**
  Observe $\mathbf{x}_k$
  Sample $\tilde{\mathbf{y}}_k \sim p_\theta(\mathbf{y}|\mathbf{x}_k)$
  Obtain feedback $\Delta(\tilde{\mathbf{y}}_k)$
  $\theta_{k+1} = \theta_k - \gamma_k \, s_k$
Choose a solution $\hat{\theta}$ from the list $\{\theta_0, \ldots, \theta_K\}$

4 Neural Bandit Structured Prediction

Algorithm 1 is an adaptation of the Bandit Structured Prediction algorithm of Sokolov et al. (2016b) to neural models: For K rounds, a model with parameters θ receives an input, samples an output structure, and receives user feedback. Based on this feedback, a stochastic gradient s_k is computed and the model parameters are updated. As a post-optimization step, a solution $\hat{\theta}$ is selected from the iterates. This is done with online-to-batch conversion by choosing the model with optimal performance on held-out data.

The core of the algorithm is the sampling: if the model distribution is very peaked, the model exploits, i.e., it presents the most probable outputs to the user. If the distribution is close to uniform, the model explores, i.e., it presents random outputs to the user. The balance between exploitation and exploration is crucial to the learning process: in the beginning the model is rather uninformed and needs to explore in order to find outputs with high reward, while in the end it ideally converges towards a peaked distribution that exactly fits the user's needs. Pre-training the model, i.e. setting θ_0 wisely, ensures a reasonable exploitation-exploration trade-off.

This online learning algorithm can be applied

to any objective L provided the stochastic gradients s_k are unbiased estimators of the true gradient of the objective, i.e., we require $\nabla L = \mathbb{E}[s_k]$. In the following, we will present objectives from Sokolov et al. (2016b) transferred to neural models, and explain how they can be enhanced by control variates.

4.1 Expected Loss (EL) Minimization

The first objective is defined as the expectation of a task loss $\Delta(\tilde{\mathbf{y}})$, e.g. $-\text{BLEU}(\tilde{\mathbf{y}})$, over all input and output structures:

$$L^{\text{EL}}(\theta) = \mathbb{E}_{p(\mathbf{x})\, p_\theta(\tilde{\mathbf{y}}|\mathbf{x})} \left[\Delta(\tilde{\mathbf{y}})\right]. \tag{1}$$

In the case of full-information learning where reference outputs are available, we could evaluate all possible outputs against the reference to obtain an exact estimation of the loss function. However, this is not feasible in our setting since we only receive partial feedback for a single output structure per input. Instead, we use stochastic approximation to optimize this loss. The stochastic gradient for this objective is computed as follows:

$$s_k^{\text{EL}} = \Delta(\tilde{\mathbf{y}}) \frac{\partial \log p_\theta(\tilde{\mathbf{y}}|\mathbf{x}_k)}{\partial \theta}. \tag{2}$$

Objective (1) is known from minimum risk training (Och, 2003) and has been lifted to NMT by Shen et al. (2016) – but not for learning from weak feedback. Equation (2) is an instance of the score function gradient estimator (Fu, 2006) where

$$\nabla \log p_\theta(\tilde{\mathbf{y}}|\mathbf{x}_k) \tag{3}$$

denotes the score function. We give an algorithm to sample structures from an encoder-decoder model in Algorithm 2. It corresponds to the algorithm presented by Shen et al. (2016) with the difference that it samples single structures, does not assume a reference structure, and additionally returns the sample probabilities. A similar objective has also been used in the REINFORCE algorithm (Williams, 1992) which has been adapted to NMT by Ranzato et al. (2016).

4.2 Pairwise Preference Ranking (PR)

The previous objective requires numerical feedback as an estimate of translation quality. Alternatively, we can learn from pairwise preference judgments that are formalized in preference ranking objectives. Let $\mathcal{P}(\mathbf{x}) = \{\langle \mathbf{y}_i, \mathbf{y}_j \rangle \,|\mathbf{y}_i, \mathbf{y}_j \in \mathcal{Y}(\mathbf{x})\}$ denote the set of output pairs for an input $\mathbf{x}$, and let $\Delta(\langle \mathbf{y}_i, \mathbf{y}_j \rangle) : \mathcal{P}(\mathbf{x}) \rightarrow [0, 1]$ denote a task loss function that specifies a dispreference of y_i over y_j. In our experimental simulations we use two types of pairwise feedback. Firstly, continuous pairwise feedback[2] is computed as

$$\Delta(\langle \mathbf{y}_i, \mathbf{y}_j \rangle) = \Delta(\mathbf{y}_j) - \Delta(\mathbf{y}_i),$$

and secondly, binary feedback is computed as

$$\Delta(\langle \mathbf{y}_i, \mathbf{y}_j \rangle) = \begin{cases} 1 & \text{if } \Delta(\mathbf{y}_j) > \Delta(\mathbf{y}_i), \\ 0 & \text{otherwise.} \end{cases}$$

Analogously to the sequence-level sampling for linear models (Sokolov et al., 2016b), we define the following probabilities for word-level sampling:

$$p_\theta^+(\tilde{y}_t = w_i|\mathbf{x}, \hat{\mathbf{y}}_{<t}) = \frac{\exp(o_{w_i})}{\sum_{v=1}^{V} \exp(o_{w_v})},$$
$$p_\theta^-(\tilde{y}_t = w_j|\mathbf{x}, \hat{\mathbf{y}}_{<t}) = \frac{\exp(-o_{w_j})}{\sum_{v=1}^{V} \exp(-o_{w_v})}.$$

The effect of the negation within the softmax is that the two distributions p_θ^+ and p_θ^- rank the next candidate target words $\tilde{y}_t$ (given the same history, here the greedy output $\hat{\mathbf{y}}_{<t}$) in opposite order. Globally normalized models as in the linear case, or LSTM-CRFs (Huang et al., 2015) for the non-linear case would allow sampling full structures such that the ranking over full structures is reversed. But in the case of locally normalized RNNs we retrieve only locally reversed-rank samples. Since we want the model to learn to rank $\tilde{\mathbf{y}}_i$ over $\tilde{\mathbf{y}}_j$, we would have to sample $\tilde{\mathbf{y}}_i$ word-by-word from p_θ^+ and $\tilde{\mathbf{y}}_j$ from p_θ^-. However, sampling all words of $\tilde{\mathbf{y}}_j$ from p_θ^- leads to translations that are neither fluent nor source-related, so we propose to randomly choose one position of $\tilde{\mathbf{y}}_j$ where the next word is sampled from p_θ^- and sample the remaining words from p_θ^+. We found that this method produces suitable negative samples, which are only slightly perturbed and still relatively fluent and source-related. A detailed algorithm is given in Algorithm 3.

In the same manner as for linear models, we define the probability of a pair of sequences as

$$p_\theta(\langle \tilde{\mathbf{y}}_i, \tilde{\mathbf{y}}_j \rangle |\mathbf{x}) = p_\theta^+(\tilde{\mathbf{y}}_i|\mathbf{x}) \times p_\theta^-(\tilde{\mathbf{y}}_j|\mathbf{x}).$$

[2]Note that our definition of continuous feedback is slightly different from the one proposed in Sokolov et al. (2016b) where updates are only made for misrankings.

Algorithm 2 Sampling Structures

Input: Model θ, target sequence length limit T_y
Output: Sequence of words $\mathbf{w} = (w_1, \ldots, w_{Ty})$ and log-probability p

$w_0 = \text{START}, p_0 = 0$
$\mathbf{w} = (w_0)$
for $t \leftarrow 1 \ldots T_y$ **do**
  $w_t \sim p_\theta(w|\mathbf{x}, \mathbf{w}_{<t})$
  $p_t = p_{t-1} + \log p_\theta(w|\mathbf{x}, \mathbf{w}_{<t})$
  $\mathbf{w} = (w_1, \ldots, w_{t-1}, w_t)$
end for
Return $\mathbf{w}$ and p_T

Note that with the word-based sampling scheme described above, the sequence $\tilde{\mathbf{y}}_j$ also includes words sampled from p_θ^+.
The pairwise preference ranking objective expresses an expectation over losses over these pairs:

$$L^{\text{PR}}(\theta) = \mathbb{E}_{p(\mathbf{x})\, p_\theta(\langle \tilde{\mathbf{y}}_i, \tilde{\mathbf{y}}_j \rangle | \mathbf{x})} \left[\Delta(\langle \tilde{\mathbf{y}}_i, \tilde{\mathbf{y}}_j \rangle) \right]. \quad (4)$$

The stochastic gradient for this objective is

$$s_k^{\text{PR}} = \Delta(\langle \tilde{\mathbf{y}}_i, \tilde{\mathbf{y}}_j \rangle) \times \left(\frac{\partial \log p_\theta^+(\tilde{\mathbf{y}}_i|\mathbf{x}_k)}{\partial \theta} + \frac{\partial \log p_\theta^-(\tilde{\mathbf{y}}_j|\mathbf{x}_k)}{\partial \theta} \right). \quad (5)$$

This training procedure resembles well-known approaches for noise contrastive estimation (Gutmann and Hyvärinen, 2010) with negative sampling that are commonly used for neural language modeling (Collobert et al., 2011; Mnih and Teh, 2012; Mikolov et al., 2013). In these approaches, negative samples are drawn from a non-parametric noise distribution, whereas we draw them from the perturbed model distribution.

4.3 Control Variates

The stochastic gradients defined in equations (2) and (5) can be used in stochastic gradient descent optimization (Bottou et al., 2016) where the full gradient is approximated using a minibatch or a single example in each update. The stochastic choice, in our case on inputs and outputs, introduces noise that leads to slower convergence and degrades performance. In the following, we explain how antithetic and additive control variate techniques from Monte Carlo simulation (Ross, 2013) can be used to remedy these problems.

The idea of additive control variates is to augment a random variable X whose expectation is sought, by another random variable Y to which X is highly correlated. Y is then called the control variate. Let $\bar{Y}$ furthermore denote its expectation. Then the following quantity $X - \hat{c}\,Y + \hat{c}\,\bar{Y}$ is an unbiased estimator of $\mathbb{E}[X]$. In our case, the random variable of interest is the noisy gradient $X = s_k$ from Equation (2). The variance reduction effect of control variates can be seen by computing the variance of this quantity:

$$\text{Var}(X - \hat{c}\,Y) = \text{Var}(X) + \hat{c}^2 \text{Var}(Y) - 2\hat{c}\,\text{Cov}(X, Y). \quad (6)$$

Choosing a control variate such that $\text{Cov}(X, Y)$ is positive and high enough, the variance of the gradient estimate will be reduced.

An example is the average reward baseline known from reinforcement learning (Williams, 1992), yielding

$$Y_k = \nabla \log p_\theta(\tilde{\mathbf{y}}|\mathbf{x}_k) \frac{1}{k} \sum_{j=1}^{k} \Delta(\tilde{\mathbf{y}}_j). \quad (7)$$

The optimal scalar $\hat{c}$ can be derived easily by taking the derivative of (6), leading to $\hat{c} = \frac{\text{Cov}(X,Y)}{\text{Var}(X)}$. This technique has been applied to using the score

Algorithm 3 Sampling Pairs of Structures

Input: Model θ, target sequence length limit T_y
Output: Pair of sequences $\langle \mathbf{w}, \mathbf{w}' \rangle$ and their log-probability p

$p_0 = 0$
$\mathbf{w}, \mathbf{w}', \hat{\mathbf{w}} = (\text{START})$
$i \sim \mathcal{U}(1, T)$
for $t \leftarrow 1 \ldots T_y$ **do**
  $\hat{w}_t = \arg\max_{w \in V} p_\theta^+(w|\mathbf{x}, \hat{\mathbf{w}}_{<t})$
  $w_t \sim p_\theta^+(w|\mathbf{x}, \hat{\mathbf{w}}_{<t})$
  $p_t = p_{t-1} + \log p_\theta^+(w_t|\mathbf{x}, \hat{\mathbf{w}}_{<t})$
  if $i = t$ **then**
    $w'_t \sim p_\theta^-(w|\mathbf{x}, \hat{\mathbf{w}}_{<t})$
    $p_t = p_t + \log p_\theta^-(w'_t|\mathbf{x}, \hat{\mathbf{w}}_{<t})$
  else
    $w'_t \sim p_\theta^+(w|\mathbf{x}, \hat{\mathbf{w}}_{<t})$
    $p_t = p_t + \log p_\theta^+(w'_t|\mathbf{x}, \hat{\mathbf{w}}_{<t})$
  end if
  $\mathbf{w} = (w_1, \ldots, w_{t-1}, w_t)$
  $\mathbf{w}' = (w'_1, \ldots, w'_{t-1}, w'_t)$
  $\hat{\mathbf{w}} = (\hat{w}_1, \ldots, \hat{w}_{t-1}, \hat{w}_t)$
end for
Return $\langle \mathbf{w}, \mathbf{w}' \rangle$ and p_T

function (Equation (3)) as control variate in Ranganath et al. (2014), yielding the following control variate:

$$Y_k = \nabla \log p_\theta(\tilde{\mathbf{y}}|\mathbf{x}_k). \quad (8)$$

Note that for both types of control variates, (7) and (8), the expectation $\bar{Y}$ is zero, simplifying the implementation. However, the optimal scalar $\hat{c}$ has to be estimated for every entry of the gradient separately for the score function control variate. We will explore both types of control variates for the stochastic gradient (2) in our experiments.

A further effect of control variates is to reduce the magnitude of the gradient, the more so the more the stochastic gradient and the control variate covary. For L-Lipschitz continuous functions, a reduced gradient norm directly leads to a bound on L which appears in the algorithmic stability bounds of Hardt et al. (2016). This effect of improved generalization by control variates is empirically validated in our experiments.

A similar variance reduction effect can be obtained by antithetic control variates. Here $\mathbb{E}[X]$ is approximated by the estimator $\frac{X_1+X_2}{2}$ whose variance is

$$\mathrm{Var}\left(\frac{X_1+X_2}{2}\right) = \frac{1}{4}\big(\mathrm{Var}(X_1) + \mathrm{Var}(X_2) + 2\mathrm{Cov}(X_1, X_2)\big). \quad (9)$$

Choosing the variates X_1 and X_2 such that $\mathrm{Cov}(X_1, X_2)$ is negative will reduce the variance of the gradient estimate. Under certain assumptions, the stochastic gradient (5) of the pairwise preference objective can be interpreted as an antithetic estimator of the score function (3). The antithetic variates in this case would be

$$X_1 = \nabla \log p^+_\theta(\tilde{\mathbf{y}}_i|\mathbf{x}_k), \quad (10)$$
$$X_2 = \nabla \log p^-_\theta(\tilde{\mathbf{y}}_j|\mathbf{x}_k),$$

where an antithetic dependence of X_2 on X_1 can be achieved by construction of p^+_θ and p^-_θ (see Capriotti (2008) which is loosely related to our approach). Similar to control variates, antithetic variates have the effect of shrinking the gradient norm, the more so the more the variates are antithetically correlated, leading to possible improvements in algorithmic stability (Hardt et al., 2016).

5 Experiments

In the following, we present an experimental evaluation of the learning objectives presented above on machine translation domain adaptation. We compare how the presented neural bandit learning objectives perform in comparison to linear models, then discuss the handling of unknown words and eventually investigate the impact of techniques for variance reduction.

Domain	Version	Train	Valid.	Test
Europarl	v.5	1.6M	2k	2k
News Commentary	WMT07	40k	1k	2k
TED	TED2013	153k	2k	2k

Table 1: Number of parallel sentences for training, validation and test sets for French-to-English domain adaptation.

5.1 Setup

Data. We perform domain adaptation from Europarl (EP) to News Commentary (NC) and TED talks (TED) for translations from French to English. Table 1 provides details about the datasets. For data pre-processing we follow the procedure of Sokolov et al. (2016a,b) using `cdec` tools for filtering, lowercasing and tokenization. The challenge for the bandit learner is to adapt from the EP domain to NC or TED with weak feedback only.

NMT Models. We choose a standard encoder-decoder architecture with single-layer GRU RNNs with 800 hidden units, a word embedding size of 300 and `tanh` activations. The encoder consists of a bidirectional RNN, where the hidden states of backward and forward RNN are concatenated. The decoder uses the attention mechanism proposed by Bahdanau et al. (2015).[3] Source and target vocabularies contain the 30k most frequent words of the respective parts of the training corpus. We limit the maximum sentence length to 50. Dropout (Srivastava et al., 2014) with a probability of 0.5 is applied to the network in several places: on the embedded inputs, before the output layer, and on the initial state of the decoder RNN. The gradient is clipped when its norms exceeds 1.0 to prevent exploding gradients and stabilize learning (Pascanu et al., 2013). All models are implemented and trained with the sequence learning framework `Neural Monkey` (Libovický et al.,

[3] We do not use beam search nor ensembling, although we are aware that higher performance is almost guaranteed with these techniques. Our goal is to show relative differences between different models, so a simple setup is sufficient for the purpose of our experiments.

2016; Bojar et al., 2016).[4] They are trained with a minibatch size of 20, fitting onto single 8GB GPU machines. The training dataset is shuffled before each epoch.

Baselines. The out-of-domain baseline is trained on the EP training set with standard MLE. For both NC and TED domains, we train two full-information in-domain baselines: The first in-domain baseline is trained on the relatively small in-domain training data. The second in-domain baseline starts from the out-of-domain model and is further trained on the in-domain data. All baselines are trained with MLE and Adam (Kingma and Ba, 2014) ($\alpha = 1 \times 10^{-4}$, $\beta_1 = 0.9$, $\beta_2 = 0.999$) until their performance stops increasing on respective held-out validation sets. The gap between the performance of the out-of-domain model and the in-domain models defines the range of possible improvements for bandit learning. All models are evaluated with Neural Monkey's `mteval`. For statistical significance tests we used Approximate Randomization testing (Noreen, 1989).

Bandit Learning. Bandit learning starts with the parameters of the out-of-domain baseline. The bandit models are expected to improve over the out-of-domain baseline by receiving feedback from the new domain, but at most to reach the in-domain baseline since the feedback is weak. The models are trained with Adam on in-domain data for at most 20 epochs. Adam's step-size parameter α was tuned on the validation set and was found to perform best when set to 1×10^{-5} for non-pairwise, 1×10^{-6} for pairwise objectives on NC, 1×10^{-7} for pairwise objectives on TED. The best model parameters, selected with early stopping on the in-domain validation set, are evaluated on the held-out in-domain test set. In the spirit of Freitag and Al-Onaizan (2016) they are additionally evaluated on the out-of-domain test set to investigate how much knowledge of the old domain the models lose while adapting to the new domain. Bandit learning experiments are repeated two times, with different random seeds, and mean BLEU scores with standard deviation are reported.

[4]The `Neural Monkey` fork `https://github.com/juliakreutzer/bandit-neuralmonkey` contains bandit learning objectives and the configuration files for our experiments.

Feedback Simulation. Weak feedback is simulated from the target side of the parallel corpus, but references are never revealed to the learner. Sokolov et al. (2016a,b) used a smoothed version of per-sentence BLEU for simulating the weak feedback for generated translations from the comparison with reference translations. Here, we use gGLEU instead, which Wu et al. (2016) recently introduced for learning from sentence-level reward signals correlating well with corpus BLEU. This metric is closely related to BLEU, but does not have a brevity penalty and considers the recall of matching n-grams. It is defined as the minimum of recall and precision over the total n-grams up to a certain n. Hence, for our experiments $\Delta(\tilde{\mathbf{y}}) = -\text{gGLEU}(\tilde{\mathbf{y}}, \mathbf{y})$, where $\tilde{\mathbf{y}}$ is a sample translation and $\mathbf{y}$ is the reference translation.

Unknown words. One drawback of NMT models is their limitation to a fixed source- and target vocabulary. In a domain adaptation setting, this limitation has a critical impact to the translation quality. The larger the distance between old and new domain, the more words in the new domain are unknown to the models trained on the old domain (represented with a special UNK token). We consider two strategies for this problem for our experiments:

1. UNK-Replace: Jean et al. (2015) and Luong et al. (2015b) replace generated UNK tokens with aligned source words or their lexical translations in a post-processing step. Freitag and Al-Onaizan (2016) and Hashimoto et al. (2016) demonstrated that this technique is beneficial for NMT domain adaptation.

2. BPE: Sennrich et al. (2016) introduce byte pair encoding (BPE) for word segmentation to build translation models on sub-word units. Rare words are decomposed into sub-word units, while the most frequent words remain single vocabulary items.

For UNK-Replace we use `fast_align` to generate lexical translations on the EP training data. When an UNK token is generated, we look up the attention weights and find the source token that receives most attention in this step. If possible, we replace the UNK token by its lexical translation. If it is not included in the lexical translations, it is replaced by the source token. The main benefit of this technique is that it deals well

Algorithm	Train data	Iter.	EP	NC	TED
MLE	EP	12.3M	31.44	26.98	23.48
MLE-UNK			31.82	28.00	24.59
MLE-BPE		12.0M	31.81	27.20	24.35

Table 2: Out-of-domain NMT baseline results (BLEU) on in- and out-of-domain test sets trained only on EP data.

with unknown named entities that are just passed through from source to target. However, since it is a non-differentiable post-processing step, the NMT model cannot directly be trained for this behavior. Therefore we also train sub-word level NMT with BPE. We apply 29,800 merge operations to obtain a vocabulary of 29,908 sub-words. The procedure for training these models is exactly the same as for the word-based models. The advantage of this method is that the model is in principle able to generate any word composing it from sub-word units. However, training sequences become longer and candidate translations are sampled on a sub-word level, which introduces the risk of sampling nonsense words.

Control variates. We implement the average baseline control variate as defined in Equation 7, which results in keeping an running average over previous losses. Intuitively, absolute gGLEU feedback is turned into relative feedback that reflects the current state of the model. The sign of the update is switched when the gGLEU for the current sample is worse than the average gGLEU, so the model makes a step away from it, while in the case of absolute feedback it would still make a small step towards it. In addition, we implement the score function control variate with a running estimate $\hat{c}_k = \frac{1}{k}\sum_{j=1}^{k} \frac{\mathrm{Cov}(s_j, \nabla \log p_\theta(\tilde{\mathbf{y}}_j|\mathbf{x}_j))}{\mathrm{Var}(s_j)}$.

5.2 Results

In the following, we discuss the results of the experimental evaluation of the models described above. The out-of-domain baseline results are given in Table 2, those for the in-domain baselines in 3. The results for bandit learning on NC and TED are reported in Table 4. For bandit learning we give mean improvements over the respective out-of-domain baselines in the Diff.-columns.

Baselines. The NMT out-of-domain baselines, reported in Table 2, perform comparable to the linear baseline from Sokolov et al. (2016a,b) on

Table 3: In-domain NMT baselines results (BLEU) on in- and out-of-domain test sets. The EP→NC is first trained on EP, then fine-tuned on NC. The EP→TED is first trained on EP, then fine-tuned on TED.

NC, but the in-domain EP→NC (Table 3) baselines outperform the linear baseline by more than 3 BLEU points. Continuing training of a pre-trained out-of-domain model on a small amount of in domain data is very hence effective, whilst the performance of the models solely trained on small in-domain data is highly dependent on the size of this training data set. For TED, the in-domain dataset is almost four times as big as the NC training set, so the in-domain baselines perform better. This effect was previously observed by Luong and Manning (2015) and Freitag and Al-Onaizan (2016).

Bandit Learning. The NMT bandit models that optimize the EL objective yield generally a much higher improvement over the out-of-domain models than the corresponding linear models: As listed in Table 4, we find improvements of between 2.33 and 2.89 BLEU points on the NC domain, and between 4.18 and 5.18 BLEU points on the TED domain. In contrast, the linear models with sparse features and hypergraph re-decoding achieved a maximum improvement of 0.82 BLEU points on NC.

Optimization of the PR objective shows improvements of up to 1.79 BLEU points on NC (compared to 0.6 BLEU points for linear models), but no significant improvement on TED. The biggest impact of this variance reduction tech-

(b) Domain adaptation from EP to TED.

Table 4: Bandit NMT results (BLEU) on EP, NC and TED test sets. UNK* models involve UNK replacement only during testing, UNK** include UNK replacement already during training. For PR, either binary (bin) or continuous feedback (cont) was used. Control variates: average reward baseline (BL) and score function (SF). Results are averaged over two independent runs and standard deviation is given in subscripts. Improvements over respective out-of-domain models are given in the Diff.-columns.

nique is a considerable speedup of training speed of 1 to 2 orders of magnitude compared to EL.

A beneficial side-effect of NMT learning from weak feedback is that the knowledge from the out-domain training is not simply "overwritten". This happens to full-information in-domain tuning where more than 4 BLEU points are lost in an evaluation on the out-domain data. On the contrary, the bandit learning models still achieve high results on the original domain. This is useful for conservative domain adaptation, where the performance of the models in the old domain is still relevant.

Unknown words. By handling unknown words with UNK-Replace or BPEs, we find consistent improvements over the plain word-based models for all baselines and bandit learning models. We observe that the models with UNK replacement essentially benefit from passing through source tokens, and only marginally from lexical translations. Bandit learning models take particular advantage of UNK replacement when it is included already during training. The sub-word models achieve the overall highest improvement over the baselines, although sometimes generating nonsense words.

Control variates. Applying the score function control variate to EL optimization does not largely change learning speed or BLEU results. However, the average reward control variate leads to improvements of around 1 BLEU over the EL optimization without variance reduction on both domains.

6 Conclusion

In this paper, we showed how to lift structured prediction under bandit feedback from linear models to non-linear sequence-to-sequence learning using recurrent neural networks with attention. We introduced algorithms to train these models under numerical feedback to single output structures or under preference rankings over pairs of structures. In our experimental evaluation on the task of neural machine translation domain adaptation, we found relative improvements of up to 5.89 BLEU points over out-of-domain seed models, outperforming also linear bandit models. Furthermore, we argued that pairwise ranking under bandit feedback can be interpreted as a use of antithetic variates, and we showed how to include average reward and score function baselines as control variates for improved training speed and generalization. In future work, we would like to apply the presented non-linear bandit learners to other structured prediction tasks.

Abstract

Although neural machine translation has made significant progress recently, how to integrate multiple overlapping, arbitrary prior knowledge sources remains a challenge. In this work, we propose to use posterior regularization to provide a general framework for integrating prior knowledge into neural machine translation. We represent prior knowledge sources as features in a log-linear model, which guides the learning process of the neural translation model. Experiments on Chinese-English translation show that our approach leads to significant improvements.

1 Introduction

The past several years have witnessed the rapid development of neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015), which aims to model the translation process using neural networks in an end-to-end manner. With the capability of capturing long-distance dependencies due to the gating (Hochreiter and Schmidhuber, 1997; Cho et al., 2014) and attention (Bahdanau et al., 2015) mechanisms, NMT has shown remarkable superiority over conventional statistical machine translation (SMT) across a variety of natural languages (Junczys-Dowmunt et al., 2016).

Despite the apparent success, NMT still suffers from one significant drawback: it is difficult to integrate prior knowledge into neural networks. On one hand, neural networks use *continuous* real-valued vectors to represent all language structures involved in the translation process. While these vector representations prove to be capable of capturing translation regularities implicitly (Sutskever et al., 2014), it is hard to interpret each hidden state in neural networks from a linguistic perspective. On the other hand, prior knowledge in machine translation is usually represented in *discrete* symbolic forms such as dictionaries and rules (Nirenburg, 1989) that explicitly encode translation regularities. It is difficult to transform prior knowledge represented in discrete forms to continuous representations required by neural networks.

Therefore, a number of authors have endeavored to integrate prior knowledge into NMT in recent years, either by modifying model architectures (Tu et al., 2016; Cohn et al., 2016; Tang et al., 2016; Feng et al., 2016) or by modifying training objectives (Cohn et al., 2016; Feng et al., 2016; Cheng et al., 2016). For example, to address the over-translation and under-translation problems widely observed in NMT, Tu et al. (2016) directly extend standard NMT to model the coverage constraint that each source phrase should be translated into exactly one target phrase (Koehn et al., 2003). Alternatively, Cohn et al. (2016) and Feng et al. (2016) propose to control the fertilities of source words by appending additional additive terms to training objectives.

Although these approaches have demonstrated clear benefits of incorporating prior knowledge into NMT, how to combine multiple overlapping, arbitrary prior knowledge sources still remains a major challenge. It is difficult to achieve this end by directly modifying model architectures because neural networks usually impose strong independence assumptions between hidden states. As a result, extending a neural model requires that the interdependence of information sources be modeled explicitly (Tu et al., 2016; Tang et al., 2016), making it hard to extend. While this drawback can be partly alleviated by appending additional additive terms to training objectives (Cohn et al., 2016; Feng et al., 2016), these terms are restricted to a

limited number of simple constraints.

In this work, we propose a general framework for integrating multiple overlapping, arbitrary prior knowledge sources into NMT using *posterior regularization* (Ganchev et al., 2010). Our framework is capable of incorporating indirect supervision via posterior distributions of neural translation models. To represent prior knowledge sources as arbitrary real-valued features, we define the posterior distribution as a log-linear model instead of a constrained posterior set (Ganchev et al., 2010). This treatment not only leads to a simpler and more efficient training algorithm but also achieves better translation performance. Experiments show that our approach is able to incorporate a variety of features and achieves significant improvements over posterior regularization using constrained posterior sets on NIST Chinese-English datasets.

2 Background

2.1 Neural Machine Translation

Given a source sentence $\mathbf{x} = x_1, \ldots, x_i, \ldots, x_I$ and a target sentence $\mathbf{y} = y_1, \ldots, y_j, \ldots, y_J$, a neural translation model (Sutskever et al., 2014; Bahdanau et al., 2015) is usually factorized as a product of word-level translation probabilities:

$$P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{j=1}^{J} P(y_j|\mathbf{x},\mathbf{y}_{<j};\boldsymbol{\theta}), \quad (1)$$

where $\boldsymbol{\theta}$ is a set of model parameters and $\mathbf{y}_{<j} = y_1, \ldots, y_{j-1}$ denotes a partial translation.

The word-level translation probability is defined using a softmax function:

$$P(y_j|\mathbf{x},\mathbf{y}_{<j};\boldsymbol{\theta}) \propto \exp\Big(f(\mathbf{v}_{y_j}, \mathbf{v}_{\mathbf{x}}, \mathbf{v}_{\mathbf{y}_{<j}}, \boldsymbol{\theta})\Big), \quad (2)$$

where $f(\cdot)$ is a non-linear function, $\mathbf{v}_{y_j}$ is a vector representation of the j-th target word y_j, $\mathbf{v}_{\mathbf{x}}$ is a vector representation of the source sentence $\mathbf{x}$ that encodes the context on the source side, and $\mathbf{v}_{\mathbf{y}_{<j}}$ is a vector representation of the partial translation $\mathbf{y}_{<j}$ that encodes the context on the target side.

Given a training set $\{\langle \mathbf{x}^{(n)}, \mathbf{y}^{(n)} \rangle\}_{n=1}^{N}$, the standard training objective is to maximize the log-likelihood of the training set:

$$\hat{\boldsymbol{\theta}}_{\text{MLE}} = \operatorname*{argmax}_{\boldsymbol{\theta}} \Big\{\mathcal{L}(\theta)\Big\}, \quad (3)$$

where

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{n=1}^{N} \log P(\mathbf{y}^{(n)}|\mathbf{x}^{(n)};\boldsymbol{\theta}). \quad (4)$$

Although the introduction of vector representations into machine translation has resulted in substantial improvements in terms of translation quality (Junczys-Dowmunt et al., 2016), it is difficult to incorporate prior knowledge represented in discrete symbolic forms into NMT. For example, given a Chinese-English dictionary containing ground-truth translational equivalents such as $\langle$*baigong*, *the White House*$\rangle$, it is non-trivial to leverage the dictionary to guide the learning process of NMT. To address this problem, Tang et al. (2016) propose a new architecture called phraseNet on top of RNNsearch (Bahdanau et al., 2015) that equips standard NMT with an external memory storing phrase tables.

Another important prior knowledge source is the coverage constraint (Koehn et al., 2003): *each source phrase should be translated into exactly one target phrase*. To encode this linguistic intuition into NMT, Tu et al. (2016) extend standard NMT with a coverage vector to keep track of the attention history.

While these approaches are capable of incorporating individual prior knowledge sources separately, how to combine multiple overlapping, arbitrary knowledge sources still remains a major challenge. This can be hardly addressed by modifying model architectures because of the lack of interpretability in NMT and the incapability of neural networks in modeling arbitrary knowledge sources. Although modifying training objectives to include additional knowledge sources as additive terms can partially alleviate this problem, these terms have been restricted to a limited number of simple constraints (Cheng et al., 2016; Cohn et al., 2016; Feng et al., 2016) and incapable of combining arbitrary knowledge sources.

Therefore, it is important to develop a new framework for integrating arbitrary prior knowledge sources into NMT.

2.2 Posterior Regularization

Ganchev et al. (2010) propose *posterior regularization* for incorporating indirect supervision via constraints on posterior distributions of structured latent-variable models. The basic idea is to penalize the log-likelihood of a neural translation model

with the KL divergence between a desired distribution that incorporates prior knowledge and the model posteriors. The posterior regularized likelihood is defined as

$$\begin{aligned} & F(\boldsymbol{\theta}, \boldsymbol{q}) \\ = \; & \lambda_1 \mathcal{L}(\boldsymbol{\theta}) - \\ & \lambda_2 \sum_{n=1}^{N} \min_{q \in \mathcal{Q}} \mathrm{KL}\Big(q(\mathbf{y}) \Big|\Big| P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta}), \Big) \end{aligned} \quad (5)$$

where λ_1 and λ_2 are hyper-parameters to balance the preference between likelihood and posterior regularization, $\mathcal{Q}$ is a set of constrained posteriors:

$$\mathcal{Q} = \{q(\mathbf{y}) : \mathbb{E}_q[\boldsymbol{\phi}(\mathbf{x}, \mathbf{y})] \leq \mathbf{b}\}, \quad (6)$$

where $\boldsymbol{\phi}(\mathbf{x}, \mathbf{y})$ is constraint feature and b is the bound of constraint feature expectations. Ganchev et al. (2010) use constraint features to encode structural bias and define the set of valid distributions with respect to the expectations of constraint features to facilitate inference.

As maximizing $F(\boldsymbol{\theta}, \boldsymbol{q})$ involves minimizing the KL divergence, Ganchev et al. (2010) present a minorization-maximization algorithm akin to EM at sentence level:

$$\mathrm{E}: q^{(t+1)} = \operatorname*{argmin}_{q} \mathrm{KL}\Big(q(\mathbf{y}) \Big|\Big| P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta}^{(t)})\Big)$$

$$\mathrm{M}: \boldsymbol{\theta}^{(t+1)} = \operatorname*{argmax}_{\boldsymbol{\theta}} \mathbb{E}_{q^{(t+1)}}\Big[\log P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})\Big]$$

However, directly applying posterior regularization to neural machine translation faces a major difficulty: it is hard to specify the hyper-parameter $\mathbf{b}$ to effectively bound the expectation of features, which are usually real-valued in translation (Och and Ney, 2002; Koehn et al., 2003; Chiang, 2005). For example, the coverage penalty constraint (Wu et al., 2016) proves to be an essential feature for controlling the length of a translation in NMT. As the value of coverage penalty varies significantly over different sentences, it is difficult to set an appropriate bound for all sentences on the training data. In addition, the minorization-maximization algorithm involves an additional step to find $q^{(t+1)}$ as compared with standard NMT, which increases training time significantly.

3 Posterior Regularization for Neural Machine Translation

3.1 Modeling

In this work, we propose to adapt posterior regularization (Ganchev et al., 2010) to neural machine translation. The major difference is that we represent the desired distribution as a log-linear model (Och and Ney, 2002) rather than a constrained posterior set as described in (Ganchev et al., 2010):

$$\begin{aligned} & \mathcal{J}(\boldsymbol{\theta}, \boldsymbol{\gamma}) \\ = \; & \lambda_1 \mathcal{L}(\boldsymbol{\theta}) - \\ & \lambda_2 \sum_{n=1}^{N} \mathrm{KL}\Big(Q(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma}) \Big|\Big| P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})\Big), \end{aligned} \quad (7)$$

where the desired distribution that encodes prior knowledge is defined as: [1]

$$Q(\mathbf{y}|\mathbf{x}; \boldsymbol{\gamma}) = \frac{\exp\Big(\boldsymbol{\gamma} \cdot \boldsymbol{\phi}(\mathbf{x}, \mathbf{y})\Big)}{\sum_{\mathbf{y}'} \exp\Big(\boldsymbol{\gamma} \cdot \boldsymbol{\phi}(\mathbf{x}, \mathbf{y}')\Big)}. \quad (8)$$

As compared to previous work on integrating prior knowledge into NMT (Tu et al., 2016; Cohn et al., 2016; Tang et al., 2016), our approach provides a general framework for combining arbitrary knowledge sources. This is due to log-linear models that offer sufficient flexibility to represent arbitrary prior knowledge sources as features. We tackle the representation discrepancy problem by associating the Q distribution that encodes *discrete* representations of prior knowledge with neural models using *continuous* representations learned from data in the KL divergence. Another advantage of our approach is the transparency to model architectures. In principle, our approach can be applied to any neural models for natural language processing.

Our approach also differs from the original version of posterior regularization (Ganchev et al., 2010) in the definition of desired distribution. We resort to log-linear models (Och and Ney, 2002) to incorporate features that have proven effective in SMT. Another benefit of using log-linear models is the differentiability of our training objective (see Eq. (7)). It is easy to leverage standard stochastic gradient descent algorithms to optimize model parameters (Section 3.3).

3.2 Feature Design

In this section, we introduce how to design features to encode prior knowledge in the desired dis-

[1] Ideally, the desired distribution Q should be fixed to guide the learning process of P. However, it is hard to manually specify the feature weights $\boldsymbol{\gamma}$. Therefore, we propose to train both $\boldsymbol{\theta}$ and $\boldsymbol{\lambda}$ jointly (see Section 3.3). We find that joint training results in significant improvements in practice (see Table 1).

tribution.

Note that not all features in SMT can be adopted to our framework. This is because features in SMT are defined on latent structures such as phrase pairs and synchronous CFG rules, which are not accessible to the decoding process of NMT. Fortunately, we can still leverage internal information in neural models that is linguistically meaningful such as the attention matrix $\mathbf{a}$ (Bahdanau et al., 2015).

We will introduce a number of features used in our experiments as follows.

3.2.1 Bilingual Dictionary

It is natural to leverage a bilingual dictionary $\mathcal{D}$ to improve neural machine translation. Arthur et al. (2016) propose to incorporate discrete translation lexicons into NMT by using the attention vector to select lexical probabilities on which to be focused.

In our work, for each entry $\langle x, y \rangle \in \mathcal{D}$ in the dictionary, a *bilingual dictionary* (BD) feature is defined at the sentence level:

$$\phi_{\mathrm{BD}_{\langle x,y \rangle}}(\mathbf{x}, \mathbf{y}) = \begin{cases} 1 & \text{if } x \in \mathbf{x} \wedge y \in \mathbf{y} \\ 0 & \text{otherwise} \end{cases} . \quad (9)$$

Note that number of bilingual dictionary features depends on the vocabulary of the neural translation model. Entries containing out-of-vocabulary words has to be discarded.

3.2.2 Phrase Table

Phrases, which are sequences of consecutive words, are capable of memorizing local context to deal with word ordering within phrases and translation of short idioms, word insertions or deletions (Koehn et al., 2003; Chiang, 2005). As a result, phrase tables that specify phrase-level correspondences between the source and target languages also prove to be an effective knowledge source in NMT (Tang et al., 2016).

Similar to the bilingual dictionary features, we define a *phrase table* (PT) feature for each entry $\langle \tilde{x}, \tilde{y} \rangle$ in a phrase table $\mathcal{P}$:

$$\phi_{\mathrm{PT}_{\langle \tilde{x}, \tilde{y} \rangle}}(\mathbf{x}, \mathbf{y}) = \begin{cases} 1 & \text{if } \tilde{x} \in \mathbf{x} \wedge \tilde{y} \in \mathbf{y} \\ 0 & \text{otherwise} \end{cases} . \quad (10)$$

The number of phrase table features also depends on the vocabulary of the neural translation model.

3.2.3 Coverage Penalty

To overcome the over-translation and under-translation problems widely observed in NMT, a number of authors have proposed to model the fertility (Brown et al., 1993) and converge constraint (Koehn et al., 2003) to improve the adequacy of translation (Tu et al., 2016; Cohn et al., 2016; Feng et al., 2016; Wu et al., 2016; Mi et al., 2016).

We follow Wu et al. (2016) to define a *coverage penalty* (CP) feature to penalize source words with lower sum of attention weights: [2]

$$\phi_{\mathrm{CP}}(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{|\mathbf{x}|} \log \left(\min \left(\sum_{j=1}^{|\mathbf{y}|} \mathbf{a}_{i,j}, 1.0 \right) \right), \quad (11)$$

where $\mathbf{a}_{i,j}$ is the attention probability of the j-th target word on the i-th source word. Note that the value of coverage penalty feature varies significantly over sentences of different lengths.

3.2.4 Length Ratio

Controlling the length of translations is very important in NMT as neural models tend to generate short translations for long sentences, which deteriorates the translation performance of NMT for long sentences as compared with SMT (Shen et al., 2016).

Therefore, we define the *length ratio* (LR) feature to encourage the length of a translation to fall in a reasonable range:

$$\phi_{\mathrm{LR}}(\mathbf{x}, \mathbf{y}) = \begin{cases} (\beta|\mathbf{x}|)/|\mathbf{y}| & \text{if } \beta|\mathbf{x}| < |\mathbf{y}| \\ |\mathbf{y}|/(\beta|\mathbf{x}|) & \text{otherwise} \end{cases} , \quad (12)$$

where β is a hyper-parameter for penalizing too long or too short translations.

For example, to convey the same meaning, an English sentence is usually about 1.2 times longer than a Chinese sentence. As a result, we can set $\beta = 1.2$. If the length of a Chinese sentence $|\mathbf{x}|$ is 10 and the length of an English sentence $|\mathbf{y}|$ is 12, then, $\phi_{\mathrm{LR}}(\mathbf{x}, \mathbf{y}) = 1$. If the translation is too long (e.g., $|\mathbf{y}| = 100$), then the feature value is 0.12. If the translation is too short (e.g., $|\mathbf{y}| = 6$), the feature value is 0.5.

3.3 Training

In training, our goal is to find a set of model parameters that maximizes the posterior regularized likelihood:

$$\hat{\boldsymbol{\theta}}, \hat{\boldsymbol{\gamma}} = \underset{\boldsymbol{\theta}, \boldsymbol{\gamma}}{\mathrm{argmax}} \left\{ \mathcal{J}(\boldsymbol{\theta}, \boldsymbol{\gamma}) \right\}. \quad (13)$$

[2] For simplicity, we omit the attention matrix $\mathbf{a}$ in the input of the coverage feature function.

Note that unlike the original version of posterior regularization (Ganchev et al., 2010) that relies on a minorization-maximization algorithm to optimize model parameters, our training objective is differentiable with respect to model parameters. Therefore, it is easy to use standard stochastic gradient descent algorithms to train our model.

However, a major difficulty in calculating gradients is that the algorithm needs to sum over all candidate translations in an exponential search space for KL divergence. For example, the partial derivative of $\mathcal{J}(\boldsymbol{\theta}, \boldsymbol{\gamma})$ with respect to γ is given by

$$\begin{aligned}&\frac{\partial \mathcal{J}(\boldsymbol{\theta}, \boldsymbol{\gamma})}{\partial \boldsymbol{\gamma}} \\ &= -\lambda_2 \times \\ &\sum_{n=1}^{N} \frac{\partial}{\partial \boldsymbol{\gamma}} \mathrm{KL}\Big(Q(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma}) \Big|\Big| P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})\Big). \quad (14)\end{aligned}$$

The KL divergence is defined as

$$\begin{aligned}&\mathrm{KL}\Big(Q(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma}) \Big|\Big| P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})\Big) \\ &= \sum_{\mathbf{y} \in \mathcal{Y}(\mathbf{x}^{(n)})} Q(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma}) \log \frac{Q(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma})}{P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})}, \quad (15)\end{aligned}$$

where $\mathcal{Y}(\mathbf{x}^{(n)})$ is a set of all possible candidate translations for the source sentence $\mathbf{x}^{(n)}$.

To alleviate this problem, we follow Shen et al. (2016) to approximate the full search space $\mathcal{Y}(\mathbf{x}^{(n)})$ with a sampled sub-space $\mathcal{S}(\mathbf{x}^{(n)})$. Therefore, the KL divergence can be approximated as

$$\begin{aligned}&\mathrm{KL}\Big(Q(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma}) \Big|\Big| P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})\Big) \\ &\approx \sum_{\mathbf{y} \in \mathcal{S}(\mathbf{x}^{(n)})} \tilde{Q}(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma}) \log \frac{\tilde{Q}(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma})}{\tilde{P}(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})}. \quad (16)\end{aligned}$$

Note that the Q distribution is also approximated on the sub-space:

$$\begin{aligned}&\tilde{Q}(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\gamma}) \\ &= \frac{\exp(\boldsymbol{\gamma} \cdot \boldsymbol{\phi}(\mathbf{x}^{(n)}, \mathbf{y}))}{\sum_{\mathbf{y}' \in \mathcal{S}(\mathbf{x}^{(n)})} \exp(\boldsymbol{\gamma} \cdot \boldsymbol{\phi}(\mathbf{x}^{(n)}, \mathbf{y}'))}. \quad (17)\end{aligned}$$

We follow Shen et al. (2016) to control the sharpness of approximated neural translation distribution normalized on the sampled sub-space:

$$\tilde{P}(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta}) = \frac{P(\mathbf{y}|\mathbf{x}^{(n)}; \boldsymbol{\theta})^{\alpha}}{\sum_{\mathbf{y}' \in \mathcal{S}(\mathbf{x}^{(n)})} P(\mathbf{y}'|\mathbf{x}^{(n)}; \boldsymbol{\theta})^{\alpha}}. \quad (18)$$

3.4 Search

Given learned model parameters $\hat{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\gamma}}$, the decision rule for translating an unseen source sentence $\mathbf{x}$ is given by

$$\hat{\mathbf{y}} = \operatorname*{argmax}_{\mathcal{Y}(\mathbf{x})} \Big\{ P(\mathbf{y}|\mathbf{x}; \hat{\boldsymbol{\theta}}) \Big\}. \quad (19)$$

The search process can be factorized at the word level:

$$\hat{y}_j = \operatorname*{argmax}_{y \in \mathcal{V}_y} \Big\{ P(y|\mathbf{x}, \hat{\mathbf{y}}_{<j}; \hat{\boldsymbol{\theta}}) \Big\}, \quad (20)$$

where $\mathcal{V}_y$ is the target language vocabulary.

Although this decision rule shares the same efficiency and simplicity with standard NMT (Bahdanau et al., 2015), it does not involve prior knowledge in decoding. Previous studies reveal that incorporating prior knowledge in decoding also significantly boosts translation performance (Arthur et al., 2016; He et al., 2016; Wang et al., 2016).

As directly incorporating prior knowledge into the decoding process of NMT depends on both model structure and the locality of features, we resort to a coarse-to-fine approach instead to keep the architecture transparency of our approach. Given a source sentence $\mathbf{x}$ in the test set, we first use the neural translation model $P(\mathbf{y}|\mathbf{x}; \hat{\boldsymbol{\theta}})$ to generate a k-best list of candidate translation $\mathcal{C}(\mathbf{x})$. Then, the algorithm decides on the most probable candidate translation using the following decision rule:

$$\hat{\mathbf{y}} = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{C}(\mathbf{x})} \Big\{ \log P(\mathbf{y}|\mathbf{x}; \hat{\boldsymbol{\theta}}) + \hat{\boldsymbol{\gamma}} \cdot \boldsymbol{\phi}(\mathbf{x}, \mathbf{y}) \Big\}. \quad (21)$$

4 Experiments

4.1 Setup

We evaluate our approach on Chinese-English translation. The evaluation metric is case-insensitive BLEU calculated by the *multi-bleu.perl* script. Our training set[3] consists of 1.25M sentence pairs with 27.9M Chinese words and 34.5M English words. We use the NIST 2002 dataset as validation set and the NIST 2003, 2004, 2005, 2006, 2008 datasets as test sets.

In the experiments, we compare our approach with the following two baseline approaches:

[3]The training set includes LDC2002E18, LDC2003E07, LDC2003E14, part of LDC2004T07, LDC2004T08 and LDC2005T06.

Table 1: Comparison of BLEU scores on the Chinese-English datasets. RNNSEARCH is an attention-based neural machine translation model (Bahdanau et al., 2015) that does not incorporate prior knowledge. CPR extends RNNSEARCH by introducing coverage penalty refinement (Eq. (11)) in decoding. POSTREG extends RNNSEARCH with posterior regularization (Ganchev et al., 2010), which uses constraint features to represent prior knowledge and a constrained posterior set to denote the desired distribution. Note that POSTREG cannot use the CP feature (Section 3.2.3) because it is hard to bound the feature value appropriately. On top of RNNSEARCH, our approach also exploits posterior regularization to incorporate prior knowledge but uses a log-linear model to denote the desired distribution. All results of *this work* are significantly better than RNNSEARCH ($p < 0.01$).

1. RNNSEARCH (Bahdanau et al., 2015): a standard attention-based neural machine translation model,

2. CPR (Wu et al., 2016): extending RNNSEARCH by introducing coverage penalty refinement (Eq. (11)) in decoding,

3. POSTREG (Ganchev et al., 2010): extending RNNSEARCH with posterior regularization using constrained posterior set.

For RNNSEARCH, we use an in-house attention-based NMT system that achieves comparable translation performance with GROUNDHOG (Bahdanau et al., 2015), which serves as a baseline approach in our experiments. We limit vocabulary size to 30K for both languages. The word embedding dimension is set to 620. The dimension of hidden layer is set to 1,000. In training, the batch size is set to 80. We use the AdaDelta algorithm (Zeiler, 2012) for optimizing model parameters. In decoding, the beam size is set to 10.

For CPR, we simply follow Wu et al. (2016) to incorporate the coverage penalty into the beam search algorithm of RNNSEARCH.

For POSTREG, we adapt the original version of posterior regularization (Ganchev et al., 2010) to NMT on top of RNNSEARCH. Following Ganchev et al. (2010), we use a ten-step projected gradient descent algorithm to search for an approximate desired distribution in the E step and a one-step gradient descent for the M step.

Our approach extends RNNSEARCH by incorporating prior knowledge. For each source sentence, we sample 80 candidate translations to approximate the $\tilde{P}$ and $\tilde{Q}$ distributions. The hyper-parameter α is set to 0.2. The batch size is 1. The hyper-parameters λ_1 and λ_2 are set to 8×10^{-5} and 2.5×10^{-4}. Note that they not only balance the preference between likelihood and posterior regularization, but also control the values of gradients to fall in a reasonable range for optimization.

We construct bilingual dictionary and phrase table in an automatic way. First, we run the statistical machine translation system MOSES (Koehn and Hoang, 2007) to obtain probabilistic bilingual dictionary and phrase table. For the bilingual dictionary, we retain entries with probabilities higher than 0.1 in both source-to-target and

Table 2: Effect of reranking on translation quality.

target-to-source directions. For phrase table, we first remove phrase pairs that occur less than 10 times and then retain entries with probabilities higher than 0.5 in both directions. As a result, both bilingual dictionary and phrase table contain high-quality translation correspondences. We estimate the length ratio on Chinese-English data and set the hyper-parameter β to 1.236.

By default, both POSTREG and our approach use reranking to search for the most probable translations (Section 3.4).

4.2 Main Results

Table 1 shows the BLEU scores obtained by RNNSEARCH, POSTREG, and our approach on the Chinese-English datasets.

We find POSTREG achieves significant improvements over RNNSEARCH by adding features that encode prior knowledge. The most effective single feature for POSTREG seems to be the length ratio (LR) feature, suggesting that it is important for NMT to control the length of translation to improve translation quality. Note that POSTREG is unable to include the coverage penalty (CP) feature because the feature value varies significantly over different sentences. It is hard to specify an appropriate bound $\mathbf{b}$ for constraining the expected feature value. We observe that a loose bound often makes the training process very unstable and fail to converge. Combining features obtains further modest improvements.

Our approach outperforms both RNNSEARCH and POSTREG significantly. The bilingual dictionary (BD) feature turns out to make the most contribution. Compared with CPR that imposes coverage penalty during decoding, our approach that using a single CP feature obtains a significant improvement (i.e., 30.76 over 29.72), suggesting that incorporating prior knowledge sources in modeling might be more beneficial than in decoding.

We find that combining features only results in modest improvements for our approach. One possible reason is that the bilingual dictionary and phrase table features overlap on single word pairs.

4.3 Effect of Reranking

Table 2 shows the effect of reranking on translation quality. We find that using prior knowledge features to rescore the k-best list produced by the neural translation model usually leads to improvements. This finding confirms that adding prior knowledge is beneficial for NMT, either in the training or decoding process.

4.4 Training Speed

Initialized with the best RNNSEARCH model trained for 300K iterations, our model converges after about 100K iterations. For each iteration, our approach is 1.5 times slower than RNNSEARCH. On a single GPU device Tesla M40, it takes four days to train the RNNSEARCH model and three extra days to train our model.

4.5 Example Translations

Table 3 gives four examples to demonstrate the benefits of adding features.

Table 3: Example translations that demonstrate the effect of adding features.

In the first example, source words "fenzhan" (*fighting*), "yuangong" (*staff*), and "yinglai" (*welcomed*) are untranslated in the output of RNNSEARCH. Adding the bilingual dictionary (BD) feature encourages the model to translate these words if they occur in the dictionary.

In the second example, while RNNSEARCH fails to capture phrase cohesion, adding the phrase table (PT) feature is beneficial for translating short idioms, word insertions or deletions that are sensitive to local context.

In the third example, RNNSEARCH tends to omit many source content words such as "chuyuan" (*discharged from the hospital*), "jianchi" (*insisted on*), and "daobie" (*say farewell*). The coverage penalty (CP) feature helps to alleviate the word omission problem.

In the fourth example, the translation produced by RNNSEARCH is too long and "the golan heights" occurs twice. The length ratio (LR) feature is capable of controlling the sentence length in a reasonable range.

5 Related Work

Our work is directly inspired by posterior regularization (Ganchev et al., 2010). The major difference is that we use a log-linear model to represent the desired distribution rather than a constrained posterior set. Using log-linear models not only enables our approach to incorporate arbitrary knowledge sources as real-valued features, but also is differentiable to be jointly trained with

neural translation models efficiently.

Our work is closely related to recent work on injecting prior knowledge into NMT (Arthur et al., 2016; Tu et al., 2016; Cohn et al., 2016; Tang et al., 2016; Feng et al., 2016; Wang et al., 2016). The major difference is that our approach aims to provide a general framework for incorporating arbitrary prior knowledge sources while keeping the neural translation model unchanged.

He et al. (2016) also propose to combine the strengths of neural networks on learning representations and log-linear models on encoding prior knowledge. But they treat neural translation models as a feature in the log-linear model. In contrast, we connect the two models via KL divergence to keep the transparency of our approach to model architectures. This enables our approach to be easily applied to other neural models in NLP.

6 Conclusion

We have presented a general framework for incorporating prior knowledge into end-to-end neural machine translation based on posterior regularization (Ganchev et al., 2010). The basic idea is to guide NMT models towards desired behavior using a log-linear model that encodes prior knowledge. Experiments show that incorporating prior knowledge leads to significant improvements over both standard NMT and posterior regularization using constrained posterior sets.

Abstract

This paper proposes three distortion models to explicitly incorporate the word reordering knowledge into attention-based Neural Machine Translation (NMT) for further improving translation performance. Our proposed models enable attention mechanism to attend to source words regarding both the semantic requirement and the word reordering penalty. Experiments on Chinese-English translation show that the approaches can improve word alignment quality and achieve significant translation improvements over a basic attention-based NMT by large margins. Compared with previous works on identical corpora, our system achieves the state-of-the-art performance on translation quality.

1 Introduction

Word reordering model is one of the most crucial sub-components in Statistical Machine Translation (SMT) (Brown et al., 1993; Koehn et al., 2003; Chiang, 2005) which provides word reordering knowledge to ensure reasonable translation order of source words. It is separately trained and then incorporated into the SMT framework in a pipeline style.

In recent years, end-to-end NMT (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) has made tremendous progress (Jean et al., 2015; Luong et al., 2015b; Shen et al., 2016; Sennrich et al., 2016; Tu et al., 2016; Zhou et al., 2016; Johnson et al., 2016). An encoder-decoder framework (Cho et al., 2014b; Sutskever et al., 2014) with attention mechanism (Bahdanau et al., 2015) is widely used, in which an encoder compresses the source sentence, an attention mechanism evaluates related source words and a decoder generates target words.

The attention mechanism evaluates the distribution of to-be-translated source words in a content-based addressing fashion (Graves et al., 2014) which tends to attend to the source words regarding the content relation with current translation status. Lack of explicit models to exploit the word reordering knowledge may lead to attention faults and generate fluent but inaccurate or inadequate translations. Table 1 shows a translation instance and Figure 1 depicts the corresponding word alignment matrix that produced by the attention mechanism. In this example, even though the word "zuixin (latest)" is a common adjective in Chinese and its following word should be translated soon in Chinese to English translation direction, the word "yiju (evidence)" does not obtain appropriate attention which leads to the incorrect translation.

https://doi.org/10.18653/v1/P17-1140

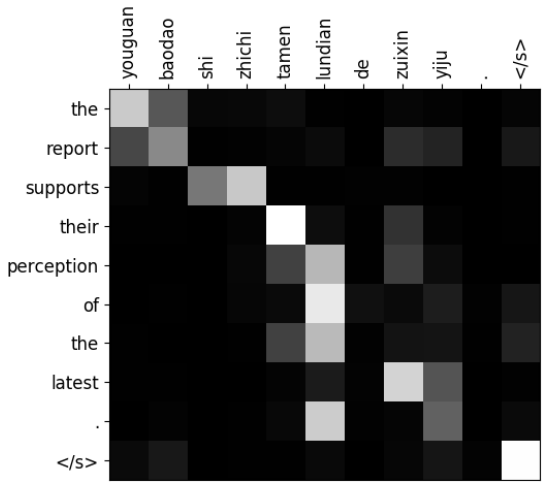

Figure 1: The source word "yiju" does not obtain appropriate attention and its word sense is completely neglected.

To enhance the attention mechanism, implicit word reordering knowledge needs to be incorporated into attention-based NMT. In this paper, we introduce three distortion models that originated from SMT (Brown et al., 1993; Koehn et al., 2003; Och et al., 2004; Tillmann, 2004; Al-Onaizan and Papineni, 2006), so as to model the word reordering knowledge as the probability distribution of the relative jump distances between the newly translated source word and the to-be-translated source word. Our focus is to extend the attention mechanism to attend to source words regarding both the semantic requirement and the word reordering penalty.

Our models have three merits:

1. *Extended word reordering knowledge.* Our models capture explicit word reordering knowledge to guide the attending process for attention mechanism.

2. *Convenient to be incorporated into attention-based NMT.* Our distortion models are differentiable and can be trained in the end-to-end style. The interpolation approach ensures that the proposed models can coordinately work with the original attention mechanism.

3. *Flexible to utilize variant context for computing the word reordering penalty.* In this paper, we exploit three categories of information as distortion context conditions to compute the word reordering penalty, but variant context information can be utilized due to our model's flexibility.

We validate our models on the Chinese-English translation task and achieve notable improvements:

- On 16K vocabularies, NMT models are usually inferior in comparison with the phrase-based SMT, but our model surpasses phrase-based Moses by average **4.43** BLEU points and outperforms the attention-based NMT baseline system by **5.09** BLEU points.

- On 30K vocabularies, the improvements over the phrase-based Moses and the attention-based NMT baseline system are average **6.06** and **1.57** BLEU points respectively.

- Compared with previous work on identical corpora, we achieve the state-of-the-art translation performance on average.

The word alignment quality evaluation shows that our model can effectively improve the word alignment quality that is crucial for improving translation quality.

2 Background

We aim to capture word reordering knowledge for the attention-based NMT by incorporating distortion models. This section briefly introduces attention-based NMT and distortion models in SMT.

2.1 Attention-based Neural Machine Translation

Formally, given a source sentence $\mathbf{x} = \mathbf{x}_1, ..., \mathbf{x}_m$ and a target sentence $\mathbf{y} = \mathbf{y}_1, ..., \mathbf{y}_n$, NMT models the translation probability as

$$P(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{n} P(\mathbf{y}_t|\mathbf{y}_{<t}, \mathbf{x}), \quad (1)$$

where $\mathbf{y}_{<t} = \mathbf{y}_1, ..., \mathbf{y}_{t-1}$. The generation probability of $\mathbf{y}_t$ is

$$P(\mathbf{y}_t|\mathbf{y}_{<t}, \mathbf{x}) = g(\mathbf{y}_{t-1}, \mathbf{c}_t, \mathbf{s}_t), \quad (2)$$

where $g(\cdot)$ is a softmax regression function, $\mathbf{y}_{t-1}$ is the newly translated target word and

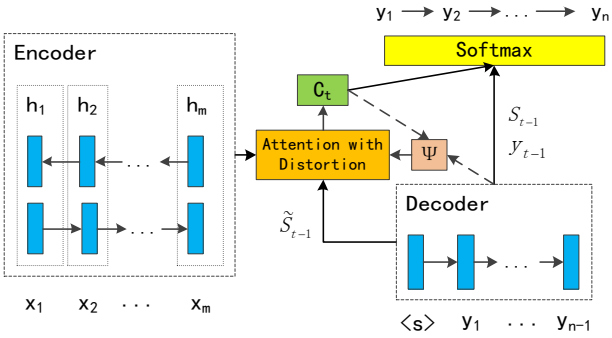

Figure 2: The general architecture of our proposed models. The dash line represents variant context can be utilized to determine the word reordering penalty.

$\mathbf{s}_t$ is the hidden states of decoder which represents the translation status.

The attention $\mathbf{c}_t$ denotes the related source words for generating $\mathbf{y}_t$ and is computed as the weighted-sum of source representation $\mathbf{h}$ upon an alignment vector α_t shown in Eq.(3) where the $align(\cdot)$ function is a feedforward network with $softmax$ normalization.

$$\begin{aligned} \mathbf{c}_t &= \sum_{j=1}^{m} \alpha_{t,j}\mathbf{h}_j \\ \alpha_{t,j} &= align(\mathbf{s}_t, \mathbf{h}_j) \end{aligned} \tag{3}$$

The hidden states $\mathbf{s}_t$ is updated as

$$\mathbf{s}_t = f(\mathbf{s}_{t-1}, \mathbf{y}_{t-1}, \mathbf{c}_t), \tag{4}$$

where $f(\cdot)$ is a recurrent function.

We adopt a varietal attention mechanism[1] in our in-house RNNsearch model which is implemented as

$$\begin{aligned} \widetilde{\mathbf{s}}_t &= f_1(\mathbf{s}_{t-1}, \mathbf{y}_{t-1}), \\ \alpha_{t,j} &= align(\widetilde{\mathbf{s}}_t, \mathbf{h}_j), \\ \mathbf{s}_t &= f_2(\widetilde{\mathbf{s}}_t, \mathbf{c}_t), \end{aligned} \tag{5}$$

where $f_1(\cdot)$ and $f_2(\cdot)$ are recurrent functions.

As shown in Eq.(3), the attention mechanism attends to source words in a content-based addressing way without considering any explicit word reordering knowledge. We introduce distortion models to capture explicit word reordering knowledge for enhancing the attention mechanism and improving translation quality.

2.2 Distortion Models in SMT

In SMT, distortion models are linearly combined with other features, as follows,

$$\begin{aligned} \mathbf{y}^* = \arg\max_{\mathbf{y}} \exp[&\lambda_d d(\mathbf{x}, \mathbf{y}, b) + \\ &\sum_{r=1}^{R-1} \lambda_r h_r(\mathbf{x}, \mathbf{y}, b)], \end{aligned} \tag{6}$$

where $d(\cdot)$ is the distortion feature, $h_r(\cdot)$ represents other features, λ_d and λ_r are the weights, b is the latent variable that represents translation knowledge and R is the number of features.

IBM Models (Brown et al., 1993) depicted the word reordering knowledge as positional relations between source and target words. Koehn et al. (2003) proposed a distortion model for phrase-based SMT based on jump distances between the newly translated phrases and to-be-translated phrases which does not consider specific lexical information. Och et al. (2004) and Tillmann (2004) proposed orientation-based distortion models that consider translation orientations. Yaser and Papineni (2006) proposed a distortion model to estimate probability distribution on possible relative jumps conditioned on source words.

These models are proposed for SMT and separately trained as sub-components. Inspired by these previous work, we introduce the distortion models into NMT model for modeling the word reordering knowledge. Our proposed models are designed for NMT which can be trained in the end-to-end style.

3 Distortion Models for attention-based NMT

The basic idea of our proposed distortion models is to estimate the probability distribution of the possible relative jump distances between the newly translated source word and the to-be-translated source word upon the context condition. Figure 2 shows the general architecture of our proposed model.

3.1 General Architecture

We employ an interpolation approach to incorporate distortion models into attention-based NMT as

$$\alpha_t = \lambda \cdot \mathbf{d}_t + (1-\lambda)\hat{\alpha}_t, \tag{7}$$

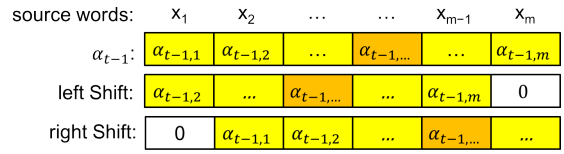

Figure 3: Illustration of shift actions of the alignment vector α_{t-1}. If α_t is the left shift of α_{t-1}, it represents the translation orientation of the source sentence is backward and if α_t is the right shift of α_{t-1}, the translation orientation is forward.

where α_t is the ultimate alignment vector for computing the related source context $\mathbf{c}_t$, $\mathbf{d}_t$ is the alignment vector calculated by the distortion model, $\hat{\alpha}_t$ is the alignment vector computed by the basic attention mechanism and λ is a hyper-parameter to control the weight of the distortion model.

In the proposed distortion model, relative jumps on source words are depicted as the "shift" actions of the alignment vector α_{t-1} which is shown in the Figure 3. The right shift of α_{t-1} indicates that the translation orientation of source words is forward and the left shift represents that the translation orientation is backward. The extent of a shift action measures the word reordering distance. Alignment vector $\mathbf{d}_t$, which is produced by the distortion model, is the expectation of all possible shifts of α_{t-1} conditioned on certain context.

Formally, the proposed distortion model is

$$\begin{aligned}\mathbf{d}_t &= E[\Gamma(\alpha_{t-1})] \\ &= \sum_{k=-l}^{l} P(k|\Psi) \cdot \Gamma(\alpha_{t-1}, k),\end{aligned} \tag{8}$$

where $k \in [-l, l]$ is the possible relative jump distance, l is the window size parameter and $P(k|\Psi)$ stands for the probability of jump distance k that conditioned on the context Ψ. Function $\Gamma(\cdot)$ for shifting the alignment vector is defined as

$$\Gamma(\alpha_{t-1}, k) = \begin{cases} \{\alpha_{t-1,-k}, ..., \alpha_{t-1,m}, 0, ..., 0\}, & \text{k<0} \\ \alpha_{t-1}, & \text{k= 0} \\ \{0, ..., 0, \alpha_{t-1,1}, ..., \alpha_{t-1,m-k}\}, & \text{k>0} \end{cases} \tag{9}$$

which can be implemented as matrix multiplication computations.

We respectively exploit source context, target context and translation status context (hidden states of decoder) as Ψ and derive three distortion models: Source-based Distortion (**S-Distortion**) model , Target-based Distortion (**T-Distortion**) model and Translation-status-based Distortion (**H-Distortion**) model. Our framework is capable of utilizing arbitrary context as the condition Ψ to predict the relative jump distances.

3.2 S-Distortion model

S-Distortion model adopts previous source context $\mathbf{c}_{t-1}$ as the context Ψ with the intuition that certain source word indicate certain jump distance. The to-be-translated source word have intense positional relations with the newly translated one.

The underlying linguistic intuition is that synchronous grammars (Yamada and Knight, 2001; Galley et al., 2004) can be extracted from language pairs. Word categories such as verb, adjective and preposition carry general word reordering knowledge and words carry specific word reordering knowledge.

To further illustrate this idea, we present some common synchronous grammar rules that can be extracted from the example in Table 1 as follows,

$$\begin{aligned} &NP \longrightarrow JJ \quad NN \,|\, JJ \quad NN \\ &JJ \longrightarrow zuixin \,|\, latest. \end{aligned} \tag{10}$$

From the above grammar, we can conjecture the speculation that after the word "zuixin(latest)" is translated, the translation orientation is forward with shift distance 1.

The probability function in S-Distortion model is defined as follows,

$$\begin{aligned} P(\cdot|\Psi) &= z(\mathbf{c}_{t-1}) \\ &= softmax(W_c \mathbf{c}_{t-1} + b_c), \end{aligned} \tag{11}$$

where $W_c \in \mathbb{R}^{(2l+1)\times dim(c_{t-1})}$ and $b_c \in \mathbb{R}^{2l+1}$ are weight matrix and bias parameters.

3.3 T-Distortion Model

T-Distortion model exploits the embedding of the previous generated target word $\mathbf{y}_{t-1}$ as the context condition to predict the probability distribution of distortion distances. It focuses on the word reordering knowledge upon target

word context. As illustrated in Eq.(10), the target word "latest" possesses word reordering knowledge that is identical with source word "zuixin".

The probability function in T-Distortion model is defined as follows,

$$\begin{aligned} P(\cdot|\Psi) &= z(\mathbf{y}_{t-1}) \\ &= softmax(W_y emb(\mathbf{y}_{t-1}) + b_{\mathbf{y}}), \end{aligned} \tag{12}$$

where $emb(\mathbf{y}_{t-1})$ is the embedding of $\mathbf{y}_{t-1}$, $W_y \in \mathbb{R}^{(2l+1)\times dim(emb(\mathbf{y}_{t-1}))}$ and $b_{\mathbf{y}} \in \mathbb{R}^{2l+1}$ are weight matrix and bias parameters.

3.4 H-Distortion Model

The hidden states $\tilde{s}_{t-1}$ reflect the translation status and contains both source context and target context information. Therefore, we exploit $\tilde{s}_{t-1}$ as context Ψ in the H-Distortion model to predict shift distances.

The probability function in H-Distortion model is defined as follows,

$$\begin{aligned} P(\cdot|\Psi) &= z(\tilde{s}_{t-1}) \\ &= softmax(W_s \tilde{s}_{t-1} + b_s) \end{aligned} \tag{13}$$

where $W_s \in \mathbb{R}^{(2l+1)\times dim(\tilde{s}_{t-1})}$ and $b_s \in \mathbb{R}^{2l+1}$ are the weight matrix and bias parameters.

4 Experiments

We carry the translation task on the Chinese-English direction to evaluate the effectiveness of our models. To investigate the word alignment quality, we take the word alignment quality evaluation on the manually aligned corpus. We also conduct the experiments to observe effects of hyper-parameters and the training strategies.

4.1 Data and Metrics

Data: Our Chinese-English training corpus consists of 1.25M sentence pairs extracted from LDC corpora[2] with 27.9M Chinese words and 34.5M English words respectively. 16K vocabularies cover approximately 95.8% and 98.3% words and 30K vocabularies cover approximately 97.7% and 99.3% words in Chinese and English respectively. We choose NIST 2002 dataset as the validation set. NIST 2003-2006 are used as test sets. To assess the word alignment quality, we employ Tsinghua dataset (Liu and Sun, 2015) which contains 900 manually aligned sentence pairs.

Metrics: The translation quality evaluation metric is the case-insensitive 4-gram BLEU[3] (Papineni et al., 2002). *Sign-test* (Collins et al., 2005) is exploited for statistical significance test. Alignment error rate (AER) (Och and Ney, 2003) is calculated to assess the word alignment quality.

4.2 Comparison Systems

We compare our approaches with three baseline systems:

Moses (Koehn et al., 2007): An open source phrase-based SMT system with default settings. Words are aligned with GIZA++ (Och and Ney, 2003). The 4-gram language model with modified Kneser-Ney smoothing is trained on the target portion of training data by SRILM (Stolcke et al., 2002).

Groundhog[4]: An open source attention-based NMT system with default settings.

RNNsearch*: Our in-house implementation of NMT system with the varietal attention mechanism and other settings that presented in section 4.3.

4.3 Training

Hyper parameters: The sentence length for training NMTs is up to 50, while SMT model exploits whole training data without any restrictions. Following Bahdanau et al. (2015), we use bi-directional Gated Recurrent Unit (GRU) as the encoder. The forward representation and the backward representation are concatenated at the corresponding position as the ultimate representation of a source word. The word embedding dimension is set to 620 and the hidden layer size is 1000. The interpolation parameter λ is 0.5 and the window size l is set to 3.

Training details:

Square matrices are initialized in a random orthogonal way. Non-square matrices are initialized by sampling each element from the

[2]The corpora includes LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

Gaussian distribution with mean 0 and variance 0.01^2. All bias are initialized to 0.

Parameters are updated by Mini-batch Gradient Descent and the learning rate is controlled by the AdaDelta (Zeiler, 2012) algorithm with decay constant $\rho = 0.95$ and denominator constant $\epsilon = 1e-6$. The batch size is 80. Dropout strategy (Srivastava et al., 2014) is applied to the output layer with the dropout rate 0.5 to avoid over-fitting. The gradients of the cost function which have $L2$ norm larger than a predefined threshold 1.0 is normalized to the threshold to avoid gradients explosion (Pascanu et al., 2013). We exploit length normalization (Cho et al., 2014a) on candidate translations and the beam size for decoding is 12. For NMT with distortion models, we use trained RNNsearch* model to initialize parameters except for those related to distortions.

4.4 Results

The translation quality experiment results are shown in Table 2. We carry the experiments on different vocabulary sizes for that different vocabulary sizes cause different degrees of the rare word collocations. Through this way, we can validate the effects of our proposed models in alleviating the rare word collocations problem that leads to incorrect word alignments.

On 16K vocabularies: The phrase-based Moses performs better than the basic NMTs including Groundhog and RNNsearch*. Besides the differences between model architectures, restricted vocabularies and sentence length also affect the performance of NMTs. However, RNNsearch* with distortion models surpass phrase-based Moses by average 3.60, 4.27 and 4.43 BLEU points. RNNsearch* outperforms Groundhog by average 1.96 BLEU points due to the varietal attention mechanism, length normalization and dropout strategies. Distortion models bring about remarkable improvements as 4.26, 4.92 and 5.09 BLEU points over the RNNsearch* model.

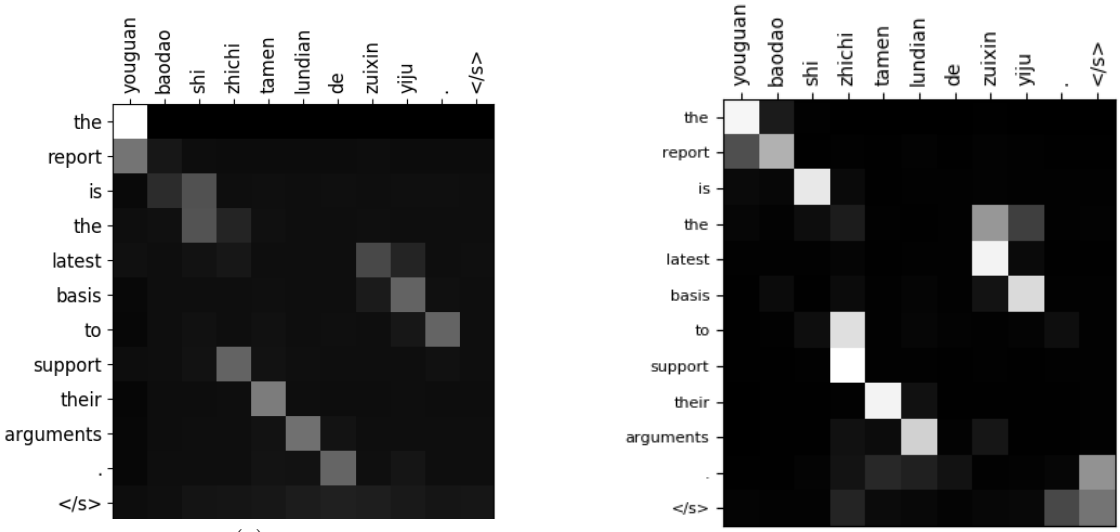
On 30K vocabularies: RNNsearch* with distortion models yield average gains by 1.57, 1.21 and 1.45 BLEU points over RNNsearch* and outperform phrase-based Moses by average 6.06, 5.70 and 5.94 BLEU points and surpass GroundHog by average 5.56, 5.20 and 5.44 BLEU points. RNNsearch*(16K) with distortion models achieve close performances with RNNsearch*(30K). The improvements on 16K vocabularies are larger than that on 30K vocabularies for the intuition that more "UNK" words lead to more rare word collocations, which results in serious attention ambiguities.

The RNNsearch* with distortion models yield tremendous improvements on BLEU scores proves the effectiveness of proposed approaches in improving translation quality.

Comparison with previous work: We present the performance comparison with pre-

System	Length	MT03	MT04	MT05	MT06	Average
Coverage	80	-	-	32.73	32.47	-
MEMDEC	50	36.16	39.81	35.91	**35.98**	36.95
NMT_{IA}	80	35.69	39.24	35.74	35.10	36.44
Our work	50	**37.93**	**40.40**	**36.81**	35.77	**37.73**

Table 3: Comparison with previous work on identical training corpora. Coverage (Tu et al., 2016) is a basic RNNsearch model with a coverage model to alleviate the over-translation and under-translation problems. MEMDEC (Wang et al., 2016) is to improve translation quality with external memory. NMT_{IA} (Meng et al., 2016) exploits a readable and writable attention mechanism to keep track of interactive history in decoding. Our work is NMT with H-Distortion model. The vocabulary sizes of all work are 30K and maximum lengths of sentence differ.



(a) (b)

Figure 4: (a) is the output of the distortion model and is calculated on shift actions of previous alignment vector. (b) is the ultimate word alignment matrix of attention-based NMT with H-Distortion model. Compared with Figure 1, (b) is more centralized and accurate.

Systems	BLEU	AER
RNNsearch*(30K)	20.90	49.73
+ T-Distortion	24.33‡	46.92
+ S-Distortion	24.10‡	47.37
+ H-Distortion	24.42‡	47.05

Table 4: BLEU-4 scores (%) and AER scores on Tsinghua manually aligned Chinese-English evaluation set. The lower the AER score, the better the alignment quality.

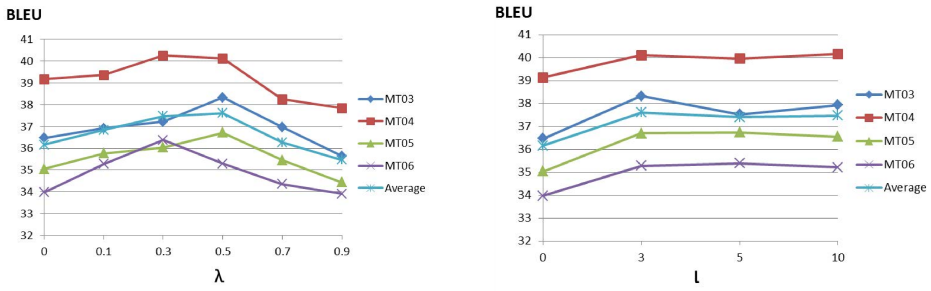
vious work that employ identical training corpora in Table 3. Our work evidently outperforms previous work on average performance. Although we restrict the maximum length of sentence to 50, our model achieves the state-of-the-art BLEU scores on almost all test sets except NIST2006.

4.5 Analysis

We investigate the effects on the alignment quality of our models and conduct the experiments to evaluate the influence of the hyper-parameter settings and the training strategies.

4.5.1 Alignment Quality

Distortion models concentrate on attending to to-be-translated words based on the word reordering knowledge and can intuitively enhance the word alignment quality. To investigate the effect on word alignment quality, we apply the BLEU and AER evaluations on Tsinghua manually aligned data set.



(a) (b)

Figure 5: Translation performance on the test sets with respect to the hyper-parameter λ and l.

System	MT03	MT04	MT05	MT06	Average
Pre-training	35.95	**38.77**	**35.33**	**34.36**	**36.10**
No pre-training	**36.99**	38.42	34.56	34.01	36.00

Table 5: Comparison between pre-training and no pre-training H-Distortion model. The performances are consistent.

Table 4 lists the BLEU and AER scores of Chinese-English translation with 30K vocabulary. RNNsearch*(30K) with distortion models achieve significant improvements on BLEU scores and obvious decrease on AER scores. The results shows that the proposed model can effectively improve the word alignment quality

Figure 4 shows the output of distortion model and ultimate alignment matrix of the above-mentioned instance. Compared with Figure 1, the alignment matrix produced by NMT with distortion models is more concentrated and accurate. The output of distortion model shows its capacity of modeling word reordering knowledge.

4.5.2 Effect of Hyper-parameters

To investigate the effect of the weight hyper-parameter λ and window hyper-parameter l in the proposed model, we carry experiments on H-Distortion model with variable hyper-parameter settings. We fix $l = 3$ for exploring the effect of λ and fix $\lambda = 0.5$ for observing the effect of l. Figure 5 presents the translation performances with respect to hyper-parameters. With the increase of weight λ, the BLEU scores first rise and then drop, which shows the distortion model provides additional helpful information while can not fully cover the attention mechanism for its insufficient content searching ability. For window l, the experiments show that larger windows bring slight further improvements, which indicates that distortion model pays more attention to the short-distance reordering knowledge.

4.5.3 Pre-training VS No Pre-training

We conduct the experiment without using pre-training strategy to observe the effect of the initialization. As is shown in Table 5, the no-pre-training model achieves consistent improvements with the pre-training one which verifies the stable effectiveness of our approach. Initialization with pre-training strategy provides a fast approach to obtain the model for it needs fewer training iterations.

5 Related Work

Our work is inspired by the distortion models that widely used in SMT. The most related work in SMT is the distortion model proposed by Yaser and Papineni (2006). Their model is identical to our S-Distortion model that captures the relative jump distance knowledge on source words. However, our approach is deliberately designed for the attention-based NMT system and is capable of exploiting variant context information to predict the relative jump distances.

Our work is related to the work (Luong et al., 2015a; Feng et al., 2016; Tu et al., 2016;

Cohn et al., 2016; Meng et al., 2016; Wang et al., 2016) that concentrate on the improvement of the attention mechanism. To remit the computing cost of the attention mechanism when dealing with long sentences, Luong et al. (2015a) proposed the local attention mechanism by just focusing on a subscope of source positions. Cohn et al. (2016) incorporated structural alignment biases into the attention mechanism and obtained improvements across several challenging language pairs in low-resource settings. Feng et al. (2016) passed the previous attention context to the attention mechanism by adding recurrent connections as the implicit distortion model. Tu et al. (2016) maintained a coverage vector for keeping the attention history to acquire accurate translations. Meng et al. (2016) proposed the interactive attention with the attentive read and attentive write operation to keep track of the interaction history. Wang et al. (2016) utilized an external memory to store additional information for guiding the attention computation. These works are different from ours, as our distortion models explicitly capture word reordering knowledge through estimating the probability distribution of relative jump distances on source words to incorporate word reordering knowledge into the attention-based NMT.

6 Conclusions

We have presented three distortion models to enhance attention-based NMT through incorporating the word reordering knowledge. The basic idea of proposed distortion models is to enable the attention mechanism to attend to the source words regarding both semantic requirement and the word reordering penalty. Experiments show that our models can evidently improve the word alignment quality and translation performance. Compared with previous work on identical corpora, our model achieves the state-of-the-art performance on average. Our model is convenient to be applied in the attention-based NMT and can be trained in the end-to-end style. We also investigated the effect of hyper-parameters and pre-training strategy and further proved the stable effectiveness of our model. In the future, we plan to validate the effectiveness of our model on more language pairs.

Lexically Constrained Decoding for Sequence Generation Using Grid Beam Search

Chris Hokamp

qun.liu@dcu.ie

Abstract

We present Grid Beam Search (GBS), an algorithm which extends beam search to allow the inclusion of pre-specified lexical constraints. The algorithm can be used with any model that generates a sequence $\hat{\mathbf{y}} = \{y_0 \dots y_T\}$, by maximizing $p(\mathbf{y}|\mathbf{x}) = \prod_t p(y_t|\mathbf{x}; \{y_0 \dots y_{t-1}\})$. Lexical constraints take the form of phrases or words that must be present in the output sequence. This is a very general way to incorporate additional knowledge into a model's output without requiring any modification of the model parameters or training data. We demonstrate the feasibility and flexibility of Lexically Constrained Decoding by conducting experiments on Neural Interactive-Predictive Translation, as well as Domain Adaptation for Neural Machine Translation. Experiments show that GBS can provide large improvements in translation quality in interactive scenarios, and that, even without any user input, GBS can be used to achieve significant gains in performance in domain adaptation scenarios.

1 Introduction

The output of many natural language processing models is a sequence of text. Examples include automatic summarization (Rush et al., 2015), machine translation (Koehn, 2010; Bahdanau et al., 2014), caption generation (Xu et al., 2015), and dialog generation (Serban et al., 2016), among others.

In some real-world scenarios, additional information that could inform the search for the optimal output sequence may be available at inference time. Humans can provide corrections after viewing a system's initial output, or separate classification models may be able to predict parts of the output with high confidence. When the domain of the input is known, a domain terminology may be employed to ensure specific phrases are present in a system's predictions. Our goal in this work is to find a way to force the output of a model to contain such *lexical constraints*, while still taking advantage of the distribution learned from training data.

For Machine Translation (MT) usecases in particular, final translations are often produced by combining automatically translated output with user inputs. Examples include Post-Editing (PE) (Koehn, 2009; Specia, 2011) and Interactive-Predictive MT (Foster, 2002; Barrachina et al., 2009; Green, 2014). These interactive scenarios can be unified by considering user inputs to be lexical constraints which guide the search for the optimal output sequence.

In this paper, we formalize the notion of lexical constraints, and propose a decoding algorithm which allows the specification of subsequences that are required to be present in a model's output. Individual constraints may be single tokens or multi-word phrases, and any number of constraints may be specified simultaneously.

Although we focus upon interactive applications for MT in our experiments, lexically constrained decoding is relevant to any scenario where a model is asked to generate a sequence $\hat{\mathbf{y}} = \{y_0 \dots y_T\}$ given both an input $\mathbf{x}$, and a set $\{\mathbf{c_0} \dots \mathbf{c_n}\}$, where each $\mathbf{c_i}$ is a sub-sequence $\{c_{i0} \dots c_{ij}\}$, that must appear somewhere in $\hat{\mathbf{y}}$. This makes our work applicable to a wide range of text generation scenarios, including image description, dialog generation, abstractive summarization, and question answering.

The rest of this paper is organized as follows: Section 2 gives the necessary background for our

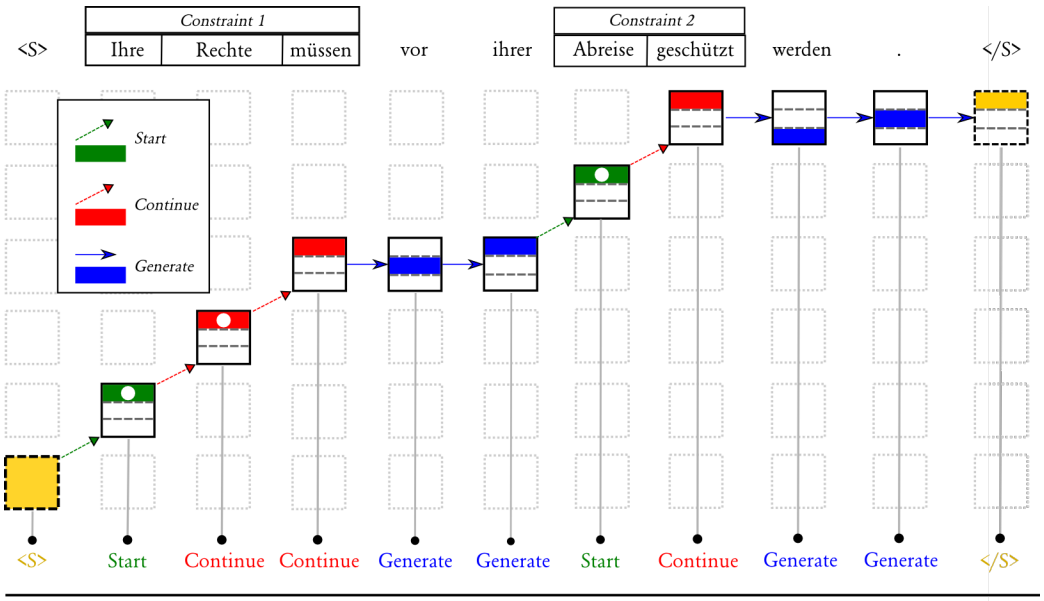

Figure 1: A visualization of the decoding process for an actual example from our English-German MT experiments. The output token at each timestep appears at the top of the figure, with lexical constraints enclosed in boxes. *Generation* is shown in blue, *Starting* new constraints in green, and *Continuing* constraints in red. The function used to create the hypothesis at each timestep is written at the bottom. Each box in the grid represents a beam; a colored strip inside a beam represents an individual hypothesis in the beam's k-best stack. Hypotheses with circles inside them are *closed*, all other hypotheses are *open*. (Best viewed in colour).

discussion of GBS, Section 3 discusses the lexically constrained decoding algorithm in detail, Section 4 presents our experiments, and Section 5 gives an overview of closely related work.

2 Background: Beam Search for Sequence Generation

Under a model parameterized by θ, let the best output sequence $\hat{\mathbf{y}}$ given input $\mathbf{x}$ be Eq. 1.

$$\hat{\mathbf{y}} = \underset{\mathbf{y} \in \{\mathbf{y}^{[\mathbf{T}]}\}}{\operatorname{argmax}} p_\theta(\mathbf{y}|\mathbf{x}), \tag{1}$$

where we use $\{\mathbf{y}^{[\mathbf{T}]}\}$ to denote the set of all sequences of length T. Because the number of possible sequences for such a model is $|\mathbf{v}|^T$, where $|\mathbf{v}|$ is the number of output symbols, the search for $\hat{\mathbf{y}}$ can be made more tractable by factorizing $p_\theta(\mathbf{y}|\mathbf{x})$ into Eq. 2:

$$p_\theta(\mathbf{y}|\mathbf{x}) = \prod_{t=0}^{T} p_\theta(y_t|\mathbf{x}; \{y_0 \dots y_{t-1}\}). \tag{2}$$

The standard approach is thus to generate the output sequence from beginning to end, conditioning the output at each timestep upon the input $\mathbf{x}$, and the already-generated symbols $\{y_0 \dots y_{i-t}\}$. However, greedy selection of the most probable output at each timestep, i.e.:

$$\hat{y}_t = \underset{y_i \in \{\mathbf{v}\}}{\operatorname{argmax}} p(y_i|\mathbf{x}; \{y_0 \dots y_{t-1}\}), \tag{3}$$

risks making locally optimal decisions which are actually globally sub-optimal. On the other hand, an exhaustive exploration of the output space would require scoring $|\mathbf{v}|^T$ sequences, which is intractable for most real-world models. Thus, a search or *decoding* algorithm is often used as a compromise between these two extremes. A common solution is to use a heuristic search to attempt to find the best output efficiently (Pearl, 1984; Koehn, 2010; Rush et al., 2013). The key idea is to discard bad options early, while trying to avoid discarding candidates that may be locally risky, but could eventually result in the best overall output.

Beam search (Och and Ney, 2004) is probably the most popular search algorithm for decoding sequences. Beam search is simple to implement, and is flexible in the sense that the semantics of the

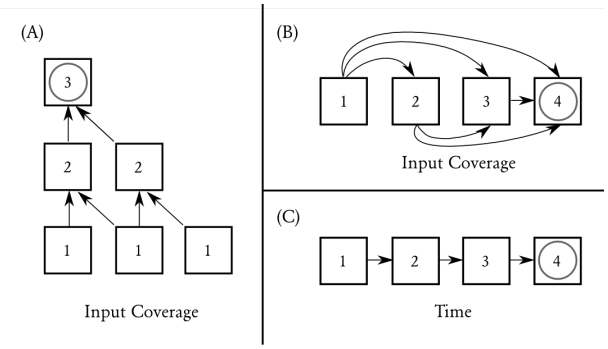

Figure 2: Different structures for beam search. Boxes represent beams which hold k-best lists of hypotheses. (A) Chart Parsing using SCFG rules to cover spans in the input. (B) Source coverage as used in PB-SMT. (C) Sequence timesteps (as used in Neural Sequence Models), GBS is an extension of (C). In (A) and (B), hypotheses are finished once they reach the final beam. In (C), a hypothesis is only complete if it has generated an end-of-sequence (EOS) symbol.

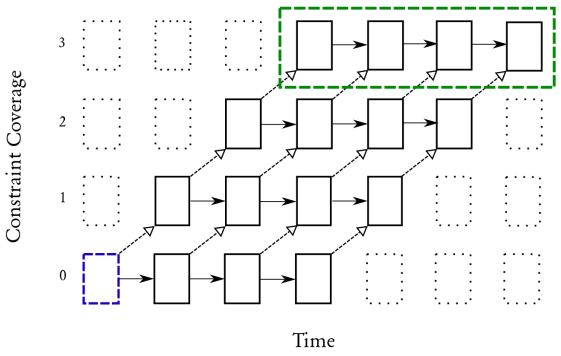

Figure 3: Visualizing the lexically constrained decoder's complete search graph. Each rectangle represents a beam containing k hypotheses. Dashed (diagonal) edges indicate *starting* or *continuing* constraints. Horizontal edges represent *generating* from the model's distribution. The horizontal axis covers the timesteps in the output sequence, and the vertical axis covers the constraint tokens (one row for each token in each constraint). Beams on the top level of the grid contain hypotheses which cover all constraints.

graph of beams can be adapted to take advantage of additional structure that may be available for specific tasks. For example, in Phrase-Based Statistical MT (PB-SMT) (Koehn, 2010), beams are organized by the number of source words that are covered by the hypotheses in the beam – a hypothesis is "finished" when it has covered all source words. In chart-based decoding algorithms such as CYK, beams are also tied to coverage of the input, but are organized as cells in a chart, which facilitates search for the optimal latent structure of the output (Chiang, 2007). Figure 2 visualizes three common ways to structure search. (A) and (B) depend upon explicit structural information between the input and output, (C) only assumes that the output is a sequence where later symbols depend upon earlier ones. Note also that (C) corresponds exactly to the bottom rows of Figures 1 and 3.

With the recent success of neural models for text generation, beam search has become the de-facto choice for decoding optimal output sequences (Sutskever et al., 2014). However, with neural sequence models, we cannot organize beams by their explicit coverage of the input. A simpler alternative is to organize beams by output timesteps from $t_0 \cdots t_N$, where N is a hyperparameter that can be set heuristically, for example by multiplying a factor with the length of the input to make an educated guess about the maximum length of the output (Sutskever et al., 2014). Output sequences are generally considered complete once a special "end-of-sentence"(EOS) token has been generated. Beam size in these models is also typically kept small, and recent work has shown that the performance of some architectures can actually degrade with larger beam size (Tu et al., 2016).

3 Grid Beam Search

Our goal is to organize decoding in such a way that we can constrain the search space to outputs which contain one or more pre-specified sub-sequences. We thus wish to use a model's distribution both to "place" lexical constraints correctly, and to generate the parts of the output which are not covered by the constraints.

Algorithm 1 presents the pseudo-code for lexically constrained decoding, see Figures 1 and 3 for visualizations of the search process. Beams in the grid are indexed by t and c. The t variable tracks the timestep of the search, while the c variable indicates how many constraint tokens are covered by the hypotheses in the current beam. Note that each step of c covers a single constraint $token$. In other words, $constraints$ is an array of sequences, where individual tokens can be indexed as $constraints_{ij}$, i.e. $token_j$ in $constraint_i$. The $numC$ parameter in Algorithm 1 represents the total number of tokens in all constraints.

The hypotheses in a beam can be separated into two types (see lines 9-11 and 15-19 of Algorithm 1):

1. ***open*** hypotheses can either generate from the model's distribution, or start available constraints,

2. ***closed*** hypotheses can only generate the next

Algorithm 1 Pseudo-code for Grid Beam Search, note that t and c indices are 0-based

token for in a currently unfinished constraint.

At each step of the search the beam at $\mathbf{Grid}[t][c]$ is filled with candidates which may be created in three ways:

1. the **open** hypotheses in the beam to the left ($\mathbf{Grid}[t-1][c]$) may ***generate*** continuations from the model's distribution $p_\theta(y_i|\mathbf{x}, \{y_0 \dots y_{i-1}\})$,

2. the **open** hypotheses in the beam to the left and below ($\mathbf{Grid}[t-1][c-1]$) may ***start*** new constraints,

3. the **closed** hypotheses in the beam to the left and below ($\mathbf{Grid}[t-1][c-1]$) may ***continue*** constraints.

Therefore, the **model** in Algorithm 1 implements an interface with three functions: $generate$, $start$, and $continue$, which build new hypotheses in each of the three ways. Note that the scoring function of the model does not need to be aware of the existence of constraints, but it may be, for example via a feature which indicates if a hypothesis is part of a constraint or not.

The beams at the top level of the grid (beams where $c = numConstraints$) contain hypotheses which cover all of the constraints. Once a hypothesis on the top level generates the EOS token, it can be added to the set of finished hypotheses. The highest scoring hypothesis in the set of finished hypotheses is the best sequence which covers all constraints.[1]

[1]Our implementation of GBS is available at https://github.com/chrishokamp/constrained_decoding

3.1 Multi-token Constraints

By distinguishing between **open** and **closed** hypotheses, we can allow for arbitrary multi-token phrases in the search. Thus, the set of constraints for a particular output may include both individual tokens and phrases. Each hypothesis maintains a coverage vector to ensure that constraints cannot be repeated in a search path – hypotheses which have already covered $constraint_i$ can only $generate$, or $start$ constraints that have not yet been covered.

Note also that discontinuous lexical constraints, such as phrasal verbs in English or German, are easy to incorporate into GBS, by adding *filters* to the search, which require that one or more conditions must be met before a constraint can be used. For example, adding the phrasal verb "ask ⟨someone⟩ out" as a constraint would mean using "ask" as $constraint_0$ and "out" as $constraint_1$, with two filters: one requiring that $constraint_1$ cannot be used before $constraint_0$, and another requiring that there must be at least one $generated$ token between the constraints.

3.2 Subword Units

Both the computation of the score for a hypothesis, and the granularity of the tokens (character, subword, word, etc...) are left to the underlying model. Because our decoder can handle arbitrary constraints, there is a risk that constraints will contain tokens that were never observed in the training data, and thus are unknown by the model. Especially in domain adaptation scenarios, some user-specified constraints are very likely to contain unseen tokens. Subword representations provide an elegant way to circumvent this problem, by breaking unknown or rare tokens into character n-grams which are part of the model's vocabulary (Sennrich et al., 2016; Wu et al., 2016). In the experiments in Section 4, we use this technique to ensure that no input tokens are unknown, even if a constraint contains words which never appeared in the training data.[2]

3.3 Efficiency

Because the number of beams is multiplied by the number of constraints, the runtime complexity of a naive implementation of GBS is $\mathcal{O}(ktc)$. Standard time-based beam search is $\mathcal{O}(kt)$; therefore, some consideration must be given to the efficiency of this algorithm. Note that the beams in each column c of Figure 3 are independent, meaning that GBS can be parallelized to allow all beams at each timestep to be filled simultaneously. Also, we find that the most time is spent computing the states for the hypothesis candidates, so by keeping the beam size small, we can make GBS significantly faster.

3.4 Models

The models used for our experiments are state-of-the-art Neural Machine Translation (NMT) systems using our own implementation of NMT with attention over the source sequence (Bahdanau et al., 2014). We used Blocks and Fuel to implement our NMT models (van Merrinboer et al., 2015). To conduct the experiments in the following section, we trained baseline translation models for English–German (EN-DE), English–French (EN-FR), and English–Portuguese (EN-PT). We created a shared subword representation for each language pair by extracting a vocabulary of 80000 symbols from the concatenated source and target data. See the Appendix for more details on our training data and hyperparameter configuration for each language pair. The $beamSize$ parameter is set to 10 for all experiments.

Because our experiments use NMT models, we can now be more explicit about the implementations of the $generate$, $start$, and $continue$ functions for this GBS instantiation. For an NMT model at timestep t, $generate(hyp_{t-1})$ first computes a vector of output probabilities $\mathbf{o}_t = softmax(g(y_{t-1}, s_i, c_i))$[3] using the state information available from hyp_{t-1}. and returns the best k continuations, i.e. Eq. 4:

$$\mathbf{g}_t = \text{k-argmax}_i \, \mathbf{o}_{ti}. \tag{4}$$

The $start$ and $continue$ functions simply index into the softmax output of the model, selecting specific tokens instead of doing a k-argmax over the entire target language vocabulary. For example, to *start* constraint $\mathbf{c}_i$, we find the score of token $\mathbf{c}_{i0}$, i.e. $\mathbf{o}_{tc_{i0}}$.

4 Experiments

4.1 Pick-Revise for Interactive Post Editing

Pick-Revise is an interaction cycle for MT Post-Editing proposed by Cheng et al. (2016). Starting

[2] If a *character* that was not observed in training data is observed at prediction time, it will be unknown. However, we did not observe this in any of our experiments.

[3] we use the notation for the g function from Bahdanau et al. (2014)

ITERATION	0	1	2	3
Strict Constraints				
EN-DE	18.44	27.64 (+9.20)	36.66 (+9.01)	**43.92** (+7.26)
EN-FR	28.07	36.71 (+8.64)	44.84 (+8.13)	**45.48** +(0.63)
EN-PT*	15.41	23.54 (+8.25)	31.14 (+7.60)	**35.89** (+4.75)
Relaxed Constraints				
EN-DE	18.44	26.43 (+7.98)	34.48 (+8.04)	**41.82** (+7.34)
EN-FR	28.07	33.8 (+5.72)	40.33 (+6.53)	**47.0** (+6.67)
EN-PT*	15.41	23.22 (+7.80)	33.82 (+10.6)	**40.75** (+6.93)

Table 1: Results for four simulated editing cycles using WMT test data. EN-DE uses *newstest2013*, EN-FR uses *newstest2014*, and EN-PT uses the Autodesk corpus discussed in Section 4.2. Improvement in BLEU score over the previous cycle is shown in parentheses. * indicates use of our test corpus created from Autodesk post-editing data.

with the original translation hypothesis, a (simulated) user first picks a part of the hypothesis which is incorrect, and then provides the correct translation for that portion of the output. The user-provided correction is then used as a constraint for the next decoding cycle. The Pick-Revise process can be repeated as many times as necessary, with a new constraint being added at each cycle.

We modify the experiments of Cheng et al. (2016) slightly, and assume that the user only provides sequences of up to three words which are missing from the hypothesis.[4] To simulate user interaction, at each iteration we chose a phrase of up to three tokens from the reference translation which does not appear in the current MT hypotheses. In the *strict* setting, the complete phrase must be missing from the hypothesis. In the *relaxed* setting, only the first word must be missing. Table 1 shows results for a simulated editing session with four cycles. When a three-token phrase cannot be found, we backoff to two-token phrases, then to single tokens as constraints. If a hypothesis already matches the reference, no constraints are added. By specifying a new constraint of up to three words at each cycle, an increase of over 20 BLEU points is achieved in all language pairs.

4.2 Domain Adaptation via Terminology

The requirement for use of domain-specific terminologies is common in real-world applications of MT (Crego et al., 2016). Existing approaches incorporate placeholder tokens into NMT systems, which requires modifying the pre- and post- processing of the data, and training the system with data that contains the same placeholders which occur in the test data (Crego et al., 2016). The MT system also loses any possibility to model the tokens in the terminology, since they are represented by abstract tokens such as "⟨TERM_1⟩". An attractive alternative is to simply provide term mappings as constraints, allowing any existing system to adapt to the terminology used in a new test domain.

For the target domain data, we use the Autodesk Post-Editing corpus (Zhechev, 2012), which is a dataset collected from actual MT post-editing sessions. The corpus is focused upon software localization, a domain which is likely to be very different from the WMT data used to train our general domain models. We divide the corpus into approximately 100,000 training sentences, and 1000 test segments, and automatically generate a terminology by computing the Pointwise Mutual Information (PMI) (Church and Hanks, 1990) between source and target n-grams in the training set. We extract all n-grams from length 2-5 as terminology candidates.

$$\mathbf{pmi}(\mathbf{x};\mathbf{y}) = \mathbf{log}\frac{p(x,y)}{p(x)p(y)} \quad (5)$$

$$\mathbf{npmi}(\mathbf{x};\mathbf{y}) = \frac{\mathbf{pmi}(\mathbf{x};\mathbf{y})}{\boldsymbol{h}(\mathbf{x},\mathbf{y})} \quad (6)$$

Equations 5 and 6 show how we compute the normalized PMI for a terminology candidate pair. The PMI score is normalized to the range $[-1,+1]$ by dividing by the entropy $\boldsymbol{h}$ of the joint probability $\mathbf{p}(\mathbf{x},\mathbf{y})$. We then filter the candidates to only include pairs whose PMI is ≥ 0.9, and where both the source and target phrases occur at least five times in the corpus. When source phrases that match the terminology are observed in the test

[4]NMT models do not use explicit alignment between source and target, so we cannot use alignment information to map target phrases to source phrases

data, the corresponding target phrase is added to the constraints for that segment. Results are shown in Table 2.

As a sanity check that improvements in BLEU are not merely due to the presence of the terms somewhere in the output, i.e. that the *placement* of the terms by GBS is reasonable, we also evaluate the results of randomly inserting terms into the baseline output, and of prepending terms to the baseline output.

This simple method of domain adaptation leads to a significant improvement in the BLEU score without any human intervention. Surprisingly, even an automatically created terminology combined with GBS yields performance improvements of approximately +2 BLEU points for En-De and En-Fr, and a gain of almost 14 points for En-Pt. The large improvement for En-Pt is probably due to the training data for this system being very different from the IT domain (see Appendix). Given the performance improvements from our automatically extracted terminology, manually created domain terminologies with good coverage of the test domain are likely to lead to even greater gains. Using a terminology with GBS is likely to be beneficial in any setting where the test domain is significantly different from the domain of the model's original training data.

System	BLEU
EN-DE	
Baseline	26.17
Random	25.18 (-0.99)
Beginning	26.44 (+0.26)
GBS	**27.99** (+1.82)
EN-FR	
Baseline	32.45
Random	31.48 (-0.97)
Beginning	34.51 (+2.05)
GBS	**35.05** (+2.59)

Baseline	15.41
Random	18.26 (+2.85)
Beginning	20.43 (+5.02)
GBS	**29.15** (+13.73)

Table 2: BLEU Results for EN-DE, EN-FR, and EN-PT terminology experiments using the Autodesk Post-Editing Corpus. "Random' indicates inserting terminology constraints at random positions in the baseline translation. "Beginning" indicates prepending constraints to baseline translations.

4.3 Analysis

Subjective analysis of decoder output shows that phrases added as constraints are not only placed correctly within the output sequence, but also have global effects upon translation quality. This is a desirable effect for user interaction, since it implies that users can bootstrap quality by adding the most critical constraints (i.e. those that are most essential to the output), first. Table 3 shows several examples from the experiments in Table 1, where the addition of lexical constraints was able to guide our NMT systems away from initially quite low-scoring hypotheses to outputs which perfectly match the reference translations.

5 Related Work

Most related work to date has presented modifications of SMT systems for specific usecases which constrain MT output via auxilliary inputs. The largest body of work considers **Interactive Machine Translation** (IMT): an MT system searches for the optimal target-language suffix given a complete source sentence and a desired prefix for the target output (Foster, 2002; Barrachina et al., 2009; Green, 2014). IMT can be viewed as subcase of constrained decoding, where there is only one constraint which is guaranteed to be placed at the beginning of the output sequence. Wuebker et al. (2016) introduce **prefix-decoding**, which modifies the SMT beam search to first ensure that the *target prefix* is covered, and only then continues to build hypotheses for the suffix using beams organized by coverage of the remaining phrases in the source segment. Wuebker et al. (2016) and Knowles and Koehn (2016) also present a simple modification of NMT models for IMT, enabling models to predict suffixes for user-supplied prefixes.

Recently, some attention has also been given to SMT decoding with multiple lexical constraints. The Pick-Revise (PRIMT) (Cheng et al., 2016) framework for Interactive Post Editing introduces the concept of *edit cycles*. Translators specify constraints by editing a part of the MT output that is incorrect, and then asking the system for a new hypothesis, which must contain the user-provided correction. This process is repeated, maintaining constraints from previous iterations and adding new ones as needed. Importantly, their approach relies upon the phrase segmentation provided by the SMT system. The decoding algorithm can

Table 3: Manual analysis of examples from lexically constrained decoding experiments. "-" followed by whitespace indicates the internal segmentation of the translation model (see Section 3.2)

only make use of constraints that match phrase boundaries, because constraints are implemented as "rules" enforcing that source phrases must be translated as the aligned target phrases that have been selected as constraints. In contrast, our approach decodes at the token level, and is not dependent upon any explicit structure in the underlying model.

Domingo et al. (2016) also consider an interactive scenario where users first choose portions of an MT hypothesis to keep, then query for an updated translation which preserves these portions. The MT system decodes the source phrases which are not aligned to the user-selected phrases until the source sentence is fully covered. This approach is similar to the system of Cheng et al., and uses the "XML input" feature in Moses (Koehn et al., 2007).

Some recent work considers the inclusion of soft lexical constraints directly into deep models for dialog generation, and special cases, such as recipe generation from a list of ingredients (Wen et al., 2015; Kiddon et al., 2016). Such constraint-aware models are complementary to our work, and could be used with GBS decoding without any change to the underlying models.

To the best of our knowledge, ours is the first work which considers general lexically constrained decoding for any model which outputs sequences, without relying upon alignments between input and output, and without using a search organized by coverage of the input.

6 Conclusion

Lexically constrained decoding is a flexible way to incorporate arbitrary subsequences into the output of any model that generates output sequences token-by-token. A wide spectrum of popular text generation models have this characteristic, and GBS should be straightforward to use with any model that already uses beam search.

In translation interfaces where translators can provide corrections to an existing hypothesis, these user inputs can be used as constraints, generating a new output each time a user fixes an error. By simulating this scenario, we have shown that such a workflow can provide a large improvement in translation quality at each iteration.

By using a domain-specific terminology to generate target-side constraints, we have shown that a general domain model can be adapted to a new domain without any retraining. Surprisingly, this simple method can lead to significant performance gains, even when the terminology is created automatically.

In future work, we hope to evaluate GBS with models outside of MT, such as automatic summarization, image captioning or dialog generation. We also hope to introduce new constraint-aware models, for example via secondary attention mechanisms over lexical constraints.

Acknowledgments

This project has received funding from Science Foundation Ireland in the ADAPT Centre for Digital Content Technology (www.adaptcentre.ie) at Dublin City University funded under the SFI Research Centres Programme (Grant 13/RC/2106) co-funded under the European Regional Development Fund and the European Union Horizon 2020 research and innovation programme under grant agreement 645452 (QT21). A NMT System Configurations

We train all systems for 500000 iterations, with validation every 5000 steps. The best single model from validation is used in all of the experiments for a language pair. We use ℓ_2 regularization on all parameters with $\alpha = 1e^{-5}$. Dropout is used on the output layers with $p(drop) = 0.5$. We sort mini-batches by source sentence length, and reshuffle training data after each epoch.

All systems use a bidirectional GRUs (Cho et al., 2014) to create the source representation and GRUs for the decoder transition. We use AdaDelta (Zeiler, 2012) to update gradients, and clip large gradients to 1.0.

Abstract

Human trafficking is a global epidemic affecting millions of people across the planet. Sex trafficking, the dominant form of human trafficking, has seen a significant rise mostly due to the abundance of escort websites, where human traffickers can openly advertise among at-will escort advertisements. In this paper, we take a major step in the automatic detection of advertisements suspected to pertain to human trafficking. We present a novel dataset called Trafficking-10k, with more than 10,000 advertisements annotated for this task. The dataset contains two sources of information per advertisement: text and images. For the accurate detection of trafficking advertisements, we designed and trained a deep multimodal model called the Human Trafficking Deep Network (HTDN).

1 Introduction

Human trafficking "a crime that shames us all" (UNODC, 2008), has seen a steep rise in the United States since 2012. The number of cases reported rose from 3,279 in 2012 to 7,572 in 2016—more than doubling over the course of five years (Hotline). Sex trafficking is a form of human trafficking, and is a global epidemic affecting millions of people each year (McCarthy, 2014). Victims of sex trafficking are subjected to coercion, force, and control, and are not able to ask for help. Put plainly, sex trafficking is modern-day slavery and is one of the top priorities of law enforcement agencies at all levels.

A major advertising ground for human traffickers is the World Wide Web. The Internet has brought traffickers the ability to advertise online and has fostered the growth of numerous adult escort sites. Each day, there are tens of thousands of Internet advertisements posted in the United States and Canada that market commercial sex. Hiding among the noise of at-will adult escort ads are ads posted by sex traffickers. Often long undetected, trafficking rings and escort websites form a profit cycle that fuels the increase of both trafficking rings and escort websites.

For law enforcement, this presents a significant challenge: how should we identify advertisements that are associated with sex trafficking? Police have limited human and technical resources, and manually sifting through thousands of ads in the hopes of finding something suspicious is a poor use of those resources, even if they know what they are looking for. Leveraging state-of-the-art machine learning approaches in Natural Language Processing and computer vision to detect and report advertisements suspected of trafficking is the main focus of our work. In other words, we strive to find the victims and perpetrators of trafficking who hide in plain sight in the massive amounts of data online. By narrowing down the number of advertisements that law enforcement must sift through, we endeavor to provide a real opportunity for law enforcement to intervene in the lives of victims. However, there are non-trivial challenges facing this line of research:

Adversarial Environment. Human trafficking rings are aware that law enforcement monitors their online activity. Over the years, law enforcement officers have populated lists of keywords that frequently occur in trafficking advertisements. However, these simplistic queries fail when traffickers use complex obfuscation. Traffickers, again aware of this, move to new keywords to blend in with the at-will escort advertisements. This trend creates an adversarial environment for any machine learning

https://doi.org/10.18653/v1/P17-1142

system that attempts to find trafficking rings hiding in plain sight.

Defective Language Compositionality. Online escort advertisements are difficult to analyze, because they lack grammatical structures such as constituency. Therefore, any form of inference must rely more on context than on grammar. This presents a significant challenge to the NLP community. Furthermore, the majority of the ads contain emojis and non-English characters.

Generalizable Language Context. Machine learning techniques can easily learn unreliable cues in training sets such as phone numbers, keywords, and other forms of semantically unreliable discriminators to reduce the training loss. Due to limited similarity between the training and test data due to the large number of ads available online, relying on these cues is futile. Learned discriminative features should be generalizable and model semantics of trafficking.

Multimodal Nature. Escort advertisements are composed of both textual and visual information. Our model should treat these features interdependently. For instance, if the text indicates that the escort is in a hotel room, our model should consider the effect that such knowledge may have on the importance of certain visual features.

We believe that studying human trafficking advertisements can be seen as a fundamental challenge to the NLP, computer vision, and machine learning communities dealing with language and vision problems. In this paper, we present the following contributions to this research direction. First, we study the language and vision modalities of the escort advertisements through deep neural modeling. Second, we take a significant step in automatic detection of advertisements suspected of sex trafficking. While previous methods (Dubrawski et al., 2015) have used simplistic classifiers, we build an end-to-end-trained multimodal deep model called the Human Trafficking Deep Network (HTDN). The HTDN uses information from both text and images to extract cues of human trafficking, and shows outstanding performance compared to previously used models. Third, we present the first rigorously annotated dataset for detection of human trafficking, called Trafficking-10k, which includes more than 10,000 trafficking ads labeled with likelihoods of having been posted by traffickers.[1]

[1]Due to the sensitive nature of this dataset, access can only be granted by emailing Cara Jones. Different levels of access are provided *only* to scientific community.

2 Related Works

Automatic detection of human trafficking has been a relatively unexplored area of machine learning research. Very few machine learning approaches have been proposed to detect signs of human trafficking online. Most of these approaches use simplistic methods such as multimedia matching (Zhou et al., 2016), text-based filtering classifiers such as random forests, logistic regression, and SVMs (Dubrawski et al., 2015), and named-entity recognition to isolate the instances of trafficking (Nagpal et al., 2015). Studies have suggested using statistical methods to find keywords and signs of trafficking from data to help law enforcement agencies (Kennedy, 2012) as well as adult content filtering using textual information (Zhou et al., 2016).

Multimodal approaches have gained popularity over the past few years. These multimodal models have been used for medical purposes, such as detection of suicidal risk, PTSD and depression (Scherer et al., 2016; Venek et al., 2016; Yu et al., 2013; Valstar et al., 2016); sentiment analysis (Zadeh et al., 2016b; Poria et al., 2016; Zadeh et al., 2016a); emotion recognition (Poria et al., 2017); image captioning and media description (You et al., 2016; Donahue et al., 2015); question answering (Antol et al., 2015); and multimodal translation (Specia et al., 2016).

To the best of our knowledge, this paper presents the first multimodal and deep model for detection of human trafficking.

3 Trafficking-10k Dataset

In this section, we present the dataset for our studies. We formalize the problem of recognizing sex trafficking as a machine learning task. The input data is text and images; this is mapped to a measure of how suspicious the advertisement is with regards to human trafficking.

3.1 Data Acquisition and Preprocessing

A subset of 10,000 ads were sampled randomly from a large cache of escort ads for annotation in Trafficking-10k dataset. The distribution of advertisements across the United States and Canada is shown in Figure 1, which indicates the diversity of advertisements in Trafficking-10k. This diversity ensures that models trained on Trafficking-10k can be applicable nationwide. The 10,000 collected ads

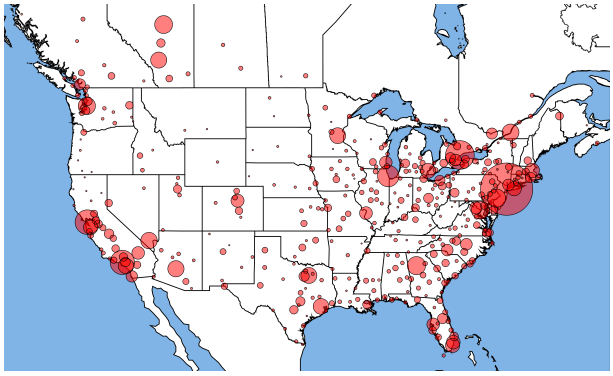

Figure 1: Distribution of advertisements in Trafficking-10k dataset across United States and Canada.

each consist of text and zero or more images. The text in the dataset is in plain text format, derived by stripping the HTML tags from the raw source of the ads. The set of characters in each advertisement is encoded as UTF-8, because there is ample usage of smilies and non-English characters. Advertisements are truncated to the first 184 words, as this covers more than 90% of the ads. Images are resized to 224×224 pixels with RGB channels.

3.2 Trafficking Annotation

Detecting whether or not an advertisement is suspicious requires years of practice and experience in working closely with law enforcement. As a result, annotation is a highly complicated and expensive process, which cannot be scaled using crowdsourcing. In our dataset, annotation is carried out by two expert annotators, each with at least five years of experience, in detection of human trafficking and another annotator with one year of experience. In our dataset, annotations were done by three experts. One expert has over a year of experience, and the other two have over five years of experience in the human trafficking domain. To calculate the inter-annotator agreement, each annotator is given the same set of 1000 ads to annotate and the nominal agreement is found: there was a 83% pairwise agreement (0.62 Krippendorff's alpha). Also, to make sure that annotations are generalizable across the annotators and law enforcement officers, two law enforcement officers annotated, respectively, a subset of 500 and 100 of the advertisements. We found a 62% average pairwise agreement (0.42 Krippendorff's alpha) with our annotators. This gap is reasonable, as law enforcement officers only have experience with local advertisements, while Trafficking-10k annotators have experience with cases across the United States.

Annotators used an annotation interface specifically designed for the Trafficking-10k dataset. In the annotation interface, each advertisement was displayed on a separate webpage. The order of the advertisements is determined uniformly randomly, and annotators were unable to move to the next advertisement without labeling the current one. For each advertisement, the annotator was presented with the question: "In your opinion, would you consider this advertisement suspicious of human trafficking?" The annotator is presented with the following options: "Certainly no," "Likely no," "Weakly no," "Unsure,"[2] "Weakly yes," "Likely yes," and "Certainly yes." Thus, the degree to which advertisements are suspicious is quantized into seven levels.

3.3 Analysis of Language

The language used in these advertisements introduces fundamental challenges to the field of NLP. The nature of the textual content in these advertisements raises the question of how we can make inferences in a linguistic environment with a constantly evolving lexicon. Language used in the Trafficking-10k dataset is highly inconsistent with standard grammar. Often, words are obfuscated by emojis and symbols. The word ordering is inconsistent, and there is rarely any form of constituency. This form of language is completely different from spoken and written English. These attributes make escort advertisements appear somewhat similar to tweets, specifically since these ads are normally short (more than 90% of the ads have at most 184 words). Another point of complexity in these advertisements is the high number of unigrams, due to usage of uncommon words and obfuscation. On top of unigram complexity, advertisers continuously change their writing pattern, making this problem more complex.

3.4 Dataset Statistics

There are 106,954 distinct unigrams, 353,324 distinct bigrams, and 565,403 trigrams in the Trafficking-10k dataset. There are 60,337 images. The total number of distinct characters including whitespace, punctuations, and hex characters is 182. The average length of an ad is 137 words, with a

[2]This option is greyed out for 10 seconds to encourage annotators to make an intuitive decision.

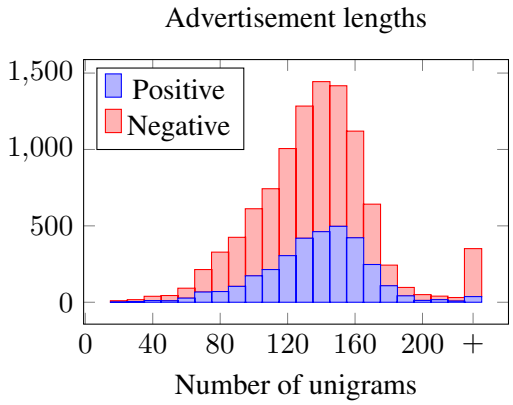

Figure 2: Distribution of the length of advertisements in Trafficking-10k. There is no significant difference between positive and negative cases purely based on length.

standard deviation of 74, median 133. The shortest advertisement has 7 unigrams, and the longest advertisement has 1810 unigrams. There are of 106,954 distinct unigrams, 353,324 distinct bigrams and 565,403 trigrams in the Trafficking-10k dataset. The average number of images in an advertisement is 5.9; the median is 5, the minimum is 0, and the maximum is 90.

The length of *suspected* advertisements is 134 unigrams; the standard deviation is 39, the minimum is 12, and the maximum is 666. The length of *non-suspected* ads is 141; the standard deviation is 85, the minimum is 7, and the maximum is 1810. The total number of suspected ads is 3257; and the total number of non-suspected ads is 6992. Figure 2 shows the histogram of number of ads based on their length. Both the positive and negative distributions are similar. This means that there is no obvious length difference between the two classes. Most of the ads have a length of 80–180 words.

4 Model

In this section, we present our deep multimodal network called the Human Trafficking Deep Network (HTDN). The HTDN is a multimodal network with language and vision components. The input to the HTDN is an ad, text and images. The HTDN is shown in Figure 3. In the remainder of this section, we will outline the different parts of the HTDN, and the input features to each component.

4.1 Trafficking Word Embeddings

Our approach to deal with the adversarial environment of escort ads is to use word vectors, defining words not based on their constituent characters, but rather based on their context. For instance, consider the two unigrams "cash" and "©a$h." While these contain different characters, semantically they are the same, and they occur in the same context. Thus, our expectation is that both the unigrams will be mapped to similar vectors. Word embeddings pretrained on general domains do not cover most of the unigrams in Trafficking-10k. For instance, the GloVe embedding (Pennington et al., 2014) trained on Wikipedia covers only 49.7% of our unigrams. The first step of the HTDN pipeline is to train word vectors (Mikolov et al., 2013) based on the skip-gram model. This is especially suitable for escort ads, because skip-gram models are able to capture context without relying on word order. We train the word embedding using 1,000,000 unlabeled ads from a dataset that does not include the Trafficking-10k data. For each advertisement, the input to the trained embedding is a sequence of words $\hat{\mathbf{w}} = [\hat{w}_1, \ldots, \hat{w}_t]$, and the output is a sequence of 100-dimensional word vectors $\mathbf{w} = [w_1, \ldots, w_t]$, where t is the size of the advertisement and $w_i \in \mathbb{R}^{100}$. Our trained word vectors cover 94.9% of the unigrams in the Trafficking-10k dataset.

4.2 Language Network

Our language network is designed to deal with two challenging aspects of escort advertisements: (1) violation of constituency, and (2) presence of irrelevant information not related to trafficking but present in ads. We address both of these issues by learning a time dependent embedding at word level. This allows the model to not rely on constituency and also remember useful information from the past, should the model get overwhelmed by irrelevant information. Our proposed language network, $\mathcal{F}_l$, takes as input a sequence of word vectors $\mathbf{w} = [w_1, \ldots, w_t]$, and outputs a neural language representation h_l. As a first step, $\mathcal{F}_l$ uses the word embeddings as input to a Long-Short Term Memory (LSTM) network and produces a new supervised context-aware word embedding $\mathbf{u} = [u_1, \ldots, u_t]$ where $u_i \in \mathbb{R}^{300}$ is the output of the LSTM at time i. Then, $\mathbf{u}$ is fed into a fully connected layer with dropout $p = 0.5$ to produce the neural language representation $h_l \in \mathbb{R}^{300}$ according to the following formulas with weights W_l for the LSTM and implicit weights in the fully

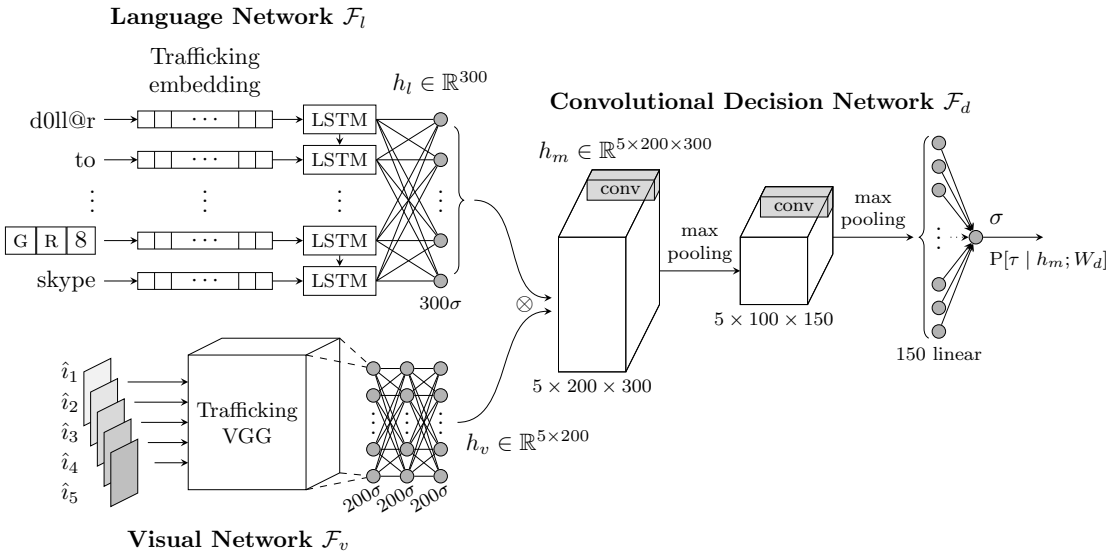

Figure 3: Overview of our proposed Human Trafficking Deep Network (HTDN). The input to HTDN is text and a set of 5 images. The text goes through the Language Network $\mathcal{F}_l$ to get the language representation h_l and the set of 5 images go through the Vision Network $\mathcal{F}_v$ to get the visual representation h_v. h_l and h_v are then fused together to get the multimodal representation h_m. The Convolutional Decision Network $\mathcal{F}_d$ conditioned on the h_m makes inference about whether or not the advertisement is suspected of trafficking

connected layers, which we represent by FC:

$$u_i = LSTM(i, w_i; W_l) \quad (1)$$

$$\mathbf{u} = [u_1, \ldots, u_t] \quad (2)$$

$$h_l = FC(\mathbf{u}). \quad (3)$$

The generated h_l is then used as part of the HTDN pipeline, and is also trained independently to assess the performance of the language-only model. The language network $\mathcal{F}_l$ is the combination of the LSTM and the fully-connected network.

4.3 Vision Network

Parallel to the language network, the vision network $\mathcal{F}_v$ takes as input advertisement images and extracts visual representations h_v. The vision network takes at most five images; the median number of images per advertisement in Trafficking-10k is 5. To learn contextual and abstract information from images, we use a deep convolutional neural network called Trafficking-VGG (T-VGG), a fine-tuned instance of the well-known VGG network (Simonyan and Zisserman, 2014). T-VGG is a deep model with 13 consecutive convolutional layers followed by 2 fully connected layers; it does not include the softmax layer of VGG. The procedure for fine-tuning T-VGG maps each individual image to a label that comes from the advertisement, and then performs end-to-end training. For example, if there are five images in an advertisement with positive label, all five images are mapped to positive label. After fine-tuning, three fully connected layers of 200 neurons with dropout $p = 0.5$ are added to the network. The combination of T-VGG and the fully connected layers is the vision network $\mathcal{F}_l$. We consider five images $\hat{\boldsymbol{i}} = \{\hat{i}_1, \ldots, \hat{i}_5\}$ from each input advertisement. If the advertisement has fewer than five images, zero-filled images are added. For each image, the output of $\mathcal{F}_v$ is a representation of five images $\mathbf{i} = \{i_1, \ldots, i_5\}$. The visual representation $h_v \in \mathbb{R}^{5\times200}$ is a matrix with a size-200 representation of each of the 5 images:

$$h_v = \mathcal{F}_v(\hat{\boldsymbol{i}}; W_v). \quad (4)$$

4.4 Multimodal Fusion

Escort advertisements have complex dynamics between text and images. Often, neither linguistic nor visual cues alone can suffice to classify whether an ad is suspicious. Interactions between linguistic and visual cues can be non-trivial, so this requires an explicit joint representation for each neuron in the linguistic and visual representations. In our multimodal fusion approach we address this by calculating an outer product between language and visual representations h_l and h_v to build the full space of possible outcomes:

$$h_m = h_l \otimes h_v, \quad (5)$$

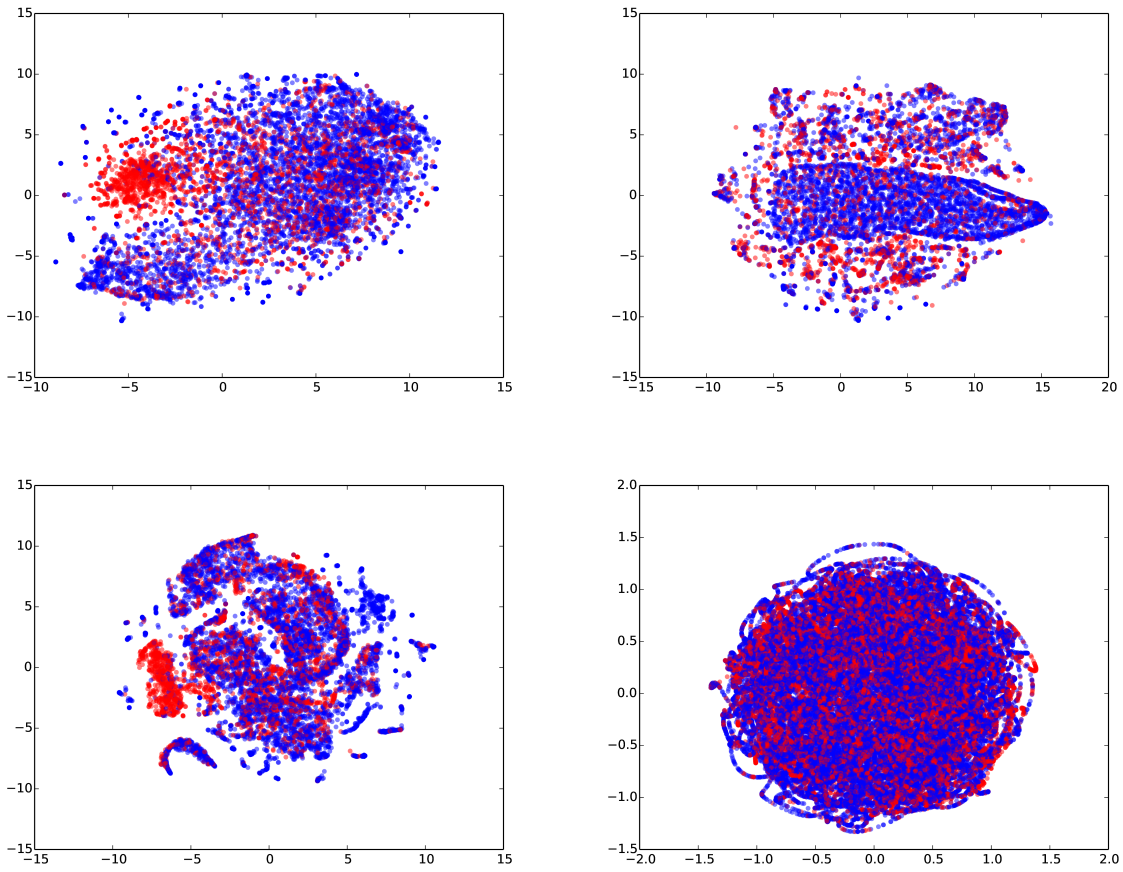

Figure 4: 2D t-SNE representation of different input features for baseline models. Clockwise from top left: one hot vectors with expert data, one hot vectors without expert data, visual features from Vision Network $\mathcal{F}_v$, and average word vectors. These representations show that inference is not trivial in Trafficking-10k dataset.

where $\otimes$ is an outer product of the two representations. This creates a joint multimodal tensor called h_m for language and visual modalities. In this tensor, every neuron in the language representation is multiplied by every neuron in vision representation, thus creating a new representation containing the information of both of them. Thus, the final fusion tensor $h_m \in \mathbb{R}^{5\times200\times300}$ contains information from the joint interaction of the language and visual modalities.

4.5 Convolutional Decision Network

The multimodal representation h_m is used as the input to the convolutional decision network $\mathcal{F}_d$. $\mathcal{F}_d$ has two layers of convolution and max pooling with a dropout rate of $p = 0.5$, followed by a fully connected layer of 150 neurons with a dropout rate of $p = 0.5$. Performing convolutions in this space enables the model to attend to small areas of linguistic and visual cues. It can thus find correspondences between specific combinations of the linguistic and visual representations. The final decision is made by a single sigmoid neuron.

5 Experiments

In our experiments, we compare the HTDN with previously used approaches for detection of trafficking suspicious ads. Furthermore, we compare the HTDN to the performance of its unimodal components. In all our experiments we perform binary classification of whether the advertisement is suspected of being related to trafficking. The main comparison method that we use is the weighted accuracy and F1-score (due to imbalance it dataset). The formulation for weighted accuracy is as follows:

$$\text{Wt. Acc.} = \frac{\text{TP} \times \text{N/P} + \text{TN}}{2\text{N}} \tag{6}$$

Model	Wt. Acc. (%)	F1 (%)	Acc. (%)	Precision (%)	Recall (%)
Random	50.0	-	68.2	-	-
Keywords					
Random Forest	67.0	55.2	78.1	78.2	42.6
Logistic Regression	69.9	57.8	78.4	75.5	46.8
Linear SVM	69.5	57.0	78.6	78.0	44.9
Average Trafficking Vectors					
Random Forest	67.3	54.1	78.0	79.3	41.1
Logistic Regression	72.2	61.7	80.2	79.2	50.6
Linear SVM	70.3	57.7	79.2	80.7	44.9
108 One-Hot					
Random Forest	62.4	60.7	72.6	61.5	60.0
Logistic Regression	62.5	45.1	72.2	60.0	36.1
Linear SVM	61.7	45.1	71.8	58.6	36.7
Bag of Words					
Random Forest	57.6	24.5	70.4	63.2	15.2
Logistic Regression	71.1	24.5	70.4	63.2	15.2
Linear SVM	71.2	24.5	70.4	63.2	15.2
HTDN Unimodal					
$\mathcal{F}_l$	74.5	65.8	78.8	69.8	62.3
$\mathcal{F}_v$ [VGG]	69.1	58.4	74.2	66.7	52.0
$\mathcal{F}_v$ [T-VGG]	70.4	59.5	77.3	78.3	48.0
HTDN	**75.3**	**66.5**	80.0	71.4	62.2
Human	83.7	73.7	84.0	76.7	70.9

Table 1: Results of our experiments. We compare our HTDN model to various baselines using different inputs. HTDN ourperforms other baselines in both weighted accuracy and F-score.

where TP (resp. TN) is true positive (resp. true negative) predictions, and P (resp. N) is the total number of positive (resp. negative) examples.

5.1 Baselines

We compare the performance of the HTDN network with baseline models divided in 4 major categories

Bag-of-Words Baselines. This set of baselines is designed to assess performance of off-the-shelf basic classifiers and basic language features. We train random forest, logistic regression and linear SVMs to show the performance of simple language-only models.

Keyword Baselines. These demonstrate the performance of models that use a set of 108 keywords, all highly related to trafficking, provided by law enforcement officers.[3] A binary one-hot vector representing these keywords is used to train the random forest, logistic regression, and linear SVM models.

108 One-Hot Baselines. Similar to Keywords Baseline, we use feature selection technique to filter the most informative 108 words for detection of trafficking. We compare the performance of this baseline to Keywords baseline to evaluate the usefulness of expert knowledge in keywords selection vs automatic data-driven keyword selection.

Average Trafficking Vectors Baselines. We assess the magnitude of success for the trafficking word embeddings for different classifiers. For the random forest, logistic regression, and linear SVM models, the average word vector is calculated and used as input.

HTDN Unimodal. These baselines show the performance of unimodal components of HTDN. For language we only use $\mathcal{F}_l$ component of the pipeline and for visual we use $\mathcal{F}_v$, using both pre-trained a VGG and finetuned T-VGG.

[3]Not presented in this paper due to sensitive nature of these keywords.

Random and Human. Random is based on assigning the more frequent class in training set to all the test data, and can be considered a lower bound for our model. Human performance metrics are upper bounds for this task's metrics.

We visualize the different inputs to our baseline models to show the complexity of the dataset when using different feature sets. Figure 4 shows the 2D t-SNE (Maaten and Hinton, 2008) representation of the training data in our dataset according to the Bag-of-Words (top right) models, expert keywords (top left), average word vectors (bottom right), and the visual representation h_v bottom left. The distribution of points suggests that none of the feature representations make the classification task trivial.

5.2 Training Parameters

All the models in our experiments are trained on the Trafficking-10k designated training set and tested on the designated test set. Hyperparameter evaluation is performed using a subset of training set as validation set. The HTDN model is trained using the Adam optimizer (Kingma and Ba, 2014). The neural weights were initialized randomly using Xavier initialization technique (Glorot and Bengio, 2010). The random forest model uses 10 estimators, with no maximum depth, and minimum-samples-per-split value of 2. The linear SVM model uses an ℓ_2-penalty and a square hinge loss with $C = 1$.

6 Results and Discussion

The results of our experiments are shown in Table 1. We report the results on three metrics: F1-score, weighted accuracy, and accuracy. Due to the imbalance between the numbers of positive and negative samples, weighted accuracy is more informative than unweighted accuracy, so we focus on the former.

HTDN. The first observation from Table 1 is that the HTDN model outperforms all the proposed baselines. There is a significant gap between the HTDN (and variants) and other non-neural approaches. This better performance is an indicator of complex interactions in detecting dynamics of human trafficking, which is captured by the HTDN.

Both Modalities are Helpful. Both modalities are helpful in predicting signs of trafficking ($\mathcal{F}_l$ and $\mathcal{F}_v$ [T-VGG]). Fine-tuning VGG network parameters shows improvement over pre-trained VGG parameters.

Language is More Important. Since $\mathcal{F}_l$ shows better performance than $\mathcal{F}_v$ [T-VGG], the language modality appears to be the more informative modality for detecting trafficking suspicious ads.

7 Conclusion and Future Work

In this paper, we took a major step in multimodal modeling of suspected online trafficking advertisements. We presented a novel dataset, Trafficking-10k, with more than 10,000 advertisements annotated for this task. The dataset contains two modalities of information per advertisement: text and images. We designed a deep multimodal model called the Human Trafficking Deep Network (HTDN). We compared the performance of the HTDN to various models that use language and vision alone. The HTDN outperformed all of these, indicating that using information from both sources may be more helpful than using just one.

Exploring language through character modeling. In order to eliminate the need for retraining the word vectors as the language of the domain evolves, we plan to use character models to learn a better language model for trafficking. As new obfuscated words are introduced in escort advertisements, our hope is that character models will stay invariant to these obfuscations.

Understanding images. While CNNs have proven to be useful for many different computer vision tasks, we seek to improve the learning capability of the visual network. Future direction involves using graphical modeling to understand interactions in the scene. Another direction involves working to understand text in images, which can provide more information about the subjects of the images.

Given that the current state of the art in this area generally does not use deep models, this may be a major opportunity for improvement. To this end, we encourage the research community to reach out to Cara Jones, an author of this paper, to obtain a copy of Trafficking-10k and other training data.

Acknowledgements

We would like to thank William Chargin for creating figures and revising this paper. We would also like to thank Torsten Wörtwein for his assistance in visualizing our data. Furthermore, we would like to thank our anonymous reviewers for their valuable feedback. Finally, we would like to acknowledge collaborators from Marinus Analytics for the time and effort that they put into annotating advertise-

ments for the dataset, and for allowing us to use their advertisement data.

Abstract

Cybersecurity risks and malware threats are becoming increasingly dangerous and common. Despite the severity of the problem, there has been few NLP efforts focused on tackling cybersecurity.

In this paper, we discuss the construction of a new database for annotated malware texts. An annotation framework is introduced based around the MAEC vocabulary for defining malware characteristics, along with a database consisting of 39 annotated APT reports with a total of 6,819 sentences. We also use the database to construct models that can potentially help cybersecurity researchers in their data collection and analytics efforts.

1 Introduction

In 2010, the malware known as Stuxnet physically damaged centrifuges in Iranian nuclear facilities (Langner, 2011). More recently in 2016, a botnet known as Mirai used infected Internet of Things (IoT) devices to conduct large-scale Distributed Denial of Service (DDoS) attacks and disabled Internet access for millions of users in the US West Coast (US-CERT, 2016). These are only two cases in a long list ranging from ransomeware on personal laptops (Andronio et al., 2015) to taking over control of moving cars (Checkoway et al., 2011). Attacks such as these are likely to become increasingly frequent and dangerous as more devices and facilities become connected and digitized.

Recently, *cybersecurity defense* has also been recognized as one of the "*problem areas likely to be important both for advancing AI and for its long-run impact on society*" (Sutskever et al., 2016). In particular, we feel that natural language processing (NLP) has the potential for substantial contribution in cybersecurity and that this is a critical research area given the urgency and risks involved.

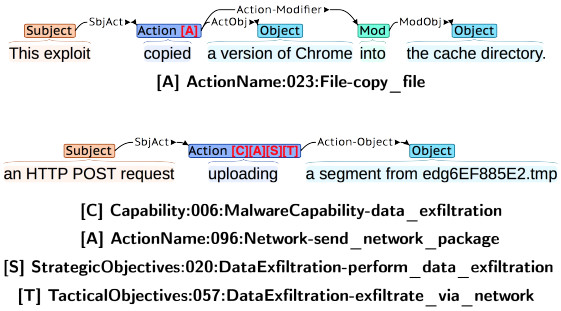

Figure 1: Annotated sentence and sentence fragment from MalwareTextDB. Such annotations provide semantic-level information to the text.

There exists a large repository of malware-related texts online, such as detailed malware reports by various cybersecurity agencies such as Symantec (DiMaggio, 2015) and Cylance (Gross, 2016) and in various blog posts. Cybersecurity researchers often consume such texts in the process of data collection. However, the sheer volume and diversity of these texts make it difficult for researchers to quickly obtain useful information. A potential application of NLP can be to quickly highlight critical information from these texts, such as the specific actions taken by a certain malware. This can help researchers quickly understand the capabilities of a specific malware and search in other texts for malware with similar capabilities.

An immediate problem preventing application of NLP techniques to malware texts is that such

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1557–1567
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1143

texts are mostly unannotated. This severely limits their use in supervised learning techniques.

In light of that, we introduce a database of annotated malware reports for facilitating future NLP work in cybersecurity. To the best of our knowledge, this is the first database consisting of annotated malware reports. It is intended for public release, where we hope to inspire contributions from other research groups and individuals.

The main contributions of this paper are:

- We initiate a framework for annotating malware reports and annotate 39 Advanced Persistent Threat (APT) reports (containing 6,819 sentences) with attribute labels from the Malware Attribute Enumeration and Characterization (MAEC) vocabulary (Kirillov et al., 2010).
- We propose the following tasks, construct models for tackling them, and discuss the challenges:
  - Classify if a sentence is useful for inferring malware actions and capabilities,
  - Predict token, relation and attribute labels for a given malware-related text, as defined by the earlier framework, and
  - Predict a malware's signatures based only on text describing the malware.

2 Background

2.1 APTnotes

The 39 APT reports in this database are sourced from APTnotes, a GitHub repository of publicly-released reports related to APT groups (Blanda, 2016). The repository is constantly updated, which means it is a constant source of reports for annotations. While the repository consists of 384 reports (as of writing), we have chosen 39 reports from the year 2014 to initialize the database.

2.2 MAEC

The MAEC vocabulary was devised by The MITRE Corporation as a standardized language for describing malware (Kirillov et al., 2010). The MAEC vocabulary is used as a source of labels for our annotations. This will facilitate cross-applications in other projects and ensure relevance in the cybersecurity community.

2.3 Related Work

There are datasets available, which are used for more general tasks such as content extraction (Walker et al., 2006) or keyword extraction (Kim et al., 2010). These may appear similar to our dataset. However, a big difference is that we are not performing general-purpose annotation and not all tokens are annotated. Instead, we only annotated tokens relevant to malware capabilities and provide more valuable information by annotating the type of malware capability or action implied. These are important differentiating factors, specifically catered to the cybersecurity domain.

While we are not aware of any database catering specifically to malware reports, there are various databases in the cybersecurity domain that provide malware hashes, such as the National Software Reference Library (NSRL) (NIST, 2017; Mead, 2006) and the File Hash Repository (FHR) by the Open Web Application Security Project (OWASP, 2015).

Most work on classifying and detecting malware has also been focusing on detecting system calls (Alazab et al., 2010; Briones and Gomez, 2008; Willems et al., 2007; Qiao et al., 2013). More recently, Rieck et al. (2011) has incorporated machine learning techniques for detecting malware, again through system calls. To the best of our knowledge, we are not aware of any work on classifying malware based on analysis of malware reports. By building a model that learns to highlight critical information on malware capabilities, we feel that malware-related texts can become a more accessible source of information and provide a richer form of malware characterization beyond detecting file hashes and system calls.

3 Data Collection

We worked together with cybersecurity researchers while choosing the preliminary dataset, to ensure that it is relevant for the cybersecurity community. The factors considered when selecting the dataset include the mention of most current malware threats, the range of author sources, with blog posts and technical security reports, and the range of actor attributions, from several suspected state actors to smaller APT groups.

3.1 Preprocessing

After the APT reports have been downloaded in PDF format, the PDFMiner tool (Shinyama, 2004) is used to convert the PDF files into plaintext format. The reports often contain non-sentences, such as the cover page or document header and

footer. We went through these non-sentences manually and subsequently removed them before the annotation. Hence only complete sentences are considered for subsequent steps.

3.2 Annotation

The Brat Rapid Annotation Tool (Stenetorp et al., 2012) is used to annotate the reports. The main aim of the annotation is to map important word phrases that describe malware actions and behaviors to the relevant MAEC vocabulary, such as the ones shown in Figure 1. We first extract and enumerate the labels from the MAEC vocabulary, which we call attribute labels. This gives us a total of 444 attribute labels, consisting of 211 ActionName labels, 20 Capability labels, 65 StrategicObjectives labels and 148 TacticalObjectives labels. These labels are elaborated in Section 3.5.

There are three main stages to the annotation process. These are cumulative and eventually build up to the annotation of the attribute labels.

3.3 Stage 1 - Token Labels

The first stage involves annotating the text with the following *token labels*, illustrated in Figure 2:

Action This refers to an event, such as "*registers*", "*provides*" and "*is written*".

Subject This refers to the initiator of the Action such as "*The dropper*" and "*This module*".

Object This refers to the recipient of the Action such as "*itself*", "*remote persistent access*" and "*The ransom note*"; it also refers to word phrases that provide elaboration on the Action such as "*a service*", "*the attacker*" and "*disk*".

Modifier This refers to tokens that link to other word phrases that provide elaboration on the Action such as "*as*" and "*to*".

This stage helps to identify word phrases that are relevant to the MAEC vocabulary. Notice that for the last sentence in Figure 2, "*The ransom note*" is tagged as an Object instead of a Subject. This is because the Action "*is written*" is not being initiated by "*The ransom note*". Instead, the Subject is absent in this sentence.

3.4 Stage 2 - Relation Labels

The second stage involves annotating the text with the following *relation labels*:

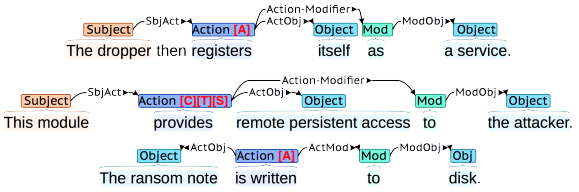

Figure 2: Examples of annotated sentences.

The regime's greatest fear is internal dissent and resulting destabilization.

Songun is North Korea's "military first" doctrine.

Figure 3: Examples of irrelevant sentences.

SubjAction This links an Action with its relevant Subject.

ActionObj This links an Action with its relevant Object.

ActionMod This links an Action with its relevant Modifier.

ModObj This links a Modifier with the Object that provides elaboration.

This stage helps to make the links between the labelled tokens explicit, which is important in cases where a single Action has multiple Subjects, Objects or Modifiers. Figure 2 demonstrates how the relation labels are used to link the token labels.

3.5 Stage 3 - Attribute Labels

The third stage involves annotating the text with the *attribute labels* extracted from the MAEC vocabulary. Since the Action is the main indicator of a malware's action or capability, the attribute labels are annotated onto the Actions tagged in Stage 1. Each Action should have one or more attribute labels.

There are four classes of attribute labels: ActionName, Capability, StrategicObjectives and TacticalObjectives. These labels describe different actions and capabilities of the malware. Refer to Appendix A for examples and elaboration.

3.6 Summary

The above stages complete the annotation process and is done for each document. There are also sentences that are not annotated at all since they do not provide any indication of malware actions or capabilities, such as the sentences in Figure 3. We call these sentences *irrelevant sentences*.

At the time of writing, the database consists of 39 annotated APT reports with a combined total of 6,819 sentences. Out of the 6,819 sentences,

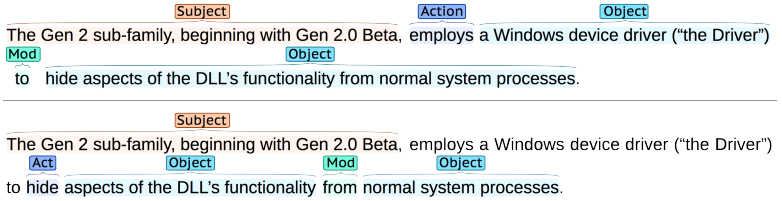

Figure 4: Two different ways for annotating a sentence, where both seem to be equally satisfactory to a human annotator. In this case, both serve to highlight the malware's ability to hide its DLL's functionality.

Token Labels (by label)		**Relation Labels** (by label)		**Attribute Labels** (by class)	
Subj	1,778	SubjAction	2,343	ActionName	982
Obj	4,411	ActionObj	2,713	Capability	2,524
Act	2,975	ActionMod	1,841	StratObj	2,004
Mod	1,819	ModObj	1,808	TactObj	1,592
Total	**10,983**	**Total**	**8,705**	**Total**	**7,102**

Table 1: Breakdown of annotation statistics.

2,080 sentences are annotated. Table 1 shows the breakdown of the annotation statistics.

3.7 Annotators' Challenges

We can calculate the Cohen's Kappa (Cohen, 1960) to quantify the agreement between annotators and to give an estimation of the difficulty of this task for human annotators. Using annotations from pairs of annotators, the Cohen's Kappa was calculated to be 0.36 for annotation of the Token labels. This relatively low agreement between annotators suggests that this is a rather difficult task. In the following subsections, we discuss some possible reasons that make this annotation task difficult.

3.7.1 Complex Sentence Structures

In many cases, there may be no definite way to label the tokens. Figure 4 shows two ways to annotate the same sentence. Both annotations essentially serve to highlight the Gen 2 sub-family's capability of hiding the DLL's functionality. The first annotation highlights the method used by the malware to hide the library, i.e., employing the Driver. The second annotation focuses on the malware hiding the library and does not include the method. Also notice that the Modifiers highlighted are different in the two cases, since this depends on the Action highlighted and are hence mutually exclusive. Such cases occur more commonly when the sentences contain complex noun- and verb-phrases that can be decomposed in several ways. Repercussions surface later in the experiments described in Section 5.2, specifically in the second point under Discussion.

3.7.2 Large Quantity of Labels

Due to the large number (444) of attribute labels, it is challenging for annotators to remember all of the attribute labels. Moreover, some of the attribute labels are subject to interpretation. For instance, should *Capability: 005: MalwareCapability-command_and_control* be tagged for sentences that mention the location or IP addresses of command and control servers, even though such sentences may not be relevant to the capabilities of the malware?

3.7.3 Specialized Domain Knowledge Required

Finally, this task requires specialized cybersecurity domain knowledge from the annotator and the ability to apply such knowledge in a natural language context. For example, given the phrase "*load the DLL into memory*", the annotator has to realize that this phrase matches the attribute label *ActionName: 119: ProcessMemory-map_library_into_process*. The abundance of labels with the many ways that each label can be expressed in natural language makes this task extremely challenging.

4 Proposed Tasks

The main goal of creating this database is to aid cybersecurity researchers in parsing malware-related texts for important information. To this end, we propose several tasks that build up to this main goal.

Task 1 Classify if a sentence is relevant for inferring malware actions and capabilities

Task 2 Predict token labels for a given malware-related text

Task 3 Predict relation labels for a given malware-related text

Task 4 Predict attribute labels for a given malware-related text

Task 5 Predict a malware's signatures based on the text describing the malware and the text's annotations

Task 1 arose from discussions with domain experts where we found that a main challenge for cybersecurity researchers is having to sift out critical sentences from lengthy malware reports and articles. Figure 3 shows sentences describing the political and military background of North Korea in the APT report *HPSR SecurityBriefing_Episode16_NorthKorea*. Such information is essentially useless for cybersecurity researchers focused on malware actions and capabilities. It will be helpful to build a model that can filter relevant sentences that pertain to malware.

Tasks 2 to 4 serve to automate the laborious annotation procedure as described earlier. With sufficient data, we hope that it becomes possible to build an effective model for annotating malware-related texts, using the framework and labels we defined earlier. Such a model will help to quickly increase the size of the database, which in turn facilitate other supervised learning tasks.

Task 5 explores the possibility of using malware texts and annotations to predict a malware's signatures. While conventional malware analyzers generate a list of malware signatures based on the malware's activities in a sandbox, such analysis is often difficult due to restricted distribution of malware samples. In contrast, numerous malware reports are freely available and it will be helpful for cybersecurity researchers if such texts can be used to predict malware signatures instead of having to rely on a limited supply of malware samples.

In the following experiments, we construct models for tackling each of these tasks and discuss the performance of our models.

5 Experiments and Results

Since the focus of this paper is on the introduction of a new framework and database for annotating malware-related texts, we only use simple algorithms for building the models and leave more complex models for future work.

For the following experiments, we use linear support vector machine (SVM) and multinomial Naive Bayes (NB) implementations in the scikit-learn library (Pedregosa et al., 2011). The regularization parameter in SVM and smoothing parameter in NB were tuned (with the values 10^{-3} to 10^{3} in logarithmic increments) by taking the value that gave the best performance in development set.

	P	R	F_1
SVM	69.7	54.0	60.5
NB	59.5	68.5	63.2

Table 2: Task 1 scores: classifying relevant sentences.

For experiments where Conditional Random Field (CRF) (Lafferty et al., 2001) is used, we utilized the CRF++ implementation (Kudo, 2005).

For scoring the predictions, unless otherwise stated, we use the metrics module in scikit-learn for SVM and NB, as well as the CoNLL2000 conlleval Perl script for CRF[1].

Also, unless otherwise mentioned, we make use of all 39 annotated documents in the database. The experiments are conducted with a 60%/20%/20% training/development/test split, resulting in 23, 8 and 8 documents in the respective datasets. Each experiment is conducted 5 times with a different random allocation of the dataset splits and we report averaged scores[2].

Since we focus on building a database, we weigh recall and precision as equally important in the following experiments and hence focus on the F_1 score metric. The relative importance of recall against precision will ultimately depend on the downstream tasks.

5.1 Task 1 - Classify sentences relevant to malware

We make use of the annotations in our database for this supervised learning task and consider a sentence to be relevant as long as it has an annotated token label. For example, the sentences in Figure 2 will be labeled relevant whereas the sentences in Figure 3 will be labeled irrelevant.

A simple bag-of-words model is used to represent each sentence. We then build two models – SVM and NB – for tackling this task.

Results: Table 2 shows that while the NB model outperforms the SVM model in terms of F_1 score, the performance of both models are still rather low with F_1 scores below 70 points. We proceed to discuss possible sources of errors for the models.

[1] www.cnts.ua.ac.be/conll2000/chunking/output.html

[2] Note that therefore the averaged F_1 may not be the harmonic mean of averaged P and R in the result tables.

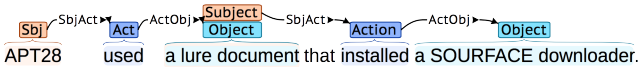

Figure 5: An example of a token ("*a lure document*") labelled as both Subject and Object. In the first case, it is the recipient of the Action "*used*", while in the latter case, it is the initiator of the Action "*installed*".

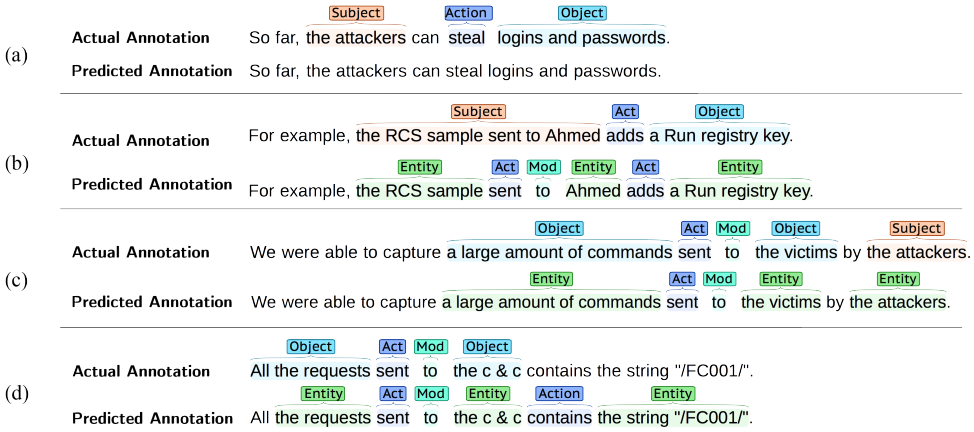

Figure 6: Actual and predicted annotations. For predicted annotations, the Entity label replaces the Subject and Object labels.

Discussion: We find that there are two main types of misclassified sentences.

1. Sentences describing malware without implying specific actions

These sentences often contain malware-specific terms, such as "*payload*" and "*malware*" in the following sentence.

This file is the main payload of the malware.

These sentences are often classified as relevant, probably due to the presence of malware-specific terms. However, such sentences are actually irrelevant because they merely describe the malware but do not indicate specific malware actions or capabilities.

2. Sentences describing attacker actions

Such sentences mostly contain the term "*attacker*" or names of attackers. For instance, the following sentence is incorrectly classified as irrelevant.

This is another remote administration tool often used by the Pitty Tiger crew.

Such sentences involving the attacker are often irrelevant since the annotations focus on the malware and not the attacker. However, the above sentence implies that the malware is a remote administration tool and hence is a relevant sentence that implies malware capability.

5.2 Task 2 - Predict token labels

Task 2 concerns automating Stage 1 for the annotation process described in Section 3.3. Within the annotated database, we find several cases where a single word-phrase may be annotated with both Subject and Object labels (see Figure 5). In order to simplify the model for prediction, we redefine Task 2 as predicting Entity, Action and Modifier labels for word-phrases. The single Entity label is used to replace both Subject and Object labels. Since the labels may extend beyond a single word token, we use the BIO format for indicating the span of the labels (Sang and Veenstra, 1999). We use two approaches for tackling this task: a) CRF is used to train a model for directly predicting token labels, b) A pipeline approach where the NB model from Task 1 is used to filter relevant sentences. A CRF model is then trained to predict token labels for relevant sentences.

The CRF model in Approach 1 is trained on the entire training set, whereas the CRF model in Approach 2 is trained only on the gold relevant sentences in the training set.

For features in both approaches, we use unigrams and bigrams, part-of-Speech labels from the Stanford POStagger (Toutanova et al., 2003), and Brown clustering features after optimizing the cluster size (Brown et al., 1992). A C++ implementation of the Brown clustering algorithm is

	Approach 1			Approach 2		
Token Label	**P**	**R**	**F_1**	**P**	**R**	**F_1**
Entity	48.8	25.1	32.9	42.8	33.8	37.6
Action	55.2	30.3	38.9	50.8	41.1	45.2
Modifier	55.7	28.4	37.3	48.9	37.4	42.1
Average	51.7	27.0	35.2	45.9	36.3	40.3

Table 3: Task 2 scores: predicting token labels.

	Approach 1			Approach 2		
Token Label	**P**	**R**	**F_1**	**P**	**R**	**F_1**
Entity	63.6	32.1	42.3	56.5	46.3	50.6
Action	60.2	31.4	41.0	54.6	42.8	47.7
Modifier	56.4	28.1	37.1	50.1	37.1	42.3
Average	62.7	31.8	41.9	55.9	45.3	49.8

Table 4: Task 2 relaxed/token-level scores.

Relation Label	**P**	**R**	**F_1**
SubjAction	86.3	82.3	84.2
ActionObj	91.6	86.2	88.8
ActionMod	98.5	96.4	97.4
ModObj	98.0	96.7	97.4
Average	89.2	89.4	89.3

Table 5: Task 3 scores: predicting relation labels.

used (Liang, 2005). The Brown cluster was trained on a larger corpus of APT reports, consisting of 103 APT reports not in the annotated database and the 23 APT reports from the training set. We group together low-frequency words that appear 4 or less times in the set of 126 APT reports into one cluster and during testing we assign new words into this cluster.

Results: Table 3 demonstrates that Approach 2 outperforms Approach 1 on most scores. Nevertheless, both approaches still give low performance for tackling Task 2 with F_1-scores below 50 points.

Discussion: There seem to be three main categories of wrong predictions:

1. Sentences describing attacker actions

Such sentences are also a main source of prediction errors in Task 1. Again, most sentences describing attackers are deemed irrelevant and left unannotated because we focus on malware actions rather than human attacker actions. However, these sentences may be annotated in cases where the attacker's actions imply a malware action or capability.

For example, the Figure 6a describes the attackers stealing credentials. This implies that the malware used is capable of stealing and exfiltrating credentials. It may be challenging for the model to distinguish whether such sentences describing attackers should be annotated since a level of inference is required.

2. Sentences containing noun-phrases made up of participial phrases and/or prepositional phrases

These sentences contain complex noun-phrases with multiple verbs and prepositions, such as in Figures 6b and 6c. In Figure 6b, "*the RCS sample sent to Ahmed*" is a noun-phrase annotated as a single Subject/Entity. However, the model decomposes the noun-phrase into the subsidiary noun "*the RCS sample*" and participial phrase "*sent to Ahmed*" and further decompose the participial phrase into the constituent words, predicting Action, Modifier and Entity labels for "*sent*", "*to*" and "*Ahmed*" respectively. There are cases where such decomposition of noun-phrases is correct, such as in Figure 6c.

As mentioned in Section 3.7, this is also a challenge for human annotators because there may be several ways to decompose the sentence, many of which serve equally well to highlight certain malware aspects (see Figure 4).

Whether such decomposition is correct depends on the information that can be extracted from the decomposition. For instance, the decomposition in Figure 6c implies that the malware can receive remote commands from attackers. In contrast, the decomposition predicted by the model in Figure 6b does not offer any insight into the malware. This is a difficult task that requires recognition of the phrase spans and the ability to decide which level of decomposition is appropriate.

3. Sentences containing noun-phrases made up of determiners and adjectives

These sentences contain noun-phrases with determiners and adjectives such as "*All the requests*" in Figure 6d. In such cases, the model may only predict the Entity label for part of the noun-phrase. This is shown in Figure 6d, where the model predicts the Entity label for "*the requests*" instead of "*All the requests*".

Thus, we also consider a relaxed scoring scheme where predictions are scored in token level instead of phrase level (see Table 4). The aim of the relaxed score is to give credit to the model when the span for a predicted label intersects with the span for the actual label, as in Figure 6d.

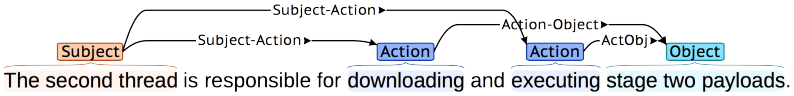

Figure 7: An example of an entity with multiple parents. In this case, *stage two payloads* has two parents by ActionObject relations - *downloading* and *executing*.

5.3 Task 3 - Predict relation labels

Following the prediction of token labels in Task 2, we move on to Task 3 for building a model for predicting relation labels. Due to the low performance of the earlier models for predicting token labels, for this experiment we decided to use the gold token labels as input into the model for predicting relation labels. Nevertheless, the models can still be chained in a pipeline context.

The task initially appeared to be similar to a dependency parsing task where the model predicts dependencies between the entities demarcated by the token labels. However, on further inspection, we realized that there are several entities which have more than one parent entity (see Figure 7). As such, we treat the task as a binary classification task, by enumerating all possible pairs of entities and predicting whether there is a relation between each pair.

Predicting the relation labels from the token labels seem to be a relatively straightforward task and hence we design a simple rule-based model for the predictions. We tuned the rule-based model on one of the documents (*AdversaryIntelligenceReport_DeepPanda_0 (1)*) and tested it on the remaining 38 documents. The rules are documented in Appendix B.

Results: Table 5 shows the scores from testing the model on the remaining 38 documents.

The results from the rule-based model are better than expected, with the average F_1-scores exceeding 84 points for all the labels. This shows that the relation labels can be reliably predicted given good predictions of the preceding token labels.

Discussion: The excellent performance from the rule-based model suggests that there is a well-defined structure in the relations between the entities. It may be possible to make use of this inherent structure to help improve the results for predicting the token labels.

Also, notice that by predicting the SubjAction, ActionObj and ActionMod relations, we are simultaneously classifying the ambiguous Entity labels into specific Subject and Object labels. For instance, Rule 1 predicts a ModObj relation between a Modifier and an Entity, implying that the Entity is an Object, whereas Rule 3 predicts a SubjAction relation between an Entity and an Action, implying that the Entity is a Subject.

Attribute Category	NB			SVM		
	P	R	F_1	P	R	F_1
ActionName	35.2	23.9	28.0	43.9	27.9	33.9
Capability	41.5	39.8	40.6	42.5	41.1	41.8
StrategicObjectives	33.7	24.4	28.3	32.2	23.5	27.2
TacticalObjectives	27.6	17.4	21.1	30.2	18.4	22.7

Table 6: Task 4 scores: predicting attribute labels.

5.4 Task 4 - Predict attribute labels

A significant obstacle in the prediction of attribute labels is the large number of attribute labels available. More precisely, we discover that many of these attribute labels occur rarely, if not never, in the annotated reports. This results in a severely sparse dataset for training a model.

Due to the lack of substantial data, we decide to use *token groups* instead of entire sentences for predicting attribute labels. Token groups are the set of tokens that are linked to each other via relation labels. We extract the token groups from the gold annotations and then build a model for predicting the attribute labels for each token group. Again, we use a bag-of-words model to represent the token groups while SVM and NB are each used to build a model for predicting attribute labels.

Results: Table 6 shows the average scores over 5 runs for the four separate attribute categories. For this task, SVM appears to perform generally better than NB, although much more data seems to be required in order to train a reliable model for predicting attribute labels. The Capability category shows the best performance, which is to be expected, since the Capability attributes occur the most frequently.

Discussion: The main challenge for this task is the sparse data and the abundant attribute labels available. In fact, out of the 444 attribute labels, 190 labels do not appear in the database. For the remaining 254 attribute labels that do occur in the database, 92 labels occur less than five times and 50 labels occur only once. With the sparse data

Features Used	NB			SVM		
	P	R	F_1	P	R	F_1
Text only	58.8	50.8	53.5	49.3	47.0	47.2
Ann. only	64.7	55.0	58.0	62.6	57.2	59.2
Text and Ann.	59.3	50.7	53.6	54.3	51.1	51.6

Table 7: Task 5 scores: predicting malware signatures using text and annotations.

available, particularly for rare attribute labels, effective one-shot learning models might have to be designed to tackle this difficult task.

5.5 Task 5 - Predict malware signatures using text and annotations

Conventional malware analyzers, such as malwr.com, generate a list of signatures based on the malware's activities in a sandbox. Examples of such signatures include *antisandbox_sleep*, which indicates anti-sandbox capabilities or *persistence_autorun*, which indicates persistence capabilities.

If it is possible to build an effective model to predict malware signatures based on natural language texts about the malware, this can help cybersecurity researchers predict signatures of malware samples that are difficult to obtain, using the malware reports freely available online.

By analyzing the hashes listed in each APT report, we obtain a list of signatures for the malware discussed in the report. However, we are unable to obtain the signatures for several hashes due to restricted distribution of malware samples. There are 8 APT reports without any obtained signatures, which are subsequently discarded for the following experiments. This leaves us with 31 out of 39 APT reports.

The current list of malware signatures from Cuckoo Sandbox[3] consists of 378 signature types. However, only 68 signature types have been identified for the malware discussed in the 31 documents. Furthermore, out of these 68 signature types, 57 signature types appear less than 10 times, which we exclude from the experiments. The experiments that follow will focus on predicting the remaining 11 signature types using the 31 documents.

The OneVsRestClassifier implementation in scikit-learn is used in the following experiments, since this is a multilabel classification problem. We also use SVM and NB to build two types of models for comparison.

Three separate methods are used to generate features for the task: a) the whole text in each APT report is used as features via a bag-of-words representation, without annotations, b) the gold labels from the annotations are used as features, without the text, and c) both the text and the gold annotations are used, via a concatenation of the two feature vectors.

Results: Comparing the first two rows in Table 7, we can see that using the annotations as features significantly improve the results, especially the precision. SVM model also seems to benefit more from the annotations, even outperforming NB in one case.

Discussion: The significant increase in precision suggests that the annotations provide a condensed source of features for predicting malware signatures, improving the models' confidence. We also observe that some signatures seem to benefit more from the annotations, such as *persistence_autorun* and *has_pdb*. In particular, *persistence_autorun* has a direct parallel in attribute labels, which is *MalwareCapability-persistence*, showing that using MAEC vocabulary as attribute labels is appropriate.

6 Conclusion

In this paper, we presented a framework for annotating malware reports. We also introduced a database with 39 annotated APT reports and proposed several new tasks and built models for extracting information from the reports. Finally, we discuss several factors that make these tasks extremely challenging given currently available models. We hope that this paper and the accompanying database serve as a first step towards NLP being applied in cybersecurity and that other researchers will be inspired to contribute to the database and to construct their own datasets and implementations. More details about this database can be found at `http://statnlp.org/research/re/`.

A Attribute Labels

The following elaborates on the types of malware actions described by each class of attribute labels and gives specific examples.

A.1 ActionName

The ActionName labels describe specific actions taken by the malware, such as downloading a file *ActionName: 090: Network- download_ file* or creating a registry key *ActionName: 135: Registry-create_registry_key*.

A.2 Capability

The Capability labels describe general capabilities of the malware, such as exfiltrating stolen data *Capability: 006: MalwareCapability-data_exfiltration* or spying on the victim *Capability: 019: MalwareCapability-spying*.

A.3 StrategicObjectives

The StrategicObjectives labels elaborate on the Capability labels and provide more details on the capabilities of the malware, such as preparing stolen data for exfiltration *StrategicObjectives: 021: DataExfiltration-stage_data_for_exfiltration* or capturing information from input devices connected to the victim's machine *StrategicObjectives: 061: Spying-capture_system_input_peripheral_data*.

Each StrategicObjectives label belongs to a Capability label.

A.4 TacticalObjectives

The TacticalObjectives labels provide third level of details on the malware's capability, such as encrypting stolen data for exfiltration *TacticalObjectives: 053: DataExfiltration-encrypt_data* or an ability to perform key-logging *TacticalObjectives: 140: Spying-capture_keyboard_input*.

Again, each TacticalObjectives label belongs to a Capability label.

B Rules for Rule-based Model in Task 3

The following are the rules used in the rule-based model described in Section 5.3.

1. If a Modifier is followed by an Entity, a ModObj relation is predicted between the Modifier and the Entity
2. If an Action is followed by an Entity, an ActionObj relation is predicted between the Action and the Entity
3. If an Entity is followed by an Action of token-length 1, a SubjAction relation is predicted between the Entity and the Action
4. An ActionObj relation is predicted between any Action that begins with *be* and the most recent previous Entity
5. An ActionObj relation is predicted between any Action that begins with *is*, *was*, *are* or *were* and ends with *-ing* and the most recent previous Entity
6. An ActionMod relation is predicted between all Modifiers and the most recent previous Action

A Corpus of Annotated Revisions for Studying Argumentative Writing

Fan Zhang **Homa B. Hashemi** **Rebecca Hwa** **Diane Litman**
University of Pittsburgh
Pittsburgh, PA, 15260
{zhangfan,hashemi,hwa,litman}@cs.pitt.edu

Abstract

This paper presents ArgRewrite, a corpus of between-draft revisions of argumentative essays. Drafts are manually aligned at the sentence level, and the writer's purpose for each revision is annotated with categories analogous to those used in argument mining and discourse analysis. The corpus should enable advanced research in writing comparison and revision analysis, as demonstrated via our own studies of student revision behavior and of automatic revision purpose prediction.

1 Introduction

Most writing-related natural language processing (NLP) research focuses on the analysis of single drafts. Examples include document-level quality assessment (Attali and Burstein, 2006; Burstein and Chodorow, 1999), discourse-level analysis and mining (Burstein et al., 2003; Falakmasir et al., 2014; Persing and Ng, 2016), and fine-grained error detection (Leacock et al., 2010; Grammarly, 2016). Less studied is the analysis of changes *between drafts* – a comparison of revisions and the properties of the differences. Research on this topic can support applications involving revision analysis (Zhang and Litman, 2015), paraphrase (Malakasiotis and Androutsopoulos, 2011) and correction detection (Swanson and Yamangil, 2012; Xue and Hwa, 2014).

Although there are some corpora resources for NLP research on writing comparisons, most tend to be between individual sentences/phrases for tasks such as paraphrase comparison (Dolan and Brockett, 2005; Tan and Lee, 2014) or grammar error correction (Dahlmeier et al., 2013; Yannakoudakis et al., 2011). In terms of revision analysis, the most relevant work analyzes Wikipedia revisions (Daxenberger and Gurevych, 2013; Bronner and Monz, 2012); however, the domain of Wikipedia is so specialized that the properties of Wikipedia revisions do not correspond well with other kinds of texts.

This work presents the ArgRewrite corpus[1] to facilitate revision analysis research for argumentative essays. The corpus consists of a collection of three drafts of essays written by university students and employees; the drafts are manually aligned at the sentence level, then the purpose of each revision is manually coded using a revision schema closely related to argument mining/discourse analysis. Within the domain of argumentative essays, the corpus will be useful for supporting research in argumentative revision analysis and the application of argument mining techniques. The corpus may also be useful for research on paraphrase comparisons, grammar error correction, and computational stylistics (Popescu and Dinu, 2008; Flekova et al., 2016). In this paper, we present two example uses of our corpus: 1) rewriting behavior data analysis, and 2) automatic revision purpose classification.

2 Corpus Design Decisions

Consider this scenario: Alice begins her social science argumentative essay with the sentence "Electronic communication allows people to make connections beyond physical limits."

An analytical system might (rightly) identify the sentence as the thesis of her essay, and an evaluative system might give the essay a low score due to this sentence's vagueness and a later lack of evidence (though Alice may not know why she received that score).

Now suppose in a revised draft, Alice expanded

[1]The corpus is based on the ArgRewrite system developed in our prior work (Zhang et al., 2016).

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1568–1578
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1144

the sentence: "Electronic communication allows people to make connections beyond physical ~~lim-its~~ *location and enriches connections that would have been impossible to make otherwise.*"

An analytical system would still identify the sentence as the thesis, and an evaluative system might raise the overall score a little higher. Alice may become satisfied with the increase and move on. However, there is an opportunity lost – neither the analytical nor the evaluative system addressed the quality of her revision.

A revision analysis system might be helpful for Alice because it would link "limits" to "location and ..." and identify the reason why she made the change – perhaps *adding precision.* If Alice had intended her change as a way to add evidential support for her thesis, she would see that her attempt was not as successful as she hoped.

The above scenario highlights the application of a revision analysis system. This paper is about creating a corpus to enable the development of such systems. Because this is a relatively new problem, there are many possible ways for us to design the corpus. Here we discuss some of our decisions.

First, we need to define the unit of revision. The example above illustrates a phrase-aligned revision. While this offers a fairly precise definition of the scope of a revision, it may be difficult to achieve consistent annotations. For example, the changes may not adhere to any syntactic linguistic unit. For this first corpus, we define our unit of revision to be at the sentence level. In other words, even if a pair of sentences contains multiple edits, the entire sentence pair will be annotated as one sentence revision.

Second, we need to define the quality we want to observe about the revision sentence pair. For this first corpus, we focus on recognizing the purpose of the revision, as in the example above. It is a useful property, and it has previously been studied by others in the literature. People have considered both binary purpose categories such as Content vs. Surface (Faigley and Witte, 1981) or Factual vs. Fluency (Bronner and Monz, 2012) as well as more fine-grained categories (Pfeil et al., 2006; Jones, 2008; Liu and Ram, 2009; Daxenberger and Gurevych, 2012; Zhang and Litman, 2015). Our corpus follows the two-tiered schema used by (Zhang and Litman, 2015) (see Section 3.2).

Third, we not only have to decide on the annotation format, we also need to decide how to obtain

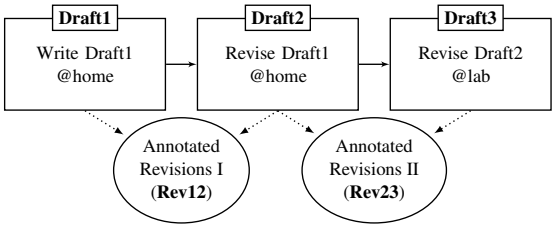

Figure 1: Our collected corpus contains five components: three drafts of an essay and two annotated revisions between drafts.

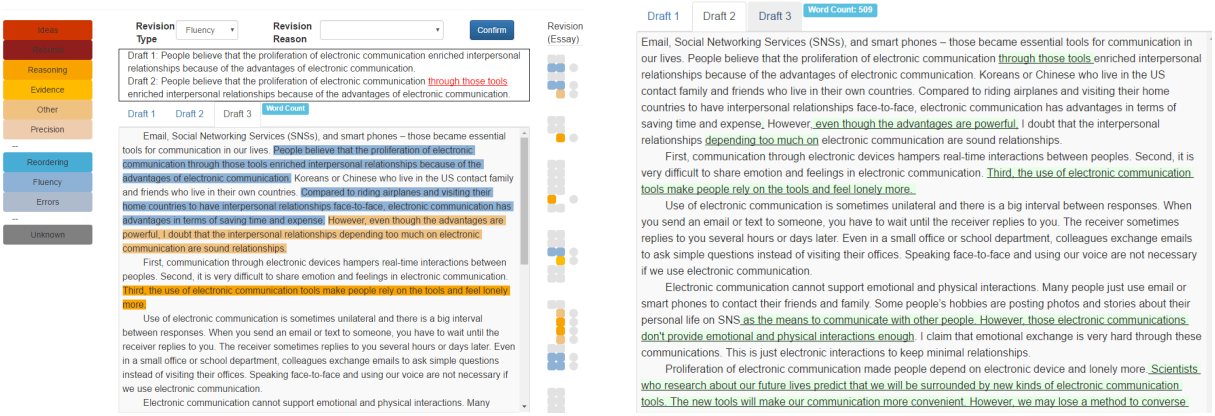
the raw text: argumentative essays with multiple drafts. We decided to sample from a population of predominantly college students, inclusive of both native and proficient non-native (aka L2) speakers. Comparing to high school students, college students are expected to produce essays having a better organization of the argument elements. Including native and L2 speakers allows for the exploration of possible rewriting differences between writers of varying backgrounds. We decided to give all subjects the same writing prompt and collect three drafts. The identical prompt minimizes the impact of topic difference for argumentation-related study. The collection of three drafts allows for a comparison of revision differences at different stages of rewriting.

Finally, we need a method for eliciting two revised drafts from each writer. Ideally, an instructor would give formative feedback after each draft for each student, but we do not have the resources to carry out such an expensive project. We simulate instructor feedback by asking students to add more examples after the first draft. To elicit a second revised draft, we use two different systems. First, we utilize an idealized[2] version of the ArgRewrite revision analysis system (Zhang et al., 2016). ArgRewrite highlights the locations of revisions at the sentence level and colors the revisions differently according to the revision purpose types. Our second system shows a character-based comparison between subsequent essay drafts[3]. This system is designed to have a similar look as ArgRewrite by highlighting the location of revisions. However, the type of revisions are not provided.

[2]All automatic revision feedback was manually examined/corrected to guarantee correctness.

[3]Code derived from https://code.google.com/p/google-diff-match-patch/ which implements Myers' algorithm (Myers, 1986).



(a) Interface A. (b) Interface B.

Figure 2: Screenshot of the interfaces. (a) *Interface A* with the annotated revision purposes, (b) *Interface B* with a streamlined character-based diff.

3 The ArgRewrite Corpus

Based on the above design decisions, we have developed a corpus of argumentative essays with three drafts and detailed annotations for sentence-aligned revisions between each consecutive pair of drafts. The main corpus has five elements, with the relationships between them shown in Figure 1; Section 3.1 describes the procedure for obtaining them. Section 3.2 briefly describes the revision schema we used and reports the inter-annotator agreement. Additionally, we have collected meta-data from the participants who contributed to the corpus (discussed in Section 3.3); these data may be useful for user behavior analysis.

3.1 Corpus Development Procedure

We have recruited 60 participants aged 18 years and older, among whom 40 were English native speakers and 20 were non-native speakers with sufficient English proficiency.[4] The study to collect the corpus is carried out in three 40-60 minute sessions over the duration of two weeks.

Draft1 Each participant begins by completing a pre-study questionnaire (Section 3.3) and writing a short essay online. Participants are instructed to keep the essay around 400 words, making a single main point with two supporting examples. They are given the following prompt:

> *"Suppose you've been asked to contribute a short op-ed piece for The New York Times. Argue whether the proliferation of electronic communications (e.g., email, text or other social media) enriches or hinders the development of interpersonal relationships."*

Draft2 A few days later, participants are asked to revise their first draft online based on the following feedback: *Strengthen the essay by adding one more example or reasoning for the claim; then add a rebuttal to an opposing idea; keep the essay at 400 words.* With this feedback we try to push participants to make revisions for later processing by the two interfaces used to create Draft3.

Annotated Revisions I (Rev12) The two drafts are semi-manually aligned at the sentence level.[5] Then, the purpose of each pair of sentence revision is manually coded by a trained annotator, following the annotation guideline (see Section 3.2).

Draft3 Participants write their third draft in a lab environment. This time, they are not given additional instructional feedback. Instead, participants are shown a computer interface that highlights the differences between their first and second drafts. They are asked to revise and create a third draft to improve the general quality of their essay. We experimented with two variations of revision elicitation. Chosen at random, half of the participants (10 L2 participants and 20 Native participants) are shown Interface A, the interface based on the ArgRewrite system (Zhang et al., 2016), which highlights the annotated differences between the drafts (Figure 2(a)); half of the participants are shown In-

[4] i.e., with a TOEFL score higher than 100.

[5] Sentences are first automatically aligned (Zhang and Litman, 2014), then manually corrected by human.

Draft1	Revision Purpose	Draft2	Revision Purpose	Draft3
This world has no restriction on who one can talk to.	Conventions/ Grammar/ Spelling	This world has no restrictions on whom one can talk to.		This world has no restrictions on whom one can talk to.
			Rebuttal/ Reservation	Unfortunately, the younger users of digital communication cannot be entirely protected from the rhetoric of any outsider.
			Warrant/ Reasoning/ Backing	Modern society is now faced with the issue of cyber bullying as a result.
The only aspects of communication that this new development improves are internet navigation and faux internet relatability.	Word-Usage/ Clarity	The only aspects of digital communication that this new development improves are internet navigation and faux internet relatability.	Word-Usage/ Clarity	The only aspects of digital communication that this new development improves are internet navigation and faux internet relationships.
	Claims/ Ideas	Being immersed in the sphere of new technologies can allow for complete isolation from the active, non-digital world.		Being immersed in the sphere of new technologies can allow for complete isolation from the active, non-digital world.

Table 1: Examples from the annotated corpus. The sentences were aligned across the drafts and the revision purposes were labeled on the aligned sentence pairs. From Draft1 to Draft2, there are two *Modify* revisions (*Spelling* and *Clarity*) and one *Add* revision. From Draft2 to Draft3, there are two *Add* revisions (*Rebuttal* and *Reasoning*) and one *Modify* revision (*Clarity*).

terface B, a streamlined character-based diff (Figure 2(b)). In Interface A, some purposes were renamed from the original annotation categories to help the participants better understand the system (as detailed in Table 2)[6]. Both interface groups are asked to read a tutorial about their respective interfaces before beginning to revise. Participants in group A are also asked to verify the manually annotated revision purposes between their first and second drafts. This information is collected to investigate the impact of the difference between the system's recognized and the participant's intended purpose. After completing the final revision, all participants are given a post-study survey about their experiences (Section 3.3). Additionally, participants in group A are asked to verify the automatically predicted revision purposes between their second and third drafts (Section 4.2).

Annotated Revisions II (Rev23) Regardless of which interface the participants used, the second and third draft are compared and annotated by the trained annotator in the same process as before.

[6]Figure 2(a) has two additional categories. Precision was intended to represent revisions that make a sentence more precise. Unknown was intended to represent revisions that cannot be categorized to existing categories. These two categories were not used during annotation as they were reported to be confusing in our pilot studies.

3.2 Revision Annotation Guidelines

Following our prior corpus annotations (Zhang and Litman, 2015), sentence revisions are first coarsely categorized as *Surface* or *Content* changes (Faigley and Witte, 1981), depending on whether any informational content was modified; within each coarse category, we distinguish between several finer categories based on the argumentative and discourse writing literature (Kneupper, 1978; Faigley and Witte, 1981; Burstein et al., 2003). Our adapted schema has three *Surface* categories (Organization, Word Usage/Clarity, and Conventions/Grammar/Spelling) and five *Content* categories (Claim/Ideas, Warrant/Reasoning/Backing, Rebuttal/Reservation, Evidence, and General Content Development). Table 1 shows example aligned sentences in three collected drafts and their annotated revision categories. The edit types of revisions (Add, Delete and Modify) are decided according to the alignment of sentences.

Two annotators (one is experienced, and the other is newly trained) participated in data annotation. The annotators first went through a "training" phase where both annotators annotated 5 files and discussed their disagreements to resolve misunderstandings. Then, both annotators separately annotated 10 new files and Kappa was calculated

Name in Schema	Name in System	Definition
Content	Content	revisions that changed the information of essay
Claims/Ideas	Ideas	revisions that aimed to change the thesis of essay
Warrant/Reasoning/Backing	Reasoning	revisions that aimed to change the reasoning of thesis
Rebuttal/Reservation	Rebuttal	revisions that aimed to change the rebuttal of thesis
Evidence	Evidence	revisions that aimed to change the evidence support for thesis
General Content	Other	other types of content revisions
Surface	Surface	revisions that did not change the information of essay
Organization	Reordering	revisions that switched the order of sentences
Word Usage/Clarity	Fluency	revisions that aimed to make the essay more fluent
Conventions/Grammar/Spelling	Errors	revisions that aimed to fix the spelling/grammar mistakes

Table 2: Definition of category names in Interface A.

L2 (20)	Draft1	Draft2	Draft3
Avg #Words	379.1	412.8	484.7
Avg #Sentences	18.6	20.2	23.7
Avg #Paragraphs	3.9	4.5	4.8
Native (40)	Draft1	Draft2	Draft3
Avg #Words	372.4	394.7	531.6
Avg #Sentences	18.8	20.4	25.8
Avg #Paragraphs	4.0	4.7	5.1

Table 3: Descriptive statistics of the ArgRewrite Corpus, including average number of words, sentences and paragraphs per essay draft.

on the annotation of these 10 new files. The Kappa on this held-out data is 0.84 on the two coarse categories of *Surface* vs. *Content* and 0.71 on the eight fine-grained categories that appear in Table 2. The disagreements between annotators were removed after discussion and the final labels were used as the gold standard annotation.

3.3 Meta-Data

In addition to the raw text and annotations, the corpus release includes participant meta-data from both a pre-study and a post-study survey.

Pre-Study Survey The pre-study survey asks for participants' demographic information as well as their self-reported writing background, such as participants' confidence in their writing ability, the number of drafts they typically make, etc. The questions are listed in Appendix A.

Post-Study Survey The post-study survey contains questions about the participants' in-lab revision experience, such as whether they found the computer interface helpful. All questions are answered on a scale of 1 to 5, ranging from "strongly disagree" to "strongly agree". Details of questions are shown in Appendix B.

3.4 Descriptive Statistics

Table 3 indicates the average number of words/sentences/paragraphs per essay draft. The corpus includes 180 essays: 120 (Draft1 and Draft2) with an average of about 400 words and 60 (Draft3) with an average of around 500 words.

Among the 40 native speakers, there were 29 (72.5%) undergraduates, 6 (15%) graduate students, and 5 (12.5%) non-students (post-docs and lecturers). Among the 20 L2 speakers, there were 4 (20%) undergraduates, and 16 (80%) graduate students; there were 9 Chinese, 2 Bengali, 2 Marathi, 2 Persian, 1 Arabic, 1 Korean, 1 Portuguese, 1 Spanish, and 1 Tamil. In terms of discipline, 33 participants (55%) were from the natural sciences, 24 (40%) from the social sciences, and 2 (3.3%) from the humanities. 1 participant (1.7%) did not reveal his/her discipline.

3.5 Public Release

The corpus is freely available for research usage[7]. The first release includes the raw text plus the revision annotations and the meta-data. The revision annotations are stored as .xlsx files. There are 60 spreadsheet files for revisions from Draft1 to Draft2 and 60 more spreadsheet files for revisions from Draft2 to Draft3. Each spreadsheet file contains two sheets: Old Draft and New Draft. Each row in the sheet represents one sentence in the corresponding draft. The index of the aligned sentence row in the other draft and the type of the revision on the sentence are recorded. The meta-data are in .log text files. Information in the text files are stored using the JSON data format.

4 Example Uses of the Corpus

While the development of a full fledged revision analysis system is outside the scope of this work, we demonstrate potential uses of our corpus with two examples. We first perform statistical analyses on the collected revision data and meta-data

Interface B	81	41	92	91
Native (40)	334	285	303	246
Interface A	177	154	149	111
Interface B	157	131	154	135

Table 4: Number of revisions, by participant groups (language, interface), coarse-grain purposes, and revision drafts (Rev12 is between Draft1-Draft2; Rev23 is between Draft2-Draft3).

to understand aspects of participant behavior. We also use the corpus to train a supervised classifier to automatically predict revision purposes.

4.1 Student Revision Behavior Analysis

While it is well-established that thoughtful revisions improve one's writing, and while many college-level courses require students to submit multiple drafts of writing assignments (Addison and McGee, 2010), instructors rarely monitor and provide feedback to students while they revise. This is partly due to instructors' time constraints and partly due to their uncertainty about how to support students' revisions (Cole, 2014; Melzer, 2014). There is much we do not know about how to stimulate students to self-reflect and revise.

4.1.1 Hypotheses

Using the ArgRewrite Corpus, we can begin to ask and address some questions about revision habits and behaviors. Our first question is: How do different types of revision feedback impact student revision? And relatedly: Does student background (e.g., native vs. L2) make a difference? We thus mine the corpus to test the following hypotheses:

H1. There is a difference in participants' revising behaviors depending on which interface is used to elicit the third draft.

H2. For participants who used Interface A, if the recognized revision purpose differs from the participants' intended revision purpose, participants will further modify their revision.

H3. L2 and native speakers have different behaviors in making revisions.

H1 and **H2** address the first question; **H3** addresses the second.

4.1.2 Methodology

To test the hypotheses, we will use both subjective and objective measures. Subjective measures are based on participant post-study survey answers. Ideally, objective measures should be based on an assessment of improvements in the revised drafts; since we do not have evaluative data at this time, we approximate the degree of improvement using the number of revisions, since these two quantities were demonstrated to be positively correlated (Zhang and Litman, 2015). The objective measures are computed from Tables 4 and 5.

To compare differences between specific subgroups on the subjective and objective measures, we conduct ANOVA tests with two factors. There are multiple factors that can influence the users' rewriting behaviors such as the user's native language, education level and previous revision behaviors, etc. In our study, we try to explore the difference between interface groups considering one of the most salient confounding factors: language. We use one factor as the participant's native language (whether the participant is native or L2) and the other factor as the interface used. To determine correlation between quantitative measures, we conduct Spearman (ρ) and Pearson (r) correlation tests.

4.1.3 Results and Discussion

Testing for H1 Comparing Group A and Group B participants, we observe some differences. First, we detect that Group A agrees with the statement "The system helps me to recognize the weakness of my essay" more so than Group B (Group A has a mean rating of 3.97 ("Agree") while Group B's is 3.17 ("Neutral"), $p < .003$). Second, in Group A, there is a trending positive correlation between the number of revisions[8] from Draft2 to Draft3 and the ratings for the statement "The system encourages me to make more revisions than I usually make" (ρ=.33 and $p < .07$); whereas there is no such correlation for Group B. Additional information about revision purposes may elicit a stronger self-reflection response in Group A participants. In contrast, in Group B, there is a significant negative correlation between the number of Rev12 and ratings for the statement "it is convenient to view my previous revisions with the system" (ρ=-.36 and $p < .05$). This suggests that the character-based interface is ineffective when participants have to reflect on many changes.

[8]The results reported are the normalized numbers $\frac{\#revisions}{\#sentences}$, where #sentences represents the number of sentences in the draft before revision. The absolute numbers were also tested and similar findings were observed.

Revision Purpose	Draft1 to Draft2			Draft2 to Draft3			Totals
	#Add	#Delete	#Modify	#Add	#Delete	#Modify

Organization	0	0	29	0	0	13	42

Table 5: Number of revisions, by fine-grain revision purposes and edit types (add, delete, modify).

On the other hand, when comparing the number of revisions made by Group A and Group B on Rev23 (controlling for their Rev12 numbers), we did not find a significant difference.

As we did not observe a significant difference in the number of revisions made by the two interface groups, we cannot verify that **H1** is true; possibly a larger pool of participants is needed, or possibly the writing assignment is not extensive enough (in length and in the number of drafts). Another possible explanation is that the system might only motivate the users to make more revisions when the feedback is different from the user's intention. To further verify the correctness of H1, we plan to have the essays graded by experts. The graded scores could allow us to analyze whether essays improved more when Interface A was used.

Testing for H2 Focusing on the 30 participants from Group A, we check the impact of the feedback regarding Rev12 on how they subsequently revise (Rev23). We counted the *Add* and *Modify* revisions where the participant disagrees with the revision purpose assigned by the annotator in Rev12. Of those, we then count the number of times the corresponding sentences were further revised[9]. Of the 53 sentences where the participants disagreed with the annotator, 45 were further revised in the third draft. The ratio is 0.849, much higher than the overall ratio of general Rev12 revisions being further revised in Rev23 (161/394 = 0.409) and the ratio of the agreed Rev12 revisions being revised in Rev23 (67/341 = 0.196). In further analysis, a Pearson correlation test is conducted to check the correlation between the number of Rev23 and the number of disagreements for different types of agreement/disagreements, controlling for the number of Rev12. We find a negative correlation between Rev23 and the number of cases (r=-0.41, $p < .03$) in which the revisions annotated as *Content* are verified by the participants; we also find a positive correlation between Rev23 and the number of cases (r=0.36, $p <= .05$) in which the revisions annotated as *Surface* are intended to be *Content* revisions by the participants. Both findings are consistent with **H2**, suggesting that participants will revise further if they perceive that their intended revisions were not recognized.

Testing for H3 We observe that native and L2 speakers exhibit different behaviors. First, we tested the difference in Content23 and Surface23[10] between these speaker groups with ANOVA. We observe significant difference in the number of content ($p < .02$) and surface ($p < .03$) revisions made by L2 and native speakers. More specifically, our native speakers make more *Content* changes while the L2 speakers make more *Surface* changes. Second, with ANOVA we found a significant interaction effect of the two factors (Group and users' L2 or native status) ($p < .021$) on their ratings for the statement "the system helps me to recognize the weakness of my essay" with L2 speakers having a stronger Interface A preference. Third, we observe a significant positive correlation in the native group between the number of content revisions in Rev23 and the ratings of the statement "the system encourages me to make more revisions than I usually make" (ρ=.4 and $p < .009$). This suggests that giving feedback (from either interface) encourages native speakers to make more content revisions. Finally, in the L2 group, there is a significant negative correlation between the number of surface revisions in Rev12 and the ratings for the statement "the system helps me to recognize the weakness of my es-

[9] *Delete* revisions were ignored as the deleted sentences are not traceable in Draft3

[10] content/surface revisions from Draft2 to Draft3

say" (ρ=-.57 and $p < .008$). This shows that giving feedback to L2 speakers is less helpful when they make more surface revisions. These results are consistent with **H3**.

Summary Our findings suggest that feedback on revisions do impact how students review and rewrite their drafts. However, there are many factors at play, including the interface design and the students' linguistic backgrounds.

4.2 Automatic Revision Identification

Another use of the corpus is to serve as a gold standard for training and testing a revision purpose prediction component for use in an automatic revision analysis system. In the version of ArgRewrite evaluated earlier (Interface A), the manual annotation of revision purposes enabled the system to provide revision feedback to users, which motivated them to improve their writing (**H2**). Automatic argumentative revision purpose prediction has been previously investigated by Zhang and Litman (2015). They developed and reported the performance of a binary classifier for each individual revision category (1 for revisions of the category and 0 for the rest of all revisions) using features from prior research. The availability of our corpus makes it possible for researchers to replicate such methods and conduct further studies.

4.2.1 Hypotheses

In this paper, we repeat the experiment of Zhang and Litman (2015) under different settings to investigate three new hypotheses that can now be investigated given the features of our corpus:

H4. The method used in Zhang and Litman (2015) for high school writings is also useful for the writings of college students.

H5. The same revision classification method works differently for first revision attempts and second revision attempts.

H6. The revision classification model trained on L2 essays has a different preference from the model trained on native essays.

4.2.2 Methodology

We followed the work of (Zhang and Litman, 2015), where unigram features (words) were used as the baseline and the SVM classifier was used. Besides unigrams, three groups of features used in revision analysis, argument mining and discourse analysis research were extracted (*Location*, *Textual* and *Language*) as in Table 6 (Bronner and Monz, 2012; Daxenberger and Gurevych, 2013; Burstein et al., 2001; Falakmasir et al., 2014).

For **H4**, 10-fold (participant) cross-validation is conducted on all the essays in the corpus. Unweighted average F-score for each revision category is reported, using unigram features versus using all features. Zhang and Litman (2015) observed a significant improvement over the unigram baseline using all the features. If **H4** is true, we should expect a similar improvement over the unigram baseline using our corpus.

For **H5**, 10-fold cross-validation was conducted for the revisions from Draft1 to Draft2 and revisions from Draft2 to Draft3 separately. We compared the improvement ratio brought by the advanced features over the unigram baseline.

For **H6**, we trained two classifiers separately with L2 and native essays with all the features. 20 native participants were first randomly selected as the test data. Afterwards classifiers were trained separately using the 20 L2 participants' essays and the remaining 20 native participants' essays. We would expect that the performance of the two trained classifiers is different on the same test data.

4.2.3 Results and Discussion

The first two rows of Table 7 support **H4**. We observe that the method (SVM + all features) used in Zhang and Litman (2015) significantly improves performance (compared to a unigram baseline) for half of the classification tasks, which is similar to Zhang and Litman's results on high school (primarily L1) writing. In our corpus, performance on *Claim*, *Evidence*, *Rebuttal* and *Organization* was not significantly better than the baseline, possibly due to the limited number of positive training samples for these categories (Table 5). For example, one reason that the performance in Table 7 for *Evidence* might be low is that there are less than 100 Evidence instances in Table 5.

For **H5**, the four rows in the middle of Table 7 show the difference of the cross-validation results on first attempt revisions and second attempt revisions. The earlier results using all the revisions, versus now just using only Rev12 or Rev23 revisions are similar, which provides little support for **H5**. With one exception, the features proposed in Zhang and Litman (2015) could again significantly improve the performance over the unigram baseline, for the same set of categories as when using all the revisions. However, for the *Conventions/Grammar/Spelling* category, we did not ob-

Group	Illustration
Location	The location of revised sentences in the paragraph/essay (e.g., whether the sentence is the first or last sentence of the paragraph/essay, the index of the sentence in the paragraph)
Textual	The textual features of revised sentences (e.g., whether the sentence contains a named entity, certain discourse markers ("because", "due to", etc), sentence difference (edit distance, difference in punctuations, etc.) and edit types (Add, Delete or Modify))
Language	The language features of revised sentences (e.g., difference in POS tags, spelling/grammar mistakes)

Table 6: Illustration of features used in the revision classification study.

Experiments	Text-based					Surface		
	Claim	Warrant	General	Evidence	Rebuttal	Org.	Word	Conv
10fold + All Revs + Unigram	0.49	0.58	0.48	0.49	0.49	0.49	0.73	0.49
10fold + All Revs + All features	0.49	0.77∗	0.55∗	0.50	0.49	0.49	0.86∗	0.62∗
10fold + Rev12 + Unigram	0.50	0.58	0.47	0.50	0.50	0.50	0.57	0.62
10fold + Rev12 + All features	0.50	0.77∗	0.56∗	0.50	0.50	0.50	0.72∗	0.72∗
10fold + Rev23 + Unigram	0.50	0.46	0.53	0.49	0.50	0.50	0.58	0.46
10fold + Rev23 + All features	0.50	0.60∗	0.65∗	0.49	0.50	0.50	0.78∗	0.50
20 L2 (train) + 20 Native (test)	0.50	0.72	0.48	0.49	0.50	0.50	0.83	**0.63**
20 Native (train) + 20 Native (test)	0.50	**0.76**	**0.52**	0.49	0.50	0.50	**0.89**	0.54

Table 7: Average unweighted F-score for each binary classification task. The first 6 rows show the average value of 10-fold cross-validation. $*$ indicates significantly better than unigram baseline ($p < .05$). The last 2 rows show the F-value for training on L2/Native data and testing on Native data. **Bold** indicates larger than the number in the other row.

serve a significant improvement for revisions from Draft2 and Draft3. A possible explanation is that there is a bigger difference in the writers' rewriting behavior from Draft2 to Draft3, which increases the difficulty of prediction.

The last two rows of Table 7 support **H6**. Interestingly, we observe a better performance on *Warrant*, *General* and *Word Usage/Clarity* with a classifier trained and tested using native essays. Perhaps essays of native speakers are more similar to each other when revised along these dimensions. For *Conventions/Grammar/Spelling*, in contrast, the classifier trained on L2 data yields a better performance on the same native test set. This may be because the L2 revisions usually include more spelling/grammar corrections.

5 Conclusion and Future Work

We have presented a new corpus for writing comparison research. Currently the corpus focuses on essay revisions made by both native and L2 college students. In addition to three drafts of essays, we have analyzed the drafts to align semantically similar sentences and to assign revision purposes for each revised aligned sentence pair. We have also conducted two studies to demonstrate the use of the corpus for revision behavior analysis and for automatic revision purpose classification.

While in this paper we explored language as one factor influencing rewriting behavior, our corpus also contains information about other potential factors such as gender and education level which we plan to investigate in the future. We also plan to augment the corpus to support additional types of research on revision analysis. Some potential augmentations include more fine-grained revision categories, revision properties such as statement strength (Tan and Lee, 2014) and quality evaluations, and sub-sentential revision scopes.

Acknowledgments

A Questions of the pre-study survey

1. Is English your native language?
2. (only L2 participants) What is your native language?
3. What is your major? Please select the closest discipline to your major.
    - Natural sciences
    - Social sciences
    - Humanities
4. Are you an undergraduate or graduate student?
5. What is your current year of study?
6. When writing a paper for a class, how many drafts of major revisions do you typically make?
7. Overall, how confident are you with your writings? (Not at all confident, Not very confident, Somewhat confident, confident, Extremely confident)
8. (only L2 participants) Please tell us how comfortable you feel about writing in the English language versus writing in your primary language. (Not at all comfortable, Not very comfortable, Somewhat comfortable, comfortable, Extremely comfortable)
9. What are some of your recent classes that have an intensive writing component to them? How did you do in these classes?
10. What aspects of writing do you think you are good at? e.g. vocabulary choice, clear sentences, writing organization.
11. What aspects of writing do you think you can improve?

B Questions of the post-study survey

1. The system allows me to have a better understanding of my previous revision efforts.
2. It is convenient to view my previous revisions with the system.
3. The system helps me to recognize the weakness of my essay.
4. The system encourages me to make more revisions than I usually make.
5. The system encourages me to think more about making more meaningful changes.
6. Overall the system is helpful to my writing.

Watset: Automatic Induction of Synsets from a Graph of Synonyms

Dmitry Ustalov[†*], **Alexander Panchenko**[‡], **and Chris Biemann**[‡]

Abstract

This paper presents a new graph-based approach that induces synsets using synonymy dictionaries and word embeddings. First, we build a weighted graph of synonyms extracted from commonly available resources, such as Wiktionary. Second, we apply word sense induction to deal with ambiguous words. Finally, we cluster the disambiguated version of the ambiguous input graph into synsets. Our meta-clustering approach lets us use an efficient hard clustering algorithm to perform a fuzzy clustering of the graph. Despite its simplicity, our approach shows excellent results, outperforming five competitive state-of-the-art methods in terms of F-score on three gold standard datasets for English and Russian derived from large-scale manually constructed lexical resources.

1 Introduction

A *synset* is a set of mutual synonyms, which can be represented as a clique graph where nodes are words and edges are synonymy relations. Synsets represent word senses and are building blocks of WordNet (Miller, 1995) and similar resources such as thesauri and lexical ontologies. These resources are crucial for many natural language processing applications that require common sense reasoning, such as information retrieval (Gong et al., 2005) and question answering (Kwok et al., 2001; Zhou et al., 2013). However, for most languages, no manually-constructed resource is available that is comparable to the English WordNet in terms of coverage and quality. For instance, Kiselev et al. (2015) present a comparative analysis of lexical resources available for the Russian language concluding that there is no resource compared to WordNet in terms of coverage and quality for Russian. This lack of linguistic resources for many languages urges the development of new methods for automatic construction of WordNet-like resources. The automatic methods foster construction and use of the new lexical resources.

Wikipedia[1], Wiktionary[2], OmegaWiki[3] and other collaboratively-created resources contain a large amount of lexical semantic information—yet designed to be human-readable and not formally structured. While semantic relations can be automatically extracted using tools such as DKPro JWKTL[4] and Wikokit[5], words in these relations are not disambiguated. For instance, the synonymy pairs (*bank*, *streambank*) and (*bank*, *banking company*) will be connected via the word "bank", while they refer to the different senses. This problem stems from the fact that articles in Wiktionary and similar resources list undisambiguated synonyms. They are easy to disambiguate for humans while reading a dictionary article, but can be a source of errors for language processing systems.

The contribution of this paper is a novel approach that resolves ambiguities in the input graph to perform fuzzy clustering. The method takes as an input synonymy relations between potentially ambiguous terms available in human-readable dictionaries and transforms them into a machine readable representation in the form of disambiguated synsets. Our method, called WATSET, is based on a new local-global meta-algorithm for fuzzy graph clustering. The underlying principle is to discover the word senses based on a *local* graph cluster-

ing, and then to induce synsets using *global* sense clustering. We show that our method outperforms other methods for synset induction. The induced resource eliminates the need in manual synset construction and can be used to build WordNet-like semantic networks for under-resourced languages. An implementation of our method along with induced lexical resources is available online.[6]

2 Related Work

Methods based on resource linking surveyed by Gurevych et al. (2016) gather various existing lexical resources and perform their linking to obtain a machine-readable repository of lexical semantic knowledge. For instance, BabelNet (Navigli and Ponzetto, 2012) relies in its core on a linking of WordNet and Wikipedia. UBY (Gurevych et al., 2012) is a general-purpose specification for the representation of lexical-semantic resources and links between them. The main advantage of our approach compared to the lexical resources is that no manual synset encoding is required.

Methods based on word sense induction try to induce sense representations without the need for any initial lexical resource by extracting semantic relations from text. In particular, word sense induction (WSI) based on word ego networks clusters graphs of semantically related words (Lin, 1998; Pantel and Lin, 2002; Dorow and Widdows, 2003; Véronis, 2004; Hope and Keller, 2013; Pelevina et al., 2016; Panchenko et al., 2017a), where each cluster corresponds to a word sense. An ego network consists of a single node (ego) together with the nodes they are connected to (alters) and all the edges among those alters (Everett and Borgatti, 2005). In the case of WSI, such a network is a local neighborhood of one word. Nodes of the ego network are the words which are semantically similar to the target word.

Such approaches are able to discover homonymous senses of words, e.g., "bank" as slope versus "bank" as organisation (Di Marco and Navigli, 2012). However, as the graphs are usually composed of semantically related words obtained using distributional methods (Baroni and Lenci, 2010; Biemann and Riedl, 2013), the resulting clusters by no means can be considered synsets. Namely, (1) they contain words related not only via synonymy relation, but via a mixture of relations such as synonymy, hypernymy, co-hyponymy, antonymy, etc. (Heylen et al., 2008; Panchenko, 2011); (2) clusters are not unique, i.e., one word can occur in clusters of different ego networks referring to the same sense, while in WordNet a word sense occurs only in a single synset.

In our synset induction method, we use word ego network clustering similarly as in word sense induction approaches, but apply them to a graph of semantically clean synonyms.

Methods based on clustering of synonyms, such as our approach, induce the resource from an ambiguous graph of synonyms where edges a extracted from manually-created resources. According to the best of our knowledge, most experiments either employed graph-based word sense induction applied to text-derived graphs or relied on a linking-based method that already assumes availability of a WordNet-like resource. A notable exception is the ECO approach by Gonçalo Oliveira and Gomes (2014), which was applied to induce a WordNet of the Portuguese language called Onto.PT.[7] We compare to this approach and to five other state-of-the-art graph clustering algorithms as the baselines.

ECO (Gonçalo Oliveira and Gomes, 2014) is a *fuzzy* clustering algorithm that was used to induce synsets for a Portuguese WordNet from several available synonymy dictionaries. The algorithm starts by adding random noise to edge weights. Then, the approach applies Markov Clustering (see below) of this graph several times to estimate the probability of each word pair being in the same synset. Finally, candidate pairs over a certain threshold are added to output synsets.

MaxMax (Hope and Keller, 2013) is a *fuzzy* clustering algorithm particularly designed for the word sense induction task. In a nutshell, pairs of nodes are grouped if they have a maximal mutual affinity. The algorithm starts by converting the undirected input graph into a directed graph by keeping the maximal affinity nodes of each node. Next, all nodes are marked as root nodes. Finally, for each root node, the following procedure is repeated: all transitive children of this root form a cluster and the root are marked as non-root nodes; a root node together with all its transitive children form a fuzzy cluster.

Markov Clustering (MCL) (van Dongen, 2000) is a *hard* clustering algorithm for graphs based on simulation of stochastic flow in graphs.

[6] https://github.com/dustalov/watset

[7] http://ontopt.dei.uc.pt

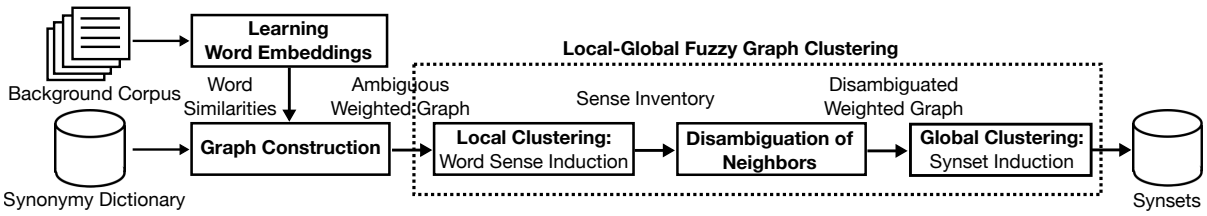

Figure 1: Outline of the WATSET method for synset induction.

MCL simulates random walks within a graph by alternation of two operators called expansion and inflation, which recompute the class labels. Notably, it has been successfully used for the word sense induction task (Dorow and Widdows, 2003).

Chinese Whispers (CW) (Biemann, 2006) is a *hard* clustering algorithm for weighted graphs that can be considered as a special case of MCL with a simplified class update step. At each iteration, the labels of all the nodes are updated according to the majority labels among the neighboring nodes. The algorithm has a meta-parameter that controls graph weights that can be set to three values: (1) *top* sums over the neighborhood's classes; (2) *nolog* downgrades the influence of a neighboring node by its degree or by (3) *log* of its degree.

Clique Percolation Method (CPM) (Palla et al., 2005) is a *fuzzy* clustering algorithm for unweighted graphs that builds up clusters from k-cliques corresponding to fully connected subgraphs of k nodes. While this method is only commonly used in social network analysis, we decided to add it to the comparison as synsets are essentially cliques of synonyms, which makes it natural to apply an algorithm based on clique detection.

3 The WATSET Method

The goal of our method is to induce a set of unambiguous synsets by grouping individual ambiguous synonyms. An outline of the proposed approach is depicted in Figure 1. The method takes a dictionary of ambiguous synonymy relations and a text corpus as an input and outputs synsets. Note that the method can be used without a background corpus, yet as our experiments will show, corpus-based information improves the results when utilizing it for weighting the word graph's edges.

A synonymy dictionary can be perceived as a graph, where the nodes correspond to lexical entries (words) and the edges connect pairs of the nodes when the synonymy relation between them holds. The cliques in such a graph naturally form densely connected sets of synonyms corresponding to concepts (Gfeller et al., 2005). Given the fact that solving the clique problem exactly in a graph is NP-complete (Bomze et al., 1999) and that these graphs typically contain tens of thousands of nodes, it is reasonable to use efficient hard graph clustering algorithms, like MCL and CW, for finding a global segmentation of the graph. However, the hard clustering property of these algorithm does not handle polysemy: while one word could have several senses, it will be assigned to only one cluster. To deal with this limitation, a word sense induction procedure is used to induce senses for all words, one at the time, to produce a disambiguated version of the graph where a word is now represented with one or many word senses. The concept of a disambiguated graph is described in (Biemann, 2012). Finally, the disambiguated word sense graph is clustered globally to induce synsets, which are hard clusters of word senses.

More specifically, the method consists of five steps presented in Figure 1: (1) learning word embeddings; (2) constructing the ambiguous weighted graph of synonyms G; (3) inducing the word senses; (4) constructing the disambiguated weighted graph G' by disambiguating of neighbors with respect to the induced word senses; (5) global clustering of the graph G'.

3.1 Learning Word Embeddings

Since different graph clustering algorithms are sensitive to edge weighting, we consider distributional semantic similarity based on word embeddings as a possible edge weighting approach for our synonymy graph. As we show further, this approach improves over unweighted versions and yields the best overall results.

3.2 Construction of a Synonymy Graph

We construct the synonymy graph $G = (V, E)$ as follows. The set of nodes V includes every lexeme appearing in the input synonymy dictionaries. The set of undirected edges E is composed of all edges

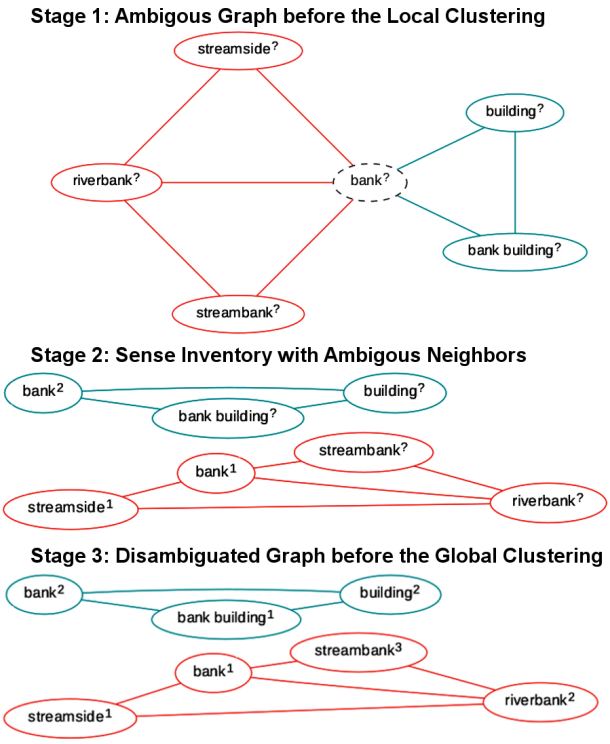

Figure 2: Disambiguation of an ambiguous input graph using local clustering (WSI) to facilitate global clustering of words into synsets.

$(u, v) \in V \times V$ retrieved from one of the input synonymy dictionaries. We consider three edge weight representations:

- **ones** that assigns every edge the constant weight of 1;
- **count** that weights the edge (u, v) as the number of times the synonymy pair appeared in the input dictionaries;
- **sim** that assigns every edge (u, v) a weight equal to the cosine similarity of skip-gram word vectors (Mikolov et al., 2013).

As the graph G is likely to have polysemous words, the goal is to separate individual word senses using graph-based word sense induction.

3.3 Local Clustering: Word Sense Induction

In order to facilitate global fuzzy clustering of the graph, we perform disambiguation of its ambiguous nodes as illustrated in Figure 2. First, we use a graph-based word sense induction method that is similar to the curvature-based approach of Dorow and Widdows (2003). In particular, removal of the nodes participating in many triangles tends to separate the original graph into several connected components. Thus, given a word u, we extract a network of its nearest neighbors from the synonymy graph G. Then, we remove the original word u from this network and run a hard graph clustering algorithm that assigns one node to one and only one cluster. In our experiments, we test Chinese Whispers and Markov Clustering. The expected result of this is that each cluster represents a different sense of the word u, e.g.:

$bank^1$ $\{streambank, riverbank, \dots\}$
$bank^2$ $\{bank\ company, \dots\}$
$bank^3$ $\{bank\ building, building, \dots\}$
$bank^4$ $\{coin\ bank, penny\ bank, \dots\}$

We denote, e.g., bank^1, bank^2 and other items as word senses referred to as $\text{senses}(\text{bank})$. We denote as $\text{ctx}(s)$ a cluster corresponding to the word sense s. Note that the context words have no sense labels. They are recovered by the disambiguation approach described next.

3.4 Disambiguation of Neighbors

Next, we disambiguate the neighbors of each induced sense. The previous step results in splitting word nodes into (one or more) sense nodes. However, nearest neighbors of each sense node are still ambiguous, e.g., ($bank^3$, $building^?$). To recover these sense labels of the neighboring words, we employ the following sense disambiguation approach proposed by Faralli et al. (2016). For each word u in the context $\text{ctx}(s)$ of the sense s, we find the most similar sense of that word $\hat{u}$ to the context. We use the cosine similarity measure between the context of the sense s and the context of each candidate sense u' of the word u:

$$\hat{u} = \arg\max_{u' \in \text{senses}(u)} \cos(\text{ctx}(s), \text{ctx}(u')).$$

A context $\text{ctx}(\cdot)$ is represented by a sparse vector in a vector space of all ambiguous words of all contexts. The result is a disambiguated context $\widehat{\text{ctx}}(s)$ in a space of *disambiguated* words derived from its *ambiguous* version $\text{ctx}(s)$:

$$\widehat{\text{ctx}}(s) = \{\hat{u} : u \in \text{ctx}(s)\}.$$

3.5 Global Clustering: Synset Induction

Finally, we construct the word sense graph $G' = (V', E')$ using the disambiguated senses instead of the original words and establishing the edges between these disambiguated senses:

$$V' = \bigcup_{u \in V} \text{senses}(u), \quad E' = \bigcup_{s \in V'} \{s\} \times \widehat{\text{ctx}}(s).$$

Running a hard clustering algorithm on G' produces the desired set of synsets as our final result. Figure 2 illustrates the process of disambiguation of an input ambiguous graph on the example of the word "bank". As one may observe, disambiguation of the nearest neighbors is a necessity to be able to construct a global version of the sense-aware graph. Note that current approaches to WSI, e.g., (Véronis, 2004; Biemann, 2006; Hope and Keller, 2013), do not perform this step, but perform only local clustering of the graph since they do not aim at a global representation of synsets.

3.6 Local-Global Fuzzy Graph Clustering

While we use our approach to synset induction in this work, the core of our method is the "local-global" fuzzy graph clustering algorithm, which can be applied to arbitrary graphs (see Figure 1). This method, summarized in Algorithm 1, takes an undirected graph $G = (V, E)$ as the input and outputs a set of fuzzy clusters of its nodes V. This is a meta-algorithm as it operates on top of two hard clustering algorithms denoted as $\text{Cluster}_{\text{local}}$ and $\text{Cluster}_{\text{global}}$, such as CW or MCL. At the first phase of the algorithm, for each node its senses are induced via ego network clustering (lines 1–7). Next, the disambiguation of each ego network is performed (lines 8–15). Finally, the fuzzy clusters are obtained by applying the hard clustering algorithm to the disambiguated graph (line 16). As a post-processing step, the sense labels can be removed to make the cluster elements subsets of V.

Algorithm 1 WATSET fuzzy graph clustering

Input: a set of nodes V and a set of edges E.
Output: a set of fuzzy clusters of V.

1: **for all** $u \in V$ **do**
2: $\quad C \leftarrow \text{Cluster}_{\text{local}}(\text{Ego}(u))$ // $C = \{C_1, ...\}$
3: $\quad$ **for** $i \leftarrow 1 \dots |C|$ **do**
4: $\quad\quad \text{ctx}(u^i) \leftarrow C_i$
5: $\quad\quad \text{senses}(u) \leftarrow \text{senses}(u) \cup \{u^i\}$
6: $\quad$ **end for**
7: **end for**
8: $V' \leftarrow \bigcup_{u \in V} \text{senses}(u)$
9: **for all** $s \in V'$ **do**
10: $\quad$ **for all** $u \in \text{ctx}(s)$ **do**
11: $\quad\quad \hat{u} \leftarrow \underset{u' \in \text{senses}(u)}{\arg\max} \cos(\text{ctx}(s), \text{ctx}(u'))$
12: $\quad$ **end for**
13: $\quad \widehat{\text{ctx}}(s) \leftarrow \{\hat{u} : u \in \text{ctx}(s)\}$
14: **end for**
15: $E' \leftarrow \bigcup_{s \in V'} \{s\} \times \widehat{\text{ctx}}(s)$
16: **return** $\text{Cluster}_{\text{global}}(V', E')$

4 Evaluation

We conduct our experiments on resources from two different languages. We evaluate our approach on two datasets for English to demonstrate its performance on a resource-rich language. Additionally, we evaluate it on two Russian datasets since Russian is a good example of an under-resourced language with a clear need for synset induction.

4.1 Gold Standard Datasets

For each language, we used two differently constructed lexical semantic resources listed in Table 1 to obtain gold standard synsets.

English. We use **WordNet**[8], a popular English lexical database constructed by expert lexicographers. WordNet contains general vocabulary and appears to be *de facto* gold standard in similar tasks (Hope and Keller, 2013). We used WordNet 3.1 to derive the synonymy pairs from synsets. Additionally, we use **BabelNet**[9], a large-scale multilingual semantic network constructed automatically using WordNet, Wikipedia and other resources. We retrieved all the synonymy pairs from the BabelNet 3.7 synsets marked as English.

Russian. As a lexical ontology for Russian, we use **RuWordNet**[10] (Loukachevitch et al., 2016), containing both general vocabulary and domain-specific synsets related to sport, finance, economics, etc. Up to a half of the words in this resource are multi-word expressions (Kiselev et al., 2015), which is due to the coverage of domain-specific vocabulary. RuWordNet is a WordNet-like version of the RuThes thesaurus that is constructed in the traditional way, namely by a small group of expert lexicographers (Loukachevitch, 2011). In addition, we use **Yet Another RussNet**[11] (**YARN**) by Braslavski et al. (2016) as another gold standard for Russian. The resource is constructed using crowdsourcing and mostly covers general vocabulary. Particularly, non-expert users are allowed to edit synsets in a collaborative way loosely supervised by a team of project curators. Due to the ongoing development of the re-

[8] https://wordnet.princeton.edu

[9] http://www.babelnet.org

[10] http://ruwordnet.ru/en

[11] https://russianword.net/en

source, we selected as the gold standard only those synsets that were edited at least eight times in order to filter out noisy incomplete synsets.

Resource		# words	# synsets	# synonyms
WordNet	En	148 730	117 659	152 254
BabelNet	En	11 710 137	6 667 855	28 822 400
RuWordNet	Ru	110 242	49 492	278 381
YARN	Ru	9 141	2 210	48 291

Table 1: Statistics of the gold standard datasets.

4.2 Evaluation Metrics

To evaluate the quality of the induced synsets, we transformed them into binary synonymy relations and computed precision, recall, and F-score on the basis of the overlap of these binary relations with the binary relations from the gold standard datasets. Given a synset containing n words, we generate a set of $\frac{n(n-1)}{2}$ pairs of synonyms. The F-score calculated this way is known as *Paired F-score* (Manandhar et al., 2010; Hope and Keller, 2013). The advantage of this measure compared to other cluster evaluation measures, such as *Fuzzy B-Cubed* (Jurgens and Klapaftis, 2013), is its straightforward interpretability.

4.3 Word Embeddings

English. We use the standard 300-dimensional word embeddings trained on the 100 billion tokens Google News corpus (Mikolov et al., 2013).[12]

Russian. We use the 500-dimensional word embeddings trained using the skip-gram model with negative sampling (Mikolov et al., 2013) using a context window size of 10 with the minimal word frequency of 5 on a 12.9 billion tokens corpus of books. These embeddings were shown to produce state-of-the-art results in the RUSSE shared task[13] and are part of the Russian Distributional Thesaurus (RDT) (Panchenko et al., 2017b).[14]

4.4 Input Dictionary of Synonyms

For each language, we constructed a synonymy graph using openly available language resources. The statistics of the graphs used as the input in the further experiments are shown in Table 2.

English. Synonyms were extracted from the English Wiktionary[15], which is the largest Wiktionary at the present moment in terms of the lexical coverage, using the DKPro JWKTL tool by Zesch et al. (2008). English words have been extracted from the dump.

Russian. Synonyms from three sources were combined to improve lexical coverage of the input dictionary and to enforce confidence in jointly observed synonyms: (1) synonyms listed in the Russian Wiktionary extracted using the Wikokit tool by Krizhanovsky and Smirnov (2013); (2) the dictionary of Abramov (1999); and (3) the Universal Dictionary of Concepts (Dikonov, 2013). While the two latter resources are specific to Russian, Wiktionary is available for most languages. Note that the same input synonymy dictionaries were used by authors of YARN to construct synsets using crowdsourcing. The results on the YARN dataset show how close an automatic synset induction method can approximate manually created synsets provided the same starting material.[16]

Language	# words	# synonyms
English	243 840	212 163
Russian	83 092	211 986

5 Results

We compare WATSET with five state-of-the art graph clustering methods presented in Section 2: Chinese Whispers (CW), Markov Clustering (MCL), MaxMax, ECO clustering, and the clique percolation method (CPM). The first two algorithms perform hard clustering, while the last three are fuzzy clustering methods just like our method. While the hard clustering algorithms are able to discover clusters which correspond to synsets composed of unambigous words, they can produce wrong results in the presence of lexical ambiguity (one node belongs to several synsets). In our experiments, we rely on our own implementation of MaxMax and ECO as reference implementations are not available. For CW[17], MCL[18]

and CPM[19], available implementations have been used. During the evaluation, we delete clusters equal or larger than the threshold of 150 words as they hardly can represent any meaningful synset. The notation WATSET[MCL, CW_{top}] means using MCL for local clustering and Chinese Whispers in the *top* mode for global clustering.

5.1 Impact of Graph Weighting Schema

Figure 3 presents an overview of the evaluation results on both datasets. The first step, common for all of the tested synset induction methods, is graph construction. Thus, we started with an analysis of three ways to weight edges of the graph introduced in Section 3.2: binary scores (*ones*), frequencies (*count*), and semantic similarity scores (*sim*) based on word vector similarity. Results across various configurations and methods indicate that using the weights based on the similarity scores provided by word embeddings is the best strategy for all methods except MaxMax on the English datasets. However, its performance using the *ones* weighting does not exceed the other methods using the *sim* weighting. Therefore, we report all further results on the basis of the *sim* weights. The edge weighting scheme impacts Russian more for most algorithms. The CW algorithm however remains sensitive to the weighting also for the English dataset due to its randomized nature.

[19] https://networkx.github.io

5.2 Comparative Analysis

Table 3 and 4 present evaluation results for both languages. For each method, we show the best configurations in terms of F-score. One may note that the granularity of the resulting synsets, especially for Russian, is very different, ranging from 4 000 synsets for the $CPM_{k=3}$ method to 67 645 induced by the ECO method. Both tables report the number of words, synsets and synonyms after pruning huge clusters larger than 150 words. Without this pruning, the MaxMax and CPM methods tend to discover giant components obtaining almost zero precision as we generate all possible pairs of nodes in such clusters. The other methods did not show such behavior.

WATSET robustly outperforms all other methods according to F-score on both English datasets (Table 3) and on the YARN dataset for Russian (Table 4). Also, it outperforms all other methods according to recall on both Russian datasets. The disambiguation of the input graph performed by the WATSET method splits nodes belonging to several local communities to several nodes, significantly facilitating the clustering task otherwise complicated by the presence of the hubs that wrongly link semantically unrelated nodes.

Interestingly, in all the cases, the toughest competitor was a hard clustering algorithm—MCL (van Dongen, 2000). We observed that the "plain" MCL successfully groups monosemous words, but

Method	# words	# synsets	# synonyms	WordNet			BabelNet

Table 4: Results on Russian sorted by F-score on YARN, top three values of each metric are boldfaced.

isolates the neighborhood of polysemous words, which results in the recall drop in comparison to WATSET. CW operates faster due to a simplified update step. On the same graph, CW tends to produce larger clusters than MCL. This leads to a higher recall of "plain" CW as compared to the "plain" MCL, at the cost of lower precision.

Using MCL instead of CW for sense induction in WATSET expectedly produces more fine-grained senses. However, at the global clustering step, these senses erroneously tend to form coarse-grained synsets connecting unrelated senses of the ambiguous words. This explains the generally higher recall of WATSET[MCL, ·]. Despite the randomized nature of CW, variance across runs do not affect the overall ranking: The rank of different versions of CW (*log, nolog, top*) can change, while the rank of the best CW configuration compared to other methods remains the same.

The MaxMax algorithm shows mixed results. On the one hand, it outputs large clusters uniting more than hundred nodes. This inevitably leads to a high recall, as it is clearly seen in the results for Russian because such synsets still pass under our cluster size threshold of 150 words. Its synsets on English datasets are even larger and get pruned, which results in low recall. On the other hand, smaller synsets having at most 10–15 words were identified correctly. MaxMax appears to be extremely sensible to edge weighting, which also complicates its practical use.

The CPM algorithm showed unsatisfactory results, emitting giant components encompassing thousands of words. Such clusters were automatically pruned, but the remaining clusters are relatively correctly built synsets, which is confirmed by the high values of precision. When increasing the minimal number of elements in the clique k, recall improves, but at the cost of a dramatic precision drop. We suppose that the network structure assumptions exploited by CPM do not accurately model the structure of our synonymy graphs.

Finally, the ECO method yielded the worst results because the most cluster candidates failed to pass through the constant threshold used for estimating whether a pair of words should be included in the same cluster. Most synsets produced by this method were trivial, i.e., containing only a single

BabelNet on YARN	Ru	0.515	0.109	0.180

Table 5: Performance of lexical resources cross-evaluated against each other.

word. The remaining synsets for both languages have at most three words that have been connected by a chance due to the edge noising procedure used in this method resulting in low recall.

6 Discussion

On the absolute scores. The results obtained on all gold standards (Figure 3) show similar trends in terms of relative ranking of the methods. Yet absolute scores of YARN and RuWordNet are substantially different due to the inherent difference of these datasets. RuWordNet is more domain-specific in terms of vocabulary, so our input set of generic synonymy dictionaries has a limited coverage on this dataset. On the other hand, recall calculated on YARN is substantially higher as this resource was manually built on the basis of synonymy dictionaries used in our experiments.

The reason for low absolute numbers in evaluations is due to an inherent vocabulary mismatch between the input dictionaries of synonyms and the gold datasets. To validate this hypothesis, we performed a cross-resource evaluation presented in Table 5. The low performance of the cross-evaluation of the two resources supports the hypothesis: no single resource for Russian can obtain high recall scores on another one. Surprisingly, even BabelNet, which integrates most of available lexical resources, still does not reach a recall substantially larger than 0.5.[20] Note that the results of this cross-dataset evaluation are not directly comparable to results in Table 4 since in our experiments we use much smaller input dictionaries than those used by BabelNet.

On sparseness of the input dictionary. Table 6 presents some examples of the obtained synsets of various sizes for the top WATSET configuration on both languages. As one might observe, the quality of the results is highly plausible. However, one limitation of all approaches considered in this paper is the dependence on the completeness of the input dictionary of synonyms. In some parts of the input synonymy graph, important bridges between words can be missing, leading to smaller-than-desired synsets. A promising extension of the present methodology is using distributional models to enhance connectivity of the graph by cautiously adding extra relations.

Size	Synset
2	{*decimal point*, *dot*}
3	{*gullet*, *throat*, *food pipe*}
4	{*microwave meal*, *ready meal*, *TV dinner*, *frozen dinner*}
5	{*objective case*, *accusative case*, *oblique case*, *object case*, *accusative*}
6	{*radio theater*, *dramatized audiobook*, *audio theater*, *radio play*, *radio drama*, *audio play*}

Table 6: Sample synsets induced by the WATSET[MCL, MCL] method for English.

7 Conclusion

We presented a new robust approach to fuzzy graph clustering that relies on hard graph clustering. Using ego network clustering, the nodes belonging to several local communities are split into several nodes each belonging to one community. The transformed "disambiguated" graph is then clustered using an efficient hard graph clustering algorithm, obtaining a fuzzy clustering as the result. The disambiguated graph facilitates clustering as it contains fewer hubs connecting unrelated nodes from different communities. We apply this meta clustering algorithm to the task of synset induction on two languages, obtaining the best results on three datasets and competitive results on one dataset in terms of F-score as compared to five state-of-the-art graph clustering methods.

Acknowledgments

We acknowledge the support of the Deutsche Forschungsgemeinschaft (DFG) foundation under the "JOIN-T" project, the DAAD, the RFBR under the project no. 16-37-00354 mol_a, and the RFH under the project no. 16-04-12019. We also thank three anonymous reviewers for their helpful comments, Andrew Krizhanovsky for providing a parsed Wiktionary, Natalia Loukachevitch for the provided RuWordNet dataset, and Denis Shirgin who suggested the WATSET name.

[20] We used BabelNet 3.7 extracting all 3 497 327 synsets that were marked as Russian.

Neural Modeling of Multi-Predicate Interactions for Japanese Predicate Argument Structure Analysis

Abstract

The performance of Japanese predicate argument structure (PAS) analysis has improved in recent years thanks to the joint modeling of interactions between multiple predicates. However, this approach relies heavily on syntactic information predicted by parsers, and suffers from error propagation. To remedy this problem, we introduce a model that uses *grid-type recurrent neural networks*. The proposed model automatically induces features sensitive to *multi-predicate interactions* from the word sequence information of a sentence. Experiments on the NAIST Text Corpus demonstrate that without syntactic information, our model outperforms previous syntax-dependent models.

1 Introduction

Predicate argument structure (PAS) analysis is a basic semantic analysis task, in which systems are required to identify the semantic units of a sentence, such as *who did what to whom*. In pro-drop languages such as Japanese, Chinese and Italian, arguments are often omitted in text, and such *argument omission* is regarded as one of the most problematic issues facing PAS analysis (Iida and Poesio, 2011; Sasano and Kurohashi, 2011; Hangyo et al., 2013).

In response to the argument omission problem, in Japanese PAS analysis, a joint model of the interactions between multiple predicates has been gaining popularity and achieved the state-of-the-art results (Ouchi et al., 2015; Shibata et al., 2016). This approach is based on the linguistic intuition that the predicates in a sentence are semantically related to each other, and capturing this relation can be useful for PAS analysis. In the example sentence in Figure 1, the word "男 $_i$ (man$_i$)" is the accusative argument of the predicate "逮捕した (arrested)" and is shared by the other predicate "逃走した (escaped)" as its nominative argument. Considering the semantic relation between "逮捕した (arrested)" and "逃走した (escaped)", we intuitively know that the person arrested by someone is likely to be the escaper. That is, information about one predicate-argument relation could help to identify another predicate-argument relation.

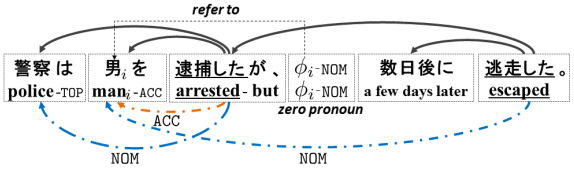

Figure 1: Example of Japanese PAS. The upper edges denote dependency relations, and the lower edges denote case arguments. "NOM" and "ACC" denote the nominative and accusative arguments, respectively. "ϕ_i" is a *zero pronoun*, referring to the *antecedent* "男 $_i$ (man$_i$)".

However, to model such *multi-predicate interactions*, the joint approach in the previous studies relies heavily on syntactic information, such as part-of-speech (POS) tags and dependency relations predicted by POS taggers and syntactic parsers. Consequently, it suffers from error propagation caused by pipeline processing.

To remedy this problem, we propose a neural model which automatically induces features sensitive to multi-predicate interactions exclusively from the word sequence information of a sentence. The proposed model takes as input all predicates and their argument candidates in a sentence at a time, and captures the interactions using grid-type recurrent neural networks (Grid-RNN) without syntactic information.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1591–1600
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1146

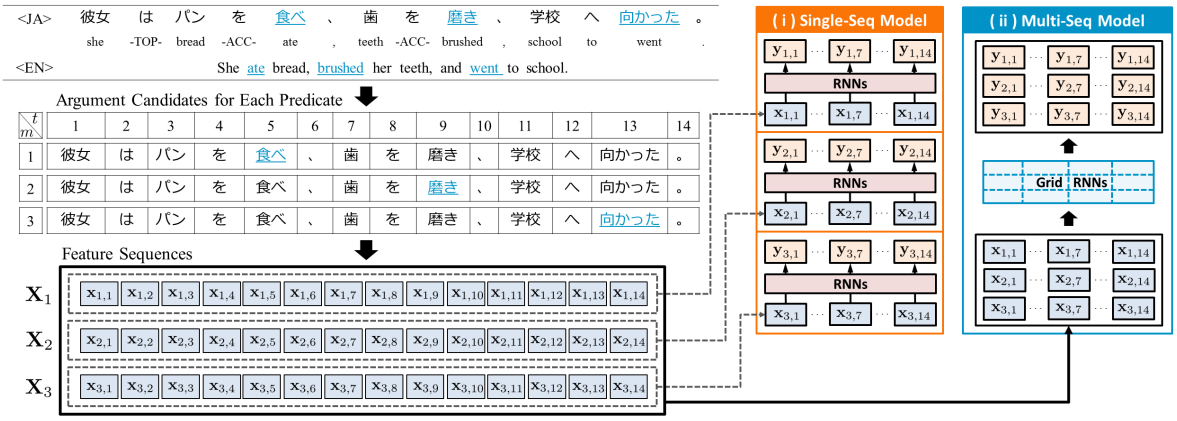

Figure 2: Overview of neural models: (i) *single-sequence* and (ii) *multi-sequence* models.

In this paper, we first introduce a basic model that uses RNNs. This model independently estimates the arguments of each predicate without considering multi-predicate interactions (Sec. 3). Then, extending this model, we propose a neural model that uses Grid-RNNs (Sec. 4).

Performing experiments on the NAIST Text Corpus (Iida et al., 2007), we demonstrate that even without syntactic information, our neural models outperform previous syntax-dependent models (Imamura et al., 2009; Ouchi et al., 2015). In particular, the neural model using Grid-RNNs achieved the best result. This suggests that the proposed grid-type neural architecture effectively captures multi-predicate interactions and contributes to performance improvements. [1]

2 Japanese Predicate Argument Structure Analysis

2.1 Task Description

In Japanese PAS analysis, arguments are identified that each fulfills one of the three major case roles, *nominative* (NOM), *accusative* (ACC) and *dative* (DAT) cases, for each predicate. Arguments can be divided into the following three categories according to the positions relative to their predicates (Hayashibe et al., 2011; Ouchi et al., 2015):

Dep: Arguments that have direct syntactic dependency on the predicate.

Zero: Arguments referred to by zero pronouns within the same sentence that have no direct syntactic dependency on the predicate.

Inter-Zero: Arguments referred to by zero pronouns outside of the same sentence.

For example, in Figure 1, the nominative argument "警察 (police)" for the predicate "逮捕した (arrested)" is regarded as a *Dep* argument, because the argument has a direct syntactic dependency on the predicate. By contrast, the nominative argument "男 $_i$ (man$_i$)" for the predicate "逃走した (escaped)" is regarded as a *Zero* argument, because the argument has no direct syntactic dependency on the predicate.

In this paper, we focus on the analysis for these intra-sentential arguments, i.e., *Dep* and *Zero*. In order to identify inter-sentential arguments (*Inter-Zero*), a much broader space must be searched (e.g., the whole document), resulting in a much more complicated analysis than intra-sentential arguments.[2] Owing to this complication, Ouchi et al. (2015) and Shibata et al. (2016) focused exclusively on intra-sentential argument analysis. Following this trend, we also restrict our focus to intra-sentential argument analysis.

2.2 Challenging Problem

Arguments are often omitted in Japanese sentences. In Figure 1, ϕ_i represents the omitted argument, called the *zero pronoun*. This zero pronoun ϕ_i refers to "男 $_i$ (man$_i$)". In Japanese PAS analysis, when an argument of the target predicate is omitted, we have to identify the antecedent of the omitted argument (i.e., the *Zero* argument).

The analysis of such *Zero* arguments is much more difficult than that for *Dep* arguments, owing to the lack of direct syntactic dependencies. For *Dep* arguments, the syntactic dependency between an argument and its predicate is a strong clue. In the sentence in Figure 1, for the predi-

[1] Our source code is publicly available at https://github.com/hiroki13/neural-pasa-system

[2] The F-measure remains 10-20% (Taira et al., 2008; Imamura et al., 2009; Sasano and Kurohashi, 2011).

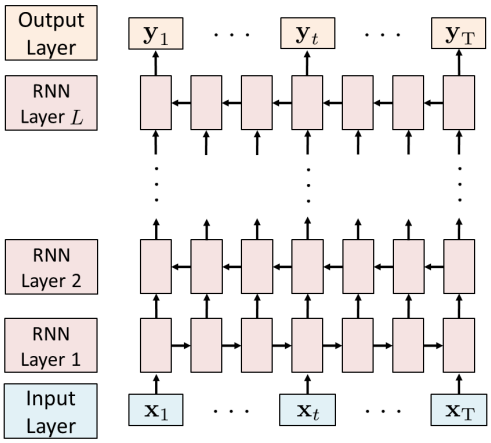

Figure 3: Overall architecture of the single-sequence model. This model consists of three components: (i) Input Layer, (ii) RNN Layer and (iii) Output Layer.

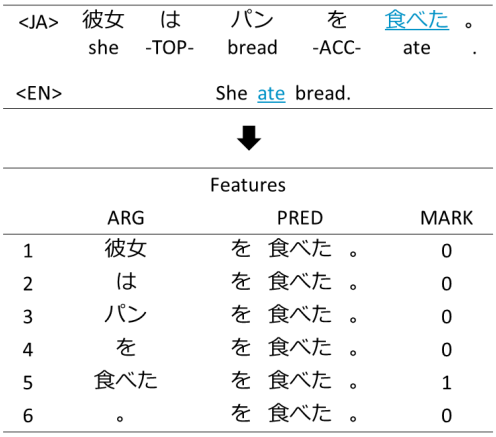

Figure 4: Example of feature extraction. The underlined word is the target predicate. From the sentence "彼女はパンを食べた。(She ate bread.)", three types of features are extracted for the target predicate "食べた (ate)".

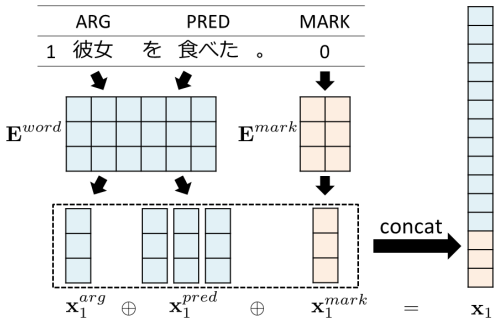

Figure 5: Example of the process of creating a feature vector. The extracted features are mapped to each vector, and all the vectors are concatenated into one feature vector.

cate "逮捕した (arrested)", the nominative argument is "警察 (police)". This argument is easily identified by relying on the syntactic dependency. By contrast, because the nominative argument "男$_i$ (man$_i$)" has no syntactic dependency on its predicate "逃走した (escaped)", we must rely on other information to identify the zero argument.

As a solution to this problem, we exploit two kinds of information: (i) the context of the entire sentence, and (ii) multi-predicate interactions. For the former, we introduce *single-sequence model* that induces context-sensitive representations from a sequence of argument candidates of a predicate. For the latter, we introduce *multi-sequence model* that induces predicate-sensitive representations from multiple sequences of argument candidates of all predicates in a sentence (shown in Figure 2).

3 Single-Sequence Model

The single-sequence model exploits stacked bidirectional RNNs (Bi-RNN) (Schuster and Paliwal, 1997; Graves et al., 2005, 2013; Zhou and Xu, 2015). Figure 3 shows the overall architecture, which consists of the following three components:

Input Layer: Map each word to a feature vector representation.

RNN Layer: Produce high-level feature vectors using Bi-RNNs.

Output Layer: Compute the probability of each case label for each word using the softmax function.

In the following subsections, we describe each of these three components in detail.

3.1 Input Layer

Given an input sentence $w_{1:T} = (w_1, \cdots, w_T)$ and a predicate p, each word w_t is mapped to a feature representation $\mathbf{x}_t$, which is the concatenation ($\oplus$) of three types of vectors:

$$\mathbf{x}_t = \mathbf{x}_t^{arg} \oplus \mathbf{x}_t^{pred} \oplus \mathbf{x}_t^{mark} \quad (1)$$

where each vector is based on the following atomic features inspired by Zhou and Xu (2015):

`ARG`**:** Word index of each word.

`PRED`**:** Word index of the target predicate and the words around the predicate.

`MARK`**:** Binary index that represents whether or not the word is the predicate.

Figure 4 presents an example of the atomic features. For the ARG feature, we extract a word index $x^{word} \in \mathcal{V}$ for each word. Similarly, for the PRED feature, we extract each word index x^{word} for the C words taking the target predicate at the center, where C denotes the window size. The MARK feature $x^{mark} \in \{0, 1\}$ is a binary value that represents whether or not the word is the predicate.

Then, using feature indices, we extract feature vector representations from each embedding matrix. Figure 5 shows the process of creating the feature vector $\mathbf{x}_1$ for the word w_1 "彼女 (she)". We set two embedding matrices: (i) a word embedding matrix $\mathbf{E}^{word} \in \mathbb{R}^{d_{word} \times |\mathcal{V}|}$, and (ii) a mark embedding matrix $\mathbf{E}^{mark} \in \mathbb{R}^{d_{mark} \times 2}$. From each embedding matrix, we extract the corresponding column vectors and concatenate them as a feature vector $\mathbf{x}_t$ based on Eq. 1.

Each feature vector $\mathbf{x}_t$ is multiplied with a parameter matrix $\mathbf{W}_x$:

$$\mathbf{h}_t^{(0)} = \mathbf{W}_x \, \mathbf{x}_t \tag{2}$$

The vector $\mathbf{h}_t^{(0)}$ is given to the first RNN layer as input.

3.2 RNN Layer

In the RNN layers, feature vectors are updated recurrently using Bi-RNNs. Bi-RNNs process an input sequence in a left-to-right manner for odd-numbered layers and in a right-to-left manner for even-numbered layers. By stacking these layers, we can construct the deeper network structures.

Stacked Bi-RNNs consist of L layers, and the hidden state in the layer $\ell \in (1, \cdots, L)$ is calculated as follows:

$$\mathbf{h}_t^{(\ell)} = \begin{cases} g^{(\ell)}(\mathbf{h}_t^{(\ell-1)}, \, \mathbf{h}_{t-1}^{(\ell)}) & (\ell = \text{odd}) \\ g^{(\ell)}(\mathbf{h}_t^{(\ell-1)}, \, \mathbf{h}_{t+1}^{(\ell)}) & (\ell = \text{even}) \end{cases} \tag{3}$$

Both of the odd- and even-numbered layers receive $\mathbf{h}_t^{(\ell-1)}$, the t-th hidden state of the $\ell-1$ layer, as the first input of the function $g^{(\ell)}$, which is an arbitrary function [3]. For the second input of $g^{(\ell)}$, odd-numbered layers receive $\mathbf{h}_{t-1}^{(\ell)}$, whereas even-numbered layers receive $\mathbf{h}_{t+1}^{(\ell)}$. By calculating the hidden states until the L-th layer, we obtain a hidden state sequence $\mathbf{h}_{1:\mathrm{T}}^{(L)} = (\mathbf{h}_1^{(L)}, \cdots, \mathbf{h}_{\mathrm{T}}^{(L)})$. Using each vector $\mathbf{h}_t^{(L)}$, we calculate the probability of case labels for each word in the output layer.

[3] In this work, we used the Gated Recurrent Unit (GRU) (Cho et al., 2014) as the function $g^{(\ell)}$.

3.3 Output Layer

For the output layer, multi-class classification is performed using the softmax function:

$$\mathbf{y}_t = \text{softmax}(\mathbf{W}_y \, \mathbf{h}_t^{(L)})$$

where $\mathbf{h}_t^{(L)}$ denotes a vector representation propagated from the last RNN layer (Fig 3). Each element of $\mathbf{y}_t$ is a probability value corresponding to each label. The label with the maximum probability among them is output as a result. In this work, we set five labels: NOM, ACC, DAT, PRED, null. PRED is the label for the predicate, and null denotes a word that does not fulfill any case role.

4 Multi-Sequence Model

Whereas the single-sequence model assumes independence between predicates, the multi-sequence model assumes *multi-predicate interactions*. To capture such interactions between all predicates in a sentence, we extend the single-sequence model to the multi-sequence model using Grid-RNNs (Graves and Schmidhuber, 2009; Kalchbrenner et al., 2016). Figure 6 presents the overall architecture for the multi-sequence model, which consists of three components:

Input Layer: Map words to M sequences of feature vectors for M predicates.

Grid Layer: Update the hidden states over different sequences using Grid-RNNs.

Output Layer: Compute the probability of each case label for each word using the softmax function.

In the following subsections, we describe these three components in detail.

4.1 Input Layer

The multi-sequence model takes as input a sentence $w_{1:\mathrm{T}} = (w_1, \cdots, w_{\mathrm{T}})$ and all predicates $\{p_m\}_1^M$ in the sentence. For each predicate p_m, the input layer creates a sequence of feature vectors $\mathbf{X}_m = (\mathbf{x}_{m,1}, \cdots, \mathbf{x}_{m,\mathrm{T}})$ by mapping each input word w_t to a feature vector $\mathbf{x}_{m,t}$ based on Eq 1. That is, for M predicates, M sequences of feature vectors $\{\mathbf{X}_m\}_1^M$ are created.

Then, using Eq. 2, each feature vector $\mathbf{x}_{m,t}$ is mapped to $\mathbf{h}_{m,t}^{(0)}$, and a feature sequence is created for a predicate p_m, i.e., $\mathbf{H}_m^{(0)} = (\mathbf{h}_{m,1}^{(0)}, \cdots, \mathbf{h}_{m,\mathrm{T}}^{(0)})$. Consequently, for M predicates, we obtain M feature sequences $\{\mathbf{H}_m^{(0)}\}_1^M$.

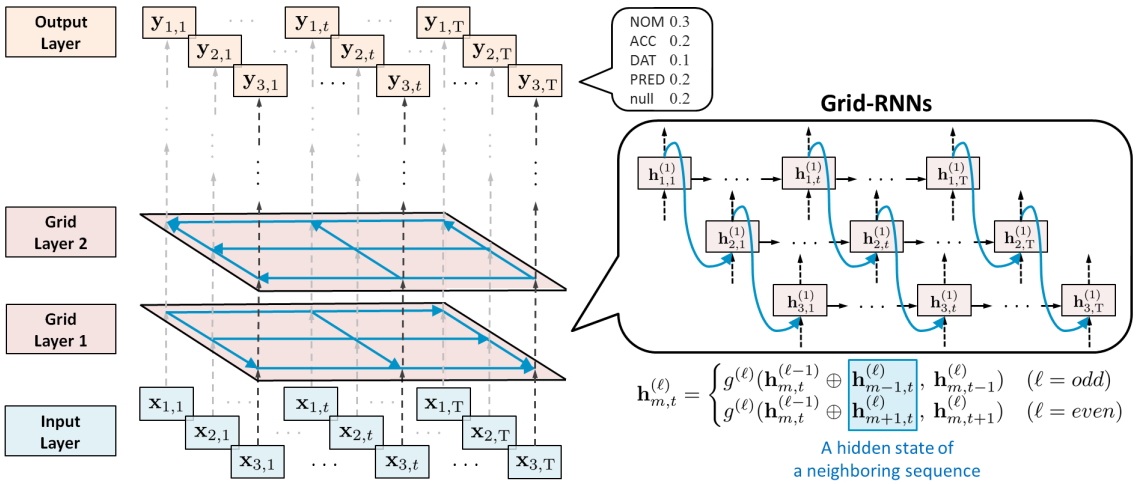

Figure 6: Overall architecture of the multi-sequence model: an example of three sequences.

4.2 Grid Layer

Inter-Sequence Connections

For the grid layers, we use Grid-RNNs to propagate the feature information over the different sequences (*inter-sequence connections*). The figure on the right in Figure 6 shows the first grid layer. The hidden state is recurrently calculated from the upper-left ($m = 1, t = 1$) to the lower-right ($m = M, t = \mathrm{T}$).

Formally, in the ℓ-th layer, the hidden state $\mathbf{h}^{(\ell)}_{m,t}$ is calculated as follows:

$$\mathbf{h}^{(\ell)}_{m,t} = \begin{cases} g^{(\ell)}(\mathbf{h}^{(\ell-1)}_{m,t} \oplus \mathbf{h}^{(\ell)}_{m-1,t}, \mathbf{h}^{(\ell)}_{m,t-1}) & (\ell = \text{odd}) \\ g^{(\ell)}(\mathbf{h}^{(\ell-1)}_{m,t} \oplus \mathbf{h}^{(\ell)}_{m+1,t}, \mathbf{h}^{(\ell)}_{m,t+1}) & (\ell = \text{even}) \end{cases}$$

This equation is similar to Eq. 3. The main difference is that the hidden state of a neighboring sequence, $\mathbf{h}^{(\ell)}_{m-1,t}$ (or $\mathbf{h}^{(\ell)}_{m+1,t}$), is concatenated ($\oplus$) with the hidden state of the previous ($\ell - 1$) layer, $\mathbf{h}^{(\ell-1)}_{m,t}$, and is taken as input of the function $g^{(\ell)}$.

In the figure on the right in Figure 6, the blue curved lines represent the inter-sequence connections. Taking as input the hidden states of neighboring sequences, the network propagates feature information over multiple sequences (i.e., predicates). By calculating the hidden states until the L-th layer, we obtain M sequences of the hidden states, i.e., $\{\mathbf{H}^{(L)}_m\}^M_1$, in which $\mathbf{H}^{(L)}_m = (\mathbf{h}^{(L)}_{m,1}, \cdots, \mathbf{h}^{(L)}_{m,\mathrm{T}})$.

Residual Connections

As more layers are stacked, it becomes more difficult to learn the model parameters, owing to various challenges such as the vanishing gradient problem (Pascanu et al., 2013). In this work, we integrate residual connections (He et al., 2015; Wu et al., 2016) with our networks to form connections between layers. Specifically, the input vector $\mathbf{h}^{(\ell-1)}_{m,t}$ of the ℓ-th layer is added to the output vector $\mathbf{h}^{(\ell)}_{m,t}$. Residual connections can also be applied to the single-sequence model. Thus, we can perform experiments on both models with/without residual connections.

4.3 Output Layer

As with the single-sequence model, we use the softmax function to calculate the probability of the case labels of each word w_t for each predicate p_m:

$$\mathbf{y}_{m,t} = \mathrm{softmax}(\mathbf{W}_y\, \mathbf{h}^{(L)}_{m,t})$$

where $\mathbf{h}^{(L)}_{m,t}$ is a hidden state vector calculated in the last grid layer.

5 Related Work

5.1 Japanese PAS Analysis Approaches

Existing approaches to Japanese PAS analysis are divided into two categories: (i) the *pointwise approach* and (ii) the *joint approach*. The pointwise approach involves estimating the score of each argument candidate for one predicate, and then selecting the argument candidate with the maximum score as an argument (Taira et al., 2008; Imamura et al., 2009; Hayashibe et al., 2011; Iida et al., 2016). The joint approach involves scoring all the predicate-argument combinations in one sentence, and then selecting the combination with the highest score (Yoshikawa et al., 2011; Sasano and Kurohashi,

2011; Ouchi et al., 2015; Shibata et al., 2016). Compared with the pointwise approach, the joint approach achieves better results.

5.2 Multi-Predicate Interactions

Ouchi et al. (2015) reported that it is beneficial to Japanese PAS analysis to capture the interactions between all predicates in a sentence. This is based on the linguistic intuition that the predicates in a sentence are semantically related to each other, and that the information regarding this semantic relation can be useful for PAS analysis.

Similarly, in semantic role labeling (SRL), Yang and Zong (2014) reported that their reranking model, which captures the multi-predicate interactions, is effective for the English constituent-based SRL task (Carreras and Màrquez, 2005). Taking this a step further, we propose a neural architecture that effectively models the multi-predicate interactions.

5.3 Neural Approaches

Japanese PAS

In recent years, several attempts have been made to apply neural networks to Japanese PAS analysis (Shibata et al., 2016; Iida et al., 2016)[4]. In Shibata et al. (2016), a feed-forward neural network is used for the score calculation part of the joint model proposed by Ouchi et al. (2015). In Iida et al. (2016), multi-column convolutional neural networks are used for the zero anaphora resolution task.

Both models exploit syntactic and selectional preference information as the atomic features of neural networks. Overall, the use of neural networks has resulted in advantageous performance levels, mitigating the cost of manually designing combination features. In this work, we demonstrate that even without such syntactic information, our neural models can realize comparable performance exclusively using the word sequence information of a sentence.

English SRL

Some neural models have achieved high performance without syntactic information in English SRL. Collobert et al. (2011) and Zhou and Xu (2015) worked on the English constituent-based SRL task (Carreras and Màrquez, 2005) using neural networks. In Collobert et al. (2011), their model exploited a convolutional neural network and achieved a 74.15% F-measure without syntactic information. In Zhou and Xu (2015), their model exploited bidirectional RNNs with linear-chain conditional random fields (CRFs) and achieved the state-of-the-art result, an 81.07% F-measure. Our models should be regarded as an extension of their model.

The main differences between Zhou and Xu (2015) and our work are: (i) constituent-based vs dependency-based argument identification and (ii) the multi-predicate consideration. For the constituent-based SRL, Zhou and Xu (2015) used CRFs to capture the IOB label dependencies, because systems are required to identify the *spans* of arguments for each predicate. By contrast, for Japanese dependency-based PAS analysis, we replaced the CRFs with the softmax function, because in Japanese, arguments are rarely adjacent to each other.[5] Furthermore, whereas the model described in Zhou and Xu (2015) predicts arguments for each predicate independently, our multi-sequence model jointly predicts arguments for all predicates in a sentence concurrently by considering the multi-predicate interactions.

6 Experiments

6.1 Experimental Settings

Dataset

We used the NAIST Text Corpus 1.5, which consists of 40,000 sentences from Japanese newspapers (Iida et al., 2007). For the experiments, we adopted standard data splits (Taira et al., 2008; Imamura et al., 2009; Ouchi et al., 2015):

Train:	Articles: Jan 1-11, Editorials: Jan-Aug
Dev:	Articles: Jan 12-13, Editorials: Sept
Test:	Articles: Jan 14-17, Editorials: Oct-Dec

We used the word boundaries annotated in the NAIST Text Corpus and the target predicates that have at least one argument in the same sentence. We did not use any external resources.

Learning

We trained the model parameters by minimizing

[4] These previous studies used unpublished datasets and evaluated the performance with different experimental settings. Consequently, we cannot compare their models with ours.

[5] In our preliminary experiment, we could not confirm the performance improvement by CRFs.

the cross-entropy loss function:

$$\mathcal{L}(\boldsymbol{\theta}) = -\sum_{n}\sum_{t} \log P(y_t|x_t) + \frac{\lambda}{2}||\boldsymbol{\theta}||^2 \quad (4)$$

where θ is a set of model parameters, and the hyper-parameter λ is the coefficient governing the L2 weight decay.

Implementation Details

We implemented our neural models using a deep learning library, Theano (Bastien et al., 2012). The number of epochs was set at 50, and we reported the result of the test set in the epoch with the best F-measure from the development set. The parameters were optimized using the stochastic gradient descent method (SGD) via a mini-batch, whose size was selected from $\{2, 4, 8\}$. The learning rate was automatically adjusted using Adam (Kingma and Ba, 2014). For the L2 weight decay, the hyper-parameter λ in Eq. 4 was selected from $\{0.001, 0.0005, 0.0001\}$.

In the neural models, the number of the RNN and Grid layers were selected from $\{2, 4, 6, 8\}$. The window size C for the PRED feature (Sec. 3.1) was set at 5. Words with a frequency of 2 or more in the training set were mapped to each word index, and the remaining words were mapped to the unknown word index. The dimensions d_{word} and d_{mark} of the embeddings were set at 32. In the single-sequence model, the parameters of GRUs were set at 32×32. In the multi-sequence model, the parameters of GRUs related to the input values were set at 64×32, and the remaining were set at 32×32. The initial values of all parameters were sampled according to a uniform distribution from $[-\frac{\sqrt{6}}{\sqrt{row+col}}, \frac{\sqrt{6}}{\sqrt{row+col}}]$, where row and col are the number of rows and columns of each matrix, respectively.

Baseline Models

We compared our models to existing models in previous works (Sec. 5.1) that use the NAIST Text Corpus 1.5. As a baseline for the pointwise approach, we used the pointwise model[6] proposed in Imamura et al. (2009). In addition, as a baseline for the joint approach, we used the model proposed in Ouchi et al. (2015). These models exploit gold annotations in the NAIST Text Corpus as POS tags and dependency relations.

[6]We compared the results of the model reimplemented by Ouchi et al. (2015).

	Dep	*Zero*	*All*
Imamura+ 09	85.06	41.65	78.15
Ouchi+ 15	86.07	44.09	79.23
Single-Seq	88.10	46.10	81.15
Multi-Seq	**88.17** †	**47.12** †	**81.42** †

Table 1: F-measures in the test set. Single-Seq is the single-sequence model, and Multi-Seq is the multi-sequence model. Imamura+ 09 is the model in Imamura et al. (2009) reimplemented by Ouchi et al. (2015), and Ouchi+ 15 is the ALL-Cases Joint Model in Ouchi et al. (2015). The mark † denotes the significantly better results with the significance level $p < 0.05$, comparing Single-Seq and Multi-Seq.

6.2 Results

Neural Models vs Baseline Models

Table 1 presents F-measures from our neural sequence models with eight RNN or Grid layers and the baseline models on the test set. For the significant test, we used the bootstrap resampling method. According to all metrics, both the single- (Single-Seq) and multi-sequence models (Multi-Seq) outperformed the baseline models. This confirms that our neural models realize high performance, even without syntactic information, by learning contextual information effective for PAS analysis from the word sequence of the sentence.

In particular, for zero arguments (*Zero*), our models achieved a considerable improvement compared to the joint model in Ouchi et al. (2015). Specifically, the single-sequence model improved by approximately 2.0 points, and the multi-sequence model by approximately 3.0 points according to the F-measure. These results suggest that modeling the context of the entire sentence using RNNs are beneficial to Japanese PAS analysis, particularly to zero argument identification.

Effects of Multiple Predicate Consideration

As Table 1 shows, the multi-sequence model significantly outperformed the single-sequence model in terms of the F-measure overall (81.42% vs 81.15%). These results demonstrate that the grid-type neural architecture can effectively capture multi-predicate interactions by connecting the sequences of the argument candidates for all predicates in a sentence.

	All	5,821	80.31	**80.69**
5+	*Dep*	6.983	**86.63**	86.30
	Zero	2,467	39.83	**40.66**
	All	9,450	**76.17**	76.00

Table 3: Performance comparison for different numbers (M) of predicates in a sentence on the test set in F-measures.

ferent argument types, the multi-sequence model achieved slightly better results for direct dependency arguments (*Dep*) (88.10% vs 88.17%). In addition, for zero arguments (*Zero*), which have no syntactic dependency on their predicate, the multi-sequence model outperformed the single-sequence model by approximately 1.0 point according to the F-measure (46.10% vs 47.12%). This shows that capturing multi-predicate interactions is particularly effective for zero arguments, which is consistent with the results in Ouchi et al. (2015).

Effects of Network Depth

Table 2 presents F-measures from the neural sequence models with different network depths and with/without residual connections. The performance tends to improve as the RNN or Grid layers get deeper with residual connections. In particular, the two models with eight layers and residual connections achieved considerable improvements of approximately 1.0 point according to the F-measure compared to models without residual connections. This means that residual connections contribute to effective parameter learning of deeper models.

Effects of the Number of Predicates

Table 3 presents F-measures from the neural sequence models with different numbers of predicates in a sentence. In Table 3, M denotes how many predicates appear in a sentence. For example, the sentence in Figure 1 includes two predicates, "arrested" and "escaped", and thus in this example $M = 2$.

Overall, performance of both models gradually deteriorated as the number of predicates in a sentence increased, because sentences that contain many predicates are complex and difficult to analyze. However, compared to the single-sequence model, the multi-sequence model suppressed performance degradation, especially for zero arguments ($Zero$). By contrast, for direct dependency arguments (Dep), both models either achieved almost equivalent performance or the single-sequence model outperformed the multi-sequence model. A Detailed investigation of the relation between the number of predicates in a sentence and the complexity of PAS analysis is an interesting line for future work.

Comparison per Case Role

Table 4 shows F-measures for each case role. For reference, we show the results of the previous studies using the NAIST Text Corpus 1.4β with external resources as well.[7]

[7]The major difference between the NAIST Text Corpus 1.4β and 1.5 is the revision of the annotation criterion for the dative case (DAT) (corresponding to Japanese case marker "に"). Argument and adjunct usages of the case marker "に" are not distinguished in 1.4β, making the identification of the dative case seemingly easy (Ouchi et al., 2015).

	Dep			*Zero*		
	NOM	ACC	DAT	NOM	ACC	DAT
NAIST Text Corpus 1.5						
Imamura+ 09	86.50	92.84	30.97	45.56	21.38	0.83
Ouchi+ 15	88.13	92.74	38.39	48.11	24.43	4.80
Single-Seq	88.32	93.89	65.91	49.51	35.07	9.83
Multi-Seq	88.75	93.68	64.38	50.65	32.35	7.52
NAIST Text Corpus 1.4β						
Taira+ 08*	75.53	88.20	89.51	30.15	11.41	3.66
Imamura+ 09*	87.0	93.9	80.8	50.0	30.8	0.0
Sasano+ 11*	-	-	-	39.5	17.5	8.9

Table 4: Performance comparison for different case roles on the test set in F-measures. NOM, ACC or DAT is the nominal, accusative or dative case, respectively. The asterisk (*) indicates that the model uses external resources.

Comparing the models using the NAIST Text Corpus 1.5, the single- and multi-sequence models outperformed the baseline models according to all metrics. In particular, for the dative case, the two neural models achieved much higher results, by approximately 30 points. This suggests that although dative arguments appear infrequently compared with the other two case arguments, the neural models can learn them robustly.

In addition, for zero arguments (*Zero*), the neural models achieved better results than the baseline models. In particular, for zero arguments of the nominative case (NOM), the multi-sequence model demonstrated a considerable improvement of approximately 2.5 points according to the F-measure compared with the joint model in Ouchi et al. (2015). To achieve high accuracy for the analysis of such zero arguments, it is necessary to capture long distance dependencies (Iida et al., 2005; Sasano and Kurohashi, 2011; Iida et al., 2015). Therefore, the improvements of the results suggest that the neural models effectively capture long distance dependencies using RNNs that can encode the context of the entire sentence.

7 Conclusion

In this work, we introduced neural sequence models that automatically induce effective feature representations from the word sequence information of a sentence for Japanese PAS analysis. The experiments on the NAIST Text Corpus demonstrated that the models realize high performance without the need for syntactic information. In particular, our multi-sequence model improved the performance of *zero argument* identification, one of the problematic issues facing Japanese PAS analysis, by considering the *multi-predicate interactions* with Grid-RNNs.

Because our neural models are applicable to SRL, applying our models for multilingual SRL tasks presents an interesting future research direction. In addition, in this work, the model parameters were learned without any external resources. In future work, we plan to explore effective methods for exploiting large-scale unlabeled data to learn the neural models.

Abstract

We present TriviaQA, a challenging reading comprehension dataset containing over 650K question-answer-evidence triples. TriviaQA includes 95K question-answer pairs authored by trivia enthusiasts and independently gathered evidence documents, six per question on average, that provide high quality distant supervision for answering the questions. We show that, in comparison to other recently introduced large-scale datasets, TriviaQA (1) has relatively complex, compositional questions, (2) has considerable syntactic and lexical variability between questions and corresponding answer-evidence sentences, and (3) requires more cross sentence reasoning to find answers. We also present two baseline algorithms: a feature-based classifier and a state-of-the-art neural network, that performs well on SQuAD reading comprehension. Neither approach comes close to human performance (23% and 40% vs. 80%), suggesting that TriviaQA is a challenging testbed that is worth significant future study.[1]

1 Introduction

Reading comprehension (RC) systems aim to answer any question that could be posed against the facts in some reference text. This goal is challenging for a number of reasons: (1) the questions can be complex (e.g. have highly compositional semantics), (2) finding the correct answer can require complex reasoning (e.g. combining facts from multiple sentences or background knowledge) and (3) individual facts can be difficult to recover from text (e.g. due to lexical and syntactic variation). Figure 1 shows examples of all these phenomena. This paper presents TriviaQA, a new reading comprehension dataset designed to simultaneously test all of these challenges.

Question: The Dodecanese Campaign of WWII that was an attempt by the Allied forces to capture islands in the Aegean Sea was the inspiration for which acclaimed 1961 commando film?
Answer: The Guns of Navarone
Excerpt: The Dodecanese Campaign of World War II was an attempt by Allied forces to capture the Italian-held Dodecanese islands in the Aegean Sea following the surrender of Italy in September 1943, and use them as bases against the German-controlled Balkans. The failed campaign, and in particular the Battle of Leros, inspired the 1957 novel **The Guns of Navarone** and the successful 1961 movie of the same name.

Question: American Callan Pinckney's eponymously named system became a best-selling (1980s-2000s) book/video franchise in what genre?
Answer: Fitness
Excerpt: Callan Pinckney was an American fitness professional. She achieved unprecedented success with her Callanetics exercises. Her 9 books all became international best-sellers and the video series that followed went on to sell over 6 million copies. Pinckney's first video release "Callanetics: 10 Years Younger In 10 Hours" outsold every other **fitness** video in the US.

Figure 1: Question-answer pairs with sample excerpts from evidence documents from TriviaQA exhibiting lexical and syntactic variability, and requiring reasoning from multiple sentences.

Recently, significant progress has been made by introducing large new reading comprehension datasets that primarily focus on one of the challenges listed above, for example by crowdsourcing the gathering of question answer pairs (Rajpurkar et al., 2016) or using cloze-style sentences instead of questions (Hermann et al., 2015; Onishi et al., 2016) (see Table 1 for more examples). In general, system performance has improved rapidly as each resource is released. The best models of-

Table 1: Comparison of TriviaQA with existing QA datasets. Our dataset is unique in that it is naturally occurring, well-formed questions collected independent of the evidences. *NewsQA uses evidence articles indirectly by using only article summaries.

ten achieve near-human performance levels within months or a year, fueling a continual need to build ever more difficult datasets. We argue that TriviaQA is such a dataset, by demonstrating that a high percentage of its questions require solving these challenges and showing that there is a large gap between state-of-the-art methods and human performance levels.

TriviaQA contains over 650K question-answer-evidence triples, that are derived by combining 95K Trivia enthusiast authored question-answer pairs with on average six supporting evidence documents per question. To our knowledge, TriviaQA is the first dataset where full-sentence questions are authored organically (i.e. independently of an NLP task) and evidence documents are collected *retrospectively* from Wikipedia and the Web. This decoupling of question generation from evidence collection allows us to control for potential bias in question style or content, while offering organically generated questions from various topics. Designed to engage humans, TriviaQA presents a new challenge for RC models. They should be able to deal with large amount of text from various sources such as news articles, encyclopedic entries and blog articles, and should handle inference over multiple sentences. For example, our dataset contains three times as many questions that require inference over multiple sentences than the recently released SQuAD (Rajpurkar et al., 2016) dataset. Section 4 present a more detailed discussion of these challenges.

Finally, we present baseline experiments on the TriviaQA dataset, including a linear classifier inspired by work on CNN Dailymail and MCTest (Chen et al., 2016; Richardson et al., 2013) and a state-of-the-art neural network baseline (Seo et al., 2017). The neural model performs best, but only achieves 40% for TriviaQA in comparison to 68% on SQuAD, perhaps due to the challenges listed above. The baseline results also fall far short of human performance levels, 79.7%, suggesting significant room for the future work. In summary, we make the following contributions.

- We collect over 650K question-answer-evidence triples, with questions originating from trivia enthusiasts independent of the evidence documents. A high percentage of the questions are challenging, with substantial syntactic and lexical variability and often requiring multi-sentence reasoning. The dataset and code are available at `http://nlp.cs.washington.edu/triviaqa/`, offering resources for training new reading-comprehension models.
- We present a manual analysis quantifying the quality of the dataset and the challenges involved in solving the task.
- We present experiments with two baseline methods, demonstrating that the TriviaQA tasks are not easily solved and are worthy of future study.
- In addition to the automatically gathered large-scale (but noisy) dataset, we present a clean, human-annotated subset of 1975 question-document-answer triples whose documents are certified to contain all facts required to answer the questions.

2 Overview

Problem Formulation We frame reading comprehension as the problem of answering a question q given the textual evidence provided by document set D. We assume access to a dataset of tuples $\{(q_i, a_i, D_i)|i = 1 \ldots n\}$ where a_i is a text string that defines the correct answer

to question q_i. Following recent formulations (Rajpurkar et al., 2016), we further assume that a_i appears as a substring for some document in the set D_i.[2] However, we differ by setting D_i as a *set* of documents, where previous work assumed a single document (Hermann et al., 2015) or even just a short paragraph (Rajpurkar et al., 2016).

Data and Distant Supervision Our evidence documents are automatically gathered from either Wikipedia or more general Web search results (details in Section 3). Because we gather evidence using an automated process, the documents are not *guaranteed* to contain all facts needed to answer the question. Therefore, they are best seen as a source of *distant supervision*, based on the assumption that the presence of the answer string in an evidence document implies that the document *does* answer the question.[3] Section 4 shows that this assumption is valid over 75% of the time, making evidence documents a strong source of distant supervision for training machine reading systems.

In particular, we consider two types of distant supervision, depending on the source of our documents. For web search results, we expect the documents that contain the correct answer a to be highly redundant, and therefore let each question-answer-document tuple be an independent data point. ($|D_i| = 1$ for all i and $q_i = q_j$ for many i, j pairs). However, in Wikipedia we generally expect most facts to be stated only once, so we instead pool all of the evidence documents and never repeat the same question in the dataset ($|D_i| = 1.8$ on average and $q_i \neq q_j$ for all i, j). In other words, each question (paired with the union of all of its evidence documents) is a single data point.

These are far from the only assumptions that could be made in this distant supervision setup. For example, our data would also support multi-instance learning, which makes the *at least once assumption*, from relation extraction (Riedel et al., 2010; Hoffmann et al., 2011) or many other possibilities. However, the experiments in Section 6 show that these assumptions do present a strong signal for learning; we believe the data will fuel significant future study.

[2]The data we will present in Section 3 would further support a task formulation where some documents D do not have the correct answer and the model must learn when to abstain. We leave this to future work.

[3]An example context for the first question in Figure 1 where such an assumption fails would be the following evidence string: *The Guns of Navarone is a 1961 British-American epic adventure war film directed by J. Lee Thompson.*

Total number of QA pairs	95,956
Number of unique answers	40,478
Number of evidence documents	662,659
Avg. question length (word)	14
Avg. document length (word)	2,895

Table 2: TriviaQA: Dataset statistics.

3 Dataset Collection

We collected a large dataset to support the reading comprehension task described above. First we gathered question-answer pairs from 14 trivia and quiz-league websites. We removed questions with less than four tokens, since these were generally either too simple or too vague.

We then collected textual evidence to answer questions using two sources: documents from Web search results and Wikipedia articles for entities in the question. To collect the former, we posed each question[4] as a search query to the Bing Web search API, and collected the top 50 search result URLs. To exclude the trivia websites, we removed from the results all pages from the trivia websites we scraped and any page whose url included the keywords *trivia*, *question*, or *answer*. We then crawled the top 10 search result Web pages and pruned PDF and other ill formatted documents. The search output includes a diverse set of documents such as blog articles, news articles, and encyclopedic entries.

Wikipedia pages for entities mentioned in the question often provide useful information. We therefore collected an additional set of evidence documents by applying TAGME, an off-the-shelf entity linker (Ferragina and Scaiella, 2010), to find Wikipedia entities mentioned in the question, and added the corresponding pages as evidence documents.

Finally, to support learning from distant supervision, we further filtered the evidence documents to exclude those missing the correct answer string and formed evidence document sets as described in Section 2. This left us with 95K question-answer pairs organized into (1) 650K training examples for the Web search results, each contain-

[4]Note that we did *not* use the answer as a part of the search query to avoid biasing the results.

Property	Example annotation	Statistics
Avg. entities / question	Which politician won the **Nobel Peace Prize** in 2009?	1.77 per question
Fine grained answer type	What **fragrant essential oil** is obtained from Damask Rose?	73.5% of questions
Coarse grained answer type	**Who** won the Nobel Peace Prize in 2009?	15.5% of questions
Time frame	What was photographed for the first time in **October 1959**	34% of questions
Comparisons	What is the appropriate name of the **largest** type of frog?	9% of questions

Table 3: Properties of questions on 200 annotated examples show that a majority of TriviaQA questions contain multiple entities. The boldfaced words hint at the presence of corresponding property.

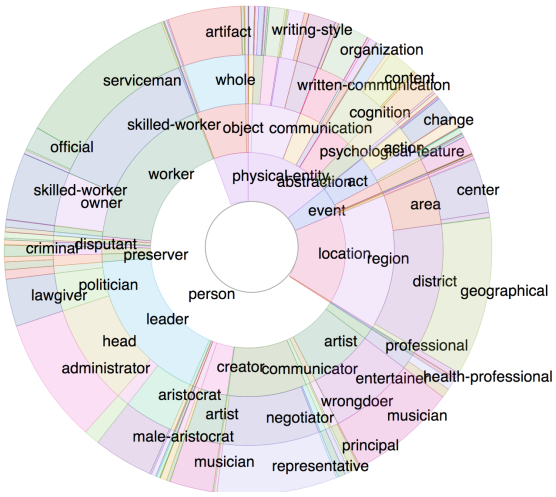

Figure 2: Distribution of hierarchical WordNet synsets for entities appearing in the answer. The arc length is proportional to the number of questions containing that category.

ing a single (combined) evidence document, and (2) 78K examples for the Wikipedia reading comprehension domain, containing on average 1.8 evidence documents per example. Table 2 contains the dataset statistics. While not the focus of this paper, we have also released the full unfiltered dataset which contains 110,495 QA pairs and 740K evidence documents to support research in allied problems such as open domain and IR-style question answering.

4 Dataset Analysis

A quantitative and qualitative analysis of TriviaQA shows it contains complex questions about a diverse set of entities, which are answerable using the evidence documents.

Question and answer analysis TriviaQA questions, authored by trivia enthusiasts, cover various topics of people's interest. The average question length is 14 tokens indicating that many questions are highly compositional. For qualitative analysis, we sampled 200 question answer pairs and manually analysed their properties. About 73.5% of these questions contain phrases that describe a fine grained category to which the answer belongs, while 15.5% hint at a coarse grained category (one of *person*, *organization*, *location*, and *miscellaneous*). Questions often involve reasoning over time frames, as well as making comparisons. A summary of the analysis is presented in Table 3.

Type	Percentage
Numerical	4.17
Free text	2.98
Wikipedia title	92.85
Person	32
Location	23
Organization	5
Misc.	40

Table 4: Distribution of answer types on 200 annotated examples.

Answers in TriviaQA belong to a diverse set of types. 92.85% of the answers are titles in Wikipedia,[5] 4.17% are numerical expressions (e.g., 9 kilometres) while the rest are open ended noun and verb phrases. A coarse grained type analysis of answers that are Wikipedia entities presented in Table 4. It should be noted that not all Wikipedia titles are named entities; many are common phrases such as *barber* or *soup*. Figure 2 shows diverse topics indicated by WordNet synsets of answer entities.

Evidence analysis A qualitative analysis of TriviaQA shows that the evidence contains answers for 79.7% and 75.4% of questions from the Wikipedia and Web domains respectively. To analyse the quality of evidence and evaluate baselines, we asked a human annotator to answer 986 and 1345 (dev and test set) questions from the Wikipedia and Web domains respectively. Trivia

[5]This is a very large set since Wikipedia has more than 11 million titles.

Reasoning	**Lexical variation (synonym)**
	Major correspondences between the question and the answer sentence are synonyms.
Frequency	41% in Wiki documents, 39% in web documents.
Examples	Q What is solid CO2 commonly called?
	S The frozen solid form of CO2, known as **dry ice** ...
	Q Who wrote the novel The Eagle Has landed?
	S The Eagle Has Landed is a book by British writer **Jack Higgins**
Reasoning	**Lexical variation and world knowledge**
	Major correspondences between the question and the document require common sense or external knowledge.
Frequency	17% in Wiki documents, 17% in web documents.
Examples	Q What is the first name of Madame Bovary in Flaubert's 1856 novel?
	S Madame Bovary (1856) is the French writer Gustave Flaubert's debut novel. The story focuses on a doctor's wife, **Emma** Bovary
	Q Who was the female member of the 1980's pop music duo, Eurythmics?
	S Eurythmics were a British music duo consisting of members **Annie Lennox** and David A. Stewart.
Reasoning	**Syntactic Variation**
	After the question is paraphrased into declarative form, its syntactic dependency structure does not match that of the answer sentence
Frequency	69% in Wiki documents, 65% in web documents.
Examples	Q In which country did the Battle of El Alamein take place?
	S The 1942 Battle of El Alamein in **Egypt** was actually two pivotal battles of World War II
	Q Whom was Ronald Reagan referring to when he uttered the famous phrase evil empire in a 1983 speech?
	S The phrase evil empire was first applied to the **Soviet Union** in 1983 by U.S. President Ronald Reagan.
Reasoning	**Multiple sentences**
	Requires reasoning over multiple sentences.
Frequency	40% in Wiki documents, 35% in web documents.
Examples	Q Name the Greek Mythological hero who killed the gorgon Medusa.
	S **Perseus** asks god to aid him. So the goddess Athena and Hermes helps him out to kill Medusa.
	Q Who starred in and directed the 1993 film A Bronx Tale?
	S **Robert De Niro** To Make His Broadway Directorial Debut With A Bronx Tale: The Musical. The actor starred and directed the 1993 film.
Reasoning	**Lists, Table**
	Answer found in tables or lists
Frequency	7% in web documents.
Examples	Q In Moh's Scale of hardness, Talc is at number 1, but what is number 2?
	Q What is the collective name for a group of hawks or falcons?

Table 5: Analysis of reasoning used to answer TriviaQA questions shows that a high proportion of evidence sentence(s) exhibit syntactic and lexical variation with respect to questions. Answers are indicated by boldfaced text.

questions contain multiple clues about the answer(s) not all of which are referenced in the documents. The annotator was asked to answer a question if the minimal set of facts (ignoring temporal references like *this year*) required to answer the question are present in the document, and abstain otherwise. For example, it is possible to answer the question, *Who became president of the Mormons in 1844, organised settlement of the Mormons in Utah 1847 and founded Salt Lake City?* using only the fact that Salt Lake City was founded by Brigham Young. We found that the accuracy (evaluated using the original answers) for the Wikipedia and Web domains was 79.6 and 75.3 respectively. We use the correctly answered questions (and documents) as verified sets for evaluation (section 6).

Challenging problem A comparison of evidence with respect to the questions shows a high proportion of questions require reasoning over multiple sentences. To compare our dataset against previous datasets, we classified 100 question-evidence pairs each from Wikipedia and the Web according to the form of reasoning required to answer them. We focus the analysis on Wikipedia since the analysis on Web documents are similar. Categories are not mutually exclusive: single example can fall into multiple categories. A summary of the analysis is presented in Table 5.

On comparing evidence sentences with their corresponding questions, we found that 69% of the questions had a different syntactic structure while 41% were lexically different. For 40% of the questions, we found that the information re-

quired to answer them was scattered over multiple sentences. Compared to SQuAD, over three times as many questions in TriviaQA require reasoning over multiple sentences. Moreover, 17% of the examples required some form of world knowledge. Question-evidence pairs in TriviaQA display more lexical and syntactic variance than SQuAD. This supports our earlier assertion that decoupling question generation from evidence collection results in a more challenging problem.

5 Baseline methods

To quantify the difficulty level of the dataset for current methods, we present results on neural and other models. We used a random entity baseline and a simple classifier inspired from previous work (Wang et al., 2015; Chen et al., 2016), and compare these to BiDAF (Seo et al., 2017), one of the best performing models for the SQuAD dataset.

5.1 Random entity baseline

We developed the random entity baseline for the Wikipedia domain since the provided documents can be directly mapped to candidate answers. In this heuristic approach, we first construct a candidate answer set using the entities associated with the provided Wikipedia pages for a given question (on average 1.8 per question). We then randomly pick a candidate that does not occur in the question. If no such candidate exists, we pick any random candidate from the candidate set.

5.2 Entity classifier

We also frame the task as a ranking problem over candidate answers in the documents. More formally, given a question q_i, an answer a_i^+, and a evidence document D_i, we want to learn a scoring function $score$, such that

$$score(a_i^+|q_i, D_i) > score(a_i^-|q_i, D_i)$$

where a_i^- is any candidate other than the answer. The function $score$ is learnt using LambdaMART (Wu et al., 2010),[6] a boosted tree based ranking algorithm.

This is similar to previous entity-centric classifiers for QA (Chen et al., 2016; Wang et al., 2015), and uses context and Wikipedia catalog based features. To construct the candidate answer set, we consider sentences that contain at least one word in common with the question. We then add every n-gram ($n \in [1, 5]$) that occurs in these sentences and is a title of some Wikipedia article.[7]

5.3 Neural model

Recurrent neural network models (RNNs) (Hermann et al., 2015; Chen et al., 2016) have been very effective for reading comprehension. For our task, we modified the BiDAF model (Seo et al., 2017), which takes a sequence of context words as input and outputs the start and end positions of the predicted answer in the context. The model utilizes an RNN at the character level, token level, and phrase level to encode context and question and uses attention mechanism between question and context.

Authored independently from the evidence document, TriviaQA does not contain the exact spans of the answers. We approximate the answer span by finding the first match of answer string in the evidence document. Developed for a dataset where the evidence document is a single paragraph (average 122 words), the BiDAF model does not scale to long documents. To overcome this, we truncate the evidence document to the first 800 words.[8]

When the data contains more than one evidence document, as in our Wikipedia domain, we predict for each document separately and aggregate the predictions by taking a sum of confidence scores. More specifically, when the model outputs a candidate answer A_i from n documents $D_{i,1}, ...D_{i,n}$ with confidences $c_{i,1}, ...c_{i,n}$, the score of A_i is given by

$$score(A_i) = \sum_k c_{i,k}$$

We select candidate answer with the highest score.

6 Experiments

An evaluation of our baselines shows that both of our tasks are challenging, and that the TriviaQA dataset supports significant future work.

[6] We use the RankLib implementation https://sourceforge.net/p/lemur/wiki/RankLib/

[7] Using a named entity recognition system to generate candidate entities is not feasible as answers can be common nouns or phrases.

[8] We found that splitting documents into smaller sub documents degrades performance since a majority of sub documents do not contain the answer.

		Train	Dev	Test
Wikipedia	Questions	61,888	7,993	7,701
	Documents	110,648	14,229	13,661
Web	Questions	76,496	9,951	9,509
	Documents	528,979	68,621	65,059
Wikipedia verified	Questions	-	297	584
	Documents	-	305	592
Web verified	Questions	-	322	733
	Documents	-	325	769

Table 6: Data statistics for each task setup. The Wikipedia domain is evaluated over questions while the web domain is evaluated over documents.

6.1 Evaluation Metrics

We use the same evaluation metrics as SQuAD – exact match (EM) and F1 over words in the answer(s). For questions that have *Numerical* and *FreeForm* answers, we use a single given answer as ground truth. For questions that have Wikipedia entities as answers, we use Wikipedia aliases as valid answer along with the given answer.

Since Wikipedia and the web are vastly different in terms of style and content, we report performance on each source separately. While using Wikipedia, we evaluate at the question level since facts needed to answer a question are generally stated only once. On the other hand, due to high information redundancy in web documents (around 6 documents per question), we report document level accuracy and F1 when evaluating on web documents. Lastly, in addition to distant supervision, we also report evaluation on the clean dev and test questions collection using a human annotator (section 4)

6.2 Experimental Setup

We randomly partition QA pairs in the dataset into train (80%), development (10%), and test set (10%). In addition to distant supervision evaluation, we also evaluate baselines on verified subsets (see section 4) of the dev and test partitions. Table 6 contains the number of questions and documents for each task. We trained the entity classifier on a random sample of 50,000 questions from the training set. For training BiDAF on the web domain, we first randomly sampled 80,000 documents. For both domains, we used only those (training) documents where the answer appears in the first 400 tokens to keep training time manageable. Designing scalable techniques that can use the entirety of the data is an interesting direction for future work.

6.3 Results

The performance of the proposed models is summarized in Table 7. The poor performance of the random entity baseline shows that the task is not already solved by information retrieval. For both Wikipedia and web documents, BiDAF (40%) outperforms the classifier (23%). The oracle score is the upper bound on the exact match accuracy.[9] All models lag significantly behind the human baseline of 79.7% on the Wikipedia domain, and 75.4% on the web domain.

We analyse the performance of BiDAF on the development set using Wikipedia as the evidence source by question length and answer type. The accuracy of the system steadily decreased as the length of the questions increased – with 50% for questions with 5 or fewer words to 32% for 20 or more words. This suggests that longer compositional questions are harder for current methods.

6.4 Error analysis

Our qualitative error analysis reveals that compositionality in questions and lexical variation and low signal-to-noise ratio in (full) documents is still a challenge for current methods. We randomly sampled 100 incorrect BiDAF predictions from the development set and used Wikipedia evidence documents for manual analysis. We found that 19 examples lacked evidence in any of the provided documents, 3 had incorrect ground truth, and 3 were valid answers that were not included in the answer key. Furthermore, 12 predictions were partially correct (*Napoleonic* vs *Napoleonic Wars*). This seems to be consistent with human performance of 79.7%.

For the rest, we classified each example into one or more categories listed in Table 8. Distractor entities refers to the presence of entities similar to ground truth. E.g., for the question, *Rebecca Front plays Detective Chief Superintendent Innocent in which TV series?*, the evidence describes all roles played by Rebecca Front.

The first two rows suggest that long and noisy documents make the question answering task more difficult, as compared for example to the short passages in SQuAD. Furthermore, a high proportion of errors are caused by paraphrasing, and the answer is sometimes stated indirectly. For

[9] A question q is considered answerable for the oracle score if the correct answer is found in the evidence D or, in case of the classifier, is a part of the candidate set. Since we truncate documents, the upper bound is not 100%.

Method	Domain	Distant Supervision						Verified					
		Dev			Test			Dev			Test		
		EM	F1	Oracle	EM	F1	Oracle	EM	F1	Oracle	EM	F1	Oracle
Random	Wiki	12.72	22.91	16.30	12.74	22.35	16.28	14.81	23.31	19.53	15.41	25.44	19.19
Classifier		23.42	27.68	71.41	22.45	26.52	71.67	24.91	29.43	80.13	27.23	31.37	77.74

Table 7: Performance of all systems on TriviaQA using distantly supervised evaluation. The best performing system is indicated in bold.

Category	Proportion
Insufficient evidence	19
Prediction from incorrect document(s)	7
Answer not in clipped document	15
Paraphrasing	29
Distractor entities	11
Reasoning over multiple sentences	18

Table 8: Qualitative error analysis of BiDAF on Wikipedia evidence documents.

example, the evidence for the question *What was Truman Capote's last name before he was adopted by his stepfather?* consists of the following text *Truman Garcia Capote born Truman Streckfus Persons, was an American ... In 1933, he moved to New York City to live with his mother and her second husband, Joseph Capote, who adopted him as his stepson and renamed him Truman Garca Capote.*

7 Related work

Recent interest in question answering has resulted in the creation of several datasets. However, they are either limited in scale or suffer from biases stemming from their construction process. We group existing datasets according to their associated tasks, and compare them against TriviaQA. The analysis is summarized in Table 1.

7.1 Reading comprehension

Reading comprehension tasks aims to test the ability of a system to understand a document using questions based upon its contents. Researchers have constructed cloze-style datasets (Hill et al., 2015; Hermann et al., 2015; Paperno et al., 2016; Onishi et al., 2016), where the task is to predict missing words, often entities, in a document. Cloze-style datasets, while easier to construct large-scale automatically, do not contain natural language questions.

Datasets with natural language questions include MCTest (Richardson et al., 2013), SQuAD (Rajpurkar et al., 2016), and NewsQA (Trischler et al., 2016). MCTest is limited in scale with only 2640 multiple choice questions. SQuAD contains 100K crowdsourced questions and answers paired with short Wikipedia passages. NewsQA uses crowdsourcing to create questions solely from news article summaries in order to control potential bias. The crucial difference between SQuAD/NewsQA and TriviaQA is that TriviaQA questions have not been crowdsourced from preselected passages. Additionally, our evidence set consists of web documents, while SQuAD and NewsQA are limited to Wikipedia and news articles respectively. Other recently released datasets include (Lai et al., 2017).

7.2 Open domain question answering

The recently released MS Marco dataset (Nguyen et al., 2016) also contains independently authored questions and documents drawn from the search results. However, the questions in the dataset are derived from search logs and the answers are crowdsourced. On the other hand, trivia enthusiasts provided both questions and answers for our dataset.

Knowledge base question answering involves converting natural language questions to logical forms that can be executed over a KB. Proposed datasets (Cai and Yates, 2013; Berant et al., 2013; Bordes et al., 2015) are either limited in scale or in the complexity of questions, and can only retrieve facts covered by the KB.

A standard task for open domain IR-style QA is the annual TREC competitions (Voorhees and Tice, 2000), which contains questions from various domains but is limited in size. Many advances from the TREC competitions were used in the IBM Watson system for *Jeopardy!* (Ferrucci et al., 2010). Other datasets includes SearchQA

(Dunn et al., 2017) where *Jeopardy!* questions are paired with search engine snippets, the WikiQA dataset (Yang et al., 2015) for answer sentence selection, and the Chinese language WebQA (Li et al., 2016) dataset, which focuses on the task of answer phrase extraction. TriviaQA contains examples that could be used for both stages of the pipeline, although our focus on this paper is instead on using the data for reading comprehension where the answer is always present.

Other recent approaches attempt to combine structured high precision KBs with semi-structured information sources like OpenIE triples (Fader et al., 2014), HTML tables (Pasupat and Liang, 2015), and large (and noisy) corpora (Sawant and Chakrabarti, 2013; Joshi et al., 2014; Xu et al., 2015). TriviaQA, which has Wikipedia entities as answers, makes it possible to leverage structured KBs like Freebase, which we leave to future work. Furthermore, about 7% of the TriviaQA questions have answers in HTML tables and lists, which could be used to augment these existing resources.

Trivia questions from quiz bowl have been previously used in other question answering tasks (Boyd-Graber et al., 2012). Quiz bowl questions are paragraph length and pyramidal.[10] A number of different aspects of this problem have been carefully studied, typically using classifiers over a pre-defined set of answers (Iyyer et al., 2014) and studying incremental answering to answer as quickly as possible (Boyd-Graber et al., 2012) or using reinforcement learning to model opponent behavior (He et al., 2016). These competitive challenges are not present in our single-sentence question setting. Developing joint models for multi-sentence reasoning for questions and answer documents is an important area for future work.

8 Conclusion and Future Work

We present TriviaQA, a new dataset of 650K question-document-evidence triples. To our knowledge, TriviaQA is the first dataset where questions are authored by trivia enthusiasts, independently of the evidence documents. The evidence documents come from two domains – Web search results and Wikipedia pages – with highly differing levels of information redundancy. Results from current state-of-the-art baselines indicate that TriviaQA is a challenging testbed that deserves significant future study.

While not the focus of this paper, TriviaQA also provides a provides a benchmark for a variety of other tasks such as IR-style question answering, QA over structured KBs and joint modeling of KBs and text, with much more data than previously available.

[10] Pyramidal questions consist of a series of clues about the answer arranged in order from most to least difficult.

Learning Semantic Correspondences in Technical Documentation

Kyle Richardson and **Jonas Kuhn**
Institute of Natural Language Processing
University of Stuttgart
{kyle,jonas}@ims.uni-stuttgart.de

Abstract

We consider the problem of translating high-level textual descriptions to formal representations in technical documentation as part of an effort to model the meaning of such documentation. We focus specifically on the problem of learning translational correspondences between text descriptions and grounded representations in the target documentation, such as formal representation of functions or code templates. Our approach exploits the parallel nature of such documentation, or the tight coupling between high-level text and the low-level representations we aim to learn. Data is collected by mining technical documents for such parallel text-representation pairs, which we use to train a simple semantic parsing model. We report new baseline results on sixteen novel datasets, including the standard library documentation for nine popular programming languages across seven natural languages, and a small collection of Unix utility manuals.

1 Introduction

Technical documentation in the computer domain, such as source code documentation and other how-to manuals, provide high-level descriptions of how lower-level computer programs and utilities work. Often these descriptions are coupled with formal representations of these lower-level features, expressed in the target programming languages. For example, Figure 1.1 shows the source code documentation (in red/bold) for the `max` function in the Java programming language paired with the representation of this function in the underlying Java language (in black). This formal representation captures the name of the function, the return value, the types of arguments the function takes, among other details related to the function's place and visibility in the overall source code collection or API.

1. Java Documentation

```
*Returns the greater of two long values
*
* @param a an argument
* @param b another argument
* @return the larger of a and b
* @see java.lang.Long#MAX_VALUE
*/
 public static long max(long a, long b)
```

2. Clojure Documentation

```
(defn random-sample
  "Returns items from coll with random
  probability of prob (0.0 - 1.0)"
  ([prob coll] ...))
```

3. PHP documentation (French)

```
Ajoute une valeur comme dernier élément
*
* @param value La valeur á ajouter
* @see ArrayIterations::next()
*/
public void append(mixed $value)
```

Figure 1: Example source code documentation.

Given the high-level nature of the textual annotations, modeling the meaning of any given description is not an easy task, as it involves much more information than what is directly provided in the associated documentation. For example, capturing the meaning of the description *the greater of* might require having a background theory about quantity/numbers and relations between different quantities. A first step towards capturing the meaning, however, is learning to translate this description to symbols in the target representation, in this case to the `max` symbol. By doing this translation to a formal language, modeling and learning the subsequent semantics becomes easier since we are eliminating the ambiguity of ordinary lan-

https://doi.org/10.18653/v1/P17-1148

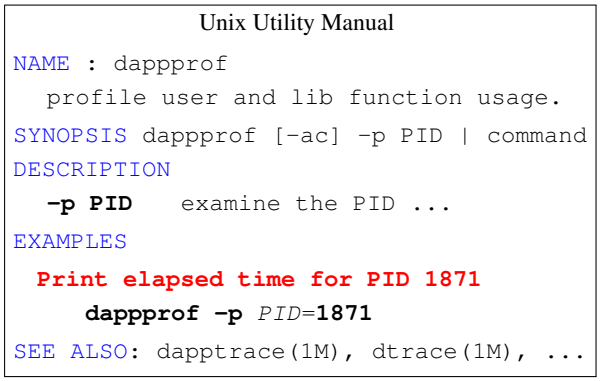

Figure 2: An example computer utility manual in the Unix domain. Descriptions of example uses are shown in red.

guage. Similarly, we would want to first translate the description *two long values*, which specifies the number and type of argument taken by this function, to the sequence `long a,long b`.

By focusing on translation, we can create new datasets by mining these types of source code collections for sets of parallel text-representation pairs. Given the wide variety of available programming languages, many such datasets can be constructed, each offering new challenges related to differences in the formal representations used by different programming languages. Figure 1.2 shows example documentation for the Clojure programming language, which is part of the Lisp family of languages. In this case, the description *Returns random probability of* should be translated to the function name `random-sample` since it describes what the overall function does. Similarly, the argument descriptions *from coll* and *of prob* should translate to `coll` and `prob`.

Given the large community of programmers around the world, many source code collections are available in languages other than English. Figure 1.3 shows an example entry from the French version of the PHP standard library, which was translated by volunteer developers. Having multilingual data raises new challenges, and broadens the scope of investigations into this type of semantic translation.

Other types of technical documentation, such as utility manuals, exhibit similar features. Figure 2 shows an example manual in the domain of Unix utilities. The textual description in red/bold describes an example use of the *dappprof* utility paired with formal representations in the form of executable code. As with the previous examples, such formal representations do not capture the full meaning of the different descriptions, but serve as a convenient operationalization, or *translational semantics*, of the meaning in Unix. *Print elapsed time*, for example, roughly describes what the `dappprof` utility does, whereas *PID 1871* describes the second half of the code sequence.

In both types of technical documentation, information is not limited to raw pairs of descriptions and representations, but can include other information and clues that are useful for learning. Java function annotations include textual descriptions of individual arguments and return values (shown in green). Taxonomic information and pointers to related functions or utilities are also annotated (e.g., the `@see` section in Figure 1, or `SEE ALSO` section in Figure 2). Structural information about code sequences, and the types of abstract arguments these sequences take, are described in the `SYNOPSIS` section of the Unix manual. This last piece of information allows us to generate abstract code templates, and generalize individual arguments. For example, the raw argument `1871` in the sequence `dappprof -p 1871` can be typed as a `PID` instance, and an argument of the `-p` flag.

Given this type of data, a natural experiment is to see whether we can build programs that translate high-level textual descriptions to correct formal representations. We aim to learn these translations using raw text-meaning pairs as the sole supervision. Our focus is on learning function translations or representations within nine programming language APIs, each varying in size, representation style, and source natural language. To our knowledge, our work is the first to look at translating source code descriptions to formal representations using such a wide variety of programming and natural languages. In total, we introduce fourteen new datasets in the source code domain that include seven natural languages, and report new results for an existing dataset. As well, we look at learning simple code templates using a small collection of English Unix manuals.

The main goal of this paper is to establish strong baselines results on these resources, which we hope can be used for benchmarking and developing new semantic parsing methods. We achieved initial baselines using the language modeling and translation approach of Deng and Chrupała (2014). We also show that modest improvements can be achieved by using a more conventional

discriminative model (Zettlemoyer and Collins, 2009) that, in part, exploits document-level features from the technical documentation sets.

2 Related Work

Our work is situated within research on semantic parsing, which focuses on the problem of generating formal meaning representations from text for natural language understanding applications. Recent interest in this topic has centered around learning meaning representation from example text-meaning pairs, for applications such as automated question-answering (Berant et al., 2013), robot control (Matuszek et al., 2012) and text generation (Wong and Mooney, 2007a).

While generating representations for natural language understanding is a complex task, most studies focus on the translation or generation problem independently of other semantic or knowledge representation issues. Earlier work looks at supervised learning of logical representations using example text-meaning pairs using tools from statistical machine translation (Wong and Mooney, 2006) and parsing (Zettlemoyer and Collins, 2009). These methods are meant to be applicable to a wide range of translation problems and representation types, which make new parallel datasets or resources useful for furthering the research.

In general, however, such datasets are hard to construct since building them requires considerable domain knowledge and knowledge of logic. Alternatively, we construct parallel datasets automatically from technical documentation, which obviates the need for annotation. While the formal representations are not actual logical forms, they still provide a good test case for testing how well semantic parsers learn translations to representations.

To date, most benchmark datasets are limited to small controlled domains, such as geography and navigation. While attempts have been made to do open-domain semantic parsing using larger, more complex datasets (Berant et al., 2013; Pasupat and Liang, 2015), such resources are still scarce. In Figure 3, we compare the details of one widely used dataset, Geoquery (Zelle and Mooney, 1996), to our new datasets. Our new resources are on average much larger than geoquery in terms of the number of example pairs, and the size of the different language vocabularies. Most existing datasets are also primarily English-based, while we focus on learning in a multilingual setting using several new moderately sized datasets.

Within semantic parsing, there has also been work on situated or grounded learning, that involves learning in domains with weak supervision and indirect cues (Liang, 2016; Richardson and Kuhn, 2016). This has sometimes involved learning from automatically generated parallel data and representations (Chen and Mooney, 2008) of the type we consider in this paper. Here one can find work in technical domains, including learning to generate regular expressions (Manshadi et al., 2013; Kushman and Barzilay, 2013) and other types of source code (Quirk et al., 2015), which ultimately aim to solve the problem of natural language programming. We view our work as one small step in this general direction.

Our work is also related to software components retrieval and builds on the approach of Deng and Chrupała (2014). Robustly learning the translation from language to code representations can help to facilitate natural language querying of API collections (Lv et al., 2015). As part of this effort, recent work in machine learning has focused on the similar problem of learning code representations using resources such as StackOverflow and Github. These studies primarily focus on learning longer programs (Allamanis et al., 2015) as opposed to function representations, or focus narrowly on a single programming language such as Java (Gu et al., 2016) or on related tasks such as text generation (Iyer et al., 2016; Oda et al., 2015). To our knowledge, none of this work has been applied to languages other than English or such a wide variety of programming languages.

3 Mapping Text to Representations

In this section, we formulate the basic problem of translating to representations in technical documentation.

3.1 Problem Description

We use the term *technical documentation* to refer to two types of resources: textual descriptions inside of source code collections, and computer utility manuals. In this paper, the first type includes high-level descriptions of functions in standard library source code documentation. The second type includes a collection of Unix manuals, also known as man pages. Both types include pairs of text and code representations.

Dataset	#Pairs	#Descr.	Symbols	#Words	Vocab.	Example Pairs (x, z), **Goal:** learn a function $x \rightarrow z$
Java	7,183	4,804	4,072	82,696	3,721	x : Compares this Calendar to the specified Object. z : `boolean util.Calendar.equals(Object obj)`
Ruby	6,885	1,849	3,803	67,274	5,131	x : Computes the arc tangent given y and x. z : `Math.atan2(y,x) → Float`
PHP$_{en}$	6,611	13,943	8,308	68,921	4,874	x : Delete an entry in the archive using its name. z : `bool ZipArchive::deleteName(string $name)`
Python	3,085	429	3,991	27,012	2,768	x : Remove the specific filter from this handler. z : `logging.Filterer.removeFilter(filter)`
Elisp	2,089	1,365	1,883	30,248	2,644	x : This function returns the total height, in lines, of the window. z : `(window-total-height window round)`
Haskell	1,633	255	1,604	19,242	2,192	x : Extract the second component of a pair. z : `Data.Tuple.snd :: (a, b) -> b`
Clojure	1,739	–	2,569	17,568	2,233	x : Returns a lazy seq of every nth item in coll. z : `(core.take-nth n coll)`
C	1,436	1,478	1,452	12,811	1,835	x : Returns the current file position of the stream stream. z : `long int ftell(FILE *stream)`
Scheme	1,301	376	1,343	15,574	1,756	x : Returns a new port with type port-type and the given state. z : `(make-port port-type state)`
Unix	921	940	1,000	11,100	2,025	x : To get policies for a specific user account. z : `pwpolicy -u username -getpolicy`
Geoquery	880	–	167	6,663	279	x : What is the tallest mountain in America? z : `(highest(mountain(loc_2(countryid usa))))`

Figure 3: Description of our English corpus collection with example text/function pairs.

We will refer to the target representations in these resources as *API components*, or components. In source code, components are formal representations of functions, or *function signatures* (Deng and Chrupała, 2014). The form of a function signature varies depending on the resource, but in general gives a specification of how a function is named and structured. The example function signatures in Figure 3 all specify a function name, a list of arguments, and other optional information such as a return value and a namespace. Components in utility manuals are short executable code sequences intended to show an example use of a utility. We assume typed code sequences following Richardson and Kuhn (2014), where the constituent parts of the sequences are abstracted by type.

Given a set of example text-component pairs, $D = \{(x_i, z_i)\}_{i=1}^{n}$, the goal is to learn how to generate correct, well-formed components $z \in \mathcal{C}$ for each input x. Viewed as a semantic parsing problem, this treats the target components as a kind of formal meaning representation, analogous to a logical form. In our experiments, we assume that the complete set of output components are known. In the API documentation sets, this is because each standard library contains a finite number of function representations, roughly corresponding to the number of pairs as shown in Figure 3. For a given input, therefore, the goal is to find the best candidate function translation within the space of the total API components $\mathcal{C}$ (Deng and Chrupała, 2014).

Given these constraints, our setup closely resembles that of Kushman et al. (2014), who learn to parse algebra word problems using a small set of equation templates. Their approach is inspired by template-based information extraction, where templates are recognized and instantiated by slot-filling. Our function signatures and code templates have a similar slot-like structure, consisting of slots such as return value, arguments, function name and namespace.

3.2 Language Modeling Baselines

Existing approaches to semantic parsing formalize the mapping from language to logic using a variety of formalisms including CFGs (Börschinger et al., 2011), CCGs (Kwiatkowski et al., 2010), synchronous CFGs (Wong and Mooney, 2007b). Deciding to use one formalism over another is often motivated by the complexities of the target representations being learned. For example, recent interest in learning graph-based representations such as those in the AMR bank (Banarescu et al., 2013)

requires parsing models that can generate complex graph shaped derivations such as CCGs (Artzi et al., 2015) or HRGs (Peng et al., 2015). Given the simplicity of our API representations, we opt for a simple semantic parsing model that exploits the finiteness of our target representations.

Following ((Deng and Chrupała, 2014); henceforth DC), we treat the problem of component translation as a language modeling problem (Song and Croft, 1999). For a given *query* sequence or text $x = w_i, .., w_I$ and *component* sequence $z = u_j, .., u_J$, the probability of the component given the query is defined as follows using Bayes' theorem: $p(z|x) \propto p(x|z)p(z)$.

By assuming a uniform prior over the probability of each component $p(z)$, the problem reduces to computing $p(x|z)$, which is where language modeling is used. Given each word w_i in the query, a unigram model is defined as $p(x|z) = \prod_{i=1}^{I} p(w_i|z)$. Using this formulation, we can then define different models to estimate $p(w|z)$.

Term Matching As a baseline for $p(w|z)$, DC define a *term matching* approach that exploits the fact that many queries in our English datasets share vocabulary with target component vocabulary. A smoothed version of this baseline is defined below, where $f(w|z)$ is the frequency of matching terms in the target signature, $f(w|\mathcal{C})$ is frequency of the term word in the overall documentation collection, and λ is a smoothing parameter (for Jelinek-Mercer smoothing):

$$p(x|z) = \prod_{w \in x} (1-\lambda) f(w|z) + \lambda f(w|\mathcal{C})$$

Translation Model In order to account for the co-occurrence between non-matching words and component terms, DC employ a word-based translation model, which models the relation between natural language words w_j and individual component terms u_j. In this paper, we limit ourselves to sequence-based word alignment models (Och and Ney, 2003), which factor in the following manner:

$$p(x|z) = \prod_{i=1}^{I} \sum_{j=0}^{J} p_t(w_i|u_j) p_d(l(j)|i, I, J)$$

Here each $p_t(w_i|u_j)$ defines an (unsmoothed) multinomial distribution over a given component term u_j for all words w_j. The function p_d is a distortion parameter, and defines a dependency between the alignment positions and the lengths of both input strings. This function, and the definition of $l(j)$, assumes different forms according to the particular alignment model being used. We consider three different types of alignment models each defined in the following way:

$$p_d(l(j)|...) = \begin{cases} \frac{1}{J+1} & (1) \\ a(j|i, I, J) & (2) \\ a(t(j)|i, I, tlen(J)) & (3) \end{cases}$$

Models (1-2) are the classic IBM word-alignment models of Brown et al. (1993). IBM Model 1, for example, assumes a uniform distribution over all positions, and is the main model investigated in DC. For comparison, we also experiment with IBM Model 2, where each $l(j)$ refers to the string position of j in the component input, and $a(..)$ defines a multinomial distribution such that $\sum_{j=0}^{J} a(j|i, I, J) = 1.0$.

We also define a new tree based alignment model (3) that takes into account the syntax associated with the function representations. Each $l(j)$ is the relative tree position of the alignment point, shown as $t(j)$, and $tlen(J)$ is the length of the tree associated with z. This approach assumes a tree representation for each z. We generated these trees heuristically by preserving the information that is lost when components are converted to a linear sequence representation. An example structure for PHP is shown in Figure 4, where the red solid line indicates the types of potential errors avoided by this model.

Learning is done by applying the standard EM training procedure of Brown et al. (1993).

Algorithm 1 Rank Decoder

Input: Query x, Components $\mathcal{C}$ of size m, rank k, model $\mathcal{A}$, sort function K-BEST
Output: Top k components ranked by $\mathcal{A}$ model score p

```
procedure RANKCOMPONENTS(x, C, k, A)
    SCORES ← [ ]                          ▷ Initialize score list
    for each component c ∈ C do
        p ← ALIGN_A(x, c)                 ▷ Score using A
        SCORES += (c, p)                  ▷ Add to list
    return K-Best(SCORES,k)               ▷ k best components
```

3.3 Ranking and Decoding

Algorithm 1 shows how to rank API components. For a text input x, we iterate through all known API components $\mathcal{C}$ and assign a score using a model $\mathcal{A}$. We then rank the components by their scores using a K-BEST function. This method serves as a type of word-based decoding algorithm

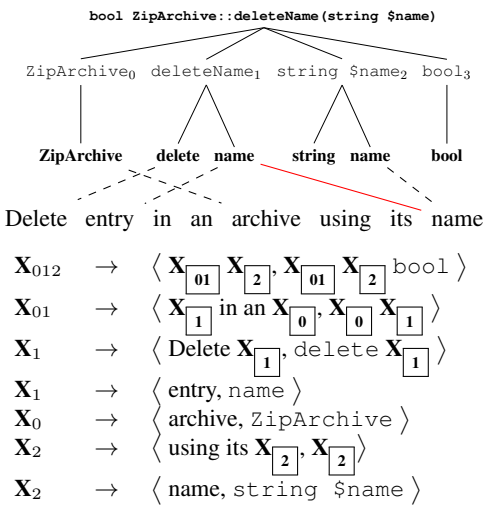

Figure 4: An example tree structure (above) associated with an input component. Below are Hiero rules (Chiang, 2007) extracted from the alignment and tree information.

which is simplified by the finite nature of the target language. The complexity of the scoring procedure, lines 3-5, is linear over the number components m in $\mathcal{C}$. In practice, we implement the K-BEST sorting function on line 6 as a binary insertion sort on line 5, resulting in an overall complexity of $O(m\ log\ m)$.

While iterating over m API components might not be feasible given more complicated formal languages with recursion, a more clever decoding algorithm could be applied, e.g., one based on the lattice decoding approach of (Dyer et al., 2008). Since we are interested in providing initial baseline results, we leave this for future work.

4 Discriminative Approach

In this section, we introduce a new model that aims to improve on the previous baseline methods.

While the previous models are restricted to word-level information, we extend this approach by using a discriminative reranking model that captures phrase information to see if this leads to an improvement. This model can also capture document-level information from the APIs, such as the additional textual descriptions of parameters, *see also* declarations or classes of related functions and syntax information.

4.1 Modeling

Like in most semantic parsing approaches (Zettlemoyer and Collins, 2009; Liang et al., 2011), our model is defined as a conditional log-linear model over components $z \in \mathcal{C}$ with parameters $\theta \in \mathbb{R}^b$, and a set of feature functions $\phi(x, z)$: $p(\, z|\, x; \theta) \propto e^{\theta \cdot \phi(x,z)}$.

Formally, our training objective is to maximize the conditional log-likehood of the correct component output z for each input x: $\mathcal{O}(\theta) = \sum_{i=1}^{n} \log\ p\,(z_i \,|\, x_i; \theta)$.

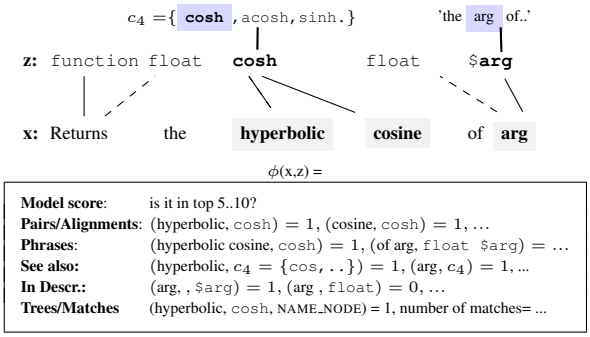

Figure 5: Example features used by our rerankers.

4.2 Features

Our model uses word-level features, such as word match, word pairs, as well as information from the underlying aligner model such as Viterbi alignment information and model score. Two additional categories of non-word features are described below. An illustration of the feature extraction procedure is shown in Figure 5 [1].

Phrases Features We extract phrase features (e.g., (hyper. cosine, `cosh`) in Figure 5) from example text component pairs by training symmetric word aligners and applying standard word-level heuristics (Koehn et al., 2003). Additional features, such as phrase match/overlap, tree positions of phrases, are defined over the extracted phrases.

We also extract hierarchical phrases (Chiang, 2007) using a variant of the SAMT method of Zollmann and Venugopal (2006) and the component syntax trees. Example rules are shown in Figure 4, where *gaps* (i.e., symbols in square brackets) are filled with smaller phrase-tree alignments.

Document Level Features Document features are of two categories. The first includes additional textual descriptions of parameters, return values, and modules. One class of features is whether certain words under consideration appear in the `@param` and `@return` descriptions of the target components. For example, the *arg* token in

[1] A more complete description of features is included as supplementary material, along with all source code.

Algorithm 2 Online Rank Learner

Input: Dataset D, components $\mathcal{C}$, iterations T, rank k, learning rate α, model $\mathcal{A}$, ranker function RANK
Output: Weight vector θ

1: **procedure** LEARNRERANKER($D, \mathcal{C}, T, k, \alpha, \mathcal{A}$, RANK)
2: $\theta \leftarrow 0$ ▷ Initialize
3: **for** t ∈ $1..T$ **do**
4: **for** pairs $(x_i, z_i) \in D$ **do**
5: $\mathcal{S} = \text{RANK}(x_i, \mathcal{C}, k, \mathcal{A})$ ▷ Scored candidates
6: $\Delta = \phi(x_i, z_i) - E_{s \in \mathcal{S} \sim p(s|x_i;\theta)}[\phi(x_i, s)]$
7: $\theta = \theta + \alpha\Delta$ ▷ Update online
8: **return** θ

Figure 5 appears in the textual description of the `$arg` parameter elsewhere in the documentation string.

Other features relate to general information about abstract symbol categories, as specified in *see-also* assertions, or *hyper-link* pointers. By exploiting this information, we extract general classes of functions, for example the set of hyperbolic function (e.g., `sinh`, `cosh`, shown as c_4 in Figure 5), and associate these classes with words and phrases (e.g., *hyperbolic* and *hyperbolic cosine*).

4.3 Learning

To optimize our objective, we use Algorithm 2. We estimate the model parameters θ using a K-best approximation of the standard stochastic gradient updates (lines 6-7), and a ranker function RANK. We note that while we use the ranker described in Algorithm 1, any suitable ranker or decoding method could be used here.

5 Experimental Setup

5.1 Datasets

Source code documentation Our source code documentation collection consists of the standard library for nine programming languages, which are listed in Figure 3. We also use the translated version of the PHP collection for six additional languages, the details of which are shown in Figure 6. The Java dataset was first used in DC, while we extracted all other datasets for this work.

The size of the different datasets are detailed in both figures. The number of pairs is the number of single sentences paired with function representations, which constitutes the core part of these datasets. The number of descriptions is the number of additional textual descriptions provided in the overall document, such as descriptions of parameters or return values.

Dataset	# Pairs	#Descr.	Symbols	Words	Vocab.
PHP_{fr}	6,155	14,058	7,922	70,800	5,904
PHP_{es}	5,823	13,285	7,571	69,882	5,790
PHP_{ja}	4,903	11,251	6,399	65,565	3,743
PHP_{ru}	2,549	6,030	3,340	23,105	4,599
PHP_{tr}	1,822	4,414	2,725	16,033	3,553
PHP_{de}	1,538	3,733	2,417	17,460	3,209

Figure 6: The non-English PHP datasets.

We also quantify the different datasets in terms of unique symbols in the target representations, shown as *Symbols*. All function representations and code sequences are linearized, and in some cases further tokenized, for example, by converting out of camel case or removing underscores.

Man pages The collection of man pages is from Richardson and Kuhn (2014) and includes 921 text-code pairs that span 330 Unix utilities and man pages. Using information from the synopsis and parameter declarations, the target code representations are abstracted by type. The extra descriptions are extracted from parameter descriptions, as shown in the `DESCRIPTION` section in Figure 1, as well as from the `NAME` sections of each manual.

5.2 Evaluation

For evaluation, we split our datasets into separate training, validation and test sets. For Java, we reserve 60% of the data for training and the remaining 40% for validation (20%) and testing (20%). For all other datasets, we use a 70%-30% split. From a retrieval perspective, these left out descriptions are meant to mimic unseen queries to our model. After training our models, we evaluate on these held out sets by ranking all known components in each resource using Algorithm 1. A predicted component is counted as correct if it matches *exactly* a gold component.

Following DC, we report the accuracy of predicting the correct representation at the first position in the ranked list (Accuracy @1) and within the top 10 positions (Accuracy @10). We also report the mean reciprocal rank MRR, or the multiplicative inverse of the rank of the correct answer.

Baselines For comparison, we trained a bag-of-words classifier (the BoW Model in Table 1). This model uses the occurrence of word-component symbol pairs as binary features, and aims to see if word co-occurrence alone is sufficient to for ranking representations.

Table 1: Test results according to the table below.

Since our discriminative models use more data than the baseline models, which therefore make the results not directly comparable, we train a more comparable translation model, shown as *M1 Descr.* in Table 1, by adding the additional textual data (i.e. parameter and return or module descriptions) to the models' parallel training data.

6 Results and Discussion

Test results are shown in Table 1. Among the baseline models, IBM Model 1 outperforms virtually all other models and is in general a strong baseline. Of particular note is the poor performance of the higher-order translation models based on Model 2 and the Tree Model. While Model 2 is known to outperform Model 1 on more conventional translation tasks (Och and Ney, 2003), it appears that such improvements are not reflected in this type of semantic translation context.

The bag-of-words (BoW) and Term Match baselines are outperformed by all other models. This shows that translation in this context is more complicated than simple word matching. In some cases the term matching baseline is competitive with other models, suggesting that API collections differ in how language descriptions overlap with component names and naming conventions. It is clear, however, that this heuristic only works for English, as shown by results on the non-English PHP datasets in Table 1.

We achieve improvements on many datasets by adding additional data to the translation model (M1 Descr.). We achieve further improvements on all datasets using the discriminative model (Reranker), with most increases in performance occurring at how the top ten items are ranked. This last result suggests that phrase-level and document-level features can help to improve the overall ranking and translation, though in some cases the improvement is rather modest.

Despite the simplicity of our semantic parsing model and decoder, there is still much room for improvement, especially on achieving better Accuracy @1. While one might expect better results when moving from a word-based model to a model that exploits phrase and hierarchical phrase features, the sparsity of the component vocabulary is such that most phrase patterns in the training are not observed in the evaluation. In many benchmark semantic parsing datasets, such sparsity issues do not occur (Cimiano and Minock, 2009), suggesting that state-of-the-art methods will have similar problems when applied to our datasets.

Recent approaches to open-domain semantic parsing have dealt with this problem by using paraphrasing techniques (Berant and Liang, 2014) or distant supervision (Reddy et al., 2014). We expect that these methods can be used to improve our models and results, especially given the wide availability of technical documentation, for example, distributed within the Opus project (Tiedemann, 2012).

Model Errors We performed analysis on some of the incorrect predictions made by our models. For some documentation sets, such as those in the GNU documentation collection[2], information is organized into a small and concrete set of categories/chapters, each corresponding to various features or modules in the language and related functions. Given this information, Figure

[2]https://www.gnu.org/doc/doc.en.html

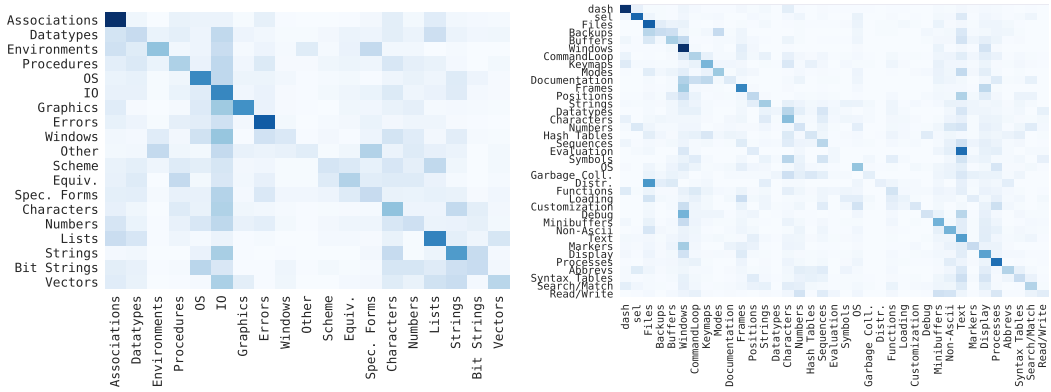

Figure 7: Function predictions by documentation category for Scheme (left) and Elisp (right).

7 shows the confusion between predicting different categories of functions, where the rows show the categories of functions to be predicted and the columns show the different categories predicted. We built these plots by finding the categories of the top 50 non-gold (or erroneous) representations generated for each validation example.

The step-like lines through the diagonal of both plots show that alternative predictions (shaded according to occurrence) are often of the same category, most strikingly for the corner categories. This trend seems stable across other datasets, even among datasets with large numbers of categories. Interestingly, many confusions appear to be between related categories. For example, when making predictions about `Strings` functions in Scheme, the model often generates function related to `BitStrings`, `Characters` and `IO`. Again, this trend seems to hold for other documentation sets, suggesting that the models are often making semantically sensible decisions.

Looking at errors in other datasets, one common error involves generating functions with the same name and/or functionality. In large libraries, different modules sometimes implement that same core functions, such the `genericpath` or `posixpath` modules in Python. When generating a representation for the text *return size of file*, our model confuses the `getsize(filename)` function in one module with others. Similarly, other subtle distinctions that are not explicitly expressed in the text descriptions are not captured, such as the distinction in Haskell between *safe* and *unsafe* bit shifting functions.

While many of these predictions might be correct, our evaluation fails to take into account these various equivalences, which is an issue that should be investigated in future work. Future work will also look systematically at the effect that types (i.e., in statically typed versus dynamic languages) have on prediction.

7 Future Work

We see two possible use cases for this data. First, for benchmarking semantic parsing models on the task of semantic translation. While there has been a trend towards learning executable semantic parsers (Berant et al., 2013; Liang, 2016), there has also been renewed interest in supervised learning of formal representations in the context of neural semantic parsing models (Dong and Lapata, 2016; Jia and Liang, 2016). We believe that good performance on our datasets should lead to better performance on more conventional semantic parsing tasks, and raise new challenges involving sparsity and multilingual learning.

We also see these resources as useful for investigations into natural language programming. While our experiments look at learning rudimentary translational correspondences between text and code, a next step might be learning to synthesize executable programs via these translations, along the lines of (Desai et al., 2016; Raza et al., 2015). Other document-level features, such as example input-output pairs, unit tests, might be useful in this endeavor.

Acknowledgements

This work was funded by the Deutsche Forschungsgemeinschaft (DFG) via SFB 732, project D2. Thanks also to our IMS colleagues, in particular Christian Scheible, for providing feedback on earlier drafts, as well as to Jonathan Berant for helpful discussions.

Abstract

Integrating text and knowledge into a unified semantic space has attracted significant research interests recently. However, the ambiguity in the common space remains a challenge, namely that the same mention phrase usually refers to various entities. In this paper, to deal with the ambiguity of entity mentions, we propose a novel Multi-Prototype Mention Embedding model, which learns multiple sense embeddings for each mention by jointly modeling words from textual contexts and entities derived from a knowledge base. In addition, we further design an efficient language model based approach to disambiguate each mention to a specific sense. In experiments, both qualitative and quantitative analysis demonstrate the high quality of the word, entity and multi-prototype mention embeddings. Using entity linking as a study case, we apply our disambiguation method as well as the multi-prototype mention embeddings on the benchmark dataset, and achieve state-of-the-art performance.

1 Introduction

Jointly learning text and knowledge representations in a unified vector space greatly benefits many Natural Language Processing (NLP) tasks, such as knowledge graph completion (Han et al., 2016; Wang and Li, 2016), relation extraction (Weston et al., 2013), word sense disambiguation (Mancini et al., 2016), entity classification (Huang et al., 2017) and linking (Huang et al., 2015).

Existing work can be roughly divided into two categories. One is encoding words and entities into a unified vector space using Deep Neural Networks (DNN). These methods suffer from the problems of expensive training and great limitations on the size of word and entity vocabulary (Han et al., 2016; Toutanova et al., 2015; Wu et al., 2016). The other is to learn word and entity embeddings separately, and then align similar words and entities into a common space with the help of Wikipedia hyperlinks, so that they share similar representations (Wang et al., 2014; Yamada et al., 2016).

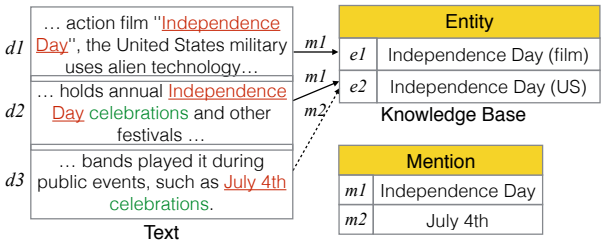

Figure 1: Examples.

However, there are two major problems arising from directly integrating word and entity embeddings into a unified semantic space. First, mention phrases are highly ambiguous and can refer to multiple entities in the common space. As shown in Figure 1, the same mention *independence day* (m_1) can either refer to a holiday: *Independence Day (US)* or a film: *Independence Day (film)*. Second, an entity often has various aliases when mentioned in various contexts, which implies a much larger size of mention vocabulary compared with entities. For example, in Figure 1, the documents d_2 and d_3 describes the same entity *Independence Day (US)* (e_2) with distinct mentions: *independence day* and *July 4th*. We observe tens of millions of mentions referring to 5 millions of entities in Wikipedia.

To address these issues, we propose to learn multiple embeddings for mentions inspired by the Word Sense Disambiguation (WSD) task (Reisinger and Mooney, 2010; Huang et al., 2012;

*Corresponding author.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1623–1633

https://doi.org/10.18653/v1/P17-1149

Tian et al., 2014; Neelakantan et al., 2014; Li and Jurafsky, 2015). The basic idea behind it is to consider entities in KBs that can provide a meaning repository of mentions (i.e. words or phrases) in texts. That is, each mention has one or multiple meanings, namely **mention senses**, and each sense corresponds to an entity. Furthermore, we assume that different mentions referring to the same entity express the same meaning and share a common mention sense embedding, which largely reduces the size of mention vocabulary to be learned. For example, the mentions *Independence Day* in d_2 and *July 4th* in d_3 have a common mention sense embedding during training since they refer to the same holiday. Thus, text and knowledge are bridged via mention sense.

In this paper, we propose a novel **M**ulti-**P**rototype **M**ention **E**mbedding (MPME) model, which jointly learns the representations of words, entities, and mentions at sense level. Different mention senses are distinguished by taking advantage of both textual context information and knowledge of reference entities. Following the frameworks in (Wang et al., 2014; Yamada et al., 2016), we use separate models to learn the representations for words, entities and mentions, and further align them by a unified optimization objective. Extending from skip-gram model and CBOW model, our model can be trained efficiently (Mikolov et al., 2013a,b) from a large scale corpus. In addition, we also design a language model based approach to determine the sense for each mention in a document based on multi-prototype mention embeddings.

For evaluation, we first provide qualitative analysis to verify the effectiveness of MPME to bridge text and knowledge representations at the sense level. Then, separate tasks for words and entities show improvements by using our word, entity and mention representations. Finally, using entity linking as a case study, experimental results on the benchmark dataset demonstrate the effectiveness of our embedding model as well as the disambiguation method.

2 Preliminaries

In this section, we formally define the input and output of multi-prototype mention embedding.

A **knowledge base** $\mathcal{KB}$ contains a set of entities $\mathcal{E} = \{e_j\}$, and their relations. We use Wikipedia as the given knowledge base, and organize it as a directed knowledge network: nodes denote entities, and edges are outlinks from Wikipedia pages. In the directed network, we define the entities that point to e_j as its neighbors $\mathcal{N}(e_j)$, but ignore those entities that e_j points to, so that the repeated computations on the same edge would be avoided if edges were undirected.

A **text corpus** $\mathcal{D}$ is a set of sequential words $\mathcal{D} = \{w_1, \cdots, w_i, \cdots, w_{|\mathcal{D}|}\}$, where w_i is the ith word and $|\mathcal{D}|$ is the length of the word sequence. Since an entity mention m_l may consist of multiple words, we define an annotated text corpus[1] as $\mathcal{D}' = \{x_1, \cdots, x_i, \cdots, x_{|\mathcal{D}'|}\}$, where x_i corresponds to either a word w_i or a mention m_l. We define the words around x_i within a predefined window as its context words $\mathcal{C}(x_i)$.

An **Anchor** is a Wikipedia hyperlink from a mention m_l linking to its entity e_j, and is represented as a pair $< m_h, e_j > \in \mathcal{A}$. The anchors provide mention boundaries as well as their reference entities from Wikipedia articles. These Wikipedia articles are used as an annotated text corpus $\mathcal{D}'$ in this paper.

Multi-Prototype Mention Embedding . Given a $\mathcal{KB}$, an annotated text corpus $\mathcal{D}'$ and a set of anchors $\mathcal{A}$, we aim to learn multi-prototype mention embedding, namely multiple sense embeddings $\mathbf{s_j}^l \in \mathbb{R}^k$ for each mention m_l as well as word embeddings $\mathbf{w}$ and entity embeddings $\mathbf{e}$. We use $\mathcal{M}_l^* = \{s_j^l\}$ to denote the sense set of mention m_l, where each s_j^l refers to an entity e_j. Thus, the vocabulary size is reduced to a fixed number $|\{s_j^*\}| = |\mathcal{E}|$. We use s_j^* to denote the shared sense of mentions referring to entity e_j.

Example As shown in Figure 1, *Independence Day* (m_1) has two mention senses s_1^1, s_2^1, and *July 4th* (m_2) has one mention sense s_2^2. Based on the assumption in Section 1, we have $s_2^* = s_2^1 = s_2^2$ referring to entity *Independence Day (US)* (e_2).

3 An Overview of Our Method

Given a knowledge base $\mathcal{KB}$, an annotated text corpus $\mathcal{D}'$ and a set of anchors $\mathcal{A}$, we aim to jointly learn word, entity and mention sense representations: $\mathbf{w}$, $\mathbf{e}$, $\mathbf{s}$.

As shown in Figure 2, our framework contains two key components:

[1]Generally, the mention boundary can be obtained by using NER tools like Standford NER (Finkel et al., 2005). In this paper, we use Wikipedia anchors as annotations of Wikipedia text corpus for the concentration of our main purpose.

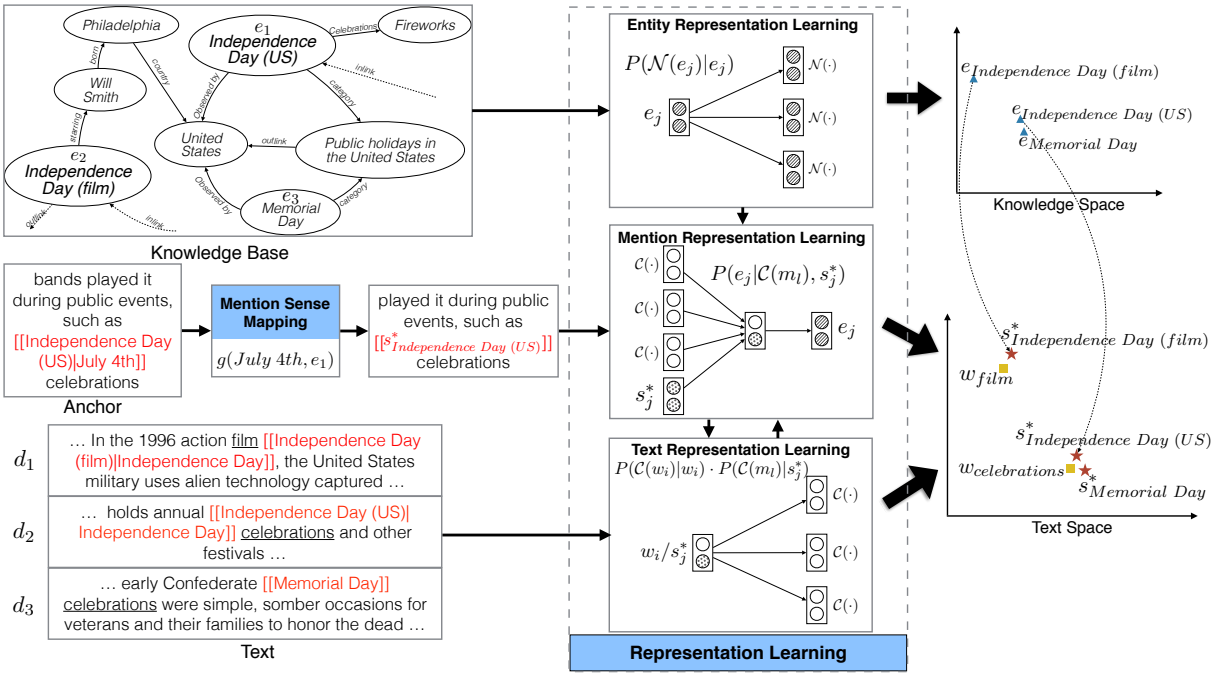

Figure 2: Framework of Multi-Prototype Mention Embedding model.

Mention Sense Mapping To reduce the size of the mention vocabulary, each mention is mapped to a set of shared mention senses according to a predefined dictionary. We build the dictionary by collecting entity-mention pairs $< m_l, e_j >$ from Wikipedia anchors and page titles, then create mention senses if there is a different entity. The sense number of a mention depends on how many different entity-mention pairs it is involved.

Formally, we have: $\mathcal{M}^*_l = g(m_l) = \bigcup g(< m_l, e_j >) = \{s^*_j\}$, where $g(\cdot)$ denotes the mapping function from an entity mention to its mention sense given an anchor. We directly use the anchors contained in the annotated text corpus $D^{'}$ for training. As Figure 2 shows, we replace the anchor *<July 4th, Independence Day (US)>* with the corresponding mention sense: $s^*_{Independence\ Day\ (US)}$.

Representation Learning Using $\mathcal{KB}$, $\mathcal{A}$ and $\mathcal{D}'$ as input, we design three separate models and a unified optimization objective to jointly learn entity, word and mention sense representations into two semantic spaces. As shown in the knowledge space in Figure 2, entity embeddings can reflect their relatedness in the network. For example, *Independence Day (US)* (e_1) and *Memorial Day* (e_3) are close to each other because they share some common neighbors, such as *United States* and *Public holidays in the United States*.

Word and mention embeddings are learned in the same semantic space. As two basic units in $\mathcal{D}'$, their embeddings represent their distributed semantics in texts. For example, mention *Independence Day* and word *celebrations* co-occur frequently when it refers to the holiday: *Independence Day (US)*, thus they have similar representations. Without disambiguating the mention senses, some words, such as *film* will also share similar representations as *Independence Day*.

Besides, by introducing entity embeddings into our MPME framework, the knowledge information will also be distilled into mention sense embeddings, so that the mention sense *Memorial Day* will be similar as *Independence Day (US)*.

Mention Sense Disambiguation According to our predefined dictionary, each mention has been mapped to more than one senses, and learned with multiple embedding vectors. Consequently, to induce the correct sense for a mention within a context is critical in the usage of the multiprototype embeddings, especially in an unsupervised way. Formally, given an annotated document $\mathcal{D}'$, we determine one sense $\hat{s}^*_j \in \mathcal{M}^*_l$ for each mention $m_l \in \mathcal{D}'$, where $\hat{s}^*_j$ is the correct sense.

Based on language model, we design a mention sense disambiguation method without using any supervision that takes into account three aspects: 1) **sense prior** denotes how dominant the sense is, 2) **local context information** reflects how semantically appropriate the sense is in the context, and

3) **global mention information** denotes how semantically consistent the sense is with the neighbor mentions. To better utilize the context information, we maintain a context cluster for each mention sense during training, which will be detailed in Section 4.4.

Since each mention sense corresponds to an entity in the given KB, the disambiguation method is equivalent to entity linking. Thus, text and knowledge base is bridged via the multiprototype mention embeddings. We will give more analysis in Section 6.4.

4 Representation Learning

Distributional representation learning plays an increasing important role in many fileds (Bengio et al., 2013; Zhang et al., 2017, 2016) due to its effectiveness for dimensionality reduction and addressing sparseness issue. For NLP tasks, this trends has been accelerated by the Skip-gram and CBOW models (Mikolov et al., 2013a,b) due to its efficiency and remarkable semantic compositionality of embedding vectors. In this section, we first briefly introduce the Skip-gram and CBOW models, and then extend them to three variants for the word, mention and entity representation learning.

4.1 Skip-Gram and CBOW model

The basic idea of the Skip-gram and CBOW models is to model the predictive relations among sequential words. Given a sequence of words $\mathcal{D}$, the optimization objective of Skip-gram model is to use the current word to predict its context words by maximizing the average log probability:

$$\mathcal{L} = \sum_{w_i \in \mathcal{D}} \sum_{w_o \in \mathcal{C}(w_i)} \log P(w_o|w_i) \tag{1}$$

In contrast, CBOW model aims to predict the current word given its context words:

$$\mathcal{L} = \sum_{w_i \in \mathcal{D}} \log P(w_i|\mathcal{C}(w_i)) \tag{2}$$

Formally, the conditional probability $P(w_o|w_i)$ is defined using a softmax function:

$$P(w_o|w_i) = \frac{\exp(\mathbf{w_i} \cdot \mathbf{w_o})}{\sum_{w_o \in \mathcal{D}} \exp(\mathbf{w_i} \cdot \mathbf{w_o})} \tag{3}$$

where $\mathbf{w_i}, \mathbf{w_o}$ denote the input and output word vectors during training. Furthermore, these two models can be accelerated by using hierarchical softmax or negative sampling (Mikolov et al., 2013a,b).

4.2 Entity Representation Learning

Given a knowledge base $\mathcal{KB}$, we aim to learn entity embeddings by modeling "contextual" entities, so that the entities sharing more common neighbors tend to have similar representations. Therefore, we extend Skip-gram model to a network by maximizing the log probability of being a neighbor entity.

$$\mathcal{L}_e = \sum_{e_j \in \mathcal{E}} \log P(\mathcal{N}(e_j)|e_j) \tag{4}$$

Clearly, the neighbor entities serve a similar role as the context words in Skip-gram model. As shown in Figure 2, entity *Memorial Day* (e_3) also share two common neighbors of *United States* and *Public holidays in the United States* with entity *Independence Day (US)*, thus their embeddings are close in the Knowledge Space. These entity embeddings will be later used to learn mention representations.

4.3 Mention Representation Learning

As mentioned above, the textual context information and reference entities are helpful to distinguish different senses for a mention. Thus, given an anchor $< m_l, e_j >$ and its context words $\mathcal{C}(m_l)$, we combine mention sense embeddings with its context word embeddings to predict the reference entity by extending CBOW model. The objective function is as follows:

$$\mathcal{L}_m = \sum_{<m_l, e_j> \in \mathcal{A}} \log P(e_j|\mathcal{C}(m_l), s_j^*) \tag{5}$$

where $s_j^* = g(< m_l, e_j >)$. Thus, if two mentions refer to similar entities and share similar contexts, they tend to be close in semantic vector space. Take Figure 1 as an example again, mentions *Independence Day* and *Memorial Day* refer to similar entities *Independence Day (US)* (e_1) and *Memorial Day* (e_2), they also share some similar context words, such as *celebrations* in documents d_2, d_3, so their sense embeddings are close to each other in the text space.

4.4 Text Representation Learning

Instead of directly using a word or a mention to predict the context words, we incorporate mention

sense to joint optimize word and sense representations, which can avoid some noise introduced by ambiguous mentions. For example, in Figure 2, without identifying the mention *Independence Day* as the holiday or the film, various dissimilar context words such as the words *celebrations* and *film* in documents d_1, d_2 will share similar semantics, which will further affect the performance of entity representations during joint training.

Given the annotated corpus $\mathcal{D}'$, we use a word w_i or a mention sense s_j^* to predict the context words by maximizing the following objective function:

$$\mathcal{L}_w = \sum_{w_i, m_l \in \mathcal{D}'} \log P(\mathcal{C}(w_i)|w_i) + \log P(\mathcal{C}(m_l)|s_j^*) \quad (6)$$

where $s_j^* = g(< m_l, e_j >)$ is obtained from anchors in Wikipedia articles.

Thus, words and mention senses will share the same vector space, where similar words and mention senses are close to each other, such as *celebrations* and *Independence Day (US)* because they frequently occur in the same contexts.

Similar to WDS, we maintain a context cluster for each mention sense, which can be used for mention sense disambiguation (Section 5). The context cluster of a mention sense s_j^* contains all the context vectors of its mention m_l. We compute context vector of m_l by averaging the sum of its context word embeddings: $\frac{1}{|\mathcal{C}(m_l)|}\sum_{w_j \in \mathcal{C}(m_l)} \mathbf{w_j}$. Further, the center of a context cluster μ_j^* is defined as the average of context vectors of all mentions which refer to the sense. These context clusters will be later used to disambiguate the sense of a given mention with its contexts.

4.5 Joint Training

Considering all of the above representation learning components, we define the overall objective function as linear combinations:

$$\mathcal{L} = \mathcal{L}_w + \mathcal{L}_e + \mathcal{L}_m \quad (7)$$

The goal of training MPME is to maximize the above function, and iteratively update three types of embeddings. Also, we use negative sampling technique for efficiency (Mikolov et al., 2013a).

MPME shares the same entity representation learning method with (Yamada et al., 2016), but the role of entities in the entire framework as well as mention representation learning is different in three aspects. First, we focus on learning embeddings for mentions, not merely words as in (Yamada et al., 2016). Clearly, MPME is more natural to integrate text and knowledge base. Second, we propose to learn multiple embeddings for each mention denoting its different meanings. Third, we prefer to use both mentions and context words to predict entities, so that the distribution of entities will help improve word embeddings, meanwhile, avoid being hurt if we force entity embeddings to satisfy word embeddings during training (Wang et al., 2014). We will give more analysis in experiments.

5 Mention Sense Disambiguation

As mentioned in Section 3, we induce a correct sense $\hat{s}_j^* \in \mathcal{M}_l^*$ for each mention m_l in an annotated document $\mathcal{D}'$. We regard this problem from the perspective of language model that maximizes a joint probability of all mention senses contained in the document. However, the global optimum is expensive with a time complexity of O($|\mathcal{M}||\mathcal{M}_l^*|$). Thus, we approximately identify each mention sense independently:

$$\begin{aligned} & P(\mathcal{D}', \ldots, s_j^*, \ldots,) \\ \approx & \prod P(\mathcal{D}'|s_j^*) \cdot P(s_j^*) \\ \approx & \prod P(\mathcal{C}(m_l)|s_j^*) \cdot P(\hat{\mathcal{N}}(m_l)|s_j^*) \cdot P(s_j^*) \end{aligned} \quad (8)$$

where $P(\mathcal{C}(m_l)|s_j^*)$, local context information (Section 3), denotes the probability of the local contexts of m_l given its mention sense s_j^*. we define it proportional to the cosine similarity between the current context vector and the sense context cluster center μ_j^* as described in Section 4.4. It measures how likely a mention sense occurring together with current context words. For example, given the mention sense *Independence Day (film)*, word *film* is more likely to appear within the context than the word *celebrations*.

$P(\hat{\mathcal{N}}(m_l)|s_j^l)$, global mention information, denotes the probability of the contextual mentions of m_l given its sense s_j^l, where $\hat{\mathcal{N}}(m_l)$ is the collection of the neighbor mentions occurring together with m_l in a predefined context window. We define it proportional to the cosine similarity between mention sense embeddings and the neighbor mention vector, which is computed similar to

context vector: $\sum \frac{1}{|\hat{\mathcal{N}}(m_l)|}\hat{\mathbf{s}}^{\mathbf{l}}_{\mathbf{j}}$, where $\hat{s}^l_j$ is the correct sense for m_l.

Considering there are usually multiple mentions in a document to be disambiguated. The mentions disambiguated first will be helpful for inducing the senses of the rest mentions. That is, how to choose the mentions disambiguated first will influence the performance. Intuitively, we adopt two orders similar to (Chen et al., 2014): 1) L2R (left to right) induces senses for all the mentions in the document following natural order that varies according to language, normally from left to right in the sequence. 2) S2C (simple to complex) denotes that we determine the correct sense for those mentions with fewer senses, which makes the problem easier.

Global mention information assumes that there should be consistent semantics in a context window, and measures whether all neighbor mentions are related. For instance, two mentions *Memorial Day* and *Independence Day* occur in the same document. If we already know that *Memorial Day* denotes a holiday, then obviously *Independence Day* has higher probability of being a holiday than a film.

$P(s^*_j)$, sense prior, is a prior probability of sense s^*_j indicating how possible it occurs without considering any additional information. We define it proportional to the frequency of sense s^*_j in Wikipedia anchors:

$$P(s^*_j) = (\frac{|\mathcal{A}_{s^*_j}|}{|\mathcal{A}|})^\gamma \quad \gamma \in [0, 1]$$

where $\mathcal{A}_{s^*_j}$ is the set of anchors annotated with s^*_j, and γ is a smoothing hyper-parameter to control the impact of prior on the overall probability, which is set by experiments (Section 6.4).

6 Experiment

Setup We choose Wikipedia, the March 2016 dump, as training corpus, which contains nearly 75 millions of anchors, 180 millions of edges among entities and 1.8 billions of tokens after preprocessing. We then train MPME[2] for 1.5 millions of words, 5 millions of entities and 1.7 millions of mentions. The entire training process in 10 iterations costs nearly 8 hours on the server with 64 core CPU and 188GB memory.

We use the default settings in word2vec[3], and set our embedding dimension as 200 and context window size as 5. For each positive example, we sample 5 negative examples[4].

Baseline Methods As far as we know, this is the first work to deal with mention ambiguity in the integration of text and knowledge representations, so there is no exact baselines for comparison. We use the method in (Yamada et al., 2016) as a baseline, marked as **ALIGN**[5], because (1) this is the most similar work that directly aligns word and entity embeddings. (2) it achieves the state-of-the-art performance in entity linking task.

To investigate the effect of multi-prototype, we degrade our method to single-prototype as another baseline, which means to use one sense to represent all mentions with the same phrase, namely **S**ingle-**P**rototype **M**ention **E**mbedding (SPME). For example, SPME only learns one unique sense vector for *Independence Day* whatever it denotes a holiday or a film.

6.1 Qualitative Analysis

We use cosine similarity to measure the similarity of two vectors, and present the top 5 nearest words and entities for two most popular senses of the mention *Independence Day*. Because ALIGN is incapable of dealing with multiple words, we only present the results of SPME and MPME.

As shown in Figure 1, without considering mention sense, the mention *Independence Day* can only show a dominant *holiday* sense based on SPME and ignore all other senses. Instead, MPME successfully learns two clear and distinct senses. For the sense *Independence Day (US)*, all of its nearest words and entities, such as *parades*, *celebrations*, and *Memorial Day*, are holiday related, while for another sense *Independence Day (film)*, its nearest words and entities, like *robocop* and *The Terminator*, are all science fiction films. The results verify the effectiveness of our framework in learning mention embeddings at the sense level.

[2]Our main code for MPME can be found in https://github.com/TaoMiner/bridgeGap.

[3]https://code.google.com/archive/p/word2vec/

[4]We tested different parameters (e.g. window size of 10 and dimension of 500) which achieve similar results, and report the current settings considering program runtime efficiency.

[5]We carefully re-implemented ALIGN and used the same shared parameters in our model for fairly comparison. However, we failed to fully reproduce the positive result in the original paper, meanwhile the authors are unable to release their code.

	Mention Sense	Nearest words	Nearest entities
SPME	Independence Day	lee-jackson, thanksgiving, diwali, strassenfest, chiraghan	National Aboriginal and Torres Strait Islander Education Policy, E. Chandrasekharan Nair, Jean Aileen Little, Thessalian barbel, 1825 in birding and ornithology
MPME	Independence Day (US)	thanksgiving, parades, lee-jackson, festivities, celebrations	Memorial Day, Labor Day, Thanksgiving, Thanksgiving (United States), Saint Patrick's Day
	Independence Day (film)	robocop, clockstoppers, mindhunters, tarantino, terminator	The Terminator, True Lies, Total Recall (1990 film), RoboCop 2, Die Hard

Table 1: The nearest neighbors of mention *Independence Day*.

6.2 Entity Relatedness

To evaluate the quality of entity embeddings, we conduct experiments using the dataset which is designed for measuring entity relatedness (Ceccarelli et al., 2013; Huang et al., 2015; Yamada et al., 2016). The dataset contains 3,314 entities, and each mention has 91 candidate entities on average with gold-standard labels indicating whether they are semantically related.

We compute cosine similarity between entity embeddings to measure their relatedness, and rank them in a descending order. To evaluate the ranking quality, we use two standard metrics: normalized discounted cumulative gain (NDCG) (Järvelin and Kekäläinen, 2002) and mean average precision (MAP) (Schütze, 2008).

We design another baseline method: **Entity2vec**, which learns entity embeddings using the method described in Section 4.2, without joint training with word and mention sense embeddings.

Table 2: Entity Relatedness.

	NDCG			MAP
	@1	@5	@10	
ALIGN	0.416	0.432	0.472	0.410
Entity2vec	0.593	0.595	0.636	0.566
SPME	0.593	0.594	0.636	0.566
MPME	**0.613**	**0.613**	**0.654**	**0.582**

As shown in Table 2, ALIGN achieves lower performance than Entity2vec, because it doesn't consider the mention phrase ambiguity and yields lots of noise when forcing entity embeddings to satisfy word embeddings and aligning them into the unified space. For example, the entity *Gente (magazine)* should be more relevant to the entity *France*, the place where its company locates. However, ALIGN mixed various meanings of mention *Gente* (e.g., the song) and ranked some bands higher (e.g., entity *Poolside (band)*).

SPME also doesn't consider the ambiguity of mentions but achieves comparative results with Entity2vec. We analyze the reasons and find that, it can avoid some noise by using word embeddings to predict entities. MPME outperforms all the other methods, which demonstrates that the unambiguous textual information is helpful to refine the entity embeddings.

6.3 Word Analogical Reasoning

Following (Mikolov et al., 2013a; Wang et al., 2014), we use the word analogical reasoning task to evaluate the quality of word embeddings. The dataset consists of 8,869 semantic questions (*"Paris":"France"::"Rome":?*), and 10,675 syntactic questions (e.g., *"sit":"sitting"::"walk":?*). We solve it by finding the closest word vector $\mathbf{w}_?$ to $\mathbf{w}_{France} - \mathbf{w}_{Paris} + \mathbf{w}_{Rome}$ according to cosine similarity. We compute accuracy for top 1 nearest word to measure the performance.

Table 3: Word Analogical Reasoning.

	Word2vec	ALIGN	SPME	MPME
Semantic	66.78	68.34	71.65	71.65
Syntactic	61.58	59.73	55.28	54.75

We also adopt Word2vec[6] as an additional baseline method, which provides a standard to measure the impact from other components on word embeddings.

Table 3 shows the results. We can see that ALIGN, SPME and MPME, achieve higher performance in dealing with semantic questions, because relations among entities (e.g., country-capital relation for entity *France* and *Paris*) enhance the semantics in word embeddings through jointly training. On the other hand, their performance for syntactic questions is weakened because more accurate semantics yields a bias to predict semantic relations even though given a syntactic query. For example, given the query *"pleasant":"unpleasant"::"possibly":?*, our

[6]https://code.google.com/archive/p/word2vec/

model tends to return the word (e.g., *probably*) highly semantical related to query words, such as *possibly*, instead of the syntactical similar word *impossibly*. In this scenario, we are more concerned about semantic task to incorporate knowledge of reference entities into word embeddings, and this issue could be tackled, to some extent, by using syntactic tool like stemming.

The word embeddings of MPME achieve the best performance for semantic questions mainly because (1) text representation learning has better generalization ability due to the larger size of training examples than entities (e.g., 1.8b v.s. 0.18b) as well as relatively smaller size of vocabulary (e.g., 1.5m v.s. 5m). (2) unambiguous mention embeddings capture both textual context information and knowledge, and thus enhance word and entity embeddings.

6.4 A Case Study: Entity Linking

Entity linking is a core NLP task of identifying the reference entity for mentions in texts. The main difficulty lies in the ambiguity of various entities sharing the same mention phrase. Previous work addressed this issue by taking advantage of the similarity between words and entities (Francis-Landau et al., 2016; Sun et al., 2015), and/or the relations among entities (Thien Huu Nguyen, 2016; Cao et al., 2015). Therefore, we use entity linking as a case study for a comprehensive measurement of the multi-prototype mention embeddings. Given mentions in a text, entity linking aims to link them to a predefined knowledge base. One of the main challenges in this task is the ambiguity of entity mentions.

We use the public dataset AIDA created by (Hoffart et al., 2011), which includes 1,393 documents and 27,816 mentions referring to Wikipedia entries. The dataset has been divided into 946, 216 and 231 documents for the purpose of training, developing and testing. Following (Pershina et al., 2015; Yamada et al., 2016), we use a publicly available dictionary to generate candidate entities and mention senses. For evaluation, we rank the candidate entities for each mention and report both standard micro (aggregates over all mentions) and macro (aggregates over all documents) precision over top-ranked entities.

Supervised Entity Linking

Yamada et al. (2016) designed a list of features for each mention and candidate entity pair. By incorporating these features into a supervised learning-to-rank algorithm, Gradient Boosting Regression Tree (GBRT), each pair is assigned a relevance score indicating whether they should be linked to each other. Following their recommended parameters, we set the number of trees as 10,000, the learning rate as 0.02 and the maximum depth of the decision tree as 4.

Based on word and entity embeddings learned by ALIGN, the key features in (Yamada et al., 2016) are from two aspects: (1) the cosine similarity between context words and candidate entity, and (2) the coherence among "contextual" entities in the same document.

To evaluate the performance of multi-prototype mention embeddings, we incorporate the following features into GBDT for comparison: (1) the cosine similarity between the current context vector and the sense context cluster center μ_j^*, which denotes how likely the mention sense refers to the candidate entity, (2) the cosine similarity between the current context vector and the mention sense embeddings.

Table 4: Performance of Supervised Method

	ALIGN	SPME	MPME
Micro P@1	0.828	0.820	**0.851**
Macro P@1	0.862	0.844	**0.881**

As shown in Table 4, we can see that ALIGN performs better than SPME. This is because SPME learns word embeddings and entity embeddings in separate semantic spaces, and fails to measure the similarity between context words and candidate entities. However, MPME computes the similarity between context words with mention sense instead of entities, thus achieves the best performance, which also demonstrates the high quality of the mention sense embeddings.

Unsupervised Entity Linking

Linking a mention to a specific entity equals to disambiguating mention senses since each candidate entity corresponds to a mention sense. As described in Section 5, we disambiguate senses in two orders: (1) **L2R** (from left to right), and (2) **S2C** (from simple to complex).

We evaluate our unsupervised disambiguation methods on the entire AIDA dataset. To be fair, we choose the state-of-the-art unsupervised methods, which are proposed in (Hoffart et al., 2011; Alhelbawy and Gaizauskas, 2014; Cucerzan, 2007;

Table 5: Performance of Unsupervised Methods

	Cucerzan	Kulkarni	Hoffart	Shirakawa	Alhelbawy	MPME (L2R)	MPME (S2C)
Micro P@1	0.510	0.729	0.818	0.823	0.842	0.882	**0.885**
Macro P@1	0.437	0.767	0.819	0.830	0.875	0.875	**0.890**

Kulkarni et al., 2009; Masumi Shirakawa and Nishio, 2011) using the same dataset.

Table 5 shows the results. We can see that our two methods outperform all other methods. MPME (L2R) is more efficient and easy to apply, while MPME (S2C) slightly outperforms it because the additional step of ranking mentions according to their candidates number guarantees a higher disambiguation performance for those simple mentions, which consequently help disambiguate those complex mentions through global mention information in Equation 8.

We analyze the results and observe a disambiguation bias to popular senses. For example, there are three mentions in the sentence "***Japan*** *began the defence of their* ***Asian Cup I*** *title with a lucky 2-1 win against* ***Syria*** *in a Group C championship match on Friday*", where the country name *Japan* and *Syria* actually denote their national football teams, while the football match name *Asian Cup I* has little ambiguity. Compared to the team, the sense of country occurs more frequently and has a dominant prior, which greatly affects the disambiguation. By incorporating local context information and global mention information, both the context words (e.g., *defence* or *match*) and the neighbor mentions (e.g., *Asian Cup I*) provide us enough clues to identify a soccer related mention sense instead of the country.

Influence of Smoothing Parameter As mentioned above, a mention sense may possess a dominant prior and greatly affect the disambiguation. So we introduce a smoothing parameter γ to control its importance to the overall probability. Figure 3 shows the linking accuracy under different values of γ on the dataset of AIDA. $\gamma = 0$ indicates we don't use any prior knowledge, and $\gamma = 1$ indicates the case without smoothing parameter.

We can see that both micro and macro accuracy decrease a lot if we don't use the parameter ($\gamma = 1$). Only using local and global probabilities for disambiguation ($\gamma = 0$) achieves a comparable performance when $\gamma = 0.05$, both accuracy reach their peaks, which is optimal and default value in our experiments.

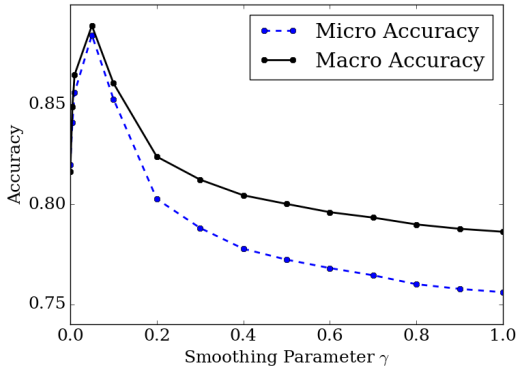

Figure 3: Impact of Smoothing Parameter γ.

7 Conclusions and Future Work

In this paper, we propose a novel Multi-Prototype Mention Embedding model that jointly learns word, entity and mention sense embeddings. These mention senses capture both textual context information and knowledge from reference entities, and provide an efficient approach to disambiguate mention sense in text. We conduct a series of experiments to demonstrate that multi-prototype mention embedding improves the quality of both word and entity representations. Using entity linking as a study case, we apply our disambiguation method as well as the multi-prototype mention embeddings on the benchmark dataset, and achieve the state-of-the-art.

In the future, we will improve the scalability of our model and learn multi-prototype embeddings for the mentions without reference entities in a knowledge base, and introduce compositional approaches to model the internal structures of multi-word mentions.

Interactive Learning of Grounded Verb Semantics towards Human-Robot Communication

Lanbo She and **Joyce Y. Chai**

Abstract

To enable human-robot communication and collaboration, previous works represent grounded verb semantics as the potential change of state to the physical world caused by these verbs. Grounded verb semantics are acquired mainly based on the parallel data of the use of a verb phrase and its corresponding sequences of primitive actions demonstrated by humans. The rich interaction between teachers and students that is considered important in learning new skills has not yet been explored. To address this limitation, this paper presents a new interactive learning approach that allows robots to proactively engage in interaction with human partners by asking good questions to learn models for grounded verb semantics. The proposed approach uses reinforcement learning to allow the robot to acquire an optimal policy for its question-asking behaviors by maximizing the long-term reward. Our empirical results have shown that the interactive learning approach leads to more reliable models for grounded verb semantics, especially in the noisy environment which is full of uncertainties. Compared to previous work, the models acquired from interactive learning result in a 48% to 145% performance gain when applied in new situations.

1 Introduction

In communication with cognitive robots, one of the challenges is that robots do not have sufficient linguistic or world knowledge as humans do. For example, if a human asks a robot to *boil the water* but the robot has no knowledge what this verb phrase means and how this verb phrase relates to its own actuator, the robot will not be able to execute this command. Thus it is important for robots to continuously learn the meanings of new verbs and how the verbs are grounded to its underlying action representations from its human partners.

To support learning of grounded verb semantics, previous works (She et al., 2014; Misra et al., 2015; She and Chai, 2016) rely on multiple instances of human demonstrations of corresponding actions. From these demonstrations, robots capture the state change of the environment caused by the actions and represent verb semantics as the desired goal state. One advantage of such state-based representation is that, when robots encounter the same verbs/commands in a new situation, the desired goal state will trigger the action planner to automatically plan a sequence of primitive actions to execute the command.

While the state-based verb semantics provides an important link to connect verbs to the robot's actuator, previous works also present several limitations. First of all, previous approaches were developed under the assumption of perfect perception of the environment (She et al., 2014; Misra et al., 2015; She and Chai, 2016). However, this assumption does not hold in real-world situated interaction. The robot's representation of the environment is often incomplete and error-prone due to its limited sensing capabilities. Thus it is not clear whether previous approaches can scale up to handle noisy and incomplete environment.

Second, most previous works rely on multiple demonstration examples to acquire grounded verb models. Each demonstration is simply a sequence of primitive actions associated with a verb. No other type of interaction between humans and robots is explored. Previous cognitive studies (Bransford et al., 2000) on how people learn have shown that social interaction (e.g., conver-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1634–1644
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1150

sation with teachers) can enhance student learning experience and improve learning outcomes. For robotic learning, previous work (Cakmak and Thomaz, 2012) has also demonstrated the necessity of question answering in the learning process. Thus, in our view, interactive learning beyond demonstration of primitive actions should play a vital role in the robot's acquisition of more reliable models of grounded verb semantics. This is especially important because the robot's perception of the world is noisy and incomplete, human language can be ambiguous, and the robot may lack the relevant linguistic or world knowledge during the learning process.

To address these limitations, we have developed a new interactive learning approach where robots actively engage with humans to acquire models of grounded verb semantics. Our approach explores the space of interactive question answering between humans and robots during the learning process. In particular, motivated by previous work on robot learning (Cakmak and Thomaz, 2012), we designed a set of questions that are pertinent to verb semantic representations. We further applied reinforcement learning to learn an optimal policy that guides the robot in deciding when to ask what questions. Our empirical results have shown that this interactive learning process leads to more reliable representations of grounded verb semantics, which contribute to significantly better action performance in new situations. When the environment is noisy and uncertain (as in a realistic situation), the models acquired from interactive learning result in a performance gain between 48% and 145% when applied in new situations. Our results further demonstrate that the interaction policy acquired from reinforcement learning leads to the most efficient interaction and the most reliable verb models.

2 Related Work

To enable human-robot communication and collaboration, recent years have seen an increasing amount of works which aim to learn semantics of language that are grounded to agents' perception (Gorniak and Roy, 2007; Tellex et al., 2014; Kim and Mooney, 2012; Matuszek et al., 2012a; Liu et al., 2014; Liu and Chai, 2015; Thomason et al., 2015, 2016; Yang et al., 2016; Gao et al., 2016) and action (Matuszek et al., 2012b; Artzi and Zettlemoyer, 2013; She et al., 2014; Misra et al., 2014, 2015; She and Chai, 2016). Specifically for verb semantics, recent works explored the connection between verbs and action planning (She et al., 2014; Misra et al., 2014, 2015; She and Chai, 2016), for example, by representing grounded verbs semantics as the desired goal state of the physical world that is a result of the corresponding actions. Such representations are learned based on example actions demonstrated by humans. Once acquired, these representations will allow agents to interpret verbs/commands issued by humans in new situations and apply action planning to execute actions. Given its clear advantage in connecting verbs with actions, our work also applies the state-based representation for verb semantics. However, we have developed a new approach which goes beyond learning from demonstrated examples by exploring how rich interaction between humans and agents can be used to acquire models for grounded verb semantics.

This approach was motivated by previous cognitive studies (Bransford et al., 2000) on how people learn as well as recent findings on robot skill learning (Cakmak and Thomaz, 2012). One of the principles for human learning is that "learning is enhanced through socially supported interactions". Studies have shown that social interaction with teachers and peers (e.g., substantive conversation) can enhance student learning experience and improve learning outcomes. In recent work on interactive robot learning of new skills (Cakmak and Thomaz, 2012), researchers identified three types of questions that can be used by a human/robot student to enhance learning outcomes: 1) *demonstration query* (i.e., asking for a full or partial demonstration of the task), 2) *label query* (i.e., asking whether an execution is correct), and 3) *feature query* (i.e., asking for a specific feature or aspect of the task). Inspired by these previous findings, our work explores interactive learning to acquire grounded verb semantics. In particular, we aim to address when to ask what questions during interaction to improve learning.

3 Acquisition of Grounded Verb Semantics

This section gives a brief review on acquisition of grounded verb semantics and illustrates the differences between previous approaches and our approach using interactive learning.

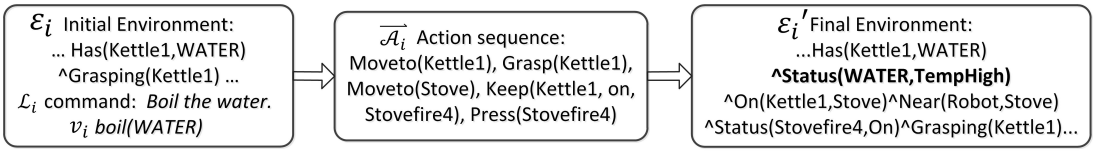

Figure 1: An example of acquiring state-based representation for verb semantics based on an initial environment $\mathcal{E}_i$, and a language command $\mathcal{L}_i$, the primitive action sequence $\overrightarrow{\mathcal{A}_i}$ demonstrated by the human, and the final environment $\mathcal{E}_i'$ that results from the execution of $\overrightarrow{\mathcal{A}_i}$ in $\mathcal{E}_i$.

3.1 State-based Representation

As shown in Figure 1, the verb semantics (e.g., *boil(x)*) is represented by the goal state (e.g., $Status(x, TempHigh)$) which is the result of the demonstrated primitive actions. Given the verb phrase *boil the water* (i.e., $\mathcal{L}_i$), the human teaches the robot how to accomplish the corresponding action based on a sequence of primitive actions $\overrightarrow{\mathcal{A}_i}$. By comparing the final environment $\mathcal{E}_i'$ with the initial environment $\mathcal{E}_i$, the robot is able to identify the state change of the environment, which becomes a hypothesis of goal state to represent verb semantics. Compared to procedure-based representations, the state-based representation supports automated planning at the execution time. It is environment-independent and more generalizable. In (She and Chai, 2016), instead of one hypothesis, it maintains a specific-to-general hypothesis space as shown in Figure 2 to capture all goal hypotheses of a particular verb frame. Specifically, it assumes that one verb frame may lead to different outcomes under different environments, where each possible outcome is represented by one node in the hierarchical graph and each node is a conjunction of multiple atomic fluents. [1]

Given a language command (i.e., a verb phrase), a robot will engage in the following processes:

- **Execution.** In this process, the robot will select a hypothesis from the space of hypotheses that is most relevant to the current situation and use the corresponding goal state to plan for actions to execute.

- **Learning.** When the robot fails to select a hypothesis or fails to execute the action, it will ask the human for a demonstration. Based on the demonstrated actions, the robot will learn a new representation (i.e., new nodes) and update the hypothesis space.

[1] In this work, we assume the set of atomic fluents representing environment state are given and do not address the question of whether these predicates are adequate to represent a domain.

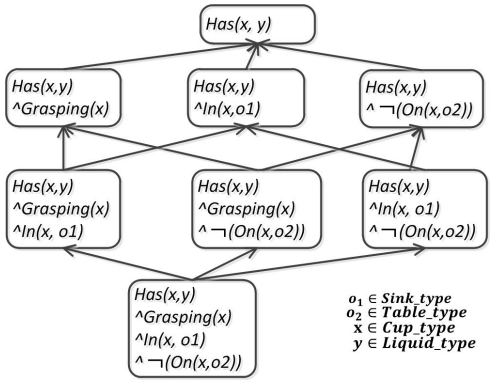

Figure 2: An example hypothesis space for the verb frame $fill(x, y)$.

3.2 Noisy Environment

Probabilistic Environment:
...^Has(Kettle1,Water) 0.64 ^Grasping(Kettle1) 0.91
^Status(Kettle1,HighTemp) 0.95 ^On(Kettle1,Stove) 0.2
^Near(Robot,Stove) 0.43 ^Status(Stovefire4,On) 0.6 ^...

Figure 3: An example probabilistic sensing result.

Previous works represent the environment $\mathcal{E}_i$ as a conjunction of grounded state fluents. Each fluent consists of a predicate and one or more arguments (i.e., objects in the physical world, or object status), representing one aspect of the perceived environment. An example of a fluent is "$Has(Kettle_1, WATER)$" meaning object $Kettle_1$ has some water inside, where Has is the predicate, and $Kettle_1$ and $WATER$ are arguments. The set of fluents include the status of the robot (e.g., $Grasping(Kettle_1)$), the status of different objects (e.g., $Status(WATER, TempHigh)$), and relations between objects (e.g., $On(Kettle_1, Stove)$). One limitation of the previous works is that the envi-

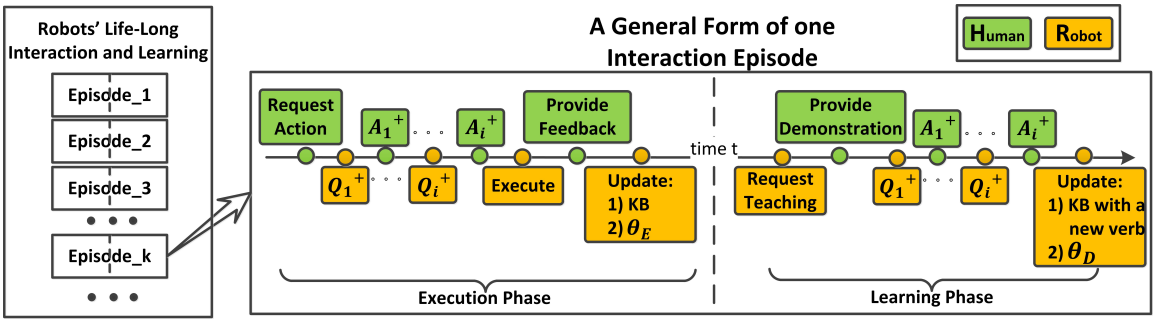

Figure 4: A general framework of robot interactive learning. KB stands for knowledge base, θ_E stands for Interaction Strategy for Execution, and θ_D stands for Interaction Strategy for Learning.

Only demonstration(She and Chai, 2016)	**Interactive learning (this work)**
Execution Example H1: Boil the water. R1: (*select a hypothesis and execute the action accordingly*) H2: (*provide true/false feedback on whether the execution is correct*)	**Execution Example** H1: Boil the water. R1: I see a silver object on the table, is that a pot? H2: Yes. R2: Should I leave the pot on the stove after boil? H3: Yes. R3: Ok. (*select a hypothesis to execute*) H4: Thank you.
Learning Example H3: Boil the water. R3: I don't know how to boil, could you show me an example? H4: (*human shows the robot how to achieve the corresponding action through a sequence of primitive actions*) R4: (*indicate the acceptance and induce a hypothesis to represent verb semantics*)	**Learning Example** H5: Boil the water. R5: I don't know how to boil, could you show me an example? H6: Ok. (*demonstrate the task, at the end put the pot on a heat pad*) R6: So after boiling something, should I put it on a heat pad? H7: No, you don't have to. R7: I see. (*induce goal state hypothesis*)

Table 1: Examples to show differences between learning through demonstrations as in the previous works (She and Chai, 2016) and the proposed learning from interaction.

ronment has a perfect, deterministic representation, as shown in Figure 1. This is clearly not the case in the realistic physical world.

In reality, given limitations of sensor capabilities, the environment representation is often partial, error prone, and full of uncertainties. Figure 3 shows an example of a more realistic representation where each fluent comes with a confidence between 0 and 1 to indicate how likely that particular fluent can be detected in the current environment. Thus, it is unclear whether the previous work is able to handle representations with uncertainties. Our interactive learning approach aims to address these uncertainties through interactive question answering with human partners.

4 Interactive Learning

4.1 Framework of Interactive Learning

Figure 4 shows a general framework for interactive learning of action verbs. It aims to support a life-long learning cycle for robots, where the robot can continuously (1) engage in collaboration and communication with humans based on its existing knowledge; (2) acquire new verbs by learning from humans and experiencing the change of the world (i.e., grounded verb semantics as in this work); and (3) learn how to interact (i.e., update interaction policies). The lifelong learning cycle is composed by a sequence of interactive learning episodes (Episode 1, 2...) where each episode consists of either an execution phase or a learning phase or both.

The execution phase starts with a human request for action (e.g., *boil the water*). According to its interaction policy, the robotic agent may choose to ask one or more questions (i.e., Q_i^+) and wait for human answers (i.e., A_i^+), or select a hypothesis from its existing knowledge base to execute the command (i.e., *Execute*). With the human feedback of the execution, the robot can update its interaction policy and existing knowledge.

In the learning phase, the robot can initiate the learning by requesting a demonstration from the human. After the human performs the task,

the robotic agent can either choose to update its knowledge if it feels confident, or it can choose to ask the human one or more questions before updating its knowledge.

4.2 Examples of Interactive Learning

Table 1 illustrates the differences between the previous approach that acquires verb models based solely on demonstrations and our current work that acquires models based on interactive learning. As shown in Table 1, under the *demonstration* setting, humans only provide a demonstration of primitive actions and there's no interactive question answering. In the *interactive learning* setting, the robot can proactively choose to ask questions regarding the uncertainties either about the environment (e.g., R1), the goal (e.g., R2), or the demonstrations (e.g., R6). Our hypothesis is that rich interactions based on question answering will allow the robot to learn more reliable models for grounded verb semantics, especially in a noisy environment.

Then the question is how to manage such interaction: when to ask and what questions to ask to most efficiently acquire reliable models and apply them in execution. Next we describe the application of reinforcement learning to manage interactive question answering for both the execution phase and the learning phase.

4.3 Formulation of Interactive Learning

Markov Decision Process (MDP) and its closely related Reinforcement Learning (RL) have been applied to sequential decision-making problems in dynamic domains with uncertainties, e.g., dialogue/interaction management (Singh et al., 2002; Paek and Pieraccini, 2008; Williams and Zweig, 2016), mapping language commands to actions (Branavan et al., 2009), interactive robot learning (Knox and Stone, 2011), and interactive information retrieval (Li et al., 2017). In this work, we formulate the choice of when to ask what questions during interaction as a sequential decision-making problem and apply reinforcement learning to acquire an optimal policy to manage interaction.

Specifically, each of the execution and learning phases is governed by one policy (i.e., θ_E and θ_D), which is updated by the reinforcement learning algorithm. The use of RL intends to obtain optimal policies that can lead to the highest long-term reward by balancing the cost of interaction (e.g., the length of interaction and difficulties of questions) and the quality of the acquired models. The reinforcement formulation for both the execution phase and the learning phase are described below.

State For the execution phase, each state $s_e \in S_E$ is a five tuple: $s_e = <l, e, KB, Grd, Goal>$. l is a language command, including a verb and multiple noun phrases extracted by the Stanford parser. For example, the command "*Microwave the ramen*" is represented as $l = microwave(ramen)$. The environment e is a probabilistic representation of the currently perceived physical world, consisting of a set of grounded fluents and the confidence of perceiving each fluent (an example is shown in Figure 3). KB stands for the existing knowledge of verb models. Grd accounts for the agent's current belief of object grounding: the probability of each noun in the l being grounded to different objects. $Goal$ represents the agent's belief of different goal state hypotheses of the current command. Within one interaction episode, command l and knowledge KB will stay the same, while e, Grd, and $Goal$ may change accordingly due to interactive question answering and robot actions. In the execution phase, Grd and $Goal$ are initialized with existing knowledge of learned verb models. For the learning phase, a state $s_d \in S_D$ is a four tuple: $s_d = <l, e_{start}, e_{end}, Grd>$. e_{start} and e_{end} stands for the environment before the demonstration and after the demonstration.

Action Motivated by previous studies on how humans ask questions while learning new skills (Cakmak and Thomaz, 2012), the agent's question set includes two categories: yes/no questions and wh- questions. These questions are designed to address ambiguities in noun phrase grounding, uncertain environment sensing, and goal states. They are domain independent in nature. For example, one of the questions is np_grd_ynq(n, o). It is a yes/no question asking whether the noun phrase n refers to an object o (e.g., "*I see a silver object, is that the pot?*"). Other questions are env_pred_ynq(p) (i.e., whether a fluent p is present in the environment; e.g., "*Is the microwave door open?*") and goal_pred_ynq(p) (i.e., whether a predicate p should be part of the goal; "*Should the pot be on a pot stand?*"). Table 2 lists all the actions available in the execution and learning phases. The select_hypo action (i.e., select a goal hypothesis to execute) is only for the execution. Ideally, after asking questions, the agent should be more likely to select a goal hy-

Action Name	Explanation	Question Example	Reward
1. **np_grd_whq**(n)	Ask for the grounding of a np.	"*Which is the cup, can you show me?*"	-6.5[1]
2. **np_grd_ynq**(n, o)	Confirm the grounding of a np.	"*I see a silver object, is that the pot?*"	-1.0 / -2.0
3. **env_pred_ynq**(p)	Confirm a predicate in current environment.	"*Is the microwave door open?*"	-1.0 / -2.0
4. **goal_pred_ynq**(p)	Confirm whether a predicate p should be in the final environment.	"*Is it true the pot should be on the counter?*"	-1.0 / -2.0
5. **select_hypo**(h)	Choose a hypothesis to use as goal and execute.		100 / -2.0
6. **bulk_np_grd_ynq**(n, o)	Confirm the grounding of multiple nps.	"*I think the pot is the red object and milk is in the white box, am I right?*"	-3.0 / -6.0[2]
7. **pred_change_ynq**(p)	Ask whether a predicate p has been changed by the action demonstration.	"*The pot is on a stand after the action, is that correct?*"	-1.0 / -2.0
8. **include_fluent**($\wedge p$)	Include $\wedge p$ into the goal state representation. Update the verb semantic knowledge.		100 / -2.0

Table 2: The action space for reinforcement learning, where n stands for a noun phrase, o a physical object, p a fluent representation of the current state of the world, h a goal hypothesis. Action 1 and 2 are shared by both the execution and learning phases. Action 3, 4, 5 are for the execution phase, and 6, 7, 8 are only used for the learning phase. -1.0/-2.0 are typically used for yes/no questions. When the human answers the question with a "yes", the reward is -1.0, otherwise it's -2.0.

pothesis that best describes the current situation. For the learning phase, the include_fluent($\wedge p$) action forms a goal hypothesis by conjoining a set of fluents ps where each p should have high probability of being part of the goal.

Transition The transition function takes action a in state s, and gives the next state s' according to human feedback. Note that the command l does not change during interaction. But the agent's belief of environment e, object grounding Grd, and goal hypotheses $Goal$ is changed according to the questions and human answers. For example, suppose the agent asks whether noun phrase n refers to the object o, if the human confirms it, the probability of n being grounded to o becomes 1.0, otherwise it will become 0.0.

Reward Finding a good reward function is a hard problem in reinforcement learning. Our current approach has followed the general practice in the spoken dialogue community (Schatzmann et al., 2006; Fang et al., 2014; Su et al., 2016). The immediate robot questions are assigned small costs to favor shorter and more efficient interaction. Furthermore, motivated by how humans ask questions (Cakmak and Thomaz, 2012), yes/no questions are easier for a human to answer than the open questions (e.g., wh-questions) and thus are given smaller costs. A large positive reward is given at the end of interaction when the task is completed successfully. Detailed reward assignment for different actions are shown in Table 2.

Algorithm 1: Policy learning. The execution and learning phases share the same learning process, but with different state s, action a spaces, and feature vectors ϕ. The e_{end} is only available to the learning phase.

Input : e, l (, e_{end});
Feature function ϕ;
Old policy θ (i.e., a weight vector)
Verb Goal States Hypotheses $\mathcal{H}$;
Initialize : state s initialized with e, l (, e_{end});
first action $a \sim P(a|s;\theta)$ with ϵ greedy
while *s is not terminal* **do**
  Take action a, receive reward r;
  $s' = T(s, a)$;
  Choose $a' \sim P(a'|s';\theta)$ with ϵ greedy;
  $\delta \leftarrow r + \gamma \cdot \theta^T \cdot \phi(s', a') - \theta^T \cdot \phi(s, a)$;
  $\theta \leftarrow \theta + \delta \cdot \eta \cdot \phi(s, a)$;
end
if *s terminates with positive feedback* **then**
  Update $\mathcal{H}$;
end
Output : Updated $\mathcal{H}$ and θ.

Learning The *SARSA* algorithm with linear function approximation is utilized to update policies θ_E and θ_D (Sutton and Barto, 1998). Specifically, the objective of training is to learn an optimal value function $Q(s, a)$ (i.e., the expected cu-

[1] According to the study in (Cakmak and Thomaz, 2012), the frequency of y/n questions used by humans is about 6.5 times the frequency of open questions (wh question), which motivates our assignment of -6.5 to wh questions.

[2] bulk_np_grd_ynq asks multiple object grounding all at once. This is harder to answer than asking for a single np. Therefore, its cost is assigned three times of the other yes/no questions.

Features shared by both phases
If a is a np_grd_whq(n).
The entropy of candidate groundings of n.
If n has more than 4 grounding candidates.
If a is a np_grd_ynq(n, o).
The probability of n grounded to o.
Additional Features specific for the Execution phase
If a is a select_hypo(h) action.
The probability of hypo h not satisfied in current environment.
Similarity between the ns used by command l and the commands from previous experiences.
Additional Features specific for the Learning phase
If a is a pred_change_ynq(p).
The probability of p been changed by demo.

Table 3: Example features used by the two phases. a stands for action. Other notations are the same as used in Table 2. The"If" features are binary, and the other features are real-valued.

mulative reward of taking action a in a state s). This value function is approximated by a linear function $Q(s,a) = \theta^{\intercal} \cdot \phi(s,a)$, where $\phi(s,a)$ is a feature vector and θ is a weight updated during training. Details of the algorithm is shown in Algorithm 1. During testing, the agent can take an action a that maximizes the Q value at a state s.

Feature Example features used by the two phases are listed in Table 3. These features intend to capture different dimensions of information such as specific types of questions, how well noun phrases are grounded to the environment, uncertainties of the environment, and consistencies between a hypothesis and the current environment.

5 Evaluation

5.1 Experiment Setup

Dataset. To evaluate our approach, we utilized the benchmark made available by (Misra et al., 2015). Individual language commands and corresponding action sequences are extracted similarly as (She and Chai, 2016). This dataset includes common tasks in the kitchen and living room domains, where each data instance comes with a language command (e.g., "*boil the water*", "*throw the beer into the trashcan*") and the corresponding sequence of primitive actions. In total, there are 979 instances, including 75 different verbs and 215 different noun phrases. The length of primitive action sequences range from 1 to 51 with an average of 4.82 (+/-4.8). We divided the dataset into three groups: (1) 200 data instances were used by reinforcement learning to acquire optimal interaction policies; (2) 600 data instances were used by different approaches (i.e., previous approaches and our interactive learning approach) to acquire grounded verb semantics models; and (3) 179 data instances were used as testing data to evaluate the learned verb models. The performance on applying the learned models to execute actions for the testing data is reported.

To learn interaction policies, a simulated human model is created from the dataset (Schatzmann et al., 2006) to continuously interact with the robot learner[3]. This simulated user can answer the robot's different types of questions and make decisions on whether the robot's execution is correct. During policy learning, one data instance can be used multiple times. At each time, the interaction sequence is different due to *exploitation and exploration* in RL in selecting the next action. The RL discount factor γ is set to 0.99, the ϵ in ϵ-greedy is 0.1, and the learning rate is 0.01.

Noisy Environment Representation. The original data provided by (Misra et al., 2015) is based on the assumption that environment sensing is perfect and deterministic. To enable incomplete and noisy environment representation, for each fluent (e.g., $grasping(Cup_3)$, $near(robot_1, Cup_3)$) in the original data, we independently sampled a confidence value to simulate the likelihood that a particular fluent can be detected correctly from the environment. We applied the following four different variations in sampling the confidence values, which correspond to different levels of sensor reliability.

(1) PerfectEnv represents the most reliable sensor. If a fluent is true in the original data, its sampled confidence is 1, and 0 otherwise.

(2) NormStd3 represents a relatively reliable sensor. For each fluent in the original environment, a confidence is sampled according to a normal distribution $\mathcal{N}(1, 0.3^2)$ with an interval [0,1]. This distribution has a large probability of sampling a number larger than 0.5, meaning the corresponding fluent is still more likely to be true.

(3) NormStd5 represents a less reliable sensor. The sampling distribution is $\mathcal{N}(1, 0.5^2)$, which has a larger probability of generating a number smaller than 0.5 compared to *NormStd3*.

[3]In our future work, interacting with real humans will be conducted through Amazon Mechanical Turk. And the policies acquired with a simulated user in this work will be used as initial policies.

(4) UniEnv represents an unreliable sensor. Each number is sampled with a uniform distribution between 0 and 1. This means the sensor works randomly. A fluent has a equal change to be true or false no matter what the true environment is.

Evaluation Metrics. We used the same evaluation metrics as in the previous works (Misra et al., 2015; She and Chai, 2016) to evaluate the performance of applying the learned models to testing instances on action planning.

- ***IED***: Instruction Editing Distance. This is a number between 0 and 1 measuring the similarity between the predicted action sequence and the ground-truth action sequence. ***IED*** equals 1 if the two sequences are exactly the same.
- ***SJI***: State Jaccard Index. This is a number between 0 and 1 measuring the similarity between the predicted and the ground-truth state changes. ***SJI*** equals 1 if action planning leads to exactly the same state change as in the ground-truth.

Configurations. To understand the role of interactive learning in model acquisition and action planning, we first compared the interactive learning approach with the previous leading approach (presented as *She16*). To further evaluate the interaction policies acquired by reinforcement learning, we also compared the learned policy (i.e., ***RLPolicy***) with the following two baseline policies:

- ***RandomPolicy*** which randomly selects questions to ask during interaction.
- ***ManualPolicy*** which continuously asks for yes/no confirmations (i.e., object grounding questions ($GroundQ$), environment questions ($EnvQ$), goal prediction questions ($GoalQ$)) until there's no more questions before making a decision on model acquisition or action execution.

5.2 Results

5.2.1 The Effect of Interactive Learning

Table 4 shows the performance comparison on the testing data between the previous approach *She16* and our interactive learning approach based on environment representations with different levels of noise. The verb models acquired by interactive learning perform better consistently across all four environment conditions. When the environment becomes noisy (i.e., *NormStd3*, *NormStd5*, and *UniEnv*), the performance of *She16* that only relies on demonstrations decreases significantly. While the interactive learning improves the performance under the perfect environment condition, its effect in noisy environment is more remarkable. It leads to a significant performance gain between 48% and 145%. These results validate our hypothesis that interactive question answering can help to alleviate the problem of uncertainties in environment representation and goal prediction.

	She16		*RL policy*		% improvement	
	IED	*SJI*	*IED*	*SJI*	*IED*	*SJI*
PerfectEnv	0.430	0.426	0.453	0.468	5.3%*	9.9%*
NormStd3	0.284	0.273	0.420	0.431	47.9%*	57.9%*
NormStd5	0.172	0.168	0.392	0.411	127.9%*	144.6%*
UniEnv	0.168	0.163	0.332	0.347	97.6%*	112.9%*

Table 4: Performance comparison between *She16* and our interactive learning based on environment representations with different levels of noise. All the improvements (marked *) are statistically significant ($p < 0.01$).

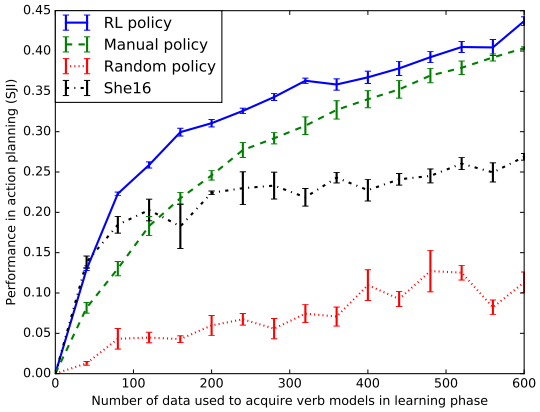

Figure 5: Performance (SJI) comparison by applying models acquired based on different interaction policies to the testing data.

Figure 5 shows the performance of the various learned models on the testing data, based on a varying number of training instances and different interaction policies. The interactive learning guided by the policy acquired from RL outperforms the previous approach *She16*. The RL policy slightly outperforms interactive learning using manually defined policy (i.e., *ManualPolicy*). However, as shown in the next section, the *Man-*

	Average number of questions							Performance	
	Learning Phase			Execution Phase					
	GroundQ	*EnvQ*	*TotalQ*	*GroundQ*	*EnvQ*	*GoalQ*	*TotalQ*	*IED*	*SJI*
RLPolicy	2.130* +/-0.231	2.615* +/-0.317	4.746* +/-0.307	0.383* +/-0.137	0.650* +/-0.366	2.626 +/-0.331	3.665* +/-0.469	0.420 +/-0.015	0.430* +/-0.018
ManualPolicy	2.495 +/-0.025	5.338 +/-0.008	7.833 +/-0.025	1.236 +/-0.002	3.202 +/-0.012	2.353 +/-0.023	6.792 +/-0.025	0.406 +/-0.002	0.404 +/-0.004
RandomPolicy	0.545 +/-0.016	0.368 +/-0.033	0.913 +/-0.040	0.678 +/-0.055	0.081 +/-0.030	0.151 +/-0.024	0.909 +/-0.018	0.114 +/-0.025	0.113 +/-0.029

Table 5: Comparison between different policies including the average number (and standard deviation) of different types of questions asked during the execution phase and the learning phase respectively, and the performance on action planning for the testing data. The results are based on the noisy environment sampled by *NormStd3*. * indicates statistically significant difference ($p < 0.05$) comparing *RLPolicy* with *ManualPolicy*.

ualPolicy results in much longer interaction (i.e., more questions) than the RL acquired policy.

5.2.2 Comparison of Interaction Policies

Table 5 compares the performance of different interaction policies. It shows the average number of questions asked under different policies. It is not surprising the *RandomPolicy* has the worst performance. For the *ManualPolicy*, its performance is similar to the *RLPolicy*. However, the average interaction length of *ManualPolicy* is 6.792, which is much longer than the *RLPolicy* (which is 3.127). These results further demonstrate that the policy learned from RL enables efficient interactions and the acquisition of more reliable verb models.

6 Conclusion

Robots live in a noisy environment. Due to the limitations in their external sensors, their representations of the shared environment can be error prone and full of uncertainties. As shown in previous work (Mourão et al., 2012), learning action models from the noisy and incomplete observation of the world is extremely challenging. The same problem applies to the acquisition of verb semantics that are grounded to the perceived world. To address this problem, this paper presents an interactive learning approach which aims to handle uncertainties of the environment as well as incompleteness and conflicts in state representation by asking human partners intelligent questions. The interaction strategies are learned through reinforcement learning. Our empirical results have shown a significant improvement in model acquisition and action prediction. When applying the learned models in new situations, the models acquired through interactive learning leads to over 140% performance gain in noisy environment.

The current investigation also has several limitations. As in previous works, we assume the world can be described by a closed set of predicates. This causes significant simplification for the physical world. One of the important questions to address in the future is how to learn new predicates through interaction with humans. Another limitation is that the current utility function is learned based on a set of pre-identified features. Future work can explore deep neural network to alleviate feature engineering.

As cognitive robots start to enter our daily lives, data-driven approaches to learning may not be possible in new situations. Human partners who work side-by-side with these cognitive robots are great resources that the robots can directly learn from. Recent years have seen an increasing amount of work on task learning from human partners (Saunders et al., 2006; Chernova and Veloso, 2008; Cantrell et al., 2012; Mohan et al., 2013; Asada et al., 2009; Mohseni-Kabir et al., 2015; Nejati et al., 2006; Liu et al., 2016). Our future work will incorporate interactive learning of verb semantics with task learning to enable autonomy that can learn by communicating with humans.

Multimodal Word Distributions

Ben Athiwaratkun

andrew@cornell.edu

Abstract

Word embeddings provide point representations of words containing useful semantic information. We introduce multimodal word distributions formed from Gaussian mixtures, for multiple word meanings, entailment, and rich uncertainty information. To learn these distributions, we propose an energy-based max-margin objective. We show that the resulting approach captures uniquely expressive semantic information, and outperforms alternatives, such as word2vec skip-grams, and Gaussian embeddings, on benchmark datasets such as word similarity and entailment.

1 Introduction

To model language, we must represent words. We can imagine representing every word with a binary one-hot vector corresponding to a dictionary position. But such a representation contains no valuable semantic information: distances between word vectors represent only differences in alphabetic ordering. Modern approaches, by contrast, learn to map words with similar meanings to nearby points in a vector space (Mikolov et al., 2013a), from large datasets such as Wikipedia. These learned word embeddings have become ubiquitous in predictive tasks.

Vilnis and McCallum (2014) recently proposed an alternative view, where words are represented by a whole probability distribution instead of a deterministic point vector. Specifically, they model each word by a Gaussian distribution, and learn its mean and covariance matrix from data. This approach generalizes any deterministic point embedding, which can be fully captured by the mean vector of the Gaussian distribution. Moreover, the full distribution provides much richer information than point estimates for characterizing words, representing probability mass and uncertainty across a set of semantics.

However, since a Gaussian distribution can have only one mode, the learned uncertainty in this representation can be overly diffuse for words with multiple distinct meanings (polysemies), in order for the model to assign *some* density to any plausible semantics (Vilnis and McCallum, 2014). Moreover, the mean of the Gaussian can be pulled in many opposing directions, leading to a biased distribution that centers its mass mostly around one meaning while leaving the others not well represented.

In this paper, we propose to represent each word with an expressive multimodal distribution, for multiple distinct meanings, entailment, heavy tailed uncertainty, and enhanced interpretability. For example, one mode of the word 'bank' could overlap with distributions for words such as 'finance' and 'money', and another mode could overlap with the distributions for 'river' and 'creek'. It is our contention that such flexibility is critical for both qualitatively learning about the meanings of words, and for optimal performance on many predictive tasks.

In particular, we model each word with a mixture of Gaussians (Section 3.1). We learn all the parameters of this mixture model using a maximum margin energy-based ranking objective (Joachims, 2002; Vilnis and McCallum, 2014) (Section 3.3), where the energy function describes the affinity between a pair of words. For analytic tractability with Gaussian mixtures, we use the inner product between probability distributions in a Hilbert space, known as the expected likelihood kernel (Jebara et al., 2004), as our energy function (Section 3.4). Additionally, we propose transformations for numerical stability and initialization A.2, resulting in a robust, straightforward, and

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1645–1656

https://doi.org/10.18653/v1/P17-1151

scalable learning procedure, capable of training on a corpus with billions of words in days. We show that the model is able to automatically discover multiple meanings for words (Section 4.3), and significantly outperform other alternative methods across several tasks such as word similarity and entailment (Section 4.4, 4.5, 4.7). We have made code available at `http://github.com/benathi/word2gm`, where we implement our model in Tensorflow (Abadi et. al, 2015).

2 Related Work

In the past decade, there has been an explosion of interest in word vector representations. `word2vec`, arguably the most popular word embedding, uses continuous bag of words and skip-gram models, in conjunction with negative sampling for efficient conditional probability estimation (Mikolov et al., 2013a,b). Other popular approaches use feedforward (Bengio et al., 2003) and recurrent neural network language models (Mikolov et al., 2010, 2011b; Collobert and Weston, 2008) to predict missing words in sentences, producing hidden layers that can act as word embeddings that encode semantic information. They employ conditional probability estimation techniques, including hierarchical softmax (Mikolov et al., 2011a; Mnih and Hinton, 2008; Morin and Bengio, 2005) and noise contrastive estimation (Gutmann and Hyvärinen, 2012).

A different approach to learning word embeddings is through factorization of word co-occurrence matrices such as `GloVe` embeddings (Pennington et al., 2014). The matrix factorization approach has been shown to have an implicit connection with skip-gram and negative sampling Levy and Goldberg (2014). Bayesian matrix factorization where row and columns are modeled as Gaussians has been explored in Salakhutdinov and Mnih (2008) and provides a different probabilistic perspective of word embeddings.

In exciting recent work, Vilnis and McCallum (2014) propose a Gaussian distribution to model each word. Their approach is significantly more expressive than typical point embeddings, with the ability to represent concepts such as *entailment*, by having the distribution for one word (e.g. 'music') encompass the distributions for sets of related words ('jazz' and 'pop'). However, with a unimodal distribution, their approach cannot capture multiple distinct meanings, much like most deterministic approaches.

Recent work has also proposed deterministic embeddings that can capture polysemies, for example through a cluster centroid of context vectors (Huang et al., 2012), or an adapted skip-gram model with an EM algorithm to learn multiple latent representations per word (Tian et al., 2014). Neelakantan et al. (2014) also extends skip-gram with multiple prototype embeddings where the number of senses per word is determined by a non-parametric approach. Liu et al. (2015) learns topical embeddings based on latent topic models where each word is associated with multiple topics. Another related work by Nalisnick and Ravi (2015) models embeddings in infinite-dimensional space where each embedding can gradually represent incremental word sense if complex meanings are observed.

Probabilistic word embeddings have only recently begun to be explored, and have so far shown great promise. In this paper, we propose, to the best of our knowledge, the first probabilistic word embedding that can capture multiple meanings. We use a Gaussian mixture model which allows for a highly expressive distributions over words. At the same time, we retain scalability and analytic tractability with an expected likelihood kernel energy function for training. The model and training procedure harmonize to learn descriptive representations of words, with superior performance on several benchmarks.

3 Methodology

In this section, we introduce our Gaussian mixture (GM) model for word representations, and present a training method to learn the parameters of the Gaussian mixture. This method uses an energy-based maximum margin objective, where we wish to maximize the similarity of distributions of nearby words in sentences. We propose an energy function that compliments the GM model by retaining analytic tractability. We also provide critical practical details for numerical stability and initialization. The code for model training and evaluation is available at `http://github.com/benathi/word2gm`.

3.1 Word Representation

We represent each word w in a dictionary as a Gaussian mixture with K components. Specifically, the distribution of w, f_w, is given by the

density

$$f_w(\vec{x}) = \sum_{i=1}^{K} p_{w,i}\, \mathcal{N}\left[\vec{x}; \vec{\mu}_{w,i}, \Sigma_{w,i}\right] \quad (1)$$

$$= \sum_{i=1}^{K} \frac{p_{w,i}}{\sqrt{2\pi|\Sigma_{w,i}|}} e^{-\frac{1}{2}(\vec{x}-\vec{\mu}_{w,i})^\top \Sigma_{w,i}^{-1}(\vec{x}-\vec{\mu}_{w,i})},$$

where $\sum_{i=1}^{K} p_{w,i} = 1$. The mean vectors $\vec{\mu}_{w,i}$ represent the location of the i^{th} component of word w, and are akin to the point embeddings provided by popular approaches like `word2vec`. $p_{w,i}$ represents the component probability (mixture weight), and $\Sigma_{w,i}$ is the component covariance matrix, containing uncertainty information. Our goal is to learn all of the model parameters $\vec{\mu}_{w,i}, p_{w,i}, \Sigma_{w,i}$ from a corpus of natural sentences to extract semantic information of words. Each Gaussian component's mean vector of word w can represent one of the word's distinct meanings. For instance, one component of a polysemous word such as 'rock' should represent the meaning related to 'stone' or 'pebbles', whereas another component should represent the meaning related to music such as 'jazz' or 'pop'. Figure 1 illustrates our word embedding model, and the difference between multimodal and unimodal representations, for words with multiple meanings.

3.2 Skip-Gram

The training objective for learning $\theta = \{\vec{\mu}_{w,i}, p_{w,i}, \Sigma_{w,i}\}$ draws inspiration from the continuous skip-gram model (Mikolov et al., 2013a), where word embeddings are trained to maximize the probability of observing a word given another nearby word. This procedure follows the *distributional hypothesis* that words occurring in natural contexts tend to be semantically related. For instance, the words 'jazz' and 'music' tend to occur near one another more often than 'jazz' and 'cat'; hence, 'jazz' and 'music' are more likely to be related. The learned word representation contains useful semantic information and can be used to perform a variety of NLP tasks such as word similarity analysis, sentiment classification, modelling word analogies, or as a preprocessed input for complex system such as statistical machine translation.

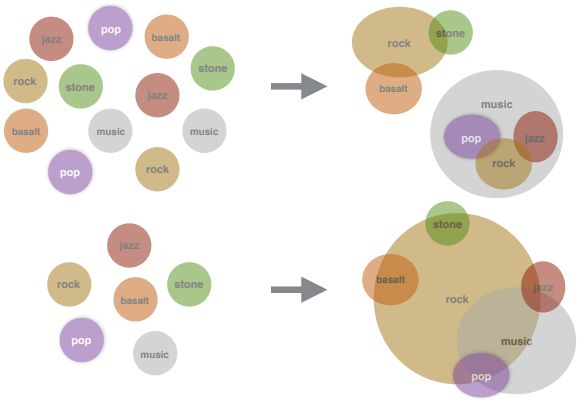

Figure 1: **Top:** A Gaussian Mixture embedding, where each component corresponds to a distinct meaning. Each Gaussian component is represented by an ellipsoid, whose center is specified by the mean vector and contour surface specified by the covariance matrix, reflecting subtleties in meaning and uncertainty. On the left, we show examples of Gaussian mixture distributions of words where Gaussian components are randomly initialized. After training, we see on the right that one component of the word 'rock' is closer to 'stone' and 'basalt', whereas the other component is closer to 'jazz' and 'pop'. We also demonstrate the entailment concept where the distribution of the more general word 'music' encapsulates words such as 'jazz', 'rock', 'pop'. **Bottom:** A Gaussian embedding model (Vilnis and McCallum, 2014). For words with multiple meanings, such as 'rock', the variance of the learned representation becomes unnecessarily large in order to assign some probability to both meanings. Moreover, the mean vector for such words can be pulled between two clusters, centering the mass of the distribution on a region which is far from certain meanings.

3.3 Energy-based Max-Margin Objective

Each sample in the objective consists of two pairs of words, (w, c) and (w, c'). w is sampled from a sentence in a corpus and c is a nearby word within a context window of length ℓ. For instance, a word w = 'jazz' which occurs in the sentence 'I listen to jazz music' has context words ('I', 'listen', 'to' , 'music'). c' is a negative context word (e.g. 'airplane') obtained from random sampling.

The objective is to maximize the energy between words that occur near each other, w and c, and minimize the energy between w and its negative context c'. This approach is similar to neg-

ative sampling (Mikolov et al., 2013a,b), which contrasts the dot product between positive context pairs with negative context pairs. The energy function is a measure of similarity between distributions and will be discussed in Section 3.4.

We use a max-margin ranking objective (Joachims, 2002), used for Gaussian embeddings in Vilnis and McCallum (2014), which pushes the similarity of a word and its positive context higher than that of its negative context by a margin m:

$$L_\theta(w, c, c') = \max(0, \\ m - \log E_\theta(w, c) + \log E_\theta(w, c'))$$

This objective can be minimized by mini-batch stochastic gradient descent with respect to the parameters $\theta = \{\vec{\mu}_{w,i}, p_{w,i}, \Sigma_{w,i}\}$ – the mean vectors, covariance matrices, and mixture weights – of our multimodal embedding in Eq. (1).

Word Sampling We use a word sampling scheme similar to the implementation in `word2vec` (Mikolov et al., 2013a,b) to balance the importance of frequent words and rare words. Frequent words such as 'the', 'a', 'to' are not as meaningful as relatively less frequent words such as 'dog', 'love', 'rock', and we are often more interested in learning the semantics of the less frequently observed words. We use subsampling to improve the performance of learning word vectors (Mikolov et al., 2013b). This technique discards word w_i with probability $P(w_i) = 1 - \sqrt{t/f(w_i)}$, where $f(w_i)$ is the frequency of word w_i in the training corpus and t is a frequency threshold.

To generate negative context words, each word type w_i is sampled according to a distribution $P_n(w_i) \propto U(w_i)^{3/4}$ which is a distorted version of the unigram distribution $U(w_i)$ that also serves to diminish the relative importance of frequent words. Both subsampling and the negative distribution choice are proven effective in `word2vec` training (Mikolov et al., 2013b).

3.4 Energy Function

For vector representations of words, a usual choice for similarity measure (energy function) is a dot product between two vectors. Our word representations are distributions instead of point vectors and therefore need a measure that reflects not only the point similarity, but also the uncertainty. We propose to use the *expected likelihood kernel*, which is a generalization of an inner product between vectors to an inner product between distributions (Jebara et al., 2004). That is,

$$E(f, g) = \int f(x)g(x)\, dx = \langle f, g \rangle_{L_2}$$

where $\langle \cdot, \cdot \rangle_{L_2}$ denotes the inner product in Hilbert space L_2. We choose this form of energy since it can be evaluated in a closed form given our choice of probabilistic embedding in Eq. (1).

For Gaussian mixtures f, g representing the words w_f, w_g, $f(x) = \sum_{i=1}^{K} p_i \mathcal{N}(x; \vec{\mu}_{f,i}, \Sigma_{f,i})$ and $g(x) = \sum_{i=1}^{K} q_i \mathcal{N}(x; \vec{\mu}_{g,i}, \Sigma_{g,i})$, $\sum_{i=1}^{K} p_i = 1$, and $\sum_{i=1}^{K} q_i = 1$, we find (see Section A.1) the log energy is

$$\log E_\theta(f, g) = \log \sum_{j=1}^{K} \sum_{i=1}^{K} p_i q_j e^{\xi_{i,j}} \qquad (2)$$

where

$$\begin{aligned} \xi_{i,j} &\equiv \log \mathcal{N}(0; \vec{\mu}_{f,i} - \vec{\mu}_{g,j}, \Sigma_{f,i} + \Sigma_{g,j}) \\ &= -\frac{1}{2} \log \det(\Sigma_{f,i} + \Sigma_{g,j}) - \frac{D}{2} \log(2\pi) \\ &-\frac{1}{2}(\vec{\mu}_{f,i} - \vec{\mu}_{g,j})^\top (\Sigma_{f,i} + \Sigma_{g,j})^{-1} (\vec{\mu}_{f,i} - \vec{\mu}_{g,j}) \end{aligned} \qquad (3)$$

We call the term $\xi_{i,j}$ partial (log) energy. Observe that this term captures the similarity between the i^{th} meaning of word w_f and the j^{th} meaning of word w_g. The total energy in Equation 2 is the sum of possible pairs of partial energies, weighted accordingly by the mixture probabilities p_i and q_j.

The term $-(\vec{\mu}_{f,i} - \vec{\mu}_{g,j})^\top (\Sigma_{f,i} + \Sigma_{g,j})^{-1} (\vec{\mu}_{f,i} - \vec{\mu}_{g,j})$ in $\xi_{i,j}$ explains the difference in mean vectors of semantic pair (w_f, i) and (w_g, j). If the semantic uncertainty (covariance) for both pairs are low, this term has more importance relative to other terms due to the inverse covariance scaling. We observe that the loss function L_θ in Section 3.3 attains a low value when $E_\theta(w, c)$ is relatively high. High values of $E_\theta(w, c)$ can be achieved when the component means across different words $\vec{\mu}_{f,i}$ and $\vec{\mu}_{g,j}$ are close together (e.g., similar point representations). High energy can also be achieved by large values of $\Sigma_{f,i}$ and $\Sigma_{g,j}$, which washes out the importance of the mean vector difference. The term $-\log \det(\Sigma_{f,i} + \Sigma_{g,j})$ serves as a regularizer that prevents the covariances from being pushed too high at the expense of learning a good mean embedding.

At the beginning of training, $\xi_{i,j}$ roughly are on the same scale among all pairs (i, j)'s. During this time, all components learn the signals from the word occurrences equally. As training progresses and the semantic representation of each mixture becomes more clear, there can be one term of $\xi_{i,j}$'s that is predominantly higher than other terms, giving rise to a semantic pair that is most related.

The negative KL divergence is another sensible choice of energy function, providing an asymmetric metric between word distributions. However, unlike the expected likelihood kernel, KL divergence does not have a closed form if the two distributions are Gaussian mixtures.

4 Experiments

We have introduced a model for multi-prototype embeddings, which expressively captures word meanings with whole probability distributions. We show that our combination of energy and objective functions, proposed in Section 3, enables one to learn interpretable multimodal distributions through unsupervised training, for describing words with multiple distinct meanings. By representing multiple distinct meanings, our model also reduces the unnecessarily large variance of a Gaussian embedding model, and has improved results on word entailment tasks.

To learn the parameters of the proposed mixture model, we train on a concatenation of two datasets: `UKWAC` (2.5 billion tokens) and `Wackypedia` (1 billion tokens) (Baroni et al., 2009). We discard words that occur fewer than 100 times in the corpus, which results in a vocabulary size of $314,129$ words. Our word sampling scheme, described at the end of Section 4.3, is similar to that of `word2vec` with one negative context word for each positive context word.

After training, we obtain learned parameters $\{\vec{\mu}_{w,i}, \Sigma_{w,i}, p_i\}_{i=1}^{K}$ for each word w. We treat the mean vector $\vec{\mu}_{w,i}$ as the embedding of the i^{th} mixture component with the covariance matrix $\Sigma_{w,i}$ representing its subtlety and uncertainty. We perform qualitative evaluation to show that our embeddings learn meaningful multi-prototype representations and compare to existing models using a quantitative evaluation on word similarity datasets and word entailment.

We name our model as Word to Gaussian Mixture (`w2gm`) in constrast to Word to Gaussian (`w2g`) (Vilnis and McCallum, 2014). Unless stated otherwise, `w2g` refers to our implementation of `w2gm` model with one mixture component.

4.1 Hyperparameters

Unless stated otherwise, we experiment with $K = 2$ components for the `w2gm` model, but we have results and discussion of $K = 3$ at the end of section 4.3. We primarily consider the spherical case for computational efficiency. We note that for diagonal or spherical covariances, the energy can be computed very efficiently since the matrix inversion would simply require $\mathcal{O}(d)$ computation instead of $\mathcal{O}(d^3)$ for a full matrix. Empirically, we have found diagonal covariance matrices become roughly spherical after training. Indeed, for these relatively high dimensional embeddings, there are sufficient degrees of freedom for the mean vectors to be learned such that the covariance matrices need not be asymmetric. Therefore, we perform all evaluations with spherical covariance models.

Models used for evaluation have dimension $D = 50$ and use context window $\ell = 10$ unless stated otherwise. We provide additional hyperparameters and training details in the supplementary material (A.2).

4.2 Similarity Measures

Since our word embeddings contain multiple vectors and uncertainty parameters per word, we use the following measures that generalizes similarity scores. These measures pick out the component pair with maximum similarity and therefore determine the meanings that are most relevant.

4.2.1 Expected Likelihood Kernel

A natural choice for a similarity score is the expected likelihood kernel, an inner product between distributions, which we discussed in Section 3.4. This metric incorporates the uncertainty from the covariance matrices in addition to the similarity between the mean vectors.

4.2.2 Maximum Cosine Similarity

This metric measures the maximum similarity of mean vectors among all pairs of mixture components between distributions f and g. That is, $d(f, g) = \max_{i,j=1,\ldots,K} \frac{\langle \boldsymbol{\mu}_{f,i}, \boldsymbol{\mu}_{g,j} \rangle}{||\boldsymbol{\mu}_{f,i}|| \cdot ||\boldsymbol{\mu}_{g,j}||}$, which corresponds to matching the meanings of f and g that are the most similar. For a Gaussian embedding, maximum similarity reduces to the usual cosine similarity.

Table 1: Nearest neighbors based on cosine similarity between the mean vectors of Gaussian components for Gaussian mixture embedding (top) (for $K = 2$) and Gaussian embedding (bottom). The notation `w:i` denotes the i^{th} mixture component of the word `w`.

4.2.3 Minimum Euclidean Distance

Cosine similarity is popular for evaluating embeddings. However, our training objective directly involves the Euclidean distance in Eq. (3), as opposed to dot product of vectors such as in `word2vec`. Therefore, we also consider the Euclidean metric: $d(f, g) = \min_{i,j=1,\ldots,K}[||\boldsymbol{\mu}_{f,i} - \boldsymbol{\mu}_{g,j}||]$.

4.3 Qualitative Evaluation

In Table 1, we show examples of polysemous words and their nearest neighbors in the embedding space to demonstrate that our trained embeddings capture multiple word senses. For instance, a word such as 'rock' that could mean either 'stone' or 'rock music' should have each of its meanings represented by a distinct Gaussian component. Our results for a mixture of two Gaussians model confirm this hypothesis, where we observe that the 0^{th} component of 'rock' being related to ('basalt', 'boulders') and the 1^{st} component being related to ('indie', 'funk', 'hip-hop'). Similarly, the word `bank` has its 0^{th} component representing the river bank and the 1^{st} component representing the financial bank.

By contrast, in Table 1 (bottom), see that for Gaussian embeddings with one mixture component, nearest neighbors of polysemous words are predominantly related to a single meaning. For instance, 'rock' mostly has neighbors related to rock music and 'bank' mostly related to the financial bank. The alternative meanings of these polysemous words are not well represented in the embeddings. As a numerical example, the cosine similarity between 'rock' and 'stone' for the Gaussian representation of Vilnis and McCallum (2014) is only 0.029, much lower than the cosine similarity 0.586 between the 0^{th} component of 'rock' and 'stone' in our multimodal representation.

In cases where a word only has a single popular meaning, the mixture components can be fairly close; for instance, one component of 'stone' is close to ('stones', 'stonework', 'slab') and the other to ('carving, 'relic', 'excavated'), which reflects subtle variations in meanings. In general, the mixture can give properties such as heavy tails and more interesting unimodal characterizations of uncertainty than could be described by a single Gaussian.

Embedding Visualization We provide an interactive visualization as part of our code repository: `https://github.com/benathi/word2gm#visualization` that allows real-time queries of words' nearest neighbors (in the `embeddings` tab) for $K = 1, 2, 3$ components. We use a notation similar to that of Table 1, where a token `w:i` represents the component `i` of a word `w`. For instance, if in the $K = 2$ link we search for `bank:0`, we obtain the nearest neigh-

bors such as river:1, confluence:0, waterway:1, which indicates that the 0^{th} component of 'bank' has the meaning 'river bank'. On the other hand, searching for bank:1 yields nearby words such as banking:1, banker:0, ATM:0, indicating that this component is close to the 'financial bank'. We also have a visualization of a unimodal (w2g) for comparison in the $K = 1$ link.

In addition, the embedding link for our Gaussian mixture model with $K = 3$ mixture components can learn three distinct meanings. For instance, each of the three components of 'cell' is close to ('keypad', 'digits'), ('incarcerated', 'inmate') or ('tissue', 'antibody'), indicating that the distribution captures the concept of 'cellphone', 'jail cell', or 'biological cell', respectively. Due to the limited number of words with more than 2 meanings, our model with $K = 3$ does not generally offer substantial performance differences to our model with $K = 2$; hence, we do not further display $K = 3$ results for compactness.

4.4 Word Similarity

We evaluate our embeddings on several standard word similarity datasets, namely, SimLex (Hill et al., 2014), WS or WordSim-353, WS-S (similarity), WS-R (relatedness) (Finkelstein et al., 2002), MEN (Bruni et al., 2014), MC (Miller and Charles, 1991), RG (Rubenstein and Goodenough, 1965), YP (Yang and Powers, 2006), MTurk(-287,-771) (Radinsky et al., 2011; Halawi et al., 2012), and RW (Luong et al., 2013). Each dataset contains a list of word pairs with a human score of how related or similar the two words are.

We calculate the Spearman correlation (Spearman, 1904) between the labels and our scores generated by the embeddings. The Spearman correlation is a rank-based correlation measure that assesses how well the scores describe the true labels.

The correlation results are shown in Table 2 using the scores generated from the expected likelihood kernel, maximum cosine similarity, and maximum Euclidean distance.

We show the results of our Gaussian mixture model and compare the performance with that of word2vec and the original Gaussian embedding by Vilnis and McCallum (2014). We note that our model of a unimodal Gaussian embedding w2g also outperforms the original model, which differs in model hyperparameters and initialization, for most datasets. Our multi-prototype model w2gm also performs better than skip-gram or Gaussian embedding methods on many datasets, namely, WS, WS-R, MEN, MC, RG, YP, MT-287, RW. The maximum cosine similarity yields the best performance on most datasets; however, the minimum Euclidean distance is a better metric for the datasets MC and RW. These results are consistent for both the single-prototype and the multi-prototype models.

We also compare out results on WordSim-353 with the multi-prototype embedding method by Huang et al. (2012) and Neelakantan et al. (2014), shown in Table 3. We observe that our single-prototype model w2g is competitive compared to models by Huang et al. (2012), even without using a corpus with stop words removed. This could be due to the auto-calibration of importance via the covariance learning which decrease the importance of very frequent words such as 'the', 'to', 'a', etc. Moreover, our multi-prototype model substantially outperforms the model of Huang et al. (2012) and the MSSG model of Neelakantan et al. (2014) on the WordSim-353 dataset.

4.5 Word Similarity for Polysemous Words

We use the dataset SCWS introduced by Huang et al. (2012), where word pairs are chosen to have variations in meanings of polysemous and homonymous words.

We compare our method with multiprototype models by Huang (Huang et al., 2012), Tian (Tian et al., 2014), Chen (Chen et al., 2014), and MSSG model by (Neelakantan et al., 2014). We note that Chen model uses an external lexical source WordNet that gives it an extra advantage.

We use many metrics to calculate the scores for the Spearman correlation. MaxSim refers to the maximum cosine similarity. AveSim is the average of cosine similarities with respect to the component probabilities.

In Table 4, the model w2g performs the best among all single-prototype models for either 50 or 200 vector dimensions. Our model w2gm performs competitively compared to other multi-prototype models. In SCWS, the gain in flexibility in moving to a probability density approach appears to dominate over the effects of using a multi-prototype. In most other examples, we see w2gm surpass w2g, where the multi-prototype structure is just as important for good performance as the

Table 2: Spearman correlation for word similarity datasets. The models `sg`, `w2g`, `w2gm` denote `word2vec` skip-gram, Gaussian embedding, and Gaussian mixture embedding (K=2). The measures `mc`, `el`, `me` denote maximum cosine similarity, expected likelihood kernel, and minimum Euclidean distance. For each of `w2g` and `w2gm`, we underline the similarity metric with the best score. For each dataset, we boldface the score with the best performance across all models. The correlation scores for `sg*`, `w2g*` are taken from Vilnis and McCallum (2014) and correspond to cosine distance.

Model	$\rho \times 100$
Huang	64.2
Huang*	71.3
MSSG 50D	63.2
MSSG 300D	71.2
w2g	70.9
w2gm	**73.5**

Table 3: Spearman's correlation (ρ) on WordSim-353 datasets for our Word to Gaussian Mixture embeddings, as well as the multi-prototype embedding by Huang et al. (2012) and the MSSG model by Neelakantan et al. (2014). `Huang*` is trained using data with all stop words removed. All models have dimension $D = 50$ except for MSSG 300D with $D = 300$ which is still outperformed by our `w2gm` model.

Model	Dimension	$\rho \times 100$
word2vec skip-gram	50	61.7
Huang-S	50	58.6
w2g	50	**64.7**
Chen-S	200	64.2
w2g	200	**66.2**
Huang-M AvgSim	50	62.8
Tian-M MaxSim	50	63.6
w2gm MaxSim	50	62.7
MSSG AvgSim	50	**64.2**
Chen-M AvgSim	200	**66.2**
w2gm MaxSim	200	65.5

Table 4: Spearman's correlation ρ on dataset SCWS. We show the results for single prototype (top) and multi-prototype (bottom) The suffix `-(S,M)` refers to single and multiple prototype models, respectively.

probabilistic representation.

4.6 Reduction in Variance of Polysemous Words

One motivation for our Gaussian mixture embedding is to model word uncertainty more accurately than Gaussian embeddings, which can have overly large variances for polysemous words (in order to assign some mass to all of the distinct meanings). We see that our Gaussian mixture model does indeed reduce the variances of each component for such words. For instance, we observe that the word `rock` in `w2g` has much higher variance per dimension ($e^{-1.8} \approx 1.65$) compared to that of Gaussian components of `rock` in `w2gm` (which has variance of roughly $e^{-2.5} \approx 0.82$). We also see, in the next section, that the Gaussian mixture model has desirable quantitative behavior for word entailment.

4.7 Word Entailment

We evaluate our embeddings on the word entailment dataset from Baroni et al. (2012). The lexical entailment between words is denoted by $w_1 \models w_2$ which means that all instances of w_1 are w_2. The entailment dataset contains positive pairs such as *aircraft* $\models$ *vehicle* and negative pairs such as *aircraft* $\not\models$ *insect*.

We generate entailment scores of word pairs and find the best threshold, measured by Average Precision (AP) or F1 score, which identifies negative versus positive entailment. We use the max-

Model	Score	Best AP	Best F1
w2g (5)	cos	73.1	76.4
w2g (5)	KL	73.7	76.0
w2gm (5)	cos	73.6	76.3
w2gm (5)	KL	75.7	77.9
w2g (10)	cos	73.0	76.1
w2g (10)	KL	74.2	76.1
w2gm (10)	cos	72.9	75.6
w2gm (10)	KL	74.7	76.3

Table 5: Entailment results for models `w2g` and `w2gm` with window size 5 and 10. The metrics used are the maximum cosine similarity, or the maximum negative KL divergence. We calculate the best average precision as well as the best F1 score. In most cases, `w2gm` outperforms `w2g` for describing entailment.

imum cosine similarity and the minimum KL divergence, $d(f, g) = \min_{i,j=1,\ldots,K} KL(f||g)$, for entailment scores. The minimum KL divergence is similar to the maximum cosine similarity, but also incorporates the embedding uncertainty. In addition, KL divergence is an asymmetric measure, which is more suitable for certain tasks such as word entailment where a relationship is unidirectional. For instance, $w_1 \models w_2$ does not imply $w_2 \models w_1$. Indeed, *aircraft* $\models$ *vehicle* does not imply *vehicle* $\models$ *aircraft*, since all aircraft are vehicles but not all vehicles are aircraft. The difference between $KL(w_1||w_2)$ versus $KL(w_2||w_1)$ distinguishes which word distribution encompasses another distribution, as demonstrated in Figure 1.

Table 5 shows the results of our `w2gm` model versus the Gaussian embedding model `w2g`. We observe a trend for both models with window size 5 and 10 that the KL metric yields improvement (both AP and F1) over cosine similarity. In addition, `w2gm` has a better performance compared to `w2g`. The multi-prototype model estimates the meaning uncertainty better since it is no longer constrained to be unimodal, leading to better characterizations of entailment. On the other hand, the Gaussian embedding model suffers from large variance problem for polysemous words, which results in less informative word distribution and inferior entailment scores.

5 Discussion

We introduced a model that represents words with expressive multimodal distributions formed from Gaussian mixtures. To learn the properties of each mixture, we proposed an analytic energy function for combination with a maximum margin objective. The resulting embeddings capture different semantics of polysemous words, uncertainty, and entailment, and also perform favorably on word similarity benchmarks.

Elsewhere, latent probabilistic representations are proving to be exceptionally valuable, able to capture nuances such as face angles with variational autoencoders (Kingma and Welling, 2013) or subtleties in painting strokes with the InfoGAN (Chen et al., 2016). Moreover, classically deterministic deep learning architectures are now being generalized to probabilistic deep models, for full predictive distributions instead of point estimates, and significantly more expressive representations (Wilson et al., 2016b,a; Al-Shedivat et al., 2016; Gan et al., 2016; Fortunato et al., 2017).

Similarly, probabilistic word embeddings can capture a range of subtle meanings, and advance the state of the art in predictive tasks. Multimodal word distributions naturally represent our belief that words do not have single precise meanings: indeed, the shape of a word distribution can express much more semantic information than any point representation.

In the future, multimodal word distributions could open the doors to a new suite of applications in language modelling, where whole word distributions are used as inputs to new probabilistic LSTMs, or in decision functions where uncertainty matters. As part of this effort, we can explore different metrics between distributions, such as KL divergences, which would be a natural choice for order embeddings that model entailment properties. It would also be informative to explore inference over the number of components in mixture models for word distributions. Such an approach could potentially discover an unbounded number of distinct meanings for words, but also distribute the support of each word distribution to express highly nuanced meanings. Alternatively, we could imagine a dependent mixture model where the distributions over words are evolving with time and other covariates. One could also build new types of supervised language models, constructed to more fully leverage the rich information provided by word distributions.

A Supplementary Material

A.1 Derivation of Expected Likelihood Kernel

We derive the form of expected likelihood kernel for Gaussian mixtures. Let f, g be Gaussian mixture distributions representing the words w_f, w_g. That is, $f(x) = \sum_{i=1}^{K} p_i \mathcal{N}(x; \mu_{f,i}, \Sigma_{f,i})$ and $g(x) = \sum_{i=1}^{K} q_i \mathcal{N}(x; \mu_{g,i}, \Sigma_{g,i})$, $\sum_{i=1}^{K} p_i = 1$, and $\sum_{i=1}^{K} q_i = 1$.

The expected likelihood kernel is given by

$$
\begin{aligned}
E_\theta(f,g) &= \int \left(\sum_{i=1}^{K} p_i \mathcal{N}(x;\mu_{f,i},\Sigma_{f,i})\right) \cdot \\
&\quad \left(\sum_{j=1}^{K} q_j \mathcal{N}(x;\mu_{g,j},\Sigma_{g,j})\right)\, dx \\
&= \sum_{i=1}^{K}\sum_{j=1}^{K} p_i q_j \int \mathcal{N}(x;\mu_{f,i},\Sigma_{f,i}) \cdot \mathcal{N}(x;\mu_{g,j},\Sigma_{g,j})\, dx \\
&= \sum_{i=1}^{K}\sum_{j=1}^{K} p_i q_j \mathcal{N}(0;\mu_{f,i}-\mu_{g,j},\Sigma_{f,i}+\Sigma_{g,j}) \\
&= \sum_{i=1}^{K}\sum_{j=1}^{K} p_i q_j e^{\xi_{i,j}}
\end{aligned}
$$

where we note that $\int \mathcal{N}(x;\mu_i,\Sigma_i)\mathcal{N}(x;\mu_j,\Sigma_j)\, dx = \mathcal{N}(0,\mu_i-\mu_j,\Sigma_i+\Sigma_j)$ (Vilnis and McCallum, 2014) and $\xi_{i,j}$ is the log partial energy, given by equation 3.

A.2 Implementation

In this section we discuss practical details for training the proposed model.

Reduction to Diagonal Covariance

We use a diagonal Σ, in which case inverting the covariance matrix is trivial and computations are particularly efficient.

Let $\boldsymbol{d}^f, \boldsymbol{d}^g$ denote the diagonal vectors of Σ_f, Σ_g The expression for $\xi_{i,j}$ reduces to

$$
\begin{aligned}
\xi_{i,j} &= -\frac{1}{2}\sum_{r=1}^{D}\log(d_r^p + d_r^q) \\
-\frac{1}{2}\sum &\left[(\boldsymbol{\mu}_{p,i}-\boldsymbol{\mu}_{q,j}) \circ \frac{1}{\boldsymbol{d^p}+\boldsymbol{d^q}} \circ (\boldsymbol{\mu}_{p,i}-\boldsymbol{\mu}_{q,j})\right]
\end{aligned}
$$

where $\circ$ denotes element-wise multiplication. The spherical case which we use in all our experiments is similar since we simply replace a vector $\boldsymbol{d}$ with a single value.

Optimization Constraint and Stability

We optimize $\log \boldsymbol{d}$ since each component of diagonal vector $\boldsymbol{d}$ is constrained to be positive. Similarly, we constrain the probability p_i to be in $[0,1]$ and sum to 1 by optimizing over unconstrained scores $s_i \in (-\infty,\infty)$ and using a softmax function to convert the scores to probability $p_i = \frac{e^{s_i}}{\sum_{j=1}^{K} e^{s_j}}$.

The loss computation can be numerically unstable if elements of the diagonal covariances are very small, due to the term $\log(d_r^f + d_r^g)$ and $\frac{1}{\boldsymbol{d^q}+\boldsymbol{d^p}}$. Therefore, we add a small constant $\epsilon = 10^{-4}$ so that $d_r^f + d_r^g$ and $\boldsymbol{d}^q + \boldsymbol{d}^p$ becomes $d_r^f + d_r^g + \epsilon$ and $\boldsymbol{d^q} + \boldsymbol{d^p} + \epsilon$.

In addition, we observe that $\xi_{i,j}$ can be very small which would result in $e^{\xi_{i,j}} \approx 0$ up to machine precision. In order to stabilize the computation in eq. 2, we compute its equivalent form

$$
\log E(f,g) = \xi_{i',j'} + \log \sum_{j=1}^{K}\sum_{i=1}^{K} p_i q_j e^{\xi_{i,j}-\xi_{i',j'}}
$$

where $\xi_{i',j'} = \max_{i,j} \xi_{i,j}$.

Model Hyperparameters and Training Details

In the loss function L_θ, we use a margin $m = 1$ and a batch size of 128. We initialize the word embeddings with a uniform distribution over $[-\sqrt{\frac{3}{D}}, \sqrt{\frac{3}{D}}]$ so that the expectation of variance is 1 and the mean is zero (LeCun et al., 1998). We initialize each dimension of the diagonal matrix (or a single value for spherical case) with a constant value $v = 0.05$. We also initialize the mixture scores s_i to be 0 so that the initial probabilities are equal among all K components. We use the threshold $t = 10^{-5}$ for negative sampling, which is the recommended value for `word2vec` skip-gram on large datasets.

We also use a separate output embeddings in addition to input embeddings, similar to `word2vec` implementation (Mikolov et al., 2013a,b). That is, each word has two sets of distributions q_I and q_O, each of which is a Gaussian mixture. For a given pair of word and context (w,c), we use the input distribution q_I for w (input word) and the output distribution q_O for context c (output word). We optimize the parameters of both q_I and q_O and use the trained input distributions q_I as our final word representations.

We use mini-batch asynchronous gradient descent with Adagrad (Duchi et al., 2011) which performs adaptive learning rate for each parameter. We also experiment with Adam (Kingma and Ba, 2014) which corrects the bias in adaptive gradient update of Adagrad and is proven very popular for most recent neural network models. However, we found that it is much slower than Adagrad ($\approx$ 10 times). This is because the gradient computation of the model is relatively fast, so a complex gradient update algorithm such as Adam becomes the bottleneck in the optimization. Therefore, we choose to use Adagrad which allows us to better scale to large datasets. We use a linearly decreasing learning rate from 0.05 to 0.00001.

Abstract

Reasoning and inference are central to human and artificial intelligence. Modeling inference in human language is very challenging. With the availability of large annotated data (Bowman et al., 2015), it has recently become feasible to train neural network based inference models, which have shown to be very effective. In this paper, we present a new state-of-the-art result, achieving the accuracy of 88.6% on the Stanford Natural Language Inference Dataset. Unlike the previous top models that use very complicated network architectures, we first demonstrate that carefully designing sequential inference models based on chain LSTMs can outperform all previous models. Based on this, we further show that by explicitly considering recursive architectures in both local inference modeling and inference composition, we achieve additional improvement. Particularly, incorporating syntactic parsing information contributes to our best result—it further improves the performance even when added to the already very strong model.

1 Introduction

Reasoning and inference are central to both human and artificial intelligence. Modeling inference in human language is notoriously challenging but is a basic problem towards true natural language understanding, as pointed out by MacCartney and Manning (2008), *"a necessary (if not sufficient) condition for true natural language understanding is a mastery of open-domain natural language inference."* The previous work has included extensive research on recognizing textual entailment.

Specifically, natural language inference (NLI) is concerned with determining whether a natural-language hypothesis h can be inferred from a premise p, as depicted in the following example from MacCartney (2009), where the hypothesis is regarded to be entailed from the premise.

p: *Several airlines polled saw costs grow more than expected, even after adjusting for inflation.*

h: *Some of the companies in the poll reported cost increases.*

The most recent years have seen advances in modeling natural language inference. An important contribution is the creation of a much larger annotated dataset, the Stanford Natural Language Inference (SNLI) dataset (Bowman et al., 2015). The corpus has 570,000 human-written English sentence pairs manually labeled by multiple human subjects. This makes it feasible to train more complex inference models. Neural network models, which often need relatively large annotated data to estimate their parameters, have shown to achieve the state of the art on SNLI (Bowman et al., 2015, 2016; Munkhdalai and Yu, 2016b; Parikh et al., 2016; Sha et al., 2016; Paria et al., 2016).

While some previous top-performing models use rather complicated network architectures to achieve the state-of-the-art results (Munkhdalai and Yu, 2016b), we demonstrate in this paper that enhancing sequential inference models based on chain

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1657–1668
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1152

models can outperform all previous results, suggesting that the potentials of such sequential inference approaches have not been fully exploited yet. More specifically, we show that our sequential inference model achieves an accuracy of 88.0% on the SNLI benchmark.

Exploring syntax for NLI is very attractive to us. In many problems, syntax and semantics interact closely, including in semantic composition (Partee, 1995), among others. Complicated tasks such as natural language inference could well involve both, which has been discussed in the context of recognizing textual entailment (RTE) (Mehdad et al., 2010; Ferrone and Zanzotto, 2014). In this paper, we are interested in exploring this within the neural network frameworks, with the presence of relatively large training data. We show that by explicitly encoding parsing information with recursive networks in both local inference modeling and inference composition and by incorporating it into our framework, we achieve additional improvement, increasing the performance to a new state of the art with an 88.6% accuracy.

2 Related Work

Early work on natural language inference has been performed on rather small datasets with more conventional methods (refer to MacCartney (2009) for a good literature survey), which includes a large bulk of work on recognizing textual entailment, such as (Dagan et al., 2005; Iftene and Balahur-Dobrescu, 2007), among others. More recently, Bowman et al. (2015) made available the SNLI dataset with 570,000 human annotated sentence pairs. They also experimented with simple classification models as well as simple neural networks that encode the premise and hypothesis independently. Rocktäschel et al. (2015) proposed neural attention-based models for NLI, which captured the attention information. In general, attention based models have been shown to be effective in a wide range of tasks, including machine translation (Bahdanau et al., 2014), speech recognition (Chorowski et al., 2015; Chan et al., 2016), image caption (Xu et al., 2015), and text summarization (Rush et al., 2015; Chen et al., 2016), among others. For NLI, the idea allows neural models to pay attention to specific areas of the sentences.

A variety of more advanced networks have been developed since then (Bowman et al., 2016; Vendrov et al., 2015; Mou et al., 2016; Liu et al., 2016; Munkhdalai and Yu, 2016a; Rocktäschel et al., 2015; Wang and Jiang, 2016; Cheng et al., 2016; Parikh et al., 2016; Munkhdalai and Yu, 2016b; Sha et al., 2016; Paria et al., 2016). Among them, more relevant to ours are the approaches proposed by Parikh et al. (2016) and Munkhdalai and Yu (2016b), which are among the best performing models.

Parikh et al. (2016) propose a relatively simple but very effective decomposable model. The model decomposes the NLI problem into subproblems that can be solved separately. On the other hand, Munkhdalai and Yu (2016b) propose much more complicated networks that consider sequential LSTM-based encoding, recursive networks, and complicated combinations of attention models, which provide about 0.5% gain over the results reported by Parikh et al. (2016).

It is, however, not very clear if the potential of the sequential inference networks has been well exploited for NLI. In this paper, we first revisit this problem and show that enhancing sequential inference models based on chain networks can actually outperform all previous results. We further show that explicitly considering recursive architectures to encode syntactic parsing information for NLI could further improve the performance.

3 Hybrid Neural Inference Models

We present here our natural language inference networks which are composed of the following major components: input encoding, local inference modeling, and inference composition. Figure 1 shows a high-level view of the architecture. Vertically, the figure depicts the three major components, and horizontally, the left side of the figure represents our sequential NLI model named ESIM, and the right side represents networks that incorporate syntactic parsing information in tree LSTMs.

In our notation, we have two sentences $\mathbf{a} = (\mathbf{a}_1, \ldots, \mathbf{a}_{\ell_a})$ and $\mathbf{b} = (\mathbf{b}_1, \ldots, \mathbf{b}_{\ell_b})$, where $\mathbf{a}$ is a premise and $\mathbf{b}$ a hypothesis. The $\mathbf{a}_i$ or $\mathbf{b}_j \in \mathbb{R}^l$ is an embedding of l-dimensional vector, which can be initialized with some pre-trained word embeddings and organized with parse trees. The goal is to predict a label y that indicates the logic relationship between $\mathbf{a}$ and $\mathbf{b}$.

3.1 Input Encoding

We employ bidirectional LSTM (BiLSTM) as one of our basic building blocks for NLI. We first use it

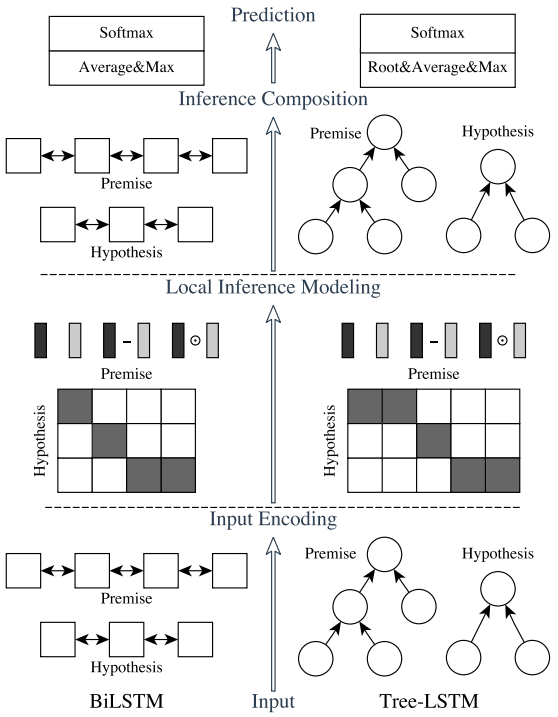

Figure 1: A high-level view of our hybrid neural inference networks.

to encode the input premise and hypothesis (Equation (1) and (2)). Here BiLSTM learns to represent a word (e.g., $\mathbf{a}_i$) and its context. Later we will also use BiLSTM to perform *inference composition* to construct the final prediction, where BiLSTM encodes local inference information and its interaction. To bookkeep the notations for later use, we write as $\bar{\mathbf{a}}_i$ the hidden (output) state generated by the BiLSTM at time i over the input sequence $\mathbf{a}$. The same is applied to $\bar{\mathbf{b}}_j$:

$$\bar{\mathbf{a}}_i = \text{BiLSTM}(\mathbf{a}, i), \forall i \in [1, \ldots, \ell_a], \quad (1)$$

$$\bar{\mathbf{b}}_j = \text{BiLSTM}(\mathbf{b}, j), \forall j \in [1, \ldots, \ell_b]. \quad (2)$$

Due to the space limit, we will skip the description of the basic chain LSTM and readers can refer to Hochreiter and Schmidhuber (1997) for details. Briefly, when modeling a sequence, an LSTM employs a set of soft gates together with a memory cell to control message flows, resulting in an effective modeling of tracking long-distance information/dependencies in a sequence.

A bidirectional LSTM runs a forward and backward LSTM on a sequence starting from the left and the right end, respectively. The hidden states generated by these two LSTMs at each time step are concatenated to represent that time step and its context. Note that we used LSTM memory blocks in our models. We examined other recurrent memory blocks such as GRUs (Gated Recurrent Units) (Cho et al., 2014) and they are inferior to LSTMs on the heldout set for our NLI task.

As discussed above, it is intriguing to explore the effectiveness of syntax for natural language inference; for example, whether it is useful even when incorporated into the best-performing models. To this end, we will also encode syntactic parse trees of a premise and hypothesis through tree-LSTM (Zhu et al., 2015; Tai et al., 2015; Le and Zuidema, 2015), which extends the chain LSTM to a recursive network (Socher et al., 2011).

Specifically, given the parse of a premise or hypothesis, a tree node is deployed with a tree-LSTM memory block depicted as in Figure 2 and computed with Equations (3–10). In short, at each node, an input vector $\mathbf{x}_t$ and the hidden vectors of its two children (the left child $\mathbf{h}^L_{t-1}$ and the right $\mathbf{h}^R_{t-1}$) are taken in as the input to calculate the current node's hidden vector $\mathbf{h}_t$.

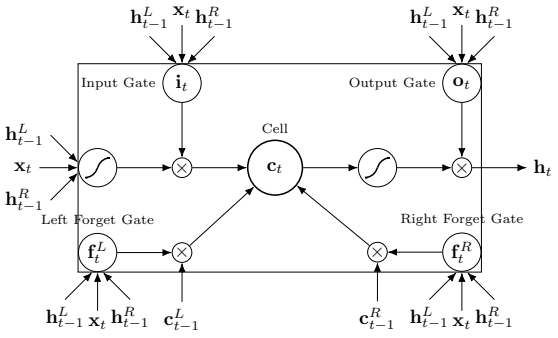

Figure 2: A tree-LSTM memory block.

We describe the updating of a node at a high level with Equation (3) to facilitate references later in the paper, and the detailed computation is described in (4–10). Specifically, the input of a node is used to configure four gates: the input gate $\mathbf{i}_t$, output gate $\mathbf{o}_t$, and the two forget gates $\mathbf{f}^L_t$ and $\mathbf{f}^R_t$. The memory cell $\mathbf{c}_t$ considers each child's cell vector, $\mathbf{c}^L_{t-1}$ and $\mathbf{c}^R_{t-1}$, which are gated by the left forget

gate $\mathbf{f}_t^L$ and right forget gate $\mathbf{f}_t^R$, respectively.

$$\mathbf{h}_t = \text{TrLSTM}(\mathbf{x}_t, \mathbf{h}_{t-1}^L, \mathbf{h}_{t-1}^R), \quad (3)$$
$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t), \quad (4)$$
$$\mathbf{o}_t = \sigma(\mathbf{W}_o \mathbf{x}_t + \mathbf{U}_o^L \mathbf{h}_{t-1}^L + \mathbf{U}_o^R \mathbf{h}_{t-1}^R), \quad (5)$$
$$\mathbf{c}_t = \mathbf{f}_t^L \odot \mathbf{c}_{t-1}^L + \mathbf{f}_t^R \odot \mathbf{c}_{t-1}^R + \mathbf{i}_t \odot \mathbf{u}_t, \quad (6)$$
$$\mathbf{f}_t^L = \sigma(\mathbf{W}_f \mathbf{x}_t + \mathbf{U}_f^{LL} \mathbf{h}_{t-1}^L + \mathbf{U}_f^{LR} \mathbf{h}_{t-1}^R), \quad (7)$$
$$\mathbf{f}_t^R = \sigma(\mathbf{W}_f \mathbf{x}_t + \mathbf{U}_f^{RL} \mathbf{h}_{t-1}^L + \mathbf{U}_f^{RR} \mathbf{h}_{t-1}^R), \quad (8)$$
$$\mathbf{i}_t = \sigma(\mathbf{W}_i \mathbf{x}_t + \mathbf{U}_i^L \mathbf{h}_{t-1}^L + \mathbf{U}_i^R \mathbf{h}_{t-1}^R), \quad (9)$$
$$\mathbf{u}_t = \tanh(\mathbf{W}_c \mathbf{x}_t + \mathbf{U}_c^L \mathbf{h}_{t-1}^L + \mathbf{U}_c^R \mathbf{h}_{t-1}^R), \quad (10)$$

where σ is the sigmoid function, $\odot$ is the element-wise multiplication of two vectors, and all $\mathbf{W} \in \mathbb{R}^{d \times l}$, $\mathbf{U} \in \mathbb{R}^{d \times d}$ are weight matrices to be learned.

In the current *input encoding* layer, $\mathbf{x}_t$ is used to encode a word embedding for a leaf node. Since a non-leaf node does not correspond to a specific word, we use a special vector $\mathbf{x}'_t$ as its input, which is like an unknown word. However, in the *inference composition* layer that we discuss later, the goal of using tree-LSTM is very different; the input $\mathbf{x}_t$ will be very different as well—it will encode local inference information and will have values at all tree nodes.

3.2 Local Inference Modeling

Modeling local subsentential inference between a premise and hypothesis is the basic component for determining the overall inference between these two statements. To closely examine local inference, we explore both the sequential and syntactic tree models that have been discussed above. The former helps collect local inference for words and their context, and the tree LSTM helps collect local information between (linguistic) phrases and clauses.

Locality of inference Modeling local inference needs to employ some forms of hard or soft alignment to associate the relevant subcomponents between a premise and a hypothesis. This includes early methods motivated from the alignment in conventional automatic machine translation (MacCartney, 2009). In neural network models, this is often achieved with soft attention.

Parikh et al. (2016) decomposed this process: the word sequence of the premise (or hypothesis) is regarded as a bag-of-word embedding vector and inter-sentence "alignment" (or attention) is computed individually to softly align each word to the content of hypothesis (or premise, respectively). While their basic framework is very effective, achieving one of the previous best results, using a pre-trained word embedding by itself does not automatically consider the context around a word in NLI. Parikh et al. (2016) did take into account the word order and context information through an optional distance-sensitive intra-sentence attention.

In this paper, we argue for leveraging attention over the bidirectional sequential encoding of the input, as discussed above. We will show that this plays an important role in achieving our best results, and the intra-sentence attention used by Parikh et al. (2016) actually does not further improve over our model, while the overall framework they proposed is very effective.

Our soft alignment layer computes the attention weights as the similarity of a hidden state tuple $<\bar{\mathbf{a}}_i, \bar{\mathbf{b}}_j>$ between a premise and a hypothesis with Equation (11). We did study more complicated relationships between $\bar{\mathbf{a}}_i$ and $\bar{\mathbf{b}}_j$ with multilayer perceptrons, but observed no further improvement on the heldout data.

$$e_{ij} = \bar{\mathbf{a}}_i^T \bar{\mathbf{b}}_j. \quad (11)$$

In the formula, $\bar{\mathbf{a}}_i$ and $\bar{\mathbf{b}}_j$ are computed earlier in Equations (1) and (2), or with Equation (3) when tree-LSTM is used. Again, as discussed above, we will use bidirectional LSTM and tree-LSTM to encode the premise and hypothesis, respectively. In our sequential inference model, unlike in Parikh et al. (2016) which proposed to use a function $F(\bar{\mathbf{a}}_i)$, i.e., a feedforward neural network, to map the original word representation for calculating e_{ij}, we instead advocate to use BiLSTM, which encodes the information in premise and hypothesis very well and achieves better performance shown in the experiment section. We tried to apply the $F(.)$ function on our hidden states before computing e_{ij} and it did not further help our models.

Local inference collected over sequences Local inference is determined by the attention weight e_{ij} computed above, which is used to obtain the local relevance between a premise and hypothesis. For the hidden state of a word in a premise, i.e., $\bar{\mathbf{a}}_i$ (already encoding the word itself and its context), the relevant semantics in the hypothesis is identified and composed using e_{ij}, more specifically

with Equation (12).

$$\tilde{\mathbf{a}}_i = \sum_{j=1}^{\ell_b} \frac{\exp(e_{ij})}{\sum_{k=1}^{\ell_b} \exp(e_{ik})} \bar{\mathbf{b}}_j, \forall i \in [1, \ldots, \ell_a], \quad (12)$$

$$\tilde{\mathbf{b}}_j = \sum_{i=1}^{\ell_a} \frac{\exp(e_{ij})}{\sum_{k=1}^{\ell_a} \exp(e_{kj})} \bar{\mathbf{a}}_i, \forall j \in [1, \ldots, \ell_b], \quad (13)$$

where $\tilde{\mathbf{a}}_i$ is a weighted summation of $\{\bar{\mathbf{b}}_j\}_{j=1}^{\ell_b}$. Intuitively, the content in $\{\bar{\mathbf{b}}_j\}_{j=1}^{\ell_b}$ that is relevant to $\bar{\mathbf{a}}_i$ will be selected and represented as $\tilde{\mathbf{a}}_i$. The same is performed for each word in the hypothesis with Equation (13).

Local inference collected over parse trees We use tree models to help collect local inference information over linguistic phrases and clauses in this layer. The tree structures of the premise and hypothesis are produced by a constituency parser.

Once the hidden states of a tree are all computed with Equation (3), we treat all tree nodes equally as we do not have further heuristics to discriminate them, but leave the attention weights to figure out their relationship. So, we use Equation (11) to compute the attention weights for all node pairs between a premise and hypothesis. This connects all words, constituent phrases, and clauses between the premise and hypothesis. We then collect the information between all the pairs with Equations (12) and (13) and feed them into the next layer.

Enhancement of local inference information In our models, we further enhance the local inference information collected. We compute the difference and the element-wise product for the tuple $<\bar{\mathbf{a}}, \tilde{\mathbf{a}}>$ as well as for $<\bar{\mathbf{b}}, \tilde{\mathbf{b}}>$. We expect that such operations could help sharpen local inference information between elements in the tuples and capture inference relationships such as contradiction. The difference and element-wise product are then concatenated with the original vectors, $\bar{\mathbf{a}}$ and $\tilde{\mathbf{a}}$, or $\bar{\mathbf{b}}$ and $\tilde{\mathbf{b}}$, respectively (Mou et al., 2016; Zhang et al., 2017). The enhancement is performed for both the sequential and the tree models.

$$\mathbf{m}_a = [\bar{\mathbf{a}}; \tilde{\mathbf{a}}; \bar{\mathbf{a}} - \tilde{\mathbf{a}}; \bar{\mathbf{a}} \odot \tilde{\mathbf{a}}], \quad (14)$$

$$\mathbf{m}_b = [\bar{\mathbf{b}}; \tilde{\mathbf{b}}; \bar{\mathbf{b}} - \tilde{\mathbf{b}}; \bar{\mathbf{b}} \odot \tilde{\mathbf{b}}]. \quad (15)$$

This process could be regarded as a special case of modeling some high-order interaction between the tuple elements. Along this direction, we have also further modeled the interaction by feeding the tuples into feedforward neural networks and added the top layer hidden states to the above concatenation. We found that it does not further help the inference accuracy on the heldout dataset.

3.3 Inference Composition

To determine the overall inference relationship between a premise and hypothesis, we explore a composition layer to compose the enhanced local inference information $\mathbf{m}_a$ and $\mathbf{m}_b$. We perform the composition sequentially or in its parse context using BiLSTM and tree-LSTM, respectively.

The composition layer In our sequential inference model, we keep using BiLSTM to compose local inference information sequentially. The formulas for BiLSTM are similar to those in Equations (1) and (2) in their forms so we skip the details, but the aim is very different here—they are used to capture local inference information $\mathbf{m}_a$ and $\mathbf{m}_b$ and their context here for inference composition.

In the tree composition, the high-level formulas of how a tree node is updated to compose local inference is as follows:

$$\mathbf{v}_{a,t} = \text{TrLSTM}(F(\mathbf{m}_{a,t}), \mathbf{h}_{t-1}^L, \mathbf{h}_{t-1}^R), \quad (16)$$

$$\mathbf{v}_{b,t} = \text{TrLSTM}(F(\mathbf{m}_{b,t}), \mathbf{h}_{t-1}^L, \mathbf{h}_{t-1}^R). \quad (17)$$

We propose to control model complexity in this layer, since the concatenation we described above to compute $\mathbf{m}_a$ and $\mathbf{m}_b$ can significantly increase the overall parameter size to potentially overfit the models. We propose to use a mapping F as in Equation (16) and (17). More specifically, we use a 1-layer feedforward neural network with the ReLU activation. This function is also applied to BiLSTM in our sequential inference composition.

Pooling Our inference model converts the resulting vectors obtained above to a fixed-length vector with pooling and feeds it to the final classifier to determine the overall inference relationship.

We consider that summation (Parikh et al., 2016) could be sensitive to the sequence length and hence less robust. We instead suggest the following strategy: compute both average and max pooling, and concatenate all these vectors to form the final fixed length vector $\mathbf{v}$. Our experiments show that this leads to significantly better results than summation. The final fixed length vector $\mathbf{v}$ is calculated

as follows:

$$\mathbf{v}_{a,\text{ave}} = \sum_{i=1}^{\ell_a} \frac{\mathbf{v}_{a,i}}{\ell_a}, \quad \mathbf{v}_{a,\max} = \max_{i=1}^{\ell_a} \mathbf{v}_{a,i}, \tag{18}$$

$$\mathbf{v}_{b,\text{ave}} = \sum_{j=1}^{\ell_b} \frac{\mathbf{v}_{b,j}}{\ell_b}, \quad \mathbf{v}_{b,\max} = \max_{j=1}^{\ell_b} \mathbf{v}_{b,j}, \tag{19}$$

$$\mathbf{v} = [\mathbf{v}_{a,\text{ave}}; \mathbf{v}_{a,\max}; \mathbf{v}_{b,\text{ave}}; \mathbf{v}_{b,\max}]. \tag{20}$$

Note that for tree composition, Equation (20) is slightly different from that in sequential composition. Our tree composition will concatenate also the hidden states computed for the roots with Equations (16) and (17), which are not shown here.

We then put $\mathbf{v}$ into a final multilayer perceptron (MLP) classifier. The MLP has a hidden layer with *tanh* activation and *softmax* output layer in our experiments. The entire model (all three components described above) is trained end-to-end. For training, we use multi-class cross-entropy loss.

Overall inference models Our model can be based only on the sequential networks by removing all tree components and we call it Enhanced Sequential Inference Model (**ESIM**) (see the left part of Figure 1). We will show that ESIM outperforms all previous results. We will also encode parse information with tree LSTMs in multiple layers as described (see the right side of Figure 1). We train this model and incorporate it into ESIM by averaging the predicted probabilities to get the final label for a premise-hypothesis pair. We will show that parsing information complements very well with ESIM and further improves the performance, and we call the final model Hybrid Inference Model (**HIM**).

4 Experimental Setup

Data The Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015) focuses on three basic relationships between a premise and a potential hypothesis: the premise entails the hypothesis (*entailment*), they contradict each other (*contradiction*), or they are not related (*neutral*). The original SNLI corpus contains also "*the other*" category, which includes the sentence pairs lacking consensus among multiple human annotators. As in the related work, we remove this category. We used the same split as in Bowman et al. (2015) and other previous work.

The parse trees used in this paper are produced by the Stanford PCFG Parser 3.5.3 (Klein and Manning, 2003) and they are delivered as part of the SNLI corpus. We use classification accuracy as the evaluation metric, as in related work.

Training We use the development set to select models for testing. To help replicate our results, we publish our code[1]. Below, we list our training details. We use the Adam method (Kingma and Ba, 2014) for optimization. The first momentum is set to be 0.9 and the second 0.999. The initial learning rate is 0.0004 and the batch size is 32. All hidden states of LSTMs, tree-LSTMs, and word embeddings have 300 dimensions.

We use dropout with a rate of 0.5, which is applied to all feedforward connections. We use pre-trained *300-D Glove 840B* vectors (Pennington et al., 2014) to initialize our word embeddings. Out-of-vocabulary (OOV) words are initialized randomly with Gaussian samples. All vectors including word embedding are updated during training.

5 Results

Overall performance Table 1 shows the results of different models. The first row is a baseline classifier presented by Bowman et al. (2015) that considers handcrafted features such as BLEU score of the hypothesis with respect to the premise, the overlapped words, and the length difference between them, etc.

The next group of models (2)-(7) are based on sentence encoding. The model of Bowman et al. (2016) encodes the premise and hypothesis with two different LSTMs. The model in Vendrov et al. (2015) uses unsupervised "skip-thoughts" pre-training in GRU encoders. The approach proposed by Mou et al. (2016) considers tree-based CNN to capture sentence-level semantics, while the model of Bowman et al. (2016) introduces a stack-augmented parser-interpreter neural network (SPINN) which combines parsing and interpretation within a single tree-sequence hybrid model. The work by Liu et al. (2016) uses BiLSTM to generate sentence representations, and then replaces average pooling with intra-attention. The approach proposed by Munkhdalai and Yu (2016a) presents a memory augmented neural network, neural semantic encoders (NSE), to encode sentences.

The next group of methods in the table, models

Table 1: Accuracies of the models on SNLI. Our final model achieves the accuracy of 88.6%, the best result observed on SNLI, while our enhanced sequential encoding model attains an accuracy of 88.0%, which also outperform the previous models.

(8)-(15), are inter-sentence attention-based model. The model marked with Rocktäschel et al. (2015) is LSTMs enforcing the so called word-by-word attention. The model of Wang and Jiang (2016) extends this idea to explicitly enforce word-by-word matching between the hypothesis and the premise. Long short-term memory-networks (LSTMN) with deep attention fusion (Cheng et al., 2016) link the current word to previous words stored in memory. Parikh et al. (2016) proposed a decomposable attention model without relying on any word-order information. In general, adding intra-sentence attention yields further improvement, which is not very surprising as it could help align the relevant text spans between premise and hypothesis. The model of Munkhdalai and Yu (2016b) extends the framework of Wang and Jiang (2016) to a full n-ary tree model and achieves further improvement. Sha et al. (2016) proposes a special LSTM variant which considers the attention vector of another sentence as an inner state of LSTM. Paria et al. (2016) use a neural architecture with a complete binary tree-LSTM encoders without syntactic information.

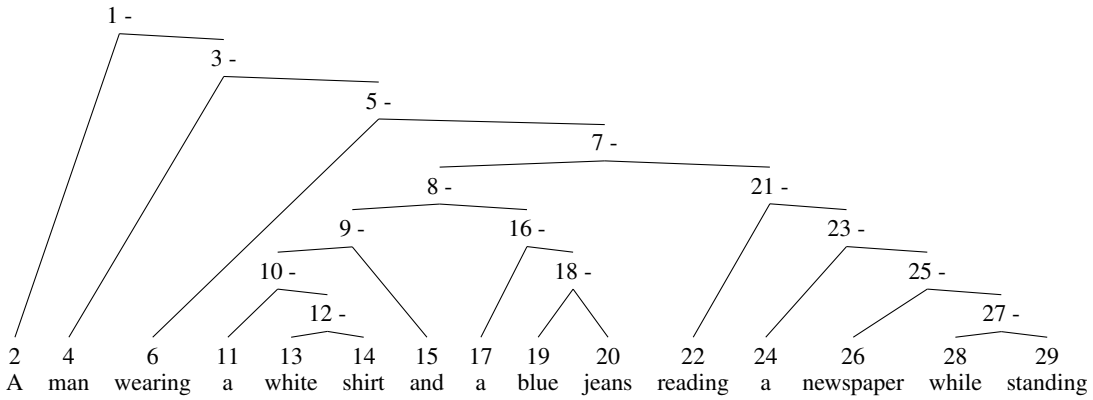
The table shows that our ESIM model achieves an accuracy of 88.0%, which has already outperformed all the previous models, including those using much more complicated network architectures (Munkhdalai and Yu, 2016b).

We ensemble our ESIM model with syntactic tree-LSTMs (Zhu et al., 2015) based on syntactic parse trees and achieve significant improvement over our best sequential encoding model ESIM, attaining an accuracy of 88.6%. This shows that syntactic tree-LSTMs complement well with ESIM.

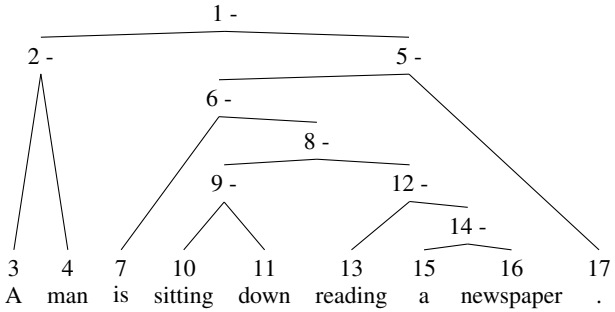
Model	Train	Test
(17) HIM (ESIM + syn.tree)	93.5	88.6
(18) ESIM + tree	91.9	88.2
(16) ESIM	92.6	88.0
(19) ESIM - ave./max	92.9	87.1
(20) ESIM - diff./prod.	91.5	87.0
(21) ESIM - inference BiLSTM	91.3	87.3
(22) ESIM - encoding BiLSTM	88.7	86.3
(23) ESIM - P-based attention	91.6	87.2
(24) ESIM - H-based attention	91.4	86.5
(25) syn.tree	92.9	87.8

Table 2: Ablation performance of the models.

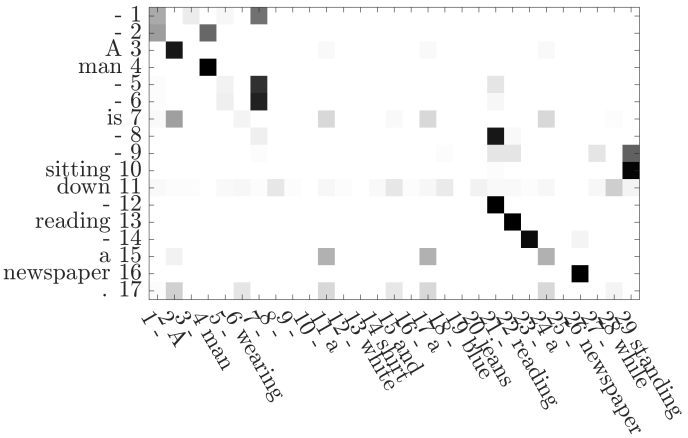
Ablation analysis We further analyze the major components that are of importance to help us achieve good performance. From the best model, we first replace the syntactic tree-LSTM with the full tree-LSTM without encoding syntactic parse information. More specifically, two adjacent words in a sentence are merged to form a parent node, and



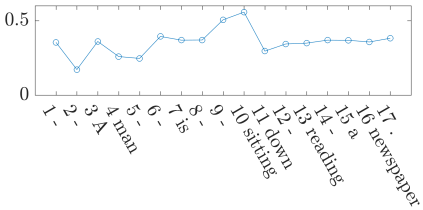
(a) Binarized constituency tree of premise



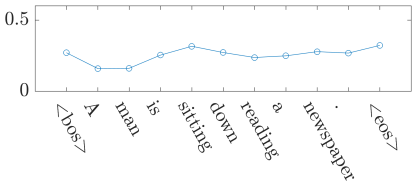
(b) Binarized constituency tree of hypothesis



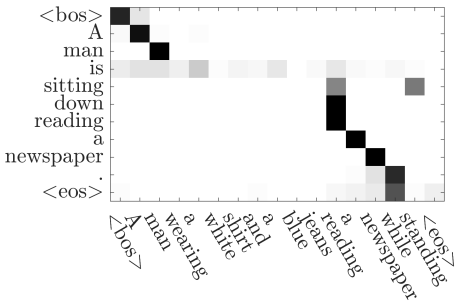
(c) Normalized attention weights of tree-LSTM



(d) Input gate of tree-LSTM in *inference composition* (l^2-norm)



(e) Input gate of BiLSTM in *inference composition* (l^2-norm)



(f) Normalized attention weights of BiLSTM

Figure 3: An example for analysis. Subfigures (a) and (b) are the constituency parse trees of the premise and hypothesis, respectively. "-" means a non-leaf or a null node. Subfigures (c) and (f) are attention visualization of the tree model and ESIM, respectively. The darker the color, the greater the value. The premise is on the x-axis and the hypothesis is on y-axis. Subfigures (d) and (e) are input gates' l^2-norm of tree-LSTM and BiLSTM in *inference composition*, respectively.

this process continues and results in a full binary tree, where padding nodes are inserted when there are no enough leaves to form a full tree. Each tree node is implemented with a tree-LSTM block (Zhu et al., 2015) same as in model (17). Table 2 shows that with this replacement, the performance drops to 88.2%.

Furthermore, we note the importance of the layer performing the enhancement for local inference information in Section 3.2 and the pooling layer in inference composition in Section 3.3. Table 2 suggests that the NLI task seems very sensitive to the

layers. If we remove the pooling layer in inference composition and replace it with summation as in Parikh et al. (2016), the accuracy drops to 87.1%. If we remove the difference and element-wise product from the local inference enhancement layer, the accuracy drops to 87.0%. To provide some detailed comparison with Parikh et al. (2016), replacing bidirectional LSTMs in *inference composition* and also *input encoding* with feedforward neural network reduces the accuracy to 87.3% and 86.3% respectively.

The difference between ESIM and each of the other models listed in Table 2 is statistically significant under the one-tailed paired t-test at the 99% significance level. The difference between model (17) and (18) is also significant at the same level. Note that we cannot perform significance test between our models with the other models listed in Table 1 since we do not have the output of the other models.

If we remove the *premise-based* attention from ESIM (model 23), the accuracy drops to 87.2% on the test set. The *premise-based* attention means when the system reads a word in a premise, it uses soft attention to consider all relevant words in hypothesis. Removing the *hypothesis-based* attention (model 24) decrease the accuracy to 86.5%, where *hypothesis-based* attention is the attention performed on the other direction for the sentence pairs. The results show that removing *hypothesis-based* attention affects the performance of our model more, but removing the attention from the other direction impairs the performance too.

The stand-alone syntactic tree-LSTM model achieves an accuracy of 87.8%, which is comparable to that of ESIM. We also computed the oracle score of merging syntactic tree-LSTM and ESIM, which picks the right answer if either is right. Such an oracle/upper-bound accuracy on test set is 91.7%, which suggests how much tree-LSTM and ESIM could ideally complement each other. As far as the speed is concerned, training tree-LSTM takes about 40 hours on Nvidia-Tesla K40M and ESIM takes about 6 hours, which is easily extended to larger scale of data.

Further analysis We showed that encoding syntactic parsing information helps recognize natural language inference—it additionally improves the strong system. Figure 3 shows an example where tree-LSTM makes a different and correct decision. In subfigure (d), the larger values at the input gates on nodes 9 and 10 indicate that those nodes are important in making the final decision. We observe that in subfigure (c), nodes 9 and 10 are aligned to node 29 in the premise. Such information helps the system decide that this pair is a contradiction. Accordingly, in subfigure (e) of sequential BiLSTM, the words *sitting* and *down* do not play an important role for making the final decision. Subfigure (f) shows that *sitting* is equally aligned with *reading* and *standing* and the alignment for word *down* is not that useful.

6 Conclusions and Future Work

We propose neural network models for natural language inference, which achieve the best results reported on the SNLI benchmark. The results are first achieved through our enhanced sequential inference model, which outperformed the previous models, including those employing more complicated network architectures, suggesting that the potential of sequential inference models have not been fully exploited yet. Based on this, we further show that by explicitly considering recursive architectures in both local inference modeling and inference composition, we achieve additional improvement. Particularly, incorporating syntactic parsing information contributes to our best result: it further improves the performance even when added to the already very strong model.

Future work interesting to us includes exploring the usefulness of external resources such as WordNet and contrasting-meaning embedding (Chen et al., 2015) to help increase the coverage of word-level inference relations. Modeling negation more closely within neural network frameworks (Socher et al., 2013; Zhu et al., 2014) may help contradiction detection.

Abstract

We examine differences in portrayal of characters in movies using psycholinguistic and graph theoretic measures computed directly from screenplays. Differences are examined with respect to characters' gender, race, age and other metadata. Psycholinguistic metrics are extrapolated to dialogues in movies using a linear regression model built on a set of manually annotated seed words. Interesting patterns are revealed about relationships between genders of production team and the gender ratio of characters. Several correlations are noted between gender, race, age of characters and the linguistic metrics.

1 Introduction

Movies are often described as having the power to influence individual beliefs and values. In (Cape, 2003), the authors assert movies' influence in both creating new thinking patterns in previously unexplored social phenomena, especially in children, as well as their ability to update an individual's existing social boundaries based on what is shown on screen as the "norm". Some authors claim the inverse (Wedding and Boyd, 1999): that movies reflect existing cultural values of the society, adding weight to their ability in influencing individual beliefs of what is accepted as the norm. As a result, they are studied in multiple disciplines to analyze their influence.

Movies are particularly scrutinized in aspects involving negative stereotyping (Cape, 2003; Dimnik and Felton, 2006; Ter Bogt et al., 2010; Hedley, 1994) since this may introduce questionable beliefs in viewers. Negative stereotyping is believed to impact society in multiple aspects such as self-induced undermining of ability (Davies et al., 2005) as well as causing forms of prejudice that can impact leadership or employment prospects (Eagly and Karau, 2002; Niven, 2006). Studies in analyzing stereotyping in movies typically rely on collecting manual annotations on a small set of movies on which hypotheses tests are conducted (Behm-Morawitz and Mastro, 2008; Benshoff and Griffin, 2011; Hooks, 2009). In this work, we present large scale automated analyses of movie characters using language used in dialogs to study stereotyping along factors such as gender, race and age.

Language use has been long known as a strong indicator of the speaker's psychological and emotional state (Gottschalk and Gleser, 1969) and is well studied in a number of applications such as automatic personality detection (Mairesse et al., 2007) and psychotherapy (Xiao et al., 2015; Pennebaker et al., 2003). Computational analysis of language has been particularly popular thanks to advancements in computing and the ease of conducting large scale analysis of text on computers (Pennebaker et al., 2015).

To perform our analysis, we construct a new movie screenplay corpus [1] that includes nearly 1000 movie scripts obtained from the Internet. For each movie in the corpus, we obtain additional metadata such as cast, genre, writers and directors, and also collect actor level demographic information such as gender, race and age.

We use two kinds of measures in our analyses: (i) linguistic metrics that capture various psychological constructs and behaviors, estimated using dialogues from the screenplay; and (ii) graph theoretic metrics estimated from character network graphs, which are constructed to model inter-character interactions in the movie. The linguistic metrics include psycholinguistic normatives,

[1] http://sail.usc.edu/mica/text_corpus_release.php

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1669–1678
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1153

which provide word level scores on a numeric scale which are then aggregated at the dialog level, and metrics from the Linguistic Inquiry and Word Counts tool (LIWC) which capture usage of well studied stereotyping dimensions such as sexuality. We estimate centrality metrics from the character network graphs to measure relative importance of the different characters, which are analyzed with respect to the different factors of gender, race and age.

The main contributions of this work are as follows: (i) we present a scalable analysis of differences in portrayal of various character subgroups in movies using their language use, (ii) we construct a new corpus with detailed annotations for our analysis and (iii) we highlight several differences in the portrayal of characters along factors such as race, age and gender.

The rest of the paper is organized as follows: in section 2 we describe related work. We explain the data collection process in section 3 and experimental procedure in section 4. We explain results in section 5 and conclude in section 6.

2 Related work

Previous works in studying representation in movies largely focus on relative frequencies, particularly on character gender. In (Smith et al., 2014), the authors studied 120 movies from around the globe which were manually annotated to capture information about character gender, age, careers, writer gender and director gender. However, since the annotations are done manually, collecting information on new movies is a laborious process. We avoided this by estimating the metadata computationally, enabling us to scale up efficiently.

Automated analyses of movies using computational techniques to analyze representation has recently gained some attention. In (NYFA, 2013; Polygraph, 2016), the authors examine differences in relative frequency of female characters and note considerable disparities in gender ratio in these movies. However, the analyses there too are limited to comparing relative frequencies. Our work is closest to (Ramakrishna et al., 2015) where the authors study difference in language used in movies across genders, but their analysis is one dimensional. In our work we perform fine grained comparisons of character portrayal using multiple language based metrics along factors such as gender, race and age on a newly created corpus.

3 Data

3.1 Raw screenplay

We fetch movie screenplay files from two primary sources: imsdb (IMSDb, 2017) and daily scripts (DailyScript, 2017). In total, we retrieved 1547 movies. After removing duplicates we retain 1434 raw screenplay files, of which 489 were corrupted or empty leaving us with 945 usable screenplays. Tables 1, 3 and 4 list statistics about the corpus.

3.2 Script parser

The screenplay files are formatted in human readable format and include dialogues tagged with character names along with auxiliary information of the scene such as shot location (interior/exterior), character placement and scene context. The screenplays are from a diverse set of writers and include a significant amount of noise and inconsistencies in their structure. To extract the relevant information, we developed a text parser [2] that accepts raw script files and outputs utterances along with character names. We ignore scene context information and primarily focus on spoken dialogues to study language usage in the movies.

3.3 Movie and character meta-data

For each parsed movie, we fetch relevant metadata such as year of release, directors, writers, and producers from the Internet Movie Database (IMDb, 2017).

Since most screenplays are drafts and subject to revisions such as changes in character names, matching them to an entry from IMDb is non-trivial. We first start with a list of all movies that have a close match with the screenplay name; given this list of potential matches we compute name alignment scores for each entry as the percentage of character names from the script found online. The character names are mapped using term frequency-inverse document frequency (TFIDF) to compute the name alignment score following (Cohen et al., 2003). Finally, the entry with highest alignment score is chosen. For all actors listed in the aligned result, we collect their age, gender and race as detailed below.

[2] https://bitbucket.org/anil_ramakrishna/scriptparser

3.3.1 Gender

Given the names of actors and other members of production team found in a movie, we use a name based gender classifier to predict their gender information. Table 4 lists statistics on gender ratios for the production team in the corpus. Female-to-male ratios were found in close agreement with previous works (Smith et al., 2014).

As mentioned above, several screenplays get revised during production. In particular character names get changed, sometimes even gender. As a result, some characters may not be aligned to the correct entry from IMDb. In addition, digitized screenplays sometime include significant noise thanks to optical character recognition errors, leading to character names failing to align with entries from IMDb. To correct these, we perform manual cleanup of all the movie alignments, fix incorrect gender maps, and manually force match movies if they're mapped to the wrong IMDb entry.

3.3.2 Age

We also extract age for each actor to study possible age related biases in movies. We include age in our analysis since studies report preferential biases with age in employment particularly when combined with gender (Lincoln and Allen, 2004). In addition, there may be biases in portrayal of specific age groups when combined with gender and race.

For each actor in the mapped IMDb entry, we collect his/her birthday information. We subtract the movie production year obtained also from IMDb from the actor's birthday to get an estimate of the actor's age during the movie's production. We note however that the age obtained in this manner may be different from the portrayed age of the character. To account for this we bin the actors into fifteen year age groups before our analysis, since its generally unlikely to have actors further than fifteen years from their portrayed age.

3.3.3 Race

We parse ethnicity information from the website (ethnicelebs.com, 2017), which includes ethnicity for approximately 8000 different actors. The information obtained from this site is primarily submitted by independent users, and exhibits significant amount of variation among the possible ethnicities with about 750 different unique ethnicity types. Since we are more specifically interested in racial representations, we map the ethnicity types to race using Amazon Mechanical Turk (MTurk). We use a modified version of the racial categories from the US census which are listed in Table 1 along with frequency of actors from each racial category in our corpus.

Race	*# Actors*	*Percentage*
African	585	7.44%
Caucasian	6539	83.24%
East Asian	73	0.93%
Latino/Hispanic	161	2.05%
Native American	15	0.19%
Pacific Islander	5	0.063%
South Asian	43	0.547%
Mixed	434	5.52%

Table 1: Racial categories

The ethnicities obtained from the site above primarily cover major actors with a fan base with no information for several actors who play minor roles. We annotate racial information for nearly 2000 such actors using MTurk with two annotations for each actor, manually correcting nearly 400 cases in which the annotators disagreed.

4 Experiments

4.1 Character portrayal using language

To study differences in portrayal of characters, we use two different metrics: psycholinguistic normatives, which are designed to capture the underlying emotional state of the speaker; and LIWC metrics, which provide a measure of the speaker's affinity to different social and physical constructs such as religion and death. We explain these two metrics in detail below.

4.1.1 Psycholinguistic normatives

Psycholinguistic normatives provide a measure of various emotional and psychological constructs of the speaker, such as arousal, valence, concreteness, intelligibility, etc. and are computed entirely from language usage. They are relatively easy to compute, provide reliable indicators of the above constructs, and have been used in a variety of tasks in natural language processing such as information retrieval (Tanaka et al., 2013), sentiment analysis (Nielsen, 2011), text based personality prediction (Mairesse et al., 2007) and opinion mining.

The numeric ratings are typically extrapolated from a small set of keywords which are annotated

by psychologists. Manual annotations of word ratings is a laborious process and is hence limited to a few thousand words (Clark and Paivio, 2004). Automatic extrapolation of these ratings to words not covered by the manual annotations can be done using structured databases which provide relationships between words such as synonymy and hyponymy (Liu et al., 2014), or using context based semantic similarity.

In this work, we use the model described in (Malandrakis and Narayanan, 2015) where the authors use linear regression to compute normative scores for an input word w based on its similarity to a set of concept words s_i.

$$r(w) = \theta_0 + \sum_i \theta_i \cdot sim(w, s_i) \qquad (1)$$

where, $r(w)$ is the computed normative score for word w, θ_0 and θ_i are regression coefficients and sim is similarity between the given word w and concept words s_i.

The concept words can either be hand crafted suitably for the domain or chosen automatically from data. Similar to (Malandrakis and Narayanan, 2015), we create training data by posing queries on the Yahoo search engine from words of the aspell spell checker of which top 500 previews are collected from each query. From this corpus, the top 10000 most frequent words with atleast 3 characters were were used as concept words in extrapolation of all the norms. The linear regression model is trained using normative ratings for the manually annotated words by computing their similarity to the concept words. The similarity function sim is the cosine of binary context vectors with window size 1. The computed normatives are in the range $[-1, 1]$.

The psycholinguistic normatives used in this work are listed in Table 2. *Valence* is the degree of positive or negative emotion evoked by the word. *Arousal* is a measure of excitement in the speaker. Valence and arousal combined are common indicators used to map emotions. *Age of Acquisition* refers to the average age at which the word is learned and it denotes sophistication of language use. *Gender Ladenness* is a measure of masculine or feminine association of a word. 10 fold Cross Validation tests are performed on the normative scores predicted by the regression model given by equation 1. Correlation coefficients of the selected normatives with the manual annotations are as follows: Arousal (0.7), Valence (0.88), Age of Acquisition (0.86) and Gender Ladenness (0.8). The high correlations render confidence in the psycholinguistic models.

In our experiments, the normative scores are computed on content words from each dialog. We filter out all words other than nouns, verbs, adjectives and adverbs. Word level scores are aggregated at the dialog level using arithmetic mean.

4.1.2 Linguistic inquiry and word counts (LIWC)

LIWC is a text processing application that processes raw text and outputs percentage of words from the text that belong to linguistic, affective, perceptual and other dimensions. It operates by maintaining a diverse set of dictionaries of words each belonging to a unique dimension. Input texts are processed word by word; each word is searched in the internal dictionaries and the corresponding counter is incremented if a word is found in that dictionary. Finally, percentage of words from the input text belonging to the different dimensions are returned.

For our experiments, we treat each utterance in the movie as a unique document and obtain values for the LIWC metrics. Table 2 lists the metrics used in our experiments.

4.2 Character network analytics

In order to study representation of the different subgroups as major characters in movies, we construct a network of interaction between characters using which we compute importance measures for each character. From each movie script, we construct an undirected and unweighted graph where nodes represent characters. We place an edge e_{ab} if two characters A and B interact at least once in the movie. For our experiments we assume interaction between A and B if there is at least one scene in which one speaks right after another. This graph creation method based on scene co-occurrence is similar to the approach used in (Beveridge and Shan, 2016).

We estimate different measures of a node's importance within the character network and use it as proxy for the character's importance. We employ two types of centralities: *betweenness centrality*, the number of shortest paths that go through the node, and *degree centrality*, which is the number of edges incident on a node. These centrality measurements have been previously used in the con-

5 Results

We study differences in various subgroups along multiple facets. We first report results on differences in character ratios from each subgroup since this has implications on employment and can have social-economic effects (Niven, 2006). We next use psycholinguistic normatives and LIWC metrics described in the previous section to study differences in character portrayal along the primary markers: age, gender and race. We finally use the graph theoretic centrality measures to estimate characters' importance and analyze differences among the different subgroups.

Since we are interested in character level analytics, we treat all utterances from the character as a single document to compute the aggregate language metrics. We perform all our experiments using non-parametric statistical tests since the data fails to satisfy preconditions such as normality and homoscedasticity required for parametric tests such as ANOVA.

5.1 Difference in relative frequency of subgroups

We first filter our characters with unknown gender/race/age leaving us with 6907 characters in total. Table 3 lists the number of characters and dialogues from each gender. As noted in previous studies, the ratio is considerably skewed with male actors having nearly twice as many roles and dialogues compared to female actors. Table 4 lists relative frequency among male and female members of the production team. Table 1 lists the percentage of actors belonging to different racial categories in the corpus.

We perform chi-squared tests between character gender and gender of production team members who are most likely to influence characters gender: writers, directors and casting directors. Table 5 shows contingency tables with gender frequencies for each of these cases along with percentages. Note we filter out nearly 100 movies for this test in which the gender of the production team members was unknown. Of the three tests we perform, character gender distributions for writer and director genders are significantly different from the overall character gender distribution ($p < 10^{-10}$ and $p < 10^{-4}$ respectively; $\alpha = 0.05$). In particular, female writers and directors appear to produce movies with relatively balanced gender proportions (still slightly skewed towards the male side) compared to male writers

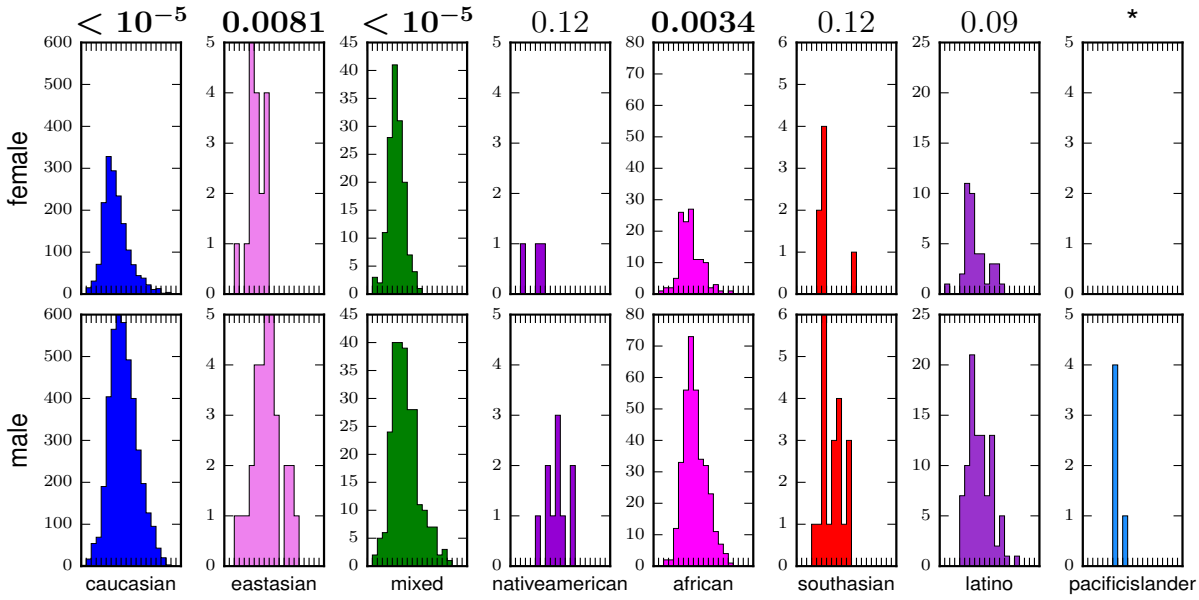

Figure 1: Histogram of age for actors belonging to different gender and racial categories with p-values on top; significant values at $\alpha = 0.05$ are highlighted; *: no test performed since the female group is empty

and directors. Casting directors however appear to have no influence on gender of the characters.

Studies report potential biases in actor employment with age (Lincoln and Allen, 2004), particularly in female actors. To evaluate this, we plot histograms of age for male and female characters for each of the racial categories in Figure 1. The distribution of age for each category appears approximately normal, except for the *nativeamerican* and *pacificislander* character groups which have a small sample size. For most categories of race, the mode of the distribution for female actors appears to be at least five years less than the mode for male actors. To check for significance in this difference we conduct Mann-Whitney U tests on male and female age groups for each race with the resulting p-values shown in the figure. We ignore characters belonging to the *pacificislander* racial group since there are no female actors from this race in our corpus. The difference in age groups is significant in most categories with large sample sizes, suggesting possible preferences towards casting younger people when casting female actors.

5.2 Character portrayal using language

To analyze differences in portrayal of subgroups, we compute psycholinguistic normatives and LIWC metrics as described before. For each of the metrics listed in Table 2, we conduct non-parametric hypothesis tests to look for differences in samples from the subgroups. We treat the different metrics independently, performing statistical tests along each separately. We avoid statistical tests combining two or more factors since some of the resulting groups would be empty due to the skewed group sizes along race. We defer such analyses to future work.

	m (4894)	f (2008)	p
age of acq.	**−0.1590**	**−0.1715**	**$< 10^{-5}$**
arousal	0.0253	0.0246	0.41
gender	**−0.0312**	**−0.0055**	**$< 10^{-5}$**
valence	**0.2284**	**0.2421**	**$< 10^{-5}$**
sex	0.00015	0.0000	0.08
achieve	**0.0087**	**0.0080**	**$< 10^{-5}$**
religion	0.0025	0.0022	0.10
death	**0.0025**	**0.0016**	**$< 10^{-5}$**
swear	**0.0037**	**0.0015**	**$< 10^{-5}$**

Table 6: Median values for male and female characters along with p values obtained by comparing the two groups using Mann-Whitney U test; highlighted differences are significant at $\alpha = 0.05$

5.2.1 Gender

We perform Mann-Whitney U tests between male and female characters along the nine dimensions and the results are shown in Table 6. In all of

the cases, higher values imply higher degree of the corresponding dimension, except for valence in which higher values imply positive valence (attractiveness) and lower values imply negative valence (averseness). The difference between male and female characters are statistically significant along six of the nine dimensions. The results indicate slightly higher age of acquisition scores for male characters. Regarding gender ladenness, male characters appear to be closer to the masculine side than female characters on average, agreeing with previous results.

Our results also indicate that female character utterances tend to be more positive in valence compared to male characters while male characters seem to have higher percentage of words related to achievement. In addition, male characters appear to be more frequent in using words related to death as well as swear words compared to female characters.

5.2.2 Race

To study differences in portrayal of the racial categories, we perform Kruskal-Wallis test (a generalization of Mann-Whitney U test for more than two groups) on each of the nine metrics with race as the independent variable. We found significant differences in distribution of samples for gender ladenness, sexuality, religion and swear words. For gender ladenness, *caucasian* and *mixed* race characters have significantly higher medians than *african* and *nativeamerican* characters. In sexuality, *latino* and *mixed* race characters were found to have higher median than at least one other racial group with significance indicating a higher degree of sexualization in these characters. *Eastasian* characters were found to be significantly lower than medians of three other races (*caucasian*, *african* and *mixed*) in using words with religious connotations. In swear word usage, the only significant difference found is between *caucasian* and *african* characters with *african* characters using higher percentage of swear words. In all of the above cases, significance was tested at $\alpha = 0.05$.

5.2.3 Age

To examine the relationship between age and the different metrics, we build separate linear regression models with each dimension as the dependent variable and character age as the independent variable. Table 7 reports regression coefficients for age along with p values for each dimension. The positive coefficient for age of acquisition indicates an increase in sophistication of word usage with age. Arousal, on the other hand, has a significant negative coefficient indicating a decrease in activation, on average, as character age increases. Gender ladenness also has a significant negative coefficient indicating that as age increases, the average gender ladenness value decreases. Similar trends are observed for sexuality and swear word usage. Usage of words related to achievement and religion however, seem to increase with age.

	$\beta_1(\times 10^{-3})$	*p-value*
age of acq.	**3.9**	$< 10^{-10}$
arousal	**-1.1**	$< 10^{-10}$
gender	**-2.5**	$< 10^{-10}$
valence	0.078	0.7
sex	**-0.25**	$< 10^{-5}$
achieve	**0.26**	$< 10^{-10}$
religion	**0.12**	0.001
death	-0.039	0.2
swear	**-0.34**	$< 10^{-5}$

Table 7: Coefficients of age for linear regression models along each dimension along with p-values; highlighted cells are significant at $\alpha = 0.05$

5.3 Character network analytics

To study differences in major roles assigned to the different subgroups, we compute two centrality metrics from the character network graph constructed for each movie: *degree* centrality measures the number of unique characters that interact with a given character, *betweenness* centrality measures how much would the plot be disrupted if said character was to disappear completely, i.e., how important is a character to the overall plot. Similar to the language analyses from previous section, we test differences in these metrics along the three factors of gender, race and age. All statistical tests reported below are conducted at $\alpha = 0.05$.

5.3.1 Gender

Male characters were found to have higher values in the two metrics compared to female characters but the differences were not statistically significant. Motivated by studies (Sapolsky et al., 2003; Linz et al., 1984) which report interactions between genre and gender, we performed Mann-Whitney U tests between male and female char-

acters given different genres. To avoid type I errors we corrected for multiple comparisons using the Holm-Bonferroni correction. Significant differences were found only in horror movies where the median *degree* centrality for females (0.221) was higher than the median *degree* centrality of males (0.166). This is in agreement with prior studies which report female characters to have a more prominent presence in horror movies, particularly as victims of violent scenes (Welsh and Brantford, 2009).

5.3.2 Race

To examine differences in major roles across the racial categories, we perform Kruskal-Wallis tests similar to previous subsection. Significant differences were found with both *degree* and *betweenness* centrality measures ($p < 0.001$; $\alpha = 0.05$).

Latino characters were found to have significantly lower *degree* centralities compared to *caucasian* and *southasian* races suggesting non-central roles in these characters. *Caucasian* characters were found to have median *betweenness* centralities significantly higher than at least one other race. Characters from the *nativeamerican* race exhibit significantly lower medians in both *degree* and *betweenness* centralities than *caucasian*, *african* and *mixed* characters, which agrees with (Rosenthal, 2012).

5.3.3 Age

We investigate the effects of age on importance of character roles by building a linear regression model on the two centralities with age as the independent variable. In both cases, age was found to be significant ($p < 0.001$; $\alpha = 0.05$). With *degree* centrality, the regression coefficient β was found to be equal to 0.003. In *betweenness* centrality, the regression coefficient was also positive, given by $\beta = 8.41 \times 10^{-4}$. Both these metrics indicate a positive correlation for character importance with age, i.e. as characters age, there is an increased interaction with other characters in the movie as well as higher prominence in the movie plot.

6 Conclusion

We present a scalable automated analyses of differences in character portrayal along multiple factors such as gender, race and age using word usage, psycholinguistic and graph theoretic measures. Several interesting patterns are revealed in the analysis. In particular, movies with female writers and directors in the production team are observed to have balanced gender ratios in characters compared to male writers/directors. Across several races, female actors are found to be younger than male actors on average.

Female characters appear to be more positive in language use with fewer references to death and fewer swear words compared to male characters. Female characters also appear to be more prominent in horror movies compared to male characters. Latino and mixed race characters appear to have higher usage of sexual words. Eastasian characters seem to use significantly fewer religious words. As characters aged, their word sophistication seems to increase along with usage of words related to achievement and religion; there was also a significant reduction in word activation, usage of sexual and swear words as character age increases.

Future work includes expanding the analyses to non-English movies and combining the linguistic metrics with character networks. Specifically, character network edges can be weighted using the psycholinguistic metrics to analyze the emotional patterns in inter-character interactions.

Abstract

This paper deals with sentence-level sentiment classification. Though a variety of neural network models have been proposed recently, however, previous models either depend on expensive phrase-level annotation, most of which has remarkably degraded performance when trained with only sentence-level annotation; or do not fully employ linguistic resources (e.g., sentiment lexicons, negation words, intensity words). In this paper, we propose simple models trained with sentence-level annotation, but also attempt to model the linguistic role of sentiment lexicons, negation words, and intensity words. Results show that our models are able to capture the linguistic role of sentiment words, negation words, and intensity words in sentiment expression.

1 Introduction

Sentiment classification aims to classify text to sentiment classes such as *positive or negative*, or more fine-grained classes such as *very positive, positive, neutral, etc*. There has been a variety of approaches for this purpose such as lexicon-based classification (Turney, 2002; Taboada et al., 2011), and early machine learning based methods (Pang et al., 2002; Pang and Lee, 2005), and recently neural network models such as convolutional neural network (CNN) (Kim, 2014; Kalchbrenner et al., 2014; Lei et al., 2015), recursive autoencoders (Socher et al., 2011, 2013), Long Short-Term Memory (LSTM) (Mikolov, 2012; Chung et al., 2014; Tai et al., 2015; Zhu et al., 2015), and many more.

In spite of the great success of these neural models, there are some defects in previous studies. First, tree-structured models such as recursive autoencoders and Tree-LSTM (Tai et al., 2015; Zhu et al., 2015), depend on parsing tree structures and expensive phrase-level annotation, whose performance drops substantially when only trained with sentence-level annotation. Second, linguistic knowledge such as sentiment lexicon, negation words or *negators* (e.g., *not, never*), and intensity words or *intensifiers* (e.g., *very, absolutely*), has not been fully employed in neural models.

The goal of this research is to developing simple sequence models but also attempts to fully employing linguistic resources to benefit sentiment classification. Firstly, we attempts to develop simple models that do not depend on parsing trees and do not require phrase-level annotation which is too expensive in real-world applications. Secondly, in order to obtain competitive performance, simple models can benefit from linguistic resources. Three types of resources will be addressed in this paper: sentiment lexicon, negation words, and intensity words. Sentiment lexicon offers the prior polarity of a word which can be useful in determining the sentiment polarity of longer texts such as phrases and sentences. Negators are typical sentiment shifters (Zhu et al., 2014), which constantly change the polarity of sentiment expression. Intensifiers change the valence degree of the modified text, which is important for fine-grained sentiment classification.

In order to model the linguistic role of sentiment, negation, and intensity words, our central idea is to regularize the difference between the predicted sentiment distribution of the current position [1], and that of the previous or next positions, in a sequence model. For instance, if the cur-

*Corresponding Author: Minlie Huang

[1]Note that in sequence models, the hidden state of the current position also encodes forward or backward contexts.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1679–1689
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1154

rent position is a negator *not*, the negator should change the sentiment distribution of the next position accordingly. To summarize, our contributions lie in two folds:

- We discover that modeling the linguistic role of sentiment, negation, and intensity words can enhance sentence-level sentiment classification. We address the issue by imposing linguistic-inspired regularizers on sequence LSTM models.

- Unlike previous models that depend on parsing structures and expensive phrase-level annotation, our models are simple and efficient, but the performance is on a par with the state-of-the-art.

The rest of the paper is organized as follows: In the following section, we survey related work. In Section 3, we briefly introduce the background of LSTM and bidirectional LSTM, and then describe in detail the lingistic regularizers for sentiment/negation/intensity words in Section 4. Experiments are presented in Section 5, and Conclusion follows in Section 6.

2 Related Work

2.1 Neural Networks for Sentiment Classification

There are many neural networks proposed for sentiment classification. The most noticeable models may be the recursive autoencoder neural network which builds the representation of a sentence from subphrases recursively (Socher et al., 2011, 2013; Dong et al., 2014; Qian et al., 2015). Such recursive models usually depend on a tree structure of input text, and in order to obtain competitive results, usually require annotation of all subphrases. Sequence models, for instance, convolutional neural network (CNN), do not require tree-structured data, which are widely adopted for sentiment classification (Kim, 2014; Kalchbrenner et al., 2014; Lei et al., 2015). Long short-term memory models are also common for learning sentence-level representation due to its capability of modeling the prefix or suffix context (Hochreiter and Schmidhuber, 1997). LSTM can be commonly applied to sequential data but also tree-structured data (Zhu et al., 2015; Tai et al., 2015).

2.2 Applying Linguistic Knowledge for Sentiment Classification

Linguistic knowledge and sentiment resources, such as sentiment lexicons, negation words (*not, never, neither, etc.*) or *negators*, and intensity words (*very, extremely, etc.*) or *intensifiers*, are useful for sentiment analysis in general.

Sentiment lexicon (Hu and Liu, 2004; Wilson et al., 2005) usually defines prior polarity of a lexical entry, and is valuable for lexicon-based models (Turney, 2002; Taboada et al., 2011), and machine learning approaches (Pang and Lee, 2008). There are recent works for automatic construction of sentiment lexicons from social data (Vo and Zhang, 2016) and for multiple languages (Chen and Skiena, 2014). A noticeable work that ultilizes sentiment lexicons can be seen in (Teng et al., 2016) which treats the sentiment score of a sentence as a weighted sum of prior sentiment scores of negation words and sentiment words, where the weights are learned by a neural network.

Negation words play a critical role in modifying sentiment of textual expressions. Some early negation models adopt the *reversing assumption* that a negator reverses the sign of the sentiment value of the modified text (Polanyi and Zaenen, 2006; Kennedy and Inkpen, 2006). The *shifting hyothesis* assumes that negators change the sentiment values by a constant amount (Taboada et al., 2011; Liu and Seneff, 2009). Since each negator can affect the modified text in different ways, the constant amount can be extended to be negator-specific (Zhu et al., 2014), and further, the effect of negators could also depend on the syntax and semantics of the modified text (Zhu et al., 2014). Other approaches to negation modeling can be seen in (Jia et al., 2009; Wiegand et al., 2010; Benamara et al., 2012; Lapponi et al., 2012).

Sentiment intensity of a phrase indicates the strength of associated sentiment, which is quite important for fine-grained sentiment classification or rating. Intensity words can change the valence degree (i.e., sentiment intensity) of the modified text. In (Wei et al., 2011) the authors propose a linear regression model to predict the valence value for content words. In (Malandrakis et al., 2013), a kernel-based model is proposed to combine semantic information for predicting sentiment score. In the SemEval-2016 task 7 subtask A, a learning-to-rank model with a pair-wise strategy is proposed to predict sentiment intensity scores (Wang

et al., 2016). Linguistic intensity is not limited to sentiment or intensity words, and there are works that assign low/medium/high intensity scales to adjectives such as *okay, good, great* (Sharma et al., 2015) or to gradable terms (e.g. *large, huge, gigantic*) (Shivade et al., 2015).

In (Dong et al., 2015), a sentiment parser is proposed, and the authors studied how sentiment changes when a phrase is modified by negators or intensifiers.

Applying linguistic regularization to text classification can be seen in (Yogatama and Smith, 2014) which introduces three linguistically motivated structured regularizers based on parse trees, topics, and hierarchical word clusters for text categorization. Our work differs in that (Yogatama and Smith, 2014) applies group lasso regularizers to logistic regression on model parameters while our regularizers are applied on intermediate outputs with KL divergence.

3 Long Short-term Memory Network

3.1 Long Short-Term Memory (LSTM)

Long Short-Term Memory has been widely adopted for text processing. Briefly speaking, in LSTM, the hidden states h_t and memory cell c_t is a function of their previous c_{t-1} and h_{t-1} and input vector x_t, or formally as follows:

$$c_t, h_t = g^{(LSTM)}(c_{t-1}, h_{t-1}, x_t) \quad (1)$$

The hidden state $h_t \in R^d$ denotes the representation of position t while also encoding the preceding contexts of the position. For more details about LSTM, we refer readers to (Hochreiter and Schmidhuber, 1997).

3.2 Bidirectional LSTM

In LSTM, the hidden state of each position (h_t) only encodes the prefix context in a forward direction while the backward context is not considered. Bidirectional LSTM (Graves et al., 2013) exploited two parallel passes (forward and backward) and concatenated hidden states of the two LSTMs as the representation of each position. The forward and backward LSTMs are respectively formulated as follows:

$$\overrightarrow{c}_t, \overrightarrow{h}_t = g^{(LSTM)}(\overrightarrow{c}_{t-1}, \overrightarrow{h}_{t-1}, x_t) \quad (2)$$

$$\overleftarrow{c}_t, \overleftarrow{h}_t = g^{(LSTM)}(\overleftarrow{c}_{t+1}, \overleftarrow{h}_{t+1}, x_t) \quad (3)$$

where $g^{(LSTM)}$ is the same as that in Eq (1). Particularly, parameters in the two LSTMs are shared. The representation of the entire sentence is $[\overrightarrow{h}_n, \overleftarrow{h}_1]$, where n is the length of the sentence. At each position t, the new representation is $h_t = [\overrightarrow{h}_t, \overleftarrow{h}_t]$, which is the concatenation of hidden states of the forward LSTM and backward LSTM. In this way, the forward and backward contexts can be considered simultaneously.

4 Linguistically Regularized LSTM

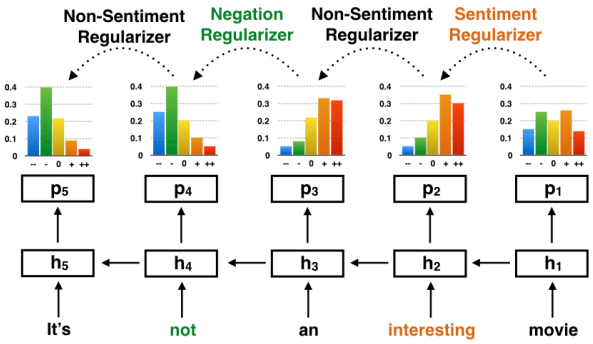

Figure 1: The overview of Linguistically Regularized LSTM. Note that we apply a backward LSTM (from right to left) to encode sentence since most negators and intensifiers are modifying their following words.

The central idea of the paper is to model the linguistic role of sentiment, negation, and intensity words in sentence-level sentiment classification by regularizing the outputs at adjacent positions of a sentence. For example in Fig 1, in sentence "*It's not an interesting movie*", the predicted sentiment distributions at "**an interesting movie*[2]" and "**interesting movie*" should be close to each other, while the predicted sentiment distribution at "**interesting movie*" should be quite different from the preceding positions (in the backward direction) ("**movie*") since a sentiment word ("*interesting*") is seen.

We propose a generic regularizer and three special regularizers based on the following linguistic observations:

- **Non-Sentiment Regularizer**: if the two adjacent positions are all non-opinion words, the sentiment distributions of the two positions should be close to each other. Though

[2]The asterisk denotes the current position.

this is not always true (e.g., *soap movie*), this assumption holds at most cases.

- **Sentiment Regularizer**: if the word is a sentiment word found in a lexicon, the sentiment distribution of the current position should be significantly different from that of the next or previous positions. We approach this phenomenon with a *sentiment class specific shifting distribution*.

- **Negation Regularizer**: Negation words such as "not" and "never" are critical sentiment shifter or converter: in general they shift sentiment polarity from the positive end to the negative end, but sometimes depend on the negation word and the words they modify. The negation regularizer models this linguistic phenomena with a *negator-specific transformation matrix*.

- **Intensity Regularizer**: Intensity words such as "very" and "extremely" change the valence degree of a sentiment expression: for instance, from *positive* to *very positive*. Modeling this effect is quite important for fine-grained sentiment classification, and the intensity regularizer is designed to formulate this effect by a *word-specific transformation matrix*.

More formally, the predicted sentiment distribution (p_t, based on h_t, see Eq. 5) at position t should be linguistically regularized with respect to that of the preceding $(t-1)$ or following $(t+1)$ positions. In order to enforce the model to produce coherent predictions, we plug a new loss term into the original cross entropy loss:

$$\mathcal{L}(\theta) = -\sum_i \hat{y}_i \log y_i + \alpha \sum_i \sum_t L_{t,i} + \beta ||\theta||^2 \quad (4)$$

where $\hat{y}_i$ is the gold distribution for sentence i, y_i is the predicted distribution, $L_{t,i}$ is one of the above regularizers or combination of these regularizers on sentence i, α is the weight for the regularization term, and t is the word position in a sentence.

Note that we do not consider the modification span of negation and intensity words to preserve the simplicity of the proposed models. Negation scope resolution is another complex problem which has been extensively studied (Zou et al., 2013; Packard et al., 2014; Fancellu et al., 2016), which is beyond the scope of this work. Instead, we resort to sequence LSTMs for encoding surrounding contexts at a given position.

4.1 Non-Sentiment Regularizer (NSR)

This regularizer constrains that the sentiment distributions of adjacent positions should not vary much if the additional input word x_t is not a sentiment word, formally as follows:

$$L_t^{(NSR)} = max(0, D_{KL}(p_t||p_{t-1}) - M) \quad (5)$$

where M is a hyperparameter for margin, p_t is the predicted distribution at state of position t, (i.e., h_t), and $D_{KL}(p||q)$ is a symmetric KL divergence defined as follows:

$$D_{KL}(p||q) = \frac{1}{2}\sum_{l=1}^{C} p(l)\log q(l) + q(l)\log p(l) \quad (6)$$

where p, q are distributions over sentiment labels l and C is the number of labels.

4.2 Sentiment Regularizer (SR)

The sentiment regularizer constrains that the sentiment distributions of adjacent positions should drift accordingly if the input word is a sentiment word. Let's revisit the example "*It's not an interesting movie*" again. At position $t = 2$ (in the backward direction) we see a positive word "*interesting*" so the predicted distribution would be more positive than that at position $t = 1$ (*movie*). This is the issue of *sentiment drift*.

In order to address the sentiment drift issue, we propose a polarity shifting distribution $s_c \in R^C$ for each sentiment class defined in a lexicon. For instance, a sentiment lexicon may have class labels like *strong positive*, *weakly positive*, *weakly negative*, and *strong negative*, and for each class, there is a shifting distribution which will be learned by the model. The sentiment regularizer states that if the current word is a sentiment word, the sentiment distribution drift should be observed in comparison to the previous position, in more details:

$$p_{t-1}^{(SR)} = p_{t-1} + s_{c(x_t)} \quad (7)$$

$$L_t^{(SR)} = max(0, D_{KL}(p_t||p_{t-1}^{(SR)}) - M) \quad (8)$$

where $p_{t-1}^{(SR)}$ is the drifted sentiment distribution after considering the shifting sentiment distribution corresponding to the state at position t, $c(x_t)$

is the prior sentiment class of word x_t, and $s_c \in \theta$ is a parameter to be optimized but could also be set fixed with prior knowledge. Note that in this way all words of the same sentiment class share the same drifting distribution, but in a refined setting, we can learn a shifting distribution for each sentiment word if large-scale datasets are available.

4.3 Negation Regularizer (NR)

The negation regularizer approaches how negation words shift the sentiment distribution of the modified text. When the input x_t is a negation word, the sentiment distribution should be shifted/reversed accordingly. However, the negation role is more complex than that by sentiment words, for example, the word *"not"* in *"not good"* and *"not bad"* have different roles in polarity change. The former changes the polarity to *negative*, while the latter changes to *neutral* instead of *positive*.

To respect such complex negation effects, we propose a transformation matrix $T_m \in R^{C \times C}$ for each negation word m, and the matrix will be learned by the model. The regularizer assumes that if the current position is a negation word, the sentiment distribution of the current position should be close to that of the next or previous position with the transformation.

$$p_{t-1}^{(NR)} = softmax(T_{x_j} \times p_{t-1}) \tag{9}$$

$$p_{t+1}^{(NR)} = softmax(T_{x_j} \times p_{t+1}) \tag{10}$$

$$L_t^{(NR)} = min \begin{cases} max(0, D_{KL}(p_t || p_{t-1}^{(NR)}) - M) \\ max(0, D_{KL}(p_t || p_{t+1}^{(NR)}) - M) \end{cases} \tag{11}$$

where $p_{t-1}^{(NR)}$ and $p_{t+1}^{(NR)}$ is the sentiment distuibution after transformation, $T_{x_j} \in \theta$ is the transformation matrix for a negation word x_j, a parameter to be learned during training. In total, we train m transformation matrixs for m negation words. Such negator-specific transformation is in accordance with the finding that each negator has its individual negation effect (Zhu et al., 2014).

4.4 Intensity Regularizer (IR)

Sentiment intensity of a phrase indicates the strength of associated sentiment, which is quite important for fine-grained sentiment classification or rating. Intensifier can change the valence degree of the content word. The intensity regularizer models how intensity words influence the sentiment valence of a phrase or a sentence.

The formulation of the intensity effect is quite the same as that in the negation regularizer, but with different parameters of course. For each intensity word, there is a transform matrix to favor the different roles of various intensifiers on sentiment drift. For brevity, we will not repeat the formulas here.

4.5 Applying Linguistic Regularizers to Bidirectional LSTM

To preserve the simplicity of our proposals, we do not consider the modification span of negation and intensity words, which is a quite challenging problem in the NLP community (Zou et al., 2013; Packard et al., 2014; Fancellu et al., 2016). However, we can alleviate the problem by leveraging bidirectional LSTM.

For a single LSTM, we employ a backward LSTM from the end to the beginning of a sentence. This is because, at most times, the modified words of negation and intensity words are usually at the right side of the modified text. But sometimes, the modified words are at the left side of negation and intensity words. To better address this issue, we employ bidirectional LSTM and let the model determine which side should be chosen.

More formally, in Bi-LSTM, we compute a transformed sentiment distribution on $\overrightarrow{p}_{t-1}$ of the forward LSTM and also that on $\overleftarrow{p}_{t+1}$ of the backward LSTM, and compute the minimum distance of the distribution of the current position to the two distributions. This could be formulated as follows:

$$\overrightarrow{p}_{t-1}^{(R)} = softmax(T_{x_j} \times \overrightarrow{p}_{t-1}) \tag{12}$$

$$\overleftarrow{p}_{t+1}^{(R)} = softmax(T_{x_j} \times \overleftarrow{p}_{t+1}) \tag{13}$$

$$L_t^{(R)} = min \begin{cases} max(0, D_{KL}(\overrightarrow{p}_t || \overrightarrow{p}_{t-1}^{(R)}) - M) \\ max(0, D_{KL}(\overleftarrow{p}_t || \overleftarrow{p}_{t+1}^{(R)}) - M) \end{cases} \tag{14}$$

where $\overrightarrow{p}_{t-1}^{(R)}$ and $\overleftarrow{p}_{t+1}^{(R)}$ are the sentiment distributions transformed from the previous distribution $\overrightarrow{p}_{t-1}$ and next distribution $\overleftarrow{p}_{t+1}$ respectively. Note that $R \in \{NR, IR\}$ indicating the formulation works for both negation and intensity regularizers.

Due to the same consideration, we redefine $L_t^{(NSR)}$ and $L_t^{(SR)}$ with bidirectional LSTM similarly. The formulation is the same and omitted for brevity.

4.6 Discussion

Our models address these linguistic factors with mathematical operations, parameterized with shifting distribution vectors or transformation matrices. In the sentiment regularizer, the sentiment shifting effect is parameterized with a *class-specific* distribution (but could also be word-specific if with more data). In the negation and intensity regularizers, the effect is parameterized with *word-specific* transformation matrices. This is to respect the fact that the mechanism of how negation and intensity words shift sentiment expression is quite complex and highly dependent on individual words. Negation/Intensity effect also depends on the syntax and semantics of the modified text, however, for simplicity we resort to sequence LSTM for encoding surrounding contexts in this paper. We partially address the modification scope issue by applying the minimization operator in Eq. 11 and Eq. 14, and the bidirectional LSTM.

5 Experiment

5.1 Dataset and Sentiment Lexicon

Two datasets are used for evaluating the proposed models: Movie Review (MR) (Pang and Lee, 2005) where each sentence is annotated with two classes as *negative, positive* and Stanford Sentiment Treebank (SST) (Socher et al., 2013) with five classes { *very negative, negative, neutral, positive, very positive*}. Note that SST has provided phrase-level annotation on all inner nodes, but we only use the sentence-level annotation since one of our goals is to avoid expensive phrase-level annotation.

The sentiment lexicon contains two parts. The first part comes from MPQA (Wilson et al., 2005), which contains $5,153$ sentiment words, each with polarity rating. The second part consists of the leaf nodes of the SST dataset (i.e., all sentiment words) and there are $6,886$ polar words except *neural* ones. We combine the two parts and ignore those words that have conflicting sentiment labels, and produce a lexicon of $9,750$ words with 4 sentiment labels. For negation and intensity words, we collect them manually since the number is small, some of which can be seen in Table 2.

Dataset	MR	SST
# sentences in total	10,662	11,885
#sen containing sentiment word	10,446	11,211
#sen containing negation word	1,644	1,832
#sen containing intensity word	2,687	2,472

Table 1: The data statistics.

5.2 The Details of Experiment Setting

In order to let others reproduce our results, we present all the details of our models. We adopt Glove vectors (Pennington et al., 2014) as the initial setting of word embeddings V. The shifting vector for each sentiment class (s_c), and the transformation matrices for negation and intensity (T_m) are initialized with a prior value. The other parameters for hidden layers ($W^{(*)}, U^{(*)}, S$) are initialized with $Uniform(0, 1/sqrt(d))$, where d is the dimension of hidden representation, and we set d=300. We adopt adaGrad to train the models, and the learning rate is 0.1. It's worth noting that, we adopt stochastic gradient descent to update the word embeddings (V), with a learning rate of 0.2 but without momentum.

The optimal setting for α and β is 0.5 and 0.0001 respectively. During training, we adopt the dropout operation before the softmax layer, with a probability of 0.5. Mini-batch is taken to train the models, each batch containing 25 samples. After training with 3,000 mini-batch (about 9 epochs on MR and 10 epochs on SST), we choose the results of the model that performs best on the validation dataset as the final performance.

Negation word	no, nothing, never, neither, not, seldom, scarcely, etc.
Intensity word	terribly, greatly, absolutely, too, very, completely, etc.

Table 2: Examples of negation and intensity words.

5.3 Overall Comparison

We include several baselines, as listed below:

RNN/RNTN: Recursive Neural Network over parsing trees, proposed by (Socher et al., 2011) and Recursive Tensor Neural Network (Socher et al., 2013) employs tensors to model correlations between different dimensions of child nodes' vectors.

LSTM/Bi-LSTM: Long Short-Term Memory

(Cho et al., 2014) and the bidirectional variant as introduced previously.

Tree-LSTM: Tree-Structured Long Short-Term Memory (Tai et al., 2015) introduces memory cells and gates into tree-structured neural network.

CNN: Convolutional Neural Network (Kalchbrenner et al., 2014) generates sentence representation by convolution and pooling operations.

CNN-Tensor: In (Lei et al., 2015), the convolution operation is replaced by tensor product and a dynamic programming is applied to enumerate all skippable trigrams in a sentence. Very strong results are reported.

DAN: Deep Average Network (DAN) (Iyyer et al., 2015) averages all word vectors in a sentence and connects an MLP layer to the output layer.

Neural Context-Sensitive Lexicon: NCSL (Teng et al., 2016) treats the sentiment score of a sentence as a weighted sum of prior scores of words in the sentence where the weights are learned by a neural network.

Method	MR	SST Phrase-level	SST Sent.-level
RNN	77.7*	44.8#	43.2*
RNTN	75.9#	45.7*	43.4#
LSTM	77.4#	46.4*	45.6#
Bi-LSTM	79.3#	49.1*	46.5#
Tree-LSTM	80.7#	51.0*	48.1#
CNN	81.5*	48.0*	46.9#
CNN-Tensor	-	51.2*	50.6*
DAN	-	-	47.7*
NCSL	82.9	51.1*	47.1#
LR-Bi-LSTM	82.1	50.6	48.6
LR-LSTM	81.5	50.2	48.2

Table 3: The accuracy on MR and SST. *Phrase-level* means the models use phrase-level annotation for training. And *Sent.-level* means the models only use sentence-level annotation. Results marked with * are re-printed from the references, while those with # are obtained either by our own implementation or with the same codes shared by the original authors.

Firstly, we evaluate our model on the MR dataset and the results are shown in Table 3. We have the following observations:

First, both LR-LSTM and LR-Bi-LSTM outperforms their counterparts (81.5% vs. 77.4% and 82.1% vs. 79.3%, resp.), demonstrating the effectiveness of the linguistic regularizers. **Second**, LR-LSTM and LR-Bi-LSTM perform slightly better than Tree-LSTM but Tree-LSTM leverages a constituency tree structure while our model is a simple sequence model. As future work, we will apply such regularizers to tree-structured models.

Last, on the MR dataset, our model is comparable to or slightly better than CNN.

For fine-grained sentiment classification, we evaluate our model on the SST dataset which has five sentiment classes { *very negative, negative, neutral, positive, very positive*} so that we can evaluate the sentiment shifting effect of intensity words. The results are shown in Table 3. We have the following observations:

First, linguistically regularized LSTM and Bi-LSTM are better than their counterparts. It's worth noting that LR-Bi-LSTM (trained with just sentence-level annotation) is even comparable to Bi-LSTM trained with phrase-level annotation. That means, LR-Bi-LSTM can avoid the heavy phrase-level annotation but still obtain comparable results.

Second, our models are comparable to Tree-LSTM but our models are not dependent on a parsing tree and more simple, and hence more efficient. Further, for Tree-LSTM, the model is heavily dependent on phrase-level annotation, otherwise the performance drops substantially (from 51% to 48.1%).

Last, on the SST dataset, our model is better than CNN, DAN, and NCSL. We conjecture that the strong performance of CNN-Tensor may be due to the tensor product operation, the enumeration of all skippable trigrams, and the concatenated representations of all pooling layers for final classification.

5.4 The Effect of Different Regularizers

In order to reveal the effect of each individual regularizer, we conduct ablation experiments. Each time, we remove a regularizer and observe how the performance varies. First of all, we conduct this experiment on the entire datasets, and then we experiment on sub-datasets that only contain negation words or intensity words.

The experiment results are shown in Table 4 where we can see that the non-sentiment regularizer (NSR) and sentiment regularizer (SR) play a key role[3], and the negation regularizer and in-

[3]Kindly note that almost all sentences contain sentiment

Method	MR	SST
LR-Bi-LSTM	82.1	48.6
LR-Bi-LSTM (-NSR)	80.8	46.9
LR-Bi-LSTM (-SR)	80.6	46.9
LR-Bi-LSTM (-NR)	81.2	47.6
LR-Bi-LSTM (-IR)	81.7	47.9
LR-LSTM	81.5	48.2
LR-LSTM (-NSR)	80.2	46.4
LR-LSTM (-SR)	80.2	46.6
LR-LSTM (-NR)	80.8	47.4
LR-LSTM (-IR)	81.2	47.4

Table 4: The accuracy for LR-Bi-LSTM and LR-LSTM with regularizer ablation. *NSR*, *SR*, *NR* and *IR* denotes *Non-sentiment Regularizer*, *Sentiment Regularizer*, *Negation Regularizer*, and *Intensity Regularizer* respectively.

tensity regularizer are effective but less important than NSR and SR. This may be due to the fact that only 14% of sentences contains negation words in the test datasets, and 23% contains intensity words, and thus we further evaluate the models on two subsets, as shown in Table 5.

The experiments on the subsets show that: 1) With linguistic regularizers, LR-Bi-LSTM outperforms Bi-LSTM remarkably on these subsets; 2) When the negation regularizer is removed from the model, the performance drops significantly on both MR and SST subsets; 3) Similar observations can be found regarding the intensity regularizer.

Method	Neg. Sub.		Int. Sub.	
	MR	SST	MR	SST
BiLSTM	72.0	39.8	83.2	48.8
LR-Bi-LSTM (-NR)	74.2	41.6	-	-
LR-Bi-LSTM (-IR)	-	-	85.2	50.0
LR-Bi-LSTM	78.5	44.4	87.1	53.2

Table 5: The accuracy on the negation sub-dataset (Neg. Sub.) that only contains negators, and intensity sub-dataset (Int. Sub.) that only contains intensifiers.

5.5 The Effect of the Negation Regularizer

To further reveal the linguistic role of negation words, we compare the predicted sentiment distributions of a phrase pair with and without a negation word. The experimental results performed on MR are shown in Fig. 2. Each dot denotes a phrase pair (for example, <*interesting, not interesting*>), where the x-axis denotes the positive score[4] of a phrase without negators (e.g., *interesting*), and the y-axis indicates the positive score for the phrase with negators (e.g., *not interesting*). The curves in the figures show this function: $[1-y, y] = softmax(T_{nw} * [1-x, x])$ where $[1-x, x]$ is a sentiment distribution on $[negative, positive]$, x is the positive score of the phrase without negators (x-axis) and y that of the phrase with negators (y-axis), and T_{nw} is the transformation matrix for the negation word nw (see Eq. 9). By looking into the

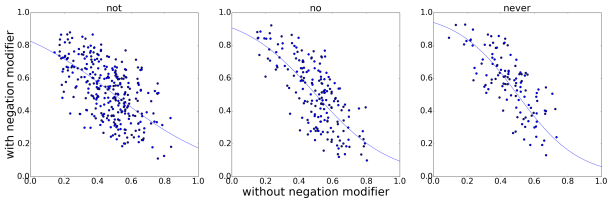

Figure 2: The sentiment shifts with negators. Each dot $< x, y >$ indicates that x is the sentiment score of a phrase without negator and y is that of the phrase with a negator.

detailed results of our model, we have the following statements:

First, there is no dot at the up-right and bottom-left blocks, indicating that negators generally shift/convert very positive or very negative phrases to other polarities. Typical phrases include *not very good, not too bad*.

Second, the dots at the up-left and bottom-right respectively indicates the negation effects: changing negative to positive and positive to negative. Typical phrases include *never seems hopelessly (up-left), no good scenes (bottom-right), not interesting (bottom-right)*, etc. There are also some positive/negative phrases shifting to neutral sentiment such as *not so good*, and *not too bad*.

Last, the dots located at the center indicate that neutral phrases maintain neutral sentiment with negators. Typical phrases include *not at home, not here*, where negators typically modify non-sentiment words.

5.6 The Effect of the Intensity Regularizer

To further reveal the linguistic role of intensity words, we perform experiments on the SST dataset, as illustrated in Figure 3. We show the

words, see Tab. 1.

[4] The score is obtained from the predicted distribution, where 1 means positive and 0 means negative.

matrix that indicates how the sentiment shifts after being modified by intensifiers. Each number in a cell (m_{ij}) indicates how many phrases are predicted with a sentiment label i but the prediction of the phrases with intensifiers changes to label j. For instance, the number 20 (m_{21}) in the second matrix , means that there are 20 phrases predicted with a class of *negative* (-) but the prediction changes to *very negative* (- -) after being modified by intensifier *"very"*. Results in the first

Figure 3: The sentiment shifting with intensifiers. The number in cell(m_{ij}) indicates how many phrases are predicted with sentiment label i but the prediction of phrases with intensifiers changes to label j.

matrix show that, for intensifier "*most*", there are 21/21/13/12 phrases whose sentiment is shifted after being modified by intensifiers, from negative to very negative (*eg. most irresponsible picture*), positive to very positive (*eg. most famous author*), neutral to negative (*eg. most plain*), and neutral to positive (*eg. most closely*), respectively.

There are also many phrases retaining the sentiment after being modified with intensifiers. Not surprisingly, for very positive/negative phrases, phrases modified by intensifiers still maintain the strong sentiment. For the left phrases, they fall into three categories: first, words modified by intensifiers are non-sentiment words, such as *most of us, most part*; second, intensifiers are not strong enough to shift sentiment, such as *most complex* (from neg. to neg.), *most traditional* (from *pos.* to *pos.*); third, our models fail to shift sentiment with intensifiers such as *most vital, most resonant film*.

6 Conclusion and Future Work

We present linguistically regularized LSTMs for sentence-level sentiment classification. The proposed models address the sentient shifting effect of sentiment, negation, and intensity words. Furthermore, our models are sequence LSTMs which do not depend on a parsing tree-structure and do not require expensive phrase-level annotation. Results show that our models are able to address the linguistic role of sentiment, negation, and intensity words.

To preserve the simplicity of the proposed models, we do not consider the modification scope of negation and intensity words, though we partially address this issue by applying a minimization operartor (see Eq. 11, Eq. 14) and bi-directional LSTM. As future work, we plan to apply the linguistic regularizers to tree-LSTM to address the scope issue since the parsing tree is easier to indicate the modification scope explicitly.

Sarcasm SIGN: Interpreting Sarcasm with Sentiment Based Monolingual Machine Translation

Lotem Peled and **Roi Reichart**
Faculty of Industrial Engineering and Management, Technion, IIT
splotem@campus.technion.ac.il, roiri@ie.technion.ac.il

Abstract

Sarcasm is a form of speech in which speakers say the opposite of what they truly mean in order to convey a strong sentiment. In other words, *"Sarcasm is the giant chasm between what I say, and the person who doesn't get it."*. In this paper we present the novel task of sarcasm interpretation, defined as the generation of a non-sarcastic utterance conveying the same message as the original sarcastic one. We introduce a novel dataset of 3000 sarcastic tweets, each interpreted by five human judges. Addressing the task as monolingual machine translation (MT), we experiment with MT algorithms and evaluation measures. We then present SIGN: an MT based sarcasm interpretation algorithm that targets sentiment words, a defining element of textual sarcasm. We show that while the scores of n-gram based automatic measures are similar for all interpretation models, SIGN's interpretations are scored higher by humans for adequacy and sentiment polarity. We conclude with a discussion on future research directions for our new task.[1]

1 Introduction

Sarcasm is a sophisticated form of communication in which speakers convey their message in an indirect way. It is defined in the Merriam-Webster dictionary (Merriam-Webster, 1983) as the use of words that mean the opposite of what one would really want to say in order to insult someone, to show irritation, or to be funny. Considering this definition, it is not surprising to find frequent use of sarcastic language in opinionated user generated content, in environments such as Twitter, Facebook, Reddit and many more.

In textual communication, knowledge about the speaker's intent is necessary in order to fully understand and interpret sarcasm. Consider, for example, the sentence *"what a wonderful day"*. A literal analysis of this sentence demonstrates a positive experience, due to the use of the word *wonderful*. However, if we knew that the sentence was meant sarcastically, *wonderful* would turn into a word of a strong negative sentiment. In spoken language, sarcastic utterances are often accompanied by a certain tone of voice which points out the intent of the speaker, whereas in textual communication, sarcasm is inherently ambiguous, and its identification and interpretation may be challenging even for humans.

In this paper we present the novel task of interpretation of sarcastic utterances. We define the purpose of the interpretation task as the capability to generate a non-sarcastic utterance that captures the meaning behind the original sarcastic text.

Our work currently targets the Twitter domain since it is a medium in which sarcasm is prevalent, and it allows us to focus on the interpretation of tweets marked with the content tag #sarcasm. And so, for example, given the tweet *"how I love Mondays. #sarcasm"* we would like our system to generate interpretations such as *"how I hate Mondays"* or *"I really hate Mondays"*. In order to learn such interpretations, we constructed a parallel corpus of 3000 sarcastic tweets, each of which has five non-sarcastic interpretations (Section 3).

Our task is complex since sarcasm can be expressed in many forms, it is ambiguous in nature and its understanding may require world knowl-

[1] Our dataset, consisting of 3000 sarcastic tweets each augmented with five interpretations, is available in the project page: https://github.com/Lotemp/SarcasmSIGN. The page also contains the sarcasm interpretation guidelines, the code of the SIGN algorithms and other materials related to this project.

Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1155

edge. Following are several examples taken from our corpus:

1. *loving life so much right now. #sarcasm*
2. *Way to go California! #sarcasm*
3. *Great, a choice between two excellent candidates, Donald Trump or Hillary Clinton. #sarcasm*

In example (1) it is quite straightforward to see the exaggerated positive sentiment used in order to convey strong negative feelings. Examples (2) and (3), however, do not contain any excessive sentiment. Instead, previous knowledge is required if one wishes to fully understand and interpret what went wrong with California, or who Hillary Clinton and Donald Trump are.

Since sarcasm is a refined and indirect form of speech, its interpretation may be challenging for certain populations. For example, studies show that children with deafness, autism or Asperger's Syndrome struggle with non literal communication such as sarcastic language (Peterson et al., 2012; Kimhi, 2014). Moreover, since sarcasm transforms the polarity of an apparently positive or negative expression into its opposite, it poses a challenge for automatic systems for opinion mining, sentiment analysis and extractive summarization (Popescu et al., 2005; Pang and Lee, 2008; Wiebe et al., 2004). Extracting the honest meaning behind the sarcasm may alleviate such issues.

In order to design an automatic sarcasm interpretation system, we first rely on previous work in established similar tasks (section 2), particularly machine translation (MT), borrowing algorithms as well as evaluation measures. In section 4 we discuss the automatic evaluation measures we apply in our work and present human based measures for: (a) the *fluency* of a generated non-sarcastic utterance, (b) its *adequacy* as interpretation of the original sarcastic tweet's meaning, and (c) whether or not it captures the sentiment of the original tweet. Then, in section 5, we explore the performance of prominent phrase-based and neural MT systems on our task in development data experiments. We next present the *Sarcasm SIGN* (***S**arcasm **S**entimental **I**nterpretation **GeN**erator*, section 6), our novel MT based algorithm which puts a special emphasis on sentiment words. Lastly, in Section 7 we assess the performance of the various algorithms and show that while they perform similarly in terms of automatic MT evaluation, SIGN is superior according to the human measures. We conclude with a discussion on future research directions for our task, regarding both algorithms and evaluation.

2 Related Work

The use of irony and sarcasm has been well studied in the linguistics (Muecke, 1982; Stingfellow, 1994; Gibbs and Colston, 2007) and the psychology (Shamay-Tsoory et al., 2005; Peterson et al., 2012) literature. In computational work, the interest in sarcasm has dramatically increased over the past few years. This is probably due to factors such as the rapid growth in user generated content on the web, in which sarcasm is used excessively (Maynard et al., 2012; Kaplan and Haenlein, 2011; Bamman and Smith, 2015; Wang, 2013) and the challenge that sarcasm poses for opinion mining and sentiment analysis systems (Pang and Lee, 2008; Maynard and Greenwood, 2014). Despite this rising interest, and despite many works that deal with sarcasm identification (Tsur et al., 2010; Davidov et al., 2010; González-Ibánez et al., 2011; Riloff et al., 2013; Barbieri et al., 2014), to the best of our knowledge, *generation of sarcasm interpretations* has not been previously attempted.

Therefore, the following sections are dedicated to previous work from neighboring NLP fields which are relevant to our work: sarcasm detection, MT, paraphrasing and text summarization.

Sarcasm Detection Recent computational work on sarcasm revolves mainly around detection. Due to the large volume of detection work, we survey only several representative examples.

Tsur et al. (2010) and Davidov et al. (2010) presented a semi-supervised approach for detecting irony and sarcasm in product-reviews and tweets, where features are based on ironic speech patterns extracted from a labeled dataset. González-Ibánez et al. (2011) used lexical and pragmatic features, e.g. emojis and whether the utterance is a comment to another person, in order to train a classifier that distinguishes sarcastic utterances from tweets of positive and negative sentiment.

Riloff et al. (2013) observed that a certain type of sarcasm is characterized by a contrast between a positive sentiment and a negative situation. Consequently, they described a bootstrapping algorithm that learns distinctive phrases connected to negative situations along with a positive sentiment and used these phrases to train their classifier. Barbieri et al. (2014) avoided using word patterns and

instead employed features such as the length and sentiment of the tweet, and the use of rare words.

Despite the differences between detection and interpretation, this line of work is highly relevant to ours in terms of feature design. Moreover, it presents fundamental notions, such as the sentiment polarity of the sarcastic utterance and of its interpretation, that we adopt. Finally, when utterances are not marked for sarcasm as in the Twitter domain, or when these labels are not reliable, detection is a necessary step before interpretation.

Machine Translation We approach our task as one of monolingual MT, where we translate sarcastic English into non-sarcastic English. Therefore, our starting point is the application of MT techniques and evaluation measures. The three major approaches to MT are phrase based (Koehn et al., 2007), syntax based (Koehn et al., 2003) and the recent neural approach. For automatic MT evaluation, often an n-gram co-occurrence based scoring is performed in order to measure the lexical closeness between a candidate and a reference translations. Example measures are NIST (Doddington, 2002), METEOR (Denkowski and Lavie, 2011), and the widely used BLEU (Papineni et al., 2002), which represents *precision*: the fraction of n-grams from the machine generated translation that also appear in the human reference.

Here we employ the phrase based Moses system (Koehn et al., 2007) and an RNN-encoder-decoder architecture, based on Cho et al. (2014). Later we will show that these algorithms can be further improved and will explore the quality of the MT evaluation measures in the context of our task.

Paraphrasing and Summarization Tasks such as paraphrasing and summarization are often addressed as monolingual MT, and so they are close in nature to our task. Quirk et al. (2004) proposed a model of paraphrasing based on monolingual MT, and utilized alignment models used in the Moses translation system (Koehn et al., 2007; Wubben et al., 2010; Bannard and Callison-Burch, 2005). Xu et al. (2015) presented the task of paraphrase generation while targeting a particular writing style, specifically paraphrasing modern English into Shakespearean English, and approached it with phrase based MT.

Work on paraphrasing and summarization is often evaluated using MT evaluation measures such as BLEU. As BLEU is *precision-oriented*, complementary *recall-oriented* measures are often used as well. A prominent example is ROUGE (Lin, 2004), a family of measures used mostly for evaluation in automatic summarization: candidate summaries are scored according to the fraction of n-grams from the human references they contain.

We also utilize PINC (Chen and Dolan, 2011), a measure which rewards paraphrases for being different from their source, by introducing new n-grams. PINC is often combined with BLEU due to their complementary nature: while PINC rewards n-gram novelty, BLEU rewards similarity to the reference. The highest correlation with human judgments is achieved by the product of PINC with a sigmoid function of BLEU (Chen and Dolan, 2011).

3 A Parallel Sarcastic Tweets Corpus

To properly investigate our task, we collected a dataset, first of its kind, of sarcastic tweets and their non-sarcastic (honest) interpretations. This data, as well as the instructions provided for our human judges, will be made publicly available and will hopefully provide a basis for future work regarding sarcasm on Twitter. Despite the focus of the current work on the Twitter domain, we consider our task as a more general one, and hope that our discussion, observations and algorithms will be beneficial for other domains as well.

Using the Twitter API[2], we collected tweets marked with the content tag #sarcasm, posted between Januray and June of 2016. Following Tsur et al. (2010), González-Ibánez et al. (2011) and Bamman and Smith (2015), we address the problem of noisy tweets with automatic filtering: we remove all tweets not written in English, discard retweets (tweets that have been forwarded or shared) and remove tweets containing URLs or images, so that the sarcasm in the tweet regards to the text only and not to an image or a link. This results in 3000 sarcastic tweets containing text only, where the average sarcastic tweet length is 13.87 utterances, the average interpretation length is 12.10 words and the vocabulary size is 8788 unique words.

In order to obtain honest interpretations for our sarcastic tweets, we used Fiverr[3] – a platform for selling and purchasing services from independent suppliers (also referred to as workers). We em-

Sarcastic Tweets	Honest Interpretations
What a great way to end my night. #sarcasm	1. Such a bad ending to my night 2. Oh what a great way to ruin my night 3. What a horrible way to end a night 4. Not a good way to end the night 5. Well that wasn't the night I was hoping for
Staying up till 2:30 was a brilliant idea, very productive #sarcasm	1. Bad idea staying up late, not very productive 2. It was not smart or productive for me to stay up so late 3. Staying up till 2:30 was not a brilliant idea, very non-productive 4. I need to go to bed on time 5. Staying up till 2:30 was completely useless

Table 1: Examples from our parallel sarcastic tweet corpus.

ployed ten Fiverr workers, half of them from the field of comedy writing, and half from the field of literature paraphrasing. The chosen workers were made sure to have an active Twitter account, in order to ensure their acquaintance with social networks and with Twitter's colorful language (hashtags, common acronyms such as LOL, etc.).

We then randomly divided our tweet corpus to two batches of size 1500 each, and randomly assigned five workers to each batch. We instructed the workers to translate each sarcastic tweet into a non sarcastic utterance, while maintaining the original meaning. We encouraged the workers to use external knowledge sources (such as Google) if they came across a subject they were not familiar with, or if the sarcasm was unclear to them.

Although our dataset consists only of tweets that were marked with the hashtag *#sarcasm*, some of these tweets were not identified as sarcastic by all or some of our Fiverr workers. In such cases the workers were instructed to keep the original tweet unchanged (i.e, uninterpreted). We keep such tweets in our dataset since we expect a sarcasm interpretation system to be able to recognize non-sarcastic utterances in its input, and to leave them in their original form.

Table 1 presents two examples from our corpus. The table demonstrates the tendency of the workers to generally agree on the core meaning of the sarcastic tweets. Yet, since sarcasm is inherently vague, it is not surprising that the interpretations differ from one worker to another. For example, some workers change only one or two words from the original sarcastic tweet, while others rephrase the entire utterance. We regard this as beneficial, since it brings a natural, human variance into the task. This variance makes the evaluation of automatic sarcasm interpretation algorithms challenging, as we further discuss in the next section.

4 Evaluation Measures

As mentioned above, in certain cases world knowledge is mandatory in order to correctly evaluate sarcasm interpretations. For example, in the case of the second sarcastic tweet in table 1, we need to know that 2:30 is considered a late hour so that *staying up till 2:30* and *staying up late* would be considered equivalent despite the lexical difference. Furthermore, we notice that transforming a sarcastic utterance into a non sarcastic one often requires to change a small number of words. For example, a single word change in the sarcastic tweet *"How I love Mondays. #sarcasm"* leads to the non-sarcastic utterance *How I hate Mondays*.

This is not typical for MT, where usually the entire source sentence is translated to a new sentence in the target language and we would expect lexical similarity between the machine generated translation and the human reference it is compared to. This raises a doubt as to whether n-gram based MT evaluation measures such as the aforementioned are suitable for our task. We hence asses the quality of an interpretation using *automatic evaluation measures* from the tasks of MT, paraphrasing, and summarization (Section 2), and compare these measures to *human-based measures*.

Automatic Measures We use BLEU and ROUGE as measures of n-gram precision and recall, respectively. We report scores of ROUGE-1, ROUGE-2 and ROUGE-L (recall based on unigrams, bigrams and longest common subsequence between candidate and reference, respectively). In order to asses the n-gram novelty of interpretations (i.e, difference from the source), we report PINC and PINC$*$sigmoid(BLEU) (see Section 2).

Human judgments We employed an additional group of five Fiverr workers and asked them to score each generated interpretations with two scores on a 1-7 scale, 7 being the best. The scores

Sarcastic Tweet	Moses Interpretation	Neural Interpretation
Boy , am I glad the rain's here #sarcasm	Boy, I'm so annoyed that the rain is here	I'm not glad to go today
Another night of work, Oh, the joy #sarcasm	Another night of work, Ugh, unbearable	Another night, I don't like it
Being stuck in an airport is fun #sarcasm	Be stuck in an airport is not fun	Yay, stuck at the office again
You're the best. #sarcasm	You're the best	You're my best friend

Table 2: Sarcasm interpretations generated by Moses and by the RNN.

	Evaluation Measure	Moses	RNN
Precision Oriented	BLEU	62.91	41.05
Novelty Oriented	PINC	51.81	76.45
	PINC∗sigmoid(BLEU)	33.79	45.96
Recall Oriented	ROUGE-1	66.44	42.20
	ROUGE-2	41.03	29.97
	ROUGE-l	65.31	40.87
Human Judgments	Fluency	6.46	5.12
	Adequacy	2.54	2.08
	% correct sentiment	28.84	17.93

Table 3: Development data results for MT models.

are: *adequacy*: the degree to which the interpretation captures the meaning of the original tweet; and *fluency*: how readable the interpretation is. In addition, reasoning that a high quality interpretation is one that captures the true intent of the sarcastic utterance by using words suitable to its sentiment, we ask the workers to assign the interpretation with a binary score indicating whether the sentiment presented in the interpretation agrees with the sentiment of the original sarcastic tweet.[4]

The human measures enjoy high agreement levels between the human judges. The averaged root mean squared error calculated on the test set across all pairs of judges and across the various algorithms we experiment with are: 1.44 for fluency and 1.15 for adequacy. For sentiment scores the averaged agreement at the same setup is 93.2%.

5 Sarcasm Interpretations as MT

As our task is about the generation of one English sentence given another, a natural starting point is treating it as monolingual MT. We hence begin with utilizing two widely used MT systems, representing two different approaches: Phrase Based MT vs. Neural MT. We then analyze the performance of these two systems, and based on our conclusions we design our SIGN model.

Phrase Based MT We employ Moses[5], using word alignments extracted by GIZA++ (Och and Ney, 2003) and symmetrized with the grow-diag-final strategy. We use phrases of up to 8 words to build our phrase table, and do not filter sentences according to length since tweets contain at most 140 characters. We employ the KenLM algorithm (Heafield, 2011) for language modeling, and train it on the non-sarcastic tweet interpretations (the target side of the parallel corpus).

Neural Machine Translation We use GroundHog, a publicly available implementation of an RNN encoder-decoder, with LSTM hidden states.[6] Our encoder and decoder contain 250 hidden units each. We use the minibatch stochastic gradient descent (SGD) algorithm together with Adadelta (Zeiler, 2012) to train each model, where each SGD update is computed using a minibatch of 16 utterances. Following Sutskever et al. (2014), we use beam search for test time decoding. Henceforth we refer to this system as *RNN*.

Performance Analysis We divide our corpus into training, development and test sets of sizes 2400, 300 and 300 respectively. We train Moses and the RNN on the training set and tune their parameters on the development set. Table 3 presents *development data* results, as these are preliminary experiments that aim to asses the compatibility of MT algorithms to our task.

Moses scores much higher in terms of BLEU and ROUGE, meaning that compared to the RNN its interpretations capture more n-grams appearing in the human references while maintaining high precision. The RNN outscores Moses in terms of PINC and PINC∗sigmoid(BLEU), meaning that its interpretations are more novel, in terms of n-grams. This alone might not be a negative trait; However, according to human judgments Moses performs better in terms of fluency, adequacy and sentiment, and so the novelty of the RNN's interpretations does not necessarily contribute to their

[4]For example, we consider *"Best day ever #sarcasm"* and its interpretation "Worst day ever" to agree on the sentiment, despite the use of opposite sentiment words.

[5]http://www.statmt.org/moses

[6]https://github.com/lisa-groundhog/GroundHog

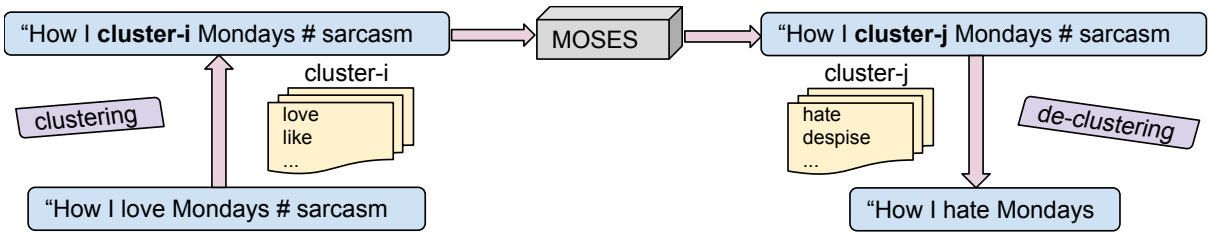

Figure 1: An illustration of the application of SIGN to the tweet *"How I love Mondays # sarcasm"*.

quality, and even possibly reduces it.

Table 2 illustrates several examples of the interpretations generated by both Moses and the RNN. While the interpretations generated by the RNN are readable, they generally do not maintain the meaning of the original tweet. We believe that this is the result of the neural network overfitting the training set, despite regularization and dropout layers, probably due to the relatively small training set size. In light of these results when we experiment with the SIGN algorithm (Section 7), we employ Moses as its MT component.

The final example of Table 2 is representative of cases where both Moses and the RNN fail to capture the sarcastic sense of the tweet, incorrectly interpreting it or leaving it unchanged. In order to deal with such cases, we wish to utilize a property typical of sarcastic language. Sarcasm is mostly used to convey a certain emotion by using strong sentiment words that express the exact opposite of their literal meaning. Hence, many sarcastic utterances can be correctly interpreted by keeping most of their words, replacing only sentiment words with expressions of the opposite sentiment. For example, the sarcasm in the utterance *"You're the best. #sarcasm"* is hidden in *best*, a word of a strong positive sentiment. If we transform this word into a word of the opposite sentiment, such as *worst*, then we get a non-sarcastic utterance with the correct sentiment.

We next present the *Sarcasm SIGN* (***S**arcasm **S**entimental **I**nterpretation **G**e**N**erator*), an algorithm which capitalizes on sentiment words in order to produce accurate interpretations.

6 The Sarcasm SIGN Algorithm

SIGN (Figure 1) targets sentiment words in sarcastic utterances. First, it clusters sentiment words according to semantic relatedness. Then, each sentiment word is replaced with its cluster [7] and the transformed data is fed into an MT system (Moses in this work), at both its training and test phases. Consequently, at test time the MT system outputs non-sarcastic utterances with clusters replacing sentiment words. Finally, SIGN performs a de-clustering process on these MT outputs, replacing sentiment clusters with suitable words.

Positive Clusters	merit, wonder, props, praise, congratulations..	patience, dignity, truth, chivalry, rationality...
Negative Clusters	hideous, horrible, nasty, obnoxious, scary, pathetic...	shame, sadness, sorrow, fear, disappointment, regret, danger...

Table 4: Examples of two positive and two negative clusters created by the SIGN algorithm.

In order to detect the sentiment of words, we turn to SentiWordNet (Esuli and Sebastiani, 2006), a lexical resource based on WordNet (Miller et al., 1990). Using SentiWordNet's positivity and negativity scores, we collect from our training data a set of distinctly positive words ($\sim$ 70) and a set of distinctly negative words ($\sim$ 160).[8] We then utilize the pre-trained dependency-based word embeddings of Levy and Goldberg (2014)[9] and cluster each set using the k-means algorithm with $L2$ distance. We aim to have ten words on average in each cluster, and so the positive set is clustered into 7 clusters, and the negative set into 16 clusters. Table 4 presents examples from our clusters.

Upon receiving a sarcastic tweet, at both training and test, SIGN searches it for sentiment words according to the positive and negative sets. If such

[7] This means that we replace a *word* with *cluster-j* where *j* is the number of the cluster to which the *word* belongs.

[8] The scores are in the [0,1] range. We set the threshold of 0.6 for both distinctly positive and distinctly negative words.

[9] https://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings/. We choose these embeddings since they are believed to better capture the relations between a word and its context, having been trained on dependency-parsed sentences.

	Evaluation Measure	Moses	SIGN-centroid	SIGN-context	SIGN-oracle
Precision Oriented	BLEU	65.24	63.52	**66.96**	67.49
Novelty Oriented	PINC	45.92	**47.11**	46.65	46.10
	PINC∗sigmoid(BLEU)	30.21	30.79	**31.13**	30.54

Table 5: Test data results with automatic evaluation measures.

a word is found, it is replaced with its cluster. For example, given the sentence *"How I love Mondays. #sarcasm"*, *love* will be recognized as a positive sentiment word, and the sarcastic tweet will become: *"How I **cluster-i** Mondays. #sarcasm"* where i is the cluster number of the word *love*.

During training, this process is also applied to the non-sarcastic references. And so, if one such reference is *"I dislike Mondays."*, then *dislike* will be identified and the reference will become *"I **cluster-j** Mondays."*, where j is the cluster number of the word *dislike*. Moses is then trained on these new representations of the corpus, using the exact same setup as before. This training process produces a mapping between positive and negative clusters, and outputs sarcastic interpretations with clustered sentiment words (e.g, *"I **cluster-j** Mondays."*). At test time, after Moses generates an utterance containing clusters, a de-clustering process takes place: the clusters are replaced with the appropriate sentiment words.

We experiment with several de-clustering approaches: **(1) SIGN-centroid:** the chosen sentiment word will be the one closest to the centroid of cluster j. For example in the tweet *"I **cluster-j** Mondays."*, the sentiment word closest to the centroid of cluster j will be chosen; **(2) SIGN-context:** the cluster is replaced with its word that has the highest average Pointwise Mutual Information (PMI) with the words in a symmetric context window of size 3 around the cluster's location in the output. For example, for *"I **cluster-j** Mondays."*, the sentiment word from cluster j which has the highest average PMI with the words in {'I','Mondays'} will be chosen. The PMI values are computed on the training data; and **(3) SIGN-Oracle:** an upper bound where a person manually chooses the most suitable word from the cluster.

We expect this process to improve the quality of sarcasm interpretations in two aspects. First, as mentioned earlier, sarcastic tweets often differ from their non sarcastic interpretations in a small number of sentiment words (sometimes even in a single word). SIGN should help highlight the sentiment words most in need of interpretation. Second, under the pre-processing SIGN performs to the input examples of Moses, the latter is inclined to learn a mapping from positive to negative clusters, and vice versa. This is likely to encourage the Moses output to generate outputs of the same sentiment as the original sarcastic tweet, but with honest sentiment words. For example, if the sarcastic tweet expresses a negative sentiment with strong positive words, the non-sarcastic interpretation will express this negative sentiment with negative words, thus stripping away the sarcasm.

	Fluency	Adequacy	% correct sentiment	% changed
Moses	**6.67**	2.55	25.7	42.3
SIGN-Centroid	6.38	3.23*	42.2*	67.4
SIGN-Context	6.66	**3.61***	**46.2***	**68.5**
SIGN-Oracle	6.69	3.67*	46.8*	68.8

Table 6: Test set results with human measures. *%changed* provides the fraction of tweets that were changed during interpretation (i.e. the tweet and its interpretation are not identical). In cases where one of our models presents significant improvement over Moses, the results are decorated with a star. Statistical significance is tested with the paired t-test for fluency and adequacy, and with the McNemar paired test for labeling disagreements (Gillick and Cox, 1989) for *% correct sentiment*, in both cases with $p < 0.05$.

7 Experiments and Results

We experiment with SIGN and the Moses and RNN baselines at the same setup of section 5. We report test set results for automatic and human measures, in Tables 5 and 6 respectively. As in the development data experiments (Table 3), the RNN presents critically low adequacy scores of 2.11 across the entire test set and of 1.89 in cases where the interpretation and the tweet differ. This, along with its low fluency scores (5.74 and 5.43

respectively) and its very low BLEU and ROUGE scores make us deem this model immature for our task and dataset, hence we exclude it from this section's tables and do not discuss it further.

In terms of automatic evaluation (Table 5), SIGN and Moses do not perform significantly different. When it comes to human evaluation (Table 6) however, SIGN-context presents substantial gains. While for fluency Moses and SIGN-context perform similarly, SIGN-context performs much better in terms of adequacy and the percentage of tweets with the correct sentiment. The differences are substantial as well as statistically significant: adequacy of 3.61 for SIGN-context compared to 2.55 of Moses, and correct sentiment for 46.2% of the SIGN interpretations, compared to only 25.7% of the Moses interpretations.

Table 6 further provides an initial explanation to the improvement of SIGN over Moses: Moses tends to keep interpretations identical to the original sarcastic tweet, altering them in only 42.3% of the cases, [10] while SIGN-context's interpretations differ from the original sarcastic tweet in 68.5% of the cases, which comes closer to the 73.8% in the gold standard human interpretations. If for each of the algorithms we only regard to interpretations that differ from the original sarcastic tweet, the differences between the models are less substantial. Nonetheless, SIGN-context still presents improvement by correctly changing sentiment in 67.5% of the cases compared to 60.8% for Moses.

Both tables consistently show that the context-based selection strategy of SIGN outperforms the centroid alternative. This makes sense as, being context-ignorant, SIGN-centroid might produce non-fluent or inadequate interpretations for a given context. For example, the tweet *"Also gotta move a piano as well. joy #sarcasm"* is changed to *"Also gotta move a piano as well. bummer"* by SIGN-context, while SIGN-centroid changes it to the less appropriate *"Also gotta move a piano as well. boring"*. Nonetheless, even this naive de-clustering approach substantially improves adequacy and sentiment accuracy over Moses.

Finally, comparison to SIGN-oracle reveals that the context selection strategy is not far from human performance with respect to both automatic and human evaluation measures. Still, some gain can be achieved, especially for the human measures on tweets that were changed at interpretation. This indicates that SIGN can improve mostly through a better clustering of sentiment words, rather than through a better selection strategy.

[10] We elaborate on this in section 8.

8 Discussion and Future Work

Automatic vs. Human Measures The performance gap between Moses and SIGN may stem from the difference in their optimization criteria. Moses aims to optimize the BLEU score and given the overall lexical similarity between the original tweets and their interpretations, it therefore tends to keep them identical. SIGN, in contrast, targets sentiment words and changes them frequently. Consequently, we do not observe substantial differences between the algorithms in the automatic measures that are mostly based on n-gram differences between the source and the interpretation. Likewise, the human fluency measure that accounts for the readability of the interpretation is not seriously affected by the translation process. When it comes to the human adequacy and sentiment measures, which account for the understanding of the tweet's meaning, SIGN reveals its power and demonstrates much better performance compared to Moses.

To further understand the relationship between the automatic and the human based measures we computed the Pearson correlations for each pair of (automatic, human) measures. We observe that all correlation values are low (up to 0.12 for fluency, 0.13-0.18 for sentiment and 0.19-0.24 for adequacy). Moreover, for fluency the correlation values are insignificant (using a correlation significance t-test with $p = 0.05$). We believe this indicates that these automatic measures do not provide appropriate evaluation for our task. Designing automatic measures is hence left for future research.

Sarcasm Interpretation as Sentiment Based Monolingual MT: Strengths and Weaknesses The SIGN models' strength is revealed when interpreting sarcastic tweets with strong sentiment words, transforming expressions such as *"Audits are a blast to do #sarcasm"* and *"Being stuck in an airport is fun #sarcasm"* into *"Audits are a bummer to do"* and *"Being stuck in an airport is boring"*, respectively. Even when there are no words of strong sentiment, the MT component of SIGN still performs well, interpreting tweets such as *"the Cavs aren't getting any calls, this is new #sarcasm"* into *"the Cavs aren't getting any calls, as usuall"*.

The SIGN models perform well even in cases where there are several sentiment words but not all of them require change. For example, for the sarcastic tweet *"Constantly being irritated, anxious and depressed is a great feeling! #sarcasm"*, SIGN-context produces the adequate interpretation: *"Constantly being irritated, anxious and depressed is a terrible feeling"*.

Future research directions rise from cases in which the SIGN models left the tweet unchanged. One prominent set of examples consists of tweets that require world knowledge for correct interpretation. Consider the tweet *"Can you imagine if Lebron had help? #sarcasm"*. The model requires knowledge of who Lebron is and what kind of help he needs in order to fully understand and interpret the sarcasm. In practice the SIGN models leave this tweet untouched.

Another set of examples consists of tweets that lack an explicit sentiment word, for example, the tweet *"Clear example they made of Sharapova then, ey? #sarcasm"*. While for a human reader it is apparent that the author means a clear example *was not* made of Sharapova, the lack of strong sentiment words results in all SIGN models leaving this tweet uninterpreted.

Finally, tweets that present sentiment in phrases or slang words are particularly challenging for our approach which relies on the identification and clustering of sentiment words. Consider, for example, the following two cases: (a) the sarcastic tweet *"Can't wait until tomorrow #sarcasm"*, where the positive sentiment is expressed in the phrase *can't wait*; and (b) the sarcastic tweet *"another shooting? yeah we totally need to make guns easier for people to get #sarcasm"*, where the word *totally* receives a strong sentiment despite its normal use in language. While we believe that identifying the role of *can't wait* and of *totally* in the sentiment of the above tweets can be a key to properly interpreting them, our approach that relies on a sentiment word lexicon is challenged by such cases.

Summary We presented a first attempt to approach the problem of sarcasm interpretation. Our major contributions are:

- Construction of a dataset, first of its kind, that consists of 3000 tweets each augmented with five non-sarcastic interpretations generated by human experts.
- Discussion of the proper evaluation in our task. We proposed a battery of human measures and compared their performance to the accepted measures in related fields such as machine translation.
- An algorithmic approach: sentiment based monolingual machine translation. We demonstrated the strength of our approach and pointed on cases that are currently beyond its reach.

Several challenges are still to be addressed in future research so that sarcasm interpretation can be performed in a fully automatic manner. These include the design of appropriate automatic evaluation measures as well as improving the algorithmic approach so that it can take world knowledge into account and deal with cases where the sentiment of the input tweet is not expressed with a clear sentiment words.

We are releasing our dataset with its sarcasm interpretation guidelines, the code of the SIGN algorithms, and the output of the various algorithms considered in this paper (`https://github.com/Lotemp/SarcasmSIGN`). We hope this new resource will help researchers make further progress on this new task.

Abstract

Domain adaptation is an important technology to handle domain dependence problem in sentiment analysis field. Existing methods usually rely on sentiment classifiers trained in source domains. However, their performance may heavily decline if the distributions of sentiment features in source and target domains have significant difference. In this paper, we propose an active sentiment domain adaptation approach to handle this problem. Instead of the source domain sentiment classifiers, our approach adapts the general-purpose sentiment lexicons to target domain with the help of a small number of labeled samples which are selected and annotated in an active learning mode, as well as the domain-specific sentiment similarities among words mined from unlabeled samples of target domain. A unified model is proposed to fuse different types of sentiment information and train sentiment classifier for target domain. Extensive experiments on benchmark datasets show that our approach can train accurate sentiment classifier with less labeled samples.

1 Introduction

Sentiment classification is widely known as a domain-dependent problem (Liu, 2012; Pang and Lee, 2008; Blitzer et al., 2007; Pan et al., 2010). This is because different domains usually have many different sentiment expressions. For example, "lengthy" and "boring" are popularly used in *Book* domain to express negative sentiment. However, they are rare in *Kitchen appliance* domain. Moreover, the same word or phrase may convey different sentiments in different domains. For instance, "unpredictable" is frequently used to express positive sentiment in *Movie* domain (e.g., "The plot of this movie is fun and unpredictable"). However, it tends to be used as a negative word in *Kitchen appliance* domain (e.g., "Even holding heat is unpredictable. It is just terrible!"). Thus, every domain has many domain-specific sentiment expressions, which cannot be captured by other domains. The performance of directly applying a general sentiment classifier or a sentiment classifier trained in other domains to target domain is usually suboptimal.

Since there are a large number of domains in user-generated content, it is impractical to manually annotate enough samples for each domain to train an accurate domain-specific sentiment classifier. Thus, sentiment domain adaptation, which transfers the sentiment classifier trained in a source domain with sufficient labeled data to a target domain with no or scarce labeled data, has been widely studied (Blitzer et al., 2007; Pan et al., 2010; He et al., 2011; Glorot et al., 2011). Existing sentiment domain adaptation methods are mainly based on transfer learning techniques. Many of them try to learn a new feature representation to augment or replace the original feature space in order to reduce the gap of sentiment feature distributions between source and target domains (Pan et al., 2010; Glorot et al., 2011). For example, Blitzer et al. (2007) proposed to learn a latent representation for domain-specific words from both source and target domains by using pivot features as bridge. The advantage of these methods is that no labeled data in target domain is needed. However, when the distributions of sentiment features in source and target domains have significant difference, the performance of domain adaptation will heavily decline (Li et al., 2013). In some cases, the performance of adaptation is even lower than

that without adaptation, which is usually known as *negative transfer* (Pan and Yang, 2010).

In this paper, we propose an active sentiment domain adaptation approach to handle this problem by incorporating both general sentiment information and a small number of actively selected labeled samples from target domain. More specifically, in our approach the general sentiment information extracted from sentiment lexicons is adapted to target domain using domain-specific sentiment similarities among words. The general sentiment information is regarded as a "background" domain to transfer. The word similarities are extracted from unlabeled samples of target domain using both syntactic rules and co-occurrence patterns. Then we actively select and annotate a small number of informative samples from target domain in an active learning manner. These labeled samples are incorporated into our approach to improve the performance of sentiment domain adaptation. A unified model is proposed to incorporate different types of sentiment information to train sentiment classifier for target domain. Extensive experiments were conducted on benchmark datasets. The experimental results show that our approach can train accurate sentiment classifiers and reduce the manual annotation effort.

2 Related Work

2.1 Sentiment Domain Adaptation

Sentiment classification is well known as a highly domain-dependent task, and domain adaptation is widely studied in sentiment analysis field to handle this problem (Blitzer et al., 2007; Pan et al., 2010; He et al., 2011; Glorot et al., 2011). Existing sentiment domain adaptation methods are mainly based on transfer learning technique (Pan and Yang, 2010), where sentiment classifiers are trained in one or multiple source domains with sufficient labeled samples, and then applied to target domain where there is no or only scarce labeled samples. In order to reduce the gap of sentiment feature distributions between source and target domains, many sentiment domain adaptation methods try to learn a new feature representation to augment or replace the original feature space. For example, Pan et al. (2010) proposed a sentiment domain adaptation method based on spectral feature alignment (*SFA*) algorithm. They first manually selected several domain-independent features and computed the associations between domain-specific features and domain-independent features. After that they built a bipartite graph where domain-independent and domain-specific features were regarded as two types of nodes. Then domain-specific features were grouped into several clusters using spectral clustering algorithm. These clusters were used to augment the original feature representations. Glorot et al. (2011) proposed a sentiment domain adaptation method based on a deep learning technique, i.e., Stacked Denoising Autoencoders. They learned the parameters of neural networks using unlabeled samples from both source and target domains, and used the hidden nodes of the neural networks as the latent feature representations of both domains. Then they trained sentiment classifiers using source domain labeled data in this new feature space and applied it to target domain. The advantage of these sentiment domain adaptation methods is that they do not rely on the labeled data in target domain. However, they have a common shortcoming, i.e., when the distributions of sentiment features in source and target domains have significant difference, the performance of domain adaptation will heavily decline (Li et al., 2013). In some cases, *negative transfer* may happen (Blitzer et al., 2007; Li et al., 2013), which means the performance of adaptation is worse than that without adaptation (Pan and Yang, 2010). Different from many existing sentiment domain adaptation methods, in our approach we adapt the general sentiment information in sentiment lexicons to target domain with the help of a small number of labeled samples which are selected and annotated in an active learning mode. Since the sentiment words in general-purpose sentiment lexicons usually convey consistent sentiment polarities in different domains, and the actively selected labeled samples contain rich domain-specific sentiment information of target domain, our approach can effectively reduce the risk of negative transfer.

The usefulness of labeled samples from target domain in sentiment domain adaptation has been observed by previous research works (Choi and Cardie, 2009; Chen et al., 2011; Li et al., 2013; Wu et al., 2016). For example, Choi and Cardie (2009) proposed to adapt a sentiment lexicon to a specific domain by exploiting both the relations among words which co-occur in the same sentiment expressions and the relations between words and labeled sentiment expressions. However, the

labeled samples used in these methods are randomly selected, while in our approach we actively select informative samples from target domain to annotate. Thus, our approach has the potential to reduce the manual annotation effort.

2.2 Active Learning

Active learning is a useful technique in scenarios where unlabeled data is abundant but their labels are difficult or expensive to obtain (Tong and Koller, 2002; Settles, 2010). By actively selecting informative samples to label, active learning can effectively reduce the annotation effort, and improve the classification performance with limited budget (Li et al., 2012). An important problem in active learning is how to evaluate the informativeness of unlabeled samples (Fu et al., 2013). Different methods have been applied to select informative samples, such as uncertainty sampling (Zhu et al., 2010; Yang et al., 2015), query-by-committee (Freund et al., 1997; Li et al., 2013) and so on. In our approach, uncertainty combined with density is used to measure the informativeness of samples. A major difference between our approach and existing active learning methods is that in existing methods the parameters of the initial classifier are either initialized as zero (Cesa-Bianchi et al., 2006) or learned from a set of randomly selected samples (Settles, 2010). In contrast, the initial sentiment classifier in our approach is constructed by adapting the general sentiment information to target domain via the domain-specific sentiment similarities among words.

There are a few works that apply active learning methods to sentiment domain adaptation task (Rai et al., 2010; Li et al., 2013). For example, Rai et al. (2010) proposed an online active learning algorithm for sentiment domain adaptation. They started with a sentiment classifier trained on the labeled samples of a source domain. Then they sequentially selected informative samples in target domain to annotate with a probability positively related to classification uncertainty. The newly annotated samples were used to update the sentiment classifier in an online learning manner. Li et al. (2013) proposed another active learning method for cross-domain sentiment classification. In their method they trained two sentiment classifiers, one on the labeled samples of source domain, and the other one on the labeled samples of target domain. Then query-by-committee strategy was used to select the informative instances from target domain. Different from these methods, our approach does not rely on the labeled data of source domains. Instead, in our approach the general sentiment information in sentiment lexicons is actively adapted to target domain, which usually has better generalization ability in various domains than the sentiment classifier trained in a source domain. In addition, our approach can incorporate the domain-specific sentiment similarities among words mined from unlabeled samples of target domain, which are not considered in these methods.

3 Active Sentiment Domain Adaptation

3.1 Notations

First we introduce several notations that will be used in remaining part of this paper. Denote the general sentiment information extracted from a general-purpose sentiment lexicon as $\mathbf{p} \in \mathbb{R}^{D\times 1}$, where D is the vocabulary size. If the i_{th} word is labeled as positive (or negative) in the sentiment lexicon, then $p_i = +1$ (or $p_i = -1$). Otherwise, $p_i = 0$. Following many previous works in sentiment classification field (Blitzer et al., 2007; Pan et al., 2010), here we select linear classifier as sentiment classifier, and denote the linear classification model as $\mathbf{w} \in \mathbb{R}^{D\times 1}$. We use $f(\mathbf{x}_i, y_i, \mathbf{w})$ to represent the loss of classifying the i_{th} labeled sample in target domain under the classification model $\mathbf{w}$, where f is the classification loss function, $\mathbf{x}_i \in \mathbb{R}^{D\times 1}$ is the feature vector of this sample and y_i is its sentiment label. In this paper we focus on binary sentiment classification and $y_i \in \{+1, -1\}$. In addition, we select log loss for f. Thus, $f(\mathbf{x}_i, y_i, \mathbf{w}) = \log(1 + \exp(-y_i \mathbf{w}^T \mathbf{x}_i))$. Besides, we use $\mathbf{S} \in \mathbb{R}^{D\times D}$ to represent the sentiment similarities among words extracted from unlabeled samples of target domain.

3.2 Domain-Specific Sentiment Similarities

Next we introduce the extraction of domain-specific sentiment similarities among words from unlabeled samples of target domain. Two types of similarities are extracted in this paper. The first one is based on syntactic rules, which is inspired by (Hatzivassiloglou and McKeown, 1997; Huang et al., 2014; Wu and Huang, 2016). If two words have the same POS-tag such as adjective, verb, and adverb, and they are connected by coordinating conjunction "and" in the same sentence, then we regard they convey the same sentiment polarity. In

addition, if two words are connected by adversative conjunction "but" and have the same POS-tag, then they are assumed to have opposite sentiment polarities. Denote $\mathbf{S}^r \in \mathbb{R}^{D\times D}$ as the sentiment similarities extracted from unlabeled samples according to syntactic rules, and the similarity score between words i and j is defined as:

$$S^r_{i,j} = \frac{N^s_{i,j} - N^o_{i,j}}{N^s_{i,j} + N^o_{i,j} + \alpha_1}, \tag{1}$$

where $N^s_{i,j}$ and $N^o_{i,j}$ are the frequencies of words i and j having the same or opposite sentiments respectively according to the syntactic rules, and α_1 is a positive smoothing factor. If two words have much higher frequency of sharing the same sentiment than opposite sentiments, then they will have a larger positive sentiment similarity score. Note that $S^r_{i,j}$ can be negative according to Eq. (1). Here we focus on sentiment similarity rather than dissimilarity, and set all the negative values in $\mathbf{S}^r$ to zero. The range of $S^r_{i,j}$ is $[0, 1]$.

The second type of sentiment similarities are extracted according to the co-occurrence patterns among words. It is inspired by the observation that words frequently co-occurring with each other not only have a high probability to have similar semantics, but also tend to share similar sentiments (Turney, 2002; Velikovich et al., 2010; Yogatama and Smith, 2014; Tang et al., 2015; Hamilton et al., 2016). In this paper, we compute the co-occurrence between words in the context of document. Denote $\mathcal{D}$ as the set of all documents, and N^i_d as the frequency of word i appearing in document d. Then, the sentiment similarity score between words i and j based on their co-occurrence patterns is defined as:

$$S^c_{i,j} = \frac{\sum_{d\in\mathcal{D}} \min\{N^i_d, N^j_d\}}{\sum_{d\in\mathcal{D}} \max\{N^i_d, N^j_d\} + \alpha_2}, \tag{2}$$

where α_2 is a positive smoothing parameter. If two words frequently co-occur with each other in many documents, then they will have a high sentiment similarity score according to Eq. (2). The range of $S^c_{i,j}$ is also $[0, 1]$. Denote $\mathbf{S}^c \in \mathbb{R}^{D\times D}$ as the set of all sentiment similarities extracted according to co-occurrence patterns.

The sentiment similarities extracted according to syntactic rules are usually of high accuracy. However, their coverage is limited, because the word pairs detected by these syntactic rules are sparse. In contrast, the coverage of sentiment similarities extracted from co-occurrence patterns is quite wide because document is a long context, while their accuracies are not as high as the similarities based on syntactic rules. Thus, we propose to combine these two types of sentiment similarities to obtain a balance between accuracy and coverage. Denote $\mathbf{S} \in \mathbb{R}^{D\times D}$ as the final sentiment similarities among words, and $S_{i,j} = \theta S^r_{i,j} + (1-\theta) S^c_{i,j}$, where $\theta \in [0, 1]$ is the combination coefficient. In this paper we set θ to 0.5, which means that we regard these two types of sentiment similarities as equally important.

3.3 Initial Sentiment Classifier Construction

In this section, we introduce the construction of the initial sentiment classifier to start the active learning process. Existing active learning methods usually randomly select a set of unlabeled samples to annotate and then train the initial classifier on them (Settles, 2010). However, these randomly selected samples may be redundant and not informative enough. In this paper, we propose to build the initial sentiment classifier by adapting the general sentiment information to target domain via domain-specific sentiment similarities as follows:

$$\mathbf{w}_0 = \arg\min_{\mathbf{w}} -\sum_{i=1}^{D} p_i w_i + \alpha \sum_{i=1}^{D}\sum_{j\neq i} S_{i,j}(w_i - w_j)^2, \tag{3}$$

where $\mathbf{w}_0 \in \mathbb{R}^{D\times 1}$ is the initial sentiment classifier, α is a positive regularization coefficient, p_i is the prior sentiment polarity of word i in sentiment lexicons, and $S_{i,j}$ is the sentiment similarity score between words i and j. Eq. (3) is motivated by (Bengio et al., 2006), and the quadratic cost criterion is equivalent to label propagation. In Eq. (3), $-\sum_{i=1}^{D} p_i w_i$ means that if a word i is labeled as a positive (or negative) word in a general-purpose sentiment lexicon, i.e., $p_i > 0$ (or $p_i < 0$), then we constrain that its sentiment weight in the sentiment classifier is also positive (or negative). Otherwise, a penalty will be added to the objective function. In addition, $\sum_{i=1}^{D}\sum_{j\neq i} S_{i,j}(w_i - w_j)^2$ represents that if two words share high sentiment similarity, then we constrain they have similar sentiment weights in sentiment classifier. For example, if we find that "great" and "easy" have high sentiment similarities in *Kitchen appliances* domain (e.g., "This is a great pan and easy to wash"), and "great" is a positive sentiment word in many sentiment lexicons, then we can infer that "easy" may also be a positive sentiment word in this domain by propagating the sentiment information from

"great" to "easy". In this way, the general sentiment information can be adapted to many domain-specific sentiment expressions in target domain.

3.4 Query Strategy

Active learning methods iteratively select the most informative instances to label and add them to the training set (Settles, 2010). Thus, an important issue in these methods is how to measure the informativeness of unlabeled samples. In this paper, we select classification uncertainty as the informativeness measure, which has been proven effective in many active learning methods (Zhu et al., 2010; Yang et al., 2015). Since we focus on binary sentiment classification and the classification loss function is log loss, the classification uncertainty of an unlabeled instance $\mathbf{x}$ is defined as:

$$U(\mathbf{x}) = 1 - \left| 1 - \frac{2}{1 + \exp(-\mathbf{w}^T \mathbf{x})} \right|, \tag{4}$$

where $\mathbf{w}$ is the linear sentiment classification model. The range of $U(\mathbf{x})$ is $[0, 1]$. If $|\mathbf{w}^T \mathbf{x}|$ is large, which means that current sentiment classifier is confident in classifying this instance, then the uncertainty of $\mathbf{x}$ (i.e., $U(\mathbf{x})$) will be low. If $|\mathbf{w}^T \mathbf{x}|$ is close to 0, then the sentiment classifier is very uncertain about this instance, probably because the sentiment expressions in this instance are not covered by current sentiment classifier, and the uncertainty of the instance $\mathbf{x}$ will be high. In this case, annotating this instance and adding it to the training set are beneficial, because it can provide the information of unknown sentiment expressions and has the potential to quickly improve the quality of target domain sentiment classifier.

However, many researchers have found that unlabeled instances with high uncertainties can be outliers, whose labels are useless and even misleading (Settles, 2010; Zhu et al., 2010). Thus, here we combine uncertainty with representativeness to avoid outliers. Density is proven to be an effective measure of representativeness in active learning methods (Zhu et al., 2010; Hajmohammadi et al., 2015). Here we use the k-nearest neighbour based density proposed by Zhu et al. (2010) as the representativeness measure, which is formulated as:

$$D(\mathbf{x}) = \frac{1}{k} \sum_{\mathbf{x}_i \in \mathcal{N}(\mathbf{x})} \frac{\mathbf{x}^T \mathbf{x}_i}{\|\mathbf{x}\|_2 \cdot \|\mathbf{x}_i\|_2}, \tag{5}$$

where $\mathcal{N}(\mathbf{x})$ is the set of k most similar instances of $\mathbf{x}$. The final informativeness score of an unlabeled sample is a linear combination of uncertainty and density which is formulated as follows:

$$I(\mathbf{x}) = \eta(t) U(\mathbf{x}) + (1 - \eta(t)) D(\mathbf{x}), \tag{6}$$

where $\eta(t) \in [0, 1]$ is the combination coefficient at the t_{th} iteration. In this paper, we select a monotonically increasing function for $\eta(t)$, i.e., $\eta(t) = \frac{1}{1+\exp(2-\frac{4t}{T})}$, where T is the total number of iterations. It means that at initial iterations we put more emphasis on instances with high representativeness, because the initial sentiment classifier built by adapting the general sentiment information via the domain-specific sentiment similarities is relatively weak, and we prefer to select instances with more popular sentiment expressions to annotate. As more and more labeled samples are added to the training set and the sentiment classifier becomes stronger, we gradually focus on more difficult instances, i.e., those having higher classification uncertainty scores.

3.5 Active Domain Adaptation

Based on previous discussions, in this section we introduce the complete procedure of our active sentiment domain adaptation (*ASDA*) approach. Different from existing sentiment domain adaptation methods which rely on the sentiment classifier trained in source domains to transfer, in our approach we regard the general sentiment information in sentiment lexicons as the "background" domain and adapt it to target domain with the help of a small number of labeled samples which are selected and annotated in an active learning mode. First, we build an initial sentiment classifier according to Eq. (3) by adapting the general sentiment information to target domain using the domain-specific sentiment similarities among words mined from unlabeled samples of target domain. Second, we compute the density of each unlabeled sample in $\mathcal{U}$ according to Eq. (5). Then we repeat following steps until the annotation budget has run out. First, we compute the uncertainty of each unlabeled sample in $\mathcal{U}$ according to Eq. (4), and further we compute their informativeness by combining uncertainty with density according to Eq. (6). Next, we select the unlabeled sample with the highest informativeness from $\mathcal{U}$ and manually annotate its sentiment polarity. Then we add it to the set of labeled samples $\mathcal{L}$ and remove it from $\mathcal{U}$. After that we retrain the sentiment classifier for target domain based on the general sentiment information $\mathbf{p}$, the labeled samples $\mathcal{L}$, and the domain-

specific sentiment similarities $\mathbf{S}$ as follows:

$$\arg\min_{\mathbf{w}} -\sum_{i=1}^{D} p_i w_i + \alpha \sum_{i=1}^{D} \sum_{j \neq i} S_{i,j}(w_i - w_j)^2 + \beta \sum_{\mathbf{x}_i \in \mathcal{L}} \log(1 + \exp(-y_i \mathbf{w}^T \mathbf{x}_i)) + \lambda \|\mathbf{w}\|_2^2, \quad (7)$$

where α, β, and λ are nonnegative coefficients. By the term $-\sum_{i=1}^{D} p_i w_i$ we constrain that the target domain sentiment classifier learned by our approach is consistent with the general sentiment information. Through this way, the general sentiment information extracted from sentiment lexicons can be adapted to target domain. The term $\sum_{i=1}^{D} \sum_{j \neq i} S_{i,j}(w_i - w_j)^2$ is motivated by label propagation (Bengio et al., 2006). If two words tend to have high sentiment similarity with each other according to many unlabeled samples of target domain, then we constrain that their sentiment weights in the target domain sentiment classifier are also similar. The term $\sum_{\mathbf{x}_i \in \mathcal{L}} \log(1 + \exp(-y_i \mathbf{w}^T \mathbf{x}_i))$ means that we hope to minimize the empirical classification loss on labeled samples of target domain. By this term the sentiment information in the labeled samples is incorporated into the learning of target domain sentiment classifier. The L_2-norm regularization term is introduced to control model complexity. The sentiment classifier trained in Eq. (7) is further used at the next iteration of active sentiment domain adaptation until all the budget of manual annotation has been used. Then we obtain the final sentiment classifier of target domain. The complete algorithm of our active sentiment domain adaptation (*ASDA*) approach is summarized in Algorithm 1.

Algorithm 1 Active sentiment domain adaptation.

1: **Input:** The set of unlabeled samples $\mathcal{U}$, the general sentiment information $\mathbf{p}$, the domain-specific sentiment similarities $\mathbf{S}$, and the total annotation budget N.
2: **Output:** Target domain sentiment classifier $\mathbf{w}$.
3: Train the initial sentiment classifier $\mathbf{w}_0$ (Eq. (3)).
4: Compute the density of each sample $\mathbf{x}_i$ in $\mathcal{U}$ (Eq. (5)).
5: Initialize the set of labeled samples $\mathcal{L} = \emptyset$, the iteration number $t = 0$, and the sentiment classifier $\mathbf{w} = \mathbf{w}_0$.
6: **while** $t < N$ **do**
7: $t = t + 1$.
8: Compute the uncertainty score of each sample $\mathbf{x}_i$ in $\mathcal{U}$ (Eq. (4)).
9: Compute the informativeness score of each sample $\mathbf{x}_i$ in $\mathcal{U}$ (Eq. (6)).
10: Select $\mathbf{x}^*$ from $\mathcal{U}$ which has the highest informativeness score.
11: Annotate $\mathbf{x}^*$ and obtain its sentiment label y.
12: $\mathcal{L} = \mathcal{L} + \{\mathbf{x}^*, y\}$, $\mathcal{U} = \mathcal{U} - \mathbf{x}^*$.
13: Update sentiment classifier $\mathbf{w}$ according to Eq. (7).
14: **end while**

4 Experiments

4.1 Datasets

The dataset used in our experiments is the Amazon product review dataset[1] collected by Blitzer et al. (2007), which is widely used in sentiment analysis and domain adaptation research (Pan et al., 2010; Bollegala et al., 2011). This dataset contains product reviews in four domains, i.e., *Book*, *DVD*, *Electronics*, and *Kitchen appliances*. In each domain, 1,000 positive and 1,000 negative reviews as well as a large number of unlabeled samples are included. The detailed statistics of this dataset are summarized in Table 1.

	Book	*DVD*	*Electronics*	*Kitchen*
positive	1,000	1,000	1,000	1,000
negative	1,000	1,000	1,000	1,000
unlabeled	973,194	122,438	21,009	17,856

Table 1: The statistics of the Amazon dataset.

Following many previous works (Blitzer et al., 2007; Bollegala et al., 2011), unigrams and bigrams were used to build feature vectors in our experiments. We randomly split the labeled samples in each domain into two parts with equal size. The first part was used as test data, and the second part was used as the pool of "unlabeled" samples to perform active learning. The general sentiment information was extracted from Bing Liu's sentiment lexicon[2] (Hu and Liu, 2004), which is one of the state-of-the-art general-purpose sentiment lexicons. The domain-specific sentiment similarities among words were extracted from the large-scale unlabeled samples. The total number of samples actively selected by our approach to annotate was set to 100. The values of α, β, and λ were set to 0.1, 1, and 1 respectively. We repeated each experiment 10 times independently and the average results were reported.

4.2 Algorithm Effectiveness

First we conducted several experiments to explore the effectiveness of our active sentiment domain adaptation (*ASDA*) approach. We hope to answer two questions via these experiments: 1) whether the domain-specific sentiment similarities among words mined from unlabeled samples of target

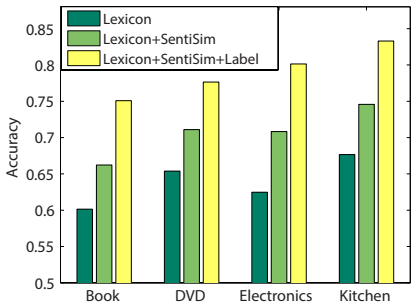

Figure 1: The performance of our approach with different combinations of sentiment information. *Lexicon*, *SentiSim*, and *Label* represent the general-purpose sentiment lexicon, the domain-specific sentiment similarities among words, and a small number of actively selected and annotated samples in target domain respectively.

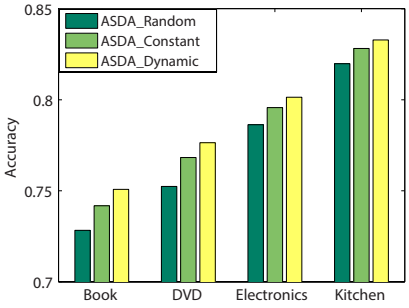

Figure 2: The performance of our approach with labeled samples selected by different strategies.

domain are useful for adapting the general sentiment information to target domain; 2) whether a small number of samples which are actively selected and annotated in target domain can help improve the domain adaptation performance. In our experiments, we implemented different versions of our *ASDA* approach using different combinations of sentiment information. The first one is *Lexicon*, which means only using the general sentiment information and no domain adaptation is conducted. It serves as a baseline. The second one is *Lexicon+SentiSim*, which means adapting general sentiment information to target domain using domain-specific sentiment similarities, but labeled samples of target domain are not incorporated. The third one is *Lexicon+SentiSim+Label*, which is the complete *ASDA* approach. The experimental results are summarized in Fig. 1.

According to Fig. 1, the performance of *Lexicon* is suboptimal. This is because the general sentiment lexicons cannot capture the domain-specific sentiment expressions in target domain (Choi and Cardie, 2009). *Lexicon+SentiSim* performs significantly better than *Lexicon*, which validates that the sentiment similarities among words extracted from unlabeled samples of target domain contain rich domain-specific sentiment information, and can help propagate the general sentiment information to many domain-specific sentiment expressions. Besides, after incorporating a small number of labeled samples which are actively selected and annotated by our approach in an active learning mode, the performance of our sentiment domain adaptation approach is significantly improved. This is because although these labeled samples are in limited size and cannot cover all the sentiment expressions in target domain, they can provide sentiment information of popular domain-specific sentiment expressions, which can be propagated to other sentiment expressions in target domain during the domain adaptation process. Thus, above experimental results validate the effectiveness of our approach.

We also conducted several experiments to verify the advantage of the actively selected samples over randomly selected samples and validate the effectiveness of our active learning algorithm. We also compared the dynamic weighting scheme for combining uncertainty and density with the constant weighting scheme. The experimental results are summarized in Fig. 2. According to Fig. 2, our approach with actively selected samples performs better than that with randomly selected samples. It indicates that these actively selected samples are more informative than randomly selected samples for sentiment domain adaptation. In addition, our approach with dynamic weighting scheme in combining uncertainty and density outperforms that with constant weighting scheme, which implies that it is beneficial to emphasize representative samples at initial iterations and gradually focus on difficult samples at later iterations. Thus, the experimental results validate the effectiveness of our active learning algorithm.

4.3 Performance Evaluation

In this section we conducted experiments to evaluate the performance of our approach by comparing it with several baseline methods. The methods to be compared include: 1) *MPQA* and *BingLiu*, using two state-of-the-art sentiment lexicons,

i.e., MPQA (Wilson et al., 2005) and Bing Liu's lexicon (Hu and Liu, 2004) for sentiment classification following the suggestions in (Hu and Liu, 2004); 2) *SVM*, *LS*, and *LR*, three popular supervised sentiment classification methods, i.e., support vector machine (Pang et al., 2002), least squares (Hu et al., 2013) and logistic regression (Wu et al., 2015); 3) *ZIAL*, the zero initialized active learning method (Cesa-Bianchi et al., 2006); 4) *LIAL*, the active learning method initialized by randomly selected labeled data (Settles, 2010); 5) *SCL* and *SFA*, two famous sentiment domain adaptation methods proposed in (Blitzer et al., 2007) and (Pan et al., 2010) respectively; 6) *ILP*, adapting sentiment lexicons to target domain via integer linear programming (Choi and Cardie, 2009); 7) *AODA*, the active online domain adaptation method (Rai et al., 2010); 8) *ALCD*, the active learning method for cross-domain sentiment classification (Li et al., 2013); 9) *ASDA*, our active sentiment domain adaptation approach. For above methods, if labeled target domain samples are needed in training, the number of labeled samples was set to 100, and if source domain labeled samples are needed in training, the number of labeled samples was set to 1,000. The parameters in baseline methods were tuned via cross-validation. The experimental results are summarized in Table 2.

	Book		*DVD*		*Electronics*		*Kitchen*

Table 2: Sentiment classification performance of different methods in different domains. *Acc* and *Fscore* represent accuracy and macro-averaged Fscore respectively.

According to Table 2, the performance of directly applying sentiment lexicons to target domain is suboptimal. This is because there are many domain-specific sentiment expressions that are not covered by these general-purpose sentiment lexicons (Choi and Cardie, 2009). In addition, the performance of supervised sentiment classification methods such as *SVM*, *LS*, and *LR* is also

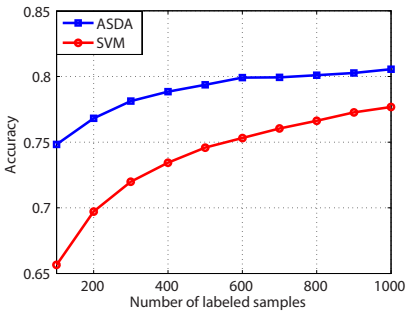

Figure 3: The performance of *ASDA* and *SVM* with different numbers of labeled samples.

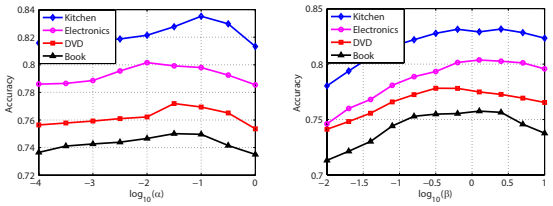
limited, because the labeled samples for training are extremely scarce. The active learning methods such as *ZIAL* (Cesa-Bianchi et al., 2006) and *LIAL* (Settles, 2010) perform relatively better, because they can actively select informative samples to annotate and learn. Our approach can outperform both of them. This is because besides the labeled samples, our approach also adapts the general sentiment information in sentiment lexicons to target domain and incorporates it into the learning of target domain sentiment classifier. Our approach also performs better than state-of-the-art domain adaptation methods such as *SCL* (Blitzer et al., 2007) and *SFA* (Pan et al., 2010). It implies that a small number of actively selected labeled samples from target domain are beneficial for sentiment domain adaptation. *ILP* (Choi and Cardie, 2009) tries to adapt a sentiment lexicon to target domain, which is similar with our approach. *ILP* relies on labeled samples to extract the relations among words and relations between words and sentiment expressions. However, labeled samples in target domain are usually limited and the sentiment information in many unlabeled samples is not exploited in *ILP*. Thus, our approach can outperform it. Similar with our approach, *AODA* (Rai et al., 2010) and *ALCD* (Li et al., 2013) also apply active learning to domain adaptation. The major difference is that in our approach the general sentiment information extracted from sentiment lexicons is adapted to target domain, while in *AODA* and *ALCD* the sentiment classifier trained in source domains is transferred. The superior performance of our approach implies that the general sentiment information has better generalization ability than the sentiment classifier trained in a specific source domain, and is more suitable for sentiment domain adaptation.



(a) Parameter α. (b) Parameter β.

Figure 4: The influence of the parameter settings of α and β on the performance of our approach.

We further conducted several experiments to validate the advantage of our approach in training accurate sentiment classifier for target domain with only a few labeled samples. We varied the annotation budget, i.e., the number of labeled samples, from 100 to 1,000. The learning curve of our *ASDA* approach in *Book* domain is shown in Fig. 3. We also included a purely supervised sentiment classification method, i.e., *SVM*, in Fig. 3 as a baseline for comparison. Fig. 3 shows that our *ASDA* approach can consistently outperform *SVM* when the same number of labeled samples are used. The performance advantage of our approach is more significant when labeled samples are scarce. For example, the performance of our approach with only 200 labeled samples is similar to *SVM* with more than 800 labeled samples. Thus, the experimental results validate that by adapting the general sentiment information to target domain and selecting the most informative samples to annotate and learn, our approach can effectively reduce the manual annotation effort, and can train accurate sentiment classifier for target domain with much less labeled samples.

4.4 Parameter Analysis

In this section, we conducted several experiments to explore the influence of parameter settings on the performance of our approach. α and β are the two most important parameters in our approach, which control the relative importance of domain-specific sentiment similarities and the actively selected samples in training sentiment classifier for target domain. The experimental results of parameters α and β are summarized in Fig. 4.

According to Fig. 4, when α and β are too small, the performance of our approach is not optimal. This is because the useful sentiment information in domain-specific sentiment similarities mined from unlabeled samples and the actively selected labeled samples of target domain is not fully exploited. Thus, the performance of our approach improves when these parameters increase from a small value. However, when these parameters become too large, the performance of our approach starts to decline. This is because when β is too large the sentiment classifier learned by our approach is mainly decided by the limited labeled samples, and the general sentiment information extracted from sentiment lexicons is not fully exploited. When α is too large, the information in domain-specific sentiment similarities is over-emphasized, and many different words will have nearly the same sentiment weights. Thus, the performance of our approach in these scenarios is also not optimal. A moderate value of α and β is most suitable for our approach.

5 Conclusion

In this paper we present an active sentiment domain adaptation approach to train accurate sentiment classifier for target domain with less labeled samples. In our approach, the general sentiment information in sentiment lexicons is adapted to target domain with the help of a small number of labeled samples which are selected and annotated in an active learning mode. Both classification uncertainty and density are considered when selecting informative samples to label. In addition, we extract domain-specific sentiment similarities among words from unlabeled samples of target domain based on both syntactic rules and co-occurrence patterns, and incorporate them into the domain adaptation process to propagate the general sentiment information to many domain-specific sentiment words in target domain. We also propose a unified model to incorporate different types of sentiment information to train sentiment classifier for target domain. Experimental results on benchmark datasets show that our approach can train accurate sentiment classifier and at same time reduce the manual annotation effort.

Abstract

Volatility prediction—an essential concept in financial markets—has recently been addressed using sentiment analysis methods. We investigate the sentiment of annual disclosures of companies in stock markets to forecast volatility. We specifically explore the use of recent Information Retrieval (IR) term weighting models that are effectively extended by related terms using word embeddings. In parallel to textual information, factual market data have been widely used as the mainstream approach to forecast market risk. We therefore study different fusion methods to combine text and market data resources. Our word embedding-based approach significantly outperforms state-of-the-art methods. In addition, we investigate the characteristics of the reports of the companies in different financial sectors.

1 Introduction

Financial volatility is an essential indicator of instability and risk of a company, sector or economy. Volatility forecasting has gained considerable attention during the last three decades. In addition to using historic stock prices, new methods in this domain use sentiment analysis to exploit various text resources, such as financial reports (Kogan et al., 2009; Wang et al., 2013; Tsai and Wang, 2014; Nopp and Hanbury, 2015), news (Kazemian et al., 2014; Ding et al., 2015), message boards (Nguyen and Shirai, 2015), and earning calls (Wang and Hua, 2014).

An interesting resource of textual information are the companies' annual disclosures, known as *10-K filing* reports. They contain comprehensive information about the companies' business as well as risk factors. Specifically, section *Item 1A - Risk Factors* of the reports contains information about the most significant risks for the company. These reports are however long, redundant, and written in a style that makes them complex to process. Dyer et al. (2016) notes that: *"10-K reports are getting more redundant and complex* [...] *(it) requires a reader to have 21.6 years of formal education to fully comprehend"*. Dyer et al. also analyse the topics discussed in the reports and observe a constant increase over the years in both the length of the documents as well as the number of topics. They claim that the increase in length is not the result of economic factors but is due to verboseness and redundancy in the reports. They suggest that only the risk factors topic appears to be useful and informative to investors. Their analysis motivates us to study the effectiveness of the Risk Factors section for volatility prediction.

Our research builds on previous studies on volatility prediction and information analysis of 10-K reports using sentiment analysis (Kogan et al., 2009; Tsai and Wang, 2014; Wang et al., 2013; Nopp and Hanbury, 2015; Li, 2010; Campbell et al., 2014), in the sense that since the reports are long (average length of 5000 words), different approaches are required, compared with studies of sentiment analysis on short-texts. Such previous studies on 10-K reports have mostly used the data before 2008 and there is little work on the analysis of the informativeness and effectiveness of the recent reports with regards to volatility prediction. We will indeed show that the content of the reports changes significantly not only before and after 2008, but rather in a cycle of 3-4 years.

In terms of use of the textual content for volatility prediction, this paper shows that state-of-the-art Information Retrieval (IR) term weighting models, which benefit from word embedding information, have a significantly positive impact on prediction accuracy. The most recent study on the topic (Tsai and Wang, 2014) used related terms obtained by word embeddings to expand the

Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1157

lexicon of sentiment terms. In contrast, similar to Rekabsaz et al. (2016b), we define the weight of each lexicon term by extending it to the similar terms in the document. The significant improvement of this approach for document retrieval by capturing the importance of the terms motivates us to apply it on sentiment analysis. We extensively evaluate various state-of-the-art sentiment analysis methods to investigate the effectiveness of our approach.

In addition to text, factual market data (i.e. historical prices) provide valuable resources for volatility prediction e.g. in the framework of GARCH models (Engle, 1982). An emerging question is how to approach the combination of the textual and factual market information. We propose various methods for this issue and show the performance and characteristics of each.

The financial system covers a wide variety of industries, from daily-consumption products to space mission technologies. It is intuitive to consider that the factors of instability and uncertainty are different between the various sectors while similar inside them. We therefore also analyse the sentiment of the reports of each sector separately and study their particular characteristics.

The present study shows the value of information in the 10-K reports for volatility prediction. Our proposed approach to sentiment analysis significantly outperforms state-of-the-art methods (Kogan et al., 2009; Tsai and Wang, 2014; Wang et al., 2013). We also show that performance can be further improved by effectively combining textual and factual market information. In addition, we shed light on the effects of tailoring the analysis to each sector: despite the reasonable expectation that domain-specific training would lead to improvements, we show that our general model generalizes well and outperforms sector-specific trained models.

The remainder of the paper is organized as follows: in the next section, we review the state-of-the-art and related studies. Section 3 formulates the problem, followed by a detailed explanation of our approach in Section 4. We explain the dataset and settings of the experiments in Section 5, followed by the full description of the experiments in Section 6. We conclude the work in Section 7.

2 Related Work

Market prediction has been attracting much attention in recent years in the natural language processing community. Kazemian et al. (2014) use sentiment analysis for predicting stock price movements in a simulated security trading system using news data, showing the advantages of the method against simple trading strategies. Ding et al. (2015) address a similar objective while using deep learning to extract and learn events in the news. Xie et al. (2013) introduce a semantic tree-based model to represent news data for predicting stock price movement. Luss et al. (2015) also exploit news in combination with return prices to predict intra-day price movements. They use the Multi Kernel Learning (MKL) algorithm for combining the two features. The combination shows improvement in final prediction in comparison to using each of the features alone. Motivated by this study, we investigate the performance of the MKL algorithm as one of the methods to combine the textual with non-textual information. Other data resources, such as stocks' message boards, are used by Nguyen and Shirai (2015) to study topic modelling for aspect-based sentiment analysis. Wang and Hua (2014) investigate the sentiment of the transcript of earning calls for volatility prediction using the Gaussian Copula regression model.

While the mentioned studies use short-length texts (sentence or paragraph level), approaching long texts (document level) for market prediction is mainly based on n-gram bag of words methods. Nopp and Hanbury (2015) study the sentiment of banks' annual reports to assess banking systems risk factors using a finance-specific lexicon, provided by Loughran and McDonald (2011), in both unsupervised and supervised manner.

More directly related to the informativeness of the 10-K reports for volatility prediction, Kogan et al. (2009) use a linear Support Vector Machine (SVM) algorithm on the reports published between 1996–2006. Wang et al. (2013) improve upon this by using the Loughran and McDonald (2011) lexicon, observing improvement in the prediction. Later, Tsai and Wang (2014) apply the same method as Wang et al. (2013) while additionally using word embedding to expand the financial lexicon. We reproduce all the methods in these studies, and show the advantage of our sentiment analysis approach.

3 Problem Formulation

In this section, we formulate the volatility forecasting problem and the prediction objectives of our experiments. Similar to previous studies (Christiansen et al., 2012; Kogan et al., 2009; Tsai and Wang, 2014), volatility is defined as the natural log of the standard deviation of (adjusted) return prices in a window of τ days. This definition is referred to as standard volatility (Li and Hong, 2011) or realized volatility (Liu and Tse, 2013), defined as follows:

$$v_{[s,s+\tau]} = ln\left(\sqrt{\frac{\sum_{t=s}^{s+\tau}(r_t - \bar{r})^2}{\tau}}\right) \quad (1)$$

where r_t is the return price and $\bar{r}$ the mean of return prices. The return price is calculated by $r_t = ln(P_t) - ln(P_{t-1})$, where P_t is the (adjusted) closing price of a given stock at the trading date t.

Given an arbitrary report i, we define a prediction label y_i^k as the volatility of the stock of the reporting company in the kth quarter-sized window starting from the issue date of the report s_i:

$$y_i^k = v_{[s_i+64(k-1),s_i+64k]} \quad (2)$$

Every quarter is considered as per convention, 64 working days, while the full year is assumed to have 256 working days.

We use 8 learners for labels y^1 to y^8. For brevity, unless otherwise mentioned, we report the volatility of the first year by calculating the mean of the first four quartiles after the publication of each report.

4 Methodology

We first describe our text sentiment analysis methods, followed by the features obtained from factual market data, and finally explain the methods to combine textual and market feature sets.

4.1 Sentiment Analysis

Similar to previous studies (Nopp and Hanbury, 2015; Wang et al., 2013), we extract the keyword set from a finance-specific lexicon (Loughran and McDonald, 2011) using the positive, negative, and uncertain groups, stemmed using the Porter stemmer. We refer to this keyword set as `Lex`. Tsai and Wang (2014) expanded this set by adding the top 20 related terms to each term to the original set. The related terms are obtained using the Word2Vec (Mikolov et al., 2013) model, built on the corpus of all the reports, with Cosine similarity. We also use this expanded set in our experiments and refer to it as `LexExt`.

The following word weighting schemes are commonly used in Information Retrieval and we consider them as well in our study:

$\mathbf{TC}: \quad log(1 + tc_{d_i}(t))$

$\mathbf{TF}: \quad \frac{log(1+tc_{d_i}(t))}{\|d_i\|}$

$\mathbf{TFIDF}: \quad \frac{log(1+tc_{d_i}(t))}{\|d_i\|} log(1 + \frac{|d_i|}{df(t)})$

$\mathbf{BM25}: \frac{(k+1)\overline{tf_{d_i}(t)}}{k+\overline{tf_{d_i}(t)}}, \quad \overline{tf_{d_i}(t)} = \frac{tc_{d_i}(t)}{(1-b)+b\frac{|d_i|}{avgdl}}$

where $tc_{d_i}(t)$ is the number of occurrences of keyword t in report i, $\|d_i\|$ denotes the Euclidean norm of the keyword weights of the report, $|d_i|$ is the length of the report (number of the words in the report), $avgdl$ is the average document length, and finally k and b are parameters. For them, we use the settings used in previous studies (Rekabsaz et al., 2016b) i.e. $k = 1.2$ and $b = 0.65$.

In addition to the standard weighting schemes, we use state-of-the-art weighting methods in Information Retrieval (Rekabsaz et al., 2016b) which benefit directly from word embedding models: They exploit similarity values between words provided by the word embedding model into the weighting schemes by extending the weight of each lexicon keyword with its similar words:

$$\widehat{tc_{d_i}}(t) = tc_{d_i}(t) + \sum_{t' \in R(t)} sim(t,t')tc_{d_i}(t') \quad (3)$$

where $R(t)$ is the list of similar words to the keyword t, and $sim(t,t')$ is the Cosine similarity value between the vector representations of the words t and t'. As previously suggested by Rekabsaz et al. (2016a, 2017), we use the Cosine similarity function with threshold 0.70 for selecting the set $R(t)$ of similar words.

We define the extended versions of the standard weighting schemes as $\widehat{\mathbf{TC}}$, $\widehat{\mathbf{TF}}$, $\widehat{\mathbf{TFIDF}}$, and $\widehat{\mathbf{BM25}}$ by replacing $tc_{d_i}(t)$ with $\widehat{tc_{d_i}}(t)$ in each of the schemes.

The feature vector generated by the weights of the `Lex` or `LexExt` lexicons is highly sparse, as the number of dimensions is larger than the number of data-points. We therefore reduce the dimensions by applying Principle Component Analysis (PCA). Our initial experiments show 400 dimen-

sion as the optimum by trying on a range of dimensions from 50 to 1000.

Given the final feature vector x with l dimensions, we apply SVM as a well-known method for training both regression and classification methods. Support Vector Regression (Drucker et al., 1997) formulates the training as the following optimization problem:

$$\min_{w \in \mathbb{R}^l} \frac{1}{2} \|w\|^2 + \frac{C}{N} \sum_{i=1}^{N} \max(0, \|y_i - f(x_i; w)\| - \epsilon) \tag{4}$$

Similar to previous studies (Tsai and Wang, 2014; Kogan et al., 2009), we set $C = 1.0$ and $\epsilon = 0.1$. To solve the above problem, the function f can be re-parametrized in terms of a kernel function K with weights α_i:

$$f(x_i; w) = \sum_{i=1}^{N} \alpha_i K(x_i, x) \tag{5}$$

The kernel can be considered as a (similarity) function between the feature vector of the document and vectors of all the other documents. Our initial experiments showed better performance of the Radial Basis Function (RBF) kernel in comparison to linear and cosine kernels and is therefore used in this paper.

In addition, motivated by Moraes et al.(Moraes et al., 2013), we use of an Artificial Neural Network (ANN) algorithm to test the effectiveness of neural networks for automatic feature learning. We tried several neural network architectures with different regularization methods (early-stopping, regularization term, dropout). The best performing results were achieved with two hidden layers (400 and 500 nodes respectively), $tanh$ for activation function, and learning rate of 0.001 in gradient decent with early stopping. However, the networks could not provide superior results than the SVM regressors. Therefore, for this report, we only report the SVM methods.

4.2 Market Features

In addition to textual features, we define three features using the factual market data and historical prices—referred to as *market features*—as follows:

Current Volatility is calculated on the window of one quartile before the issue date of the report: $v_{[s_i-64, s_i]}$.

GARCH (Bollerslev, 1986) is a common econometric time-series model used for predicting stock price volatility. We use a GARCH (1, 1) model, trained separately for each report on intra-day return prices. We use all price data available before the issue date of the report for fitting the model. The GARCH (1, 1) model used predicts the volatility of the next day by looking at the previous day's volatility. When forecasting further than one day into the future one needs to use the model's own predictions in order to be able to make predictions for more than one day ahead. When forecasting further into the future these conditional forecasts of the variance will converge to a value called *unconditional variance*. As our forecast period is one quarter, we will approximate the volatility of future quarters with the unconditional variance.

Sector is the sector that the corresponding company of the report belongs to, namely energy (ene), basic industries (ind), finance (fin), technology (tech), miscellaneous (misc), consumer non-durables (n-dur), consumer durables (dur), capital goods (capt), consumer services (serv), public utilities (pub), and health care (hlth)[1]. The feature is converted to numerical representation using one-hot encoding.

4.3 Feature Fusion

To combine the text and market feature sets, the first approach, used also in previous studies ((Kogan et al., 2009; Wang et al., 2013)) is simply joining all the features in one feature space. In the context of multi-model learning, the method is referred to as *early fusion*.

In contrast, *late fusion* approaches first learn a model on each feature set and then use/learn a meta model to combine their results. As our second approach, we use *stacking* (Wolpert, 1992), a special case of late fusion. In stacking, we first split the training set into two parts (70%-30% portions). Using the first portion, we train separate machine learning models for each of the text and market feature sets. Next, we predict labels of the second portion with the trained models and finally train another model to capture the combinations between the outputs of the base models. In our experiments, the final model is always trained with SVM with RBF kernel.

Stacking is computationally inexpensive. How-

[1] We follow NASDAQ categorization of sectors.

ever, due to the split of the training set, the base models or the meta model may suffer from lack of training data. A potential approach to learn both the feature sets in one model is the MKL method.

The MKL algorithm (also called *intermediate fusion* (Noble et al., 2004)) extends the kernel of the SVM model by learning (simultaneous to the parameter learning) an optimum combination of several kernels. The MKL algorithm as formulated in Lanckriet et al. (2004) adds the following criterion to Eq. 5 for kernel learning:

$$K^* = \sum_i d_i K_i \quad \text{where} \sum_i d_i = 1,\ d_i \geq 0 \quad (6)$$

where K_i is a predefined kernel. Gönen and Alpaydın (2011) mention two uses of MKL: learning the optimum kernel in SVM, and combining multiple modalities (feature sets) via each kernel.

However, the optimization can be computationally challenging. We use the mklaren method (Stražar and Curk, 2016) which has linear complexity in the number of data instances and kernels. It has been shown to outperform recent multi kernel approximation approaches. We use RBF kernels for both the text and market feature sets.

5 Experiment Setup

In this section, we first describe the data, followed by introducing the baselines. We report the parameters applied in various algorithms and describe the evaluation metrics.

Dataset We download the reports of companies of the U.S. stock markets from 2006 to 2015 from the U.S. Securities and Exchange Commission (SEC) website[2]. We remove HTML tags and extract the text parts. We extract the Risk Factors section using term matching heuristics. Finally, the texts are stemmed using the Porter stemmer. We calculate the volatility values (Eq 1) and the volatility of the GARCH model based on the stock prices, collected from the Yahoo website. We filter the volatility values greater/smaller than the mean plus/minus three times the standard deviation of all the volatility values[3].

Baselines **GARCH:** although the GARCH model is of market factual information, we use it as a baseline to compare the effectiveness of text-based methods with mainstream approaches.

Market: uses all the market features. For both the GARCH and Market baselines, we use an SVM learner with RBF kernel.

Wang et al. (2013): they use the `Lex` keyword set with TC weighting scheme and the SVM method. They combine the textual features with current volatility using the early fusion method.

Tsai et al. (2014): similar to Wang et al. (2013), while they use the `LexExt` keyword set.

Evaluation Metrics As a common metric in volatility prediction, we use the r^2 metric (square of the correlation coefficient) for evaluation:

$$r^2 = \left(\frac{\sum_{i=1}^{n}(\hat{y}_i - \bar{\hat{y}})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(\hat{y}_i - \bar{\hat{y}})^2}\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2}} \right)^2 \quad (7)$$

where $\hat{y}_i$ is the predicted value, y_i denotes the labels and $\bar{y}$, their mean. The r^2 metric indicates the proportion of variance in the labels explained by the prediction. The measure is close to 1 when the predicted values can explain a large proportion of the variability in the labels and 0 when it fails to explain the labels' variabilities. An alternative metric, used in previous studies (Wang et al., 2013; Tsai and Wang, 2014; Kogan et al., 2009) is Mean Squared Error $MSE = \sum_i (\hat{y}_i - y_i)^2/n$. However, especially when comparing models, applied on different test sets (e.g. performance of first quartile with second quartile), r^2 has better interpretability since it is independent of the scale of y. We use r^2 in all the experiments while the MSE measure is reported only when the models are evaluated on the same test set.

6 Experiments and Results

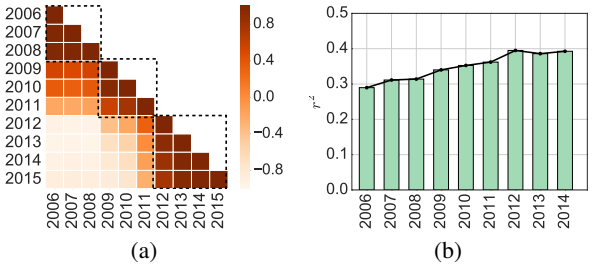
In this section, first we analyse the contents of the reports, followed by studying our sentiment analysis methods for volatility prediction. Finally, we investigate the effect of sentiment analysis of the reports in different industry sectors.

6.1 Content Analysis of 10-K Reports

Let us start our experiment with observing changes in the feature vectors of the reports over the years. To compare them, we use the state-of-the-art sentiment analysis method, introduced by Tsai and Wang (2014). We first represent the feature vector of each year by calculating the centroid

[2] https://www.sec.gov

[3] The complete dataset is available in http://ifs.tuwien.ac.at/~admire/financialvolatility



(a) (b)

Figure 1: (a) Cosine similarity between the centroid vectors of the years. (b) Volatility prediction performance when using reports from the specified year to 2015

(element-wise mean) of the feature vectors of all reports published that year and then calculate the Cosine similarity of each pair of centroid vectors, for the years 2006–2015.

Figure 1a shows the similarity heat-map for each pair of the years. We observe a high similarity between three ranges of years: 2006–2008, 2009–2011, and 2012–2015. These considerable differences between the centroid reports in years across these three groups hints at probable issues when using the data of the older years for the more recent ones.

To validate this, we apply 5-fold cross validation, first on all the data (2006–2015), and then on smaller sets by dropping the oldest year i.e. the next subsets use the reports 2007–2015, 2008–2015 and so forth. The results of the r^2 measure are shown in Figure 1b. We observe that by dropping the oldest years one by one (from left to right in the figure), the performance starts improving. We argue that this improvement is due to the reduction of noise in data, noise caused by conceptual drifts in the reports as also mentioned by Dyer et al. (2016). In fact, although in machine learning in general using more data results in better generalization of the model and therefore better prediction, the reports of the older years introduce noise.

As shown, the most coherent and largest data consists of the subset of the reports published between 2012 to 2015. This subset is also the most recent cluster and presumably more similar to the future reports. Therefore, in the following, we only use this subset, which consists of 3892 reports, belonging to 1323 companies.

Table 1: Performance of sentiment analysis methods for the first year.

Component	Method	Text (r^2)	Text (MSE)	Text+Market (r^2)	Text+Market (MSE)

6.2 Volatility Prediction

Given the dataset of the 2012–2015 reports, we try all combinations of different term weighting schemes using the `LexExt` keyword set. All weighting schemes are then combined with the market features with the introduced fusion methods. The prediction is done with 5-fold cross validation. The averages of the results of the first four quartiles (first year) are reported in Table 1. To make showing the results tractable, we use the best fusion (stacking) for the weighting schemes and the best scheme ($\widehat{BM25}$) for fusions.

Regarding the weighting schemes, $\widehat{BM25}$, $BM25$, and $\widehat{TC}$ show the best results. In general, the extended schemes (with hat) improve upon their normal forms. For the feature fusion methods, stacking outperforms the other approaches in both evaluation measures. MKL however has better performance than early fusion while it has the highest computational complexity among the methods. Based on these results, as our best performing approach in the remainder of the paper, we use $\widehat{BM25}$ (with `LexExt` set), reduced to 400 dimensions and stacking as the fusion method. Table 2 summarizes the results of our best per-

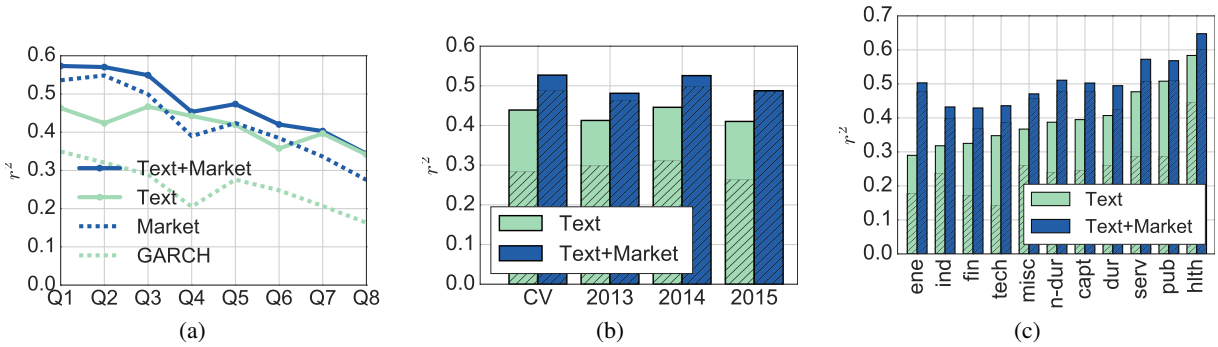

Figure 2: (a) Performance of our approach on 8 quartiles using the Text and Text+Market feature sets. The dashed lines show the market-based baselines. (b) Performance of volatility prediction of each year given the past data. The hashed areas show corresponding baselines. (c) Performance per sector. Abbreviations are defined in Section 4.2

forming method compared with previously existing methods. Our method outperforms all state-of-the-art methods both when using textual features only as well as a combination of textual and market features.

Let us now take a closer look on the changes in the performance of the prediction in time. The results of 5-fold cross validation for both tasks on the dataset of the reports, published between 2012–2015 are shown in Figure 2a. The X-axes show eight quartiles after the publication date of the report. For comparison, the GARCH and only market features are depicted with dashed lines.

As shown, the performance of the GARCH method as well as that using only market features (Market) decrease faster in the later quartiles since the historical prices used for prediction become less relevant as time goes by. Using only text features (Text), we see a roughly similar performance between the first four quartiles (first year), while the performance, in general, slightly decreases in the second year. By combining the textual and market features (Text+Market), we see a consistent improvement in comparison to each of them alone. In comparison to using only market features, the combination of the features shows more stable results in the later quartiles. These results support the informativeness of the 10-K reports to more effectively foreseen volatility in long-term windows.

While the above experiments are based on cross-validation, for the sake of completeness it is noteworthy to consider the scenarios of real-world applications where the future prediction is based on past data. We therefore design three experiments by considering the reports published in 2013, 2014, and 2015 as test set and the reports published before each year as training set (only 2012, 2012–2013, and 2012–2014 respectively). The results of predicting the reports of each year together with the cross validation scenario (CV) are shown in Figure 2b. While the performance becomes slightly worse in the target years 2013 and 2015, in general the combination of textual and market features can explain approximately half of volatility in the financial system.

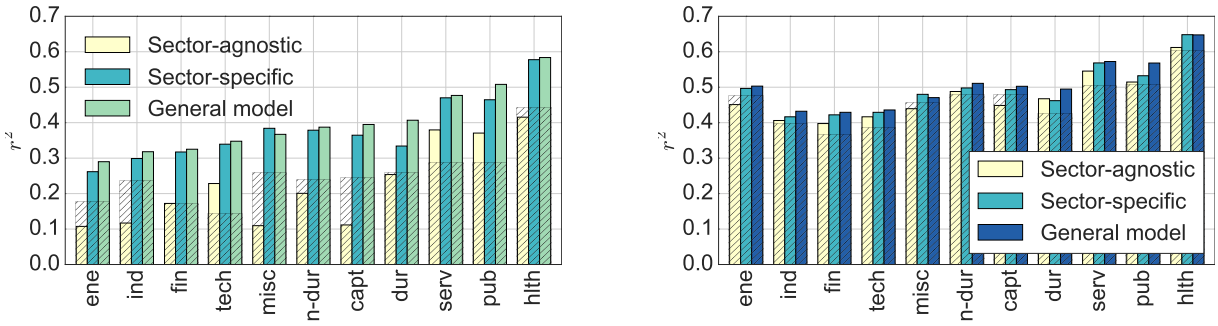
6.3 Sectors

Corporations in the same sector share not only similar products or services but also risks and instability factors. Considering the sentiment of the financial system as a homogeneous body may neglect the specific factors of each sector. We therefore set out to investigate the existence and nature of these differences.

We start by observing the prediction performance on different sectors: We use our method from the previous section, but split the test set across sectors and plot the results in Figure 2c. The hashed areas indicate the GARCH and Market baselines for the Text and Text+Market feature sets, respectively. We observe considerable differences between the performance of the sectors, especially when using only sentiment analysis methods (i.e. only text features).

Given these differences and also the probable similarities between the risk factors of the reports in the same sector, a question immediately arises: can training different models for different sectors improve the performance of prediction?

To answer it, for each sector, we train a model using only the subset of the reports in that sec-



(a) Text

(b) Text+Market

Figure 3: Results when retraining on sector-specific subsets versus the general model and versus subsets of the same size but sector-agnostic. The hashed area in (a) indicates the GARCH and in (b) the Market baseline.

tor and use 5-fold validation to observe performance. We refer to these models as sector-specific in contrast to the general model, trained on all the data. Figures 3a and 3b compare their results: we can see that the sector-specific bars are lower than the general model ones. This is to some extent surprising, as one would expect that domain-specific training would improve the performance of sentiment analysis in text. However, we need to consider the size of the training set. By training on each sector we have reduced the size of our training sets to those reported in Table 3. To verify the effect of the size of training data, we train a sector-agnostic model for each sector. Each sector-agnostic model is trained by random sampling of a training set of the same size as the set available for its sector from all the reports, but evaluated–similar to sector-specific models–on the test set of the sector. Figures 3a and 3b also plot the results of the sector-agnostic models.

The large performance differences between sector-agnostic and -specific show the existence of particular risk factors in each sector and their importance. Results also confirm the hypothesis that the data for training in each sector is simply too small, and as additional data is accumulated, we can further improve on the results by training on different sectors independently.

We continue by examining some examples of essential terms in sectors. To address this, we have to train a linear regression method on all the reports of each sector, without using any dimensionality reduction. Linear regression without dimensionality reduction has the benefit of interpretability: the coefficient of each feature (i.e. term in the lexicon) can be seen as its importance with regards to volatility prediction. After training, we observe that some keywords e.g. *crisis*, or *delist* constantly have high coefficient values in the sector-specific as well as general model. However, some keywords are particularly weighted high in specific-sector models.

For instance, the keyword *fire* has a high coefficient in the energy sector, but very low in the others. The reason is due to the problem of ambiguity i.e. in the energy sector, *fire* is widely used to refer to *explosion* e.g. 'fire and explosion hazards' while in the lexicon, it is stemmed from *firing* and *fired*: the act of dismissing from a job. This later sense of word is however weighted as a low risk-sensitive keyword in the other sectors. Such an ambiguity can indeed be mitigated by sector-specific models since the variety of the words' senses are more restricted inside each sector. Another example is an interesting observation on the word *beneficial*. The word is introduced as a positive sentiment in the lexicon while it gains highly negative sentiments in some sectors (health care, and basic industries). Investigating in the reports, we observe the broad use of the expression 'beneficial owner' which is normally followed by risk-full sentences since the beneficial owners can potentially influence shareholders' decision power.

7 Conclusion

In this work, we studied the sentiment of recent 10-K annual disclosures of companies in stock markets for forecasting volatility. Our bag-of-words sentiment analysis approach benefits from state-of-the-art models in information retrieval which use word embeddings to extend the weight of the terms to the similar terms in the document. Additionally, we explored fusion methods to combine the text features with factual market features, achieved from historical prices i.e. GARCH prediction model, and current volatility. In both cases, our approach outperforms state-of-the-art volatility prediction methods with 10-K reports and demonstrates the effectiveness of sentiment analysis in long-term volatility forecasting.

In addition, we studied the characteristics of each individual sector with regard to risk-sensitive terms. Our analysis shows that reports in same sectors considerably share particular risk and instability factors. However, despite expectations, training different models on different sectors does not improve performance compared to the general model. We traced this to the size of the available data in each sector, and show that there are still benefits in considering sectors, which could be further explored in the future as more data becomes available.

Abstract

Network embedding (NE) is playing a critical role in network analysis, due to its ability to represent vertices with efficient low-dimensional embedding vectors. However, existing NE models aim to learn a fixed context-free embedding for each vertex and neglect the diverse roles when interacting with other vertices. In this paper, we assume that one vertex usually shows different aspects when interacting with different neighbor vertices, and should own different embeddings respectively. Therefore, we present Context-Aware Network Embedding (CANE), a novel NE model to address this issue. CANE learns context-aware embeddings for vertices with mutual attention mechanism and is expected to model the semantic relationships between vertices more precisely. In experiments, we compare our model with existing NE models on three real-world datasets. Experimental results show that CANE achieves significant improvement than state-of-the-art methods on link prediction and comparable performance on vertex classification. The source code and datasets can be obtained from https://github.com/thunlp/CANE.

1 Introduction

Network embedding (NE), i.e., network representation learning (NRL), aims to map vertices of a network into a low-dimensional space according to their structural roles in the network. NE provides an efficient and effective way to represent and manage large-scale networks, alleviating the computation and sparsity issues of conventional symbol-based representations. Hence, NE is attracting many research interests in recent years (Perozzi et al., 2014; Tang et al., 2015; Grover and Leskovec, 2016), and achieves promising performance on many network analysis tasks including link prediction, vertex classification, and community detection.

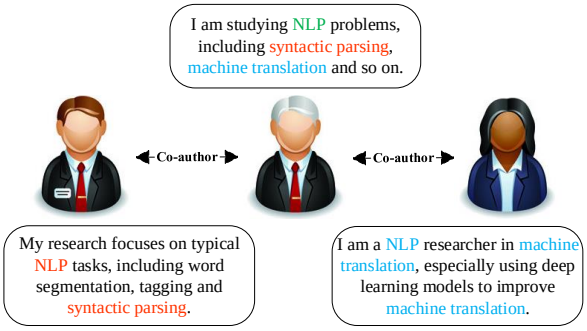

Figure 1: Example of a text-based information network. (Red, blue and green fonts represent concerns of the left user, right user and both respectively.)

In real-world social networks, it is intuitive that one vertex may demonstrate various aspects when interacting with different neighbor vertices. For example, a researcher usually collaborates with various partners on diverse research topics (as illustrated in Fig. 1), a social-media user contacts with various friends sharing distinct interests, and a web page links to multiple pages for different purposes. However, most existing NE methods only arrange one single embedding vector to each vertex, and give rise to the following two invertible issues: (1) These methods cannot flexibly cope with the aspect transition of a vertex when interacting with different neighbors. (2) In these models, a vertex tends to force the embeddings of its

https://doi.org/10.18653/v1/P17-1158

neighbors close to each other, which may be not the case all the time. For example, the left user and right user in Fig. 1, share less common interests, but are learned to be close to each other since they both link to the middle person. This will accordingly make vertex embeddings indiscriminative.

To address these issues, we aim to propose a **C**ontext-**A**ware **N**etwork **E**mbedding (CANE) framework for modeling relationships between vertices precisely. More specifically, we present CANE on information networks, where each vertex also contains rich external information such as text, labels or other meta-data, and the significance of context is more critical for NE in this scenario. Without loss of generality, we implement CANE on text-based information networks in this paper, which can easily extend to other types of information networks.

In conventional NE models, each vertex is represented as a static embedding vector, denoted as **context-free embedding**. On the contrary, CANE assigns dynamic embeddings to a vertex according to different neighbors it interacts with, named as **context-aware embedding**. Take a vertex u and its neighbor vertex v for example. The context-free embedding of u remains unchanged when interacting with different neighbors. On the contrary, the context-aware embedding of u is dynamic when confronting different neighbors.

When u interacting with v, their context embeddings concerning each other are derived from their text information, S_u and S_v respectively. For each vertex, we can easily use neural models, such as convolutional neural networks (Blunsom et al., 2014; Johnson and Zhang, 2014; Kim, 2014) and recurrent neural networks (Kiros et al., 2015; Tai et al., 2015), to build **context-free** text-based embedding. In order to realize **context-aware** text-based embeddings, we introduce the selective attention scheme and build **mutual attention** between u and v into these neural models. The mutual attention is expected to guide neural models to emphasize those words that are focused by its neighbor vertices and eventually obtain context-aware embeddings.

Both context-free embeddings and context-aware embeddings of each vertex can be efficiently learned together via concatenation using existing NE methods such as DeepWalk (Perozzi et al., 2014), LINE (Tang et al., 2015) and node2vec (Grover and Leskovec, 2016).

We conduct experiments on three real-world datasets of different areas. Experimental results on link prediction reveal the effectiveness of our framework as compared to other state-of-the-art methods. The results suggest that context-aware embeddings are critical for network analysis, in particular for those tasks concerning about complicated interactions between vertices such as link prediction. We also explore the performance of our framework via vertex classification and case studies, which again confirms the flexibility and superiority of our models.

2 Related Work

With the rapid growth of large-scale social networks, network embedding, i.e. network representation learning has been proposed as a critical technique for network analysis tasks.

In recent years, there have been a large number of NE models proposed to learn efficient vertex embeddings (Tang and Liu, 2009; Cao et al., 2015; Wang et al., 2016; Tu et al., 2016a). For example, DeepWalk (Perozzi et al., 2014) performs random walks over networks and introduces an efficient word representation learning model, Skip-Gram (Mikolov et al., 2013a), to learn network embeddings. LINE (Tang et al., 2015) optimizes the joint and conditional probabilities of edges in large-scale networks to learn vertex representations. Node2vec (Grover and Leskovec, 2016) modifies the random walk strategy in DeepWalk into biased random walks to explore the network structure more efficiently. Nevertheless, most of these NE models only encode the structural information into vertex embeddings, without considering heterogeneous information accompanied with vertices in real-world social networks.

To address this issue, researchers make great efforts to incorporate heterogeneous information into conventional NE models. For instance, Yang et al. (2015) present text-associated DeepWalk (TADW) to improve matrix factorization based DeepWalk with text information. Tu et al. (2016b) propose max-margin DeepWalk (MMDW) to learn discriminative network representations by utilizing labeling information of vertices. Chen et al. (2016) introduce group-enhanced network embedding (GENE) to integrate existing group information in NE. Sun et al. (2016) regard text content as a special kind

of vertices, and propose context-enhanced network embedding (CENE) through leveraging both structural and textural information to learn network embeddings.

To the best of our knowledge, all existing NE models focus on learning context-free embeddings, but ignore the diverse roles when a vertex interacts with others. In contrast, we assume that a vertex has different embeddings according to which vertex it interacts with, and propose CANE to learn context-aware vertex embeddings.

3 Problem Formulation

We first give basic notations and definitions in this work. Suppose there is an information network $G = (V, E, T)$, where V is the set of vertices, $E \subseteq V \times V$ are edges between vertices, and T denotes the text information of vertices. Each edge $e_{u,v} \in E$ represents the relationship between two vertices (u, v), with an associated weight $w_{u,v}$. Here, the text information of a specific vertex $v \in V$ is represented as a word sequence $S_v = (w_1, w_2, \ldots, w_{n_v})$, where $n_v = |S_v|$. NRL aims to learn a low-dimensional embedding $\mathbf{v} \in \mathbb{R}^d$ for each vertex $v \in V$ according to its network structure and associated information, e.g. text and labels. Note that, $d \ll |V|$ is the dimension of representation space.

Definition 1. Context-free Embeddings: Conventional NRL models learn context-free embedding for each vertex. It means the embedding of a vertex is fixed and won't change with respect to its context information (i.e., another vertex it interacts with).

Definition 2. Context-aware Embeddings: Different from existing NRL models that learn context-free embeddings, CANE learns various embeddings for a vertex according to its different contexts. Specifically, for an edge $e_{u,v}$, CANE learns context-aware embeddings $\mathbf{v}_{(u)}$ and $\mathbf{u}_{(v)}$.

4 The Method

4.1 Overall Framework

To take full use of both network structure and associated text information, we propose two types of embeddings for a vertex v, i.e., structure-based embedding $\mathbf{v}^s$ and text-based embedding $\mathbf{v}^t$. Structure-based embedding can capture the information in the network structure, while text-based embedding can capture the textual meanings lying in the associated text information. With these embeddings, we can simply concatenate them and obtain the vertex embeddings as $\mathbf{v} = \mathbf{v}^s \oplus \mathbf{v}^t$, where $\oplus$ indicates the concatenation operation. Note that, the text-based embedding $\mathbf{v}^t$ can be either context-free or context-aware, which will be introduced detailedly in section 4.4 and 4.5 respectively. When $\mathbf{v}^t$ is context-aware, the overall vertex embeddings $\mathbf{v}$ will be context-aware as well.

With above definitions, CANE aims to maximize the overall objective of edges as follows:

$$\mathcal{L} = \sum_{e \in E} L(e). \tag{1}$$

Here, the objective of each edge $L(e)$ consists of two parts as follows:

$$L(e) = L_s(e) + L_t(e), \tag{2}$$

where $L_s(e)$ denotes the structure-based objective and $L_t(e)$ represents the text-based objective.

In the following part, we give the detailed introduction to the two objectives respectively.

4.2 Structure-based Objective

Without loss of generality, we assume the network is directed, as an undirected edge can be considered as two directed edges with opposite directions and equal weights.

Thus, the structure-based objective aims to measure the log-likelihood of a directed edge using the structure-based embeddings as

$$L_s(e) = w_{u,v} \log p(\mathbf{v}^s | \mathbf{u}^s). \tag{3}$$

Following LINE (Tang et al., 2015), we define the conditional probability of v generated by u in Eq. (3) as

$$p(\mathbf{v}^s | \mathbf{u}^s) = \frac{\exp(\mathbf{u}^s \cdot \mathbf{v}^s)}{\sum_{z \in V} \exp(\mathbf{u}^s \cdot \mathbf{z}^s)}. \tag{4}$$

4.3 Text-based Objective

Vertices in real-world social networks usually accompany with associated text information. Therefore, we propose the text-based objective to take advantage of these text information, as well as learn text-based embeddings for vertices.

The text-based objective $L_t(e)$ can be defined with various measurements. To be compatible with $L_s(e)$, we define $L_t(e)$ as follows:

$$L_t(e) = \alpha \cdot L_{tt}(e) + \beta \cdot L_{ts}(e) + \gamma \cdot L_{st}(e), \tag{5}$$

where α, β and γ control the weights of various parts, and

$$L_{tt}(e) = w_{u,v} \log p(\mathbf{v}^t|\mathbf{u}^t),$$
$$L_{ts}(e) = w_{u,v} \log p(\mathbf{v}^t|\mathbf{u}^s), \quad (6)$$
$$L_{st}(e) = w_{u,v} \log p(\mathbf{v}^s|\mathbf{u}^t).$$

The conditional probabilities in Eq. (6) map the two types of vertex embeddings into the same representation space, but do not enforce them to be identical for the consideration of their own characteristics. Similarly, we employ softmax function for calculating the probabilities, as in Eq. (4).

The structure-based embeddings are regarded as parameters, the same as in conventional NE models. But for text-based embeddings, we intend to obtain them from associated text information of vertices. Besides, the text-based embeddings can be obtained either in context-free ways or context-aware ones. In the following sections, we will give detailed introduction respectively.

4.4 Context-Free Text Embedding

There has been a variety of neural models to obtain text embeddings from a word sequence, such as convolutional neural networks (CNN) (Blunsom et al., 2014; Johnson and Zhang, 2014; Kim, 2014) and recurrent neural networks (RNN) (Kiros et al., 2015; Tai et al., 2015).

In this work, we investigate different neural networks for text modeling, including CNN, Bidirectional RNN (Schuster and Paliwal, 1997) and GRU (Cho et al., 2014), and employ the best performed CNN, which can capture the local semantic dependency among words.

Taking the word sequence of a vertex as input, CNN obtains the text-based embedding through three layers, i.e. looking-up, convolution and pooling.

Looking-up. Given a word sequence $S = (w_1, w_2, \ldots, w_n)$, the looking-up layer transforms each word $w_i \in S$ into its corresponding word embedding $\mathbf{w}_i \in \mathbb{R}^{d'}$ and obtains embedding sequence as $\mathbf{S} = (\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_n)$. Here, d' indicates the dimension of word embeddings.

Convolution. After looking-up, the convolution layer extracts local features of input embedding sequence $\mathbf{S}$. To be specific, it performs convolution operation over a sliding window of length l using a convolution matrix $\mathbf{C} \in \mathbb{R}^{d \times (l \times d')}$ as follows:

$$\mathbf{x}_i = \mathbf{C} \cdot \mathbf{S}_{i:i+l-1} + \mathbf{b}, \quad (7)$$

where $\mathbf{S}_{i:i+l-1}$ denotes the concatenation of word embeddings within the i-th window and $\mathbf{b}$ is the bias vector. Note that, we add zero padding vectors (Hu et al., 2014) at the edge of the sentence.

Max-pooling. To obtain the text embedding $\mathbf{v}^t$, we operate max-pooling and non-linear transformation over $\{\mathbf{x}_0^i, \ldots, \mathbf{x}_n^i\}$ as follows:

$$r_i = \tanh(\max(\mathbf{x}_0^i, \ldots, \mathbf{x}_n^i)), \quad (8)$$

At last, we encode the text information of a vertex with CNN and obtain its text-based embedding $\mathbf{v}^t = [r_1, \ldots, r_d]^T$. As $\mathbf{v}^t$ is irrelevant to the other vertices it interacts with, we name it as context-free text embedding.

4.5 Context-Aware Text Embedding

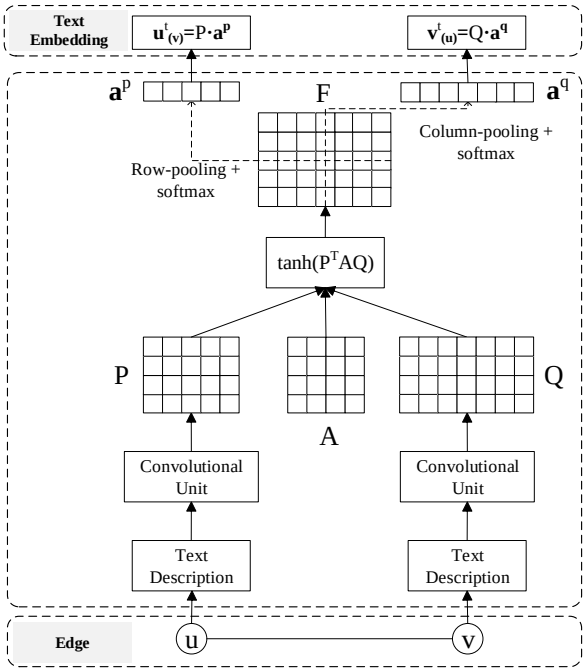

Figure 2: An illustration of context-aware text embedding.

As stated before, we assume that a specific vertex plays different roles when interacting with others vertices. In other words, each vertex should have its own points of focus about a specific vertex, which leads to its context-aware text embeddings.

To achieve this, we employ **mutual attention** to obtain context-aware text embedding. It enables the pooling layer in CNN to be aware of the vertex pair in an edge, in a way that text information from a vertex can directly affect the text embedding of the other vertex, and vice versa.

In Fig. 2, we give an illustration of the generating process of context-aware text embedding. Given an edge $e_{u,v}$ with two corresponding text sequences S_u and S_v, we can get the matrices $\mathbf{P} \in \mathbb{R}^{d\times m}$ and $\mathbf{Q} \in \mathbb{R}^{d\times n}$ through convolution layer. Here, m and n represent the lengths of S_u and S_v respectively. By introducing an attentive matrix $\mathbf{A} \in \mathbb{R}^{d\times d}$, we compute the correlation matrix $\mathbf{F} \in \mathbb{R}^{m\times n}$ as follows:

$$\mathbf{F} = \tanh(\mathbf{P}^T\mathbf{A}\mathbf{Q}). \tag{9}$$

Note that, each element $\mathbf{F}_{i,j}$ in $\mathbf{F}$ represents the pair-wise correlation score between two hidden vectors, i.e., $\mathbf{P}_i$ and $\mathbf{Q}_j$.

After that, we conduct pooling operations along rows and columns of $\mathbf{F}$ to generate the importance vectors, named as row-pooling and column pooling respectively. According to our experiments, mean-pooling performs better than max-pooling. Thus, we employ mean-pooling operation as follows:

$$\begin{aligned} g_i^p &= \mathbf{mean}(\mathbf{F}_{i,1}, \ldots, \mathbf{F}_{i,n}), \\ g_i^q &= \mathbf{mean}(\mathbf{F}_{1,i}, \ldots, \mathbf{F}_{m,i}). \end{aligned} \tag{10}$$

The importance vectors of $\mathbf{P}$ and $\mathbf{Q}$ are obtained as $\mathbf{g}^p = [g_1^p, \ldots, g_m^p]^T$ and $\mathbf{g}^q = [g_1^q, \ldots, g_n^q]^T$.

Next, we employ softmax function to transform importance vectors $\mathbf{g}^p$ and $\mathbf{g}^q$ to attention vectors $\mathbf{a}^p$ and $\mathbf{a}^q$. For instance, the i-th element of $\mathbf{a}^p$ is formalized as follows:

$$a_i^p = \frac{\exp(g_i^p)}{\sum_{j\in[1,m]} \exp(g_j^p)}. \tag{11}$$

At last, the context-aware text embeddings of u and v are computed as

$$\begin{aligned} \mathbf{u}_{(v)}^t &= \mathbf{P}\mathbf{a}^p, \\ \mathbf{v}_{(u)}^t &= \mathbf{Q}\mathbf{a}^q. \end{aligned} \tag{12}$$

Now, given an edge (u, v), we can obtain the context-aware embeddings of vertices with their structure embeddings and context-aware text embeddings as $\mathbf{u}_{(v)} = \mathbf{u}^s \oplus \mathbf{u}_{(v)}^t$ and $\mathbf{v}_{(u)} = \mathbf{v}^s \oplus \mathbf{v}_{(u)}^t$.

4.6 Optimization of CANE

According to Eq. (3) and Eq. (6), CANE aims to maximize several conditional probabilities between $\mathbf{u} \in \{\mathbf{u}^s, \mathbf{u}_{(v)}^t\}$ and $\mathbf{v} \in \{\mathbf{v}^s, \mathbf{v}_{(u)}^t\}$. It is intuitive that optimizing the conditional probability using softmax function is computationally expensive. Thus, we employ negative sampling (Mikolov et al., 2013b) and transform the objective into the following form:

$$\log\sigma(\mathbf{u}^T\cdot\mathbf{v}) + \sum_{i=1}^{k} E_{z\sim P(v)}[\log\sigma(-\mathbf{u}^T\cdot\mathbf{z})], \tag{13}$$

where k is the number of negative samples and σ represents the sigmoid function. $P(v) \propto {d_v}^{3/4}$ denotes the distribution of vertices, where d_v is the out-degree of v.

Afterward, we employ Adam (Kingma and Ba, 2015) to optimize the transformed objective. Note that, CANE is exactly capable of zero-shot scenarios, by generating text embeddings of new vertices with well-trained CNN.

5 Experiments

To investigate the effectiveness of CANE on modeling relationships between vertices, we conduct experiments of link prediction on several real-world datasets. Besides, we also employ vertex classification to verify whether context-aware embeddings of a vertex can compose a high-quality context-free embedding in return.

5.1 Datasets

Datasets	**Cora**	**HepTh**	**Zhihu**
#Vertices	2,277	1,038	10,000
#Edges	5,214	1,990	43,894
#Labels	7	–	–

Table 1: Statistics of Datasets.

We select three real-world network datasets as follows:

Cora[1] is a typical paper citation network constructed by (McCallum et al., 2000). After filtering out papers without text information, there are 2,277 machine learning papers in this network, which are divided into 7 categories.

HepTh[2] (High Energy Physics Theory) is another citation network from arXiv[3] released by (Leskovec et al., 2005). We filter out papers without abstract information and retain 1,038 papers at last.

Table 2: AUC values on Cora. ($\alpha = 1.0, \beta = 0.3, \gamma = 0.3$)

Zhihu[4] is the largest online Q&A website in China. Users follow each other and answer questions on this site. We randomly crawl $10,000$ active users from Zhihu, and take the descriptions of their concerned topics as text information.

The detailed statistics are listed in Table 1.

5.2 Baselines

We employ the following methods as baselines:

Structure-only:

MMB (Airoldi et al., 2008) (Mixed Membership Stochastic Blockmodel) is a conventional graphical model of relational data. It allows each vertex to randomly select a different "topic" when forming an edge.

DeepWalk (Perozzi et al., 2014) performs random walks over networks and employ Skip-Gram model (Mikolov et al., 2013a) to learn vertex embeddings.

LINE (Tang et al., 2015) learns vertex embeddings in large-scale networks using first-order and second-order proximities.

Node2vec (Grover and Leskovec, 2016) proposes a biased random walk algorithm based on DeepWalk to explore neighborhood architecture more efficiently.

Structure and Text:

Naive Combination: We simply concatenate the best-performed structure-based embeddings with CNN based embeddings to represent the vertices.

TADW (Yang et al., 2015) employs matrix factorization to incorporate text features of vertices into network embeddings.

CENE (Sun et al., 2016) leverages both structure and textural information by regarding text content as a special kind of vertices, and optimizes the probabilities of heterogeneous links.

[4]https://www.zhihu.com/

5.3 Evaluation Metrics and Experiment Settings

For link prediction, we adopt a standard evaluation metric **AUC** (Hanley and McNeil, 1982), which represents the probability that vertices in a random unobserved link are more similar than those in a random nonexistent link.

For vertex classification, we employ L2-regularized logistic regression (L2R-LR) (Fan et al., 2008) to train classifiers, and evaluate the classification accuracies of various methods.

To be fair, we set the embedding dimension to 200 for all methods. In LINE, we set the number of negative samples to 5; we learn the 100 dimensional first-order and second-order embeddings respectively, and concatenate them to form the 200 dimensional embeddings. In node2vec, we employ grid search and select the best-performed hyper-parameters for training. We also apply grid search to set the hyper-parameters α, β and γ in CANE. Besides, we set the number of negative samples k to 1 in CANE to speed up the training process. To demonstrate the effectiveness of considering attention mechanism and two types of objectives in Eqs. (3) and (6), we design three versions of CANE for evaluation, i.e., CANE with text only, CANE without attention and CANE.

5.4 Link Prediction

As shown in Table 2, Table 3 and Table 4, we evaluate the AUC values while removing different ratios of edges on Cora, HepTh and Zhihu respectively. Note that, when we only keep 5% edges for training, most vertices are isolated, which results in the poor and meaningless performance of all the methods. Thus, we omit the results under this training ratio. From these tables, we have the following observations:

%Training edges	15%	25%	35%	45%	55%	65%	75%	85%	95%
MMB	54.6	57.9	57.3	61.6	66.2	68.4	73.6	76.0	80.3

Table 4: AUC values on Zhihu. ($\alpha = 1.0, \beta = 0.3, \gamma = 0.3$)

(1) Our proposed CANE consistently achieves significant improvement comparing to all the baselines on all different datasets and different training ratios. It indicates the effectiveness of CANE when applied to link prediction task, and verifies that CANE has the capability of modeling relationships between vertices precisely.

(2) What calls for special attention is that, both CENE and TADW exhibit unstable performance under various training ratios. Specifically, CENE performs poorly under small training ratios, because it reserves much more parameters (e.g., convolution kernels and word embeddings) than TADW, which need more data for training. Different from CENE, TADW performs much better under small training ratios, because DeepWalk based methods can explore the sparse network structure well through random walks even with limited edges. However, it achieves poor performance under large ones, as its simplicity and the limitation of bag-of-words assumption. On the contrary, CANE has a stable performance in various situations. It demonstrates the flexibility and robustness of CANE.

(3) By introducing attention mechanism, the learnt context-aware embeddings obtain considerable improvements than the ones without attention. It verifies our assumption that a specific vertex should play different roles when interacting with other vertices, and thus benefits the relevant link prediction task.

To summarize, all the above observations demonstrate that CANE can learn high-quality context-aware embeddings, which are conducive to estimating the relationship between vertices precisely. Moreover, the experimental results on link prediction task state the effectiveness and robustness of CANE.

5.5 Vertex Classification

In CANE, we obtain various embeddings of a vertex according to the vertex it connects to. It's intuitive that the obtained context-aware embeddings are naturally applicable to link prediction task. However, network analysis tasks, such as vertex classification and clustering, require a global embedding, rather than several context-aware embeddings for each vertex.

To demonstrate the capability of CANE to solve these issues, we generate the global embedding of a vertex u by simply averaging all the context-

aware embeddings as follows:

$$\mathbf{u} = \frac{1}{N} \sum_{(u,v)|(v,u)\in E} \mathbf{u}_{(v)},$$

where N indicates the number of context-aware embeddings of u.

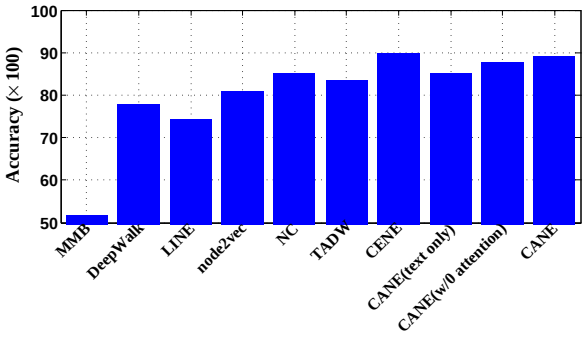

Figure 3: Vertex classification results on Cora.

With the generated global embeddings, we conduct 2-fold cross-validation and report the average accuracy of vertex classification on Cora. As shown in Fig. 3, we observe that:

(1) CANE achieves comparable performance with state-of-the-art model CENE. It states that the learnt context-aware embeddings can transform into high-quality context-free embeddings through simple average operation, which can be further employed to other network analysis tasks.

(2) With the introduction of mutual attention mechanism, CANE has an encouraging improvement than the one without attention, which is in accordance with the results of link prediction. It denotes that CANE is flexible to various network analysis tasks.

5.6 Case Study

To demonstrate the significance of **mutual attention** on selecting meaningful features from text information, we visualize the heat maps of two vertex pairs in Fig. 4. Note that, every word in this figure accompanies with various background colors. The stronger the background color is, the larger the weight of this word is. The weight of each word is calculated according to the attention weights as follows.

For each vertex pair, we can get the attention weight of each convolution window according to Eq. (11). To obtain the weights of words, we assign the attention weight to each word in this window, and add the attention weights of a word together as its final weight.

Figure 4: Visualizations of mutual attention.

The proposed attention mechanism makes the relations between vertices explicit and interpretable. We select three connected vertices in Cora for example, denoted as A, B and C. From Fig. 4, we observe that, though there exists citation relations with identical paper A, paper B and C concern about different parts of A. The attention weights over A in edge #1 are assigned to "reinforcement learning". On the contrary, the weights in edge #2 are assigned to "machine learning'", "supervised learning algorithms" and "complex stochastic models". Moreover, all these key elements in A can find corresponding words in B and C. It's intuitive that these key elements give an exact explanation of the citation relations. The discovered significant correlations between vertex pairs reflect the effectiveness of mutual attention mechanism, as well as the capability of CANE for modeling relations precisely.

6 Conclusion and Future Work

In this paper, we propose the concept of Context-Aware Network Embedding (CANE) for the first

time, which aims to learn various context-aware embeddings for a vertex according to the neighbors it interacts with. Specifically, we implement CANE on text-based information networks with proposed mutual attention mechanism, and conduct experiments on several real-world information networks. Experimental results on link prediction demonstrate that CANE is effective for modeling the relationship between vertices. Besides, the learnt context-aware embeddings can compose high-quality context-free embeddings.

We will explore the following directions in future:

(1) We have investigated the effectiveness of CANE on text-based information networks. In future, we will strive to implement CANE on a wider variety of information networks with multi-modal data, such as labels, images and so on.

(2) CANE encodes latent relations between vertices into their context-aware embeddings. Furthermore, there usually exist explicit relations in social networks (e.g., families, friends and colleagues relations between social network users), which are expected to be critical to NE. Thus, we want to explore how to incorporate and predict these explicit relations between vertices in NE.

Abstract

Singlish can be interesting to the ACL community both linguistically as a major creole based on English, and computationally for information extraction and sentiment analysis of regional social media. We investigate dependency parsing of Singlish by constructing a dependency treebank under the Universal Dependencies scheme, and then training a neural network model by integrating English syntactic knowledge into a state-of-the-art parser trained on the Singlish treebank. Results show that English knowledge can lead to 25% relative error reduction, resulting in a parser of 84.47% accuracies. To the best of our knowledge, we are the first to use neural stacking to improve cross-lingual dependency parsing on low-resource languages. We make both our annotation and parser available for further research.

1 Introduction

Languages evolve temporally and geographically, both in vocabulary as well as in syntactic structures. When major languages such as English or French are adopted in another culture as the primary language, they often mix with existing languages or dialects in that culture and evolve into a stable language called a creole. Examples of creoles include the French-based Haitian Creole, and Colloquial Singaporean English (Singlish) (Mian-Lian and Platt, 1993), an English-based creole. While the majority of the natural language processing (NLP) research attention has been focused on the major languages, little work has been done on adapting the components to creoles. One notable body of work originated from the featured translation task of the EMNLP 2011 Workshop on Statistical Machine Translation (WMT11) to translate Haitian Creole SMS messages sent during the 2010 Haitian earthquake. This work highlights the importance of NLP tools on creoles in crisis situations for emergency relief (Hu et al., 2011; Hewavitharana et al., 2011).

Singlish is one of the major languages in Singapore, with borrowed vocabulary and grammars[1] from a number of languages including Malay, Tamil, and Chinese dialects such as Hokkien, Cantonese and Teochew (Leimgruber, 2009, 2011), and it has been increasingly used in written forms on web media. Fluent English speakers unfamiliar with Singlish would find the creole hard to comprehend (Harada, 2009). Correspondingly, fundamental English NLP components such as POS taggers and dependency parsers perform poorly on such Singlish texts as shown in Table 2 and 4. For example, Seah et al. (2015) adapted the Socher et al. (2013) sentiment analysis engine to the Singlish vocabulary, but failed to adapt the parser. Since dependency parsers are important for tasks such as information extraction (Miwa and Bansal, 2016) and discourse parsing (Li et al., 2015), this hinders the development of such downstream applications for Singlish in written forms and thus makes it crucial to build a dependency parser that can perform well natively on Singlish.

To address this issue, we start with investigating the linguistic characteristics of Singlish and specifically the causes of difficulties for understanding Singlish with English syntax. We found that, despite the obvious attribute of inheriting a large portion of basic vocabularies and grammars from English, Singlish not only imports terms from regional languages and dialects, its lexical

[1] We follow Leimgruber (2011) in using "grammar" to describe "syntactic constructions" and we do not differentiate the two expressions in this paper.

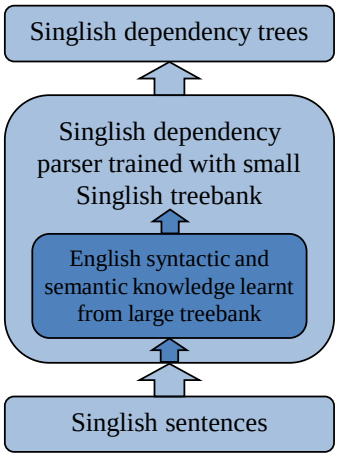

Figure 1: Overall model diagram

semantics and syntax also deviate significantly from English (Leimgruber, 2009, 2011). We categorize the challenges and formalize their interpretation using Universal Dependencies (Nivre et al., 2016), which extends to the creation of a Singlish dependency treebank with 1,200 sentences.

Based on the intricate relationship between Singlish and English, we build a Singlish parser by leveraging knowledge of English syntax as a basis. This overall approach is illustrated in Figure 1. In particular, we train a basic Singlish parser with the best off-the-shelf neural dependency parsing model using biaffine attention (Dozat and Manning, 2017), and improve it with knowledge transfer by adopting neural stacking (Chen et al., 2016; Zhang and Weiss, 2016) to integrate the English syntax. Since POS tags are important features for dependency parsing (Chen and Manning, 2014; Dyer et al., 2015), we train a POS tagger for Singlish following the same idea by integrating English POS knowledge using neural stacking.

Results show that English syntax knowledge brings 51.50% and 25.01% relative error reduction on POS tagging and dependency parsing respectively, resulting in a Singlish dependency parser with 84.47% unlabeled attachment score (UAS) and 77.76% labeled attachment score (LAS).

We make our Singlish dependency treebank, the source code for training a dependency parser and the trained model for the parser with the best performance freely available online[2].

2 Related Work

Neural networks have led to significant advance in the performance for dependency parsing, including transition-based parsing (Chen and Manning, 2014; Zhou et al., 2015; Weiss et al., 2015; Dyer et al., 2015; Ballesteros et al., 2015; Andor et al., 2016), and graph-based parsing (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017). In particular, the biaffine attention method of Dozat and Manning (2017) uses deep bi-directional long short-term memory (bi-LSTM) networks for high-order non-linear feature extraction, producing the highest-performing graph-based English dependency parser. We adopt this model as the basis for our Singlish parser.

Our work belongs to a line of work on transfer learning for parsing, which leverages English resources in Universal Dependencies to improve the parsing accuracies of low-resource languages (Hwa et al., 2005; Cohen and Smith, 2009; Ganchev et al., 2009). Seminal work employed statistical models. McDonald et al. (2011) investigated delexicalized transfer, where word-based features are removed from a statistical model for English, so that POS and dependency label knowledge can be utilized for training a model for low-resource language. Subsequent work considered syntactic similarities between languages for better feature transfer (Täckström et al., 2012; Naseem et al., 2012; Zhang and Barzilay, 2015).

Recently, a line of work leverages neural network models for multi-lingual parsing (Guo et al., 2015; Duong et al., 2015; Ammar et al., 2016). The basic idea is to map the word embedding spaces between different languages into the same vector space, by using sentence-aligned bilingual data. This gives consistency in tokens, POS and dependency labels thanks to the availability of Universal Dependencies (Nivre et al., 2016). Our work is similar to these methods in using a neural network model for knowledge sharing between different languages. However, ours is different in the use of a neural stacking model, which respects the distributional differences between Singlish and English words. This empirically gives higher accuracies for Singlish.

Neural stacking was previously used for cross-annotation (Chen et al., 2016) and cross-task (Zhang and Weiss, 2016) joint-modelling on monolingual treebanks. To the best of our knowledge, we are the first to employ it on cross-lingual

feature transfer from resource-rich languages to improve dependency parsing for low-resource languages. Besides these three dimensions in dealing with heterogeneous text data, another popular area of research is on the topic of domain adaption, which is commonly associated with cross-lingual problems (Nivre et al., 2007). While this large strand of work is remotely related to ours, we do not describe them in details.

Unsupervised rule-based approaches also offer an competitive alternative for cross-lingual dependency parsing (Naseem et al., 2010; Gillenwater et al., 2010; Gelling et al., 2012; Søgaard, 2012a,b; Martínez Alonso et al., 2017), and recently been benchmarked for the Universal Dependencies formalism by exploiting the linguistic constraints in the Universal Dependencies to improve the robustness against error propagation and domain adaption (Martínez Alonso et al., 2017). However, we choose a data-driven supervised approach given the relatively higher parsing accuracy owing to the availability of resourceful treebanks from the Universal Dependencies project.

3 Singlish Dependency Treebank

3.1 Universal Dependencies for Singlish

Since English is the major genesis of Singlish, we choose English as the source of lexical feature transfer to assist Singlish dependency parsing. Universal Dependencies provides a set of multilingual treebanks with cross-lingually consistent dependency-based lexicalist annotations, designed to aid development and evaluation for cross-lingual systems, such as multilingual parsers (Nivre et al., 2016). The current version of Universal Dependencies comprises not only major treebanks for 47 languages but also their siblings for domain-specific corpora and dialects. With the aligned initiatives for creating transfer-learning-friendly treebanks, we adopt the Universal Dependencies protocol for constructing the Singlish dependency treebank, both as a new resource for the low-resource languages and to facilitate knowledge transfer from English.

On top of the general Universal Dependencies guidelines, English-specific dependency relation definitions including additional subtypes are employed as the default standards for annotating the Singlish dependency treebank, unless augmented or redefined when necessary. The latest English corpus in Universal Dependencies v1.4[3] collection is constructed from the English Web Treebank (Bies et al., 2012), comprising of web media texts, which potentially smooths the knowledge transfer to our target Singlish texts in similar domains. The statistics of this dataset, from which we obtain English syntactic knowledge, is shown in Table 1 and we refer to this corpus as UD-Eng. This corpus uses 47 dependency relations and we show below how to conform to the same standard while adapting to unique Singlish grammars.

	UD English		Singlish	
	Sentences	Words	Sentences	Words
Train	12,543	204,586	900	8,221
Dev	2,002	25,148	150	1,384
Test	2,077	25,096	150	1,381

Table 1: Division of training, development, and test sets for Singlish Treebank

3.2 Challenges and Solutions for Annotating Singlish

The deviations of Singlish from English come from both the lexical and the grammatical levels (Leimgruber, 2009, 2011), which bring challenges for analysis on Singlish using English NLP tools. The former involves imported vocabularies from the first languages of the local people and the latter can be represented by a set of relatively localized features which collectively form 5 unique grammars of Singlish according to Leimgruber (2011). We find empirically that all these deviations can be accommodated by applying the existing English dependency relation definitions while ensuring consistency with the annotations in other non-English UD treebanks, which are explained with examples as follows.

Imported vocabulary: Singlish borrows a number of words and expressions from its non-English origins (Leimgruber, 2009, 2011), such as "Kiasu", which originates from Hokkien meaning "very anxious not to miss an opportunity".[4] These imported terms often constitute out-of-vocabulary (OOV) words with respect to a standard English treebank and result in difficulties for using English-trained tools on Singlish. All borrowed words are annotated based on their usages in Singlish, which mainly inherit the POS from their genesis languages. Table A4 in Appendix A

[3]Only guidelines for Universal Dependencies v2 but not the English corpus is available when this work is completed.

[4]Definition by the Oxford living Dictionaries for English.

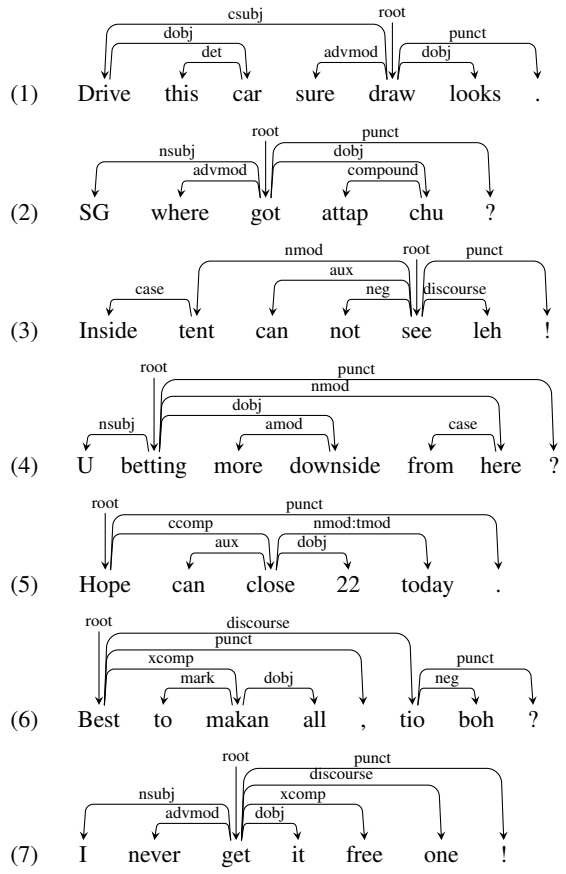

Figure 2: Unique Singlish grammars. (Arcs represent dependencies, pointing from the head to the dependent, with the dependency relation label right on top of the arc)

summarizes all borrowed terms in our treebank.

Topic-prominence: This type of sentences start with establishing its topic, which often serves as the default one that the rest of the sentence refers to, and they typically employ an object-subject-verb sentence structure (Leimgruber, 2009, 2011). In particular, three subtypes of topic-prominence are observed in the Singlish dependency treebank and their annotations are addressed as follows:

First, topics framed as clausal arguments at the beginning of the sentence are labeled as "csubj" (clausal subject), as shown by "Drive this car" of (1) in Figure 2, which is consistent with the dependency relations in its Chinese translation.

Second, noun phrases used to modify the predicate with the absence of a preposition is regarded as a "nsubj" (nominal subject). Similarly, this is a common order of words used in Chinese and one example is the "SG" of (2) in Figure 2.

Third, prepositional phrases moved in front are still treated as "nmod" (nominal modifier) of their intended heads, following the exact definition but as a Singlish-specific form of exemplification, as shown by the "Inside tent" of (3) in Figure 2.

Although the "dislocated" (dislocated elements) relation in UD is also used for preposed elements, but it captures the ones "that do not fulfill the usual core grammatical relations of a sentence" and "not for a topic-marked noun that is also the subject of the sentence" (Nivre et al., 2016). In these three scenarios, the topic words or phrases are in relatively closer grammatical relations to the predicate, as subjects or modifiers.

Copula deletion: Imported from the corresponding Chinese sentence structure, this copula verb is often optional and even deleted in Singlish, which is one of its diagnostic characteristics (Leimgruber, 2009, 2011). In UD-Eng standards, predicative "be" is the only verb used as a copula and it often depends on its complement to avoid copular head. This is explicitly designed in UD to promote parallelism for zero-copula phenomenon in languages such as Russian, Japanese, and Arabic. The deleted copula and its "cop" (copula) arcs are simply ignored, as shown by (4) in Figure 2.

NP deletion: Noun-phrase (NP) deletion often results in null subjects or objects. It may be regarded as a branch of "Topic-prominence" but is a distinctive feature of Singlish with relatively high frequency of usage (Leimgruber, 2011). NP deletion is also common in pronoun-dropping languages such as Spanish and Italian, where the anaphora can be morphologically inferred. In one example, "Vorrei ora entrare brevemente nel merito."[5], from the Italian treebank in UD, "Vorrei" means "I would like to" and depends on the sentence root, "entrare", with the "aux"(auxiliary) relation, where the subject "I" is absent but implicitly understood. Similarly, we do not recover such relations since the deleted NP imposes negligible alteration to the dependency tree, as exemplified by (5) in Figure 2.

Inversion: Inversion in Singlish involves either keeping the subject and verb in interrogative sentences in the same order as in statements, or tag questions in polar interrogatives (Leimgruber, 2011). The former also exists in non-English languages, such as Spanish and Italian, where the subject can prepose the verb in questions (La-

[5]In English: (I) would now like to enter briefly on the merit (of the discussion).

housse and Lamiroy, 2012). This simply involves a change of word orders and thus requires no special treatments. On the other hand, tag questions should be carefully analyzed in two scenarios. One type is in the form of "isn't it?" or "haven't you?", which are dependents of the sentence root with the "parataxis" relation.[6] The other type is exemplified as "right?", and its Singlish equivalent "tio boh?" (a transliteration from Hokkien) are labeled with the "discourse" (discourse element) relation with respect to the sentence root. See example (6) in Figure 2.

Discourse particles: Usage of clausal-final discourse particles, which originates from Hokkien and Cantonese, is one of the most typical feature of Singlish (Leimgruber, 2009, 2011; Lim, 2007). All discourse particles that appear in our treebank are summarized in Table A3 in Appendix A with the imported vocabulary:. These words express the tone of the sentence and thus have the "INTJ" (interjection) POS tag and depend on the root of the sentence or clause labeled with "discourse", as is shown by the "leh" of (3) in Figure 2. The word "one" is a special instance of this type with the sole purpose being a tone marker in Singlish but not English, as shown by (7) in Figure 2.

3.3 Data Selection and Annotation

Data Source: Singlish is used in written form mainly in social media and local Internet forums. After comparison, we chose the *SG Talk Forum*[7] as our data source due to its relative abundance in Singlish contents. We crawled 84,459 posts using the Scrapy framework[8] from pages dated up to 25th December 2016, retaining sentences of length between 5 and 50, which total 58,310. Sentences are reversely sorted according to the log likelihood of the sentence given by an English language model trained using the KenLM toolkit (Heafield et al., 2013)[9] normalized by the sentence length, so that those most different from standard English can be chosen. Among the top 10,000 sentences, 1,977 sentences contain unique Singlish vocabularies defined by *The Coxford Singlish Dictionary*[10], *A Dictionary of Singlish and Singapore English*[11], and the *Singlish Vocabulary* Wikipedia page[12]. The average normalized log likelihood of these 10,000 sentences is -5.81, and the same measure for all sentences in UD-Eng is -4.81. This means these sentences with Singlish contents are 10 times less probable expressed as standard English than the UD-Eng contents in the web domain. This contrast indicates the degree of lexical deviation of Singlish from English. We chose 1,200 sentences from the first 10,000. More than 70% of the selected sentences are observed to consist of the Singlish grammars and imported vocabularies described in section 3.2. Thus the evaluations on this treebank can reflect the performance of various POS taggers and parsers on Singlish in general.

Annotation: The chosen texts are divided by random selection into training, development, and testing sets according to the proportion of sentences in the training, development, and test division for UD-Eng, as summarized in Table 1. The sentences are tokenized using the NLTK Tokenizer,[13] and then annotated using the Dependency Viewer.[14] In total, all 17 UD-Eng POS tags and 41 out of the 47 UD-Eng dependency labels are present in the Singlish dependency treebank. Besides, 100 sentences are randomly selected and double annotated by one of the coauthors, and the inter-annotator agreement has a 97.76% accuracy on POS tagging and a 93.44% UAS and a 89.63% LAS for dependency parsing. A full summary of the numbers of occurrences of each POS tag and dependency label are included in Appendix A.

4 Part-of-Speech Tagging

In order to obtain automatically predicted POS tags as features for a base English dependency parser, we train a POS tagger for UD-Eng using the baseline model of Chen et al. (2016), depicted in Figure 3. The bi-LSTM networks with a CRF layer (bi-LSTM-CRF) have shown state-of-the-art performance by globally optimizing the tag sequence (Huang et al., 2015; Chen et al., 2016).

[6] In UD: Relation between the main verb of a clause and other sentential elements, such as sentential parenthetical clause, or adjacent sentences without any explicit coordination or subordination.

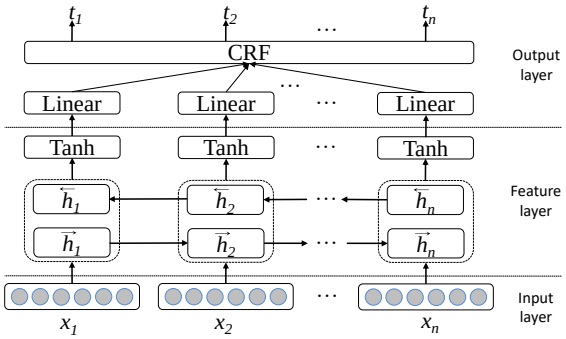

Figure 3: Base POS tagger

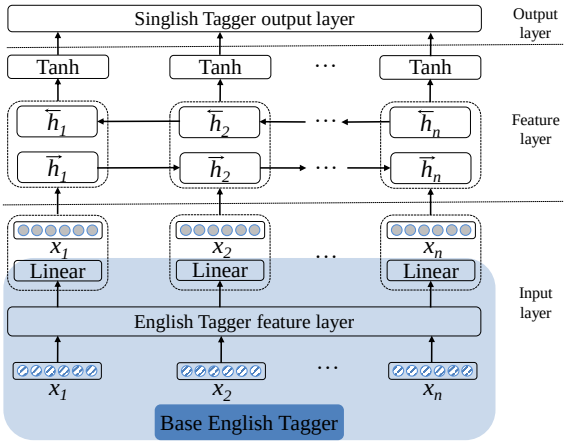

Figure 4: POS tagger with neural stacking

System	Accuracy
ENG-on-SIN	81.39%
Base-ICE-SIN	78.35%
Stack-ICE-SIN	**89.50%**

Table 2: POS tagging accuracies

Based on this English POS tagging model, we train a POS tagger for Singlish using the feature-level neural stacking model of Chen et al. (2016). Both the English and Singlish models consist of an input layer, a feature layer, and an output layer.

4.1 Base Bi-LSTM-CRF POS Tagger

Input Layer: Each token is represented as a vector by concatenating a word embedding from a lookup table with a weighted average of its character embeddings given by the attention model of Bahdanau et al. (2014). Following Chen et al. (2016), the input layer produces a dense representation for the current input token by concatenating its word vector and the ones for its surrounding context tokens in a window of finite size.

Feature Layer: This layer employs a bi-LSTM network to encode the input into a sequence of hidden vectors that embody global contextual information. Following Chen et al. (2016), we adopt bi-LSTM with peephole connections (Graves and Schmidhuber, 2005).

Output layer: This is a CRF layer to predict the POS tags for the input words by maximizing the conditional probability of the sequence of tags given input sentence.

4.2 POS Tagger with Neural Stacking

We adopt the deep integration neural stacking structure presented in Chen et al. (2016). As shown in Figure 4, the distributed vector representation for the target word at the input layer of the Singlish Tagger is augmented by concatenating the emission vector produced by the English Tagger with the original word and character-based embeddings, before applying the concatenation within a context window in section 4.1. During training, loss is back-propagated to all trainable parameters in both the Singlish Tagger and the pre-trained feature layer of the base English Tagger. At test time, the input sentence is fed to the integrated tagger model as a whole for inference.

4.3 Results

We use the publicly available source code[15] by Chen et al. (2016) to train a 1-layer bi-LSTM-CRF based POS tagger on UD-Eng, using 50-dimension pre-trained SENNA word embeddings (Collobert et al., 2011). We set the hidden layer size to 300, the initial learning rate for Adagrad (Duchi et al., 2011) to 0.01, the regularization parameter λ to 10^{-6}, and the dropout rate to 15%. The tagger gives 94.84% accuracy on the UD-Eng test set after 24 epochs, chosen according to development tests, which is comparable to the state-of-the-art accuracy of 95.17% reported by Plank et al. (2016). We use these settings to perform 10-fold jackknifing of POS tagging on the UD-Eng training set, with an average accuracy of 95.60%.

Similarly, we trained a POS tagger using the Singlish dependency treebank alone with pre-trained word embeddings on The Singapore Component of the International Corpus of English (ICE-SIN) (Nihilani, 1992; Ooi, 1997), which consists of both spoken and written texts. However, due to limited amount of training data, the

[15] https://github.com/chenhongshen/NNHetSeq

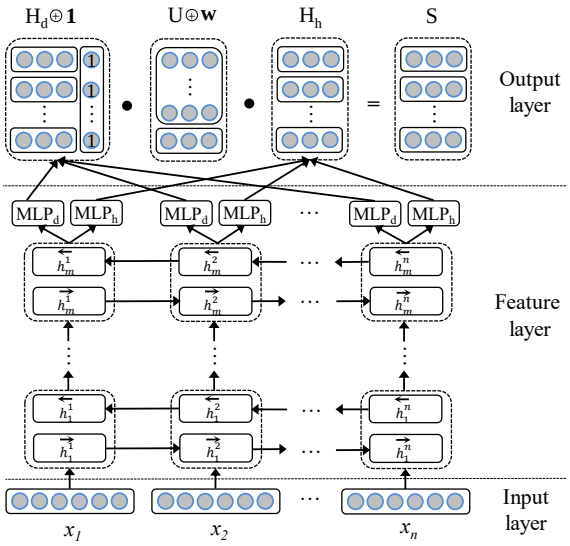

Figure 5: Base parser

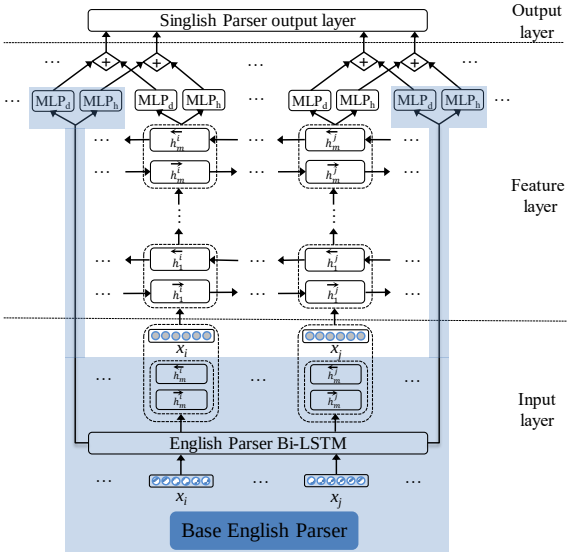

Figure 6: Parser with neural stacking

tagging accuracy is not satisfactory even with a larger dropout rate to avoid over-fitting. In contrast, the neural stacking structure on top of the English base model trained on UD-Eng achieves a POS tagging accuracy of 89.50%[16], which corresponds to a 51.50% relative error reduction over the baseline Singlish model, as shown in Table 2. We use this for 10-fold jackknifing on Singlish parsing training data, and tagging the Singlish development and test data.

5 Dependency Parsing

We adopt the Dozat and Manning (2017) parser[17] as our base model, as displayed in Figure 5, and apply neural stacking to achieve improvements over the baseline parser. Both the base and neural stacking models consist of an input layer, a feature layer, and an output layer.

5.1 Base Parser with Bi-affine Attentions

Input Layer: This layer encodes the current input word by concatenating a pre-trained word embedding with a trainable word embedding and POS tag embedding from the respective lookup tables.

Feature Layer: The two recurrent vectors produced by the multi-layer bi-LSTM network from each input vector are concatenated and mapped to multiple feature vectors in lower-dimension space by a set of parallel multilayer perceptron (MLP) layers. Following Dozat and Manning (2017), we adopt Cif-LSTM cells (Greff et al., 2016).

Output Layer: This layer applies biaffine transformation on the feature vectors to calculate the score of the directed arcs between every pair of words. The inferred trees for input sentence are formed by choosing the head with the highest score for each word and a cross-entropy loss is calculated to update the model parameters.

5.2 Parser with Neural Stacking

Inspired by the idea of feature-level neural stacking (Chen et al., 2016; Zhang and Weiss, 2016), we concatenate the pre-trained word embedding, trainable word and tag embeddings, with the two recurrent state vectors at the last bi-LSTM layer of the English Tagger as the input vector for each target word. In order to further preserve syntactic knowledge retained by the English Tagger, the feature vectors from its MLP layer is added to the ones produced by the Singlish Parser, as illustrated in Figure 6, and the scoring tensor of the Singlish Parser is initialized with the one from the trained English Tagger. Loss is back-propagated by reversely traversing all forward paths to all trainable parameter for training and the whole model is used collectively for inference.

6 Experiments

6.1 Experimental Settings

We train an English parser on UD-Eng with the default model settings in Dozat and Manning (2017).

[16] We empirically find that using ICE-SIN embeddings in neural stacking model performs better than using English SENNA embeddings. Similar findings are found for the parser, of which more details are given in section 6.

[17] https://github.com/tdozat/Parser

	Sentences	Words	Vocabulary
GloVe6B	N.A.	6000m	400,000
Giga100M	57,000	1.26m	54,554
ICE-SIN	87,084	1.26m	40,532

Table 3: Comparison of the scale of sources for training word embeddings

Trained on	System	UAS	LAS
English	ENG-on-SIN	75.89	65.62
Singlish	Baseline	75.98	66.55
	Base-Giga100M	77.67	67.23
	Base-GloVe6B	78.18	68.51
	Base-ICE-SIN	79.29	69.27
Both	ENG-plus-SIN	82.43	75.64
	Stack-ICE-SIN	**84.47**	**77.76**

Table 4: Dependency parser performances

It achieves an UAS of 88.83% and a LAS of 85.20%, which are close to the state-of-the-art 85.90% LAS on UD-Eng reported by Ammar et al. (2016), and the main difference is caused by us not using fine-grained POS tags. We apply the same settings for a baseline Singlish parser. We attempt to choose a better configuration of the number of bi-LSTM layers and the hidden dimension based on the development set performance, but the default settings turn out to perform the best. Thus we stick to all default hyper-parameters in Dozat and Manning (2017) for training the Singlish parsers.

We experimented with different word embeddings, as with the raw text sources summarized in Table 3 and further described in section 6.2. When using the neural stacking model, we fix the model configuration for the base English parser model and choose the size of the hidden vector and the number of bi-LSTM layers stacked on top based on the performance on the development set. It turns out that a 1-layer bi-LSTM with 900 hidden dimension performs the best, where the bigger hidden layer accommodates the elongated input vector to the stacked bi-LSTM and the fewer number of recurrent layers avoids over-fitting on the small Singlish dependency treebank, given the deep bi-LSTM English parser network at the bottom. The evaluation of the neural stacking model is further described in section 6.3.

System	UAS	LAS
Base-ICE-SIN	77.00	66.69
Stack-ICE-SIN	**82.43**	**73.96**

Table 5: Dependency parser performances by the 5-cross-fold validation

6.2 Investigating Distributed Lexical Characteristics

In order to learn characteristics of distributed lexical semantics for Singlish, we compare performances of the Singlish dependency parser using several sets of pre-trained word embeddings: GloVe6B, large-scale English word embeddings[18]; ICE-SIN, Singlish word embeddings trained using GloVe (Pennington et al., 2014) on the ICE-SIN (Nihilani, 1992; Ooi, 1997) corpus; Giga100M, a small-scale English word embeddings trained using GloVe (Pennington et al., 2014) with the same settings on a comparable size of English data randomly selected from the English Gigaword Fifth Edition for a fair comparison with ICE-SIN embeddings.

First, the English Giga100M embeddings marginally improve the Singlish parser from the baseline without pre-trained embeddings and also using the UD-Eng parser directly on Singlish, represented as "ENG-on-SIN" in Table 4. With much more English lexical semantics being fed to the Singlish parser using the English GloVe6B embeddings, further enhancement is achieved. Nevertheless, the Singlish ICE-SIN embeddings lead to even more improvement, with 13.78% relative error reduction, compared with 7.04% using the English Giga100M embeddings and 9.16% using the English GloVe6B embeddings, despite the huge difference in sizes in the latter case. This demonstrates the distributional differences between Singlish and English tokens, even though they share a large vocabulary. More detailed comparison is described in section 6.4.

6.3 Knowledge Transfer Using Neural Stacking

We train a parser with neural stacking and Singlish ICE-SIN embeddings, which achieves the best performance among all the models, with a UAS of 84.47%, represented as "Stack-ICE-SIN" in Table 4, which corresponds to 25.01% relative error reduction compared to the baseline. This demonstrates that knowledge from English can be successfully incorporated to boost the Singlish parser. To further evaluate the effectiveness of the neural stacking model, we also trained a base model with the combination of UD-Eng and the Singlish tree-

Table 6: Error analysis with respect to grammar types

bank, represented as "ENG-plus-SIN" in Table 4, which is still outperformed by the neural stacking model. Besides, we performed a 5-cross-fold validation for the base parser with Singlish ICE-SIN embeddings and the parser using neural stacking, where half of the held-out fold is used as the development set. The average UAS and LAS across the 5 folds shown in Table 5 and the relative error reduction on average 23.61% suggest that the overall improvement from knowledge transfer using neural stacking remains consistent. This significant improvement is further explained in section 6.4.

6.4 Improvements over Grammar Types

To analyze the sources of improvements for Singlish parsing using different model configurations, we conduct error analysis over 5 syntactic categories[19], including 4 types of grammars mentioned in section 3.2[20], and 1 for all other cases, including sentences containing imported vocabularies but expressed in basic English syntax. The number of sentences and the results in each group of the test set are shown in Table 6.

The neural stacking model leads to the biggest improvement over all categories except for a tie UAS performance on "NP Deletion" cases, which explains the significant overall improvement.

Comparing the base model with ICE-SIN embeddings with the base parser trained on UD-Eng, which contain syntactic and semantic knowledge in Singlish and English, respectively, the former outperforms the latter on all 4 types of Singlish grammars but not for the remaining samples. This suggests that the base English parser mainly contributes to analyzing basic English syntax, while the base Singlish parser models unique Singlish grammars better.

Similar trends are also observed on the base model using the English Giga100M embeddings, but the overall performances are not as good as using ICE-SIN embeddings, especially over basic English syntax where it undermines the performance to a greater extent. This suggests that only limited English distributed lexical semantic information can be integrated to help modelling Singlish syntactic knowledge due to the differences in distributed lexical semantics.

7 Conclusion

We have investigated dependency parsing for Singlish, an important English-based creole language, through annotations of a Singlish dependency treebank with 10,986 words and building an enhanced parser by leveraging on knowledge transferred from a 20-times-bigger English treebank of Universal Dependencies. We demonstrate the effectiveness of using neural stacking for feature transfer by boosting the Singlish dependency parsing performance to from UAS 79.29% to UAS 84.47%, with a 25.01% relative error reduction over the parser with all available Singlish resources. We release the annotated Singlish dependency treebank, the trained model and the source code for the parser with free public access. Possible future work include expanding the investigation to other regional languages such as Malay and Indonesian.

Generic Axiomatization of Families of Noncrossing Graphs in Dependency Parsing

Anssi Yli-Jyrä
University of Helsinki, Finland
anssi.yli-jyra@helsinki.fi

Carlos Gómez-Rodríguez
Universidade da Coruña, Spain
carlos.gomez@udc.es

Abstract

We present a simple encoding for unlabeled noncrossing graphs and show how its latent counterpart helps us to represent several families of directed and undirected graphs used in syntactic and semantic parsing of natural language as context-free languages. The families are separated purely on the basis of forbidden patterns in latent encoding, eliminating the need to differentiate the families of non-crossing graphs in inference algorithms: one algorithm works for all when the search space can be controlled in parser input.

1 Introduction

Dependency parsing has received wide attention in recent years, as accurate and efficient dependency parsers have appeared that are applicable to many languages. Traditionally, dependency parsers have produced syntactic analyses in tree form, including exact inference algorithms that search for maximum projective trees (Eisner and Satta, 1999) and maximum spanning trees (McDonald et al., 2005) in weighted digraphs, as well as greedy and beam-search approaches that forgo exact search for extra efficiency (Zhang and Nivre, 2011).

Recently, there has been growing interest in providing a richer analysis of natural language by going beyond trees. In semantic dependency parsing (Oepen et al., 2015; Kuhlmann and Oepen, 2016), the desired syntactic representations can have in-degree greater than 1 (re-entrancy), suggesting the search for maximum acyclic subgraphs (Schluter, 2014, 2015). As this inference task is intractable (Guruswami et al., 2011), noncrossing digraphs have been studied instead, e.g. by Kuhlmann and Johnsson (2015) who provide a $O(n^3)$ parser for maximum noncrossing acyclic subgraphs.

Yli-Jyrä (2005) studied how to axiomatize dependency trees as a special case of noncrossing digraphs. This gave rise to a new homomorphic representation of context-free languages that proves the classical Chomsky and Schützenberger theorem using a quite different internal language. In this language, the brackets indicate arcs in a dependency tree in a way that is reminiscent to encoding schemes used earlier by Greibach (1973) and Oflazer (2003). Cubic-time parsing algorithms that are incidentally or intentionally applicable to this kind of homomorphic representations have been considered, e.g., by Nederhof and Satta (2003), Hulden (2011), and Yli-Jyrä (2012).

Extending these insights to arbitrary noncrossing digraphs, or to relevant families of them, is far from obvious. In this paper, we develop (1) a *linear encoding* supporting general noncrossing digraphs, and (2) show that the encoded noncrossing digraphs form a *context-free language*. We then give it (3) two *homomorphic, nonderivative representations* and use the latent local features of the latter to characterize various families of digraphs.

Apart from the obvious relevance to the theory of context-free languages, this contribution has the practical potential to enable (4) *generic context-free parsers* that produce different families of noncrossing graphs with the same set of inference rules while the search space in each case is restricted with lexical features and the grammar.

Outline After some background on graphs and parsing as inference (Section 2), we use an **ontology of digraphs** to illustrate natural families of noncrossing digraphs in Section 3. We then develop, in Section 4, the first **latent context-free representation** for the set of noncrossing digraphs, then extended in Section 5 with additional latent states supporting our **finite-state axiomatization** of digraph properties, and allowing us to

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1745–1755

control the search space using the lexicon. The **experiments** in Section 6 cross-validate our axioms and sample the growth of the constrained search spaces. Section 7 outlines the applications for practical parsing, and Section 8 concludes.

2 Background

Graphs and Digraphs A *graph* is a pair (V,E) where V is a finite set of vertices and $E \subseteq \{\{u,v\} \subseteq V\}$ is a set of edges. A sequence of edges of the form $\{v_0,v_1\}$, $\{v_1,v_2\}$, ..., $\{v_{m-1},v_m\}$, with no repetitions in $v_1,...,v_m$, is a *path* between vertices v_0 and v_m and *empty* if $m = 0$. A graph is a *forest* if no vertex has a non-empty path to itself and *connected* if all pairs of vertices have a path. A *tree* is a connected forest.

A *digraph* is a pair (V,A) where $A \subseteq V \times V$ is a set of arcs $u \to v$, thus a *directed* graph. Its *underlying graph*, (V,E_A), has edges $E_A = \{\{u,v\} \mid (u,v) \in A\}$. A sequence of arcs $v_0 \to v_1, v_1 \to v_2, ..., v_{m-1} \to v_m$, with no repetitions in $v_1,\ldots,v_m$, is a *directed path*, and *empty* if $m = 0$.

A digraph without self-loops $v \to v$ is *loop-free* (property $\mathbf{DIGRAPH_{LF}}$). We will focus on loop-free digraphs unless otherwise specified, and denote them just by **DIGRAPH** for brevity. A digraph is d-acyclic ($\mathbf{ACYC_D}$), aka a *dag* if no vertex has a non-empty directed path to itself, *u-acyclic* ($\mathbf{ACYC_U}$) aka a *m(ixed)-forest* if its underlying graph is a forest, and *weakly connected* (w.c., $\mathbf{CONN_W}$) if its underlying graph is connected.

Dependency Parsing The *complete digraph* $G_S(V,A)$ *of a sentence* $S = x_1...x_n$ consists of vertices $V = \{1,...,n\}$ and all possible arcs $A = V \times V - \{(i,i)\}$. The vertex $i \in V$ corresponds to the word x_i and the arc $i \to j \in A$ corresponds to a possible dependency between the words x_i and x_j.

The task of *dependency parsing* is to find a constrained subgraph $G'_S(V,A')$ of the complete digraph G_S of the sentence. The standard solution is a rooted directed tree called a *dependency tree* or a dag called a *dependency graph*.

Constrained Inference In *arc-factored parsing* (McDonald et al., 2005), each possible arc $i \to j$ is equipped with a positive weight w_{ij}, usually computed as a weighted sum $w_{ij} = \mathbf{w} \cdot \Phi(S, i \to j)$ where $\mathbf{w}$ is a weight vector and $\Phi(\mathbf{x}, i \to j)$ a feature vector extracted from the sentence $\mathbf{x}$, considering the dependency relation from word x_i to word x_j. Parsing then consists in finding an arc subset $A' \subseteq A$ that gives us a constrained subgraph $(V,A') \in \text{Constrained}(V,A)$ of the complete digraph (V,A) with maximum sum of arc weights:

$$(V,A') = \underset{(V,A') \in \text{Constrained}(V,A)}{\arg\max} \sum_{i \to j \in A'} w_{i,j}.$$

The complexity of this inference task depends on the constraints imposed on the subgraph. Under no constraints, we simply set $A' = A$. Inference over dags is intractable (Guruswami et al., 2011). Efficient solutions are known for projective trees (Eisner, 1996), various classes of mildly non-projective trees (Gómez-Rodríguez, 2016), unrestricted spanning trees (McDonald et al., 2005), and both unrestricted and weakly connected non-crossing dags (Kuhlmann and Johnsson, 2015).

Parsimony Semantic parsers must be able to produce more than projective trees because the share of projective trees is pretty low (under 3%) in semantic graph banks (Kuhlmann and Johnsson, 2015). However, if we know that the parses have some restrictions, it is better to use them to restrict the search space as much as possible.

There are two strategies for reducing the search space. One is to develop a specialized inference algorithm for a particular natural language or family of dags, such as weakly connected graphs (Kuhlmann and Johnsson, 2015). The other strategy is to control the local complexity of digraphs through lexical categories (Baldridge and Kruijff, 2003) or equivalent mechanisms. This strategy produces a more sensitive model of the language, but requires a principled insight on how the complexity of digraphs can be characterized.

3 Constraints on the Search Space

We will now present a classification of digraphs on the basis of their formal properties.

The Noncrossing Property For convenience, graphs and digraphs may be ordered like in a complete digraph of a sentence. Two edges $\{i,j\}$, $\{k,l\}$ in an ordered graph or arcs $i \to j, k \to l$ in an ordered digraph are said to be *crossing* if $\min\{i,j\} < \min\{k,l\} < \max\{i,j\} < \max\{k,l\}$. A graph or digraph is *noncrossing* if it has no crossing edges or arcs. Noncrossing (di)graphs (**NC-(DI)GRAPH**) are the largest possible (di)graphs that can be drawn on a circle without crossing arcs. In the following, we assume that all digraphs and graphs are noncrossing.

An arc $x \to y$ is *(properly) covered by* an arc $z \to t$ if $(\{x,y\} \neq \{z,t\})$ and $\min\{z,t\} \leq \min\{x,y\} \leq \max\{x,y\} \leq \max\{z,t\}$.

Ontology Fig. 1 presents an ontology of such families of loop-free noncrossing digraphs that can be distinguished by digraphs with 5 vertices.

In the digraph ontology, a *multitree* aka mangrove is a dag with the property of being *strongly unambiguous* (**UNAMB**$_{\mathrm{S}}$), which asserts that, given two distinct vertices, there is at most one repeat-free path between them (Lange, 1997).[1] A *polytree* (Rebane and Pearl, 1987) is a multitree whose underlying graph is a tree. The *out* property (**OUT**) of a digraph (V,E) means that no vertex $i \in V$ has two incoming arcs $\{j,k\} \to i$ s.t. $j \neq k$.

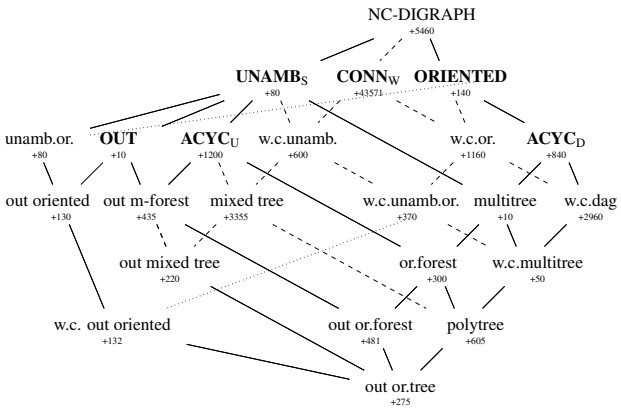

Figure 1: Basic properties split the set of 62464 noncrossing digraphs for 5 vertices into 23 classes

An ordered digraph is *weakly projective* (**PROJ**$_{\mathrm{W}}$) if for all vertices i, j and k, if $k \to j \to i$, then either $\{i,j\} < k$ or $\{i,j\} > k$. In other words, the constraint, aka the *outside-to-inside constraint* (Yli-Jyrä, 2005), states that no outgoing arc of a vertex properly covers an incoming arc. This is implied by a stronger constraint known as *Harper, Hays, Lecerf and Ihm projectivity* (Marcus, 1967).

We can embed the ontology of graphs (unrestricted, connected, forests and trees) into the ontology of digraphs by viewing an undirected graph (V,E) as an inverse digraph $(V, \{(i,j),(j,i) \mid \{i,j\} \in E\})$. This kind of digraph has an *inverse property* (**INV**). Its opposite is an *oriented (or.)* digraph (V,A) where $i \to j \in A$ implies $j \to i \notin A$ (defines the property **ORIENTED**). Out forests and trees are, by convention, oriented digraphs with an underlying forest or tree, respectively.

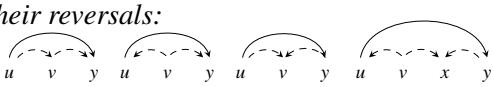
[1] A different definition forbids diamonds as minors.

Distinctive Properties A few important properties of digraphs are local and can be verified by inspecting each vertex separately with its incident arcs. These include (i) the out property (**OUT**), (ii) the nonstandard projectivity property (**PROJ**$_{\mathrm{W}}$), (iii) the inverse property (**INV**) and (iv) the orientedness (or.) property.

Properties **UNAMB**$_{\mathrm{S}}$, **ACYC**$_{\mathrm{D}}$, **CONN**$_{\mathrm{W}}$, and **ACYC**$_{\mathrm{U}}$ are nonlocal properties of digraphs and cannot be generally verified locally, through finite spheres of vertices (Grädel et al., 2005). The following proposition covers the configurations that we have to detect in order to decide the nonlocal properties of noncrossing digraphs.

Proposition 1. *Let $G = (V,E)$ be a noncrossing digraph.*

- *If $G \notin$ **UNAMB**$_S$, then the digraph contains one of the following four configurations or their reversals:*



- *If $G \notin$ **ACYC**$_D$, then the graph contains one of the configurations*

- *If $G \notin$ **ACYC**$_U$, then the underlying graph contains the following configuration:*

- *If $G \notin$ **CONN**$_W$, then the underlying graph contains one of the following configurations:*

Proposition 1 gives us a means to implement the property tests in practice. It tells us intuitively that although the paths can be arbitrarily long, any underlying cycle containing more than 2 arcs consists of one covering arc and a linear chain of edges between its end points.

4 The Set of Digraphs as a Language

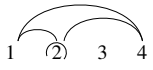
In this section, we show that the set of noncrossing digraphs is isomorphic to an unambiguous context-free language over a bracket alphabet.

4.1 Basic Encoding

Any noncrossing ordered graph $([1,\ldots,n],E)$, even with self-loops, can be encoded as a string of brackets using the algorithm `enc` in Fig. 2. For example, the output for the ordered graph

```
func enc(n,E):                    func dec(stdin):
  for i in [1,...,n]:               n = 1; E = {}; s = []
    for j in [i-1,...,2,1]:         while c in stdin:
      if {j,i} in E:                   if c == "[":
        print "]"                         s.push(n)
    for j in [n,n-1,...,i+1]:           if c == "]":
      if {i,j} in E:                       i = s.pop()
        print "["                          E.insert((i,n))
    if {i,i} in E:                      if c == "{":
      print "[]"                           n = n + 1
    if i<n:
      print "{}"                        return (n,E)
```

Figure 2: The encoding and decoding algorithms



$$n = 4, \quad E = \begin{Bmatrix} \{1,2\}, & \{2,2\} \\ \{2,4\}, & \{1,4\} \end{Bmatrix}$$

is the string `[[{}][[]{}{}]]`. Intuitively, pairs of brackets of the form {} can be interpreted as spaces between vertices, and then each set of matching brackets `[...]` encodes an arc that covers the spaces represented inside the brackets.

Any noncrossing ordered digraph $([1,\ldots,n],A)$ can be encoded with slight modifications to the algorithm. Instead of printing `[ ]` for an edge $\{i,j\} \in E_A$, $i \le j$, the algorithm should now print

$$\begin{array}{ll} \texttt{/ >} & \text{if } (i,j) \in A, (j,i) \notin A; \\ \texttt{< \textbackslash} & \text{if } (i,j) \notin A, (j,i) \in A; \\ \texttt{[ ]} & \text{if } (i,j), (j,i) \in A. \end{array}$$

In this way, we can simply encode the digraph $(\{1,2,3,4\}, \{(1,2),(2,2),(4,1),(4,2)\})$ as the string `</{}><[]{}{}\\`.

Proposition 2. *The encoding respects concatenation where the adjacent nonempty operands have a common vertex.*

Context-Freeness Arbitrary strings with balanced brackets form a context-free language that is known, generically, as a Dyck language. It is easy to see that the graphs **NC-GRAPH** are encoded with strings that belong to the Dyck language D_2 generated by the context-free grammar: $S \to \texttt{[}S\texttt{]}S \mid \{S\}S \mid \varepsilon$. The *encoded graphs*, $L_{\textbf{NC-GRAPH}}$, are, however, generated exactly by the context-free grammar $S \to \texttt{[}S'\texttt{]}\ S \mid \{\}\ S \mid \varepsilon$, $S' \to \texttt{[}S'\texttt{]}\ T \mid \{\}\ S$, $T \to \texttt{[}S'\texttt{]}\ S \mid \{\}\ S$. This language is an *unambiguous* context-free language.

Proposition 3. *The encoded graphs, $L_{\textbf{NC-GRAPH}}$, make an unambiguous context-free language.*

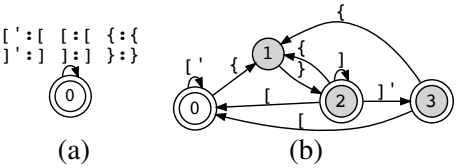
The practical significance of Proposition 3 is that there is a bijection between $L_{\textbf{NC-GRAPH}}$ and the derivation trees of a context-free grammar.

4.2 Bracketing Beyond the Encoding

Non-Derivational Representation A non-derivational representation for any context-free language L has been given by Chomsky and Schützenberger (1963). This replaces the stack with a Dyck language D and the grammar rules with co-occurrence patterns specified by a regular language *Reg*. To hide the internal alphabet from the strings of the represented language, there is a homomorphism that cleans the internal strings of *Reg* and D from internal markup to get actual strings of the target language:

$$L_{\textbf{NC-GRAPH}} = h(D \cap Reg).$$

To make this concrete, replace the previous context free grammar by $S'' \to \texttt{[}'S'\texttt{]}'\ S \mid \{\}\ S \mid \varepsilon$, $S \to \texttt{[}S'\texttt{]}\ S \mid \{\}\ S \mid \varepsilon$, $S' \to \texttt{[}'S'\texttt{]}'\ T \mid \{\}\ S$, $T \to \texttt{[}S'\texttt{]}\ S \mid \{\}\ S$. The homomorphism h (Fig. 3a) would now relate this language to the original language, mapping the string `['['{}]'[['{}]'{}]]'` to the string `[[{}][[{}]{}]]`, for example. The Dyck language $D = D_3$ checks that the internal brackets are balanced, and the regular component *Reg* (Fig. 3b) checks that the new brackets are used correctly. A similar representation for the language $L_{\textbf{NC-DIGRAPH}}$ of encoded digraphs can be obtained with straightforward extensions.



(a) (b)

Figure 3: The h and *Reg* components

The representation $L = h(D \cap Reg)$ is *unambiguous* if, for every word $w \in L$, the preimage $h^{-1}(w) \cap D \cap Reg$ is a single string. This implies that L is an *unambiguous* context-free language.

Proposition 4. *The set of encoded digraphs, $L_{\textbf{NC-DIGRAPH}}$, has an unambiguous representation.*

Proposition 5. *Let $L_i = h(D \cap R_i)$, $i \in \{0,1,2\}$ be unambiguous representations with $R_1, R_2 \subseteq R_0$. Then $L_3 = h(D \cap (R_1 \cap R_2))$ is an unambiguous context-free language and the same as $L_1 \cap L_2$.*

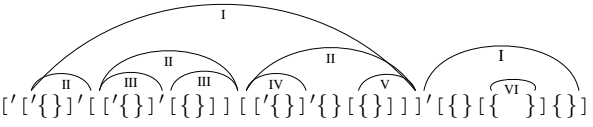
Proof. It is immediate that $L_3 \subseteq L_1 \cap L_2$ and L_3 is an unambiguous context-free language. To show that $L_1 \cap L_2 \subseteq L_3$, take an arbitrary $s \in L_1 \cap L_2$. Since $R_1, R_2 \subseteq R_0$ there is a unique $s' \in h^{-1}(s)$ such that $s' \in D \cap (R_1 \cap R_2)$. Thus $s \in L_3$. □

5 Latent Bracketing

In this section, we extend the internal strings of the non-derivational representation of $L_{\textbf{NC-DIGRAPH}}$ in

such a way that the configurations given in Proposition 1 can be detected locally from these.

Classification of Underlying Chains A *maximal linear chain* is a maximally long sequence of one or more edges that correspond to an underlying left-to-right path in the underlying graph in such a way that no edge in this chain is properly covered by an edge that does not properly cover all the edges in the chain. For example, the graph



contains six maximal linear chains, indicated with their Roman numbers on each arc. We decide nonlocal properties of noncrossing digraphs by recognizing maximal linear chains as parts of configurations presented in Proposition 1.

Every *loose* chain (like V and VI) starts with a bracket that is adjacent to a }-bracket. Such a chain can contribute only a covering edge to an underlying cycle. In contrast, a bracket with an apostrophe marks the beginning of a *non-loose* chain that can either start at the first vertex, or share starting point with a covering chain. When a nonloose chain is covered, it can be touched twice by a covering edge. The prefixes of chains are classified incrementally, from left to right, with a finite automaton (Figure 4). All states of the automaton are final and correspond to distinct classes of the chains. These classes are encoded to an extended set of brackets.

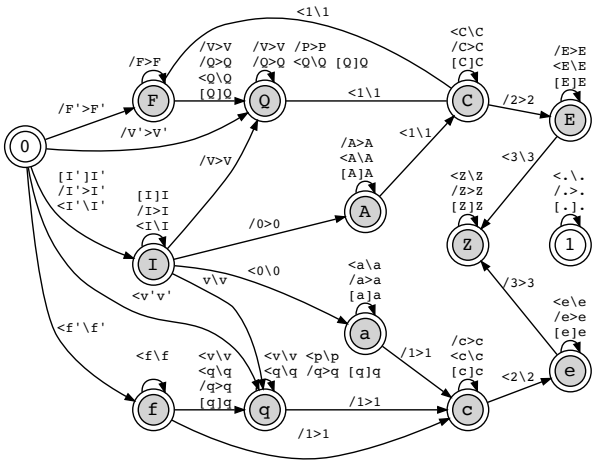


Figure 4: The finite automaton whose state 0 begins non-loose chains and state 1 loose chains

The automaton is symmetric: states with uppercase names are symmetrically related with corresponding lowercase states. Thus, it suffices to define the initial and uppercase-named states:

0	the initial state for a non-loose chain;
I	a bidirectional chain: $u \leftrightarrow (v \leftrightarrow)y$;
A	a primarily bidirectional forward chain: $u \leftrightarrow v \rightarrow y$;
F	a forward chain: $u \rightarrow v \rightarrow y$;
Q	a primarily forward chain: $u \rightarrow v \leftrightarrow (\cdots \rightarrow)y$;
C	a primarily forward 1-turn chain: $u \rightarrow v \leftarrow y$;
E	a primarily forward 2-turn chain: $u \rightarrow v \leftarrow x \rightarrow y$;
Z	a 3-turn chain;
1	the initial (and only) state for a loose chain;

Recognition of ambiguous paths in configurations $u\overleftrightarrow{\rightarrow\rightarrow}v \leftarrow y$ and $u\overleftarrow{\leftarrow v \rightarrow x \leftarrow \leftarrow}y$ involves three chain levels. To support the recognition, subtypes of edges are defined according to the chains they cover. The brackets >I', \I', >I, \I, \A, >a, \Q, >Q, >q,\q, >C, \c, \E, >e indicate edges that constitute a cycle with the chain they cover. The brackets >V', \v', >V, \v indicate edges that cover 2-turn chains. Not all states make these distinctions.

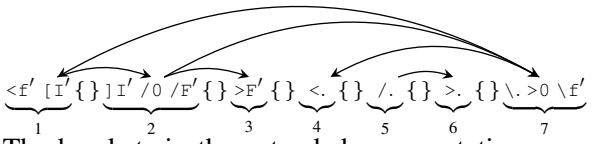
Extended Representation The extended brackets encode the latent structure of digraphs: the orientation and the subtype of the edge and the class of the chain. The total alphabet Σ of the strings now contains the boundary brackets {} and 54 pairs of brackets (Figure 4) for edges from which we obtain a new Dyck language, D_{55}, and an extended homomorphism h_{lat}.

The *Reg* component of the language representation is replaced with Reg_{lat}, that is, an intersection of (1) an inverse homomorphic image of *Reg* to strings over the extended alphabet, (2) a local language that constrains adjacent edges according to Figure 4, (3) a local language specifying how the chains start, and (4) a local language that distinguishes pure oriented edges from those that cover a cycle or a 2-turn chain. The new component requires only 24 states as a deterministic automaton.

Proposition 6. *$h_{lat}(D_{55} \cap Reg_{lat})$ is an unambiguous representation for $L_{\text{NC-DIGRAPH}}$.*

The internal language $L_{\text{NC-DIGRAPH}_{\text{lat}}} = D_{55} \cap Reg_{\text{lat}}$ is called the set of *latent encoded digraphs*.

Example Here is a digraph with its latent encoding:



The brackets in the extended representation contain information that helps us recognize, through local patterns, that this graph has a directed cycle

Forbidden patterns in noncrossing digraphs	Property	Constraint language
	**ACYC**$_{\text{U}}$	$A_U = \Sigma^* - \Sigma^* R_{\overline{\text{loose}}} R \Sigma^*$
	CONN$_{\text{W}}$	$C_W = \Sigma^* - \Sigma^* R_{\text{loose}}(\varepsilon \cup B\Sigma^*) - (B\Sigma^* \cup \Sigma^* B)$
	ACYC$_{\text{D}}$	$A_D = \Sigma^* - \Sigma^*(R_{\text{right}}R_{\setminus} \cup R_{\text{left}}R_{>} \cup \Sigma_{\text{inv}})\Sigma^*$
	UNAMB$_{\text{S}}$	$U_S = \Sigma^* - \Sigma^*(R_{\text{right}}R_{>} \cup R_{\text{left}}R_{\setminus} \cup R_{\text{vergent}}R)\Sigma^*$ $-\Sigma^*(R_{\text{left2}}R_{>} \cup R_{\text{right2}}R_{\setminus})\Sigma^*$
	PROJ$_{\text{W}}$	$P_W = \Sigma^* - \Sigma^*(L_{/}L_{<} \cup R_{>}R_{\setminus})\Sigma^*$
(an arc without inverse)	**INV**	$I = \Sigma^* - \Sigma^*\Sigma_{\text{or}}\Sigma^*$
(a state with more than 2 incoming arcs)	**OUT**	$Out = \Sigma^* - \Sigma^*\Sigma_{\text{in}}(\Sigma - B)^*\Sigma_{\text{in}}\Sigma^*$
(an inverted edge)	**ORIENTED**	$O = \Sigma^* - \Sigma^*\Sigma_{\text{inv}}\Sigma^*$

Table 1: Properties of encoded noncrossing digraphs as constraint languages

(directed path $1 \to 2 \to 7 \to 1$), is strongly ambiguous (two directed paths $2 \to 1$ and $2 \to 7 \to 1$) and is not weakly connected (vertices 5 and 6 are not connected to the rest of the digraph).

Expressing Properties via Forbidden Patterns We now demonstrate that all the mentioned nonlocal properties of graphs have become local in the extended internal representation of the code strings $L_{\text{NC-DIGRAPH}}$ for noncrossing digraphs.

These distinctive properties of graph families reduce to forbidden patterns in bracket strings and then compile into regular constraint languages. These are presented in Table 1. To keep the patterns simple, subsets of brackets are defined:

$L_{/}$	`[`-,/-brackets	$L_{<}$	`[`-,<-brackets
$R_{>}$	`]`-,>-brackets	$R_{\setminus}$	`]`-,\-brackets
B	{, }	R	$R_{>} \cup R_{\setminus}$
R_{loose}	}, `>.`, `\.`, `].`	$R_{\overline{\text{loose}}}$	$R - R_{\text{loose}}$
R_{right}	R reaching `F,Q,I,A`	R_{left}	R reaching `f,q,i,a`
R_{right2}	`>P`, `>2`, `>E`, `\E`, `]E`	R_{left2}	`\p`, `\2`, `\e`, `>e`, `]e`
Σ_{in}	$L_{<} \cup R_{>}$	$\overline{B}$	$\Sigma - B$
R_{vergent}	non-' R reaching `I,Q,q,A,a,C,c`		
Σ_{or}	all brackets for oriented edges		
Σ_{inv}	all brackets for inverted edges		

6 Validation Experiments

The current experiments were designed (1) to help in developing the components of Reg_{lat} and the constraint languages of axiomatic properties, (2) to validate the representation, the constraint languages and their unambiguity, (3) to learn about the ontology and (4) to sample the integer sequences associated with the cardinality of each family in the ontology.

Finding the Components Representations of Reg_{lat} were built with scripts written using a finite-state toolkit (Hulden, 2009) that supports rapid exploration with regular languages and transducers.

Validation of Languages Our scripts presented alternative approaches to compute languages of encoded digraphs with n vertices up to $n = 9$. We also implemented a Python script that enumerated elements of families of graphs up to $n = 6$. The solutions were used to cross-validate one another.

The constraint $G_n = \overline{B}^*(\{\}\overline{B}^*)^{n-1}$ ensures n-vertices in encoded digraphs. The finite set of encoded acyclic 5-vertex digraphs was computed with a finite-state approach (Yli-Jyrä et al., 2012) that takes the input projection of the composition

$$\text{Id}(Reg_{lat} \cap A_D \cap G_5) \circ T_{55} \circ T_{55} \circ T_{55} \circ T_{55} \circ T_{55} \circ \text{Id}(\varepsilon)$$

where Id defines an identity relation and transducer T_{55} eliminates matching adjacent brackets. This composition differs from the typical use where the purpose is to construct a regular relation (Kaplan and Kay, 1994) or its output projection (Roche, 1996; Oflazer, 2003).

For digraphs with a lot of vertices, we had an option to employ a dynamic programming scheme (Yli-Jyrä, 2012) that uses weighted transducers.

Building the Ontology To build the ontology in Figure 1 we first found out which combinations of digraph properties co-occur to define distinguishable families of digraphs. After the nodes of the

lattice were found, we were able to see the partial order between these.

Integer Sequences We sampled, for important families of digraphs, the prefixes of their related integer sequences. We found out that each family of graphs is pretty much described by its cardinality, see Table 2. In many cases, the number sequence was already well documented (OEIS Foundation Inc., 2017).

7 The Formal Basis of Practical Parsing

While presenting a practical parser implementation is outside of the scope of this paper, which focuses in the theory, we outline in this section the aspects to take into account when applying our representation to build practical natural language parsers.

Positioned Brackets In order to do inference in arc-factored parsing, we incorporate weights to the representation. For each vertex in G_n, the brackets are decorated with the respective position number. Then, we define an input-specific grammar representation where each pair of brackets in D gets an arc-factored weight given the directions and the vertex numbers associated with the brackets.

Grammar Intersection We associate, to each G_n, a quadratic-size context-free grammar that generates all noncrossing digraphs with n vertices. This grammar is obtained by computing (or even precomputing) the intersection $D_{55} \cap Reg_{\text{lat}} \cap G_n$ in any order, exploiting the closure of context-free languages under intersection with regular languages (Bar-Hillel et al., 1961). The introduction of the position numbers and weights in the Dyck language gives us, instead, a weighted grammar and its intersection (Lang, 1994). This grammar is a compact representation for a finite set of weighted latent encoded digraphs. Additional constraints during the intersection tailors the grammar to different families of digraphs.

Dynamic Programming The heaviest digraph is found with a dynamic programming algorithm that computes, for each nonterminal in the grammar, the weight of the heaviest subtree. A careful reader may notice some connections to Eisner algorithm (Eisner and Satta, 1999), context-free parsing through intersection (Nederhof and Satta, 2003), and a dynamic programming scheme that uses contracting transducers and factorized composition (Yli-Jyrä, 2012). Unfortunately, space does not permit discussing the connections here.

Lexicalized Search Space In practical parsing, we want the parser behavior and the dependency structure to be sensitive to the lexical entries or features of each word. We can replace the generic vertex description $\overline{B}^*$ in G_n with subsets that depend on respective lexical entries. Graphical constraints can be applied to some vertices but relaxed for others. This application of current results gives a principled, graphically motivated solution to lexicalized control over the search space.

8 Conclusion

We have investigated the search space of parsers that produce noncrossing digraphs. Parsers that can be adapted to different needs are less dependent on artificial assumptions on the search space. Adaptivity gives us freedom to model how the properties of digraphs are actually distributed in linguistic data. As the adaptive data analysis deserves to be treated in its own right, the current work focuses on the separation of the parsing algorithm from the properties of the search space.

This paper makes four significant contributions.

Contribution 1: Digraph Encoding The paper introduces, for noncrossing digraphs, an encoding that uses brackets to indicate edges.

Bracketed trees are widely used in generative syntax, treebanks and structured document formats. There are established conversions between phrase structure and projective dependency trees, but the currently advocated edge bracketing is expressive and captures more than just projective dependency trees. This capacity is welcome as syntactic and semantic analysis with dependency graphs is a steadily growing field.

The edge bracketing creates new avenues for the study of connections between noncrossing graphs and context-free languages, as well as their recognizable properties. By demonstrating that digraphs can be treated as strings, we suggest that practical parsing to these structures could be implemented with existing methods that restrict context-free grammars to a regular yield language.

Contribution 2: Context-Free Properties Acyclicity and other important properties of noncrossing digraphs are expressible as unambiguous context-free sets of encoded noncrossing

digraphs. This facilitates the incorporation of property testing to dynamic programming algorithms that implement exact inference.

Descriptive complexity helps us understand to which degree various graphical properties are local and could be incorporated into efficient dynamic programming during exact inference. It is well known that acyclicity and connecticity are not definable in first-order logic (FO) while they can be defined easily in monadic second order logic (MSO) (Courcelle, 1997). MSO involves set-valued variables whose use in dynamic programming algorithms and tabular parsing is inefficient. MSO queries have a brute force transformation to first-order (FO) logic, but this does not generally help either as it is well known that MSO can express intractable problems.

The interesting observation of the current work is that some MSO definable properties of digraphs become local in our extended encoding. This encoding is linear compared to the size of digraphs: each string over the extended bracket alphabet encodes a fixed assignment of MSO variables. The properties of noncrossing digraphs now reduce to properties of bracketed trees with linear amount of latent information that is fixed for each digraph.

```
func noncrossing_ACYCU(n,E):
   for {u,y} in E and u < y:     # covering edge
      [v,p] = [u,u]
      while p != -1:             # chain continues
         [v,p] = [p,-1]
         for vv in [v+1,...,y]: # next vertex
            if {v,vv} in E and {v,vv} != {u,y}:
               if vv == y:
                  return False  # found cycle uvy
               p = vv           # find longest edge
   return True                  # acyclic
```

Figure 5: Testing $\mathbf{ACYC}_{\mathrm{U}}$ in logarithmic space

A deeper explanation for our observation comes from the fact that the treewidth of noncrossing and other outerplanar graphs is bounded to 2. When the treewidth is bounded, all MSO definable properties, including the intractable ones, become linear time decidable for individual structures (Courcelle, 1990). They can also be decided in a logarithmic amount of writable space (Elberfeld et al., 2010), e.g. with element indices instead of sets. By combining this insight with Proposition 1, we obtain a logspace solution for testing acyclicity of a noncrossing graph (Figure 5).

Although bounded treewidth is a weaker constraint than so-called bounded treedepth that would immediately guarantee first-order definabil-

ity (Elberfeld et al., 2016), it can sometimes turn intractable search problems to dynamic programming algorithms (Akutsu and Tamura, 2012). In our case, Proposition 1 gave rise to unambiguous context-free subsets of $L_{\text{NC-DIGRAPH}}$. These can be recognized with dynamic programming and used in efficient constrained inference when we add vertex indices to the brackets and weights to the grammar of the corresponding Dyck language.

Contribution 3: Digraph Ontology The context-free properties of encoded digraphs have elegant nonderivative language representations and they generate a semi-lattice under language intersection. Although context-free languages are not generally closed under intersection, all combinations of the properties in this lattice are context-free and define natural families of digraphs. The nonderivative representations for our axiomatic properties share the same Dyck language D_{55} and homomorphism, but differ in terms of forbidden patterns. As a consequence, also any conjunctive combination of these two properties shares these components and thus define a context-free language. The obtained semilattice is an ontology of families of noncrossing digraphs.

Our ontology contains important families of noncrossing digraphs used in syntactic and semantic dependency parsing: out trees, dags, and weakly connected digraphs. It shows the entailment between the properties and proves the existence of less known families of noncrossing digraphs such as strongly unambiguous digraphs and oriented graphs, multitrees, oriented forests and polytrees. These are generalizations of out oriented trees. However, these families can still be weakly projective. Table 2 shows integer sequences obtained by enumerating digraphs in each family. At least twelve of these sequences are previously known, which indicates that the families are natural.

We used a finite-state toolkit to build the components of the nongenerative language representation for latent encoded digraphs and the axioms.[2]

Contribution 4: Generic Parsing The fourth contribution of this paper is to show that parsing algorithms can be separated from the formal properties of their search space.

All the presented families of digraphs can be treated by parsers and other algorithms (e.g. enumeration algorithms) in a uniform manner. The parser's inference rules can stay constant and the choice of the search space is made by altering the regular component of the language representation.

The ontology of the search space can be combined with a constraint relaxation strategy, for example, when an out tree is a preferred analysis, but a dag is also possible as an analysis when no tree is strong enough. The flexibility applies also to dynamic programming algorithms that complement with the encoding and allow inference of best dependency graphs in a family simply by intersection with a weighted CFG grammar for a Dyck language that models position-indexed edges of the complete digraph.

Since the families of digraphs are distinguished by forbidden local patterns, the choice of search space can be made purely on lexical grounds, blending well with lexicalized parsing and allowing possibilities such as choosing, per each word, what kind of structures the word can go with.

Future work We are planning to extend the coverage of the approach by exploring 1-endpoint-crossing and MH_k trees (Pitler et al., 2013; Gómez-Rodríguez, 2016), and related digraphs — see (Yli-Jyrä, 2004; Gómez-Rodríguez et al., 2011). Properties such as *weakly projective*, *out*, and *strongly unambiguous* prompt further study.

An interesting avenue for future work is to explore higher order factorizations for noncrossing digraphs and the related inference. We would also like to have more insight on the transformation of MSO definable properties to the current framework and to logspace algorithms.

Semi-supervised sequence tagging with bidirectional language models

Matthew E. Peters, Waleed Ammar, Chandra Bhagavatula, Russell Power

Abstract

Pre-trained word embeddings learned from unlabeled text have become a standard component of neural network architectures for NLP tasks. However, in most cases, the recurrent network that operates on word-level representations to produce context sensitive representations is trained on relatively little labeled data. In this paper, we demonstrate a general semi-supervised approach for adding pre-trained context embeddings from bidirectional language models to NLP systems and apply it to sequence labeling tasks. We evaluate our model on two standard datasets for named entity recognition (NER) and chunking, and in both cases achieve state of the art results, surpassing previous systems that use other forms of transfer or joint learning with additional labeled data and task specific gazetteers.

1 Introduction

Due to their simplicity and efficacy, pre-trained word embedding have become ubiquitous in NLP systems. Many prior studies have shown that they capture useful semantic and syntactic information (Mikolov et al., 2013; Pennington et al., 2014) and including them in NLP systems has been shown to be enormously helpful for a variety of downstream tasks (Collobert et al., 2011).

However, in many NLP tasks it is essential to represent not just the meaning of a word, but also the word in context. For example, in the two phrases "A Central Bank spokesman" and "The Central African Republic", the word 'Central' is used as part of both an Organization and Location. Accordingly, current state of the art sequence tagging models typically include a bidirectional recurrent neural network (RNN) that encodes token sequences into a context sensitive representation before making token specific predictions (Yang et al., 2017; Ma and Hovy, 2016; Lample et al., 2016; Hashimoto et al., 2016).

Although the token representation is initialized with pre-trained embeddings, the parameters of the bidirectional RNN are typically learned only on labeled data. Previous work has explored methods for jointly learning the bidirectional RNN with supplemental labeled data from other tasks (e.g., Søgaard and Goldberg, 2016; Yang et al., 2017).

In this paper, we explore an alternate semi-supervised approach which does not require additional labeled data. We use a neural language model (LM), pre-trained on a large, unlabeled corpus to compute an encoding of the context at each position in the sequence (hereafter an *LM embedding*) and use it in the supervised sequence tagging model. Since the LM embeddings are used to compute the probability of future words in a neural LM, they are likely to encode both the semantic and syntactic roles of words in context.

Our main contribution is to show that the context sensitive representation captured in the LM embeddings is useful in the supervised sequence tagging setting. When we include the LM embeddings in our system overall performance increases from 90.87% to 91.93% F_1 for the CoNLL 2003 NER task, a more then 1% absolute F1 increase, and a substantial improvement over the previous state of the art. We also establish a new state of the art result (96.37% F_1) for the CoNLL 2000 Chunking task.

As a secondary contribution, we show that using both forward and backward LM embeddings boosts performance over a forward only LM. We also demonstrate that domain specific pre-training is not necessary by applying a LM trained in the news domain to scientific papers.

2 Language model augmented sequence taggers (TagLM)

2.1 Overview

The main components in our language-model-augmented sequence tagger (TagLM) are illustrated in Fig. 1. After pre-training word embeddings and a neural LM on large, unlabeled corpora (Step 1), we extract the word and LM embeddings for every token in a given input sequence (Step 2) and use them in the supervised sequence tagging model (Step 3).

2.2 Baseline sequence tagging model

Our baseline sequence tagging model is a hierarchical neural tagging model, closely following a number of recent studies (Ma and Hovy, 2016; Lample et al., 2016; Yang et al., 2017; Chiu and Nichols, 2016) (left side of Figure 2).

Given a sentence of tokens $(t_1, t_2, \ldots, t_N)$ it first forms a representation, $\mathbf{x}_k$, for each token by concatenating a character based representation $\mathbf{c}_k$ with a token embedding $\mathbf{w}_k$:

$$\begin{aligned} \mathbf{c}_k &= C(t_k; \theta_c) \\ \mathbf{w}_k &= E(t_k; \theta_w) \\ \mathbf{x}_k &= [\mathbf{c}_k; \mathbf{w}_k] \end{aligned} \quad (1)$$

The character representation $\mathbf{c}_k$ captures morphological information and is either a convolutional neural network (CNN) (Ma and Hovy, 2016; Chiu and Nichols, 2016) or RNN (Yang et al., 2017; Lample et al., 2016). It is parameterized by $C(\cdot, \theta_c)$ with parameters θ_c. The token embeddings, $\mathbf{w}_k$, are obtained as a lookup $E(\cdot, \theta_w)$, initialized using pre-trained word embeddings, and fine tuned during training (Collobert et al., 2011).

To learn a context sensitive representation, we employ multiple layers of bidirectional RNNs. For each token position, k, the hidden state $\mathbf{h}_{k,i}$ of RNN layer i is formed by concatenating the hidden states from the forward ($\overrightarrow{\mathbf{h}}_{k,i}$) and backward ($\overleftarrow{\mathbf{h}}_{k,i}$) RNNs. As a result, the bidirectional RNN is able to use both past and future information to make a prediction at token k. More formally, for the first RNN layer that operates on $\mathbf{x}_k$ to output $\mathbf{h}_{k,1}$:

$$\begin{aligned} \overrightarrow{\mathbf{h}}_{k,1} &= \overrightarrow{R}_1(\mathbf{x}_k, \overrightarrow{\mathbf{h}}_{k-1,1}; \theta_{\overrightarrow{R}_1}) \\ \overleftarrow{\mathbf{h}}_{k,1} &= \overleftarrow{R}_1(\mathbf{x}_k, \overleftarrow{\mathbf{h}}_{k+1,1}; \theta_{\overleftarrow{R}_1}) \\ \mathbf{h}_{k,1} &= [\overrightarrow{\mathbf{h}}_{k,1}; \overleftarrow{\mathbf{h}}_{k,1}] \end{aligned} \quad (2)$$

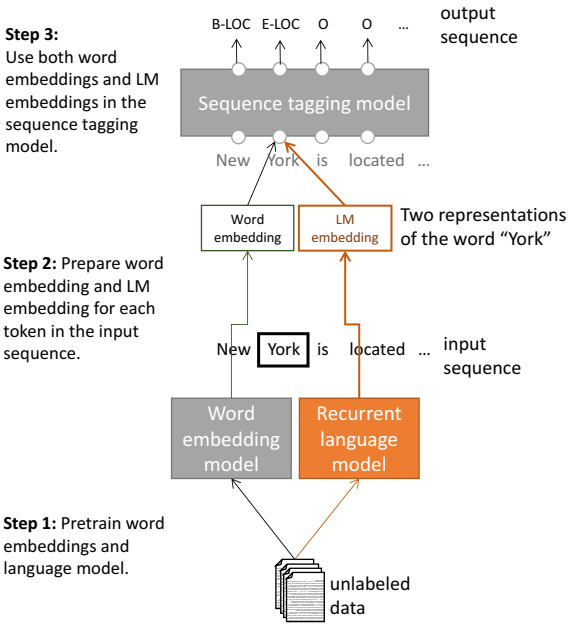

Figure 1: The main components in TagLM, our language-model-augmented sequence tagging system. The language model component (in orange) is used to augment the input token representation in a traditional sequence tagging models (in grey).

The second RNN layer is similar and uses $\mathbf{h}_{k,1}$ to output $\mathbf{h}_{k,2}$. In this paper, we use $L = 2$ layers of RNNs in all experiments and parameterize R_i as either Gated Recurrent Units (GRU) (Cho et al., 2014) or Long Short-Term Memory units (LSTM) (Hochreiter and Schmidhuber, 1997) depending on the task.

Finally, the output of the final RNN layer $\mathbf{h}_{k,L}$ is used to predict a score for each possible tag using a single dense layer. Due to the dependencies between successive tags in our sequence labeling tasks (e.g. using the BIOES labeling scheme, it is not possible for `I-PER` to follow `B-LOC`), it is beneficial to model and decode each sentence jointly instead of independently predicting the label for each token. Accordingly, we add another layer with parameters for each label bigram, computing the sentence conditional random field (CRF) loss (Lafferty et al., 2001) using the forward-backward algorithm at training time, and using the Viterbi algorithm to find the most likely tag sequence at test time, similar to Collobert et al. (2011).

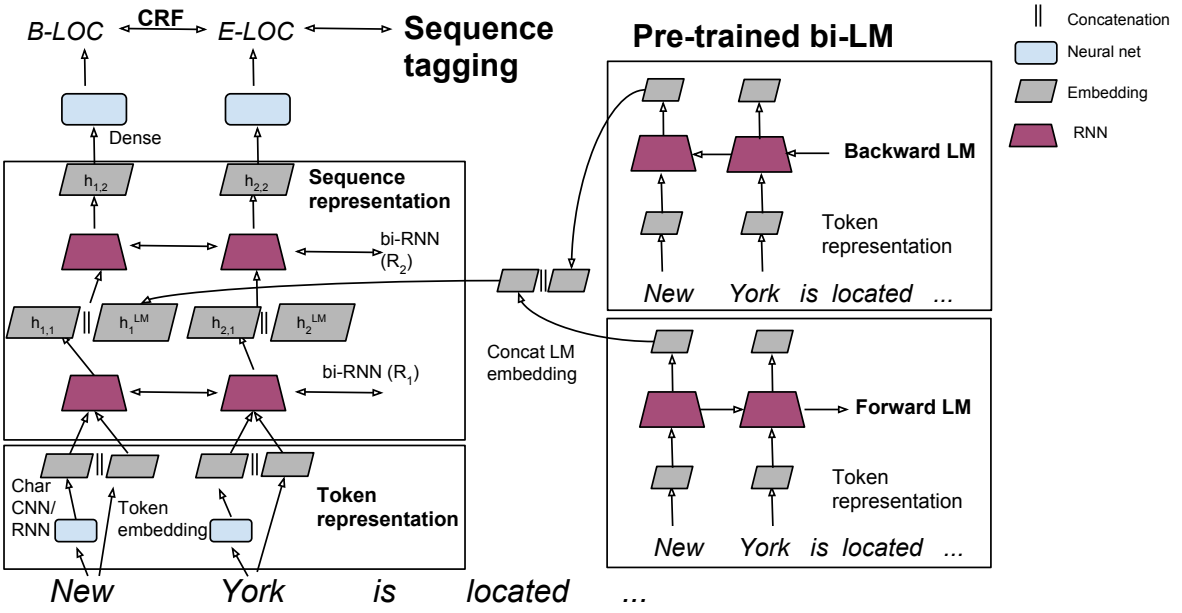

Figure 2: Overview of TagLM, our language model augmented sequence tagging architecture. The top level embeddings from a pre-trained bidirectional LM are inserted in a stacked bidirectional RNN sequence tagging model. See text for details.

2.3 Bidirectional LM

A language model computes the probability of a token sequence $(t_1, t_2, \ldots, t_N)$

$$p(t_1, t_2, \ldots, t_N) = \prod_{k=1}^{N} p(t_k \mid t_1, t_2, \ldots, t_{k-1}).$$

Recent state of the art neural language models (Józefowicz et al., 2016) use a similar architecture to our baseline sequence tagger where they pass a token representation (either from a CNN over characters or as token embeddings) through multiple layers of LSTMs to embed the history $(t_1, t_2, \ldots, t_k)$ into a fixed dimensional vector $\overrightarrow{\mathbf{h}}_k^{LM}$. This is the *forward LM embedding* of the token at position k and is the output of the top LSTM layer in the language model. Finally, the language model predicts the probability of token t_{k+1} using a softmax layer over words in the vocabulary.

The need to capture future context in the LM embeddings suggests it is beneficial to also consider a *backward* LM in additional to the traditional *forward* LM. A backward LM predicts the previous token given the future context. Given a sentence with N tokens, it computes

$$p(t_1, t_2, \ldots, t_N) = \prod_{k=1}^{N} p(t_k \mid t_{k+1}, t_{k+2}, \ldots, t_N).$$

A backward LM can be implemented in an analogous way to a forward LM and produces the *backward LM embedding* $\overleftarrow{\mathbf{h}}_k^{LM}$, for the sequence $(t_k, t_{k+1}, \ldots, t_N)$, the output embeddings of the top layer LSTM.

In our final system, after pre-training the forward and backward LMs separately, we remove the top layer softmax and concatenate the forward and backward LM embeddings to form bidirectional LM embeddings, i.e., $\mathbf{h}_k^{LM} = [\overrightarrow{\mathbf{h}}_k^{LM}; \overleftarrow{\mathbf{h}}_k^{LM}]$. Note that in our formulation, the forward and backward LMs are independent, without any shared parameters.

2.4 Combining LM with sequence model

Our combined system, TagLM, uses the LM embeddings as additional inputs to the sequence tagging model. In particular, we concatenate the LM embeddings $\mathbf{h}^{LM}$ with the output from one of the bidirectional RNN layers in the sequence model. In our experiments, we found that introducing the LM embeddings at the output of the first layer performed the best. More formally, we simply replace (2) with

$$\mathbf{h}_{k,1} = [\overrightarrow{\mathbf{h}}_{k,1}; \overleftarrow{\mathbf{h}}_{k,1}; \mathbf{h}_k^{LM}]. \quad (3)$$

There are alternate possibilities for adding the LM embeddings to the sequence model. One pos-

sibility adds a non-linear mapping after the concatenation and before the second RNN (e.g. replacing (3) with $f([\overrightarrow{\mathbf{h}}_{k,1}; \overleftarrow{\mathbf{h}}_{k,1}; \mathbf{h}_k^{LM}])$ where f is a non-linear function). Another possibility introduces an attention-like mechanism that weights the all LM embeddings in a sentence before including them in the sequence model. Our initial results with the simple concatenation were encouraging so we did not explore these alternatives in this study, preferring to leave them for future work.

3 Experiments

We evaluate our approach on two well benchmarked sequence tagging tasks, the CoNLL 2003 NER task (Sang and Meulder, 2003) and the CoNLL 2000 Chunking task (Sang and Buchholz, 2000). We report the official evaluation metric (micro-averaged F_1). In both cases, we use the BIOES labeling scheme for the output tags, following previous work which showed it outperforms other options (e.g., Ratinov and Roth, 2009). Following Chiu and Nichols (2016), we use the Senna word embeddings (Collobert et al., 2011) and pre-processed the text by lowercasing all tokens and replacing all digits with 0.

CoNLL 2003 NER. The CoNLL 2003 NER task consists of newswire from the Reuters RCV1 corpus tagged with four different entity types (`PER`, `LOC`, `ORG`, `MISC`). It includes standard train, development and test sets. Following previous work (Yang et al., 2017; Chiu and Nichols, 2016) we trained on both the train and development sets after tuning hyperparameters on the development set.

The hyperparameters for our baseline model are similar to Yang et al. (2017). We use two bidirectional GRUs with 80 hidden units and 25 dimensional character embeddings for the token character encoder. The sequence layer uses two bidirectional GRUs with 300 hidden units each. For regularization, we add 25% dropout to the input of each GRU, but not to the recurrent connections.

CoNLL 2000 chunking. The CoNLL 2000 chunking task uses sections 15-18 from the Wall Street Journal corpus for training and section 20 for testing. It defines 11 syntactic chunk types (e.g., `NP`, `VP`, `ADJP`) in addition to `other`. We randomly sampled 1000 sentences from the training set as a held-out development set.

The baseline sequence tagger uses 30 dimensional character embeddings and a CNN with 30 filters of width 3 characters followed by a tanh non-linearity for the token character encoder. The sequence layer uses two bidirectional LSTMs with 200 hidden units. Following Ma and Hovy (2016) we added 50% dropout to the character embeddings, the input to each LSTM layer (but not recurrent connections) and to the output of the final LSTM layer.

Pre-trained language models. The primary bidirectional LMs we used in this study were trained on the 1B Word Benchmark (Chelba et al., 2014), a publicly available benchmark for large-scale language modeling. The training split has approximately 800 million tokens, about a 4000X increase over the number training tokens in the CoNLL datasets. Józefowicz et al. (2016) explored several model architectures and released their best single model and training recipes. Following Sak et al. (2014), they used linear projection layers at the output of each LSTM layer to reduce the computation time but still maintain a large LSTM state. Their single best model took three weeks to train on 32 GPUs and achieved 30.0 test perplexity. It uses a character CNN with 4096 filters for input, followed by two stacked LSTMs, each with 8192 hidden units and a 1024 dimensional projection layer. We use `CNN-BIG-LSTM` to refer to this language model in our results.

In addition to `CNN-BIG-LSTM` from Józefowicz et al. (2016),[1] we used the same corpus to train two additional language models with fewer parameters: forward `LSTM-2048-512` and backward `LSTM-2048-512`. Both language models use token embeddings as input to a single layer LSTM with 2048 units and a 512 dimension projection layer. We closely followed the procedure outlined in Józefowicz et al. (2016), except we used synchronous parameter updates across four GPUs instead of asynchronous updates across 32 GPUs and ended training after 10 epochs. The test set perplexities for our forward and backward `LSTM-2048-512` language models are 47.7 and 47.3, respectively.[2]

[1] `https://github.com/tensorflow/models/tree/master/lm_1b`

[2] Due to different implementations, the perplexity of the forward LM with similar configurations in Józefowicz et al. (2016) is different (45.0 vs. 47.7).

Model	$F_1 \pm$ std
Chiu and Nichols (2016)	90.91 ± 0.20
Lample et al. (2016)	90.94
Ma and Hovy (2016)	91.37
Our baseline without LM	90.87 ± 0.13
TagLM	$\mathbf{91.93 \pm 0.19}$

Table 1: Test set F_1 comparison on CoNLL 2003 NER task, using only CoNLL 2003 data and unlabeled text.

Model	$F_1 \pm$ std
Yang et al. (2017)	94.66
Hashimoto et al. (2016)	95.02
Søgaard and Goldberg (2016)	95.28
Our baseline without LM	95.00 ± 0.08
TagLM	$\mathbf{96.37 \pm 0.05}$

Table 2: Test set F_1 comparison on CoNLL 2000 Chunking task using only CoNLL 2000 data and unlabeled text.

Training. All experiments use the Adam optimizer (Kingma and Ba, 2015) with gradient norms clipped at 5.0. In all experiments, we fine tune the pre-trained Senna word embeddings but fix all weights in the pre-trained language models. In addition to explicit dropout regularization, we also use early stopping to prevent over-fitting and use the following process to determine when to stop training. We first train with a constant learning rate $\alpha = 0.001$ on the training data and monitor the development set performance at each epoch. Then, at the epoch with the highest development performance, we start a simple learning rate annealing schedule: decrease α an order of magnitude (i.e., divide by ten), train for five epochs, decrease α an order of magnitude again, train for five more epochs and stop.

Following Chiu and Nichols (2016), we train each final model configuration ten times with different random seeds and report the mean and standard deviation F_1. It is important to estimate the variance of model performance since the test data sets are relatively small.

3.1 Overall system results

Tables 1 and 2 compare results from TagLM with previously published state of the art results without additional labeled data or task specific gazetteers. Tables 3 and 4 compare results of TagLM to other systems that include additional labeled data or gazetteers. In both tasks, TagLM establishes a new state of the art using bidirectional LMs (the forward `CNN-BIG-LSTM` and the backward `LSTM-2048-512`).

In the CoNLL 2003 NER task, our model scores 91.93 mean F_1, which is a statistically significant increase over the previous best result of 91.62 $\pm$0.33 from Chiu and Nichols (2016) that used gazetteers (at 95%, two-sided Welch t-test, $p = 0.021$).

In the CoNLL 2000 Chunking task, TagLM achieves 96.37 mean F_1, exceeding all previously published results without additional labeled data by more then 1% absolute F_1. The improvement over the previous best result of 95.77 in Hashimoto et al. (2016) that jointly trains with Penn Treebank (PTB) POS tags is statistically significant at 95% ($p < 0.001$ assuming standard deviation of 0.1).

Importantly, the LM embeddings amounts to an average absolute improvement of 1.06 and 1.37 F_1 in the NER and Chunking tasks, respectively.

Adding external resources. Although we do not use external labeled data or gazetteers, we found that TagLM outperforms previous state of the art results in both tasks when external resources (labeled data or task specific gazetteers) are available. Furthermore, Tables 3 and 4 show that, in most cases, the improvements we obtain by adding LM embeddings are larger then the improvements previously obtained by adding other forms of transfer or joint learning. For example, Yang et al. (2017) noted an improvement of only 0.06 F_1 in the NER task when transfer learning from both CoNLL 2000 chunks and PTB POS tags and Chiu and Nichols (2016) reported an increase of 0.71 F_1 when adding gazetteers to their baseline. In the Chunking task, previous work has reported from 0.28 to 0.75 improvement in F_1 when including supervised labels from the PTB POS tags or CoNLL 2003 entities (Yang et al., 2017; Søgaard and Goldberg, 2016; Hashimoto et al., 2016).

3.2 Analysis

To elucidate the characteristics of our LM augmented sequence tagger, we ran a number of additional experiments on the CoNLL 2003 NER task.

How to use LM embeddings? In this experiment, we concatenate the LM embeddings at dif-

Model	External resources	F_1 Without	F_1 With	Δ
Yang et al. (2017)	transfer from CoNLL 2000/PTB-POS	91.2	91.26	+0.06
Chiu and Nichols (2016)	with gazetteers	90.91	91.62	+0.71
Collobert et al. (2011)	with gazetteers	88.67	89.59	+0.92
Luo et al. (2015)	joint with entity linking	89.9	91.2	**+1.3**
Ours	no LM vs TagLM *unlabeled data only*	90.87	**91.93**	+1.06

Table 3: Improvements in test set F_1 in CoNLL 2003 NER when including additional labeled data or task specific gazetteers (except the case of TagLM where we do not use additional labeled resources).

Model	External resources	F_1 Without	F_1 With	Δ
Yang et al. (2017)	transfer from CoNLL 2003/PTB-POS	94.66	95.41	+0.75
Hashimoto et al. (2016)	jointly trained with PTB-POS	95.02	95.77	+0.75
Søgaard and Goldberg (2016)	jointly trained with PTB-POS	95.28	95.56	+0.28
Ours	no LM vs TagLM *unlabeled data only*	95.00	**96.37**	**+1.37**

Table 4: Improvements in test set F_1 in CoNLL 2000 Chunking when including additional labeled data (except the case of TagLM where we do not use additional labeled data).

Use LM embeddings at	$F_1 \pm$ std
input to the first RNN layer	91.55 ± 0.21
output of the first RNN layer	$\mathbf{91.93 \pm 0.19}$
output of the second RNN layer	91.72 ± 0.13

Table 5: Comparison of CoNLL-2003 test set F_1 when the LM embeddings are included at different layers in the baseline tagger.

ferent locations in the baseline sequence tagger. In particular, we used the LM embeddings $\mathbf{h}_k^{LM}$ to:

- augment the *input* of the *first* RNN layer; i.e., $\mathbf{x}_k = [\mathbf{c}_k; \mathbf{w}_k; \mathbf{h}_k^{LM}]$,
- augment the *output* of the *first* RNN layer; i.e., $\mathbf{h}_{k,1} = [\overrightarrow{\mathbf{h}}_{k,1}; \overleftarrow{\mathbf{h}}_{k,1}; \mathbf{h}_k^{LM}]$,[3] and
- augment the *output* of the *second* RNN layer; i.e., $\mathbf{h}_{k,2} = [\overrightarrow{\mathbf{h}}_{k,2}; \overleftarrow{\mathbf{h}}_{k,2}; \mathbf{h}_k^{LM}]$.

Table 5 shows that the second alternative performs best. We speculate that the second RNN layer in the sequence tagging model is able to capture interactions between task specific context as expressed in the first RNN layer and general context as expressed in the LM embeddings in a way that improves overall system performance. These results are consistent with Søgaard and Goldberg (2016) who found that chunking performance was sensitive to the level at which additional POS supervision was added.

Does it matter which language model to use? In this experiment, we compare six different configurations of the forward and backward language models (including the baseline model which does not use any language models). The results are reported in Table 6.

We find that adding backward LM embeddings consistently outperforms forward-only LM embeddings, with F_1 improvements between 0.22 and 0.27%, even with the relatively small backward `LSTM-2048-512` LM.

LM size is important, and replacing the forward `LSTM-2048-512` with `CNN-BIG-LSTM` (test perplexities of 47.7 to 30.0 on 1B Word Benchmark) improves F_1 by 0.26 - 0.31%, about as much as adding backward LM. Accordingly, we hypothesize (but have not tested) that replacing the backward `LSTM-2048-512` with a backward LM analogous to the `CNN-BIG-LSTM` would further improve performance.

To highlight the importance of including language models trained on a large scale data, we also experimented with training a language model on just the CoNLL 2003 training and development data. Due to the much smaller size of this data

[3]This configuration the same as Eq. 3 in §2.4. It was reproduced here for convenience.

Forward language model	Backward language model	LM perplexity		$F_1 \pm$ std
		Fwd	Bwd	
—	—	N/A	N/A	90.87 ± 0.13
LSTM-512-256*	LSTM-512-256*	106.9	104.2	90.79 ± 0.15
LSTM-2048-512	—	47.7	N/A	91.40 ± 0.18
LSTM-2048-512	LSTM-2048-512	47.7	47.3	91.62 ± 0.23
CNN-BIG-LSTM	—	30.0	N/A	91.66 ± 0.13
CNN-BIG-LSTM	LSTM-2048-512	30.0	47.3	$\mathbf{91.93 \pm 0.19}$

Table 6: Comparison of CoNLL-2003 test set F_1 for different language model combinations. All language models were trained and evaluated on the 1B Word Benchmark, except LSTM-512-256* which was trained and evaluated on the standard splits of the NER CoNLL 2003 dataset.

set, we decreased the model size to 512 hidden units with a 256 dimension projection and normalized tokens in the same manner as input to the sequence tagging model (lower-cased, with all digits replaced with 0). The test set perplexities for the forward and backward models (measured on the CoNLL 2003 test data) were 106.9 and 104.2, respectively. Including embeddings from these language models *decreased* performance slightly compared to the baseline system without any LM. This result supports the hypothesis that adding language models help because they learn composition functions (i.e., the RNN parameters in the language model) from much larger data compared to the composition functions in the baseline tagger, which are only learned from labeled data.

Importance of task specific RNN. To understand the importance of including a task specific sequence RNN we ran an experiment that removed the task specific sequence RNN and used only the LM embeddings with a dense layer and CRF to predict output tags. In this setup, performance was very low, 88.17 F_1, well below our baseline. This result confirms that the RNNs in the baseline tagger encode essential information which is not encoded in the LM embeddings. This is unsurprising since the RNNs in the baseline tagger are trained on labeled examples, unlike the RNN in the language model which is only trained on unlabeled examples. Note that the LM weights are fixed in this experiment.

Dataset size. *A priori*, we expect the addition of LM embeddings to be most beneficial in cases where the task specific annotated datasets are small. To test this hypothesis, we replicated the setup from Yang et al. (2017) that samples 1% of the CoNLL 2003 training set and compared the performance of TagLM to our baseline without LM. In this scenario, test F_1 increased 3.35% (from 67.66 to 71.01%) compared to an increase of 1.06% F_1 for a similar comparison with the full training dataset. The analogous increases in Yang et al. (2017) are 3.97% for cross-lingual transfer from CoNLL 2002 Spanish NER and 6.28% F_1 for transfer from PTB POS tags. However, they found only a 0.06% F_1 increase when using the full training data and transferring from both CoNLL 2000 chunks and PTB POS tags. Taken together, this suggests that for very small labeled training sets, transferring from other tasks yields a large improvement, but this improvement almost disappears when the training data is large. On the other hand, our approach is less dependent on the training set size and significantly improves performance even with larger training sets.

Number of parameters. Our TagLM formulation increases the number of parameters in the second RNN layer R_2 due to the increase in the input dimension $\mathbf{h}_1$ if all other hyperparameters are held constant. To confirm that this did not have a material impact on the results, we ran two additional experiments. In the first, we trained a system without a LM but increased the second RNN layer hidden dimension so that number of parameters was the same as in TagLM. In this case, performance *decreased* slightly (by 0.15% F_1) compared to the baseline model, indicating that solely increasing parameters does not improve performance. In the second experiment, we decreased the hidden dimension of the second RNN layer in TagLM to give it the same number of parameters as the baseline no LM model. In this case, test F_1 *increased* slightly to 92.00 ± 0.11 indicating that the additional parameters in TagLM are slightly hurting

performance.[4]

Does the LM transfer across domains? One artifact of our evaluation framework is that both the labeled data in the chunking and NER tasks and the unlabeled text in the 1 Billion Word Benchmark used to train the bidirectional LMs are derived from news articles. To test the sensitivity to the LM training domain, we also applied TagLM with a LM trained on news articles to the SemEval 2017 Shared Task 10, ScienceIE.[5] ScienceIE requires end-to-end joint entity and relationship extraction from scientific publications across three diverse fields (computer science, material sciences, and physics) and defines three broad entity types (Task, Material and Process). For this task, TagLM increased F_1 on the development set by 4.12% (from 49.93 to to 54.05%) for entity extraction over our baseline without LM embeddings and it was a major component in our winning submission to ScienceIE, Scenario 1 (Ammar et al., 2017). We conclude that LM embeddings can improve the performance of a sequence tagger even when the data comes from a different domain.

4 Related work

Unlabeled data. TagLM was inspired by the widespread use of pre-trained word embeddings in supervised sequence tagging models. Besides pre-trained word embeddings, our method is most closely related to Li and McCallum (2005). Instead of using a LM, Li and McCallum (2005) uses a probabilistic generative model to infer context-sensitive latent variables for each token, which are then used as extra features in a supervised CRF tagger (Lafferty et al., 2001). Other semi-supervised learning methods for structured prediction problems include co-training (Blum and Mitchell, 1998; Pierce and Cardie, 2001), expectation maximization (Nigam et al., 2000; Mohit and Hwa, 2005), structural learning (Ando and Zhang, 2005) and maximum discriminant functions (Suzuki et al., 2007; Suzuki and Isozaki, 2008). It is easy to combine TagLM with any of the above methods by including LM embeddings as additional features in the discriminative components of the model (except for expectation maximization). A detailed discussion of semi-supervised learning methods in NLP can be found in (Søgaard, 2013).

Melamud et al. (2016) learned a context encoder from unlabeled data with an objective function similar to a bi-directional LM and applied it to several NLP tasks closely related to the unlabeled objective function: sentence completion, lexical substitution and word sense disambiguation.

LM embeddings are related to a class of methods (e.g., Le and Mikolov, 2014; Kiros et al., 2015; Hill et al., 2016) for learning sentence and document encoders from unlabeled data, which can be used for text classification and textual entailment among other tasks. Dai and Le (2015) pre-trained LSTMs using language models and sequence autoencoders then fine tuned the weights for classification tasks. In contrast to our method that uses unlabeled data to learn token-in-context embeddings, all of these methods use unlabeled data to learn an encoder for an entire text sequence (sentence or document).

Neural language models. LMs have always been a critical component in statistical machine translation systems (Koehn, 2009). Recently, neural LMs (Bengio et al., 2003; Mikolov et al., 2010) have also been integrated in neural machine translation systems (e.g., Kalchbrenner and Blunsom, 2013; Devlin et al., 2014) to score candidate translations. In contrast, TagLM uses neural LMs to encode words in the input sequence.

Unlike forward LMs, bidirectional LMs have received little prior attention. Most similar to our formulation, Peris and Casacuberta (2015) used a bidirectional neural LM in a statistical machine translation system for instance selection. They tied the input token embeddings and softmax weights in the forward and backward directions, unlike our approach which uses two distinct models without any shared parameters. Frinken et al. (2012) also used a bidirectional n-gram LM for handwriting recognition.

Interpreting RNN states. Recently, there has been some interest in interpreting the activations of RNNs. Linzen et al. (2016) showed that single LSTM units can learn to predict singular-plural distinctions. Karpathy et al. (2015) visualized character level LSTM states and showed that individual cells capture long-range dependencies such as line lengths, quotes and brackets. Our work complements these studies by showing that LM states are useful for downstream tasks as a way

[4] A similar experiment for the Chunking task did not improve F_1 so this conclusion is task dependent.

[5] https://scienceie.github.io/

of interpreting what they learn.

Other sequence tagging models. Current state of the art results in sequence tagging problems are based on bidirectional RNN models. However, many other sequence tagging models have been proposed in the literature for this class of problems (e.g., Lafferty et al., 2001; Collins, 2002). LM embeddings could also be used as additional features in other models, although it is not clear whether the model complexity would be sufficient to effectively make use of them.

5 Conclusion

In this paper, we proposed a simple and general semi-supervised method using pre-trained neural language models to augment token representations in sequence tagging models. Our method significantly outperforms current state of the art models in two popular datasets for NER and Chunking. Our analysis shows that adding a backward LM in addition to traditional forward LMs consistently improves performance. The proposed method is robust even when the LM is trained on unlabeled data from a different domain, or when the baseline model is trained on a large number of labeled examples.

Learning Symmetric Collaborative Dialogue Agents with Dynamic Knowledge Graph Embeddings

Abstract

We study a *symmetric collaborative dialogue* setting in which two agents, each with private knowledge, must strategically communicate to achieve a common goal. The open-ended dialogue state in this setting poses new challenges for existing dialogue systems. We collected a dataset of 11K human-human dialogues, which exhibits interesting lexical, semantic, and strategic elements. To model both structured knowledge and unstructured language, we propose a neural model with dynamic knowledge graph embeddings that evolve as the dialogue progresses. Automatic and human evaluations show that our model is both more effective at achieving the goal and more human-like than baseline neural and rule-based models.

1 Introduction

Current task-oriented dialogue systems (Young et al., 2013; Wen et al., 2017; Dhingra et al., 2017) require a pre-defined dialogue state (e.g., slots such as food type and price range for a restaurant searching task) and a fixed set of dialogue acts (e.g., request, inform). However, human conversation often requires richer dialogue states and more nuanced, pragmatic dialogue acts. Recent open-domain chat systems (Shang et al., 2015; Serban et al., 2015b; Sordoni et al., 2015; Li et al., 2016a; Lowe et al., 2017; Mei et al., 2017) learn a mapping directly from previous utterances to the next utterance. While these models capture open-ended aspects of dialogue, the lack of structured dialogue state prevents them from being directly applied to settings that require interfacing with structured knowledge.

In order to bridge the gap between the two types of systems, we focus on a *symmetric collaborative dialogue* setting, which is task-oriented but encourages open-ended dialogue acts. In our setting, two agents, each with a private list of items with attributes, must communicate to identify the unique shared item. Consider the dialogue in Figure 1, in which two people are trying to find their mutual friend. By asking "do you have anyone who went to columbia?", B is suggesting that she has some Columbia friends, and that they probably work at Google. Such conversational implicature is lost when interpreting the utterance as simply an information request. In addition, it is hard to define a structured state that captures the diverse semantics in many utterances (e.g., defining "most of", "might be"; see details in Table 1).

To model both structured and open-ended context, we propose the *Dynamic Knowledge Graph Network* (DynoNet), in which the dialogue state is modeled as a knowledge graph with an embedding

Friends of agent A:

Name	School	Major	Company
Jessica	Columbia	Computer Science	Google
Josh	Columbia	Linguistics	Google
...	...	...	...

A: Hi! Most of my friends work for Google
B: do you have anyone who went to columbia?
A: *Hello?*
A: I have Jessica a friend of mine
A: and Josh, both went to columbia
B: *or anyone working at apple?*
B: SELECT (Jessica, Columbia, Computer Science, Google)
A: SELECT (Jessica, Columbia, Computer Science, Google)

Figure 1: An example dialogue from the MutualFriends task in which two agents, A and B, each given a private list of a friends, try to identify their mutual friend. Our objective is to build an agent that can perform the task with a human. Crosstalk (Section 2.3) is *italicized*.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1766–1776
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1162

for each node (Section 3). Our model is similar to EntNet (Henaff et al., 2017) in that node/entity embeddings are updated recurrently given new utterances. The difference is that we structure entities as a knowledge graph; as the dialogue proceeds, new nodes are added and new context is propagated on the graph. An attention-based mechanism (Bahdanau et al., 2015) over the node embeddings drives generation of new utterances. Our model's use of knowledge graphs captures the grounding capability of classic task-oriented systems and the graph embedding provides the representational flexibility of neural models.

The naturalness of communication in the symmetric collaborative setting enables large-scale data collection: We were able to crowdsource around 11K human-human dialogues on Amazon Mechanical Turk (AMT) in less than 15 hours.[1] We show that the new dataset calls for more flexible representations beyond fully-structured states (Section 2.2).

In addition to conducting the third-party human evaluation adopted by most work (Liu et al., 2016; Li et al., 2016b,c), we also conduct partner evaluation (Wen et al., 2017) where AMT workers rate their conversational partners (other workers or our models) based on fluency, correctness, cooperation, and human-likeness. We compare DynoNet with baseline neural models and a strong rule-based system. The results show that DynoNet can perform the task with humans efficiently and naturally; it also captures some strategic aspects of human-human dialogues.

The contributions of this work are: (i) a new symmetric collaborative dialogue setting and a large dialogue corpus that pushes the boundaries of existing dialogue systems; (ii) DynoNet, which integrates semantically rich utterances with structured knowledge to represent open-ended dialogue states; (iii) multiple automatic metrics based on bot-bot chat and a comparison of third-party and partner evaluation.

2 Symmetric Collaborative Dialogue

We begin by introducing a collaborative task between two agents and describe the human-human dialogue collection process. We show that our data exhibits diverse, interesting language phenomena.

[1]The dataset is available publicly at https://stanfordnlp.github.io/cocoa/.

2.1 Task Definition

In the symmetric collaborative dialogue setting, there are two agents, A and B, each with a private knowledge base—KB_A and KB_B, respectively. Each knowledge base includes a list of *items*, where each item has a value for each *attribute*. For example, in the MutualFriends setting, Figure 1, items are friends and attributes are name, school, etc. There is a shared item that A and B both have; their goal is to converse with each other to determine the shared item and select it. Formally, an agent is a mapping from its private KB and the dialogue thus far (sequence of utterances) to the next utterance to generate or a selection. A dialogue is considered *successful* when both agents correctly select the shared item. This setting has parallels in human-computer collaboration where each agent has complementary expertise.

2.2 Data collection

We created a schema with 7 attributes and approximately 3K entities (attribute values). To elicit linguistic and strategic variants, we generate a random scenario for each task by varying the number of items (5 to 12), the number attributes (3 or 4), and the distribution of values for each attribute (skewed to uniform). See Appendix A and B for details of schema and scenario generation.

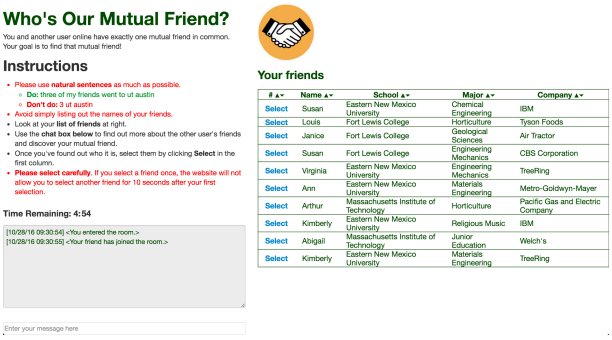

Figure 2: Screenshot of the chat interface.

We crowdsourced dialogues on AMT by randomly pairing up workers to perform the task within 5 minutes.[2] Our chat interface is shown in Figure 2. To discourage random guessing, we prevent workers from selecting more than once every 10 seconds. Our task was very popular and we col-

[2]If the workers exceed the time limit, the dialogue is marked as unsuccessful (but still logged).

Type	%	Easy example	Hard example
Inform	30.4	I know a judy. / I have someone who studied the bible in the afternoon.	**About equal** indoor and outdoor friends / **me too**. his major is forestry / **might be** kelly
Ask	17.7	Do any of them like Poi? / What does your henry do?	What can you tell me about our friend? / **Or maybe** north park college?
Answer	7.4	None of mine did / Yup / They do. / Same here.	yes 3 of them / No he likes poi / yes if boston college

Table 1: Main utterance types and examples. We show both standard utterances whose meaning can be represented by simple logical forms (e.g., ask(`indoor`)), and open-ended ones which require more complex logical forms (difficult parts in bold). Text spans corresponding to entities are underlined.

Phenomenon	Example
Coreference	(I know one Debra) does she like the indoors? / (I have two friends named TIffany) at World airways?
Coordination	keep on going with the fashion / Ok. let's try something else. / go by hobby / great. select him. thanks!
Chit-chat	Yes, that is **good ole** Terry. / All indoorsers! **my friends hate nature**
Categorization	same, most of mine are **female too / Does any of them names start with B**
Correction	I know one friend into Embroidery - her name is Emily. **Sorry – Embroidery friend is named Michelle**

Table 2: Communication phenomena in the dataset. Evident parts is in bold and text spans corresponding to an entity are underlined. For coreference, the antecedent is in parentheses.

lected 11K dialogues over a period of 13.5 hours.[3] Of these, over 9K dialogues are successful. Unsuccessful dialogues are usually the result of either worker leaving the chat prematurely.

2.3 Dataset statistics

We show the basic statistics of our dataset in Table 3. An utterance is defined as a message sent by one of the agents. The average utterance length is short due to the informality of the chat, however, an agent usually sends multiple utterances in one turn. Some example dialogues are shown in Table 6 and Appendix I.

# dialogues	11157
# completed dialogues	9041
Vocabulary size	5325
Average # of utterances	11.41
Average time taken per task (sec.)	91.18
Average utterance length (tokens)	5.08
Number of linguistic templates[4]	41561

Table 3: Statistics of the MutualFriends dataset.

We categorize utterances into coarse types—inform, ask, answer, greeting, apology—by pattern matching (Appendix E). There are 7.4% multi-type utterances, and 30.9% utterances contain more than one entity. In Table 1, we show example utterances with rich semantics that cannot be sufficiently represented by traditional slot-values. Some of the standard ones are also non-trivial due to coreference and logical compositionality.

Our dataset also exhibits some interesting communication phenomena. Coreference occurs frequently when people check multiple attributes of one item. Sometimes mentions are dropped, as an utterance simply continues from the partner's utterance. People occasionally use external knowledge to group items with out-of-schema attributes (e.g., gender based on names, location based on schools). We summarize these phenomena in Table 2. In addition, we find 30% utterances involve cross-talk where the conversation does not progress linearly (e.g., italic utterances in Figure 1), a common characteristic of online chat (Ivanovic, 2005).

One strategic aspect of this task is choosing the order of attributes to mention. We find that people tend to start from attributes with fewer unique values, e.g., "all my friends like morning" given the KB_B in Table 6, as intuitively it would help exclude items quickly given fewer values to check.[5] We provide a more detailed analysis of strategy in Section 4.2 and Appendix F.

3 Dynamic Knowledge Graph Network

The diverse semantics in our data motivates us to combine unstructured representation of the dialogue history with structured knowledge. Our

[3] Tasks are put up in batches; the total time excludes intervals between batches.

[4] Entity names are replaced by their entity types.

[5] Our goal is to model human behavior thus we do not discuss the optimal strategy here.

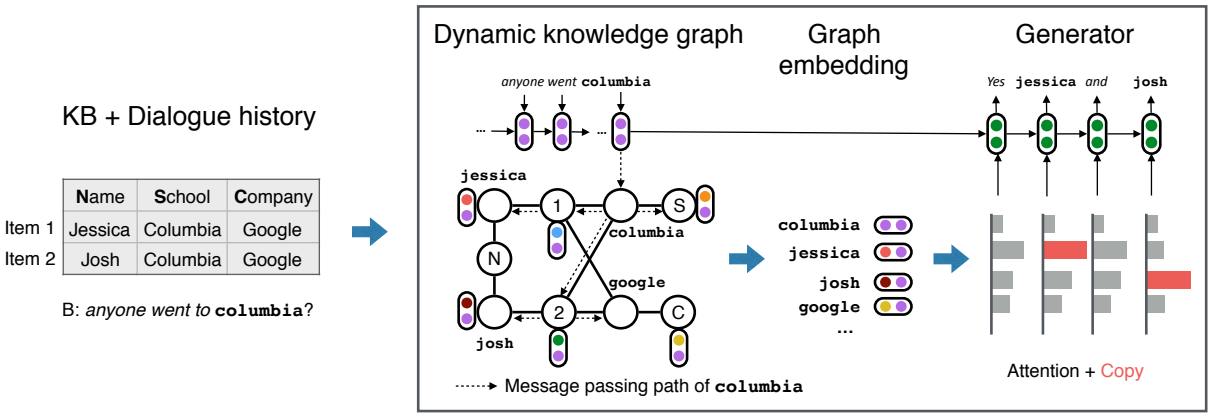

Figure 3: Overview of our approach. First, the KB and dialogue history (entities in **bold**) is mapped to a graph. Here, an item node is labeled by the item ID and an attribute node is labeled by the attribute's first letter. Next, each node is embedded using relevant utterance embeddings through message passing. Finally, an LSTM generates the next utterance based on attention over the node embeddings.

model consists of three components shown in Figure 3: (i) a dynamic knowledge graph, which represents the agent's private KB and shared dialogue history as a graph (Section 3.1), (ii) a graph embedding over the nodes (Section 3.2), and (iii) an utterance generator (Section 3.3).

The knowledge graph represents entities and relations in the agent's private KB, e.g., `item-1`'s `company` is `google`. As the conversation unfolds, utterances are embedded and incorporated into node embeddings of mentioned entities. For instance, in Figure 3, "anyone went to columbia" updates the embedding of `columbia`. Next, each node recursively passes its embedding to neighboring nodes so that related entities (e.g., those in the same row or column) also receive information from the most recent utterance. In our example, `jessica` and `josh` both receive new context when `columbia` is mentioned. Finally, the utterance generator, an LSTM, produces the next utterance by attending to the node embeddings.

3.1 Knowledge Graph

Given a dialogue of T utterances, we construct graphs $(G_t)_{t=1}^{T}$ over the KB and dialogue history for agent A.[6] There are three types of nodes: item nodes, attribute nodes, and entity nodes. Edges between nodes represent their relations. For example, `(item-1, hasSchool, columbia)` means that the first item has attribute `school` whose value is `columbia`. An example graph is shown in Figure 3. The graph G_t is updated based on utterance t by taking G_{t-1} and adding a new node for any entity mentioned in utterance t but not in KB_A.[7]

3.2 Graph Embedding

Given a knowledge graph, we are interested in computing a vector representation for each node v that captures both its unstructured context from the dialogue history and its structured context in the KB. A node embedding $V_t(v)$ for each node $v \in G_t$ is built from three parts: structural properties of an entity defined by the KB, embeddings of utterances in the dialogue history, and message passing between neighboring nodes.

Node Features. Simple structural properties of the KB often govern what is talked about; e.g., a high-frequency entity is usually interesting to mention (consider "All my friends like dancing."). We represent this type of information as a feature vector $F_t(v)$, which includes the degree and type (item, attribute, or entity type) of node v, and whether it has been mentioned in the current turn. Each feature is encoded as a one-hot vector and they are concatenated to form $F_t(v)$.

Mention Vectors. A mention vector $M_t(v)$ contains unstructured context from utterances relevant to node v up to turn t. To compute it, we first define the utterance representation $\tilde{u}_t$ and the set of relevant entities E_t. Let u_t be the embedding of utterance t (Section 3.3). To differentiate between

[6] It is important to differentiate perspectives of the two agents as they have different KBs. Thereafter we assume the perspective of agent A, i.e., accessing KB_A for A only, and refer to B as the partner.

[7] We use a rule-based lexicon to link text spans to entities. See details in Appendix D.

the agent's and the partner's utterances, we represent it as $\tilde{u}_t = \left[u_t \cdot \mathbb{1}_{\{u_t \in U_{\text{self}}\}}, u_t \cdot \mathbb{1}_{\{u_t \in U_{\text{partner}}\}}\right]$, where U_{self} and U_{partner} denote sets of utterances generated by the agent and the partner, and $[\cdot, \cdot]$ denotes concatenation. Let E_t be the set of entity nodes mentioned in utterance t if utterance t mentions some entities, or utterance $t-1$ otherwise.[8] The mention vector $M_t(v)$ of node v incorporates the current utterance if v is mentioned and inherits $M_{t-1}(v)$ if not:

$$M_t(v) = \lambda_t M_{t-1}(v) + (1-\lambda_t)\tilde{u}_t; \quad (1)$$

$$\lambda_t = \begin{cases} \sigma\left(W^{\text{inc}}\left[M_{t-1}(v), \tilde{u}_t\right]\right) & \text{if } v \in E_t, \\ 1 & \text{otherwise.} \end{cases}$$

Here, σ is the sigmoid function and W^{inc} is a parameter matrix.

Recursive Node Embeddings. We propagate information between nodes according to the structure of the knowledge graph. In Figure 3, given "anyone went to columbia?", the agent should focus on her friends who went to Columbia University. Therefore, we want this utterance to be sent to item nodes connected to `columbia`, and one step further to other attributes of these items because they might be mentioned next as relevant information, e.g., `jessica` and `josh`.

We compute the node embeddings recursively, analogous to belief propagation:

$$V_t^k(v) = \max_{v' \in N_t(v)} \tanh \left(W^{\text{mp}}\left[V_t^{k-1}(v'), R(e_{v \to v'})\right]\right), \quad (2)$$

where $V_t^k(v)$ is the depth-k node embedding at turn t and $N_t(v)$ denotes the set of nodes adjacent to v. The message from a neighboring node v' depends on its embedding at depth-$(k-1)$, the edge label $e_{v \to v'}$ (embedded by a relation embedding function R), and a parameter matrix W^{mp}. Messages from all neighbors are aggregated by $\max$, the element-wise max operation.[9] Example message passing paths are shown in Figure 3.

The final node embedding is the concatenation of embeddings at each depth:

$$V_t(v) = \left[V_t^0(v), \ldots, V_t^K(v)\right], \quad (3)$$

where K is a hyperparameter (we experiment with $K \in \{0, 1, 2\}$) and $V_t^0(v) = [F_t(v), M_t(v)]$.

[8] Relying on utterance $t-1$ is useful when utterance t answers a question, e.g., "do you have any google friends?" "No."

[9] Using sum or mean slightly hurts performance.

3.3 Utterance Embedding and Generation

We embed and generate utterances using Long Short Term Memory (LSTM) networks that take the graph embeddings into account.

Embedding. On turn t, upon receiving an utterance consisting of n_t tokens, $x_t = (x_{t,1}, \ldots, x_{t,n_t})$, the LSTM maps it to a vector as follows:

$$h_{t,j} = \text{LSTM}_{\text{enc}}(h_{t,j-1}, A_t(x_{t,j})), \quad (4)$$

where $h_{t,0} = h_{t-1,n_{t-1}}$, and A_t is an *entity abstraction* function, explained below. The final hidden state h_{t,n_t} is used as the utterance embedding u_t, which updates the mention vectors as described in Section 3.2.

In our dialogue task, the identity of an entity is unimportant. For example, replacing `google` with `alphabet` in Figure 1 should make little difference to the conversation. The role of an entity is determined instead by its relation to other entities and relevant utterances. Therefore, we define the abstraction $A_t(y)$ for a word y as follows: if y is linked to an entity v, then we represent an entity by its type (`school`, `company` etc.) embedding concatenated with its current node embedding: $A_t(y) = [E_{\text{type}(y)}, V_t(v)]$. Note that $V_t(v)$ is determined only by its structural features and its context. If y is a non-entity, then $A_t(y)$ is the word embedding of y concatenated with a zero vector of the same dimensionality as $V_t(v)$. This way, the representation of an entity only depends on its structural properties given by the KB and the dialogue context, which enables the model to generalize to unseen entities at test time.

Generation. Now, assuming we have embedded utterance x_{t-1} into $h_{t-1,n_{t-1}}$ as described above, we use another LSTM to generate utterance x_t. Formally, we carry over the last utterance embedding $h_{t,0} = h_{t-1,n_{t-1}}$ and define:

$$h_{t,j} = \text{LSTM}_{\text{dec}}(h_{t,j-1}, [A_t(x_{t,j}), c_{t,j}]), \quad (5)$$

where $c_{t,j}$ is a weighted sum of node embeddings in the current turn: $c_{t,j} = \sum_{v \in G_t} \alpha_{t,j,v} V_t(v)$, where $\alpha_{t,j,v}$ are the attention weights over the nodes. Intuitively, high weight should be given to relevant entity nodes as shown in Figure 3,. We compute the weights through standard attention mechanism (Bahdanau et al., 2015):

$$\alpha_{t,j} = \text{softmax}(s_{t,j}),$$

$$s_{t,j,v} = w^{\text{attn}} \cdot \tanh\left(W^{\text{attn}}\left[h_{t,j-1}, V_t(v)\right]\right),$$

where vector w^{attn} and W^{attn} are parameters.

Finally, we define a distribution over both words in the vocabulary and nodes in G_t using the copying mechanism of Jia and Liang (2016):

$$p(x_{t,j+1} = y \mid G_t, x_{t,\leq j}) \propto \exp\left(W^{\text{vocab}} h_{t,j} + b\right),$$
$$p(x_{t,j+1} = r(v) \mid G_t, x_{t,\leq j}) \propto \exp\left(s_{t,j,v}\right),$$

where y is a word in the vocabulary, W^{vocab} and b are parameters, and $r(v)$ is the realization of the entity represented by node v, e.g., `google` is realized to "Google" during copying.[10]

4 Experiments

We compare our model with a rule-based system and a baseline neural model. Both automatic and human evaluations are conducted to test the models in terms of fluency, correctness, cooperation, and human-likeness. The results show that DynoNet is able to converse with humans in a coherent and strategic way.

4.1 Setup

We randomly split the data into train, dev, and test sets (8:1:1). We use a one-layer LSTM with 100 hidden units and 100-dimensional word vectors for both the encoder and the decoder (Section 3.3). Each successful dialogue is turned into two examples, each from the perspective of one of the two agents. We maximize the log-likelihood of all utterances in the dialogues. The parameters are optimized by AdaGrad (Duchi et al., 2010) with an initial learning rate of 0.5. We trained for at least 10 epochs; after that, training stops if there is no improvement on the dev set for 5 epochs. By default, we perform $K = 2$ iterations of message passing to compute node embeddings (Section 3.2). For decoding, we sequentially sample from the output distribution with a softmax temperature of 0.5.[11] Hyperparameters are tuned on the dev set.

We compare DynoNet with its static cousion (StanoNet) and a rule-based system (Rule). StanoNet uses G_0 throughout the dialogue, thus the dialogue history is completely contained in the LSTM states instead of being injected into the knowledge graph. Rule maintains weights for each entity and each item in the KB to decide what to talk about and which item to select. It has a pattern-matching semantic parser, a rule-based policy, and a templated generator. See Appendix G for details.

4.2 Evaluation

We test our systems in two interactive settings: bot-bot chat and bot-human chat. We perform both automatic evaluation and human evaluation.

Automatic Evaluation. First, we compute the cross-entropy (ℓ) of a model on test data. As shown in Table 4, DynoNet has the lowest test loss. Next, we have a model chat with itself on the scenarios from the test set.[12] We evaluate the chats with respect to language variation, effectiveness, and strategy.

For language variation, we report the average utterance length L_u and the unigram entropy H in Table 4. Compared to Rule, the neural models tend to generate shorter utterances (Li et al., 2016b; Serban et al., 2017b). However, they are more diverse; for example, questions are asked in multiple ways such as "Do you have ...", "Any friends like ...", "What about ...".

At the discourse level, we expect the distribution of a bot's utterance types to match the distribution of human's. We show percentages of each utterance type in Table 4. For Rule, the decision about which action to take is written in the rules, while StanoNet and DynoNet learned to behave in a more human-like way, frequently informing and asking questions.

To measure effectiveness, we compute the overall success rate (C) and the success rate per turn (C_T) and per selection (C_S). As shown in Table 4, humans are the best at this game, followed by Rule which is comparable to DynoNet.

Next, we investigate the strategies leading to these results. An agent needs to decide which entity/attribute to check first to quickly reduce the search space. We hypothesize that humans tend to first focus on a majority entity and an attribute with fewer unique values (Section 2.3). For example, in the scenario in Table 6, `time` and `location` are likely to be mentioned first. We show the average frequency of first-mentioned entities (#Ent$_1$) and the average number of unique values for first-mentioned attributes ($|\text{Attr}_1|$) in Ta-

[10] We realize an entity by sampling from the empirical distribution of its surface forms found in the training data.

[11] Since selection is a common 'utterance' in our dataset and neural generation models are susceptible to over-generating common sentences, we halve its probability during sampling.

[12] We limit the number of turns in bot-bot chat to be the maximum number of turns humans took in the test set (46 turns).

System	$\ell \downarrow$	L_u	H	$C \uparrow$	$C_T \uparrow$	$C_S \uparrow$	Sel	Inf	Ask	Ans	Greet	#Ent$_1$	|Attr$_1$|	#Ent	#Attr
Human	-	5.10	4.57	.82	.07	.38	.21	.31	.17	.08	.08	.55	.35	6.1	2.6
Rule	-	7.61	3.37	.90	.05	**.29**	.18	**.34**	.23	.00	.12	.24	.61	9.9	3.0
StanoNet	2.20	4.01	**4.05**	.78	.04	.18	.19	.26	.12	.23	**.09**	.61	**.19**	7.1	2.9
DynoNet	**2.13**	3.37	3.90	**.96**	**.06**	.25	**.22**	.26	**.13**	.20	.12	**.55**	.18	**5.2**	**2.5**

Table 4: Automatic evaluation on human-human and bot-bot chats on test scenarios. We use ↑ / ↓ to indicate that higher / lower values are better; otherwise the objective is to match humans' statistics. Best results (except Human) are in bold. Neural models generate shorter (lower L_u) but more diverse (higher H) utterances. Overall, their distributions of utterance types match those of the humans'. (We only show the most frequent speech acts therefore the numbers do not sum to 1.) Rule is effective in completing the task (higher C_S), but it is not information-efficient given the large number of attributes (#Attr) and entities (#Ent) mentioned.

ble 4.[13] Both DynoNet and StanoNet successfully match human's starting strategy by favoring entities of higher frequency and attributes of smaller domain size.

To examine the overall strategy, we show the average number of attributes (#Attr) and entities (#Ent) mentioned during the conversation in Table 4. Humans and DynoNet strategically focus on a few attributes and entities, whereas Rule needs almost twice entities to achieve similar success rates. This suggests that the effectiveness of Rule mainly comes from large amounts of unselective information, which is consistent with comments from their human partners.

Partner Evaluation. We generated 200 new scenarios and put up the bots on AMT using the same chat interface that was used for data collection. The bots follow simple turn-taking rules explained in Appendix H. Each AMT worker is randomly paired with Rule, StanoNet, DynoNet, or another human (but the worker doesn't know which), and we make sure that all four types of agents are tested in each scenario at least once. At the end of each dialogue, humans are asked to rate their partner in terms of fluency, correctness, cooperation, and human-likeness from 1 (very bad) to 5 (very good), along with optional comments.

We show the average ratings (with significance tests) in Table 5 and the histograms in Appendix J. In terms of fluency, the models have similar performance since the utterances are usually short. Judgment on correctness is a mere guess since the evaluator cannot see the partner's KB; we will analyze correctness more meaningfully in the third-party evaluation below.

[13] Both numbers are normalized to $[0, 1]$ with respect to all entities/attributes in the corresponding KB.

Noticeably, DynoNet is more cooperative than the other models. As shown in the example dialogues in Table 6, DynoNet cooperates smoothly with the human partner, e.g., replying with relevant information about morning/indoor friends when the partner mentioned that all her friends prefer morning and most like indoor. StanoNet starts well but doesn't follow up on the morning friend, presumably because the `morning` node is not updated dynamically when mentioned by the partner. Rule follows the partner poorly. In the comments, the biggest complaint about Rule was that it was not 'listening' or 'understanding'. Overall, DynoNet achieves better partner satisfaction, especially in cooperation.

Third-party Evaluation. We also created a *third-party evaluation* task, where an independent AMT worker is shown a conversation and the KB of one of the agents; she is asked to rate the same aspects of the agent as in the partner evaluation and provide justifications. Each agent in a dialogue is rated by at least 5 people.

The average ratings and histograms are shown in Table 5 and Appendix J. For correctness, we see that Rule has the best performance since it always tells the truth, whereas humans can make mistakes due to carelessness and the neural models can generate false information. For example, in Table 6, DynoNet 'lied' when saying that it has a morning friend who likes outdoor.

Surprisingly, there is a discrepancy between the two evaluation modes in terms of cooperation and human-likeness. Manual analysis of the comments indicates that third-party evaluators focus less on the dialogue strategy and more on linguistic features, probably because they were not fully engaged in the dialogue. For example, justification

System	C	C_T	C_S	Partner eval				Third-party eval			
				Flnt	Crct	Coop	Human	Flnt	Crct	Coop	Human
Human	.89	.07	.36	4.2^{rds}	4.3^{rds}	4.2^{rds}	4.1^{rds}	4.0	4.3^{ds}	4.0^{ds}	4.1^{rds}
Rule	**.88**	**.06**	**.29**	3.6	4.0	3.5	3.5	4.0	$\mathbf{4.4}^{hds}$	$\mathbf{3.9}^{s}$	$\mathbf{4.0}^{s}$
StanoNet	.76	.04	.23	3.5	3.8	3.4	3.3	4.0	4.0	3.8	3.8
DynoNet	.87	.05	.27	$\mathbf{3.8}^{s}$	4.0	$\mathbf{3.8}^{rs}$	$\mathbf{3.6}^{s}$	4.0	4.1	3.9	3.9

Table 5: Results on human-bot/human chats. Best results (except Human) in each column are in bold. We report the average ratings of each system. For third-party evaluation, we first take mean of each question then average the ratings. DynoNet has the best partner satisfaction in terms of fluency (Flnt), correctness (Crct), cooperation (Coop), human likeness (Human). The superscript of a result indicates that its advantage over other systems (r: Rule, s: StanoNet, d: DynoNet) is statistically significant with $p < 0.05$ given by paired t-tests.

for cooperation often mentions frequent questions and timely answers, less attention is paid to what is asked about though.

For human-likeness, partner evaluation is largely correlated with coherence (e.g., not repeating or ignoring past information) and task success, whereas third-party evaluators often rely on informality (e.g., usage of colloquia like "hiya", capitalization, and abbreviation) or intuition. Interestingly, third-party evaluators noted most phenomena listed in Table 2 as indicators of human-beings, e.g., correcting oneself, making chit-chat other than simply finishing the task. See example comments in Appendix K.

4.3 Ablation Studies

Our model has two novel designs: entity abstraction and message passing for node embeddings. Table 7 shows what happens if we ablate these. When the number of message passing iterations, K, is reduced from 2 to 0, the loss consistently increases. Removing entity abstraction—meaning adding entity embeddings to node embeddings and the LSTM input embeddings—also degrades performance. This shows that DynoNet benefits from contextually-defined, structural node embeddings rather than ones based on a classic lookup table.

Model	ℓ
DynoNet (K = 2)	**2.16**
DynoNet (K = 1)	2.20
DynoNet (K = 0)	2.26
DynoNet (K = 2) w/o entity abstraction	2.21

Table 7: Ablations of our model on the dev set show the importance of entity abstraction and message passing ($K = 2$).

5 Discussion and Related Work

There has been a recent surge of interest in end-to-end task-oriented dialogue systems, though progress has been limited by the size of available datasets (Serban et al., 2015a). Most work focuses on information-querying tasks, using Wizard-of-Oz data collection (Williams et al., 2016; Asri et al., 2016) or simulators (Bordes and Weston, 2017; Li et al., 2016d), In contrast, collaborative dialogues are easy to collect as natural human conversations, and are also challenging enough given the large number of scenarios and diverse conversation phenomena. There are some interesting strategic dialogue datasets—settlers of Catan (Afantenos et al., 2012) (2K turns) and the cards corpus (Potts, 2012) (1.3K dialogues), as well as work on dialogue strategies (Keizer et al., 2017; Vogel et al., 2013), though no full dialogue system has been built for these datasets.

Most task-oriented dialogue systems follow the POMDP-based approach (Williams and Young, 2007; Young et al., 2013). Despite their success (Wen et al., 2017; Dhingra et al., 2017; Su et al., 2016), the requirement for handcrafted slots limits their scalability to new domains and burdens data collection with extra state labeling. To go past this limit, Bordes and Weston (2017) proposed a Memory-Networks-based approach without domain-specific features. However, the memory is unstructured and interfacing with KBs relies on API calls, whereas our model embeds both the dialogue history and the KB structurally. Williams et al. (2017) use an LSTM to automatically infer the dialogue state, but as they focus on dialogue control rather than the full problem, the response is modeled as a templated action, which restricts the generation of richer utterances. chitecture is most similar to EntNet (Henaff et al., 2017), where memories are also updated by input sentences recurrently. The main difference is that our model allows information to be propagated between structured entities, which is shown to be crucial in our setting (Section 4.3).

Our work is also related to language generation conditioned on knowledge bases (Mei et al., 2016; Kiddon et al., 2016). One challenge here is to avoid generating false or contradicting statements, which is currently a weakness of neural models. Our model is mostly accurate when generating facts and answering existence questions about a single entity, but will need a more advanced attention mechanism for generating utterances involving multiple entities, e.g., attending to items or attributes first, then selecting entities; generating high-level concepts before composing them to natural tokens (Serban et al., 2017a).

In conclusion, we believe the symmetric collaborative dialogue setting and our dataset provide unique opportunities at the interface of traditional task-oriented dialogue and open-domain chat. We also offered DynoNet as a promising means for open-ended dialogue state representation. Our dataset facilitates the study of pragmatics and human strategies in dialogue—a good stepping stone towards learning more complex dialogues such as negotiation.

Neural Belief Tracker: Data-Driven Dialogue State Tracking

Abstract

One of the core components of modern spoken dialogue systems is the *belief tracker*, which estimates the user's goal at every step of the dialogue. However, most current approaches have difficulty scaling to larger, more complex dialogue domains. This is due to their dependency on either: **a)** Spoken Language Understanding models that require large amounts of annotated training data; or **b)** hand-crafted lexicons for capturing some of the linguistic variation in users' language. We propose a novel Neural Belief Tracking (NBT) framework which overcomes these problems by building on recent advances in representation learning. NBT models reason over pre-trained word vectors, learning to compose them into distributed representations of user utterances and dialogue context. Our evaluation on two datasets shows that this approach surpasses past limitations, matching the performance of state-of-the-art models which rely on hand-crafted semantic lexicons and outperforming them when such lexicons are not provided.

1 Introduction

Spoken dialogue systems (SDS) allow users to interact with computer applications through conversation. Task-based systems help users achieve goals such as finding restaurants or booking flights. The *dialogue state tracking* (DST) component of an SDS serves to interpret user input and update the *belief state*, which is the system's internal representation of the state of the conversation (Young et al., 2010). This is a probability distribution over dialogue states used by the downstream *dialogue manager* to decide which action the system should perform next (Su et al., 2016a,b); the system action is then verbalised by the natural language generator (Wen et al., 2015a,b; Dušek and Jurčíček, 2015).

User: I'm looking for a cheaper restaurant
`inform(price=cheap)`
System: Sure. What kind - and where?
User: Thai food, somewhere downtown
`inform(price=cheap, food=Thai, area=centre)`
System: The House serves cheap Thai food
User: Where is it?
`inform(price=cheap, food=Thai, area=centre); request(address)`
System: The House is at 106 Regent Street

Figure 1: Annotated dialogue states in a sample dialogue. Underlined words show rephrasings which are typically handled using semantic dictionaries.

The Dialogue State Tracking Challenge (DSTC) series of shared tasks has provided a common evaluation framework accompanied by labelled datasets (Williams et al., 2016). In this framework, the dialogue system is supported by a *domain ontology* which describes the range of user intents the system can process. The ontology defines a collection of *slots* and the *values* that each slot can take. The system must track the search constraints expressed by users (*goals* or *informable* slots) and questions the users ask about search results (*requests*), taking into account each user utterance (input via a speech recogniser) and the dialogue context (e.g., what the system just said). The example in Figure 1 shows the true state after each user utterance in a three-turn conversation. As can be seen in this example, DST models depend on identifying mentions of ontology items in user utterances. This becomes a non-trivial task when confronted with lexical variation, the dynamics of context and noisy automated speech recognition (ASR) output.

Figure 2: An example semantic dictionary with rephrasings for three ontology values in a *restaurant search* domain.

Traditional statistical approaches use separate Spoken Language Understanding (SLU) modules to address lexical variability within a single dialogue turn. However, training such models requires substantial amounts of domain-specific annotation. Alternatively, turn-level SLU and cross-turn DST can be coalesced into a single model to achieve superior belief tracking performance, as shown by Henderson et al. (2014d). Such coupled models typically rely on manually constructed semantic dictionaries to identify alternative mentions of ontology items that vary lexically or morphologically. Figure 2 gives an example of such a dictionary for three slot-value pairs. This approach, which we term *delexicalisation*, is clearly not scalable to larger, more complex dialogue domains. Importantly, the focus on English in DST research understates the considerable challenges that morphology poses to systems based on exact matching in morphologically richer languages such as Italian or German (see Vulić et al. (2017)).

In this paper, we present two new models, collectively called the Neural Belief Tracker (NBT) family. The proposed models couple SLU and DST, efficiently learning to handle variation without requiring any hand-crafted resources. To do that, NBT models move away from exact matching and instead reason entirely over pre-trained word vectors. The vectors making up the user utterance and preceding system output are first composed into intermediate representations. These representations are then used to decide which of the ontology-defined intents have been expressed by the user up to that point in the conversation.

To the best of our knowledge, NBT models are the first to successfully use pre-trained word vector spaces to improve the language understanding capability of belief tracking models. In evaluation on two datasets, we show that: **a)** NBT models match the performance of delexicalisation-based models which make use of hand-crafted semantic lexicons; and **b)** the NBT models significantly outperform those models when such resources are not available. Consequently, we believe this work proposes a framework better-suited to scaling belief tracking models for deployment in real-world dialogue systems operating over sophisticated application domains where the creation of such domain-specific lexicons would be infeasible.

2 Background

Models for probabilistic dialogue state tracking, or *belief tracking*, were introduced as components of spoken dialogue systems in order to better handle noisy speech recognition and other sources of uncertainty in understanding a user's goals (Bohus and Rudnicky, 2006; Williams and Young, 2007; Young et al., 2010). Modern dialogue management policies can learn to use a tracker's distribution over intents to decide whether to execute an action or request clarification from the user. As mentioned above, the DSTC shared tasks have spurred research on this problem and established a standard evaluation paradigm (Williams et al., 2013; Henderson et al., 2014b,a). In this setting, the task is defined by an *ontology* that enumerates the goals a user can specify and the attributes of entities that the user can request information about. Many different belief tracking models have been proposed in the literature, from generative (Thomson and Young, 2010) and discriminative (Henderson et al., 2014d) statistical models to rule-based systems (Wang and Lemon, 2013). To motivate the work presented here, we categorise prior research according to their reliance (or otherwise) on a separate SLU module for interpreting user utterances:[1]

Separate SLU Traditional SDS pipelines use Spoken Language Understanding (SLU) decoders to detect slot-value pairs expressed in the Automatic Speech Recognition (ASR) output. The downstream DST model then combines this information with the past dialogue context to update the belief state (Thomson and Young, 2010; Wang and Lemon, 2013; Lee and Kim, 2016; Perez, 2016; Perez and Liu, 2017; Sun et al., 2016; Jang et al., 2016; Shi et al., 2016; Dernoncourt et al., 2016; Liu and Perez, 2017; Vodolán et al., 2017).

[1]The best-performing models in DSTC2 all used both raw ASR output and the output of (potentially more than one) SLU decoders (Williams, 2014; Williams et al., 2016). This does not mean that those models are immune to the drawbacks identified here for the two model categories; in fact, they share the drawbacks of both.

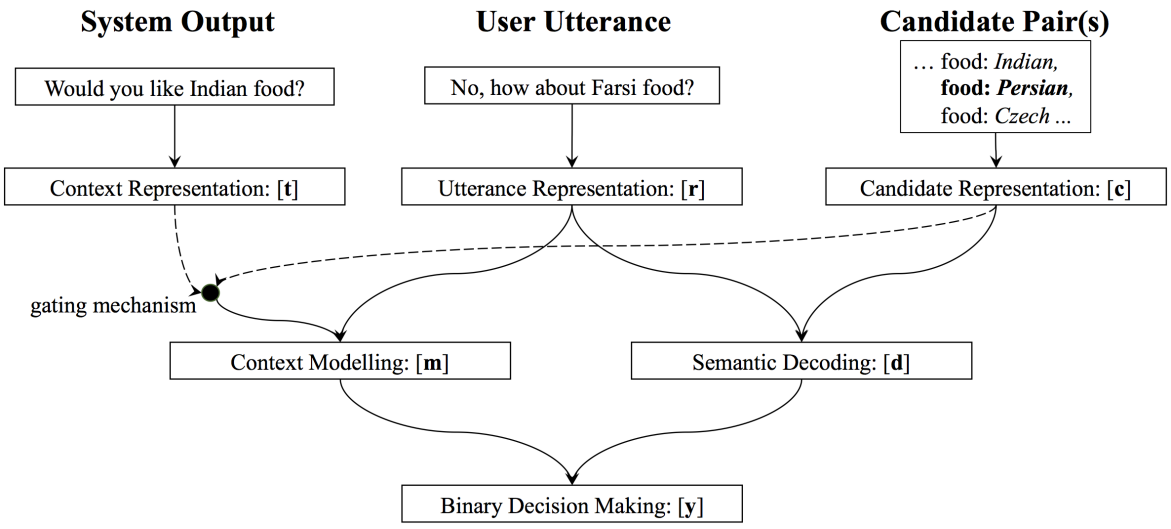

Figure 3: Architecture of the NBT Model. The implementation of the three representation learning subcomponents can be modified, as long as these produce adequate vector representations which the downstream model components can use to decide whether the current candidate slot-value pair was expressed in the user utterance (taking into account the preceding system act).

In the DSTC challenges, some systems used the output of template-based matching systems such as Phoenix (Wang, 1994). However, more robust and accurate statistical SLU systems are available. Many discriminative approaches to spoken dialogue SLU train independent binary models that decide whether each slot-value pair was expressed in the user utterance. Given enough data, these models can learn which lexical features are good indicators for a given value and can capture elements of paraphrasing (Mairesse et al., 2009). This line of work later shifted focus to robust handling of rich ASR output (Henderson et al., 2012; Tur et al., 2013). SLU has also been treated as a sequence labelling problem, where each word in an utterance is labelled according to its role in the user's intent; standard labelling models such as CRFs or Recurrent Neural Networks can then be used (Raymond and Ricardi, 2007; Yao et al., 2014; Celikyilmaz and Hakkani-Tur, 2015; Mesnil et al., 2015; Peng et al., 2015; Zhang and Wang, 2016; Liu and Lane, 2016b; Vu et al., 2016; Liu and Lane, 2016a, i.a.). Other approaches adopt a more complex modelling structure inspired by semantic parsing (Saleh et al., 2014; Vlachos and Clark, 2014). One drawback shared by these methods is their resource requirements, either because they need to learn independent parameters for each slot and value or because they need fine-grained manual annotation at the word level. This hinders scaling to larger, more realistic application domains.

Joint SLU/DST Research on belief tracking has found it advantageous to reason about SLU and DST jointly, taking ASR predictions as input and generating belief states as output (Henderson et al., 2014d; Sun et al., 2014; Zilka and Jurcicek, 2015; Mrkšić et al., 2015). In DSTC2, systems which used no external SLU module outperformed all systems that only used external SLU features. Joint models typically rely on a strategy known as *delexicalisation* whereby slots and values mentioned in the text are replaced with generic labels. Once the dataset is transformed in this manner, one can extract a collection of template-like n-gram features such as **[want *tagged-value* food]**. To perform belief tracking, the shared model iterates over all slot-value pairs, extracting delexicalised feature vectors and making a separate binary decision regarding each pair. Delexicalisation introduces a hidden dependency that is rarely discussed: how do we identify slot/value mentions in text? For toy domains, one can manually construct *semantic dictionaries* which list the potential rephrasings for all slot values. As shown by Mrkšić et al. (2016), the use of such dictionaries is essential for the performance of current delexicalisation-based models. Again though, this will not scale to the rich variety of user language or to general domains.

The primary motivation for the work presented in this paper is to overcome the limitations that affect previous belief tracking models. The NBT model efficiently learns from the avail-

able data by: **1)** leveraging semantic information from pre-trained word vectors to resolve lexical/morphological ambiguity; **2)** maximising the number of parameters shared across ontology values; and **3)** having the flexibility to learn domain-specific paraphrasings and other kinds of variation that make it infeasible to rely on exact matching and delexicalisation as a robust strategy.

3 Neural Belief Tracker

The Neural Belief Tracker (NBT) is a model designed to detect the slot-value pairs that make up the user's goal at a given turn during the flow of dialogue. Its input consists of the system dialogue acts preceding the user input, the user utterance itself, and a single candidate slot-value pair that it needs to make a decision about. For instance, the model might have to decide whether the goal FOOD=ITALIAN has been expressed in *'I'm looking for good pizza'*. To perform belief tracking, the NBT model *iterates* over all candidate slot-value pairs (defined by the ontology), and decides which ones have just been expressed by the user.

Figure 3 presents the flow of information in the model. The first layer in the NBT hierarchy performs representation learning given the three model inputs, producing vector representations for the user utterance ($\mathbf{r}$), the current candidate slot-value pair ($\mathbf{c}$) and the system dialogue acts ($\mathbf{t_q}, \mathbf{t_s}, \mathbf{t_v}$). Subsequently, the learned vector representations interact through the *context modelling* and *semantic decoding* submodules to obtain the intermediate *interaction summary* vectors $\mathbf{d_r}, \mathbf{d_c}$ and $\mathbf{d}$. These are used as input to the final *decision-making* module which decides whether the user expressed the intent represented by the candidate slot-value pair.

3.1 Representation Learning

For any given user utterance, system act(s) and candidate slot-value pair, the representation learning submodules produce vector representations which act as input for the downstream components of the model. All representation learning subcomponents make use of pre-trained collections of word vectors. As shown by Mrkšić et al. (2016), specialising word vectors to express *semantic similarity* rather than *relatedness* is essential for improving belief tracking performance. For this reason, we use the semantically-specialised Paragram-SL999 word vectors (Wieting et al., 2015) throughout this work. The NBT training procedure keeps these vectors fixed: that way, at test time, unseen words semantically related to familiar slot values (i.e. *inexpensive* to *cheap*) will be recognised purely by their position in the original vector space (see also Rocktäschel et al. (2016)). This means that the NBT model parameters can be shared across all values of the given slot, or even across all slots.

Let u represent a user utterance consisting of k_u words $u_1, u_2, \ldots, u_{k_u}$. Each word has an associated word vector $\mathbf{u}_1, \ldots, \mathbf{u}_{k_u}$. We propose two model variants which differ in the method used to produce vector representations of u: NBT-DNN and NBT-CNN. Both act over the constituent n-grams of the utterance. Let $\mathbf{v}_i^n$ be the concatenation of the n word vectors starting at index i, so that:

$$\mathbf{v}_i^n = \mathbf{u}_i \oplus \ldots \oplus \mathbf{u}_{i+n-1} \tag{1}$$

where $\oplus$ denotes vector concatenation. The simpler of our two models, which we term NBT-DNN, is shown in Figure 4. This model computes cumulative n-gram representation vectors $\mathbf{r}_1$, $\mathbf{r}_2$ and $\mathbf{r}_3$, which are the n-gram 'summaries' of the unigrams, bigrams and trigrams in the user utterance:

$$\mathbf{r}_n = \sum_{i=1}^{k_u - n + 1} \mathbf{v}_i^n \tag{2}$$

Each of these vectors is then non-linearly mapped to intermediate representations of the same size:

$$\mathbf{r}'_n = \sigma(W_n^s \mathbf{r}_n + b_n^s) \tag{3}$$

where the weight matrices and bias terms map the cumulative n-grams to vectors of the same dimensionality and σ denotes the sigmoid activation function. We maintain a separate set of parameters for each slot (indicated by superscript s). The three vectors are then summed to obtain a single representation for the user utterance:

$$\mathbf{r} = \mathbf{r}'_1 + \mathbf{r}'_2 + \mathbf{r}'_3 \tag{4}$$

The cumulative n-gram representations used by this model are just unweighted sums of all word vectors in the utterance. Ideally, the model should learn to recognise which parts of the utterance are more relevant for the subsequent classification task. For instance, it could learn to ignore verbs or stop words and pay more attention to adjectives and nouns which are more likely to express slot values.

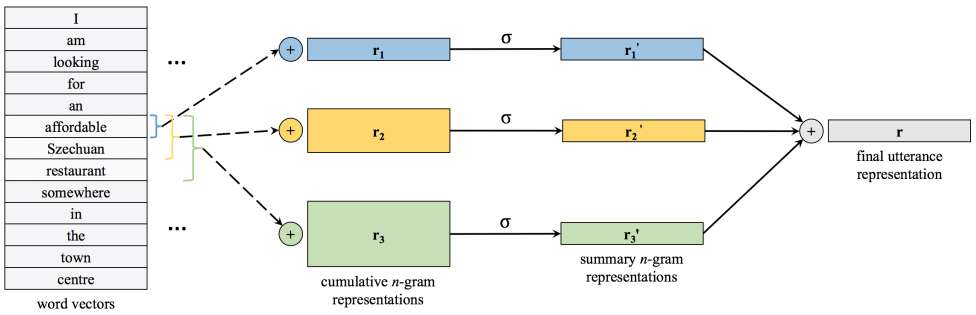

Figure 4: NBT-DNN MODEL. Word vectors of n-grams ($n = 1, 2, 3$) are summed to obtain *cumulative* n-grams, then passed through another hidden layer and summed to obtain the utterance representation $\mathbf{r}$.

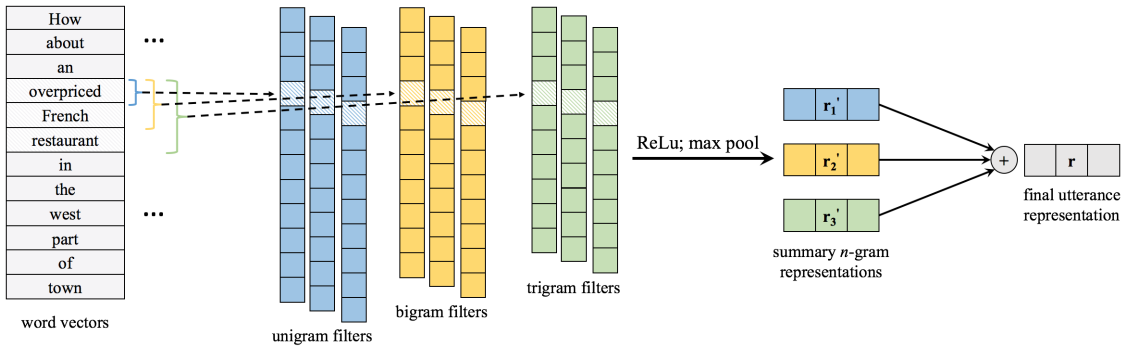

Figure 5: NBT-CNN Model. L convolutional filters of window sizes $1, 2, 3$ are applied to word vectors of the given utterance ($L = 3$ in the diagram, but $L = 300$ in the system). The convolutions are followed by the ReLU activation function and max-pooling to produce summary n-gram representations. These are summed to obtain the utterance representation $\mathbf{r}$.

NBT-CNN Our second model draws inspiration from successful applications of Convolutional Neural Networks (CNNs) for language understanding (Collobert et al., 2011; Kalchbrenner et al., 2014; Kim, 2014). These models typically apply a number of convolutional filters to n-grams in the input sentence, followed by non-linear activation functions and max-pooling. Following this approach, the NBT-CNN model applies $L = 300$ different filters for n-gram lengths of $1, 2$ and 3 (Figure 5). Let $F_n^s \in R^{L \times nD}$ denote the collection of filters for each value of n, where $D = 300$ is the word vector dimensionality. If $\mathbf{v}_i^n$ denotes the concatenation of n word vectors starting at index i, let $\mathbf{m}_n = [\mathbf{v}_1^n; \mathbf{v}_2^n; \ldots; \mathbf{v}_{k_u-n+1}^n]$ be the list of n-grams that convolutional filters of length n run over. The three intermediate representations are then given by:

$$R_n = F_n^s \, \mathbf{m}_n \tag{5}$$

Each column of the intermediate matrices R_n is produced by a single convolutional filter of length n. We obtain summary n-gram representations by pushing these representations through a rectified linear unit (ReLU) activation function (Nair and Hinton, 2010) and max-pooling over time (i.e. columns of the matrix) to get a single feature for each of the L filters applied to the utterance:

$$\mathbf{r}'_n = \texttt{maxpool}\left(\texttt{ReLU}\left(R_n + b_n^s\right)\right) \tag{6}$$

where b_n^s is a bias term broadcast across all filters. Finally, the three summary n-gram representations are summed to obtain the final utterance representation vector $\mathbf{r}$ (as in Equation 4). The NBT-CNN model is (by design) better suited to longer utterances, as its convolutional filters interact directly with subsequences of the utterance, and not just their noisy summaries given by the NBT-DNN's cumulative n-grams.

3.2 Semantic Decoding

The NBT diagram in Figure 3 shows that the utterance representation $\mathbf{r}$ and the candidate slot-value pair representation $\mathbf{c}$ directly interact through the *semantic decoding* module. This component decides whether the user explicitly expressed an intent matching the current candidate pair

(i.e. without taking the dialogue context into account). Examples of such matches would be *'I want Thai food'* with `food=Thai` or more demanding ones such as *'a pricey restaurant'* with `price=expensive`. This is where the use of high-quality pre-trained word vectors comes into play: a delexicalisation-based model could deal with the former example but would be helpless in the latter case, unless a human expert had provided a semantic dictionary listing all potential rephrasings for each value in the domain ontology.

Let the vector space representations of a candidate pair's slot name and value be given by $\mathbf{c_s}$ and $\mathbf{c_v}$ (with vectors of multi-word slot names/values summed together). The NBT model learns to map this tuple into a single vector $\mathbf{c}$ of the same dimensionality as the utterance representation $\mathbf{r}$. These two representations are then forced to interact in order to learn a similarity metric which discriminates between interactions of utterances with slot-value pairs that they either do or do not express:

$$\mathbf{c} = \sigma\big(W_c^s(\mathbf{c_s} + \mathbf{c_v}) + b_c^s\big) \quad (7)$$

$$\mathbf{d} = \mathbf{r} \otimes \mathbf{c} \quad (8)$$

where $\otimes$ denotes *element-wise* vector multiplication. The dot product, which may seem like the more intuitive similarity metric, would reduce the rich set of features in $\mathbf{d}$ to a single scalar. The element-wise multiplication allows the downstream network to make better use of its parameters by learning non-linear interactions between sets of features in $\mathbf{r}$ and $\mathbf{c}$.[2]

3.3 Context Modelling

This 'decoder' does not yet suffice to extract intents from utterances in human-machine dialogue. To understand some queries, the belief tracker must be aware of *context*, i.e. the flow of dialogue leading up to the latest user utterance. While all previous system and user utterances are important, the most relevant one is the last system utterance, in which the dialogue system could have performed (among others) one of the following two *system acts*:

1. **System Request**: The system asks the user about the value of a specific slot T_q. If the system utterance is: *'what price range would you like?'* and the user answers with *any*, the model must infer the reference to *price range*, and not to other slots such as *area* or *food*.

2. **System Confirm:** The system asks the user to confirm whether a specific slot-value pair (T_s, T_v) is part of their desired constraints. For example, if the user responds to *'how about Turkish food?'* with *'yes'*, the model must be aware of the system act in order to correctly update the belief state.

If we make the Markovian decision to only consider the last set of system acts, we can incorporate context modelling into the NBT. Let $\mathbf{t_q}$ and $(\mathbf{t_s}, \mathbf{t_v})$ be the word vectors of the arguments for the system request and confirm acts (zero vectors if none). The model computes the following measures of similarity between the system acts, candidate pair $(\mathbf{c_s}, \mathbf{c_v})$ and utterance representation $\mathbf{r}$:

$$\mathbf{m_r} = (\mathbf{c_s} \cdot \mathbf{t_q})\mathbf{r} \quad (9)$$

$$\mathbf{m_c} = (\mathbf{c_s} \cdot \mathbf{t_s})(\mathbf{c_v} \cdot \mathbf{t_v})\mathbf{r} \quad (10)$$

where $\cdot$ denotes dot product. The computed similarity terms act as gating mechanisms which only pass the utterance representation through if the system asked about the current candidate slot or slot-value pair. This type of interaction is particularly useful for the confirm system act: if the system asks the user to confirm, the user is likely not to mention any slot values, but to just respond affirmatively or negatively. This means that the model must consider the *three-way interaction* between the utterance, candidate slot-value pair and the slot value pair offered by the system. If (and only if) the latter two are the same should the model consider the affirmative or negative polarity of the user utterance when making the subsequent binary decision.

Binary Decision Maker The intermediate representations are passed through another hidden layer and then combined. If $\phi_{dim}(\mathbf{x}) = \sigma(W\mathbf{x} + b)$ is a layer which maps input vector $\mathbf{x}$ to a vector of size dim, the input to the final binary softmax (which represents the decision) is given by:

$$\mathbf{y} = \phi_2\big(\phi_{100}(\mathbf{d}) + \phi_{100}(\mathbf{m_r}) + \phi_{100}(\mathbf{m_c})\big)$$

4 Belief State Update Mechanism

In spoken dialogue systems, belief tracking models operate over the output of automatic speech recognition (ASR). Despite improvements to speech

[2] We also tried to concatenate $\mathbf{r}$ and $\mathbf{c}$ and pass that vector to the downstream decision-making neural network. However, this set-up led to very weak performance since our relatively small datasets did not suffice for the network to learn to model the interaction between the two feature vectors.

recognition, the need to make the most out of imperfect ASR will persist as dialogue systems are used in increasingly noisy environments.

In this work, we define a simple rule-based belief state update mechanism which can be applied to ASR N-best lists. For dialogue turn t, let sys^{t-1} denote the preceding system output, and let h^t denote the list of N ASR hypotheses h_i^t with posterior probabilities p_i^t. For any hypothesis h_i^t, slot s and slot value $v \in V_s$, NBT models estimate $\mathbb{P}(s, v \mid h_i^t, sys^{t-1})$, which is the (turn-level) probability that (s, v) was expressed in the given hypothesis. The predictions for N such hypotheses are then combined as:

$$\mathbb{P}(s, v \mid h^t, sys^{t-1}) = \sum_{i=1}^{N} p_i^t \, \mathbb{P}\left(s, v \mid h_i^t, sys^t\right)$$

This turn-level belief state estimate is then combined with the (cumulative) belief state up to time $(t-1)$ to get the updated belief state estimate:

$$\begin{aligned}\mathbb{P}(s, v \mid h^{1:t}, sys^{1:t-1}) \; = \; & \lambda \, \mathbb{P}\left(s, v \mid h^t, sys^{t-1}\right) \\ & + (1-\lambda) \, \mathbb{P}\left(s, v \mid h^{1:t-1}, sys^{1:t-2}\right)\end{aligned}$$

where λ is the coefficient which determines the relative weight of the turn-level and previous turns' belief state estimates.[3] For slot s, the set of its *detected values* at turn t is then given by:

$$V_s^t = \{v \in V_s \mid \mathbb{P}\left(s, v \mid h^{1:t}, sys^{1:t-1}\right) \geq 0.5\}$$

For informable (i.e. goal-tracking) slots, the value in V_s^t with the highest probability is chosen as the current goal (if $V_s^t \neq \{\emptyset\}$). For requests, all slots in V_{req}^t are deemed to have been requested. As requestable slots serve to model single-turn user queries, they require no belief tracking across turns.

5 Experiments

5.1 Datasets

Two datasets were used for training and evaluation. Both consist of user conversations with task-oriented dialogue systems designed to help users find suitable restaurants around Cambridge, UK. The two corpora share the same domain ontology, which contains three *informable* (i.e. goal-tracking) slots: FOOD, AREA and PRICE. The users can specify values for these slots in order to find restaurants which best meet their criteria. Once the system suggests a restaurant, the users can ask about the values of up to eight *requestable* slots (PHONE NUMBER, ADDRESS, etc.). The two datasets are:

1. **DSTC2**: We use the transcriptions, ASR hypotheses and turn-level semantic labels provided for the Dialogue State Tracking Challenge 2 (Henderson et al., 2014a). The official transcriptions contain various spelling errors which we corrected manually; the cleaned version of the dataset is available at `mi.eng.cam.ac.uk/~nm480/dstc2-clean.zip`. The training data contains 2207 dialogues and the test set consists of 1117 dialogues. We train NBT models on transcriptions but report belief tracking performance on test set ASR hypotheses provided in the original challenge.

2. **WOZ 2.0**: Wen et al. (2017) performed a Wizard of Oz style experiment in which Amazon Mechanical Turk users assumed the role of the system or the user of a task-oriented dialogue system based on the DSTC2 ontology. Users typed instead of using speech, which means performance in the WOZ experiments is more indicative of the model's capacity for semantic understanding than its robustness to ASR errors. Whereas in the DSTC2 dialogues users would quickly adapt to the system's (lack of) language understanding capability, the WOZ experimental design gave them freedom to use more sophisticated language. We expanded the original WOZ dataset from Wen et al. (2017) using the same data collection procedure, yielding a total of 1200 dialogues. We divided these into 600 training, 200 validation and 400 test set dialogues. The WOZ 2.0 dataset is available at `mi.eng.cam.ac.uk/~nm480/woz_2.0.zip`.

Training Examples The two corpora are used to create training data for two separate experiments. For each dataset, we iterate over all train set utterances, generating one example for *each* of the slot-value pairs in the ontology. An example consists of a transcription, its context (i.e. list of preceding system acts) and a candidate slot-value pair. The binary label for each example indicates whether or not its utterance and context express the example's candidate pair. For instance, '*I would like Irish*

[3] This coefficient was tuned on the DSTC2 development set. The best performance was achieved with $\lambda = 0.55$.

food' would generate a positive example for candidate pair FOOD=IRISH, and a negative example for every other slot-value pair in the ontology.

Evaluation We focus on two key evaluation metrics introduced in (Henderson et al., 2014a):

1. **Goals** ('joint goal accuracy'): the proportion of dialogue turns where all the user's search goal constraints were correctly identified;

2. **Requests**: similarly, the proportion of dialogue turns where user's requests for information were identified correctly.

5.2 Models

We evaluate two NBT model variants: NBT-DNN and NBT-CNN. To train the models, we use the Adam optimizer (Kingma and Ba, 2015) with cross-entropy loss, backpropagating through all the NBT subcomponents while keeping the pre-trained word vectors fixed (in order to allow the model to deal with unseen words at test time). The model is trained separately for each slot. Due to the high class bias (most of the constructed examples are negative), we incorporate a fixed number of positive examples in each mini-batch.[4]

Baseline Models For each of the two datasets, we compare the NBT models to:

1. A baseline system that implements a well-known competitive delexicalisation-based model for that dataset. For DSTC2, the model is that of Henderson et al. (2014c; 2014d). This model is an n-gram based neural network model with recurrent connections between turns (but not inside utterances) which replaces occurrences of slot names and values with generic delexicalised features. For WOZ 2.0, we compare the NBT models to a more sophisticated belief tracking model presented in (Wen et al., 2017). This model uses an RNN for belief state updates and a CNN for turn-level feature extraction. Unlike NBT-CNN, their CNN operates not over vectors, but over delexicalised features akin to those used by Henderson et al. (2014c).

2. The same baseline model supplemented with a task-specific semantic dictionary (produced by the baseline system creators). The two dictionaries are available at `mi.eng.cam.ac.uk/~nm480/sem-dict.zip`. The DSTC2 dictionary contains only three rephrasings. Nonetheless, the use of these rephrasings translates to substantial gains in DST performance (see Sect. 6.1). We believe this result supports our claim that the vocabulary used by Mechanical Turkers in DSTC2 was constrained by the system's inability to cope with lexical variation and ASR noise. The WOZ dictionary includes 38 rephrasings, showing that the unconstrained language used by Mechanical Turkers in the Wizard-of-Oz setup requires more elaborate lexicons.

Both baseline models map exact matches of ontology-defined intents (and their lexicon-specified rephrasings) to one-hot delexicalised n-gram features. This means that pre-trained vectors cannot be incorporated directly into these models.

6 Results

6.1 Belief Tracking Performance

Table 1 shows the performance of NBT models trained and evaluated on DSTC2 and WOZ 2.0 datasets. The NBT models outperformed the baseline models in terms of both joint goal and request accuracies. For goals, the gains are *always* statistically significant (paired t-test, $p < 0.05$). Moreover, there was no statistically significant variation between the NBT and the lexicon-supplemented models, showing that the NBT can handle semantic relations which otherwise had to be explicitly encoded in semantic dictionaries.

While the NBT performs well across the board, we can compare its performance on the two datasets to understand its strengths. The improvement over the baseline is greater on WOZ 2.0, which corroborates our intuition that the NBT's ability to learn linguistic variation is vital for this dataset containing longer sentences, richer vocabulary and no ASR errors. By comparison, the language of the subjects in the DSTC2 dataset is less rich, and compensating for ASR errors is the main hurdle: given access to the DSTC2 test set transcriptions, the NBT models' goal accuracy rises to 0.96. This

[4] Model hyperparameters were tuned on the respective validation sets. For both datasets, the initial Adam learning rate was set to 0.001, and $\frac{1}{8}$th of positive examples were included in each mini-batch. The batch size did not affect performance: it was set to 256 in all experiments. Gradient clipping (to $[-2.0, 2.0]$) was used to handle exploding gradients. Dropout (Srivastava et al., 2014) was used for regularisation (with 50% dropout rate on all intermediate representations). Both NBT models were implemented in TensorFlow (Abadi et al., 2015).

DST Model	DSTC2		WOZ 2.0	
	Goals	Requests	Goals	Requests
Delexicalisation-Based Model	69.1	95.7	70.8	87.1
Delexicalisation-Based Model + Semantic Dictionary	72.9*	95.7	83.7*	87.6
NEURAL BELIEF TRACKER: NBT-DNN	72.6*	96.4	**84.4***	91.2*
NEURAL BELIEF TRACKER: NBT-CNN	**73.4***	**96.5**	84.2*	**91.6***

Table 1: DSTC2 and WOZ 2.0 test set accuracies for: **a)** joint goals; and **b)** turn-level requests. The asterisk indicates statistically significant improvement over the baseline trackers (paired t-test; $p < 0.05$).

indicates that future work should focus on better ASR compensation if the model is to be deployed in environments with challenging acoustics.

6.2 The Importance of Word Vector Spaces

The NBT models use the semantic relations embedded in the pre-trained word vectors to handle semantic variation and produce high-quality intermediate representations. Table 2 shows the performance of NBT-CNN[5] models making use of three different word vector collections: **1)** 'random' word vectors initialised using the XAVIER initialisation (Glorot and Bengio, 2010); **2)** distributional GloVe vectors (Pennington et al., 2014), trained using co-occurrence information in large textual corpora; and **3)** *semantically specialised* Paragram-SL999 vectors (Wieting et al., 2015), which are obtained by injecting *semantic similarity constraints* from the Paraphrase Database (Ganitkevitch et al., 2013) into the distributional GloVe vectors in order to improve their semantic content.

The results in Table 2 show that the use of semantically specialised word vectors leads to considerable performance gains: Paragram-SL999 vectors (significantly) outperformed GloVe and XAVIER vectors for goal tracking on both datasets. The gains are particularly robust for noisy DSTC2 data, where both collections of pre-trained vectors consistently outperformed random initialisation. The gains are weaker for the noise-free WOZ 2.0 dataset, which seems to be large (and clean) enough for the NBT model to learn task-specific rephrasings and compensate for the lack of semantic content in the word vectors. For this dataset, GloVe vectors do not improve over the randomly initialised ones. We believe this happens because distributional models keep related, yet antonymous words close together (e.g. *north* and *south*, *expensive* and *inexpensive*), offsetting the useful semantic content embedded in this vector spaces.

[5]The NBT-DNN model showed the same trends. For brevity, Table 2 presents only the NBT-CNN figures.

Word Vectors	DSTC2		WOZ 2.0	
	Goals	Requests	Goals	Requests
XAVIER (No Info.)	64.2	81.2	81.2	90.7
GloVe	69.0*	96.4*	80.1	91.4
Paragram-SL999	**73.4***	**96.5***	**84.2***	**91.6**

Table 2: DSTC2 and WOZ 2.0 test set performance (*joint goals* and *requests*) of the NBT-CNN model making use of three different word vector collections. The asterisk indicates statistically significant improvement over the baseline XAVIER (random) word vectors (paired t-test; $p < 0.05$).

7 Conclusion

In this paper, we have proposed a novel neural belief tracking (NBT) framework designed to overcome current obstacles to deploying dialogue systems in real-world dialogue domains. The NBT models offer the known advantages of coupling Spoken Language Understanding and Dialogue State Tracking, without relying on hand-crafted semantic lexicons to achieve state-of-the-art performance. Our evaluation demonstrated these benefits: the NBT models match the performance of models which make use of such lexicons and vastly outperform them when these are not available. Finally, we have shown that the performance of NBT models improves with the semantic quality of the underlying word vectors. To the best of our knowledge, we are the first to move past intrinsic evaluation and show that *semantic specialisation* boosts performance in downstream tasks.

In future work, we intend to explore applications of the NBT for multi-domain dialogue systems, as well as in languages other than English that require handling of complex morphological variation.

Abstract

This paper tackles the task of event detection (ED), which involves identifying and categorizing events. We argue that arguments provide significant clues to this task, but they are either completely ignored or exploited in an indirect manner in existing detection approaches. In this work, we propose to exploit argument information explicitly for ED via supervised attention mechanisms. In specific, we systematically investigate the proposed model under the supervision of different attention strategies. Experimental results show that our approach advances state-of-the-arts and achieves the best F_1 score on ACE 2005 dataset.

1 Introduction

In the ACE (Automatic Context Extraction) event extraction program, an event is represented as a structure comprising an **event trigger** and a set of **arguments**. This work tackles event detection (ED) task, which is a crucial part of event extraction (EE) and focuses on identifying event triggers and categorizing them. For instance, in the sentence "**He *died* in the hospital**", an ED system is expected to detect a ***Die*** event along with the trigger word "*died*". Besides, the task of EE also includes event argument extraction (AE), which involves event argument identification and role classification. In the above sentence, the arguments of the event include "He"($Role = Person$) and "hospital"($Role = Place$). However, this paper does not focus on AE and only tackles the former task.

According to the above definitions, event arguments seem to be not essentially necessary to ED. However, we argue that they are capable of providing significant clues for identifying and categorizing events. They are especially useful for ambiguous trigger words. For example, consider a sentence in ACE 2005 dataset:

> **Mohamad *fired* Anwar**, his **former protege**, in **1998**.

In this sentence, "*fired*" is the trigger word and the other bold words are event arguments. The correct type of the event triggered by "*fired*" in this case is ***End-Position***. However, it might be easily misidentified as ***Attack*** because "*fired*" is a multivocal word. In this case, if we consider the phrase "former protege", which serves as an argument ($Role = Position$) of the target event, we would have more confidence in predicting it as an ***End-Position*** event.

Unfortunately, most existing methods performed event detection individually, where the annotated arguments in training set are totally ignored (Ji and Grishman, 2008; Gupta and Ji, 2009; Hong et al., 2011; Chen et al., 2015; Nguyen and Grishman, 2015; Liu et al., 2016a,b; Nguyen and Grishman, 2016). Although some joint learning based methods have been proposed, which tackled event detection and argument extraction simultaneously (Riedel et al., 2009; Li et al., 2013; Venugopal et al., 2014; Nguyen et al., 2016), these approaches usually only make remarkable improvements to AE, but insignificant to ED. Table 1 illustrates our observations. Li et al. (2013) and Nguyen et al. (2016) are state-of-the-art joint models in symbolic and embedding methods for event extraction, respectively. Compared with state-of-the-art pipeline systems, both join-

Methods		ED	AE
Symbolic Methods	Hong's pipeline (2011)	68.3	48.3
	Li's joint (2013)	67.5	52.7
Embedding Methods	Chen's pipeline (2015)	69.1	53.5
	Nguyen's joint (2016)	69.3	55.4

Table 1: Performances of pipeline and joint approaches on ACE 2005 dataset. The pipeline method in each group was the state-of-the-art system when the corresponding joint method was proposed.

t methods achieved remarkable improvements on AE (over 1.9 points), whereas achieved insignificant improvements on ED (less than 0.2 points). The symbolic joint method even performed worse (67.5 vs. 68.3) than pipeline system on ED.

We believe that this phenomenon may be caused by the following two reasons. On the one hand, since joint methods simultaneously solve ED and AE, methods following this paradigm usually combine the loss functions of these two tasks and are jointly trained under the supervision of annotated triggers and arguments. However, training corpus contains much more annotated arguments than triggers (about 9800 arguments and 5300 triggers in ACE 2005 dataset) because each trigger may be along with multiple event arguments. Thus, the unbalanced data may cause joint models to favor AE task. On the other hand, in implementation, joint models usually pre-predict several potential triggers and arguments first and then make global inference to select correct items. When pre-predicting potential triggers, almost all existing approaches do not leverage any argument information. In this way, ED does hardly benefit from the annotated arguments. By contrast, the component for pre-prediction of arguments always exploits the extracted trigger information. Thus, we argue that annotated arguments are actually used for AE, not for ED in existing joint methods, which is also the reason we call it an indirect way to use arguments for ED.

Contrast to joint methods, this paper proposes to exploit argument information explicitly for ED. We have analyzed that arguments are capable of providing significant clues to ED, which gives us an enlightenment that arguments should be focused on when performing this task. Therefore, we propose a neural network based approach to detect events in texts. And in the proposed approach, we adopt a supervised attention mechanism to achieve this goal, where argument words are expected to acquire more attention than other words. The attention value of each word in a given sentence is calculated by an operation between the current word and the target trigger candidate. Specifically, in training procedure, we first construct gold attentions for each trigger candidate based on annotated arguments. Then, treating gold attentions as the supervision to train the attention mechanism, we learn attention and event detector jointly both in supervised manner. In testing procedure, we use the ED model with learned attention mechanisms to detect events.

In the experiment section, we systematically conduct comparisons on a widely used benchmark dataset ACE2005[1]. In order to further demonstrate the effectiveness of our approach, we also use events from FrameNet (FN) (F. Baker et al., 1998) as extra training data, as the same as Liu et al. (2016a) to alleviate the data-sparseness problem for ED to augment the performance of the proposed approach. The experimental results demonstrate that the proposed approach is effective for ED task, and it outperforms state-of-the-art approaches with remarkable gains.

To sum up, our main contributions are: (1) we analyze the problem of joint models on the task of ED, and propose to use the annotated argument information explicitly for this task. (2) to achieve this goal, we introduce a supervised attention based ED model. Furthermore, we systematically investigate different attention strategies for the proposed model. (3) we improve the performance of ED and achieve the best performance on the widely used benchmark dataset ACE 2005.

2 Task Description

The ED task is a subtask of ACE event evaluations where an event is defined as a specific occurrence involving one or more participants. Event extraction task requires certain specified types of events, which are mentioned

[1]https://catalog.ldc.upenn.edu/LDC2006T06

in the source language data, be detected. We firstly introduce some ACE terminologies to facilitate the understanding of this task:

Entity: an object or a set of objects in one of the semantic categories of interests.

Entity mention: a reference to an entity (typically, a noun phrase).

Event trigger: the main word that most clearly expresses an event occurrence.

Event arguments: the mentions that are involved in an event (participants).

Event mention: a phrase or sentence within which an event is described, including the trigger and arguments.

The goal of ED is to identify event triggers and categorize their event types. For instance, in the sentence "**He *died* in the hospital**", an ED system is expected to detect a ***Die*** event along with the trigger word "*died*". The detection of event arguments "He"($Role = Person$) and "hospital"($Role = Place$) is not involved in the ED task. The 2005 ACE evaluation included 8 super types of events, with 33 subtypes. Following previous work, we treat these simply as 33 separate event types and ignore the hierarchical structure among them.

3 The Proposed Approach

Similar to existing work, we model ED as a multi-class classification task. In detail, given a sentence, we treat every token in that sentence as a trigger candidate, and our goal is to classify each of these candidates into one of 34 classes (33 event types plus an NA class).

In our approach, every word along with its context, which includes the contextual words and entities, constitute an event trigger candidate. Figure 1 describes the architecture of the proposed approach, which involves two components: (i) Context Representation Learning (CRL), which reveals the representation of both contextual words and entities via attention mechanisms; (ii) Event Detector (ED), which assigns an event type (including the NA type) to each candidate based on the learned contextual representations.

3.1 Context Representation Learning

In order to prepare for Context Representation Learning (CRL), we limit the context to a fixed length by trimming longer sentences and padding shorter sentences with a special token when necessary. Let n be the fixed length and w_0 be the current candidate trigger word, then its contextual words $\mathbf{C_w}$ is $[w_{-\frac{n}{2}}, w_{-\frac{n}{2}+1}, ..., w_{-1}, w_1, ..., w_{\frac{n}{2}-1}, w_{\frac{n}{2}}]$[2], and its contextual entities, which is the corresponding entity types (including an NA type) of $\mathbf{C_w}$, is $[e_{-\frac{n}{2}}, e_{-\frac{n}{2}+1}, ..., e_{-1}, e_1, ..., e_{\frac{n}{2}-1}, e_{\frac{n}{2}}]$. For convenience, we use w to denote the current word, $[w_1, w_2, ..., w_n]$ to denote the contextual words $\mathbf{C_w}$ and $[e_1, e_2, ..., e_n]$ to denote the contextual entities $\mathbf{C_e}$ in figure 1. Note that, both w, $\mathbf{C_w}$ and $\mathbf{C_e}$ mentioned above are originally in symbolic representation. Before entering CRL component, we transform them into real-valued vector by looking up word embedding table and entity type embedding table. Then we calculate attention vectors for both contextual words and entities by performing operations between the current word w and its contexts. Finally, the contextual words representation c_w and contextual entities representation c_e are formed by the weighted sum of the corresponding embeddings of each word and entity in $\mathbf{C_w}$ and $\mathbf{C_e}$, respectively. We will give the details in the fol-

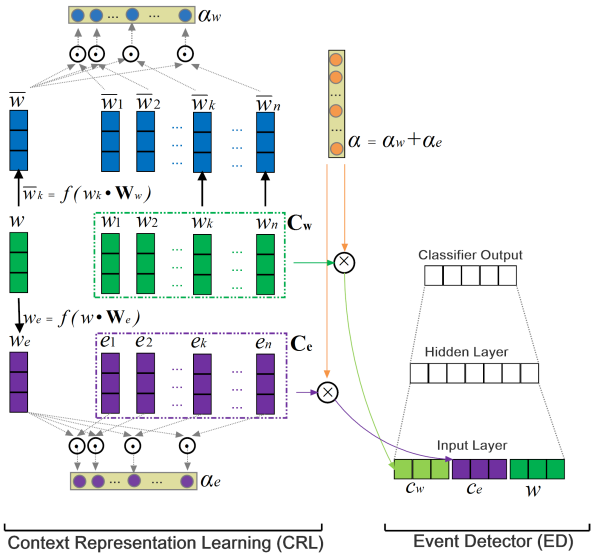

Figure 1: The architecture of the proposed approach for event detection. In this figure, w is the candidate word, $[w_1, ..., w_n]$ is the contextual words of w, and $[e_1, ..., e_n]$ is the corresponding entity types of $[w_1, ..., w_n]$.

[2]The current candidate trigger word w_0 is not included in the context.

lowing subsections.

3.1.1 Word Embedding Table

Word embeddings learned from a large amount of unlabeled data have been shown to be able to capture the meaningful semantic regularities of words (Bengio et al., 2003; Erhan et al., 2010). This paper uses the learned word embeddings as the source of basic features. Specifically, we use the Skip-gram model (Mikolov et al., 2013) to learn word embeddings on the NYT corpus[3].

3.1.2 Entity Type Embedding Table

The ACE 2005 corpus annotated not only events but also entities for each given sentence. Following existing work (Li et al., 2013; Chen et al., 2015; Nguyen and Grishman, 2015), we exploit the annotated entity information in our ED system. We randomly initialize embedding vector for each entity type (including the NA type) and update it in training procedure.

3.1.3 Representation Learning

In this subsection, we illustrate our proposed approach to learn representations of both contextual words and entities, which serve as inputs to the following event detector component. Recall that, we use the matrix $\mathbf{C_w}$ and $\mathbf{C_e}$ to denote contextual words and contextual entities, respectively.

As illustrated in figure 1, the CRL component needs three inputs: the current candidate trigger word w, the contextual words $\mathbf{C_w}$ and the contextual entities $\mathbf{C_e}$. Then, two attention vectors, which reflect different aspects of the context, are calculated in the next step.

The contextual word attention vector α_w is computed based on the current word w and its contextual words $\mathbf{C_w}$. We firstly transform each word w_k (including w and every word in $\mathbf{C_w}$) into a hidden representation $\overline{w}_k$ by the following equation:

$$\overline{w}_k = f(w_k \cdot W_w) \tag{1}$$

where $f(\cdot)$ is a non-linear function such as the hyperbolic tangent, and W_w is the transformation matrix. Then, we use the hidden representations to compute the attention value for each word in $\mathbf{C_w}$:

$$\alpha_w^k = \frac{\exp(\overline{w} \cdot \overline{w}_k^{\mathrm{T}})}{\sum_i \exp(\overline{w} \cdot \overline{w}_i^{\mathrm{T}})} \tag{2}$$

The contextual entity attention vector α_e is calculated with a similar method to α_w.

$$\alpha_e^k = \frac{\exp(w_e \cdot e_k^{\mathrm{T}})}{\sum_i \exp(w_e \cdot e_i^{\mathrm{T}})} \tag{3}$$

Note that, we do not use the entity information of the current candidate token to compute the attention vector. The reason is that only a small percentage of true event triggers are entities[4]. Therefore, the entity type of a candidate trigger is meaningless for ED. Instead, we use w_e, which is calculated by transforming w from the word space into the entity type space, as the attention source.

We combine α_w and α_e to obtain the final attention vector, $\alpha = \alpha_w + \alpha_e$. Finally, the contextual words representation c_w and the contextual entities representation c_e are formed by weighted sum of $\mathbf{C_w}$ and $\mathbf{C_e}$, respectively:

$$c_w = \mathbf{C_w}\alpha^{\mathrm{T}} \tag{4}$$

$$c_e = \mathbf{C_e}\alpha^{\mathrm{T}} \tag{5}$$

3.2 Event Detector

As illustrated in figure 1, we employ a three-layer (an input layer, a hidden layer and a softmax output layer) Artificial Neural Networks (ANNs) (Hagan et al., 1996) to model the ED task, which has been demonstrated very effective for event detection by Liu et al. (2016a).

3.2.1 Basic ED Model

Given a sentence, as illustrated in figure 1, we concatenate the embedding vectors of the context (including contextual words and entities) and the current candidate trigger to serve as the input to ED model. Then, for a given input sample $\mathbf{x}$, ANN with parameter θ outputs a vector $\mathbf{O}$, where the i-th value o_i of $\mathbf{O}$ is the confident score for classifying $\mathbf{x}$ to the i-th event type. To obtain the conditional probability $p(i|\mathbf{x}, \theta)$, we apply a softmax operation over all event types:

$$p(i|\mathbf{x}, \theta) = \frac{e^{o_i}}{\sum_{k=1}^{m} e^{o_k}} \tag{6}$$

[3] https://catalog.ldc.upenn.edu/LDC2008T19

[4] Only 10% of triggers in ACE 2005 are entities.

Given all of our (suppose T) training instances $(\mathbf{x}^{(\mathbf{i})}; y^{(i)})$, we can then define the negative log-likelihood loss function:

$$J(\theta) = -\sum_{i=1}^{T} \log p(y^{(i)}|\mathbf{x}^{(\mathbf{i})}, \theta) \quad (7)$$

We train the model by using a simple optimization technique called stochastic gradient descent (SGD) over shuffled mini-batches with the Adadelta rule (Zeiler, 2012). Regularization is implemented by a dropout (Kim, 2014; Hinton et al., 2012) and L_2 norm.

3.2.2 Supervised Attention

In this subsection, we introduce supervised attention to explicitly use annotated argument information to improve ED. Our basic idea is simple: argument words should acquire more attention than other words. To achieve this goal, we first construct vectors using annotated arguments as the gold attentions. Then, we employ them as supervision to train the attention mechanism.

Constructing Gold Attention Vectors

Our goal is to encourage argument words to obtain more attention than other words. To achieve this goal, we propose two strategies to construct gold attention vectors:

S1: only pay attention to argument words. That is, all argument words in the given context obtain the same attention, whereas other words get no attention. For candidates without any annotated arguments in context (such as negative samples), we force all entities to average the whole attention. Figure 2 illustrates the details, where α^* is the final gold attention vector.

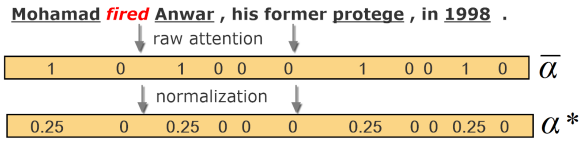

Figure 2: An example of S1 to construct gold attention vector. The word *fired* is the trigger candidate, and underline words are arguments of *fired* annotated in the corpus.

S2: pay attention to both arguments and the words around them. The assumption is that, not only arguments are important to ED, the words around them are also helpful. And the nearer a word is to arguments, the more attention it should obtain. Inspired by Mi et al. (2016), we use a gaussian distribution $g(\cdot)$ to model the attention distribution of words around arguments. In detail, given an instance, we first obtain the raw attention vector $\overline{\alpha}$ in the same manner as S1 (see figure 2). Then, we create a new vector $\alpha^{'}$ with all points initialized with zero, and for each $\overline{\alpha}_i = 1$, we update $\alpha^{'}$ by the following algorithm:

Algorithm 1: Updating $\alpha^{'}$

for $k \in \{-w, ..., 0, ..., w\}$ **do**
  $\alpha^{'}_{i+k} = \alpha^{'}_{i+k} + g(|k|, \mu, \sigma)$
end

where w is the window size of the attention mechanism and μ, σ are hyper-parameters of the gaussian distribution. Finally, we normalize $\alpha^{'}$ to obtain the target attention vector α^*. Similar with S1, we treat all entities in the context as arguments if the current candidate does not has any annotated arguments (such as netative samples).

Jointly Training ED and Attention

Given the gold attention α^* (see subsection 3.2.2) and the machine attention α produced by our model (see subsection 3.1.3), we employ the square error as the loss function of attentions:

$$D(\theta) = \sum_{i=1}^{T} \sum_{j=1}^{n} ({\alpha^*}^i_j - \alpha^i_j)^2 \quad (8)$$

Combining equation 7 and equation 8, we define the joint loss function of our proposed model as follows:

$$J^{'}(\theta) = J(\theta) + \lambda D(\theta) \quad (9)$$

where λ is a hyper-parameter for trade-off between J and D. Similar to basic ED model, we minimize the loss function $J^{'}(\theta)$ by using SGD over shuffled mini-batches with the Adadelta update rule.

4 Experiments

4.1 Dataset and Experimental Setup

Dataset

We conducted experiments on ACE 2005 dataset. For the purpose of comparison, we fol-

lowed the evaluation of (Li et al., 2013; Chen et al., 2015; Liu et al., 2016b): randomly selected 30 articles from different genres as the development set, and subsequently conducted a blind test on a separate set of 40 ACE 2005 newswire documents. We used the remaining 529 articles as our training set.

Hyper-parameter Setting

Hyper-parameters are tuned on the development dataset. We set the dimension of word embeddings to 200, the dimension of entity type embeddings to 50, the size of hidden layer to 300, the output size of word transformation matrix W_w in equation 1 to 200, the batch size to 100, the hyper-parameter for the L_2 norm to 10^{-6} and the dropout rate to 0.6. In addition, we use the standard normal distribution to model attention distributions of words around arguments, which means that $\mu = 0.0, \sigma = 1.0$, and the window size is set to 3 (see Subsection 3.2.2). The hyper-parameter λ in equation 9 is various for different attention strategies, we will give its setting in the next section.

4.2 Correctness of Our Assumption

In this section, we conduct experiments on ACE 2005 corpus to demonstrate the correctness of our assumption that argument information is crucial to ED. To achieve this goal, we design a series of systems for comparison.

ANN is the basic event detection model, in which the hyper-parameter λ is set to 0. This system does not employ argument information and computes attentions without supervision (see Subsection 3.1.3).

ANN-ENT assigns λ with 0, too. The difference is that it constructs the attention vector α by forcing all entities in the context to average the attention instead of computing it in the manner introduced in Subsection 3.1.3. Since all arguments are entities, this system is designed to investigate the effects of entities.

ANN-Gold1 uses the gold attentions constructed by strategy S1 in both **training** and **testing** procedure.

ANN-Gold2 is akin to *ANN-Gold1*, but uses the second strategy to construct its gold attentions.

Note that, in order to avoid the interference of attention mechanisms, the last two systems are designed to use argument information (via gold attentions) in both training and testing procedure. Thus both *ANN-Gold1* and *ANN-Gold2* assign λ with 0.

Methods	P	R	F_1
ANN	69.9	60.8	65.0
ANN-ENT	79.4	60.7	68.8
ANN-Gold1†	**81.9**	65.1	72.5
ANN-Gold2†	81.4	**66.9**	**73.4**

Table 2: Experimental results on ACE 2005 corpus. † designates the systems that employ argument information.

Table 2 compares these systems on ACE 2005 corpus. From the table, we observe that systems with argument information (the last two systems) significantly outperform systems without argument information (the first two systems), which demonstrates that argument information is very useful for this task. Moreover, since all arguments are entities, for preciseness we also investigate that whether *ANN-Gold1/2* on earth benefits from entities or arguments. Compared with *ANN-ENT* (revising that this system only uses entity information), *ANN-Gold1/2* performs much better, which illustrates that entity information is not enough and further demonstrates that argument information is necessary for ED.

4.3 Results on ACE 2005 Corpus

In this section, we conduct experiments on ACE 2005 corpus to demonstrate the effectiveness of the proposed approach. Firstly, we introduce systems implemented in this work.

ANN-S1 uses gold attentions constructed by strategy **S1** as supervision to learn attention. In our experiments, λ is set to 1.0.

ANN-S2 is akin to *ANN-S1*, but use strategy **S2** to construct gold attentions and the hyper-parameter λ is set to 5.0.

These two systems both employ supervised attention mechanisms. For comparison, we use an unsupervised-attention system *ANN* as our baseline, which is introduced in Subsection 4.2. In addition, we select the following state-of-the-art methods for comparison.

1). *Li's joint model* (Li et al., 2013) extracts events based on structure prediction. It is the best structure-based system.

Methods	P	R	F_1
Li's joint model (2013)	73.7	62.3	67.5
Liu's PSL (2016)	75.3	64.4	69.4
Liu's FN-Based (2016)	77.6	65.2	70.7
Ngyuen's joint (2016)	66.0	**73.0**	69.3
Skip-CNN (2016)	N/A		71.3
ANN	69.9	60.8	65.0
ANN-S1†	**81.4**	62.4	70.8
ANN-S2†	78.0	66.3	**71.7**

Table 3: Experimental results on ACE 2005. The first group illustrates the performances of state-of-the-art approaches. The second group illustrates the performances of the proposed approach. † designates the systems that employ arguments information.

2). *Liu's PSL* (Liu et al., 2016b) employs both latent local and global information for event detection. It is the best-reported feature-based system.

3). *Liu's FN-Based approach* (Liu et al., 2016a) leverages the annotated corpus of FrameNet to alleviate data sparseness problem of ED based on the observation that frames in FN are analogous to events in ACE.

4). *Ngyen's joint model* (Nguyen et al., 2016) employs a bi-directional RNN to jointly extract event triggers and arguments. It is the best-reported representation-based joint approach proposed on this task.

5). *Skip-CNN* (Nguyen and Grishman, 2016) introduces the non-consecutive convolution to capture non-consecutive k-grams for event detection. It is the best reported representation-based approach on this task.

Table 3 presents the experimental results on ACE 2005 corpus. From the table, we make the following observations:

1). *ANN* performs unexpectedly poorly, which indicates that unsupervised-attention mechanisms do not work well for ED. We believe the reason is that the training data of ACE 2005 corpus is insufficient to train a precise attention in an unsupervised manner, considering that data sparseness is an important issue of ED (Zhu et al., 2014; Liu et al., 2016a).

2). With argument information employed via supervised attention mechanisms, both *ANN-S1* and *ANN-S2* outperform *ANN* with remarkable gains, which illustrates the effectiveness of the proposed approach.

3). *ANN-S2* outperforms *ANN-S1*, but the latter achieves higher precision. It is not difficult to understand. On the one hand, strategy **S1** only focuses on argument words, which provides accurate information to identify event type, thus *ANN-S1* could achieve higher precision. On the other hand, **S2** focuses on both arguments and words around them, which provides more general but noised clues. Thus, *ANN-S2* achieves higher recall with a little loss of precision.

4). Compared with state-of-the-art approaches, our method *ANN-S2* achieves the best performance. We also perform a t-test ($p \leqslant 0.05$), which indicates that our method significantly outperforms all of the compared methods. Furthermore, another noticeable advantage of our approach is that it achieves much higher precision than state-of-the-arts.

4.4 Augmentation with FrameNet

Recently, Liu et al. (2016a) used events automatically detected from FN as extra training data to alleviate the data-sparseness problem for event detection. To further demonstrate the effectiveness of the proposed approach, we also use the events from FN to augment the performance of our approach.

In this work, we use the events published by Liu et al. (2016a)[5] as extra training data. However, their data can not be used in the proposed approach without further processing, because it lacks of both argument and entity information. Figure 3 shows several examples of this data.

##001 **Grandad was [dead] by then and so were the two great-uncles .**
Event Type: Die

##002 **I [divorced] my wife for smoking in the toilet !**
Event Type: Divorce

##003 **He was [executed] yesterday.**
Event Type: Execute

Figure 3: Examples of events detected from FrameNet (published by Liu et al. (2016a)).

Processing of Events from FN

Liu et al. (2016a) detected events from FrameNet based on the observation that frames in FN are analogous to events in ACE

[5]https://github.com/subacl/acl16

(lexical unit of a frame ↔ trigger of an event, frame elements of a frame ↔ arguments of an event). All events they published are also frames in FN. Thus, we treat frame elements annotated in FN corpus as event arguments. Since frames generally contain more frame elements than events, we only use core[6] elements in this work. Moreover, to obtain entity information, we use RPI Joint Information Extraction System[7] (Li et al., 2013, 2014; Li and Ji, 2014) to label ACE entity mentions.

Experimental Results

We use the events from FN as extra training data and keep the development and test datasets unchanged.Table 4 presents the experimental results.

Methods	P	R	F_1
ANN	69.9	60.8	65.0
ANN-S1	**81.4**	62.4	70.8
ANN-S2	78.0	66.3	71.7
ANN +FrameNet	72.5	61.7	66.7
ANN-S1 +FrameNet	80.1	63.6	70.9
ANN-S2 +FrameNet	76.8	**67.5**	**71.9**

Table 4: Experimental results on ACE 2005 corpus. "+FrameNet" designates the systems that are augmented by events from FrameNet.

From the results, we observe that:

1). With extra training data, *ANN* achieves significant improvements on F_1 measure (66.7 vs. 65.0). This result, to some extent, demonstrates the correctness of our assumption that the data sparseness problem is the reason that causes unsupervised attention mechanisms to be ineffective to ED.

2). Augmented with external data, both *ANN-S1* and *ANN-S2* achieve higher recall with a little loss of precision. This is to be expected. On the one hand, more positive training samples consequently make higher recall. On the other hand, the extra event samples are automatically extracted from FN, thus false-positive samples are inevitable to be involved, which may result in hurting the precision. Anyhow, with events from FN, our approach achieves higher F_1 score.

[6]FrameNet classifies frame elements into three groups: core, peripheral and extra-thematic.

5 Related Work

Event detection is an increasingly hot and challenging research topic in NLP. Generally, existing approaches could roughly be divided into two groups.

The first kind of approach tackled this task under the supervision of annotated triggers and entities, but totally ignored annotated arguments. The majority of existing work followed this paradigm, which includes feature-based methods and representation-based methods. Feature-based methods exploited a diverse set of strategies to convert classification clues (i.e., POS tags, dependency relations) into feature vectors (Ahn, 2006; Ji and Grishman, 2008; Patwardhan and Riloff, 2009; Gupta and Ji, 2009; Liao and Grishman, 2010; Hong et al., 2011; Liu et al., 2016b). Representation-based methods typically represent candidate event mentions by embeddings and feed them into neural networks (Chen et al., 2015; Nguyen and Grishman, 2015; Liu et al., 2016a; Nguyen and Grishman, 2016).

The second kind of approach, on the contrast, tackled event detection and argument extraction simultaneously, which is called joint approach (Riedel et al., 2009; Poon and Vanderwende, 2010; Li et al., 2013, 2014; Venugopal et al., 2014; Nguyen et al., 2016). Joint approach is proposed to capture internal and external dependencies of events, including trigger-trigger, argument-argument and trigger-argument dependencies. Theoretically, both ED and AE are expected to benefit from joint methods because triggers and arguments are jointly considered. However, in practice, existing joint methods usually only make remarkable improvements to AE, but insignificant to ED. Different from them, this work investigates the exploitation of argument information to improve the performance of ED.

6 Conclusions

In this work, we propose a novel approach to model argument information explicitly for ED via supervised attention mechanisms. Besides, we also investigate two strategies to construct gold attentions using the annotated arguments. To demonstrate the effectiveness of the proposed method, we systematically conduc-

t a series of experiments on the widely used benchmark dataset ACE 2005. Moreover, we also use events from FN to augment the performance of the proposed approach. Experimental results show that our approach outperforms state-of-the-art methods, which demonstrates that the proposed approach is effective for event detection.

Abstract

This paper presents an LDA-based model that generates topically coherent segments within documents by jointly segmenting documents and assigning topics to their words. The coherence between topics is ensured through a copula, binding the topics associated to the words of a segment. In addition, this model relies on both document and segment specific topic distributions so as to capture fine grained differences in topic assignments. We show that the proposed model naturally encompasses other state-of-the-art LDA-based models designed for similar tasks. Furthermore, our experiments, conducted on six different publicly available datasets, show the effectiveness of our model in terms of perplexity, Normalized Pointwise Mutual Information, which captures the coherence between the generated topics, and the Micro F1 measure for text classification.

1 Introduction

Since the seminal works of Hofmann (1999) and Blei et al. (2003), there have been several developments in probabilistic topic models. Many extensions have indeed been proposed for different applications, including ad-hoc information retrieval (Wei and Croft, 2006), clustering search results (Zeng et al., 2004) and driving faceted browsing (Mimno and McCallum, 2007). In most of these studies, the initial exchangeability assumptions of PLSA and LDA, stipulating that words within a document are interdependent, has led to incoherent topic assignments within semantically meaningful text units, even though the importance of having topically coherent phrases is generally admitted (Griffiths et al., 2005). More recently, (Balikas et al., 2016b) has shown that binding topics, so as to obtain more coherent topic assignments, within such text segments as noun phrases improves the performance (*e.g.* in terms of perplexity) of LDA-based models. The question nevertheless remains as to which segmentation one should rely on.

Furthermore, text segments can refer to topics that are barely present in other parts of the document. For example, the segment "*the Kurdish regional capital*" in the sentence[1] "*A thousand protesters took to the main street in Erbil, the Kurdish regional capital, to condemn a new law requiring all public demonstrations to have government permits.*" refers to geography in a document that is mainly devoted to politics. Relying on a single topic distribution, as done in most previous studies including (Balikas et al., 2016b), may prevent one from capturing those segment specific topics.

In this paper, we propose a novel LDA-based model that automatically segments documents into topically coherent sequences of words. The coherence between topics is ensured through *copulas* (Elidan, 2013) that bind the topics associated to the words of a segment. In addition, this model relies on both document and segment specific topic distri-

[1] This sentence is taken from New York Times news (NYT) collection described in Section 4.

https://doi.org/10.18653/v1/P17-1165

butions so as to capture fine grained differences in topic assignments. A simple switching mechanism is used to select the appropriate distribution (document or segment specific) for assigning a topic to a word. We show that this model naturally encompasses other state-of-the-art LDA-based models proposed to accomplish the same task, and that it outperforms these models over six publicly available collections in terms of perplexity, Normalized Pointwise Mutual Information (NPMI), a measure used to assess the coherence of topics with documents, and the Micro F1-measure in a text classification context.

2 Related work

Probabilistic Latent Semantic Analysis (PLSA) proposed by (Hofmann, 1999) is the first probabilistic model that explains the generation of co-occurrence data using latent random topics and, the EM algorithm for parameter estimation. The model was found more flexible and scalable than the Latent Semantic Analysis (Deerwester et al., 1990), which is based on the singular value decomposition of the document-term matrix, however PLSA is not a generative model as parameter estimation should be performed at each addition of new documents. To overcome this drawback, Blei et al. (2003) proposed the Latent Dirichlet Allocation (LDA) by assuming that the latent topics are random variables sampled from a Dirichlet distribution and that the generated words, occurring in a document, are exchangeable. The interdependence assumption allows the parameter estimation and the inference of the LDA model to be carried out efficiently, but it is not realistic in the sense that topics assigned to similar words of a text span are generally incoherent.

Different studies, presented in the following sections, attempted to remedy this problem and they can be grouped in two broad families depending on whether they make use of external knowledge-based tools or not in order to exhibit text structure for word-topic assignment.

2.1 Knowledge-based topic assignments

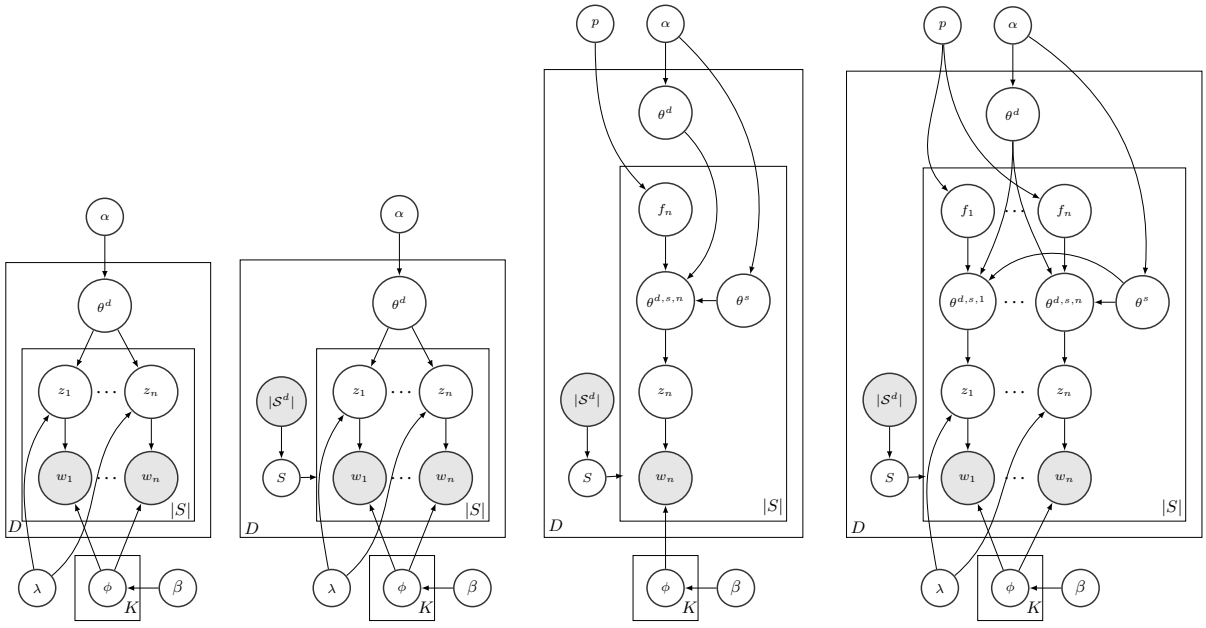
The main assumption behind these models are that text-spans such as sentences, phrases or segments are related in their content. Therefore, the integration of these dependent structures can help to discover coherent latent topics for words. Different attempts to combine LDA-based models with statistical tools to discover document structures have been successfully proposed, such as the study of Griffiths et al. (2005) who investigated the effect of combining a Hidden Markov Model with LDA to capture long and short distance dependencies. Similarly, (Boyd-Graber and Blei, 2008; Balikas et al., 2016a,b) integrated text structure exhibited by a parser or a chunker in their topic models. In this line, Du et al. (2013) following (Du et al., 2010) presented a hierarchical Bayesian model for unsupervised topic segmentation. This model integrates a boundary sampling method used in a Bayesian segmentation model introduced by Purver et al.(2006) to the topic model. For inference, a non-parametric Markov Chain inference is used that splits and merges the segments while a Pitman-Yor process (Teh, 2006) binds the topics. Recently, Tamura and Sumita (2016) extended this idea to the bilingual setting. They assume that documents consist of segments and the topic distribution of each segment is generated using a Pitman-Yor process (Teh, 2006).

Though, the topic assignments follow the structure of the text; these models suffer from the bias of statistical or linguistic tools they rely on. To overpass this limitation, other systems integrated automatically the extraction of text structure, in the form of phrases, in their process.

2.2 Knowledge-free topic assignments

This type of models extract text-spans using n-gram counts and word collections and use bigrams to integrate the order of words as well as to capture the topical content of a phrase (Lau et al., 2013). In (Wang et al., 2007), depending on the topic a particular bigram can be either considered as a single token or as two unigrams. Further, Wang et al. (2009) merged topic models with a unigram model over sentences that assigns topics to the sentences instead of the words.

Our proposed approach also does not make use of external statistical tools to find text segments. The main difference with the previous knowledge-free topic model approaches is that the proposed approach assigns topics to words based on two, segment-specific and document-specific distributions selected from a Bernoulli law. Topics within segments are then constrained using copulas that bind their distributions. In this way, segmentation is embedded in the model and it naturally comes along with the topic assignment.



(a) copLDA (b) segLDAcop$_{p=0}$ (c) segLDAcop$_{\lambda=0}$ (d) segLDAcop

Figure 1: Graphical model for Copula LDA (copLDA), extension of Copula LDA with segmentation (segLDAcop$_{p=0}$), LDA with segmentation and topic shift (segLDAcop$_{\lambda=0}$) and complete model (segLDAcop).

3 Joint latent model for topics and segments

We define here a *segment* as a topically coherent sequence of contiguous words. By topically coherent, we mean that, even though words in a segment can be associated to different topics, these topics are usually related. This view is in line with the one expressed in (Balikas et al., 2016b), in which a latent topic model, referred to as copLDA in the remainder, includes a binding mechanism between topics within coherent text spans, defined in their study as noun phrases (NPs). The relation between topics is captured through a copula that provides a joint probability for all the topics used in a segment. That is, to generate words in a segment, one first jointly generates all the word specific topics z via a copula, and then generates each word in the segment from its word specific topic and the word-topic distribution ϕ. Figure 1(a) illustrates this.

Copulas are particularly useful when modeling dependencies between random variables, as the joint cumulative distribution function (CDF) $F_{X_1,\cdots,X_n}$ of any random vector $\mathbf{X} = (X_1, \cdots, X_n)$ can be written as a function of its marginals, according to Sklar's Theorem (Nelsen, 2006):

$$F_{X_1,\cdots,X_n}(x_1, \cdots, x_p) = C(F_{X_1}(x_1), \cdots, F_{X_n}(x_n))$$

where C is a copula. For latent topic models, as discussed in (Amoualian et al., 2016), Frank's copula is particularly interesting as (a) it is invariant by permutations and associative, as are the words and topics z in each segment due to the exchangeability assumption, and (b) it relies on a single parameter (denoted λ here) that controls the strength of dependence between the variables and is thus easy to implement. In Frank's copula, when the parameter λ approaches 0, the variables are independent of each other, whereas when λ approaches $+\infty$, the variables take the same value. For further details on copulas, we refer the reader to (Nelsen, 2006).

One important problem, however, with copLDA is its reliance on a predefined segmentation. Although the information brought by the segmentation based on NPs helps to improve topic assignment, it may not be flexible enough to capture all the possible segments of a text. It is easy to correct this problem by considering all possible segmentations of a document and by choosing the most appropriate one at the same time that topics are assigned to words. This is illustrated in Figure 1(b), where a segmentation S is chosen from the set $\mathcal{S}^d$ of possible segmentations for a document d, and where each segment in S are generated in turn. We refer to the associated model as segLDAcop$_{p=0}$ for reasons that will become clear later.

Another point to be noted about copLDA (and

segLDAcop$_{p=0}$) is that the topics used in each segment come from the same document specific topic distribution θ^d. This entails that, in these models, one cannot differentiate the main topics of a document from potential segment specific topics that can explain some parts of it. Indeed, some text segments can refer to topics that are barely present in other parts of the document; relying on a single topic distribution may prevent one from capturing those segment specific topics.

It is possible to overcome this difficulty by generating a segment specific topic distribution as illustrated in Figure 1(c) (this model is referred to as segLDAcop$_{\lambda=0}$, again for reasons that will become clear later). However, as some words in a segment can be associated to the general topics of a document, we introduce a mechanism to choose, for each word in a segment, a topic either from the segment specific topic distribution θ^s or from the document specific topic distribution θ^d (this mechanism is similar to the one used for routes and levels in (Paul and Girju, 2010)). The choice between them is based on the Bernoulli variable f, as explained in the generative story given below.

The above developments can be combined in a single, complete model, illustrated in Figure 1(d) and detailed below. We will simply refer to this model as segLDAcop.

3.1 Complete generative model

As in standard LDA based models, with V denoting the size of the vocabulary of the collection and K the number of latent topics, β and ϕ^k, $1 \leq k \leq K$, are V dimensional vectors, α and θ (*i.e.*, $\theta^d, \theta^s, \theta^{d,s,n}$) are K dimensional vectors, whereas z_n takes value in $\{1, \cdots, K\}$. Lower indices are used to denote coordinates of the above vectors. Lastly, Dir denotes the Dirichlet distribution, Cat the categorical distribution (which is a multinomial distribution with one draw) and we omit, as is usual, the generation of the length of the document. The complete model segLDAcop is then based on the following generative process:

1. Generate, for each topic $k, 1 \leq k \leq K$, a distribution over the words: $\phi^k \sim Dir(\beta)$;
2. For each document $d, 1 \leq d \leq D$:
   (a) Choose a document specific topic distribution: $\theta^d \sim Dir(\alpha)$;
   (b) Choose a segmentation S of the document uniformly from the set of all possible segmentations $\mathcal{S}^d$: $P(S) = \frac{1}{|\mathcal{S}^d|}$;
   (c) For each segment s in S:
      (i) Choose a segment specific topic distribution: $\theta^s \sim Dir(\alpha)$;
      (ii) For each position n in s, choose $f_n \sim Ber(p)$ and set:

$$\theta^{d,s,n} = \begin{cases} \theta^s & \text{if } f_n = 1 \\ \theta^d & \text{otherwise} \end{cases}$$

      (iii) Choose topics $\mathcal{Z}^s = \{z_1, \ldots, z_n\}$ from Frank's copula with parameter λ and marginals $Cat(\theta^{d,s,n})$;
      (iv) For each position n in s, choose word w_n: $w_n \sim Cat(\phi^{z_n})$.

As on can note, the generative process relies on a segmentation uniformly chosen from the set of possible segmentations (step *2.b*) to generate related topics within each segment (Frank's copula in step *2.c.(iii)*), the distribution underlying each word specific topic z_n being either specific to the segment or general to the document (steps *2.c.(i)* and *2.c.(ii)*). The other steps are similar to the standard LDA steps.

As in almost all previous studies on LDA, α and β are considered fixed and symmetric, each coordinate of the vector being equal: $\alpha_1 = \cdots = \alpha_K$. The hyperparameters p ($\in [0, 1]$) of the Bernoulli distribution and λ ($\in [0, +\infty]$) of Frank's copula respectively regulate the choice between the segment specific and the document specific topic distributions and the strength of the dependence between topics in a segment. As for the other hyperparameters, we consider them fixed here (the values for all hyperparameters are given in Section 4).

As mentioned before, all the models presented in Figure 1 are special cases of the complete model segLDAcop: hence segLDAcop$_{\lambda=0}$ is obtained by dropping the topic dependencies, which amounts to setting λ to (a value close to) 0, segLDAcop$_{p=0}$ is obtained by relying only on the topic distribution obtained for the document, which amounts to setting p to 0, and the previously introduced copLDA model is obtained by setting p to 0, and fixing the segmentation.

3.2 Inference with Gibbs sampling

The parameters of the complete model can be directly estimated through Gibbs sampling. The Gibbs updates for the parameters ϕ and θ are the same as the ones for standard LDA (Blei et al.,

2003). The parameters f_n are directly estimated through: $f_n \sim Ber(p)$. Lastly, for the variables z, we follow the same strategy as the one described in (Balikas et al., 2016b) and based on (Amoualian et al., 2016), leading to:

$$P(\mathcal{Z}^s|\mathcal{Z}^{-s}, W, \Theta, \Phi, \lambda) = p(\mathcal{Z}^s|\Theta, \lambda) \prod_n \phi_{w_n}^{z_n}$$

where W denotes the document collection, and Θ and Φ the sets of all θ and ϕ^k, $1 \leq k \leq K$, vectors. $p(\mathcal{Z}^s|\Theta, \lambda)$ is obtained by Frank's copula with parameter λ and marginals $Cat(\theta^{d,s,n})$. As is standard in topic models, the notation $-s$ means excluding the information from s.

From the above equation, one can formulate an acceptance/rejection algorithm based on the following steps: (a) sample $\mathcal{Z}^s$ from $p(\mathcal{Z}^s|\Theta, \lambda)$ using Frank's copula, and (b) accept the sample with probability $\prod_n \phi_{w_n}^{z_n}$, where n runs over all the positions in segment s.

3.3 Efficient segmentation

As topics may change from one sentence to another, we assume here that segments cannot overlap sentence boundaries. The different segmentations of a document are thus based on its sentence segmentations. In the remainder, we use L to denote the maximum length of a segment and $g(M; L)$ to denote the number of segmentations in a sentence of length M, each segment comprising at most L words.

Generating all possible segmentations of a sentence and then selecting one at random is not an efficient process as the number of segments rapidly grows with the length of the sentence. In practice, however, one can define an efficient segmentation on the basis of the following proposition, the proof of which is given in Appendix A:

Proposition 3.1. *Let l_i^s be the random variable associated to the length of the segment starting at position i in a sentence of length M (positions go from 1 to M and l_i^s takes value in $\{1, \cdots, L\}$). Then $P(l_i^s = l) := \frac{g(M+1-i-l);L)}{g(M+1-i;L)}$ defines a probability distribution over l_i^s.*

Furthermore, the following process is equivalent to choosing sentence segmentations uniformly from the set of possible segmentations.

```
From pos. 1, repeat till end of sentence:
(a) Generate segment length acc. to P;
(b) Add segment to current segmentation;
(c) Move to position after the segment.
```

In practice, we thus replace steps *2.b* and *2.c* of the generative story by a loop over all sentences, and in each sentence use the process described in Prop, 3.1. Furthermore, as described in Appendix A, the values of g needed to compute $P(l_i^s = l)$ can be efficiently computed by recurrence.

4 Experiments

We conducted a number of experiments aimed at studying the impact of simultaneously segmenting and assigning topics to words within segments using the proposed `segLDAcop` model.

Datasets: We considered six publicly available datasets derived from Pubmed[2] (Tsatsaronis et al., 2015), Wikipedia (Partalas et al., 2015), Reuters[3] and New York Times (NYT)[4] (Yao et al., 2016). The first two collections were considered in (Balikas et al., 2016a), we followed their setup by considering 3 subsets of Wikipedia with different number of classes (namely, Wiki0, Wiki1 and Wiki2). The Reuters dataset comes from Reuters-21578, Distribution 1.0 as investigated in (Bird et al., 2009) and the NYT dataset is collected from full text of New York Times global news, from January 1st to December 31st, 2011.

These collections were processed following (Blei et al., 2003) by removing a standard list of 50 stop words, lemmatizing, lowercasing and keeping only words made of letters. To deal with relatively homogeneous collections, we also removed documents that are too long. The statistics of these datasets, as well as the admissible maximal length for documents, in terms of the number of words they contain, can be found in Table 1.

Settings: We compared our models (`segLDAcop`$_{p=0}$, `segLDAcop`$_{\lambda=0}$, `segLDAcop`) with three models, namely the standard `LDA` model, and two previously introduced models aiming at binding topics within segments:

1. `LDA`: Standard Latent Dirichlet Allocation implemented using collapsed Gibbs sampling inference (Griffiths and Steyvers, 2004)[5]. Note

Table 1: Dataset statistics.

that there are neither segmentation nor topic binding mechanisms in this model;

2. `senLDA`: Sentence LDA, introduced in (Balikas et al., 2016a), which forces all words within a sentence to be assigned to the same topic. The segments considered thus correspond to sentences, and the binding between topics within segments is maximal as all word specific topics are equal;
3. `copLDA`: Copula LDA, introduced in (Balikas et al., 2016b) already discussed before, which relies on two types of segments, namely NPs (extracted with the `nltk.chunk` package (Bird et al., 2009)) and single words. In addition, a copula is also used to bind topics within NPs, from the document specific topic distribution.

Both `senLDA` and `copLDA` implementations, can be found in `https://github.com/balikasg/topicModelling`.

In all models α and β play a symmetric role and are respectively fixed to $1/K$, following (Asuncion et al., 2009). For copula based models, λ is set to 5, following (Balikas et al., 2016b). As already discussed, p is set to 0 for $\texttt{segLDAcop}_{p=0}$; it is set to 0.5 for `segLDAcop` so as not to privilege *a priori* one topic distribution (document or segment specific) over the other. For sampling from Frank's copula, we relied on the R copula package (Hofert and Maechler, 2011) [6]. We chose L (the maximum length of a segment) using line search for $L \in [2, 5]$ and used $L = 3$ in all our experiments. Finally, to illustrate the behaviors of the different models with different number of topics, we present here the results obtained with $K = 20$ and $K = 100$.

We now compare the different models along three main dimensions: perplexity, use of topic representations for classification and topic coherence.

[6] Our complete code will be available for research purposes.

4.1 Perplexity

We first randomly split here all the collections, using 75% of them for training, and 25% for testing.

In order to see how well the models fit the data and following (Blei et al., 2003), we first evaluated the methods in terms of perplexity defined as:

$$Perplexity = \exp\left(\frac{-\sum_{d\in D}\sum_{w\in d}\log\sum_{k=1}^{K}\theta_k^d\phi_w^k}{\sum_{d\in D}|d|}\right),$$

where d is a test document from the test set D, and $|d|$ is the total number of words in d, and K is the total number of topics. The lower the perplexity is, the better the model fits the test data. Table 2 shows perplexities of different methods for $K = 20$ and $K = 100$ topics.

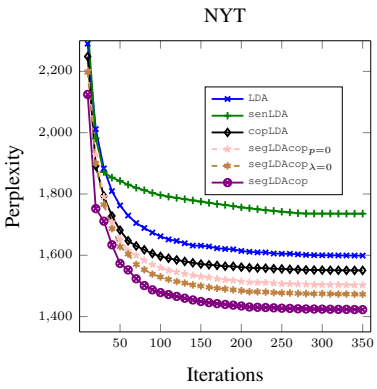

Figure 2: Perplexity with respect to training iteration on NYT collection (20 topics).

From Table 2, it comes out that the best performing model in terms of perplexity over all datasets and for different number of topics is `segLDAcop`. Further, $\texttt{segLDAcop}_{\lambda=0}$, that uses both document and segment specific topic distributions, performs better than $\texttt{segLDAcop}_{p=0}$, which in turn outperforms `copLDA`, bringing evidence that using all possible segmentations rather than only NPs unit extracted using a chunker yields a more flexible and natural topic assignment.

`segLDAcop` also converges faster than the other methods to its minimum as it is shown in Figure 2, depicting the evolution of perplexity of different models over the number of iterations on the NYT collection (a similar behavior is observed on the other collections).

Table 3: MiF score (percent) with respect to different number of topics (20 and 100).

4.2 Topical induced representation for classification

Some studies compare topic models using extrinsic tasks such as document classification. In this case, it is possible to reduce the dimensionality of the representation space by using the induced topics (Blei et al., 2003). In this study, we first randomly splitted the datasets, except NYT that does not contain class information, into training (75%) and test (25%) sets. We then applied SVMs with a linear kernel; the value of the hyperparameter C was found by cross-validation over the training set $\{0.01, 0.1, 1, 10, 100\}$. For datasets where certain documents have more than one label (Pubmed, Reuters), we used the one-versus-all approach for performing multi-label classification.

In Table 3, we report the Micro F1 (MiF) score of different models on the test sets. Again, the best results are obtained with segLDAcop, followed by segLDAcop$_{\lambda=0}$. This shows the importance of relying on both document and segment specific topic distributions. As conjectured before, our model is able to captures fine grained topic assignments within documents. In addition, all models relying on an inferred segmentation (segLDAcop$_{p=0}$, segLDAcop$_{\lambda=0}$, segLDAcop) outperform the models relying on fixed segmentations (sentences or NPs). This shows the importance of being able to discover flexible segmentations for assigning topics within documents.

4.3 Topic coherence

Another common way to evaluate topic models is by examining how coherent the produced topics are. Doing this manually is a time consuming process and cannot scale. To overcome this limitation the task of automatically evaluating the coherence of topics produced by topic models received a lot of attention (Mimno et al., 2011). It has been found that scoring the topics using co-occurrence measures, such as the pointwise mutual information (PMI) between the top-words of a topic, correlates well with human judgments (Newman et al., 2010). For this purpose an external, large corpus is used as a meta-document where the PMI scores of pairs of words are estimated using a sliding window. As discussed above, calculating the co-occurrence measures requires selecting the top-N words of a topic and performing the manual or automatic evaluation. Hence, N is a hyper-parameter to be chosen and its value can impact the results. Very recently, Lau and Baldwin (2016) showed that N actually impacts the quality of the obtained results and, in particular, the correlation with human judgments. In their work, they found that aggregating the topic coherence scores over several topic cardinalities leads to a substantially more stable and robust evaluation.

Following the findings of Lau and Baldwin (2016) and using (Newman et al., 2010)'s equation, we present in Figure 3 the topic coherence scores as measured by the Normalized Pointwise Mutual Information (NPMI) . Their values are in [-1,1], where in the limit of -1 two words w_1 and w_2 never occur together, while in the limit of +1 they always occur together (complete co-occurrence). For the reported scores, we aggregate the topic coherence scores over three different topic cardinalities: $N \in \{5, 10, 15\}$. segLDAcop model which

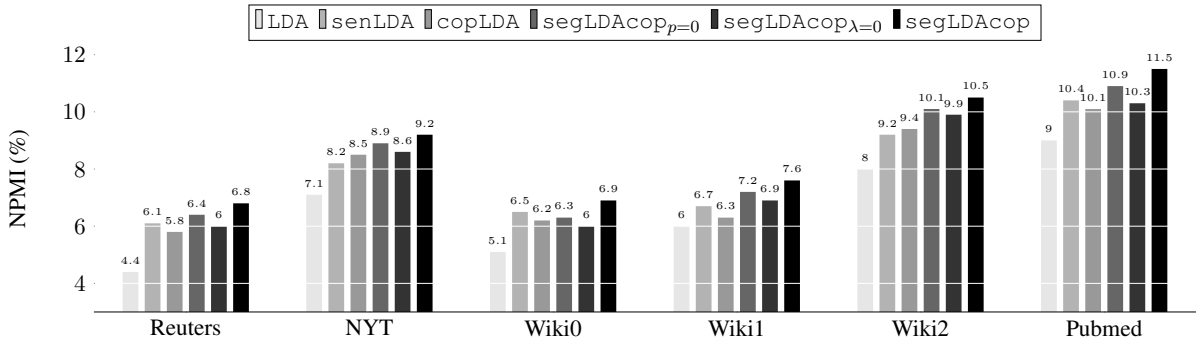

Figure 3: Topic coherence (NPMI) score with respect to 100 of topics.

uses copulas and segmentation together, shows the best score for the given reference meta-data (Wikipedia) in all of the datasets. It should be noted that segLDAcop$_{\lambda=0}$ which has not copula binder inside the model has less improvement against the segLDAcop$_{p=0}$ which has the copula. This means using copula has more effect on the topic coherence than only the segment-specific topic distribution.

4.4 Visualization

In order to illustrate the results obtained by segLDAcop, we display in Figure 4 the top 10 most probable words over 5 topics ($K = 20$) for the Reuters dataset, for both segLDAcop and LDA. In segLDAcop, topic 1, the top-ranked words are mostly relevant to the topic "date" (*e.g.*, march, january, year, fall, february, week). However, a similar topic learned by LDA appears to involve less such words (year, january, february), indicating a less coherent topic.

Topic1	march, fell, rose, january, rise, year, fall, february, pct, week	fell, mln, year, january, dlrs, rise, rose, pct, billion, february
Topic2	currency, bank, pct, cut, rate, day, prime, exchange, interest, national	billion, prime, day, rate, dlrs, pct, reserve, federal, fed, bank
Topic3	term, agreement, acquire, buy, sell, unit, acquisition, corp, company, sale	term, dlrs, buy, company, sell, unit, corp, acquisition, sale, mln
Topic4	approved, american, common, split, merger, company, board, stock, share, shareholder	acquire, mln, company, common, stock, shareholder, share, corp, merger, dlrs
Topic5	tokyo, life, intent, letter, buy, insurance, yen, japan, dealer, dollar	central, european, japan, yen, ec, dollar, bank, rate, dealer, market

Figure 4: Top-10 words of segLDAcop (left) vs LDA (right) for the Reuters (5 out of 20 topics).

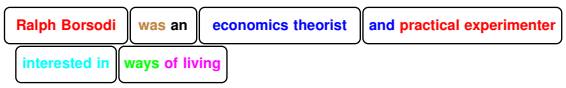

Figure 5: Topic assignments with segmentation boundaries using segLDAcop. Colors are topics (examples from Wiki0 including stopwords with 20 topics).

Figure 5 illustrates another aspect of our model, namely the possibility to detect topically coherent segments. In particular, as one can note, the sentence is segmented in six parts by our model, the first one is a NP, *Ralph Borsodi* where one single topic is assigned to both words. We observe a similar coherence in topic assignments on other NPs and segments, in which a single topic is used for the words involved. The data-driven approach we have adopted here can discover such fine grained differences, something the approaches based on fixed segmentations (either based on sentences or NPs), are less likely to achieve.

5 Discussion

In this paper, we have introduced an LDA-based model that generates topically coherent segments within documents by jointly segmenting documents and assigning topics to their words. The coherence between topics is ensured through Frank's copula, that binds the topics associated to the words of a segment. In addition, this model relies on both document and segment specific topic distributions so as to capture fine grained differences in topic assignments. We have shown that this model naturally encompasses other state-of-the-art LDA-based models proposed to accomplish the same task, and that it outperforms these models over six publicly available collections in terms of perplexity, Normalized Pointwise Mutual Information (NPMI), a measure used to assess the coherence of topics with documents, and the Micro F1-measure in a text classification context. Our results confirm the importance of a flexible segmentation as well as a

binding mechanism to produce topically coherent segments.

As regards complexity, it is true that more complex models, as the one we are considering, are more prone to underfitting (when data is scarce) and overfitting than simpler models. This said, the experimental results on perplexity (in which the word-topic distributions are fixed) and on classification (based on the topical induced representations) suggest that our model neither underfits nor overfits compared to simpler models. We believe that this is due to the fact that the main additional parameters in our model (the segment specific topic distribution) do not really add complexity as they are drawn from the same distribution as the standard document specific topics. Furthermore, the parameters p and f are simple parameters to choose between these two distributions.

The comparison with other segmentation methods is also an important point. While state-of-the-art supervised segmentation models can be used before applying the `LDA` model, we note such a pipeline approach comes with several limitations. The approach requires external annotated data to train the segmentation models, where certain domain and language specific information need to be captured. By contrast, our unsupervised approach learns both segmentations and topics jointly in a domain and language independent manner. Furthermore, existing supervised segmentation models are largely designed for a very different purpose with strong linguistic motivations, which may not align well with our main goal in this paper which is improving topic coherence in topic modeling. Similarly, unsupervised approaches, used for example in the TDT (Topic Detection and Tracking) campaigns or more recently in Du et al. (2013), usually consider coarse-grained topics, that can encompass several sentences. In contrast, our approach aims at identifying fine-grained topics associated with coherent segments that do not overlap sentence boundaries. These considerations, explain the choice of the baselines retained: they are based on segments of different granularities (words, NPs, sentences) that do not overlap sentence boundaries.

In the future, we plan on relying on other inference approaches, based for example on variational Bayes known to yield better estimates for perplexity (Asuncion et al., 2009); it is however not certain that the gain in perplexity one can expect from the use of variational Bayes approaches will necessarily result in a gain in, say, topic coherence. Indeed, the impact of the inference approach on the different usages of latent topic models for text collections remains to be better understood.

A Efficient segmentation

Let us recall the property presented before:

Proposition A.1. *Let l_i^s be the random variable associated to the length of the segment starting at position i in a sentence of length M (positions go from 1 to M and l_i^s takes value in $\{1, \cdots, L\}$). Then $P(l_i^s = l) := \frac{g(M+1-i-l);L)}{g(M+1-i;L)}$ defines a probability distribution over l_i^s.*

Furthermore, the following process is equivalent to choosing sentence segmentations uniformly from the set of possible segmentations.

```
From pos. 1, repeat till end of sentence:
(a) Generate segment length acc. to P;
(b) Add segment to current segmentation;
(c) Move to position after the segment.
```

Proof Any segmentation of the sentence of length M starts with either a segment of length 1, a segment of length 2, $\cdots$, or a segment of length L. Thus, $g(M; L)$ can be defined through the following recurrence relation:

$$g(M; L) = \sum_{l=1}^{L} g(M - l; L) \tag{1}$$

together with the initial values $g(1; L), g(2; L), \cdots, g(L; L)$, which can be computed offline (for example, for $L = 3$, one has: $g(1; 3) = 1, g(2; 3) = 2, g(3; 3) = 4$). Note that $g(1; L) = 1$ for all L.

Thus:

$$\sum_{l=1}^{L} P(l_i^s = l) = \sum_{l=1}^{L} \frac{g(M + 1 - i - l); L)}{g(M + 1 - i; L)} = 1$$

due to the recurrence relation on g. This proves the first part of the proposition.

Using the process described above where segments are generated one after another according to P, for a segmentation S, comprising $|S|$ segments, let us denote by $l_1, l_2, \cdots, l_{|S|}$ the lengths of each segment and by $i_1, i_2, \cdots, i_{|S|}$ the starting positions of each segment (with $i_1 = 1$). One has, as segments are independent of each other:

$$P(S) = \prod_{j=1}^{|S|} P(l_{i_j}^s = l_j) = \prod_{j=1}^{|S|} \frac{g(M + 1 - (i_j + l_j); L)}{g(M + 1 - i_j; L)}$$
$$= \frac{g(M - l_1; L)}{g(M; L)} \frac{g(M - l_1 - l_2; L)}{g(M - l_1; L)} \cdots = \frac{1}{g(M; L)}$$

as $g(1; L) = 1$. This concludes the proof of the proposition. □

Furthermore, as one can note from Eq. 1, the various elements needed to compute $P(l_i^s = l)$ can be efficiently computed, the time complexity being equal to $O(M)$. In addition, as the number of different sentence lengths is limited, one can store the values of g to reuse them during the segmentation phase.

Jointly Extracting Relations with Class Ties via Effective Deep Ranking

Abstract

Connections between relations in relation extraction, which we call *class ties*, are common. In distantly supervised scenario, one entity tuple may have multiple relation facts. Exploiting class ties between relations of one entity tuple will be promising for distantly supervised relation extraction. However, previous models are not effective or ignore to model this property. In this work, to effectively leverage class ties, we propose to make joint relation extraction with a unified model that integrates convolutional neural network (CNN) with a general pairwise ranking framework, in which three novel ranking loss functions are introduced. Additionally, an effective method is presented to relieve the severe class imbalance problem from NR (not relation) for model training. Experiments on a widely used dataset show that leveraging class ties will enhance extraction and demonstrate the effectiveness of our model to learn class ties. Our model outperforms the baselines significantly, achieving state-of-the-art performance.

1 Introduction

Relation extraction (RE) aims to classify the relations between two given named entities from natural-language text. Supervised machine learning methods require numerous labeled data to work well. With the rapid growth of volume of relation types, traditional methods can not keep up with the step for the limitation of labeled data. In order to narrow down the gap of data sparsity, Mintz et al. (2009) propose *distant supervision (DS)* for relation extraction, which automatically generates training data by aligning a knowledge facts database (ie. Freebase (Bollacker et al., 2008)) with texts.

place_lived (Patsy Ramsey, Atlanta)
place_of_birth (Patsy Ramsey, Atlanta)

	Sentence	Latent Label
#1	*Patsy Ramsey* has been living in *Atlanta* since she was born.	*place_of_birth*
#2	*Patsy Ramsy* always loves *Atlanta* since it is her hometown.	*place_lived*

Table 1: Training instances generated by freebase.

Class ties mean the connections between relations in relation extraction. In general, we conclude that class ties can have two types: weak class ties and strong class ties. Weak class ties mainly involve the co-occurrence of relations such as *place_of_birth* and *place_lived*, *CEO_of* and *founder_of*. On the contrary, strong class ties mean that relations have latent logical entailments. Take the two relations of *capital_of* and *city_of* for example, if one entity tuple has the relation of *capital_of*, it must express the relation fact of *city_of*, because the two relations have the entailment of *capital_of* $\Rightarrow$ *city_of*. Obviously the opposite induction is not correct. Further take the sentence of *"Jonbenet told me that her mother [Patsy Ramsey]*$_{e_1}$ *never left [Atlanta]*$_{e_2}$ *since she was born."* in DS scenario for example. This sentence expresses two relation facts which are *place_of_birth* and *place_lived*. However, the word "born" is a strong bios to extract *place_of_birth*, so it may not be easy to predict the relation of *place_lived*, but if we can incorporate the weak ties between the two relations, extracting *place_of_birth* will provide evidence for prediction of *place_lived*.

Exploiting class ties is necessary for DS based relation extraction. In DS scenario, there is a challenge that one entity tuple can have multiple rela-

tion facts as shown in Table 1, which is called *relation overlapping* (Hoffmann et al., 2011; Surdeanu et al., 2012). However, the relations of one entity tuple can have class ties mentioned above which can be leveraged to enhance relation extraction for it narrowing down potential searching spaces and reducing uncertainties between relations when predicting unknown relations. If one pair entities has *CEO_of*, it will contain *founder_of* with high possibility.

To exploit class ties between relations, we propose to make joint extraction for all positive labels of one entity tuple with considering *pairwise* connections between positive and negative labels inspired by (Fürnkranz et al., 2008; Zhang and Zhou, 2006). As the two relations with class ties shown in Table 1, by joint extraction of two relations, we can maintain the *class ties* (co-occurrence) of them from training samples to be learned by potential model, and then leverage this learned information to extract instances with unknown relations, which can not be achieved by separated extraction for it dividing labels apart losing information of co-occurrence. To classify positive labels from negative ones, we adopt pairwise ranking to rank positive ones higher than negative ones, exploiting pairwise connections between them. In a word, joint extraction exploits class ties between relations and pairwise ranking classify positive labels from negative ones. Furthermore, combining information across sentences will be more appropriate for joint extraction which provides more information from other sentences to extract each relation (Zheng et al., 2016; Lin et al., 2016). In Table 1, sentence #1 is the evidence for *place_of_birth*, but it also expresses the meaning of "living in someplace", so it can be aggregated with sentence #2 to extract *place_lived*. Meanwhile, the word of "hometown" in sentence #2 can provide evidence for *place_of_birth* which should be combined with sentence #1 to extract *place_of_birth*.

In this work, we propose a unified model that integrates pairwise ranking with CNN to exploit class ties. Inspired by the effectiveness of deep learning for modeling sentences (LeCun et al., 2015), we use CNN to encode sentences. Similar to (Santos et al., 2015; Lin et al., 2016), we use class embeddings to represent relation classes. The whole model architecture is presented in Figure 1. We first use CNN to embed sentences, then we introduce two variant methods to combine the

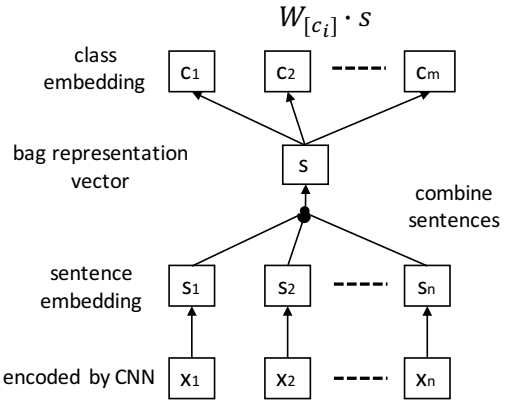

Figure 1: The main architecture of our model.

embedded sentences into one bag representation vector aiming to aggregate information across sentences, after that we measure the similarity between bag representation and relation class in real-valued space. With two variants for combining sentences, three novel pairwise ranking loss functions are proposed to make joint extraction. Besides, to relieve the bad impact of class imbalance from NR (not relation) (Japkowicz and Stephen, 2002) for training our model, we cut down loss propagation from NR class during training.

Our experimental results on dataset of Riedel et al. (2010) are evident that: (1) Our model is much more effective than the baselines; (2) Leveraging class ties will enhance relation extraction and our model is efficient to learn class ties by joint extraction; (3) A much better model can be trained after relieving class imbalance from NR.

Our contributions in this paper can be encapsulated as follows:

- We propose to leverage class ties to enhance relation extraction. An effective deep ranking model which integrates CNN and pairwise ranking framework is introduced to exploit class ties.
- We propose an effective method to relieve the impact of data imbalance from NR for model training.
- Our method achieves state-of-the-art performance.

2 Related Work

We summarize related works on two main aspects:

2.1 Distant Supervision Relation Extraction

Previous works on DS based RE ignore or are not effective to leverage class ties between rela-

tions.

Riedel et al. (2010) introduce multi-instance learning to relieve the wrong labelling problem, ignoring class ties. Afterwards, Hoffmann et al. (2011) and Surdeanu et al. (2012) model this problem by multi-instance multi-label learning to extract overlapping relations. Though they also propose to make joint extraction of relations, they only use information from single sentence losing information from other sentences. Han and Sun (2016) try to use *Markov logic* model to capture consistency between relation labels, on the contrary, our model leverages deep ranking to learn class ties automatically.

With the remarkable success of deep learning in CV and NLP (LeCun et al., 2015), deep learning has been applied to relation extraction (Zeng et al., 2014, 2015; Santos et al., 2015; Lin et al., 2016), the specific deep learning architecture can be CNN (Zeng et al., 2014), RNN (Zhou et al., 2016), etc. Zeng et al. (2015) propose a piecewise convolutional neural network with multi-instance learning for DS based relation extraction, which improves the precision and recall significantly. Afterwards, Lin et al. (2016) introduce the mechanism of attention (Luong et al., 2015; Bahdanau et al., 2014) to select the sentences to relieve the wrong labelling problem and use all the information across sentences. However, the two deep learning based models only make separated extraction thus can not model class ties between relations.

2.2 Deep Learning to Rank

Deep learning to rank has been widely used in many problems to serve as a classification model. In image retrieval, Zhao et al. (2015) apply deep semantic ranking for multi-label image retrieval. In text matching, Severyn and Moschitti (2015) adopt learning to rank combined with deep CNN for short text pairs matching. In traditional supervised relation extraction, Santos et al. (2015) design a pairwise loss function based on CNN for single label relation extraction. Based on the advantage of deep learning to rank, we propose pairwise learning to rank (LTR) (Liu, 2009) combined with CNN in our model aiming to jointly extract multiple relations.

3 Proposed Model

In this section, we first conclude the notations used in this paper, then we introduce the used CNN for sentence embedding, afterwards, we present our algorithm of how to learn class ties between relations of one entity tuple.

3.1 Notation

We define the relation classes as $\mathcal{L} = \{1, 2, \cdots, C\}$, entity tuples as $\mathcal{T} = \{t_i\}_{i=1}^{M}$ and mentions[1] as $\mathcal{X} = \{x_i\}_{i=1}^{N}$. Dataset is constructed as follows: for entity tuple $t_i \in \mathcal{T}$ and its relation class set $L_i \subseteq \mathcal{L}$, we collect all the mentions X_i that contain t_i, the dataset we use is $\mathcal{D} = \{(t_i, L_i, X_i)\}_{i=1}^{H}$. Given a data $(t_k, L_k, X_k) \in \{(t_i, L_i, X_i)\}_{i=1}^{H}$, the sentence embeddings of X_k encoded by CNN are defined as $S_k = \{s_i\}_{i=1}^{|X_k|}$ and we use class embeddings $W \in R^{|\mathcal{L}| \times d}$ to represent the relation classes.

3.2 CNN for Sentence Embedding

We take the effective CNN architecture adopted from (Zeng et al., 2015; Lin et al., 2016) to encode sentence and we briefly introduce CNN in this section. More details of our CNN can be obtained from previous work.

3.2.1 Words Representations

• **Word Embedding** Given a word embedding matrix $V \in \mathbb{R}^{l^w \times d^1}$ where l^w is the size of word dictionary and d^1 is the dimension of word embedding, the words of a mention $x = \{w_1, w_2, \cdots, w_n\}$ will be represented by real-valued vectors from V.

• **Position Embedding** The position embedding of a word measures the distance from the word to entities in a mention. We add position embeddings into words representations by appending position embedding to word embedding for every word. Given a position embedding matrix $P \in \mathbb{R}^{l^p \times d^2}$ where l^p is the number of distances and d^2 is the dimension of position embeddings, the dimension of words representations becomes $d^w = d^1 + d^2 \times 2$.

3.2.2 Convolution, Piecewise max-pooling

After transforming words in x to real-valued vectors, we get the sentence $q \in \mathbb{R}^{n \times d^w}$. The set of kernels K is $\{K_i\}_{i=1}^{d^s}$ where d^s is the number of kernels. Define the window size as d^{win} and given one kernel $K_k \in \mathbb{R}^{d^{win} \times d^w}$, the convolution operation is defined as follows:

$$m_{[i]} = q_{[i:i+d^{win}-1]} \odot K_k + b_{[k]} \quad (1)$$

[1]The sentence containing one certain entity is called mention.

where m is the vector after conducting convolution along q for $n - d^{win} + 1$ times and $b \in \mathbb{R}^{d^s}$ is the bias vector. For these vectors whose indexes out of range of $[1, n]$, we replace them with zero vectors.

By piecewise max-pooling, when pooling, the sentence is divided into three parts: $m_{[p_0:p_1]}$, $m_{[p_1:p_2]}$ and $m_{[p_2:p_3]}$ (p_1 and p_2 are the positions of entities, p_0 is the beginning of sentence and p_3 is the end of sentence). This piecewise max-pooling is defined as follows:

$$z_{[j]} = max(m_{[p_{j-1}:p_j]}) \tag{2}$$

where $z \in \mathbb{R}^3$ is the result of mention x processed by kernel K_k; $1 \leq j \leq 3$. Given the set of kernels K, following the above steps, the mention x can be embedded to o where $o \in R^{d^s * 3}$.

3.2.3 Non-Linear Layer, Regularization

To learn high-level features of mentions, we apply a non-linear layer after pooling layer. After that, a dropout layer is applied to prevent overfitting. We define the final fixed sentence representation as $s \in \mathbb{R}^{d^f}$ ($d^f = d^s * 3$).

$$s = g(o) \circ h \tag{3}$$

where $g(\cdot)$ is a non-linear function and we use $tanh(\cdot)$ in this paper; h is a Bernoulli random vector with probability p to be 1.

3.3 Learning Class Ties by Joint Extraction with Pairwise Ranking

As mentioned above, to learn class ties, we propose to make joint extraction with considering pairwise connections between positive labels and negative ones. Pairwise ranking is applied to achieve this goal. Besides, combining information across sentences is necessary for joint extraction. More specifically, as shown in Figure 2, from down to top, all information from sentences is pre-propagated to provide enough information for joint extraction. From top to down, pairwise ranking jointly extracting positive relations by combining losses, which are back-propagated to CNN to learn class ties.

3.3.1 Combining Information across Sentences

We propose two options to combine sentences to provide enough information for joint extraction.

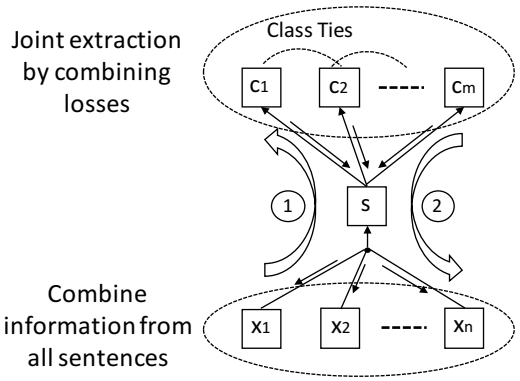

Figure 2: Illustration of mechanism of our model to model class ties between relations.

• **AVE** The first option is average method. This method regards all the sentences equally and directly average the values in all dimensions of sentence embedding. This **AVE** function is defined as follows:

$$s = \frac{1}{n} \sum_{s_i \in S_k} s_i \tag{4}$$

where n is the number of sentences and s is the representation vector combining all sentence embeddings. Because it weights the importance of sentences equally, this method may bring much noise data from two aspects: (1) the wrong labelling data; (2) irrelated mentions for one relation class, for all sentences containing the same entity tuple being combined together to construct the bag representation.

• **ATT** The second one is a sentence-level attention algorithm used by Lin et al. (2016) to measure the importance of sentences aiming to relieve the wrong labelling problem. For every sentence, **ATT** will calculate a weight by comparing the sentence to one relation. We first calculate the similarity between one sentence embedding and relation class as follows:

$$e_j = a \cdot W_{[c]} \cdot s_j \tag{5}$$

where e_j is the similarity between sentence embedding s_j and relation class c and a is a bias factor. In this paper, we set a as 0.5. Then we apply $\mathrm{Softmax}$ to rescale $\mathbf{e}$ ($\mathbf{e} = \{e_i\}_{i=1}^{|X_k|}$) to $[0, 1]$. We get the weight α_j for s_j as follows:

$$\alpha_j = \frac{\exp(e_j)}{\sum_{e_i \in \mathbf{e}} \exp(e_i)} \tag{6}$$

so the function to merge s with **ATT** is as follows:

$$s = \sum_{i=1}^{|X_k|} \alpha_i \cdot s_i \tag{7}$$

3.3.2 Joint Extraction by Combining Losses to Learn Class Ties

Firstly, we have to present the score function to measure the similarity between s and relation c.

• **Score Function** We use dot function to produce score for s to be predicted as relation c. The score function is as follows:

$$\mathcal{F}(s, c) = W_{[c]} \cdot s \tag{8}$$

There are other options for score function. In Wang et al. (2016), they propose a margin based loss function that measures the similarity between s and $W_{[c]}$ by distance. Because score function is not an important issue in our model, we adopt dot function, also used by Santos et al. (2015) and Lin et al. (2016), as our score function.

Now we start to introduce the ranking loss function.

Pairwise ranking aims to learn the score function $\mathcal{F}(s, c)$ that ranks positive classes higher than negative ones. This goal can be summarized as follows:

$$\forall c^+ \in L_k, \forall c^- \in \mathcal{L} - L_k : \mathcal{F}(s, c^+) > \mathcal{F}(s, c^-) + \beta \tag{9}$$

where β is a margin factor which controls the minimum margin between the positive scores and negative scores.

To learn class ties between relations, we extend the formula (9) to make joint extraction and we propose three ranking loss functions with variants of combining sentences. Followings are the proposed loss functions:

• **with AVE (Variant-1)** We define the margin-based loss function with option of **AVE** to aggregate sentences as follows:

$$G_{[ave]} = \sum_{c^+ \in L_k} \rho[0, \sigma^+ - \mathcal{F}(s, c^+)]_+ + \rho|L_k|[0, \sigma^- + \mathcal{F}(s, c^-)]_+ \tag{10}$$

where $[0, \cdot\,]_+ = max(0, \cdot\,)$; ρ is the rescale factor, σ^+ is positive margin and σ^- is negative margin. Similar to Santos et al. (2015) and Wang et al. (2016), this loss function is designed to rank positive classes higher than negative ones controlled by the margin of $\sigma^+ - \sigma^-$. In reality, $\mathcal{F}(s, c^+)$ will be higher than σ^+ and $\mathcal{F}(s, c^-)$ will be lower than σ^-. In our work, we set ρ as 2, σ^+ as 2.5 and σ^- as 0.5 adopted from Santos et al. (2015).

Similar to Weston et al. (2011) and Santos et al. (2015), we update one negative class at every training round but to balance the loss between positive classes and negative ones, we multiply $|L_k|$ before the right term in function (10) to expand the negative loss. We apply mini-bach based stochastic gradient descent (SGD) to minimize the loss function. The negative class is chosen as the one with highest score among all negative classes (Santos et al., 2015), i.e.:

$$c^- = \underset{c \in \mathcal{L} - L_k}{\operatorname{argmax}} \mathcal{F}(s, c) \tag{11}$$

• **with ATT (Variant-2)** Now we define the loss function for the option of **ATT** to combine sentences as follows:

$$G_{[att]} = \sum_{c^+ \in L_k} (\rho[0, \sigma^+ - \mathcal{F}(s^{c^+}, c^+)]_+ + \rho[0, \sigma^- + \mathcal{F}(s^{c^+}, c^-)]_+) \tag{12}$$

where s^c means the attention weights of representation s are merged by comparing sentence embeddings with relation class c and c^- is chosen by the following function:

$$c^- = \underset{c \in \mathcal{L} - L_k}{\operatorname{argmax}} \mathcal{F}(s^{c^+}, c) \tag{13}$$

which means we update one negative class in every training round. We keep the values of ρ, σ^+ and σ^- same as values in function (10).

According to this loss function, we can see that: for each class $c^+ \in L_k$, it will capture the most related information from sentences to merge s^{c^+}, then rank $\mathcal{F}(s^{c^+}, c^+)$ higher than all negative scores which each is $\mathcal{F}(s^{c^+}, c^-)$ ($c^- \in \mathcal{L} - L_k$). We use the same update algorithm to minimize this loss.

• **Extended with ATT (Variant-3)** According to function (12), for each c^+, we only select one negative class to update the parameters, which only considers the connections between positive classes and negative ones, ignoring connections between positive classes, so we extend function (12) to better exploit class ties by considering the connections between positive classes. We give out the extended loss function as follows:

$$G_{[Exatt]} = \sum_{c^* \in L_k} (\sum_{c^+ \in L_k} \rho[0, \sigma^+ - \mathcal{F}(s^{c^*}, c^+)]_+ + \rho[0, \sigma^- + \mathcal{F}(s^{c^*}, c^-)]_+) \tag{14}$$

Pro.	Training	Test
SemE.	17.63%	16.71%
Riedel	72.52%	96.26%

Table 2: The proportions of NR samples from SemEval-2010 Task 8 dataset and Riedel dataset.

Similar to function (13), we select c^- as follows:

$$c^- = \underset{c \in \mathcal{L} - L_k}{\operatorname{argmax}} \mathcal{F}(s^{c^*}, c) \tag{15}$$

and we use the same method to update this loss function as discussed above. From the function (14), we can see that: for $c^* \in L_k$, after merging the bag representation s with c^*, we share s with all the other positive classes and update the class embeddings of other positive classes with s, in this way, the connections between positive classes can be captured and learned by our model.

In loss function (10), (12) and (14), we combine losses from all positive labels to make joint extraction to capture the class ties among relations. Suppose we make separated extraction, the losses from positive labels will be divided apart and will not get enough information of connections between positive labels, comparing to joint extraction. Connections between positive labels and negative ones are exploited by controlling margins: σ^+ and σ^-.

3.4 Relieving Impact of NR

In relation extraction, the dataset will always contain certain negative samples which do not express relations classified as NR (not relation). Table 2 presents the proportion of NR samples in SemEval-2010 Task 8 dataset[2] (Erk and Strapparava, 2010) and dataset from Riedel et al. (2010), which shows almost data is about NR in the latter dataset. Data imbalance will severely affect the model training and cause the model only sensitive to classes with high proportion (He and Garcia, 2009).

In order to relieve the impact of NR in DS based relation extraction, we cut the propagation of loss from NR, which means if relation c is NR, we set its loss as 0. Our method is similar to Santos et al. (2015) with slight variance. Santos et al. (2015) directly omit the NR class embedding, but we keep it. If we use **ATT** method to combine information across sentences, we can not omit NR class embedding according to function (6) and (7), on the contrary, it will be updated from the negative classes' loss.

Algorithm 1: Merging loss function of **Variant-3**

input : $\mathcal{L}$, (t_k, L_k, X_k) and S_k;
output: $G_{[Exatt]}$;

```
G_[Exatt] ← 0;
for c* ∈ L_k do
    Merge representation s^{c*} by function (5), (6), (7);
    for c+ ∈ L_k do
        if c+ is not NR then
            G_[Exatt] ← G_[Exatt] + ρ[0, σ+ − F(s^{c*}, c+)]+;
    c− ← argmax_{c∈L−L_k} F(s^{c*}, c);
    G_[Exatt] ← G_[Exatt] + ρ[0, σ− + F(s^{c*}, c−)]+;
return G_[Exatt];
```

In Algorithm 1, we give out the pseudocodes of merging loss with **Variant-3** and considering to relieve the impact of NR.

4 Experiments

4.1 Dataset and Evaluation Criteria

We conduct our experiments on a widely used dataset, developed by Riedel et al. (2010) and has been used by Hoffmann et al. (2011), Surdeanu et al. (2012), Zeng et al. (2015) and Lin et al. (2016). The dataset aligns Freebase relation facts with the New York Times corpus, in which training mentions are from 2005-2006 corpus and test mentions from 2007.

Following Mintz et al. (2009), we adopt held-out evaluation framework in all experiments. Aggregated precision/recall curves are drawn and precision@N (P@N) is reported to illustrate the model performance.

4.2 Experimental Settings

Word Embeddings. We use a word2vec tool that is gensim[3] to train word embeddings on NYT corpus. Similar to Lin et al. (2016), we keep the words that appear more than 100 times to construct word dictionary and use "UNK" to represent the other ones.

[2]This is a dataset for relation extraction in traditional supervision framework.

[3]http://radimrehurek.com/gensim/models/word2vec.html

Parameter Name	Symbol	Value
Window size	d^{win}	3
Sentence. emb. dim.	d^f	690
Word. emb. dim.	d^1	50
Position. emb. dim.	d^2	5
Batch size	$\mathcal{B}$	160
Learning rate	λ	0.03
Dropout pos.	p	0.5

Table 3: Hyper-parameter settings.

Hyper-parameter Settings. Three-fold validation on the training dataset is adopted to tune the parameters following Surdeanu et al. (2012). We use grid search to determine the optimal hyper-parameters. We select word embedding size from $\{50, 100, 150, 200, 250, 300\}$. Batch size is tuned from $\{80, 160, 320, 640\}$. We determine learning rate among $\{0.01, 0.02, 0.03, 0.04\}$. The window size of convolution is tuned from $\{1, 3, 5\}$. We keep other hyper-parameters same as Zeng et al. (2015): the number of kernels is 230, position embedding size is 5 and dropout rate is 0.5. Table 3 shows the detailed parameter settings.

4.3 Comparisons with Baselines

Baseline. We compare our model with the following baselines:

- **Mintz** (Mintz et al., 2009) the original distantly supervised model.
- **MultiR** (Hoffmann et al., 2011) a multi-instance learning based graphical model which aims to address overlapping relation problem.
- **MIML** (Surdeanu et al., 2012) also solving overlapping relations in a multi-instance multi-label framework.
- **PCNN+ATT** (Lin et al., 2016) the state-of-the-art model in dataset of Riedel et al. (2010) which applies **ATT** to combine the sentences.

Results and Discussion. We compare our three variants of loss functions with the baselines and the results are shown in Figure 3. From the results we can see that: (1) Rank + AVE (Variant-1) achieves comparable results with PCNN+ATT; (2) Rank + ATT (Variant-2) and Rank + ExATT (Variant-3) significantly outperform PCNN + ATT with much higher precision and slightly higher recall in whole view; (3) Rank + ExATT (Variant-3) exhibits the best performances comparing with all the other methods including PCNN + ATT, Rank + AVE and Rank + ATT.

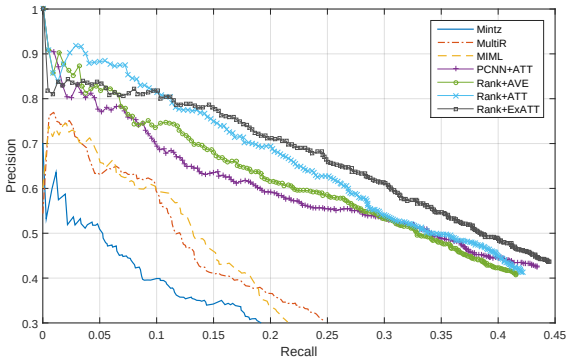

Figure 3: Performance comparison of our model and the baselines.

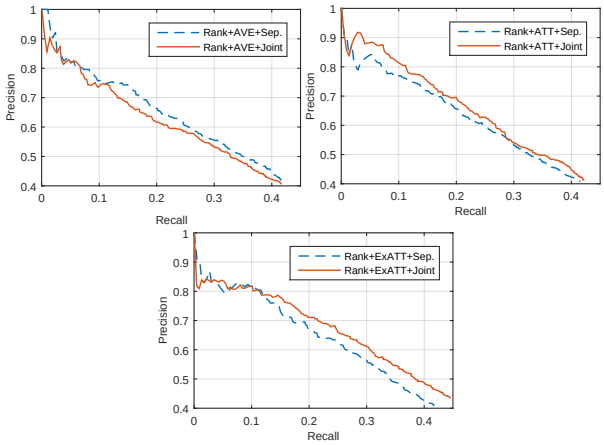

Figure 4: Results for impact of joint extraction and class ties with methods of Rank + AVE, Rank + ATT and Rank + ExATT under the setting of relieving impact of NR.

4.4 Impact of Joint Extraction and Class Ties

In this section, we conduct experiments to reveal the effectiveness of our model to learn class ties with three variant loss functions mentioned above, and the impact of class ties for relation extraction. As mentioned above, we make joint extraction to learn class ties, so to achieve the goal of this set of experiments, we compare joint extraction with separated extraction. To make separated extraction, we divide the labels of entity tuple into single label and for one relation label we only select the sentences expressing this relation, then we use this dataset to train our model with the three variant loss functions. We conduct experiments with Rank + AVE (Variant-1), Rank + ATT (Variant-2) and Rank + ExATT (Variant-3) relieving impact of NR. Aggregated P/R curves are drawn and precisions@N (100, 200, $\cdots$, 500) are reported to show the model performances.

P@N(%)	100	200	300	400	500	Ave.
R.+AVE+J.	81.3	76.4	74.6	69.6	66.0	73.6
R.+AVE+S.	**82.4**	**79.6**	74.6	**74.4**	**69.9**	**76.2**
R.+ATT+J.	**87.9**	**84.3**	**78.0**	**74.9**	**70.3**	**79.1**
R.+ATT+S.	82.4	79.1	75.9	71.9	69.5	75.7
R.+ExATT+J.	**83.5**	82.2	78.7	**77.2**	**73.1**	**79.0**
R.+ExATT+S.	82.4	**82.7**	**79.4**	74.2	69.2	77.6

Table 4: Precisions for top 100, 200, 300, 400, 500 and average of them for impact of joint extraction and class ties.

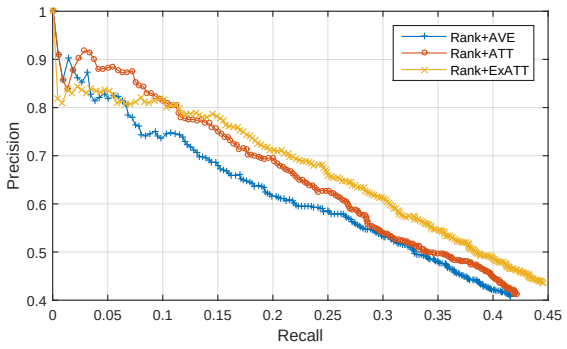

Figure 5: Results for comparisons of variant joint extractions.

P@N(%)	100	200	300	400	500	Ave.
R.+AVE	81.3	76.4	74.6	69.6	66.0	73.6
R.+ATT	**87.9**	**84.3**	78.0	74.9	70.3	**79.1**
R.+ExATT	83.5	82.2	**78.7**	**77.2**	**73.1**	79.0

Table 5: Precisions for top 100, 200, 300, 400, 500 and average of them for Rank + AVE, Rank + ATT and Rank + ExATT.

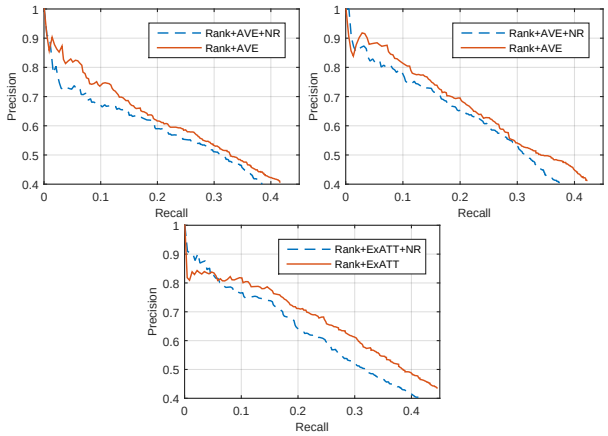

Figure 6: Results for impact of relation NR with methods of Rank + AVE, Rank + ATT and Rank + ExATT. "+NR" means not relieving impact of NR.

Experimental results are shown in Figure 4 and Table 4. From the results we can see that: (1) For Rank + ATT and Rank + ExATT, joint extraction exhibits better performance than separated extraction, which demonstrates class ties will improve relation extraction and the two methods are effective to learn class ties; (2) For Rank + AVE, surprisingly joint extraction does not keep up with separated extraction. For the second phenomenon, the explanation may lie in the **AVE** method to aggregate sentences will incorporate noise data consistent with the finding in Lin et al. (2016). When make joint extraction, we will combine all sentences containing the same entity tuple no matter which class type is expressed, so it will engender much noise if we only combine them equally.

4.5 Comparisons of Variant Joint Extractions

To make joint extraction, we have proposed three variant loss functions including Rank + AVE, Rank + ATT and Rank + ExATT in the above discussion and Figure 3 shows that the three variants achieve different performances. In this experiment, we aim to compare the three variants in detail. We conduct the experiments with the three variants under the setting of relieving impact of NR and joint extraction. We draw the P/R curves and report the top N (100, 200, $\cdots$, 500) precisions to compare model performance with the three variants.

From the results as shown in Figure 5 and Table 5 we can see that: (1) Comparing Rank + AVE with Rank + ATT, from the whole view, they can achieve the similar maximal recall point, but Rank + ATT exhibits higher precision in all range of recall; (2) Comparing Rank + ATT with Rank + ExATT, Rank + ExATT achieves much better performance with broader range of recall and higher precision in almost range of recall.

4.6 Impact of NR Relation

The goal of this experiment is to inspect how much relation of NR can affect the model performance. We use Rank + AVE, Rank + ATT, Rank + ExATT under the setting of relieving impact of NR or not to conduct experiments. We draw the aggregated P/R curves as shown in Figure 6, from which we can see that after relieving the impact of NR, the model performance can be improved significantly.

Then we further evaluate the impact of NR for convergence behavior of our model in model train-

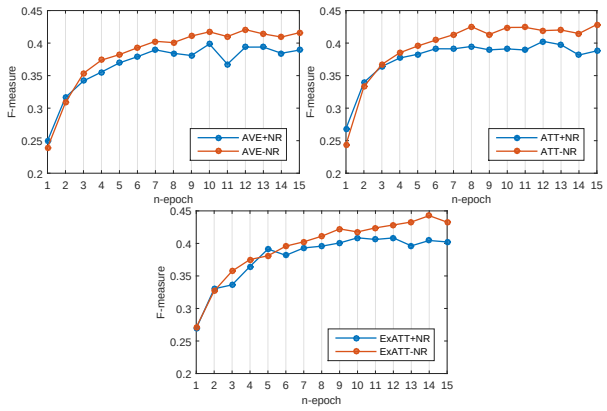

Figure 7: Impact of NR for model convergence. "+NR" means not relieving NR impact; "-NR" is opposite.

ing. Also with the three variant loss functions, in each iteration, we record the maximal value of F-measure [4] to represent the model performance at current epoch. Model parameters are tuned for 15 times and the convergence curves are shown in Figure 7. From the result, we can find out: "+NR" converges quicker than "-NR" and arrives to the final score at the around 11 or 12 epoch. In general, "-NR" converges more smoothly and will achieve better performance than "+NR" in the end.

4.7 Case Study

Joint vs. Sep. Extraction (Class Ties). We randomly select an entity tuple *(Cuyahoga County, Cleveland)* from test set to see its scores for every relation class with the method of Rank + ATT under the setting of relieving impact of NR with joint extraction and separated extraction. This entity tuple have two relations: */location/./county_seat* and */location/./contains*, which derive from the same root class and they have weak class ties for they all relating to topic of "location". We rescale the scores by adding value 10. The results are shown in Figure 8, from which we can see that: under joint extraction setting, the two gold relations have the highest scores among the other relations but under separated extraction setting, only */location/./contains* can be distinguished from the negative relations, which demonstrates that joint extraction is better than separated extraction by capturing the class ties between relations.

[4] $F = 2 * P * R/(P + R)$

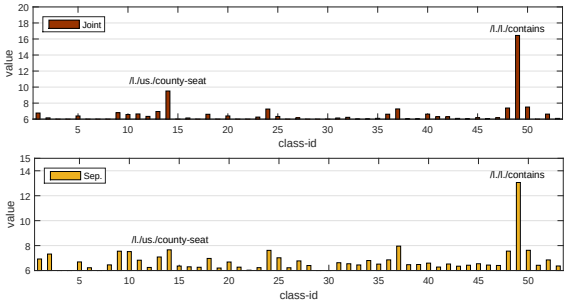

Figure 8: The output scores for every relation with method of Rank + ATT. The top is under joint extraction setting; the bottom is under separated extraction.

5 Conclusion and Future Works

In this paper, we leverage class ties to enhance relation extraction by joint extraction using pairwise ranking combined with CNN. An effective method is proposed to relieve the impact of NR for model training. Experimental results on a widely used dataset show that leveraging class ties will enhance relation extraction and our model is effective to learn class ties. Our method significantly outperforms the baselines.

In the future, we will focus on two aspects: (1) Our method in this paper considers pairwise intersections between labels, so to better exploit class ties, we will extend our method to exploit all other labels' influences on each relation for relation extraction, transferring *second-order* to *high-order* (Zhang and Zhou, 2014); (2) We will focus on other problems by leveraging class ties between labels, specially on multi-label learning problems (Zhou et al., 2012) such as multi-category text categorization (Rousu et al., 2005) and multi-label image categorization (Zha et al., 2008).

Acknowledgments

Firstly, we would like to thank Xianpei Han and Kang Liu for their valuable suggestions on the initial version of this paper, which have helped a lot to improve the paper. Secondly, we also want to express gratitudes to the anonymous reviewers for their hard work and kind comments, which will further improve our work in the future. Abstract

Recent work in semantic parsing for question answering has focused on long and complicated questions, many of which would seem unnatural if asked in a normal conversation between two humans. In an effort to explore a conversational QA setting, we present a more realistic task: answering sequences of simple but inter-related questions. We collect a dataset of 6,066 question sequences that inquire about semi-structured tables from Wikipedia, with 17,553 question-answer pairs in total. To solve this sequential question answering task, we propose a novel dynamic neural semantic parsing framework trained using a weakly supervised reward-guided search. Our model effectively leverages the sequential context to outperform state-of-the-art QA systems that are designed to answer highly complex questions.

1 Introduction

Semantic parsing, which maps natural language text to meaning representations in formal logic, has emerged as a key technical component for building question answering systems (Liang, 2016). Once a natural language question has been mapped to a formal query, its answer can be retrieved by executing the query on a back-end structured database.

One of the main focuses of semantic parsing research is how to address *compositionality* in language, and complicated questions have been specifically targeted in the design of a recently-released QA dataset (Pasupat and Liang, 2015). Take for example the following question: "*of those actresses who won a Tony after 1960, which one took the most amount of years after winning the Tony to win an Oscar?*" The corresponding logical form is highly compositional; in order to answer it, many sub-questions must be implicitly answered in the process (e.g., *"who won a Tony after 1960?"*).

While we agree that semantic parsers *should* be able to answer very complicated questions, in reality these questions are rarely issued by users.[1] Because users can interact with a QA system repeatedly, there is no need to assume a single-turn QA setting where the exact *question intent* has to be captured with just one complex question. The same intent can be more naturally expressed through a sequence of simpler questions, as shown below:

1. *What actresses won a Tony after 1960?*
2. *Of those, who later won an Oscar?*
3. *Who had the biggest gap between their two award wins?*

Decomposing complicated intents into multiple related but simpler questions is arguably a more effective strategy to explore a topic of interest, and it reduces the cognitive burden on both the person who asks the question and the one who answers it.[2]

In this work, we study semantic parsing for answering *sequences* of simple related questions. We collect a dataset of question sequences called SequentialQA (SQA; Section 2)[3] by asking crowdsourced workers to decompose complicated questions sampled from the WikiTableQuestions dataset (Pasupat and Liang, 2015) into multiple easier ones. SQA, which contains 6,066 question sequences with 17,553 total question-answer pairs, is to the best of our knowledge the first semantic parsing dataset for sequential question answering. Section 3 describes our novel dynamic neural semantic parsing framework (DynSP), a weakly su-

*Work done during an internship at Microsoft Research

[1] For instance, there are only 3.75% questions with more than 15 words in WikiAnswers (Fader et al., 2014).

[2] Studies have shown increased sentence complexity links to longer reading times (Hale, 2006; Levy, 2008; Frank, 2013).

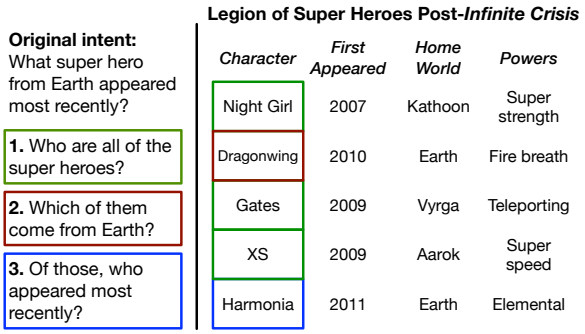

Figure 1: An example question sequence created from a compositional question intent. Workers must write questions whose answers are subsets of cells in the table.

pervised structured-output learning approach based on reward-guided search that is designed for solving sequential QA. We demonstrate in Section 4 that DynSP achieves higher accuracies than existing systems on SQA, and we offer a qualitative analysis of question types that our method answers effectively, as well as those on which it struggles.

2 A Dataset of Question Sequences

We collect the SequentialQA (SQA) dataset via crowdsourcing by leveraging WikiTableQuestions (Pasupat and Liang, 2015, henceforth WTQ), which contains highly compositional questions associated with HTML tables from Wikipedia. Each crowdsourcing task contains a long, complex question originally from WTQ as the question *intent*. The workers are asked to compose a sequence of simpler questions that lead to the final intent; an example of this process is shown in Figure 1.

To simplify the task for workers, we only use questions from WTQ whose answers are cells in the table, which excludes those involving arithmetic and counting. We likewise also restrict the questions our workers can write to those answerable by only table cells. These restrictions speed the annotation process because workers can just click on the table to answer their question. They also allow us to collect answer coordinates (row and column in the table) as opposed to answer text, which removes many normalization issues for answer string matching in evaluation. Finally, we only use long questions that contain nine or more words as intents; shorter questions tend to be simpler and are thus less amenable to decomposition.

2.1 Properties of SQA

In total, we used 2,022 question intents from the train and test folds of the WTQ for decomposition. We had three workers decompose each intent, resulting in 6,066 unique questions sequences containing 17,553 total question-answer pairs (for an average of 2.9 questions per sequence). We divide the dataset into train and test using the original WTQ folds, resulting in an 83/17 train/test split. Importantly, just like in WTQ, none of the tables in the test set are seen in the training set.

We identify three frequently-occurring question classes: *column selection*, *subset selection*, and *row selection*.[4] In column selection questions, the answer is an entire column of the table; these questions account for 23% of all questions in SQA. Subset and row selection are more complicated than column selection, as they usually contain coreferences to the previous question's answer. In subset selections, the answer is a subset of the previous question's answer; similarly, the answers to row selections occur in the same row(s) as the previous answer but in a different column. Subset selections make up 27% of SQA, while row selections are an additional 19%. The remaining 31% contains more complex combinations of these three types.

We also observe dramatic differences in the types of questions that are asked at each position of the sequence. For example, 51% of the first questions in the sequences are column selections (e.g., "*what are all of the teams?*"). This number dwindles to just 18% when we look at the second question of each sequence, which indicates that the collected sequences start with general questions and progress to more specific ones.

3 Dynamic Neural Semantic Parsing

The unique setting of SQA provides both opportunities and challenges. On the one hand, it contains short questions with less compositionality, which in theory should reduce the difficulty of the semantic parsing problem; on the other hand, the additional contextual dependencies of the preceding questions and their answers increase modeling complexity. These observations lead us to propose a dynamic neural semantic parsing framework (DynSP) trained using a reward-guided search pro-

[4] In the example sequence "*what are all of the tournaments? in which one did he score the least points? on what date was that?*", the first question is a column selection, the second is a subset selection, and the last one is a row selection.

cedure for solving SQA.

Given a question (optionally along with previous questions and answers) and a table, DynSP formulates the semantic parsing problem as a state–action search problem. Each state represents a complete or partial parse, while each action corresponds to an operation to extend a parse. The goal during inference is to find an end state with the highest score as the predicted parse.

The quality of the induced semantic parse obviously depends on the scoring function. In our design, the score of a state is determined by the scores of actions taken from the initial state to the target state, which are predicted by different neural network modules based on action type. By leveraging a margin-based objective function, the model learning procedure resembles several structured-output learning algorithms such as structured SVMs (Tsochantaridis et al., 2005), but can take either strong or weak supervision seamlessly.

DynSP is inspired by STAGG, a search-based semantic parser (Yih et al., 2015), as well as the dynamic neural module network (DNMN) of Andreas et al. (2016). Much like STAGG, DynSP chains together different modules as search progresses; however, these modules are implemented as neural networks, which enables end-to-end training as in DNMN. The key difference between DynSP and DNMN is that in DynSP the network structure of an example is not predetermined. Instead, different network structures are constructed dynamically as our learning procedure explores the state space. It is straightforward to answer *sequential* questions using our framework: we allow the model to take the previous question and its answers as input, with a slightly modified action space to reflect a *dependent* semantic parse. The same search / learning procedure is then able to effortlessly adapt to the new setting. In this section, we first describe the formal language underlying DynSP, followed by the model formulation and learning algorithm.

3.1 Semantic parse language

Because tables are used as the data source to answer questions in SQA, we decide to form our semantic parses in an SQL-like language[5]. Our parses consist of two parts: a ***select*** statement and conjunctions of zero or more ***conditions***.

A ***select*** statement is associated with a column name, which is referred to as the *answer* column. Conditions enforce additional constraints on which cells in the answer column can be chosen; a ***select*** statement without any conditions indicates that an entire column of the table is the answer to the question. In particular, each condition contains a column name as the *condition* column and an operator with zero or more arguments. The operators in this work include: $=, \neq, >, \geq, <, \leq$, $\arg\min, \arg\max$. A cell in the answer column is only a legitimate answer if the cell of the corresponding row in the condition column satisfies the constraint defined by the operator and its arguments. As a concrete example, suppose the data source is the same table in Fig. 1. The semantic parse of the question "*Which super heroes came from Earth and first appeared after 2009?*" is "Select **Character** Where {**Home World** = *Earth*} $\wedge$ {**First Appeared** $>$ *2009*}" and the answers are {Dragonwing, Harmonia}.

In order to handle the *sequential* aspect of SQA, we extend the semantic parse language by adding a preamble statement ***subsequent***. A ***subsequent*** statement contains only conditions, as it essentially adds constraints to the semantic parse of the previous question. For instance, if the follow-up question is "*Which of them breathes fire?*", then the corresponding semantic parse is "Subsequent Where {**Powers** = *Fire breath*}". The answer to this question is {Dragonwing}, a subset of the previous answer.

3.2 Model formulation

We start introducing our model design by first defining the state and action space. Let $\mathcal{S}$ be the set of states and $\mathcal{A}$ the set of all actions. A state $s \in \mathcal{S}$ is simply a sequence of variable length of actions $\{a_1, a_2, a_3, \cdots, a_t\}$, where $a_i \in \mathcal{A}$. An empty sequence, $s_0 = \phi$, is a special state used as the starting point of search.

As mentioned earlier, a state represents a (partial) semantic parse of *one* question. Each action is thus a legitimate operation that can be added to *grow* the semantic parse. Our action space design is tied closely to the statements defined by our parse language; in particular, an action *instance* is either a complete or partial statement, and action instances are grouped by *type*. For example, ***select*** and ***subsequent*** operations are two action types. A ***condition*** statement is formed by two different action types:

[5] Our framework is not restricted to the formal language we use in this work. In addition, the structured query can be straightforwardly represented in other formal languages, such as the lambda DCS logic used in (Pasupat and Liang, 2015).

Id	Type	# Action instances
$\mathcal{A}_1$	Select-column	# columns
$\mathcal{A}_2$	Cond-column	# columns
$\mathcal{A}_3$	Op-Equal (=)	# rows
$\mathcal{A}_4$	Op-NotEqual ($\neq$)	# rows
$\mathcal{A}_5$	Op-GT ($>$)	# numbers / datetimes
$\mathcal{A}_6$	Op-GE ($\geq$)	# numbers / datetimes
$\mathcal{A}_7$	Op-LT ($<$)	# numbers / datetimes
$\mathcal{A}_8$	Op-LE ($\leq$)	# numbers / datetimes
$\mathcal{A}_9$	Op-ArgMin	# numbers / datetimes
$\mathcal{A}_{10}$	Op-ArgMax	# numbers / datetimes
$\mathcal{A}_{11}$	Subsequent	1
$\mathcal{A}_{12}$	S-Cond-column	# columns
$\mathcal{A}_{13}$	S-Op-Equal (=)	# rows
$\mathcal{A}_{14}$	S-Op-NotEqual ($\neq$)	# rows
$\mathcal{A}_{15}$	S-Op-GT ($>$)	# numbers / datetimes
$\mathcal{A}_{16}$	S-Op-GE ($\geq$)	# numbers / datetimes
$\mathcal{A}_{17}$	S-Op-LT ($<$)	# numbers / datetimes
$\mathcal{A}_{18}$	S-Op-LE ($\leq$)	# numbers / datetimes
$\mathcal{A}_{19}$	S-Op-ArgMin	# numbers / datetimes
$\mathcal{A}_{20}$	S-Op-ArgMax	# numbers / datetimes

Table 1: Types of actions and the number of action instances in each type. Numbers / datetimes are the mentions discovered in the question (plus the previous question if it is a subsequent condition).

(1) selection of the condition column, and (2) the comparison operator. The instances of each action type differ in their arguments (e.g., column names, or specific cells in a column). Because conditions in a ***subsequent*** parse rely on previous questions and answers, they belong to different action types from regular conditions. Table 1 summarizes the action space defined in this work.

Any state that represents a complete and legitimate parse is an end state. Notice that search does not necessarily need to stop at an end state, because adding more actions (e.g., condition statements) can lead to another end state. Take the same example question from before: "*Which super heroes came from Earth and first appeared after 2009?*". One action sequence that represents the parse is {($\mathcal{A}_1$) select-column **Character**, ($\mathcal{A}_2$) cond-column **Home World**, ($\mathcal{A}_3$) op-equal *Earth*, ($\mathcal{A}_2$) cond-column **First Appeared**, ($\mathcal{A}_5$) op-gt *2009*}.

Notice that many states represent semantically equivalent parses (e.g., those with the same actions ordered differently, or states with repeated conditions). To prune the search space, we introduce the function $Act(s) \subset \mathcal{A}$, which defines the actions that can be taken when given a state s. Borrowing the idea of *staged* state generation in (Yih et al., 2015), we choose a default ordering of actions based on their types, dictating that a *select* action must be picked first and that a *condition-column* needs to be determined before the *operator* is chosen. The full transition diagram is presented in Fig. 2. Note that to implement this transition order, we only need to check the last action in the state. In addition, we also disallow adding duplicates of actions that already exist in the state.

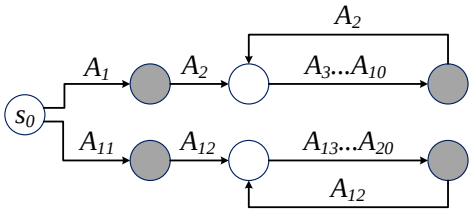

Figure 2: Possible action transitions based on their types (see Table 1). Shaded circles are end states.

We use beam search to find an end state with the highest score for inference. Let s_t be a state consisting of a sequence of actions $a_1, a_2, \cdots, a_t$. The state value function V is defined recursively as $V(s_t) = V(s_{t-1}) + \pi(s_{t-1}, a_t), V(s_0) = 0$, where the *policy* function $\pi(s, a)$ scores an action $a \in Act(s)$ given the current state.

3.3 Policy function

The intuition behind the policy function can be summarized as follows. Halfway through the construction of a semantic parse, the policy function measures the quality of an immediate action that can be taken next given the current state (i.e., the question and actions that have previously been chosen). To enable integrated, end-to-end learning, the policy function in our framework is parameterized using neural networks. Because each action type has very different semantics, we design different network structures (i.e., modules) accordingly.

Most of our network structures encourage learning semantic matching functions between the words in the question and table (either the column names or cells). Here we illustrate the design using the *select-column* action type ($\mathcal{A}_1$). Conceptually, the corresponding module is a combination of various matching scores. Let W_Q be the embeddings of words in the question and W_C be the embeddings of words in the target column name. The component matching functions are:

$$f_{max} = \frac{1}{|W_C|} \sum_{w_c \in W_C} \max_{w_q \in W_Q} w_q^T w_c$$

$$f_{avg} = \left(\frac{1}{|W_C|} \sum_{w_c \in W_C} w_c \right)^T \left(\frac{1}{|W_Q|} \sum_{w_q \in W_Q} w_q \right)$$

Essentially, for each word in the column name, f_{max} finds the highest matching question word and outputs the average score. Conversely, f_{avg} simply uses the average word vectors of the question and column name and returns their inner product. In another variant of f_{avg}, we replace the question representation with the output of a bi-directional LSTM model. These matching component functions are combined by a 2-layer feed-forward neural network, which outputs a scalar value as the action score. Details of the neural module design for other action types can be found in Appendix A.

3.4 Model learning

Because the state value function V is defined recursively as the sum of scores of actions in the sequence, the goal of model optimization is to learn the parameters in the neural networks behind the policy function. Let θ be the collection of all the model parameters. Then the state value function can be written as: $V_\theta(s_t) = \sum_{i=1}^{t} \pi_\theta(s_{i-1}, a_i)$.

In a fully supervised setting where the correct semantic parse of each question is available, learning the policy function can be reduced to a sequence prediction problem. However, while having full supervision leads to a better semantic parser, collecting the correct parses requires a much more sophisticated UI design (Yih et al., 2016). In many scenarios, such as the one in the SQA dataset, it is often the case that only the answers to the questions are available. Adapting a learning algorithm to this *weakly* supervised setting is thus critical.

Generally speaking, weakly supervised semantic parsers operate on one assumption — a candidate semantic parse is treated as a correct one if it results in answers that are identical to the gold answers. Therefore, a straightforward modification of existing structured learning algorithms in our setting is to use any semantic parse found to evaluate to the correct answers during beam search as a *reference* parse, and then update the model parameters accordingly. In practice, however, this approach is often problematic: the search space can grow enormously, and when coupled with poor model performance early during training, this leads to beams that contain no parses evaluating to the correct answer. As a result, learning becomes inefficient and takes a long time to converge.

In this work, we propose a conceptually simple learning algorithm for weakly supervised training that sidesteps the inefficient learning problem. Our key insight is to conduct inference using a beam search procedure guided by an *approximate reward* function. The search procedure is executed *twice* for each training example, one for finding the best possible reference semantic parse and the other for finding the predicted semantic parse to update the model. Our framework is suitable for learning from either implicit or explicit supervision, and is detailed in a companion paper (Peng et al., 2017). Below we describe how we adapt it to the semantic parsing problem in this work.

Approximate reward Let $A(s)$ be the answers retrieved by executing the semantic parse represented by state s, and let A^* be the set of gold answers of a given question. We define the *reward* $R(s; A^*) = \mathbb{1}[A(s) = A^*]$, or the accuracy of the retrieved answers. We use $R(s)$ as the abbreviation for $R(s; A^*)$. A state s with $R(s) = 1$ is called a goal state. Directly using this reward function in search of goal states can be difficult, as rewards of most states are 0. However, even when the answers from a semantic parse are not completely correct, some overlap with the gold answers can still hint that the state is close to a goal state, thus providing useful information to guide search. To formalize this idea, we define an *approximated reward* $\tilde{R}(s)$ in this work using the Jaccard coefficient ($\tilde{R}(s) = |A(s) \cap A^*|/|A(s) \cup A^*|$). If s is a goal state, then obviously $\tilde{R}(s) = R(s) = 1$. Also because our actions effectively add additional constraints to exclude some table cells, any succeeding states of s' with $\tilde{R}(s') = 0$ will also have 0 approximate reward and can be pruned from search immediately.

We use the approximate reward $\tilde{R}$ to guide our beam search to find the reference parses (i.e., goal states). Some variations of the approximate reward can be used to make learning more efficient. For instance, we use the model score for tie-breaking, effectively making the approximate reward function depend on the model parameters:

$$\tilde{R}_\theta(s) = |A(s) \cap A^*|/|A(s) \cup A^*| + \epsilon V_\theta(s), \quad (1)$$

where ϵ is a small constant. When a goal state is not found, the state with the highest approximate reward can still be used as a surrogate reference.

Updating parameters The model parameters are updated by first finding the most *violated* state $\hat{s}$ and then comparing $\hat{s}$ with a reference state s^* to compute a loss. The idea of finding the most violated state comes from Taskar et al. (2004), with the

Algorithm 1 Model parameter updates

1: **for** pick a labeled data (x, A^*) **do**
2: $\quad s^* \leftarrow \arg\max_{s \in \mathcal{E}(x)} \tilde{R}(s; A^*)$
3: $\quad \hat{s} \leftarrow \arg\max_{s \in \mathcal{E}(x)} V_\theta(s) - \tilde{R}(s; A^*)$
4: $\quad$ update θ by minimizing $\max(\mathcal{L}(s), 0)$
5: **end for**

intuition that the learning algorithm should make the state value function behave similarly to the reward. Formally, for every state s, we would like the value function to satisfy the following constraint:

$$V_\theta(s^*) - V_\theta(s) \geq R(s^*) - R(s) \quad (2)$$

$R(s^*) - R(s)$ is thus the margin. As discussed above, we use approximate reward function $\tilde{R}_\theta$ instead of the true reward. We want to update the model parameters θ to make sure that the constraint is satisfied. When the constraint is violated, the degree of violation can be written as:

$$\mathcal{L}(s) = V_\theta(s) - V_\theta(s^*) - \tilde{R}_\theta(s) + \tilde{R}_\theta(s^*) \quad (3)$$

In the algorithm, we want to find the state such that the corresponding constraint is most violated. Finding the most violated state is then equivalent to finding the state with the highest value of $V_\theta(s) - \tilde{R}_\theta(s)$ as the other two terms are constant.

Algorithm 1 sketches the key steps of our method in each iteration. It first picks a training instance (x and y), where x represents the table and the question, and y is the gold answer set. The approximate reward function $\tilde{R}$ is defined by y, while $\mathcal{E}(x)$ is the set of end states for this instance. Line 2 finds the best reference and Line 3 finds the most violated state, both relying on beam search for approximate inference. Line 4 computes the gradient of the loss in Eq. (3), which is then used in backpropagation to update the model parameters.

4 Experiments

Since the questions in SQA are decomposed from those in WTQ, we compare our method, `DynSP`, to two existing semantic parsers designed for WTQ: (1) the *floating parser* (`FP`) of Pasupat and Liang (2015), and (2) the *neural programmer* (`NP`) of Neelakantan et al. (2017). We describe below each system's configurations in more detail and qualitatively compare and contrast their performance on SQA.

Floating parser: The floating parser (Pasupat and Liang, 2015) maps questions to logical forms and then executes them on the table to retrieve the answers. It was designed specifically for the WTQ task (achieving 37.0% accuracy on the WTQ test set) and differs from other semantic parsers by not anchoring predicates to tokens in the question, relying instead on typing constraints to reduce the search space. Using `FP` as-is results in poor performance on SQA because the system is configured for questions with single answers, while SQA contains many questions with multiple-cell answers. We address this issue by removing a pruning hyperparameter (*tooManyValues*) and features that add bias on the denotation size.

Neural programmer: The neural programmer proposed by Neelakantan et al. (2017) has shown promising results on WTQ, achieving accuracies on par with those of `FP`. Similar to our method, `NP` contains specialized neural modules that perform discrete operations such as argmax and argmin, and it is able to chain together multiple modules to answer a single question. However, module selection in `NP` is computed via soft attention (Cho et al., 2014), and information is propagated from one module to the next using a recurrent neural network. Since module selection is not tied to a pre-defined parse language like `DynSP`, `NP` simply runs for a fixed number of recurrent timesteps per question rather than growing a parse until it is complete.

Comparing the baseline systems: `FP` and `NP` exemplify two very different paradigms for designing a semantic parsing system to answer questions using structured data. `FP` is a feature-rich system that aims to output the correct semantic parse (in a logical parse language) for a given question. On the other hand, the end-to-end neural network of `NP` relies on its modular architectures to output a probability distribution over cells in a table given a question. While `NP` can learn more powerful neural matching functions between questions and tables than `FP`'s simpler feature-based matching, `NP` cannot produce a complete, discrete semantic parse, which means that its actions can only be interpreted coarsely by looking at the order of the modules selected at each timestep.[6] Furthermore, `FP`'s design theoretically allows it to operate on partial tables

[6] Since `NP` uses a fixed number of timesteps for each question, the module order is not guaranteed to correspond to a complete parse.

indirectly through an API, which is necessary if tables are large and stored in a backend database, while NP requires upfront access to the full tables to facilitate end-to-end model differentiability.[7]

Even though FP and NP are powerful systems designed for the more difficult, compositional questions in WTQ, our method outperforms both systems on SQA when we consider all questions within a sequence independently of each other (a fair comparison), demonstrating the power of our search-based semantic parsing framework. More interestingly, when we leverage the sequential information by including the ***subsequent*** action, our method improves almost 3% in absolute accuracy.

DynSP combines the best parts of both FP and NP. Given a question, we try to generate its correct semantic parse in a formal language that can be predefined by the choice of structured data source (e.g., SQL). However, we push the burden of feature engineering to neural networks as in NP. Our framework is easier to extend to the sequential setting of SQA than either baseline system, requiring just the additional ***subsequent*** action. FP's reliance on a hand-designed grammar necessitates extra rules that operate over partial tables from the previous question, which if added would blow up the search space. Meanwhile, modifying NP to handle sequential QA is non-trivial due to soft module and answer selection; it is not immediately clear how to constrain predictions for one question based on the probability distribution over table cells from the previous question in the sequence.

To more fairly compare DynSP to the baseline systems, we also experiment with a "concatenated questions" setting, which allows the baselines to access sequential context. Here, we treat concatenated question prefixes of a sequence as additional training examples, where a question prefix includes all questions prior to the current question in the sequence.

For example, suppose the question sequence is: *1. what are all of the teams? 2. of those, which won championships?* For the second question, in addition to the original question–answer pair, we add the concatenated question sequence *"what are all of the teams? of those, which won championships?"* paired with the second question's answer. We refer to these concatenated question baselines as FP^+ and NP^+.

[7] In fact, NP is restricted during training to only questions whose associated tables have fewer than a certain threshold of rows and columns due to computational constraints.

4.1 DynSP implementation details

Unlike previous dynamic neural network frameworks (Andreas et al., 2016; Looks et al., 2017), where each example can have different but *predetermined* structure, DynSP needs to dynamically explores and constructs different neural network structures for each question. Therefore, we choose DyNet (Neubig et al., 2017) as our implementation platform for its flexibility in composing computation graphs. We optimize our model parameters using standard stochastic gradient descent. The word embeddings are initialized with 100-d pretrained GloVe vectors (Pennington et al., 2014) and fine-tuned during training with dropout rate 0.5. For follow-up questions, we choose uniformly at random to use either gold answers to the previous question or the model's previous predictions.[8] We constrain the maximum length of actions to 3 for computational efficiency and set the beam size to 15 in our reported models, as accuracy gains are negligible with larger beam sizes. We train our model for 30 epochs, although the best model on the validation set is usually found within the first 20 epochs. Only CPU is used in model training, and each epoch in the beam size 15 setting takes about 30 minutes to complete.

4.2 Results & Analysis

Table 2 shows the results of the baseline systems as well as our method on SQA's test set. For each system, we show both the overall accuracy, the sequence accuracy (the percentage of sequences for which every question was answered correctly), and the accuracy at each position in the sequence. Our method without any sequential information (DynSP) outperforms the standard baselines, and when the *subsequent* action is added (DynSP^*), we improve both overall and sequence accuracy over the concatenated-question baselines.

With that said, all of the systems struggle to answer all questions within a sequence correctly, despite the fact that each individual question is simpler on average than those in WTQ. Most of the errors made by our system are due to either semantic matching challenges or limitations of the underlying parse language. In the middle example of Figure 3, the first question asks for a list of super heroes; from the model's point of view, *Real name* is a more relevant column than *Character*, although the latter is correct. The second question also con-

[8] Only predicted answers are used at test time.

Model	All	Seq	Pos 1	Pos 2	Pos 3
FP	34.1	7.2	52.6	25.6	**25.9**
NP	39.4	10.8	58.9	35.9	24.6
DynSP	42.0	10.2	**70.9**	35.8	20.1
FP$^+$	33.2	7.7	51.4	22.2	22.3
NP$^+$	40.2	11.8	60.0	35.9	25.5
DynSP*	**44.7**	**12.8**	70.4	**41.1**	23.6

Table 2: Accuracies of all systems on SQA; the models in the first half of the table treat questions independently, while those in the second half consider sequential context. Our method outperforms existing ones both in terms of overall accuracy as well as sequence accuracy.

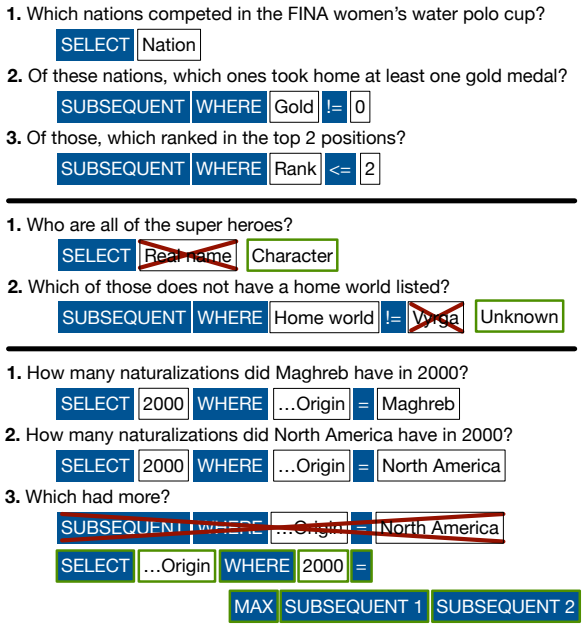

Figure 3: Parses computed by DynSP for three test sequences (actions in blue boxes, values from table in white boxes). *Top*: all three questions are parsed correctly. *Middle*: semantic matching errors cause the model to select incorrect columns and conditions. *Bottom*: The final question is unanswerable due to limitations of our parse language.

tains a challenging matching problem where the unlisted home worlds referred to in the question are marked as *Unknown* in the table. Many of these matching issues are resolved by humans using common sense, which for computers requires far more data than is available in SQA to learn.

Even when there are no tricky discrepancies between question and table text, questions are often complex enough that their semantic parses cannot be expressed in our parse language. Although trivial on the surface, the final question in the bottom sequence of Figure 3 is one such example; the correct semantic parse requires access to the answers of both the first and second question, actions that we have not currently implemented in our language due to concerns with the search space size. Increasing the number of complex actions requires designing smarter optimization procedures, which we leave to future work.

5 Related Work

Previous work on conversational QA has focused on small, single-domain datasets. Perhaps most related to our task is the context-dependent sentence analysis described in (Zettlemoyer and Collins, 2009), where conversations between customers and travel agents are mapped to logical forms after resolving referential expressions. Another dataset of travel booking conversations is used by Artzi and Zettlemoyer (2011) to learn a semantic parser for complicated queries given user clarifications. More recently, Long et al. (2016) collect three contextual semantic parsing datasets (from synthetic domains) that contain coreferences to entities and actions. We differentiate ourselves from these prior works in two significant ways: first, our dataset is not restricted to a particular domain, and second, a major goal of our work is to analyze the different types of sequence progressions people create when they are trying to express a complicated intent.

Complex, interactive QA tasks have also been proposed in the information retrieval community, where the data source is a corpus of newswire text (Kelly and Lin, 2007). We also build on aspects of some existing interactive question-answering systems. For example, the system of Harabagiu et al. (2005) includes a module that predicts what a user will ask next given their current question.

Other than FP and NP, the work of Neural Symbolic Machines (NSM) (Liang et al., 2017) is perhaps the closest to ours. NSM aims to generate formal semantic parses of questions that can be executed on Freebase to retrieve answers, and is trained using the REINFORCE algorithm (Williams, 1992) augmented with approximate gold parses found in a separate curriculum learning stage. In comparison, finding reference parses is an integral part of our algorithm. Our non-

probabilistic, margin-based objective function also helps avoid the need for empirical tricks to handle normalization and proper sampling, which are crucial when applying REINFORCE in practice.

6 Conclusion & Future Work

In this work we move towards a conversational, multi-turn QA scenario in which systems must rely on prior context to answer the user's current question. To this end, we introduce SQA, a dataset that consists of 6,066 unique sequences of inter-related questions about Wikipedia tables, with 17,553 questions-answer pairs in total. To the best of our knowledge, SQA is the first semantic parsing dataset that addresses sequential question answering. We propose `DynSP`, a dynamic neural semantic parsing framework, for solving SQA. By formulating semantic parsing as a state–action search problem, our method learns modular neural network models through reward-guided search. `DynSP` outperforms existing state-of-the-art systems designed for answering complex questions when applied to SQA, and increases the gain after incorporating the subsequent actions.

In the future, we plan to investigate several interesting research questions triggered by this work. For instance, although our current formal language design covers most question types in SQA, it is nevertheless important to extend it further to make the semantic parser more robust (e.g., by including UNION or allowing comparison of multiple previous answers). Practically, allowing a more complicated semantic parse structure—either by increasing the number of primitive statements or the length of the parse—poses serious computational challenges in both model learning and inference. Because of the dynamic nature of our framework, it is not trivial to leverage the computational capabilities of GPUs using minibatched training; we plan to investigate ways to take full advantage of modern computing machinery in the near future. Finally, better resolution of semantic matching errors is a top priority, and unsupervised learning from large external corpora is one way to make progress in this direction.

Acknowledgments

We thank the anonymous reviewers for their insightful comments. We are also grateful to Panupong Pasupat for his help in configuring the floating parser baseline, and to Arvind Neelakantan for his help with the neural programmer model.

A Action Neural Module Design

We describe here the neural module design for each action. As most actions try to match question text to column names or table entries, the neural network architectures are essentially various kinds of semantic similarity matching functions.

$\mathcal{A}_1$ **Select-column** Conceptually, the corresponding module is a combination of various matching scores. Let W_Q be the embeddings of words in the question and W_C be the embeddings of words in the target column name. The component matching functions are:

$$f_{max} = \frac{1}{|W_C|} \sum_{w_c \in W_C} \max_{w_q \in W_Q} w_q^T w_c$$

$$f_{avg} = \left(\frac{1}{|W_C|} \sum_{w_c \in W_C} w_c \right)^T \left(\frac{1}{|W_Q|} \sum_{w_q \in W_Q} w_q \right)$$

Essentially, for each word in the column name, f_{max} finds the highest matching question word and outputs the average score. Conversely, f_{avg} simply uses the average word vectors of the question and column name and returns their inner product. In another variant of f_{avg}, we replace the question representation with the output of a bidirectional LSTM model. These matching component functions are combined by a 2-layer feed-forward neural network, which outputs a scalar value as the action score.

$\mathcal{A}_2$ **Cond-column** Because this action also tries to find the correct column (but for conditions), we use the same matching scoring functions as in $\mathcal{A}_1$ module. However, a different 2-layer feed-forward neural network is used to combine the scores, as well as two binary features that indicate whether all the cells in this column are numeric values or not.

$\mathcal{A}_3$ **Op-Equal** This action checks whether a particular column value matches the question text. Suppose the average of the word vectors of the particular cell is w_x and the question word vectors are W_Q. Here the matching function is:

$$f_{max} = \max_{w_q \in W_Q} w_q^T w_x$$

$\mathcal{A}_4$ **Op-NotEqual** The neural module for this action extends the design for $\mathcal{A}_3$. It first uses a $\max$ function similar to f_{max} in $\mathcal{A}_3$ to compare the vector of the negation word "not", and the question words. This score is combined with the f_{max} score in $\mathcal{A}_3$ using a 2-layer feed-forward neural network as the final module score.

$\mathcal{A}_5$-$\mathcal{A}_8$ **Op-GT, Op-GE, Op-LT, Op-LE** The arguments of these comparison operations are extracted from question in advance. Therefore, the action modules just need to decide whether such relations are indeed used in the question. We take a simple strategy by initialing a special word vector that tries to capture the semantics of the relation. Take op-gt, *greater than*, for example. We use the average of the vectors of words like *more*, *greater* and *larger* to initialize the special word vector, denoted as w_{gt}. Let w_{arg} be the averaged vectors of words within a $[-2, +2]$ window centered at the argument in the question. The inner product of w_{gt} and w_{arg} is then used as the scoring function.

$\mathcal{A}_9$-$\mathcal{A}_{10}$ **Op-ArgMin, Op-ArgMax** We handle ArgMin and ArgMax similarly to the comparison operations. The difference is that we compare the special word vector to the averaged vector of all the question words, instead of a short subsequence of words.

Subsequent actions The modules in subsequent actions use basically the same design as their counterparts in the independent question setting. The main difference is that we extend the question representation to words from not just the target question, but also the question that immediately precedes it.

Gated-Attention Readers for Text Comprehension

Abstract

In this paper we study the problem of answering cloze-style questions over documents. Our model, the Gated-Attention (GA) Reader[1], integrates a multi-hop architecture with a novel attention mechanism, which is based on multiplicative interactions between the query embedding and the intermediate states of a recurrent neural network document reader. This enables the reader to build query-specific representations of tokens in the document for accurate answer selection. The GA Reader obtains state-of-the-art results on three benchmarks for this task–the CNN & Daily Mail news stories and the Who Did What dataset. The effectiveness of multiplicative interaction is demonstrated by an ablation study, and by comparing to alternative compositional operators for implementing the gated-attention.

1 Introduction

A recent trend to measure progress towards machine reading is to test a system's ability to answer questions about a document it has to comprehend. Towards this end, several large-scale datasets of cloze-style questions over a context document have been introduced recently, which allow the training of supervised machine learning systems (Hermann et al., 2015; Hill et al., 2016; Onishi et al., 2016). Such datasets can be easily constructed automatically and the unambiguous nature of their queries provides an objective benchmark to measure a system's performance at text comprehension.

Deep learning models have been shown to outperform traditional shallow approaches on text comprehension tasks (Hermann et al., 2015). The success of many recent models can be attributed primarily to two factors: (1) *Multi-hop architectures* (Weston et al., 2015; Sordoni et al., 2016; Shen et al., 2016), allow a model to scan the document and the question iteratively for multiple passes. (2) *Attention mechanisms*, (Chen et al., 2016; Hermann et al., 2015) borrowed from the machine translation literature (Bahdanau et al., 2014), allow the model to focus on appropriate subparts of the context document. Intuitively, the multi-hop architecture allows the reader to incrementally refine token representations, and the attention mechanism re-weights different parts in the document according to their relevance to the query.

The effectiveness of multi-hop reasoning and attentions have been explored orthogonally so far in the literature. In this paper, we focus on combining both in a complementary manner, by designing a novel attention mechanism which gates the evolving token representations across hops. More specifically, unlike existing models where the query attention is applied either token-wise (Hermann et al., 2015; Kadlec et al., 2016; Chen et al., 2016; Hill et al., 2016) or sentence-wise (Weston et al., 2015; Sukhbaatar et al., 2015) to allow weighted aggregation, the Gated-Attention (GA) module proposed in this work allows the query to directly interact with each dimension of the token embeddings at the semantic-level, and is applied layer-wise as information filters during the multi-hop representation learning process. Such a fine-grained attention enables our model to learn conditional token representations w.r.t. the given question, leading to accurate answer selections.

We show in our experiments that the proposed GA reader, despite its relative simplicity, consis-

tently improves over a variety of strong baselines on three benchmark datasets . Our key contribution, the GA module, provides a significant improvement for large datasets. Qualitatively, visualization of the attentions at intermediate layers of the GA reader shows that in each layer the GA reader attends to distinct salient aspects of the query which help in determining the answer.

2 Related Work

The cloze-style QA task involves tuples of the form $(d, q, a, \mathcal{C})$, where d is a document (context), q is a query over the contents of d, in which a phrase is replaced with a placeholder, and a is the answer to q, which comes from a set of candidates $\mathcal{C}$. In this work we consider datasets where each candidate $c \in \mathcal{C}$ has at least one token which also appears in the document. The task can then be described as: given a document-query pair (d, q), find $a \in \mathcal{C}$ which answers q. Below we provide an overview of representative neural network architectures which have been applied to this problem.

LSTMs with Attention: Several architectures introduced in Hermann et al. (2015) employ LSTM units to compute a combined document-query representation $g(d, q)$, which is used to rank the candidate answers. These include the **DeepLSTM Reader** which performs a single forward pass through the concatenated *(document, query)* pair to obtain $g(d, q)$; the **Attentive Reader** which first computes a document vector $d(q)$ by a weighted aggregation of words according to attentions based on q, and then combines $d(q)$ and q to obtain their joint representation $g(d(q), q)$; and the **Impatient Reader** where the document representation is built incrementally. The architecture of the Attentive Reader has been simplified recently in **Stanford Attentive Reader**, where shallower recurrent units were used with a bilinear form for the query-document attention (Chen et al., 2016).

Attention Sum: The **Attention-Sum (AS) Reader** (Kadlec et al., 2016) uses two bi-directional GRU networks (Cho et al., 2015) to encode both d and q into vectors. A probability distribution over the entities in d is obtained by computing dot products between q and the entity embeddings and taking a softmax. Then, an aggregation scheme named *pointer-sum attention* is further applied to sum the probabilities of the same entity, so that frequent entities the document will be favored compared to rare ones. Building on the AS Reader, the **Attention-over-Attention (AoA) Reader** (Cui et al., 2017) introduces a two-way attention mechanism where the query and the document are mutually attentive to each other.

Mulit-hop Architectures: **Memory Networks (MemNets)** were proposed in Weston et al. (2015), where each sentence in the document is encoded to a memory by aggregating nearby words. Attention over the memory slots given the query is used to compute an overall memory and to renew the query representation over multiple iterations, allowing certain types of reasoning over the salient facts in the memory and the query. **Neural Semantic Encoders (NSE)** (Munkhdalai & Yu, 2017a) extended MemNets by introducing a *write* operation which can evolve the memory over time during the course of reading. Iterative reasoning has been found effective in several more recent models, including the **Iterative Attentive Reader** (Sordoni et al., 2016) and **ReasoNet** (Shen et al., 2016). The latter allows dynamic reasoning steps and is trained with reinforcement learning.

Other related works include **Dynamic Entity Representation network (DER)** (Kobayashi et al., 2016), which builds dynamic representations of the candidate answers while reading the document, and accumulates the information about an entity by max-pooling; **EpiReader** (Trischler et al., 2016) consists of two networks, where one proposes a small set of candidate answers, and the other reranks the proposed candidates conditioned on the query and the context; **Bi-Directional Attention Flow network (BiDAF)** (Seo et al., 2017) adopts a multi-stage hierarchical architecture along with a flow-based attention mechanism; Bajgar et al. (2016) showed a 10% improvement on the CBT corpus (Hill et al., 2016) by training the AS Reader on an augmented training set of about 14 million examples, making a case for the community to exploit data abundance. The focus of this paper, however, is on designing models which exploit the available data efficiently.

3 Gated-Attention Reader

Our proposed GA readers perform multiple hops over the document (context), similar to the Memory Networks architecture (Sukhbaatar et al., 2015). Multi-hop architectures mimic the multi-step comprehension process of human readers, and have shown promising results in several recent models for text comprehension (Sordoni et al.,

2016; Kumar et al., 2016; Shen et al., 2016). The contextual representations in GA readers, namely the embeddings of words in the document, are iteratively refined across hops until reaching a final attention-sum module (Kadlec et al., 2016) which maps the contextual representations in the last hop to a probability distribution over candidate answers.

The attention mechanism has been introduced recently to model human focus, leading to significant improvement in machine translation and image captioning (Bahdanau et al., 2014; Mnih et al., 2014). In reading comprehension tasks, ideally, the semantic meanings carried by the contextual embeddings should be aware of the query across hops. As an example, human readers are able to keep the question in mind during multiple passes of reading, to successively mask away information irrelevant to the query. However, existing neural network readers are restricted to either attend to tokens (Hermann et al., 2015; Chen et al., 2016) or entire sentences (Weston et al., 2015), with the assumption that certain sub-parts of the document are more important than others. In contrast, we propose a finer-grained model which attends to components of the semantic representation being built up by the GRU. The new attention mechanism, called *gated-attention*, is implemented via *multiplicative* interactions between the query and the contextual embeddings, and is applied per hop to act as fine-grained information filters during the multi-step reasoning. The filters weigh individual components of the vector representation of *each* token in the document separately.

The design of gated-attention layers is motivated by the effectiveness of multiplicative interaction among vector-space representations, e.g., in various types of recurrent units (Hochreiter & Schmidhuber, 1997; Wu et al., 2016) and in relational learning (Yang et al., 2014; Kiros et al., 2014). While other types of compositional operators are possible, such as concatenation or addition (Mitchell & Lapata, 2008), we find that multiplication has strong empirical performance (section 4.3), where query representations naturally serve as information filters across hops.

3.1 Model Details

Several components of the model use a Gated Recurrent Unit (GRU) (Cho et al., 2015) which maps an input sequence $X = [x_1, x_2, \ldots, x_T]$ to an ouput sequence $H = [h_1, h_2, \ldots, h_T]$ as follows:

$$
\begin{aligned}
r_t &= \sigma(W_r x_t + U_r h_{t-1} + b_r), \\
z_t &= \sigma(W_z x_t + U_z h_{t-1} + b_z), \\
\tilde{h}_t &= \tanh(W_h x_t + U_h(r_t \odot h_{t-1}) + b_h), \\
h_t &= (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t.
\end{aligned}
$$

where $\odot$ denotes the Hadamard product or the element-wise multiplication. r_t and z_t are called the *reset* and *update* gates respectively, and $\tilde{h}_t$ the *candidate output*. A Bi-directional GRU (Bi-GRU) processes the sequence in both forward and backward directions to produce two sequences $[h_1^f, h_2^f, \ldots, h_T^f]$ and $[h_1^b, h_2^b, \ldots, h_T^b]$, which are concatenated at the output

$$
\overleftrightarrow{\text{GRU}}(X) = [h_1^f \| h_T^b, \ldots, h_T^f \| h_1^b] \tag{1}
$$

where $\overleftrightarrow{\text{GRU}}(X)$ denotes the *full output* of the Bi-GRU obtained by concatenating each forward state h_i^f and backward state h_{T-i+1}^b at step i given the input X. Note $\overleftrightarrow{\text{GRU}}(X)$ is a matrix in $\mathbb{R}^{2n_h \times T}$ where n_h is the number of hidden units in GRU.

Let $X^{(0)} = [x_1^{(0)}, x_2^{(0)}, \ldots x_{|D|}^{(0)}]$ denote the token embeddings of the document, which are also inputs at layer 1 for the document reader below, and $Y = [y_1, y_2, \ldots y_{|Q|}]$ denote the token embeddings of the query. Here $|D|$ and $|Q|$ denote the document and query lengths respectively.

3.1.1 Multi-Hop Architecture

Fig. 1 illustrates the Gated-Attention (GA) reader. The model reads the document and the query over K horizontal layers, where layer k receives the contextual embeddings $X^{(k-1)}$ of the document from the previous layer. The document embeddings are transformed by taking the full output of a document Bi-GRU (indicated in blue in Fig. 1):

$$
D^{(k)} = \overleftrightarrow{\text{GRU}}_D^{(k)}(X^{(k-1)}) \tag{2}
$$

At the same time, a layer-specific query representation is computed as the full output of a separate query Bi-GRU (indicated in green in Figure 1):

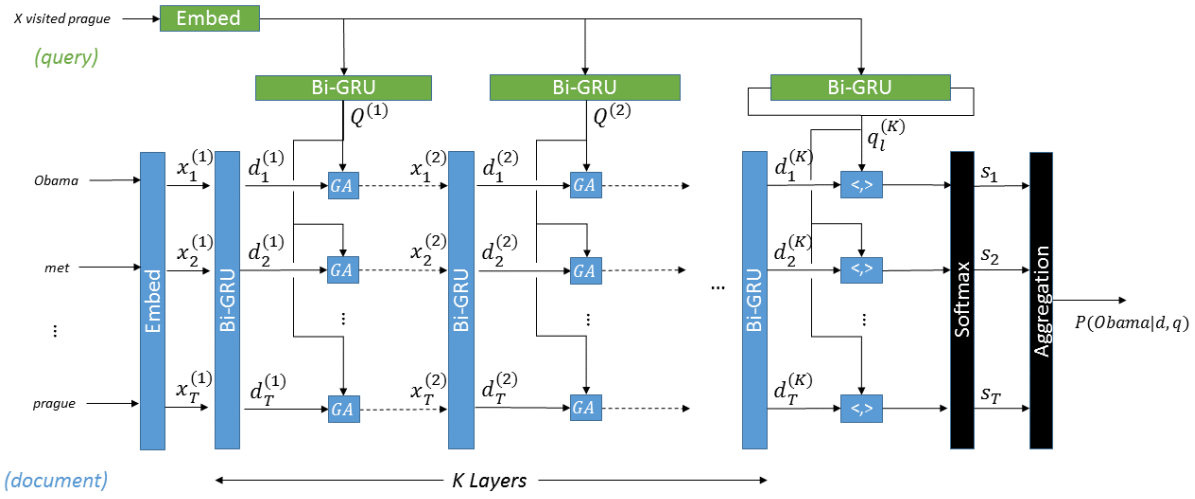
$$
Q^{(k)} = \overleftrightarrow{\text{GRU}}_Q^{(k)}(Y) \tag{3}
$$

Next, *Gated-Attention* is applied to $D^{(k)}$ and $Q^{(k)}$ to compute inputs for the next layer $X^{(k)}$.

$$
X^{(k)} = \text{GA}(D^{(k)}, Q^{(k)}) \tag{4}
$$

where GA is defined in the following subsection.

Figure 1: Gated-Attention Reader. Dashed lines represent dropout connections.



3.1.2 Gated-Attention Module

For brevity, let us drop the superscript k in this subsection as we are focusing on a particular layer. For each token d_i in D, the GA module forms a token-specific representation of the query $\tilde{q}_i$ using soft attention, and then multiplies the query representation element-wise with the document token representation. Specifically, for $i = 1, \ldots, |D|$:

$$\alpha_i = \text{softmax}(Q^\top d_i) \tag{5}$$
$$\tilde{q}_i = Q\alpha_i$$
$$x_i = d_i \odot \tilde{q}_i \tag{6}$$

In equation (6) we use the multiplication operator to model the interactions between d_i and $\tilde{q}_i$. In the experiments section, we also report results for other choices of gating functions, including addition $x_i = d_i + \tilde{q}_i$ and concatenation $x_i = d_i \| \tilde{q}_i$.

3.1.3 Answer Prediction

Let $q_\ell^{(K)} = q_\ell^f \| q_{T-\ell+1}^b$ be an intermediate output of the final layer query Bi-GRU at the location ℓ of the cloze token in the query, and $D^{(K)} = \overleftrightarrow{\text{GRU}}_D^{(K)}(X^{(K-1)})$ be the full output of final layer document Bi-GRU. To obtain the probability that a particular token in the document answers the query, we take an inner-product between these two, and pass through a softmax layer:

$$s = \text{softmax}((q_\ell^{(K)})^T D^{(K)}) \tag{7}$$

where vector s defines a probability distribution over the $|D|$ tokens in the document. The probability of a particular candidate $c \in \mathcal{C}$ as being the answer is then computed by aggregating the probabilities of all document tokens which appear in c and renormalizing over the candidates:

$$\Pr(c|d,q) \propto \sum_{i \in \mathbb{I}(c,d)} s_i \tag{8}$$

where $\mathbb{I}(c,d)$ is the set of positions where a token in c appears in the document d. This aggregation operation is the same as the *pointer sum attention* applied in the AS Reader (Kadlec et al., 2016).

Finally, the candidate with maximum probability is selected as the predicted answer:

$$a^* = \text{argmax}_{c \in \mathcal{C}} \ \Pr(c|d,q). \tag{9}$$

During the training phase, model parameters of GA are updated w.r.t. a cross-entropy loss between the predicted probabilities and the true answers.

3.1.4 Further Enhancements

Character-level Embeddings: Given a token w from the document or query, its vector space representation is computed as $x = L(w)||C(w)$. $L(w)$ retrieves the word-embedding for w from a lookup table $L \in \mathbb{R}^{|V| \times n_l}$, whose rows hold a vector for each unique token in the vocabulary. We also utilize a character composition model $C(w)$ which generates an orthographic embedding of the token. Such embeddings have been previously shown to be helpful for tasks like Named Entity Recognition (Yang et al., 2016) and dealing with OOV tokens at test time (Dhingra et al., 2016). The embedding $C(w)$ is generated by taking the final outputs $z_{n_c}^f$ and $z_{n_c}^b$ of a Bi-GRU applied to embeddings from

a lookup table of characters in the token, and applying a linear transformation:

$$z = z^f_{n_c} || z^b_{n_c}$$
$$C(w) = Wz + b$$

Question Evidence Common Word Feature (qe-comm): Li et al. (2016) recently proposed a simple token level indicator feature which significantly boosts reading comprehension performance in some cases. For each token in the document we construct a one-hot vector $f_i \in \{0, 1\}^2$ indicating its presence in the query. It can be incorporated into the GA reader by assigning a feature lookup table $F \in \mathbb{R}^{n_F \times 2}$ (we use $n_F = 2$), taking the feature embedding $e_i = f_i^T F$ and appending it to the inputs of the last layer document BiGRU as, $x_i^{(K)} \| f_i$ for all i. We conducted several experiments both with and without this feature and observed some interesting trends, which are discussed below. Henceforth, we refer to this feature as the *qe-comm feature* or just *feature*.

4 Experiments and Results

4.1 Datasets

We evaluate the GA reader on five large-scale datasets recently proposed in the literature. The first two, CNN and Daily Mail news stories[2] consist of articles from the popular CNN and Daily Mail websites (Hermann et al., 2015). A query over each article is formed by removing an entity from the short summary which follows the article. Further, entities within each article were anonymized to make the task purely a comprehension one. N-gram statistics, for instance, computed over the entire corpus are no longer useful in such an anonymized corpus.

The next two datasets are formed from two different subsets of the Children's Book Test (CBT)[3] (Hill et al., 2016). Documents consist of 20 contiguous sentences from the body of a popular children's book, and queries are formed by deleting a token from the 21st sentence. We only focus on subsets where the deleted token is either a common noun (CN) or named entity (NE) since simple language models already give human-level performance on the other types (cf. (Hill et al., 2016)).

The final dataset is Who Did What[4] (WDW) (Onishi et al., 2016), constructed from the LDC English Gigaword newswire corpus. First, article pairs which appeared around the same time and with overlapping entities are chosen, and then one article forms the document and a cloze query is constructed from the other. Missing tokens are always person named entities. Questions which are easily answered by simple baselines are filtered out, to make the task more challenging. There are two versions of the training set—a small but focused "Strict" version and a large but noisy "Relaxed" version. We report results on both settings which share the same validation and test sets. Statistics of all the datasets used in our experiments are summarized in the Appendix (Table 5).

4.2 Performance Comparison

Tables 1 and 3 show a comparison of the performance of GA Reader with previously published results on WDW and CNN, Daily Mail, CBT datasets respectively. The numbers reported for GA Reader are for single best models, though we compare to both ensembles and single models from prior work. GA Reader-- refers to an earlier version of the model, unpublished but described in a preprint, with the following differences—(1) it does not utilize token-specific attentions within the GA module, as described in equation (5), (2) it does not use a character composition model, (3) it is initialized with word embeddings pretrained on the corpus itself rather than GloVe. A detailed analysis of these differences is studied in the next section. Here we present 4 variants of the latest GA Reader, using combinations of whether the qe-comm feature is used (+feature) or not, and whether the word lookup table $L(w)$ is updated during training or fixed to its initial value. Other hyperparameters are listed in Appendix A.

Interestingly, we observe that feature engineering leads to significant improvements for WDW and CBT datasets, but not for CNN and Daily Mail datasets. We note that anonymization of the latter datasets means that there is already some feature engineering (it adds hints about whether a token is an entity), and these are much larger than the other four. In machine learning it is common to see the effect of feature engineering diminish with increasing data size. Similarly, fixing the word embeddings provides an improvement for the WDW

GA (update $L(w)$)	67.8	67.0	67.0	66.6
GA (fix $L(w)$)	68.3	68.0	69.6	69.1
GA (+feature, update $L(w)$)	70.1	69.5	70.9	71.0
GA (+feature, fix $L(w)$)	**71.6**	**71.2**	**72.6**	**72.6**

Table 2: **Top:** Performance of different gating functions. **Bottom:** Effect of varying the number of hops K. Results on WDW without using the qe-comm feature and with fixed $L(w)$.

Gating Function	Accuracy	
	Val	Test
Sum	64.9	64.5
Concatenate	64.4	63.7
Multiply	**68.3**	**68.0**
K		
1 (AS) †	–	57
2	65.6	65.6
3	**68.3**	68.0
4	**68.3**	**68.2**

and CBT, but not for CNN and Daily Mail. This is not surprising given that the latter datasets are larger and less prone to overfitting.

Comparing with prior work, on the WDW dataset the basic version of the GA Reader outperforms all previously published models when trained on the Strict setting. By adding the qe-comm feature the performance increases by 3.2% and 3.5% on the Strict and Relaxed settings respectively to set a new state of the art on this dataset. On the CNN and Daily Mail datasets the GA Reader leads to an improvement of 3.2% and 4.3% respectively over the best previous single models. They also outperform previous ensemble models, setting a new state of that art for both datasets. For CBT-NE, GA Reader with the qe-comm feature outperforms all previous single and ensemble models except the AS Reader trained on the much larger BookTest Corpus (Bajgar et al., 2016). Lastly, on CBT-CN the GA Reader with the qe-comm feature outperforms all previously published single models except the NSE, and AS Reader trained on a larger corpus. For each of the 4 datasets on which GA achieves the top performance, we conducted one-sample proportion tests to test whether GA is significantly better than the second-best baseline. The p-values are 0.319 for CNN, <0.00001 for DailyMail, 0.028 for CBT-NE, and <0.00001 for WDW. In other words, GA statistically significantly outperforms all other baselines on 3 out of those 4 datasets at the 5% significance level. The results could be even more significant under paired tests, however we did not have access to the predictions from the baselines.

4.3 GA Reader Analysis

In this section we do an ablation study to see the effect of Gated Attention. We compare the GA Reader as described here to a model which is exactly the same in all aspects, except that it passes document embeddings $D^{(k)}$ in each layer directly to the inputs of the next layer without using the GA module. In other words $X^{(k)} = D^{(k)}$ for all $k > 0$. This model ends up using only one query GRU at the output layer for selecting the answer from the document. We compare these two variants both with and without the qe-comm feature on CNN and WDW datasets for three subsets of the training data - 50%, 75% and 100%. Test set accuracies for these settings are shown in Figure 2. On CNN when tested without feature engineering, we observe that GA provides a significant boost in performance compared to without GA. When tested with the feature it still gives an improvement, but the improvement is significant only with 100% training data. On WDW-Strict, which is a third of the size of CNN, without the feature we see an improvement when using GA versus without using GA, which becomes significant as the training set size increases. When tested with the feature on WDW, for a small data size without GA does better than with GA, but as the dataset size increases they become equivalent. We conclude that GA provides a boost in the absence of feature engineering, or as the training set size increases.

Next we look at the question of how to gate intermediate document reader states from the query, i.e. what operation to use in equation 6. Table

Table 3: Validation/Test accuracy (%) on CNN, Daily Mail and CBT. Results marked with "†" are cf previously published works. Results marked with "‡" were obtained by training on a larger training set. Best performance on standard training sets is in bold, and on larger training sets in italics.

2 (top) shows the performance on WDW dataset for three common choices – `sum` ($x = d + q$), `concatenate` ($x = d \| q$) and `multiply` ($x = d \odot q$). Empirically we find element-wise multiplication does significantly better than the other two, which justifies our motivation to "filter" out document features which are irrelevant to the query.

At the bottom of Table 2 we show the effect of varying the number of hops K of the GA Reader on the final performance. We note that for $K = 1$, our model is equivalent to the AS Reader without any GA modules. We see a steep and steady rise in accuracy as the number of hops is increased from $K = 1$ to 3, which remains constant beyond that. This is a common trend in machine learning as model complexity is increased, however we note that a multi-hop architecture is important to achieve a high performance for this task, and provide further evidence for this in the next section.

4.4 Ablation Study for Model Components

Table 4 shows accuracy on WDW by removing one component at a time. The steepest reduction is observed when we replace pretrained GloVe vectors with those pretrained on the corpus itself. GloVe vectors were trained on a large corpus of about 6 billion tokens (Pennington et al., 2014), and provide an important source of prior knowl-

Figure 2: Performance in accuracy with and without the Gated-Attention module over different training sizes. p-values for an exact one-sided Mcnemar's test are given inside the parentheses for each setting.

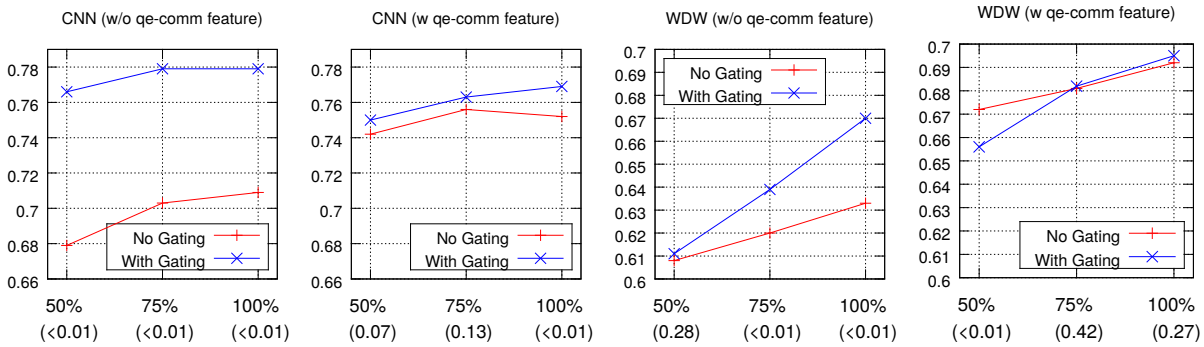

Table 4: Ablation study on WDW dataset, without using the qe-comm feature and with fixed $L(w)$. Results marked with † are cf Onishi et al. (2016).

Model	Accuracy	
	Val	Test
GA	**68.3**	**68.0**

−token-attentions (eq. 5)	65.7	65.0
−glove, +corpus	64.0	62.5
GA--†	–	57

edge for the model. Note that the strongest baseline on WDW, NSE (Munkhdalai & Yu, 2017b), also uses pretrained GloVe vectors, hence the comparison is fair in that respect. Next, we observe a substantial drop when removing token-specific attentions over the query in the GA module, which allow gating individual tokens in the document only by parts of the query relevant to that token rather than the overall query representation. Finally, removing the character embeddings, which were only used for WDW and CBT, leads to a reduction of about 1% in the performance.

4.5 Attention Visualization

To gain an insight into the reading process employed by the model we analyzed the attention distributions at intermediate layers of the reader. Figure 3 shows an example from the validation set of WDW dataset (several more are in the Appendix). In each figure, the left and middle plots visualize attention over the query (equation 5) for candidates in the document after layers 1 & 2 respectively. The right plot shows attention over candidates in the document of cloze placeholder (XXX) in the query at the final layer. The full document, query and correct answer are shown at the bottom.

A generic pattern observed in these examples is that in intermediate layers, candidates in the document (shown along rows) tend to pick out salient tokens in the query which provide clues about the cloze, and in the final layer the candidate with the highest match with these tokens is selected as the answer. In Figure 3 there is a high attention of the correct answer on `financial regulatory standards` in the first layer, and on `us president` in the second layer. The incorrect answer, in contrast, only attends to one of these aspects, and hence receives a lower score in the final layer despite the n-gram overlap it has with the cloze token in the query. Importantly, different layers tend to focus on different tokens in the query, supporting the hypothesis that the multi-hop architecture of GA Reader is able to combine distinct pieces of information to answer the query.

5 Conclusion

We presented the Gated-Attention reader for answering cloze-style questions over documents. The GA reader features a novel multiplicative gating mechanism, combined with a multi-hop architecture. Our model achieves the state-of-the-art performance on several large-scale benchmark datasets with more than 4% improvements over competitive baselines. Our model design is backed up by an ablation study showing statistically significant improvements of using Gated Attention as information filters. We also showed empirically that multiplicative gating is superior to addi-

tion and concatenation operations for implementing gated-attentions, though a theoretical justification remains part of future research goals. Analysis of document and query attentions in intermediate layers of the reader further reveals that the model iteratively attends to different aspects of the query to arrive at the final answer. In this paper we have focused on text comprehension, but we believe that the Gated-Attention mechanism may benefit other tasks as well where multiple sources of information interact.

A Implementation Details

Our model was implemented using the Theano (Theano Development Team, 2016) and Lasagne[5] Python libraries. We used stochastic gradient descent with ADAM updates for optimization, which combines classical momentum and adaptive gradients (Kingma & Ba, 2015). The batch size was 32 and the initial learning rate was 5×10^{-4} which was halved every epoch after the second epoch. The same setting is applied to all models and datasets. We also used gradient clipping with a threshold of 10 to stabilize GRU training (Pascanu et al., 2013). We set the number of layers K to be 3 for all experiments. The number of hidden units for the character GRU was set to 50. The remaining two hyperparameters—size of document and query GRUs, and dropout rate—were tuned on the validation set, and their optimal values are shown in Table 6. In general, the optimal GRU size increases and the dropout rate decreases as the corpus size increases.

The word lookup table was initialized with $100d$ GloVe vectors[6] (Pennington et al., 2014) and OOV tokens at test time were assigned unique random vectors. We empirically observed that initializing with pre-trained embeddings gives higher performance compared to random initialization for all

$\dim(\overleftrightarrow{\text{GRU}}_*)$	256	256	128	128	128	128

datasets. Furthermore, for smaller datasets (WDW and CBT) we found that fixing these embeddings to their pretrained values led to higher test performance, possibly since it avoids overfitting. We do not use the character composition model for CNN and Daily Mail, since their entities (and hence candidate answers) are anonymized to generic tokens. For other datasets the character lookup table was randomly initialized with $25d$ vectors. All other parameters were initialized to their default values as specified in the Lasagne library.

Determining Gains Acquired from Word Embedding Quantitatively Using Discrete Distribution Clustering

Jianbo Ye[⋆], Yanran Li[†], Zhaohui Wu[‡], James Z. Wang[⋆], Wenjie Li[†] and Jia Li[⋆]

Abstract

Word embeddings have become widely-used in document analysis. While a large number of models for mapping words to vector spaces have been developed, it remains undetermined how much net gain can be achieved over traditional approaches based on bag-of-words. In this paper, we propose a new document clustering approach by combining any word embedding with a state-of-the-art algorithm for clustering empirical distributions. By using the Wasserstein distance between distributions, the word-to-word semantic relationship is taken into account in a principled way. The new clustering method is easy to use and consistently outperforms other methods on a variety of data sets. More importantly, the method provides an effective framework for determining when and how much word embeddings contribute to document analysis. Experimental results with multiple embedding models are reported.

1 Introduction

Word embeddings (a.k.a. word vectors) have been broadly adopted for document analysis (Mikolov et al., 2013a,b). The embeddings can be trained from external large-scale corpus and then easily utilized for different data. To a certain degree, the knowledge mined from the corpus, possibly in very intricate ways, is coded in the vector space, the samples of which are easy to describe and ready for mathematical modeling. Despite the appeal, researchers will be interested in knowing how much gain an embedding can bring forth over the performance achievable by existing bag-of-words based approaches. Moreover, how can the gain be quantified? Such a preliminary evaluation will be carried out before building a sophisticated pipeline of analysis.

Almost every document analysis model used in practice is constructed assuming a certain basic representation—bag-of-words or word embeddings—for the sake of computational tractability. For example, after word embedding is done, high-level models in the embedded space, such as entity representations, similarity measures, data manifolds, hierarchical structures, language models, and neural architectures, are designed for various tasks. In order to invent or enhance analysis tools, we want to understand precisely the pros and cons of the high-level models and the underlying representations. Because the model and the representation are tightly coupled in an analytical system, it is not easy to pinpoint where the gain or loss found in practice comes from. Should the gain be credited to the mechanism of the model or to the use of word embeddings? As our experiments demonstrate, introducing certain assumptions will make individual methods effective only if certain constraints are met. We will address this issue under an unsupervised learning framework.

Our proposed clustering paradigm has several advantages. Instead of packing the information of a document into a fixed-length vector for subsequent analysis, we treat a document more thoroughly as a distributional entity. In our approach, the distance between two empirical

nonparametric measures (or discrete distributions) over the word embedding space is defined as the Wasserstein metric (a.k.a. the Earth Mover's Distance or EMD) (Wan, 2007; Kusner et al., 2015). Comparing with a vector representation, an empirical distribution can represent with higher fidelity a cloud of points such as words in a document mapped to a certain space. In the extreme case, the empirical distribution can be set directly as the cloud of points. In contrast, a vector representation reduces data significantly, and its effectiveness relies on the assumption that the discarded information is irrelevant or nonessential to later analysis. This simplification itself can cause degradation in performance, obscuring the inherent power of the word embedding space.

Our approach is intuitive and robust. In addition to a high fidelity representation of the data, the Wasserstein distance takes into account the cross-term relationship between different words in a *principled* fashion. According to the definition, the distance between two documents A and B are the minimum cumulative cost that words from document A need to "travel" to match exactly the set of words for document B. Here, the travel cost of a path between two words is their (squared) Euclidean distance in the word embedding space. Therefore, how much benefit the Wasserstein distance brings also depends on how well the word embedding space captures the semantic difference between words.

While Wasserstein distance is well suited for document analysis, a major obstacle of approaches based on this distance is the computational intensity, especially for the original D2-clustering method (Li and Wang, 2008). The main technical hurdle is to compute efficiently the Wasserstein barycenter, which is itself a discrete distribution, for a given set of discrete distributions. Thanks to the recent advances in the algorithms for solving Wasserstein barycenters (Cuturi and Doucet, 2014; Ye and Li, 2014; Benamou et al., 2015; Ye et al., 2017), one can now perform document clustering by directly treating them as empirical measures over a word embedding space. Although the computational cost is still higher than the usual vector-based clustering methods, we believe that the new clustering approach has reached a level of efficiency to justify its usage given how important it is to obtain high-quality clustering of unstructured text data. For instance, clustering is a crucial step performed ahead of cross-document co-reference resolution (Singh et al., 2011), document summarization, retrospective events detection, and opinion mining (Zhai et al., 2011).

1.1 Contributions

Our work has two main contributions. First, we create a basic tool of document clustering, which is easy to use and scalable. The new method leverages the latest numerical toolbox developed for optimal transport. It achieves state-of-the-art clustering performance across heterogeneous text data—an advantage over other methods in the literature. Second, the method enables us to quantitatively inspect how well a word-embedding model can fit the data and how much gain it can produce over the bag-of-words models.

2 Related Work

In the original D2-clustering framework proposed by Li and Wang (2008), calculating Wasserstein barycenter involves solving a large-scale LP problem at each inner iteration, severely limiting the scalability and robustness of the framework. Such high magnitude of computations had prohibited it from deploying in many real-world applications until recently. To accelerate the computation of Wasserstein barycenter, and ultimately to improve D2-clustering, multiple numerical algorithmic efforts have been made in the recent few years (Cuturi and Doucet, 2014; Ye and Li, 2014; Benamou et al., 2015; Ye et al., 2017).

Although the effectiveness of Wasserstein distance has been well recognized in the computer vision and multimedia literature, the property of Wasserstein barycenter has not been well understood. To our knowledge, there still lacks systematic study of applying Wasserstein barycenter and D2-clustering in document analysis with word embeddings.

A closely related work by Kusner et al. (2015) connects the Wasserstein distance to the word embeddings for comparing documents. Our work differs from theirs in the methodology. We directly pursue a scalable clustering setting rather than construct a nearest neighbor graph based on calculated distances, because the calculation of the Wasserstein distances of all pairs is too expensive to be practical. Kusner et al. (2015) used a lower bound that was less costly to compute in order to prune unnecessary full distance calculation, but

the scalability of this modified approach is still limited, an issue to be discussed in Section 4.3. On the other hand, our approach adopts the framework similar to the K-means which is of complexity $O(n)$ per iteration and usually converges within just tens of iterations. The computation of D2-clustering, though in its original form was magnitudes heavier than typical document clustering methods, can now be efficiently carried out with parallelization and proper implementations (Ye et al., 2017).

3 The Method

This section introduces the distance, the D2-clustering technique, the fast computation framework, and how they are used in the proposed document clustering method.

3.1 Wasserstein Distance

Suppose we represent each document d_k consisting m_k unique words by a discrete measure or a discrete distribution, where $k = 1, \ldots, N$ with N being the sample size:

$$d_k = \sum_{i=1}^{m_k} w_i^{(k)} \delta_{x_i^{(k)}} \ . \tag{1}$$

Here δ_x denotes the Dirac measure with support x, and $w_i^{(k)} \geq 0$ is the "importance weight" for the i-th word in the k-th document, with $\sum_{i=1}^{m_k} w_i^{(k)} = 1$. And $x_i^{(k)} \in \mathbb{R}^d$, called a support point, is the semantic embedding vector of the i-th word. The 2nd-order Wasserstein distance between two documents d_1 and d_2 (and likewise for any document pairs) is defined by the following LP problem: $W^2(d_1, d_2) :=$

$$\begin{aligned} \min_{\Pi} \quad & \textstyle\sum_{i,j} \pi_{i,j} \|x_i^{(1)} - x_j^{(2)}\|_2^2 \\ \text{s.t.} \quad & \textstyle\sum_{j=1}^{m_2} \pi_{i,j} = w_i, \forall i, \quad \sum_{i=1}^{m_1} \pi_{i,j} = w_j, \forall j \\ & \pi_{i,j} \geq 0, \forall i, j \ , \end{aligned} \tag{2}$$

where $\Pi = \{\pi_{i,j}\}$ is a $m_1 \times m_2$ coupling matrix, and let $\{C_{i,j} := \|x_i^{(1)} - x_j^{(2)}\|_2^2\}$ be transportation costs between words. Wasserstein distance is a true metric (Villani, 2003) for measures, and its best exact algorithm has a complexity of $O(m^3 \log m)$ (Orlin, 1993), if $m_1 = m_2 = m$.

3.2 Discrete Distribution (D2-) Clustering

D2-clustering (Li and Wang, 2008) iterates between the assignment step and centroids updating step in a similar way as the Lloyd's K-means. Suppose we are to find K clusters. The assignment step finds each member distribution its nearest mean from K candidates. The mean of each cluster is again a discrete distribution with m support points, denoted by c_i, $i = 1, \ldots, K$. Each mean is iteratively updated to minimize its total within cluster variation. We can write the D2-clustering problem as follows: given sample data $\{d_k\}_{k=1}^N$, support size of means m, and desired number of clusters K, D2-clustering solves

$$\min_{c_1, \ldots, c_K} \sum_{k=1}^{N} \min_{1 \leq i \leq K} W^2(d_k, c_i) \ , \tag{3}$$

where $c_1, \ldots, c_K$ are Wasserstein barycenters. At the core of solving the above formulation is an optimization method that searches the Wasserstein barycenters of varying partitions. Therefore, we concentrate on the following problem. For each cluster, we reorganize the index of member distributions from $1, \ldots, n$. The Wasserstein barycenter (Agueh and Carlier, 2011; Cuturi and Doucet, 2014) is by definition the solution of

$$\min_{c} \sum_{k=1}^{n} W^2(d_k, c) \ , \tag{4}$$

where $c = \sum_{i=1}^{m} w_i \delta_{x_i}$. The above Wasserstein barycenter formulation involves two levels of optimization: the outer level finding the minimizer of total variations, and the inner level solving Wasserstein distances. We remark that in D2-clustering, we need to solve multiple Wasserstein barycenters rather than a single one. This constitutes the third level of optimization.

3.3 Modified Bregman ADMM for Computing Wasserstein Barycenter

The recent modified Bregman alternating direction method of multiplier (B-ADMM) algorithm (Ye et al., 2017), motivated by the work by Wang and Banerjee (2014), is a practical choice for computing Wasserstein barycenters. We briefly sketch their algorithmic procedure of this optimization method here for the sake of completeness. To solve for Wasserstein barycenter defined in Eq. (4), the key procedure of the modified Bregman ADMM involves iterative updates of four block of primal variables: the support points of c — $\{x_i\}_{i=1}^m$ (with transportation costs $\{C_{i,j}\}^{(k)}$ for $k = 1, \ldots, n$), the importance weights of c — $\{w_i\}_{i=1}^m$, and two sets of split matching variables — $\{\pi_{i,j}^{(k,1)}\}$ and $\{\pi_{i,j}^{(k,2)}\}$, for $k = 1, \ldots, n$, as well as Lagrangian variables $\{\lambda_{i,j}^{(k)}\}$ for $k = 1, \ldots, n$.

In the end, both $\{\pi_{i,j}^{(k,1)}\}$ and $\{\pi_{i,j}^{(k,2)}\}$ converge to the matching weight in Eq. (2) with respect to $d(c, d_k)$. The iterative algorithm proceeds as follows until c converges or a maximum number of iterations are reached: given constant $\tau \geq 10$, $\rho \propto \frac{\sum_{i,j,k} C_{i,j}^{(k)}}{\sum_{k=1}^{n} m_k m}$ and round-off tolerance $\epsilon = 10^{-10}$, those variables are updated in the following order.

Update $\{x_i\}_{i=1}^{m}$ **and** $\{C_{i,j}^{(k)}\}$ in every τ iterations:

$$x_i := \frac{1}{n w_i} \sum_{k=1}^{n} \sum_{j=1}^{m_k} \pi_{i,j}^{(k,1)} x_j^{(k)}, \forall i, \quad (5)$$

$$C_{i,j}^{(k)} := \|x_i - x_j^{(k)}\|_2^2, \quad \forall i, j \text{ and } k. \quad (6)$$

Update $\{\pi_{i,j}^{(k,1)}\}$ **and** $\{\pi_{i,j}^{(k,2)}\}$. For each i, j and k,

$$\pi_{i,j}^{(k,2)} := \pi_{i,j}^{(k,2)} \exp\left(\frac{-C_{i,j}^{(k)} - \lambda_{i,j}^{(k)}}{\rho}\right) + \epsilon\,, \quad (7)$$

$$\pi_{i,j}^{(k,1)} := w_j^{(k)} \pi_{i,j}^{(k,2)} \Big/ \left(\sum_{l=1}^{m} \pi_{l,j}^{(k,2)}\right), \quad (8)$$

$$\pi_{i,j}^{(k,1)} := \pi_{i,j}^{(k,1)} \exp\left(\lambda_{i,j}^{(k)}/\rho\right) + \epsilon\,. \quad (9)$$

Update $\{w_i\}_{i=1}^{m}$. For $i = 1, \ldots, m$,

$$w_i := \sum_{k=1}^{n} \frac{\sum_{j=1}^{m_k} \pi_{i,j}^{(k,1)}}{\sum_{i,j} \pi_{i,j}^{(k,1)}}, \quad (10)$$

$$w_i := w_i \Big/ \left(\sum_{i=1}^{m} w_i\right). \quad (11)$$

Update $\{\pi_{i,j}^{(k,2)}\}$ **and** $\{\lambda_{i,j}^{(k)}\}$. For each i, j and k,

$$\pi_{i,j}^{(k,2)} := w_i \pi_{i,j}^{(k,1)} \Big/ \left(\sum_{l=1}^{m_k} \pi_{i,l}^{(k,1)}\right), \quad (12)$$

$$\lambda_{i,j}^{(k)} := \lambda_{i,j}^{(k)} + \rho\left(\pi_{i,l}^{(k,1)} - \pi_{i,l}^{(k,2)}\right). \quad (13)$$

Eq. (5)-(13) can all be vectorized as very efficient numerical routines. In a data parallel implementation, only Eq. (5) and Eq. (10) (involving $\sum_{k=1}^{n}$) needs to be synchronized. The software package detailed in (Ye et al., 2017) was used to generate relevant experiments. We make available our codes and pre-processed datasets for reproducing all experiments of our approach.

4 Experimental Results

4.1 Datasets and Evaluation Metrics

We prepare six datasets to conduct a set of experiments. Two short-text datasets are created as follows. (D1) BBCNews abstract: We concatenate the title and the first sentence of news posts from BBCNews dataset[1] to create an abstract version. (D2) Wiki events: Each cluster/class contains a set of news abstracts on the same story such as "2014 Crimean Crisis" crawled from Wikipedia current events following (Wu et al., 2015); this dataset offers more challenges because it has more fine-grained classes and fewer documents (with shorter length) per class than the others. It also shows more realistic nature of applications such as news event clustering.

We also experiment with two long-text datasets and two domain-specific text datasets. (D3) Reuters-21578: We obtain the original Reuters-21578 text dataset and process as follows: remove documents with multiple categories, remove documents with empty body, remove duplicates, and select documents from the largest ten categories. Reuters dataset is a highly unbalanced dataset (the top category has more than 3,000 documents while the 10-th category has fewer than 100). This imbalance induces some extra randomness in comparing the results. (D4) 20Newsgroups "bydate" version: We obtain the raw "bydate" version and process them as follows: remove headers and footers, remove URLs and Email addresses, delete documents with less than ten words. 20Newsgroups have roughly comparable sizes of categories. (D5) BBCSports. (D6) Ohsumed and Ohsumed-full: Documents are medical abstracts from the MeSH categories of the year 1991. Specifically, there are 23 cardiovascular diseases categories.

Evaluating clustering results is known to be nontrivial. We use the following three sets of quantitative metrics to assess the quality of clusters by knowing the ground truth categorical labels of documents: (i) Homogeneity, Completeness, and V-measure (Rosenberg and Hirschberg, 2007); (ii) Adjusted Mutual Information (AMI) (Vinh et al., 2010); and (iii) Adjusted Rand Index (ARI) (Rand, 1971). For sensitivity analysis, we use the homogeneity score (Rosenberg and Hirschberg, 2007) as a projection dimension of other metrics, creating a 2D plot to visualize the metrics of a method along different homogeneity levels. Generally speaking, more clusters leads to higher homogeneity by chance.

[1] BBCNews and BBCSport are downloaded from http://mlg.ucd.ie/datasets/bbc.html

4.2 Methods in Comparison

We examine four categories of methods that assume a vector-space model for documents, and compare them to our D2-clustering framework. When needed, we use K-means++ to obtain clusters from dimension reduced vectors. To diminish the randomness brought by K-mean initialization, we ensemble the clustering results of 50 repeated runs (Strehl and Ghosh, 2003), and report the metrics for the ensembled one. The largest possible vocabulary used, excluding word embedding based approaches, is composed of words appearing in at least two documents. On each dataset, we select the same set of Ks, the number of clusters, for all methods. Typically, Ks are chosen around the number of ground truth categories in logarithmic scale.

We prepare two versions of the TF-IDF vectors as the unigram model. The ensembled K-means methods are used to obtain clusters. (1) *TF-IDF* vector (Sparck Jones, 1972). (2) *TF-IDF-N* vector is found by choosing the most frequent N words in a corpus, where $N \in \{500, 1000, 1500, 2000\}$. The difference between the two methods highlights the sensitivity issue brought by the size of chosen vocabulary.

We also compare our approach with the following seven additional baselines. They are (3) *Spectral Clustering (Laplacian)*, (4) *Latent Semantic Indexing (LSI)* (Deerwester et al., 1990), (5) *Locality Preserving Projection (LPP)* (He and Niyogi, 2004; Cai et al., 2005), (6) *Non-negative Matrix Factorization (NMF)* (Lee and Seung, 1999; Xu et al., 2003), (7) *Latent Dirichlet Allocation (LDA)* (Blei et al., 2003; Hoffman et al., 2010), (8) *Average of word vectors (AvgDoc)*, and (9) *Paragraph Vectors (PV)* (Le and Mikolov, 2014). Details on their experimental setups and hyper-parameter search strategies can be found in the Appendix.

4.3 Runtime

We report the runtime for our approach on two largest datasets. The experiments regarding other smaller datasets all terminate within minutes in a single machine, which we omit due to space limitation. Like K-means, the runtime by our approach depends on the number of actual iterations before a termination criterion is met. In the Newsgroups dataset, with $m = 100$ and $K = 45$, the time per iteration is 121 seconds on 48 processors. In Reuters dataset, with $m = 100$ and $K = 20$, the time per iteration is 190 seconds on 24 processors. Each run terminates in around tens of iterations typically, upon which the percentage of label changes is less than 0.1%.

Our approach adopts the Elkan's algorithm (2003) pruning unnecessary computations of Wasserstein distance in assignment steps of K-means. For the Newsgroups data (with $m = 100$ and $K = 45$), our approach terminates in 36 iterations, and totally computes $12,162,717$ ($\approx 3.5\% \times 18612^2$) distance pairs in assignment steps, saving 60% ($\approx 1 - \frac{12,162,717}{36 \times 45 \times 18612}$) distance pairs to calculate in the standard D2-clustering. In comparison, the clustering approaches based on K-nearest neighbor (KNN) graph with the prefetch-and-prune method of (Kusner et al., 2015) needs substantially more pairs to compute Wasserstein distance, meanwhile the speed-ups also suffer from the curse of dimensionality. Their detailed statistics are reported in Table 1. Based on the results, our approach is much more practical as a basic document clustering tool.

Method		EMD counts (%)
Our approach	$d = 400, K = 10$	**2.0**
Our approach	$d = 400, K = 40$	**3.5**
KNN	$d = 400, K = 1$	73.9
KNN	$d = 100, K = 1$	53.0
KNN	$d = 50, K = 1$	23.4

Table 1: Percentage of total 18612^2 Wasserstein distance pairs needed to compute on the full Newsgroup dataset. The KNN graph based on 1st order Wasserstein distance is computed from the prefetch-and-prune approach according to (Kusner et al., 2015).

4.4 Results

We now summarize our numerical results.

Regular text datasets. The first four datasets in Table 2 cover quite general and broad topics. We consider them to be regular and representative datasets encountered more frequently in applications. We report the clustering performances of the ten methods in Fig. 1, where three different metrics are plotted against the clustering homogeneity. The higher result at the same level of homogeneity is better, and the ability to achieve higher homogeneity is also welcomed. *Clearly, D2-clustering is the only method that shows ro-*

Y-axis corresponds to AMI, ARI, and Completeness, respective (column-wise, from left to right). X-axis corresponds to Homogeneity for sensitivity analysis.

bustly superior performances among all ten methods. Specifically, it ranks first in three datasets, and second in the other one. In comparison, LDA performs competitively on the "Reuters" dataset, but is substantially unsuccessful on others. Meanwhile, LPP performs competitively on the "Wiki events" and "Newsgroups" datasets, but it underperforms on the other two. Laplacian, LSI, and Tfidf-N can achieve comparably performance if their reduced dimensions are fine tuned, which

Dataset	size	class	length	est. #voc.

unfortunately is unrealistic in practice. NMF is a simple and effective method which always gives stable, though subpar, performance.

Short texts vs. long texts. D2-clustering performs much more impressively on short texts ("BBC abstract" and "Wiki events") than it does on long texts ("Reuters" and "Newsgroups"). This outcome is somewhat expected, because the bag-of-words method suffers from high sparsity for short texts, and word-embedding based methods in theory should have an edge here. As shown in Fig. 1, D2-clustering has indeed outperformed other non-embedding approaches by a large margin on short texts (improved by about 40% and 20% respectively). Nevertheless, we find lifting from word embedding to document clustering is not without a cost. Neither AvgDoc nor PV can perform as competitively as D2-clustering performs on both.

Domain-specific text datasets. We are also interested in how word embedding can help group domain-specific texts into clusters. In particular, does the semantic knowledge "embedded" in words provides enough clues to discriminate fine-grained concepts? We report the best AMI achieved by each method in Table 3. Our preliminary result indicates state-of-the-art word embeddings do not provide enough gain here to exceed the performance of existing methodologies. On the unchallenging one, the "BBCSport" dataset, basic bag-of-words approaches (Tfidf and Tfidf-N) already suffice to discriminate different sport categories; and on the difficult one, the "Ohsumed" dataset, D2-clustering only slightly improves over Tfidf and others, ranking behind LPP. Meanwhile, we feel the overall quality of clustering "Ohsumed" texts is quite far from useful in practice, no matter which method to use. More discussions will be provided next.

4.5 Sensitivity to Word Embeddings.

We validate the robustness of D2-clustering with different word embedding models, and we also show all their results in Fig. 2. As we mentioned, the effectiveness of Wasserstein document clustering depends on how relevant the utilized word embeddings are with the tasks. In those general document clustering tasks, however, word embedding models trained on general corpus perform robustly well with acceptably small variations. This outcome reveals our framework as generally effective and not dependent on a specific word embedding model. In addition, we also conduct experiments with word embeddings with smaller dimensions, at 50 and 100. Their results are not as good as those we have reported (therefore detailed numbers are not included due to space limitation).

Inadequate embeddings may not be disastrous. In addition to our standard running set, we also used D2-clustering with purely random word embeddings, meaning each word vector is independently sampled from spherical Gaussian at 300 dimension, to see how deficient it can be. Experimental results show that random word embeddings degrade the performance of D2-clustering, but it still performs much better than purely random clustering, and is even consistently better than LDA. Its performances across different datasets is highly correlated with the bag-of-words (Tfidf and Tfidf-N). By comparing a pre-trained word embedding model to a randomly generated one, we find that the extra gain is significant ($> 10\%$) in clustering four of the six datasets. Their detailed statistics are in Table 4 and Fig. 3.

5 Discussions

Performance advantage. There has been one immediate observation from these studies, D2-clustering always outperforms two of its degenerated cases, namely Tf-idf and AvgDoc, and three other popular methods: LDA, NMF, and PV, on all tasks. Therefore, for document clustering, users can expect to gain performance improvements by using our approach.

Clustering sensitivity. From the four 2D plots in Fig. 1, we notice that the results of Laplacian,

set, weight scheme and embeddings of words are fixed, our framework involves only two additional hyper-parameters: the number of intended clusters, K, and the selected support size of centroid distributions, m. We have chosen more than one m in all related experiments ($m = \{64, 100\}$ for long documents, and $m = \{10, 20\}$ for short documents). Our empirical experiments show that the effect of m on different metrics is less

sensitive than the change of K. Results at different K are plotted for each method (Fig. 1). The gray dots denote results of multiple runs of D2-clustering. They are always contracted around the top-right region of the whole population, revealing the predictive and robustly supreme performance.

When bag-of-words suffices. Among the results of "BBCSport" dataset, Tfidf-N shows that by restricting the vocabulary set into a smaller one (which may be more relevant to the interest of tasks), it already can achieve highest clustering AMI without any other techniques. Other unsupervised regularization over data is likely unnecessary, or even degrades the performance slightly.

Toward better word embeddings. Our experiments on the Ohsumed dataset have been limited. The result shows that it could be highly desirable to incorporate certain domain knowledge to derive more effective vector embeddings of words and phrases to encode their domain-specific knowledge, such as jargons that have knowledge dependencies and hierarchies in educational data mining, and signal words that capture multi-dimensional aspects of emotions in sentiment analysis.

Finally, we report the best AMIs of all methods on all datasets in Table 3. By looking at each method and the average of best AMIs over six datasets, we find our proposed clustering framework often performs competitively and robustly, which is the only method reaching more than 90% of the best AMI on each dataset. Furthermore, this observation holds for varying lengths of documents and varying difficulty levels of clustering tasks.

6 Conclusions and Future Work

This paper introduces a nonparametric clustering framework for document analysis. Its computational tractability, robustness and supreme performance, as a fundamental tool, are empirically validated. Its ease of use enables data scientists to apply it for the pre-screening purpose of examining word embeddings in a specific task. Finally, the gains acquired from word embeddings are quantitatively measured from a nonparametric unsupervised perspective.

It would also be interesting to investigate several possible extensions to the current clustering work. One direction is to learn a proper ground distance for word embeddings such that the final document clustering performance can be improved with labeled data. The work by (Huang et al., 2016; Cuturi and Avis, 2014) have partly touched this goal with an emphasis on document proximities. A more appealing direction is to develop problem-driven methods to represent a document as a distributional entity, taking into consideration of phrases, sentence structures, and syntactical characteristics. We believe the framework of Wasserstein distance and D2-clustering creates room for further investigation on complex structures and knowledge carried by documents.

Abstract

Lexical ambiguity can impede NLP systems from accurate understanding of semantics. Despite its potential benefits, the integration of sense-level information into NLP systems has remained understudied. By incorporating a novel disambiguation algorithm into a state-of-the-art classification model, we create a pipeline to integrate sense-level information into downstream NLP applications. We show that a simple disambiguation of the input text can lead to consistent performance improvement on multiple topic categorization and polarity detection datasets, particularly when the fine granularity of the underlying sense inventory is reduced and the document is sufficiently large. Our results also point to the need for sense representation research to focus more on *in vivo* evaluations which target the performance in downstream NLP applications rather than artificial benchmarks.

1 Introduction

As a general trend, most current Natural Language Processing (NLP) systems function at the word level, i.e. individual words constitute the most fine-grained meaning-bearing elements of their input. The word level functionality can affect the performance of these systems in two ways: (1) it can hamper their efficiency in handling words that are not encountered frequently during training, such as multiwords, inflections and derivations, and (2) it can restrict their semantic understanding to the level of words, with all their ambiguities, and thereby prevent accurate capture of the intended meanings.

The first issue has recently been alleviated by techniques that aim to boost the generalisation power of NLP systems by resorting to sub-word or character-level information (Ballesteros et al., 2015; Kim et al., 2016). The second limitation, however, has not yet been studied sufficiently. A reasonable way to handle word ambiguity, and hence to tackle the second issue, is to *semantify* the input text: transform it from its surface-level semantics to the deeper level of word senses, i.e. their intended meanings. We take a step in this direction by designing a pipeline that enables seamless integration of word senses into downstream NLP applications, while benefiting from knowledge extracted from semantic networks. To this end, we propose a quick graph-based Word Sense Disambiguation (WSD) algorithm which allows high confidence disambiguation of words without much computation overload on the system. We evaluate the pipeline in two downstream NLP applications: polarity detection and topic categorization. Specifically, we use a classification model based on Convolutional Neural Networks which has been shown to be very effective in various text classification tasks (Kalchbrenner et al., 2014; Kim, 2014; Johnson and Zhang, 2015; Tang et al., 2015; Xiao and Cho, 2016). We show that a simple disambiguation of input can lead to performance improvement of a state-of-the-art text classification system on multiple datasets, particularly for long inputs and when the granularity of the sense inventory is reduced. Our pipeline is quite flexible and modular, as it permits the integration of different WSD and sense representation techniques.

2 Motivation

With the help of an example news article from the BBC, shown in Figure 1, we highlight some of the potential deficiencies of word-based models.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1857–1869
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1170

Lewis Hamilton is heading to his fourth **F1** drivers' title after **German GP** win

The **German Grand Prix** was the last **race** before **Formula 1** heads off for its four-week summer break, so it was fitting that it consolidated the two overriding trends that have emerged so far this year.

[...]

Hockenheim was **Hamilton**'s sixth win in seven races, a remarkable run that has seen a 62-point swing between himself and **Mercedes** team-mate **Nico Rosberg**, turning a 43-point deficit into a 19-point lead.

Figure 1: Excerpt of a news article from the BBC.

Algorithm 1 Disambiguation algorithm

Input: Input text T and semantic network N
Output: Set of disambiguated senses $\hat{S}$

Graph representation of T: $(S, E) \leftarrow \text{getGraph}(T, N)$
$\hat{S} \leftarrow \emptyset$
for each iteration $i \in \{1, ..., len(T)\}$
  $\hat{s} = \text{argmax}_{s \in S} |\{(s, s') \in E : s' \in S\}|$
  $\text{maxDeg} = |\{(\hat{s}, s') \in E : s' \in S\}|$
  if $\text{maxDeg} < \theta |S| \ / \ 100$ **then**
    break
  else
    $\hat{S} \leftarrow \hat{S} \cup \{\hat{s}\}$
    $E \leftarrow E \setminus \{(s, s') : s \vee s' \in \text{getLex}(\hat{s})\}$
return Disambiguation output $\hat{S}$

Ambiguity. Language is inherently ambiguous. For instance, *Mercedes*, *race*, *Hamilton* and *Formula* can refer to several different entities or meanings. Current neural models have managed to successfully represent complex semantic associations by effectively analyzing large amounts of data. However, the word-level functionality of these systems is still a barrier to the depth of their natural language understanding. Our proposal is particularly tailored towards addressing this issue.

Multiword expressions (MWE). MWE are lexical units made up of two or more words which are idiosyncratic in nature (Sag et al., 2002), e.g, *Lewis Hamilton*, *Nico Rosberg* and *Formula 1*. Most existing word-based models ignore the interdependency between MWE's subunits and treat them as individual units. Handling MWE has been a long-standing problem in NLP and has recently received a considerable amount of interest (Tsvetkov and Wintner, 2014; Salehi et al., 2015). Our pipeline facilitates this goal.

Co-reference. Co-reference resolution of concepts and entities is not explicitly tackled by our approach. However, thanks to the fact that words that refer to the same meaning in context, e.g., *Formula 1-F1* or *German Grand Prix-German GP-Hockenheim*, are all disambiguated to the same concept, the co-reference issue is also partly addressed by our pipeline.

3 Disambiguation Algorithm

Our proposal relies on a seamless integration of word senses in word-based systems. The goal is to semantify the text prior to its being fed into the system by transforming its individual units from word surface form to the deeper level of word senses. The semantification step is mainly tailored towards resolving ambiguities, but it brings about other advantages mentioned in the previous section. The aim is to provide the system with an input of reduced ambiguity which can facilitate its decision making.

To this end, we developed a simple graph-based joint disambiguation and entity linking algorithm which can take any arbitrary semantic network as input. The gist of our disambiguation technique lies in its speed and scalability. Conventional knowledge-based disambiguation systems (Hoffart et al., 2012; Agirre et al., 2014; Moro et al., 2014; Ling et al., 2015; Pilehvar and Navigli, 2014) often rely on computationally expensive graph algorithms, which limits their application to on-the-fly processing of large number of text documents, as is the case in our experiments. Moreover, unlike supervised WSD and entity linking techniques (Zhong and Ng, 2010; Cheng and Roth, 2013; Melamud et al., 2016; Limsopatham and Collier, 2016), our algorithm relies only on semantic networks and does not require any sense-annotated data, which is limited to English and almost non-existent for other languages.

Algorithm 1 shows our procedure for disambiguating an input document T. First, we retrieve from our semantic network the list of candidate senses[1] for each content word, as well as semantic relationships among them. As a result, we obtain a graph representation (S, E) of the input text, where S is the set of candidate senses and E is the set of edges among different senses in S. The graph is, in fact, a small sub-graph of the input semantic network, N. Our algorithm then selects the best candidates iteratively. In each iteration, the

[1] As defined in the underlying sense inventory, up to trigrams. We used Stanford CoreNLP (Manning et al., 2014) for tokenization, Part-of-Speech (PoS) tagging and lemmatization.

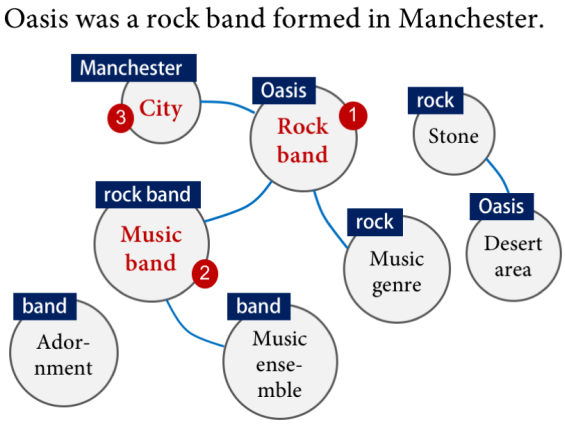

Figure 2: Simplified graph-based representation of a sample sentence.

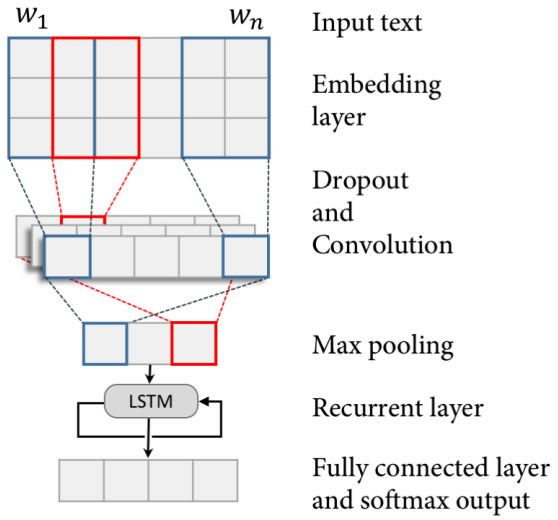

Figure 3: Text classification model architecture.

candidate sense that has the highest graph degree maxDeg is chosen as the winning sense:

$$\text{maxDeg} = \max_{s \in S} |\{(s, s') \in E : s' \in S\}| \quad (1)$$

After each iteration, when a candidate sense $\hat{s}$ is selected, all the possible candidate senses of the corresponding word (i.e. $\text{getLex}(\hat{s})$) are removed from E (line 10 in the algorithm).

Figure 2 shows a simplified version of the graph for a sample sentence. The algorithm would disambiguate the content words in this sentence as follows. It first associates *Oasis* with its *rock band* sense, since its corresponding node has the highest degree, i.e. 3. On the basis of this, the *desert* sense of *Oasis* and its link to the *stone* sense of *rock* are removed from the graph. In the second iteration, *rock band* is disambiguated as *music band* given that its degree is 2.[2] Finally, *Manchester* is associated with its *city* sense (with a degree of 1).

In order to enable disambiguating at different confidence levels, we introduce a threshold θ which determines the stopping criterion of the algorithm. Iteration continues until the following condition is fulfilled: $\text{maxDeg} < \theta|S| \,/\, 100$. This ensures that the system will only disambiguate those words for which it has a high confidence and backs off to the word form otherwise, avoiding the introduction of unwanted noise in the data for uncertain cases or for word senses that are not defined in the inventory.

[2]For bigrams and trigrams whose individual words might also be disambiguated (such as *rock* and *band* in *rock band*), the longest unit has the highest priority (i.e. *rock band*).

4 Classification Model

In our experiments, we use a standard neural network based classification approach which is similar to the Convolution Neural Network classifier of Kim (2014) and the pioneering model of Collobert et al. (2011). Figure 3 depicts the architecture of the model. The network receives the concatenated vector representations of the input words, $\mathbf{v}_{1:n} = \mathbf{v}_1 \oplus \mathbf{v}_2 \oplus \cdots \oplus \mathbf{v}_n$, and applies (convolves) filters F on windows of h words, $m_i = f(\text{F}.\mathbf{v}_{i:i+h-1} + b)$, where b is a bias term and $f()$ is a non-linear function, for which we use ReLU (Nair and Hinton, 2010). The convolution transforms the input text to a feature map $m = [m_1, m_2, \ldots, m_{n-h+1}]$. A max pooling operation then selects the most salient feature $\hat{m} = \max\{m\}$ for each filter.

In the network of Kim (2014), the pooled features are directly passed to a fully connected softmax layer whose outputs are class probabilities. However, we add a recurrent layer before softmax in order to enable better capturing of long-distance dependencies. It has been shown by Xiao and Cho (2016) that a recurrent layer can replace multiple layers of convolution and be beneficial, particularly when the length of input text grows. Specifically, we use a Long Short-Term Memory (Hochreiter and Schmidhuber, 1997, LSTM) as our recurrent layer which was originally proposed to avoid the vanishing gradient problem and has proven its abilities in capturing distant dependencies. The LSTM unit computes three gate vectors

(forget, input, and output) as follows:

$$\begin{aligned}\mathbf{f}_t &= \sigma(\mathbf{W}_f\ g_t + \mathbf{U}_f\ h_{t-1} + \mathbf{b}_f),\\ \mathbf{i}_t &= \sigma(\mathbf{W}_i\ g_t + \mathbf{U}_i\ h_{t-1} + \mathbf{b}_i),\\ \mathbf{o}_t &= \sigma(\mathbf{W}_o\ g_t + \mathbf{U}_o\ h_{t-1} + \mathbf{b}_o),\end{aligned} \quad (2)$$

where $\mathbf{W}$, $\mathbf{U}$, and $\mathbf{b}$ are model parameters and g and h are input and output sequences, respectively. The cell state vector $\mathbf{c}_t$ is then computed as $\mathbf{c}_t = \mathbf{f}_t\ \mathbf{c}_{t-1} + \mathbf{i}_t\ \tanh(\tilde{\mathbf{c}}_t)$ where $\tilde{c}_t = \mathbf{W}_c\ g_t + \mathbf{U}_c\ h_{t-1}$. Finally, the output sequence is computed as $h_t = \mathbf{o}_t\ \tanh(\mathbf{c}_t)$. As for regularization, we used dropout (Hinton et al., 2012) after the embedding layer.

We perform experiments with two configurations of the embedding layer: (1) *Random*, initialized randomly and updated during training, and (2) *Pre-trained*, initialized by pre-trained representations and updated during training. In the following section we describe the pre-trained word and sense representation used for the initialization of the second configuration.

4.1 Pre-trained Word and Sense Embeddings

One of the main advantages of neural models is that they usually represent the input words as dense vectors. This can significantly boost a system's generalisation power and results in improved performance (Zou et al., 2013; Bordes et al., 2014; Kim, 2014; Weiss et al., 2015, *inter-alia*). This feature also enables us to directly plug in pre-trained sense representations and check them in a downstream application.

In our experiments we generate a set of sense embeddings by extending DeConf, a recent technique with state-of-the-art performance on multiple semantic similarity benchmarks (Pilehvar and Collier, 2016). We leave the evaluation of other representations to future work. DeConf gets a pre-trained set of word embeddings and computes sense embeddings in the same semantic space. To this end, the approach exploits the semantic network of WordNet (Miller, 1995), using the Personalized PageRank (Haveliwala, 2002) algorithm, and obtains a set of *sense biasing words* $\mathcal{B}_s$ for a word sense s. The sense representation of s is then obtained using the following formula:

$$\hat{\mathbf{v}}(s) = \frac{1}{|\mathcal{B}_s|}\sum_{i=1}^{|\mathcal{B}_s|} \mathrm{e}^{\frac{-i}{\delta}}\mathbf{v}(w_i), \quad (3)$$

where δ is a decay parameter and $\mathbf{v}(w_i)$ is the embedding of w_i, i.e. the i^{th} word in the sense biasing list of s, i.e. $\mathcal{B}_s$. We follow Pilehvar and Collier (2016) and set $\delta = 5$. Finally, the vector for sense s is calculated as the average of $\hat{\mathbf{v}}(s)$ and the embedding of its corresponding word.

Owing to its reliance on WordNet's semantic network, DeConf is limited to generating only those word senses that are covered by this lexical resource. We propose to use Wikipedia in order to expand the vocabulary of the computed word senses. Wikipedia provides a high coverage of named entities and domain-specific terms in many languages, while at the same time also benefiting from a continuous update by collaborators. Moreover, it can easily be viewed as a sense inventory where individual articles are word senses arranged through hyperlinks and redirections.

Camacho-Collados et al. (2016b) proposed NASARI[3], a technique to compute the most salient words for each Wikipedia page. These salient words were computed by exploiting the structure and content of Wikipedia and proved effective in tasks such as Word Sense Disambiguation (Tripodi and Pelillo, 2017; Camacho-Collados et al., 2016a), knowledge-base construction (Lieto et al., 2016), domain-adapted hypernym discovery (Espinosa-Anke et al., 2016; Camacho-Collados and Navigli, 2017) or object recognition (Young et al., 2016). We view these lists as *biasing words* for individual Wikipedia pages, and then leverage the exponential decay function (Equation 3) to compute new sense embeddings in the same semantic space. In order to represent both WordNet and Wikipedia sense representations in the same space, we rely on the WordNet-Wikipedia mapping provided by BabelNet[4] (Navigli and Ponzetto, 2012). For the WordNet synsets which are mapped to Wikipedia pages in BabelNet, we average the corresponding Wikipedia-based and WordNet-based sense embeddings.

4.2 Pre-trained Supersense Embeddings

It has been argued that WordNet sense distinctions are too fine-grained for many NLP applications (Hovy et al., 2013). The issue can be tackled by grouping together similar senses of the same word, either using automatic clustering techniques (Navigli, 2006; Agirre and Lopez, 2003; Snow et al., 2007) or with the help of WordNet's lexicographer

[3]We downloaded the salient words for Wikipedia pages (NASARI English lexical vectors, version 3.0) from http://lcl.uniroma1.it/nasari/

[4]We used the Java API from http://babelnet.org

files[5]. Various applications have been shown to improve upon moving from senses to supersenses (Rüd et al., 2011; Severyn et al., 2013; Flekova and Gurevych, 2016). In WordNet's lexicographer files there are a total of 44 sense clusters, referred to as supersenses, for categories such as *event*, *animal*, and *quantity*. In our experiments we use these supersenses in order to reduce granularity of our WordNet and Wikipedia senses. To generate supersense embeddings, we simply average the embeddings of senses in the corresponding cluster.

5 Evaluation

We evaluated our model on two classification tasks: topic categorization (Section 5.2) and polarity detection (Section 5.3). In the following section we present the common experimental setup.

5.1 Experimental setup

Classification model. Throughout all the experiments we used the classification model described in Section 4. The general architecture of the model was the same for both tasks, with slight variations in hyperparameters given the different natures of the tasks, following the values suggested by Kim (2014) and Xiao and Cho (2016) for the two tasks. Hyperparameters were fixed across all configurations in the corresponding tasks. The embedding layer was fixed to 300 dimensions, irrespective of the configuration, i.e. Random and Pre-trained. For both tasks the evaluation was carried out by 10-fold cross-validation unless standard training-testing splits were available. The disambiguation threshold θ (cf. Section 3) was tuned on the training portion of the corresponding data, over seven values in [0,3] in steps of 0.5.[6] We used Keras (Chollet, 2015) and Theano (Team, 2016) for our model implementations.

Semantic network. The integration of senses was carried out as described in Section 3. For disambiguating with both WordNet and Wikipedia senses we relied on the joint semantic network of Wikipedia hyperlinks and WordNet via the mapping provided by BabelNet.[7]

Pre-trained word and sense embeddings. Throughout all the experiments we used Word2vec (Mikolov et al., 2013) embeddings, trained on the Google News corpus.[8] We truncated this set to its 250K most frequent words. We also used WordNet 3.0 (Fellbaum, 1998) and the Wikipedia dump of November 2014 to compute the sense embeddings (see Section 4.1). As a result, we obtained a set of 757,262 sense embeddings in the same space as the pre-trained Word2vec word embeddings. We used DeConf (Pilehvar and Collier, 2016) as our pre-trained WordNet sense embeddings. All vectors had a fixed dimensionality of 300.

Supersenses. In addition to WordNet senses, we experimented with supersenses (see Section 4.2) to check how reducing granularity would affect system performance. For obtaining supersenses in a given text we relied on our disambiguation pipeline and simply clustered together senses belonging to the same WordNet supersense.

Evaluation measures. We report the results in terms of standard accuracy and F1 measures.[9]

5.2 Topic Categorization

The task of topic categorization consists of assigning a label (i.e. topic) to a given document from a pre-defined set of labels.

5.2.1 Datasets

For this task we used two newswire and one medical topic categorization datasets. Table 1 summarizes the statistics of each dataset.[10] The **BBC news** dataset[11] (Greene and Cunningham, 2006) comprises news articles taken from BBC, divided into five topics: business, entertainment, politics, sport and tech. **Newsgroups** (Lang, 1995) is a collection of 11,314 documents for training and 7532 for testing[12] divided into six topics: computing, sport and motor vehicles, science, politics, reli-

[5] https://wordnet.princeton.edu/man/lexnames.5WN.html

[6] We observed that values higher than 3 led to very few disambiguations. While the best results were generally achieved in the [1.5,2.5] range, performance differences across threshold values were not statistically significant in most cases.

[7] For simplicity we refer to this joint sense inventory as Wikipedia, but note that WordNet senses are also covered.

[8] https://code.google.com/archive/p/word2vec/

[9] Since all models in our experiments provide full coverage, accuracy and F1 denote micro- and macro-averaged F1, respectively (Yang, 1999).

[10] The coverage of the datasets was computed using the 250K top words in the Google News Word2vec embeddings.

[11] http://mlg.ucd.ie/datasets/bbc.html

[12] We used the train-test partition available at http://qwone.com/~jason/20Newsgroups/

Dataset	Domain	No. of classes	No. of docs	Avg. doc. size	Size of vocab.	Coverage	Evaluation
BBC	News	5	2,225	439.5	35,628	87.4%	10 cross valid.

gion and sales.[13] Finally, **Ohsumed**[14] is a collection of medical abstracts from MEDLINE, an online medical information database, categorized according to 23 cardiovascular diseases. For our experiments we used the partition split of 10,433 documents for training and 12,733 for testing.[15]

5.2.2 Results

Table 2 shows the results of our classification model and its variants on the three datasets.[16] When the embedding layer is initialized randomly, the model integrated with word senses consistently improves over the word-based model, particularly when the fine-granularity of the underlying sense inventory is reduced using supersenses (with statistically significant gains on the three datasets). This highlights the fact that a simple disambiguation of the input can bring about performance gain for a state-of-the-art classification system. Also, the better performance of supersenses suggests that the sense distinctions of WordNet are too fine-grained for the topic categorization task. However, when pre-trained representations are used to initialize the embedding layer, no improvement is observed over the word-based model. This can be attributed to the quality of the representations, as the model utilizing them was unable to benefit from the advantage offered by sense distinctions. Our results suggest that research in sense representation should put special emphasis on real-world evaluations on benchmarks for downstream applications, rather than on artificial tasks such as word similarity. In fact, research has previously shown that word similarity might not constitute a reliable proxy to measure the performance of word embeddings in downstream applications (Tsvetkov et al., 2015; Chiu et al., 2016).

Among the three datasets, Ohsumed proves to be the most challenging one, mainly for its larger number of classes (i.e. 23) and its domain-specific nature (i.e. medicine). Interestingly, unlike for the other two datasets, the introduction of pre-trained word embeddings to the system results in reduced performance on Ohsumed. This suggests that general domain embeddings might not be beneficial

[13] The dataset has 20 fine-grained categories clustered into six general topics. We used the coarse-grained labels for their clearer distinction and consistency with BBC topics.

[14] ftp://medir.ohsu.edu/pub/ohsumed

[15] http://disi.unitn.it/moschitti/corpora.htm

[16] Symbols * and † indicate the sense-based model with the smallest margin to the word-based model whose accuracy is statistically significant at 0.95 confidence level according to unpaired t-test (* for positive and † for negative change).

in specialized domains, which corroborates previous findings by Yadav et al. (2017) on a different task, i.e. entity extraction. This performance drop may also be due to diachronic issues (Ohsumed dates back to the 1980s) and low coverage: the pre-trained Word2vec embeddings cover 79.3% of the words in Ohsumed (see Table 1), in contrast to the higher coverage on the newswire datasets, i.e. Newsgroups (83.4%) and BBC (87.4%). However, also note that the best overall performance is attained when our pre-trained Wikipedia sense embeddings are used. This highlights the effectiveness of Wikipedia in handling domain-specific entities, thanks to its broad sense inventory.

5.3 Polarity Detection

Polarity detection is the most popular evaluation framework for sentiment analysis (Dong et al., 2015). The task is essentially a binary classification which determines if the sentiment of a given sentence or document is negative or positive.

5.3.1 Datasets

For the polarity detection task we used five standard evaluation datasets. Table 1 summarizes statistics. **PL04** (Pang and Lee, 2004) is a polarity detection dataset composed of full movie reviews. **PL05**[18] (Pang and Lee, 2005), instead, is composed of short snippets from movie reviews. **RTC** contains critic reviews from Rotten Tomatoes[19], divided into 436,000 training and 2,000 test instances. **IMDB** (Maas et al., 2011) includes 50,000 movie reviews, split evenly between training and test. Finally, we used the **Stanford** Sentiment dataset (Socher et al., 2013), which associates each review with a value that denotes its sentiment. To be consistent with the binary classification of the other datasets, we removed the neutral phrases according to the dataset's scale (between 0.4 and 0.6) and considered the reviews whose values were below 0.4 as negative and above 0.6 as positive. This resulted in a binary polarity dataset of 119,783 phrases. Unlike the previous four datasets, this dataset does not contain an even distribution of positive and negative labels.

5.3.2 Results

Table 4 lists accuracy performance of our classification model and all its variants on five polarity detection datasets. Results are generally better than those of Kim (2014), showing that the addition of the recurrent layer to the model (cf. Section 4) was beneficial. However, interestingly, no consistent performance gain is observed in the polarity detection task, when the model is provided with disambiguated input, particularly for datasets with relatively short reviews. We attribute this to the nature of the task. Firstly, given that words rarely happen to be ambiguous with respect to their sentiment, the semantic sense distinctions provided by the disambiguation stage do not assist the classifier in better decision making, and instead introduce data sparsity. Secondly, since the datasets mostly contain short texts, e.g., sentences or snippets, the disambiguation algorithm does not have sufficient context to make high-confidence judgements, resulting in fewer disambiguations or less reliable ones. In the following section we perform a more in-depth analysis of the impact of document size on the performance of our sense-based models.

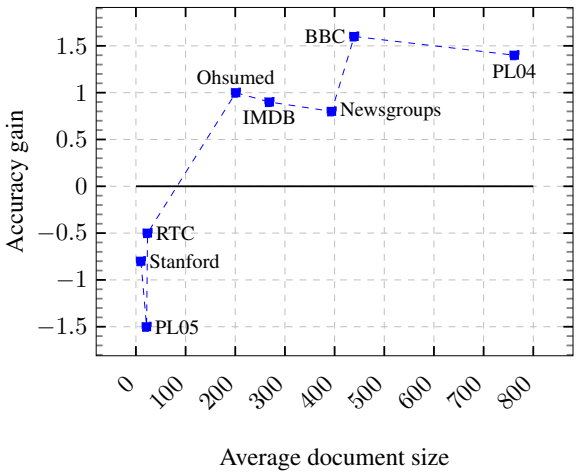

Figure 4: Relation between average document size and performance improvement using Wikipedia supersenses with random initialization.

5.4 Analysis

Document size. A detailed analysis revealed a relation between document size (the number of tokens) and performance gain of our sense-level model. We show in Figure 4 how these two vary for our most consistent configuration, i.e. Wikipedia supersenses, with random initialization. Interestingly, as a general trend, the performance gain increases with average document size, irre-

[18] Both PL04 and PL05 were downloaded from http://www.cs.cornell.edu/people/pabo/movie-review-data/

[19] http://www.rottentomatoes.com

[19] Stanford is the only unbalanced dataset, but F1 results were almost identical to accuracy.

Dataset	Type	No. of docs	Avg. doc. size	Vocabulary size	Coverage	Evaluation
RTC	Snippets	438,000	23.4	128,056	81.3%	Train-Test
IMDB	Reviews	50,000	268.8	140,172	82.5%	Train-Test
PL05	Snippets	10,662	21.5	19,825	81.3%	10 cross valid.
PL04	Reviews	2,000	762.1	45,077	82.4%	10 cross valid.
Stanford	Phrases	119,783	10.0	19,400	81.6%	10 cross valid.

Table 3: Statistics of the polarity detection datasets.

Initialization	Input type		RTC	IMDB	PL05	PL04	Stanford
Random	**Word**		83.6	87.7	77.3	67.9	91.8
	Sense	**WordNet**	83.2	87.4	76.6	67.4	91.3
		Wikipedia	83.1	**88.0**	75.9†	67.1	91.0
	Supersense	**WordNet**	**84.4**	**88.0**	75.9	66.2	91.4†
		Wikipedia	83.1	**88.4***	75.8	**69.3***	91.0
Pre-trained	**Word**		85.5	88.3	80.2	72.5	93.1
	Sense	**WordNet**	83.4	**88.3**	79.2	69.7†	92.6
		Wikipedia	83.8	87.0†	79.2	**73.1**	92.3
	Supersense	**WordNet**	85.2	**88.8**	79.5	**73.8**	92.7†
		Wikipedia	84.2	87.9	78.3†	**72.6**	92.2

Table 4: Accuracy performance on five polarity detection datasets. Given that polarity datasets are balanced[17], we do not report F1 which would have been identical to accuracy.

spective of the classification task. We attribute this to two main factors:

1. **Sparsity**: Splitting a word into multiple word senses can have the negative side effect that the corresponding training data for that word is distributed among multiple independent senses. This reduces the training instances per word sense, which might affect the classifier's performance, particularly when senses are semantically related (in comparison to fine-grained senses, supersenses address this issue to some extent).

2. **Disambiguation quality**: As also mentioned previously, our disambiguation algorithm requires the input text to be sufficiently large so as to create a graph with an adequate number of coherent connections to function effectively. In fact, for topic categorization, in which the documents are relatively long, our algorithm manages to disambiguate a larger proportion of words in documents with high confidence. The lower performance of graph-based disambiguation algorithms on short texts is a known issue (Moro et al., 2014; Raganato et al., 2017), the tackling of which remains an area of exploration.

Senses granularity. Our results showed that reducing fine-granularity of sense distinctions can be beneficial to both tasks, irrespective of the underlying sense inventory, i.e. WordNet or Wikipedia, which corroborates previous findings (Hovy et al., 2013; Flekova and Gurevych, 2016). This suggests that text classification does not require fine-grained semantic distinctions. In this work we used a simple technique based on WordNet's lexicographer files for coarsening senses in this sense inventory as well as in Wikipedia. We leave the exploration of this promising area as well as the evaluation of other granularity reduction techniques for WordNet (Snow et al., 2007; Bhagwani et al., 2013) and Wikipedia (Dandala et al., 2013) sense inventories to future work.

6 Related Work

The past few years have witnessed a growing research interest in semantic representation, mainly as a consequence of the word embedding tsunami

(Mikolov et al., 2013; Pennington et al., 2014). Soon after their introduction, word embeddings were integrated into different NLP applications, thanks to the migration of the field to deep learning and the fact that most deep learning models view words as dense vectors. The waves of the word embedding tsunami have also lapped on the shores of sense representation. Several techniques have been proposed that either extend word embedding models to cluster contexts and induce senses, usually referred to as unsupervised sense representations (Schütze, 1998; Reisinger and Mooney, 2010; Huang et al., 2012; Neelakantan et al., 2014; Guo et al., 2014; Tian et al., 2014; Šuster et al., 2016; Ettinger et al., 2016; Qiu et al., 2016) or exploit external sense inventories and lexical resources for generating sense representations for individual meanings of words (Chen et al., 2014; Johansson and Pina, 2015; Jauhar et al., 2015; Iacobacci et al., 2015; Rothe and Schütze, 2015; Camacho-Collados et al., 2016b; Mancini et al., 2016; Pilehvar and Collier, 2016).

However, the integration of sense representations into deep learning models has not been so straightforward, and research in this field has often opted for alternative evaluation benchmarks such as WSD, or artificial tasks, such as word similarity. Consequently, the problem of integrating sense representations into downstream NLP applications has remained understudied, despite the potential benefits it can have. Li and Jurafsky (2015) proposed a "multi-sense embedding" pipeline to check the benefit that can be gained by replacing word embeddings with sense embeddings in multiple tasks. With the help of two simple disambiguation algorithms, unsupervised sense embeddings were integrated into various downstream applications, with varying degrees of success. Given the interdependency of sense representation and disambiguation in this model, it is very difficult to introduce alternative algorithms into its pipeline, either to benefit from the state of the art, or to carry out an evaluation. Instead, our pipeline provides the advantage of being modular: thanks to its use of disambiguation in the pre-processing stage and use of sense representations that are linked to external sense inventories, different WSD techniques and sense representations can be easily plugged in and checked. Along the same lines, Flekova and Gurevych (2016) proposed a technique for learning supersense representations, using automatically-annotated corpora. Coupled with a supersense tagger, the representations were fed into a neural network classifier as additional features to the word-based input. Through a set of experiments, Flekova and Gurevych (2016) showed that the supersense enrichment can be beneficial to a range of binary classification tasks. Our proposal is different in that it focuses directly on the benefits that can be gained by semantifying the input, i.e. reducing lexical ambiguity in the input text, rather than assisting the model with additional sources of knowledge.

7 Conclusion and Future Work

We proposed a pipeline for the integration of sense level knowledge into a state-of-the-art text classifier. We showed that a simple disambiguation of the input can lead to consistent performance gain, particularly for longer documents and when the granularity of the underlying sense inventory is reduced. Our pipeline is modular and can be used as an *in vivo* evaluation framework for WSD and sense representation techniques. We release our code and data (including pre-trained sense and supersense embeddings) at https://pilehvar.github.io/sensecnn/ to allow further checking of the choice of hyperparameters and to allow further analysis and comparison. We hope that our work will foster future research on the integration of sense-level knowledge into downstream applications. As future work, we plan to investigate the extension of the approach to other languages and applications. Also, given the promising results observed for supersenses, we plan to investigate task-specific coarsening of sense inventories, particularly Wikipedia, or the use of SentiWordNet (Baccianella et al., 2010), which could be more suitable for polarity detection.

Abstract

This paper proposes to tackle open-domain question answering using Wikipedia as the unique knowledge source: the answer to any factoid question is a text span in a Wikipedia article. This task of *machine reading at scale* combines the challenges of document retrieval (finding the relevant articles) with that of machine comprehension of text (identifying the answer spans from those articles). Our approach combines a search component based on bigram hashing and TF-IDF matching with a multi-layer recurrent neural network model trained to detect answers in Wikipedia paragraphs. Our experiments on multiple existing QA datasets indicate that (1) both modules are highly competitive with respect to existing counterparts and (2) multitask learning using distant supervision on their combination is an effective complete system on this challenging task.

1 Introduction

This paper considers the problem of answering factoid questions in an open-domain setting using Wikipedia as the unique knowledge source, such as one does when looking for answers in an encyclopedia. Wikipedia is a constantly evolving source of detailed information that could facilitate intelligent machines — if they are able to leverage its power. Unlike knowledge bases (KBs) such as Freebase (Bollacker et al., 2008) or DBPedia (Auer et al., 2007), which are easier for computers to process but too sparsely populated for open-domain question answering (Miller et al., 2016), Wikipedia contains up-to-date knowledge that humans are interested in. It is designed, however, for humans – not machines – to read.

Using Wikipedia articles as the knowledge source causes the task of question answering (QA) to combine the challenges of both large-scale open-domain QA and of machine comprehension of text. In order to answer any question, one must first retrieve the few relevant articles among more than 5 million items, and then scan them carefully to identify the answer. We term this setting, *machine reading at scale* (MRS). Our work treats Wikipedia as a collection of articles and does not rely on its internal graph structure. As a result, our approach is generic and could be switched to other collections of documents, books, or even daily updated newspapers.

Large-scale QA systems like IBM's DeepQA (Ferrucci et al., 2010) rely on multiple sources to answer: besides Wikipedia, it is also paired with KBs, dictionaries, and even news articles, books, etc. As a result, such systems heavily rely on information redundancy among the sources to answer correctly. Having a single knowledge source forces the model to be very precise while searching for an answer as the evidence might appear only once. This challenge thus encourages research in the ability of a machine to read, a key motivation for the machine comprehension subfield and the creation of datasets such as SQuAD (Rajpurkar et al., 2016), CNN/Daily Mail (Hermann et al., 2015) and CBT (Hill et al., 2016).

However, those machine comprehension resources typically assume that a short piece of relevant text is already identified and given to the model, which is not realistic for building an open-domain QA system. In sharp contrast, methods that use KBs or information retrieval over documents have to employ search as an integral part of

Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1171

the solution. Instead MRS is focused on simultaneously maintaining the challenge of machine comprehension, which requires the deep understanding of text, while keeping the realistic constraint of searching over a large open resource.

In this paper, we show how multiple existing QA datasets can be used to evaluate MRS by requiring an open-domain system to perform well on all of them at once. We develop DrQA, a strong system for question answering from Wikipedia composed of: (1) Document Retriever, a module using bigram hashing and TF-IDF matching designed to, given a question, efficiently return a subset of relevant articles and (2) Document Reader, a multi-layer recurrent neural network machine comprehension model trained to detect answer spans in those few returned documents. Figure 1 gives an illustration of DrQA.

Our experiments show that Document Retriever outperforms the built-in Wikipedia search engine and that Document Reader reaches state-of-the-art results on the very competitive SQuAD benchmark (Rajpurkar et al., 2016). Finally, our full system is evaluated using multiple benchmarks. In particular, we show that performance is improved across all datasets through the use of multitask learning and distant supervision compared to single task training.

2 Related Work

Open-domain QA was originally defined as finding answers in collections of unstructured documents, following the setting of the annual TREC competitions[1]. With the development of KBs, many recent innovations have occurred in the context of QA from KBs with the creation of resources like WebQuestions (Berant et al., 2013) and SimpleQuestions (Bordes et al., 2015) based on the Freebase KB (Bollacker et al., 2008), or on automatically extracted KBs, e.g., OpenIE triples and NELL (Fader et al., 2014). However, KBs have inherent limitations (incompleteness, fixed schemas) that motivated researchers to return to the original setting of answering from raw text.

A second motivation to cast a fresh look at this problem is that of machine comprehension of text, i.e., answering questions after reading a short text or story. That subfield has made considerable progress recently thanks to new deep learning architectures like attention-based and memory-augmented neural networks (Bahdanau et al., 2015; Weston et al., 2015; Graves et al., 2014) and release of new training and evaluation datasets like QuizBowl (Iyyer et al., 2014), CNN/Daily Mail based on news articles (Hermann et al., 2015), CBT based on children books (Hill et al., 2016), or SQuAD (Rajpurkar et al., 2016) and WikiReading (Hewlett et al., 2016), both based on Wikipedia. An objective of this paper is to test how such new methods can perform in an open-domain QA framework.

QA using Wikipedia as a resource has been explored previously. Ryu et al. (2014) perform open-domain QA using a Wikipedia-based knowledge model. They combine article content with multiple other answer matching modules based on different types of semi-structured knowledge such as infoboxes, article structure, category structure, and definitions. Similarly, Ahn et al. (2004) also combine Wikipedia as a text resource with other resources, in this case with information retrieval over other documents. Buscaldi and Rosso (2006) also mine knowledge from Wikipedia for QA. Instead of using it as a resource for seeking answers to questions, they focus on validating answers returned by their QA system, and use Wikipedia categories for determining a set of patterns that should fit with the expected answer. In our work, we consider the comprehension of text only, and use Wikipedia text documents as the sole resource in order to emphasize the task of machine reading at scale, as described in the introduction.

There are a number of highly developed full pipeline QA approaches using either the Web, as does QuASE (Sun et al., 2015), or Wikipedia as a resource, as do Microsoft's AskMSR (Brill et al., 2002), IBM's DeepQA (Ferrucci et al., 2010) and YodaQA (Baudiš, 2015; Baudiš and Šedivỳ, 2015) — the latter of which is open source and hence reproducible for comparison purposes. AskMSR is a search-engine based QA system that relies on "data redundancy rather than sophisticated linguistic analyses of either questions or candidate answers", i.e., it does not focus on machine comprehension, as we do. DeepQA is a very sophisticated system that relies on both unstructured information including text documents as well as structured data such as KBs, databases and ontologies to generate candidate answers or vote over evidence. YodaQA is an open source system modeled after DeepQA, similarly combining websites,

[1] http://trec.nist.gov/data/qamain.html

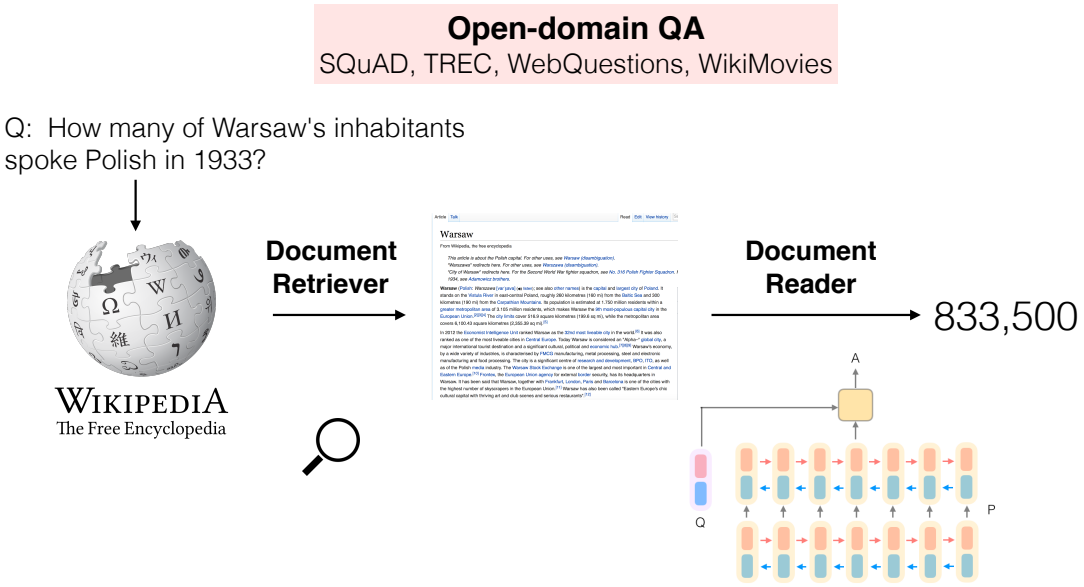

Figure 1: An overview of our question answering system DrQA.

information extraction, databases and Wikipedia in particular. Our comprehension task is made more challenging by only using a single resource. Comparing against these methods provides a useful datapoint for an "upper bound" benchmark on performance.

Multitask learning (Caruana, 1998) and task transfer have a rich history in machine learning (e.g., using ImageNet in the computer vision community (Huh et al., 2016)), as well as in NLP in particular (Collobert and Weston, 2008). Several works have attempted to combine multiple QA training datasets via multitask learning to (i) achieve improvement across the datasets via task transfer; and (ii) provide a single general system capable of asking different kinds of questions due to the inevitably different data distributions across the source datasets. Fader et al. (2014) used WebQuestions, TREC and WikiAnswers with four KBs as knowledge sources and reported improvement on the latter two datasets through multitask learning. Bordes et al. (2015) combined WebQuestions and SimpleQuestions using distant supervision with Freebase as the KB to give slight improvements on both datasets, although poor performance was reported when training on only one dataset and testing on the other, showing that task transfer is indeed a challenging subject; see also (Kadlec et al., 2016) for a similar conclusion. Our work follows similar themes, but in the setting of having to retrieve and then read text documents, rather than using a KB, with positive results.

3 Our System: DrQA

In the following we describe our system DrQA for MRS which consists of two components: (1) the Document Retriever module for finding relevant articles and (2) a machine comprehension model, Document Reader, for extracting answers from a single document or a small collection of documents.

3.1 Document Retriever

Following classical QA systems, we use an efficient (non-machine learning) document retrieval system to first narrow our search space and focus on reading only articles that are likely to be relevant. A simple inverted index lookup followed by term vector model scoring performs quite well on this task for many question types, compared to the built-in ElasticSearch based Wikipedia Search API (Gormley and Tong, 2015). Articles and questions are compared as TF-IDF weighted bag-of-word vectors. We further improve our system by taking local word order into account with n-gram features. Our best performing system uses bigram counts while preserving speed and memory efficiency by using the hashing of (Weinberger et al., 2009) to map the bigrams to 2^{24} bins with an unsigned *murmur3* hash.

We use Document Retriever as the first part of our full model, by setting it to return 5 Wikipedia

articles given any question. Those articles are then processed by Document Reader.

3.2 Document Reader

Our Document Reader model is inspired by the recent success of neural network models on machine comprehension tasks, in a similar spirit to the *AttentiveReader* described in (Hermann et al., 2015; Chen et al., 2016).

Given a question q consisting of l tokens $\{q_1, \ldots, q_l\}$ and a document or a small set of documents of n paragraphs where a single paragraph p consists of m tokens $\{p_1, \ldots, p_m\}$, we develop an RNN model that we apply to each paragraph in turn and then finally aggregate the predicted answers. Our method works as follows:

Paragraph encoding We first represent all tokens p_i in a paragraph p as a sequence of feature vectors $\tilde{\mathbf{p}}_i \in \mathbb{R}^d$ and pass them as the input to a recurrent neural network and thus obtain:

$$\{\mathbf{p}_1, \ldots, \mathbf{p}_m\} = \text{RNN}(\{\tilde{\mathbf{p}}_1, \ldots, \tilde{\mathbf{p}}_m\}),$$

where $\mathbf{p}_i$ is expected to encode useful context information around token p_i. Specifically, we choose to use a multi-layer bidirectional long short-term memory network (LSTM), and take $\mathbf{p}_i$ as the concatenation of each layer's hidden units in the end.

The feature vector $\tilde{\mathbf{p}}_i$ is comprised of the following parts:

- *Word embeddings*: $f_{emb}(p_i) = \mathbf{E}(p_i)$. We use the 300-dimensional Glove word embeddings trained from 840B Web crawl data (Pennington et al., 2014). We keep most of the pre-trained word embeddings fixed and only fine-tune the 1000 most frequent question words because the representations of some key words such as *what*, *how*, *which*, *many* could be crucial for QA systems.

- *Exact match*: $f_{exact\_match}(p_i) = \mathbb{I}(p_i \in q)$. We use three simple binary features, indicating whether p_i can be exactly matched to one question word in q, either in its original, lowercase or lemma form. These simple features turn out to be extremely helpful, as we will show in Section 5.

- *Token features*: $f_{token}(p_i) = (\text{POS}(p_i), \text{NER}(p_i), \text{TF}(p_i))$. We also add a few manual features which reflect some properties of token p_i in its context, which include its part-of-speech (POS) and named entity recognition (NER) tags and its (normalized) term frequency (TF).

- *Aligned question embedding*: Following (Lee et al., 2016) and other recent works, the last part we incorporate is an aligned question embedding $f_{align}(p_i) = \sum_j a_{i,j}\mathbf{E}(q_j)$, where the attention score $a_{i,j}$ captures the similarity between p_i and each question words q_j. Specifically, $a_{i,j}$ is computed by the dot products between nonlinear mappings of word embeddings:

$$a_{i,j} = \frac{\exp\left(\alpha(\mathbf{E}(p_i)) \cdot \alpha(\mathbf{E}(q_j))\right)}{\sum_{j'} \exp\left(\alpha(\mathbf{E}(p_i)) \cdot \alpha(\mathbf{E}(q_{j'}))\right)},$$

and $\alpha(\cdot)$ is a single dense layer with ReLU nonlinearity. Compared to the *exact match* features, these features add soft alignments between similar but non-identical words (e.g., *car* and *vehicle*).

Question encoding The question encoding is simpler, as we only apply another recurrent neural network on top of the word embeddings of q_i and combine the resulting hidden units into one single vector: $\{\mathbf{q}_1, \ldots, \mathbf{q}_l\} \rightarrow \mathbf{q}$. We compute $\mathbf{q} = \sum_j b_j \mathbf{q}_j$ where b_j encodes the importance of each question word:

$$b_j = \frac{\exp(\mathbf{w} \cdot \mathbf{q}_j)}{\sum_{j'} \exp(\mathbf{w} \cdot \mathbf{q}_{j'})},$$

and $\mathbf{w}$ is a weight vector to learn.

Prediction At the paragraph level, the goal is to predict the span of tokens that is most likely the correct answer. We take the the paragraph vectors $\{\mathbf{p}_1, \ldots, \mathbf{p}_m\}$ and the question vector $\mathbf{q}$ as input, and simply train two classifiers independently for predicting the two ends of the span. Concretely, we use a bilinear term to capture the similarity between $\mathbf{p}_i$ and $\mathbf{q}$ and compute the probabilities of each token being start and end as:

$$\begin{aligned} P_{start}(i) &\propto \exp\left(\mathbf{p}_i \mathbf{W}_s \mathbf{q}\right) \\ P_{end}(i) &\propto \exp\left(\mathbf{p}_i \mathbf{W}_e \mathbf{q}\right) \end{aligned}$$

During prediction, we choose the best span from token i to token i' such that $i \leq i' \leq i + 15$ and $P_{start}(i) \times P_{end}(i')$ is maximized. To make scores

compatible across paragraphs in one or several retrieved documents, we use the unnormalized exponential and take argmax over all considered paragraph spans for our final prediction.

4 Data

Our work relies on three types of data: (1) Wikipedia that serves as our knowledge source for finding answers, (2) the SQuAD dataset which is our main resource to train Document Reader and (3) three more QA datasets (CuratedTREC, WebQuestions and WikiMovies) that in addition to SQuAD, are used to test the open-domain QA abilities of our full system, and to evaluate the ability of our model to learn from multitask learning and distant supervision. Statistics of the datasets are given in Table 2.

4.1 Wikipedia (Knowledge Source)

We use the 2016-12-21 dump[2] of English Wikipedia for all of our full-scale experiments as the knowledge source used to answer questions. For each page, only the plain text is extracted and all structured data sections such as lists and figures are stripped.[3] After discarding internal disambiguation, list, index, and outline pages, we retain 5,075,182 articles consisting of 9,008,962 unique uncased token types.

4.2 SQuAD

The Stanford Question Answering Dataset (SQuAD) (Rajpurkar et al., 2016) is a dataset for machine comprehension based on Wikipedia. The dataset contains 87k examples for training and 10k for development, with a large hidden test set which can only be accessed by the SQuAD creators. Each example is composed of a paragraph extracted from a Wikipedia article and an associated human-generated question. The answer is always a span from this paragraph and a model is given credit if its predicted answer matches it. Two evaluation metrics are used: exact string match (EM) and F1 score, which measures the weighted average of precision and recall at the token level.

In the following, we use SQuAD for training and evaluating our Document Reader for the standard machine comprehension task given the relevant paragraph as defined in (Rajpurkar et al., 2016). For the task of evaluating open-domain question answering over Wikipedia, we use the SQuAD development set QA pairs only, and we ask systems to uncover the correct answer spans *without* having access to the associated paragraphs. That is, a model is required to answer a question given the whole of Wikipedia as a resource; it is *not* given the relevant paragraph as in the standard SQuAD setting.

4.3 Open-domain QA Evaluation Resources

SQuAD is one of the largest general purpose QA datasets currently available. SQuAD questions have been collected via a process involving showing a paragraph to each human annotator and asking them to write a question. As a result, their distribution is quite specific. We hence propose to train and evaluate our system on other datasets developed for open-domain QA that have been constructed in different ways (not necessarily in the context of answering from Wikipedia).

CuratedTREC This dataset is based on the benchmarks from the TREC QA tasks that have been curated by Baudiš and Šedivỳ (2015). We use the large version, which contains a total of 2,180 questions extracted from the datasets from TREC 1999, 2000, 2001 and 2002.[4]

WebQuestions Introduced in (Berant et al., 2013), this dataset is built to answer questions from the Freebase KB. It was created by crawling questions through the Google Suggest API, and then obtaining answers using Amazon Mechanical Turk. We convert each answer to text by using entity names so that the dataset does not reference Freebase IDs and is purely made of plain text question-answer pairs.

WikiMovies This dataset, introduced in (Miller et al., 2016), contains 96k question-answer pairs in the domain of movies. Originally created from the OMDb and MovieLens databases, the examples are built such that they can also be answered by using a subset of Wikipedia as the knowledge source (the title and the first section of articles from the movie domain).

[2] https://dumps.wikimedia.org/enwiki/latest

[3] We use the WikiExtractor script: https://github.com/attardi/wikiextractor.

[4] This dataset is available at https://github.com/brmson/dataset-factoid-curated.

Dataset	Example	Article / Paragraph
SQuAD	**Q**: How many provinces did the Ottoman empire contain in the 17th century? **A**: 32	**Article**: Ottoman Empire **Paragraph**: ... At the beginning of the 17th century the empire contained 32 provinces and numerous vassal states. Some of these were later absorbed into the Ottoman Empire, while others were granted various types of autonomy during the course of centuries.
CuratedTREC	**Q**: What U.S. state's motto is "Live free or Die"? **A**: New Hampshire	**Article**: Live Free or Die **Paragraph**: "Live Free or Die" is the official motto of the U.S. state of New Hampshire, adopted by the state in 1945. It is possibly the best-known of all state mottos, partly because it conveys an assertive independence historically found in American political philosophy and partly because of its contrast to the milder sentiments found in other state mottos.
WebQuestions	**Q**: What part of the atom did Chadwick discover?† **A**: neutron	**Article**: Atom **Paragraph**: ... The atomic mass of these isotopes varied by integer amounts, called the whole number rule. The explanation for these different isotopes awaited the discovery of the neutron, an uncharged particle with a mass similar to the proton, by the physicist James Chadwick in 1932. ...
WikiMovies	**Q**: Who wrote the film Gigli? **A**: Martin Brest	**Article**: Gigli **Paragraph**: Gigli is a 2003 American romantic comedy film written and directed by Martin Brest and starring Ben Affleck, Jennifer Lopez, Justin Bartha, Al Pacino, Christopher Walken, and Lainie Kazan.

Table 1: Example training data from each QA dataset. In each case we show an associated paragraph where distant supervision (DS) correctly identified the answer within it, which is highlighted.

Dataset	Train		Test
	Plain	DS	
SQuAD	87,599	71,231	10,570†
CuratedTREC	1,486*	3,464	694
WebQuestions	3,778*	4,602	2,032
WikiMovies	96,185*	36,301	9,952

Table 2: Number of questions for each dataset used in this paper. DS: distantly supervised training data. *: These training sets are not used as is because no paragraph is associated with each question. †: Corresponds to SQuAD development set.

Dataset	Wiki	Doc. Retriever	
	Search	plain	+bigrams
SQuAD	62.7	76.1	**77.8**
CuratedTREC	81.0	85.2	**86.0**
WebQuestions	73.7	**75.5**	74.4
WikiMovies	61.7	54.4	**70.3**

Table 3: Document retrieval results. % of questions for which the answer segment appears in one of the top 5 pages returned by the method.

4.4 Distantly Supervised Data

All the QA datasets presented above contain training portions, but CuratedTREC, WebQuestions and WikiMovies only contain question-answer pairs, and not an associated document or paragraph as in SQuAD, and hence cannot be used for training Document Reader directly. Following previous work on distant supervision (DS) for relation extraction (Mintz et al., 2009), we use a procedure to automatically associate paragraphs to such training examples, and then add these examples to our training set.

We use the following process for each question-answer pair to build our training set. First, we run Document Retriever on the question to retrieve the top 5 Wikipedia articles. All paragraphs from those articles without an exact match of the known answer are directly discarded. All paragraphs shorter than 25 or longer than 1500 characters are also filtered out. If any named entities are detected in the question, we remove any paragraph that does not contain them at all. For every remaining paragraph in each retrieved page, we score all positions that match an answer using unigram and bigram overlap between the question and a 20 token window, keeping up to the top 5 paragraphs with the highest overlaps. If there is no paragraph with non-zero overlap, the example is discarded; otherwise we add each found pair to our DS training dataset. Some examples are shown in Table 1 and data statistics are given in Table 2.

Note that we can also generate additional DS data for SQuAD by trying to find mentions of the answers not just in the paragraph provided, but also from other pages or the same page that the given paragraph was in. We observe that around half of the DS examples come from pages outside of the articles used in SQuAD.

5 Experiments

This section first presents evaluations of our Document Retriever and Document Reader modules separately, and then describes tests of their combination, DrQA, for open-domain QA on the full Wikipedia.

5.1 Finding Relevant Articles

We first examine the performance of our Document Retriever module on all the QA datasets. Table 3 compares the performance of the two approaches described in Section 3.1 with that of the Wikipedia Search Engine[5] for the task of finding articles that contain the answer given a question. Specifically, we compute the ratio of questions for which the text span of any of their associated answers appear in at least one the top 5 relevant pages returned by each system. Results on all datasets indicate that our simple approach outperforms Wikipedia Search, especially with bigram hashing. We also compare doing retrieval with Okapi BM25 or by using cosine distance in the word embeddings space (by encoding questions and articles as bag-of-embeddings), both of which we find performed worse.

5.2 Reader Evaluation on SQuAD

Next we evaluate our Document Reader component on the standard SQuAD evaluation (Rajpurkar et al., 2016).

Implementation details We use 3-layer bidirectional LSTMs with $h = 128$ hidden units for both paragraph and question encoding. We apply the Stanford CoreNLP toolkit (Manning et al., 2014) for tokenization and also generating lemma, part-of-speech, and named entity tags.

Lastly, all the training examples are sorted by the length of paragraph and divided into mini-batches of 32 examples each. We use *Adamax* for optimization as described in (Kingma and Ba, 2014). Dropout with $p = 0.3$ is applied to word embeddings and all the hidden units of LSTMs.

Result and analysis Table 4 presents our evaluation results on both development and test sets. SQuAD has been a very competitive machine comprehension benchmark since its creation and we only list the best-performing systems in the table. Our system (single model) can achieve 70.0% exact match and 79.0% F1 scores on the test set, which surpasses all the published results and can match the top performance on the SQuAD leaderboard at the time of writing. Additionally, we think that our model is conceptually simpler than most of the existing systems. We conducted an ablation analysis on the feature vector of paragraph tokens. As shown in Table 5 all the features contribute to the performance of our final system. Without the aligned question embedding feature (only word embedding and a few manual features), our system is still able to achieve F1 over 77%. More interestingly, if we remove both $f_{aligned}$ and f_{exact_match}, the performance drops dramatically, so we conclude that both features play a similar but complementary role in the feature representation related to the paraphrased nature of a question vs. the context around an answer.

5.3 Full Wikipedia Question Answering

Finally, we assess the performance of our full system DrQA for answering open-domain questions using the four datasets introduced in Section 4. We compare three versions of DrQA which evaluate the impact of using distant supervision and multitask learning across the training sources provided to Document Reader (Document Retriever remains the same for each case):

- SQuAD: A single Document Reader model is trained on the SQuAD training set only and used on all evaluation sets.
- Fine-tune (DS): A Document Reader model is pre-trained on SQuAD and then fine-tuned for each dataset independently using its distant supervision (DS) training set.
- Multitask (DS): A single Document Reader model is jointly trained on the SQuAD training set and *all* the DS sources.

For the full Wikipedia setting we use a streamlined model that does not use the CoreNLP parsed f_{token} features or lemmas for f_{exact_match}. We

[5] We use the Wikipedia Search API `https://www.mediawiki.org/wiki/API:Search`.

Method	Dev		Test	
	EM	F1	EM	F1
Dynamic Coattention Networks (Xiong et al., 2016)	65.4	75.6	66.2	75.9
Multi-Perspective Matching (Wang et al., 2016)†	66.1	75.8	65.5	75.1
BiDAF (Seo et al., 2016)	67.7	77.3	68.0	77.3
R-net†	n/a	n/a	71.3	79.7
DrQA (Our model, Document Reader Only)	**69.5**	**78.8**	70.0	79.0

Table 4: Evaluation results on the SQuAD dataset (single model only). †: Test results reflect the SQuAD leaderboard (https://stanford-qa.com) as of Feb 6, 2017.

Features	F1
Full	78.8
No f_{token}	78.0 (-0.8)
No f_{exact_match}	77.3 (-1.5)
No $f_{aligned}$	77.3 (-1.5)
No $f_{aligned}$ and f_{exact_match}	59.4 (-19.4)

Table 5: Feature ablation analysis of the paragraph representations of our Document Reader. Results are reported on the SQuAD development set.

find that while these help for more exact paragraph reading in SQuAD, they don't improve results in the full setting. Additionally, WebQuestions and WikiMovies provide a list of candidate answers (e.g., 1.6 million Freebase entity strings for WebQuestions) and we restrict the answer span must be in this list during prediction.

Results Table 6 presents the results. Despite the difficulty of the task compared to machine comprehension (where you are given the right paragraph) and unconstrained QA (using redundant resources), DrQA still provides reasonable performance across all four datasets.

We are interested in a single, full system that can answer any question using Wikipedia. The single model trained only on SQuAD is outperformed on all four of the datasets by the multitask model that uses distant supervision. However performance when training on SQuAD alone is not far behind, indicating that task transfer is occurring. The majority of the improvement from SQuAD to Multitask (DS) however is likely not from task transfer as fine-tuning on each dataset alone using DS also gives improvements, showing that is is the introduction of extra data in the same domain that helps. Nevertheless, the best single model that we can find is our overall goal, and that is the Multitask (DS) system.

We compare to an unconstrained QA system using redundant resources (not just Wikipedia), YodaQA (Baudiš, 2015), giving results which were previously reported on CuratedTREC and WebQuestions. Despite the increased difficulty of our task, it is reassuring that our performance is not too far behind on CuratedTREC (31.3 vs. 25.4). The gap is slightly bigger on WebQuestions, likely because this dataset was created from the specific structure of Freebase which YodaQA uses directly.

DrQA's performance on SQuAD compared to its Document Reader component on machine comprehension in Table 4 shows a large drop (from 69.5 to 27.1) as we now are given Wikipedia to read, not a single paragraph. Given the correct document (but not the paragraph) we can achieve 49.4, indicating many false positives come from highly topical sentences. This is despite the fact that the Document Retriever works relatively well (77.8% of the time retrieving the answer, see Table 3). It is worth noting that a large part of the drop comes from the nature of the SQuAD questions. They were written with a specific paragraph in mind, thus their language can be ambiguous when the context is removed. Additional resources other than SQuAD, specifically designed for MRS, might be needed to go further.

6 Conclusion

We studied the task of machine reading at scale, by using Wikipedia as the unique knowledge source for open-domain QA. Our results indicate that MRS is a key challenging task for researchers to focus on. Machine comprehension systems alone cannot solve the overall task. Our method integrates search, distant supervision, and multitask learning to provide an effective complete system. Evaluating the individual components as well as the full system across multiple benchmarks showed the efficacy of our approach.

Dataset	YodaQA	DrQA		
		SQuAD	+Fine-tune (DS)	+Multitask (DS)
SQuAD *(All Wikipedia)*	n/a	27.1	28.4	29.8
CuratedTREC	31.3	19.7	25.7	25.4
WebQuestions	39.8	11.8	19.5	20.7
WikiMovies	n/a	24.5	34.3	36.5

Table 6: Full Wikipedia results. Top-1 exact-match accuracy (in %, using SQuAD eval script). +Fine-tune (DS): Document Reader models trained on SQuAD and fine-tuned on each DS training set independently. +Multitask (DS): Document Reader single model trained on SQuAD and all the distant supervision (DS) training sets jointly. YodaQA results are extracted from https://github.com/brmson/yodaqa/wiki/Benchmarks and use additional resources such as Freebase and DBpedia, see Section 2.

Future work should aim to improve over our DrQA system. Two obvious angles of attack are: (i) incorporate the fact that Document Reader aggregates over multiple paragraphs and documents directly in the training, as it currently trains on paragraphs independently; and (ii) perform end-to-end training across the Document Retriever and Document Reader pipeline, rather than independent systems.

Acknowledgments

The authors thank Pranav Rajpurkar for testing Document Reader on the test set of SQuAD.

Abstract

Recurrent Neural Networks are showing much promise in many sub-areas of natural language processing, ranging from document classification to machine translation to automatic question answering. Despite their promise, many recurrent models have to read the whole text word by word, making it slow to handle long documents. For example, it is difficult to use a recurrent network to read a book and answer questions about it. In this paper, we present an approach of reading text while skipping irrelevant information if needed. The underlying model is a recurrent network that learns how far to jump after reading a few words of the input text. We employ a standard policy gradient method to train the model to make discrete jumping decisions. In our benchmarks on four different tasks, including number prediction, sentiment analysis, news article classification and automatic Q&A, our proposed model, a modified LSTM with jumping, is up to 6 times faster than the standard sequential LSTM, while maintaining the same or even better accuracy.

1 Introduction

The last few years have seen much success of applying neural networks to many important applications in natural language processing, e.g., part-of-speech tagging, chunking, named entity recognition (Collobert et al., 2011), sentiment analysis (Socher et al., 2011, 2013), document classification (Kim, 2014; Le and Mikolov, 2014; Zhang et al., 2015; Dai and Le, 2015), machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014; Sennrich et al., 2015; Wu et al., 2016), conversational/dialogue modeling (Sordoni et al., 2015; Vinyals and Le, 2015; Shang et al., 2015), document summarization (Rush et al., 2015; Nallapati et al., 2016), parsing (Andor et al., 2016) and automatic question answering (Q&A) (Weston et al., 2015; Hermann et al., 2015; Wang and Jiang, 2016; Wang et al., 2016; Trischler et al., 2016; Lee et al., 2016; Seo et al., 2016; Xiong et al., 2016). An important characteristic of all these models is that they read all the text available to them. While it is essential for certain applications, such as machine translation, this characteristic also makes it slow to apply these models to scenarios that have long input text, such as document classification or automatic Q&A. However, the fact that texts are usually written with redundancy inspires us to think about the possibility of reading selectively.

In this paper, we consider the problem of understanding documents with partial reading, and propose a modification to the basic neural architectures that allows them to read input text with skipping. The main benefit of this approach is faster inference because it skips irrelevant information. An unexpected benefit of this approach is that it also helps the models generalize better.

In our approach, the model is a recurrent network, which learns to predict the number of jumping steps after it reads one or several input tokens. Such a discrete model is therefore not fully differentiable, but it can be trained by a standard policy gradient algorithm, where the reward can be the accuracy or its proxy during training.

In our experiments, we use the basic LSTM recurrent networks (Hochreiter and Schmidhuber, 1997) as the base model and benchmark the proposed algorithm on a range of document classification or reading comprehension tasks, using various datasets such as Rotten Tomatoes (Pang

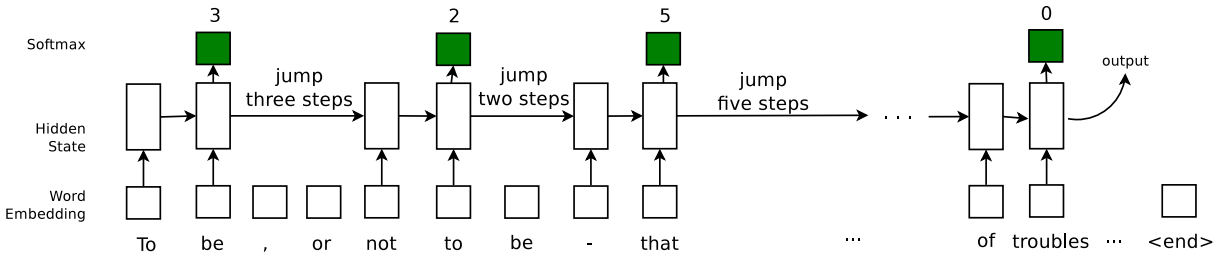

Figure 1: A synthetic example of the proposed model to process a text document. In this example, the maximum size of jump K is 5, the number of tokens read before a jump R is 2 and the number of jumps allowed N is 10. The green softmax are for jumping predictions. The processing stops if a) the jumping softmax predicts a 0 or b) the jump times exceeds N or c) the network processed the last token. We only show the case a) in this figure.

and Lee, 2005), IMDB (Maas et al., 2011), AG News (Zhang et al., 2015) and Children's Book Test (Hill et al., 2015). We find that the proposed approach of selective reading speeds up the base model by two to six times. Surprisingly, we also observe our model beats the standard LSTM in terms of accuracy.

In summary, the main contribution of our work is to design an architecture that learns to skim text and show that it is both faster and more accurate in practical applications of text processing. Our model is simple and flexible enough that we anticipate it would be able to incorporate to recurrent nets with more sophisticated structures to achieve even better performance in the future.

2 Methodology

In this section, we introduce the proposed model named LSTM-Jump. We first describe its main structure, followed by the difficulty of estimating part of the model parameters because of non-differentiability. To address this issue, we appeal to a reinforcement learning formulation and adopt a policy gradient method.

2.1 Model Overview

The main architecture of the proposed model is shown in Figure 1, which is based on an LSTM recurrent neural network. Before training, the number of jumps allowed N, the number of tokens read between every two jumps R and the maximum size of jumping K are chosen ahead of time. While K is a fixed parameter of the model, N and R are hyperparameters that can vary between training and testing. Also, throughout the paper, we would use $d_{1:p}$ to denote a sequence $d_1, d_2, ..., d_p$.

In the following, we describe in detail how the model operates when processing text. Given a training example $x_{1:T}$, the recurrent network will read the embedding of the first R tokens $x_{1:R}$ and output the hidden state. Then this state is used to compute the jumping softmax that determines a distribution over the jumping steps between 1 and K. The model then samples from this distribution a jumping step, which is used to decide the next token to be read into the model. Let κ be the sampled value, then the next starting token is $x_{R+\kappa}$. Such process continues until either

a) the jump softmax samples a 0; or
b) the number of jumps exceeds N; or
c) the model reaches the last token x_T.

After stopping, as the output, the latest hidden state is further used for predicting desired targets. How to leverage the hidden state depends on the specifics of the task at hand. For example, for classification problems in Section 3.1, 3.2 and 3.3, it is directly applied to produce a softmax for classification, while in automatic Q&A problem of Section 3.4, it is used to compute the correlation with the candidate answers in order to select the best one. Figure 1 gives an example with $K = 5$, $R = 2$ and $N = 10$ terminating on condition a).

2.2 Training with REINFORCE

Our goal for training is to estimate the parameters of LSTM and possibly word embedding, which are denoted as θ_m, together with the jumping action parameters θ_a. Once obtained, they can be used for inference.

The estimation of θ_m is straightforward in the tasks that can be reduced as classification problems (which is essentially what our experiments cover), as the cross entropy objective $J_1(\theta_m)$ is

differentiable over θ_m that we can directly apply backpropagation to minimize.

However, the nature of discrete jumping decisions made at every step makes it difficult to estimate θ_a, as cross entropy is no longer differentiable over θ_a. Therefore, we formulate it as a reinforcement learning problem and apply policy gradient method to train the model. Specifically, we need to maximize a reward function over θ_a which can be constructed as follows.

Let $j_{1:N}$ be the jumping action sequence during the training with an example $x_{1:T}$. Suppose h_i is a hidden state of the LSTM right before the i-th jump j_i,[1] then it is a function of $j_{1:i-1}$ and thus can be denoted as $h_i(j_{1:i-1})$. Now the jump is attained by sampling from the multinomial distribution $p(j_i|h_i(j_{1:i-1}); \theta_a)$, which is determined by the jump softmax. We can receive a reward R after processing $x_{1:T}$ under the current jumping strategy.[2] The reward should be positive if the output is favorable or non-positive otherwise. In our experiments, we choose

$$R = \begin{cases} 1 & \text{if prediction correct;} \\ -1 & \text{otherwise.} \end{cases}$$

Then the objective function of θ_a we want to maximize is the expected reward under the distribution defined by the current jumping policy, i.e.,

$$J_2(\theta_a) = \mathbb{E}_{p(j_{1:N};\theta_a)}[R]. \quad (1)$$

where $p(j_{1:N}; \theta_a) = \prod_i p(j_{1:i}|h_i(j_{1:i-1}); \theta_a)$.

Optimizing this objective numerically requires computing its gradient, whose exact value is intractable to obtain as the expectation is over high dimensional interaction sequences. By running S examples, an approximated gradient can be computed by the following REINFORCE algorithm (Williams, 1992):

$$\begin{aligned} \nabla_{\theta_a} J_2(\theta_a) &= \sum_{i=1}^{N} \mathbb{E}_{p(j_{1:N};\theta_a)}[\nabla_{\theta_a} \log p(j_{1:i}|h_i; \theta_a) R] \\ &\approx \frac{1}{S} \sum_{s=1}^{S} \sum_{i=1}^{N} [\nabla_{\theta_a} \log p(j^s_{1:i}|h^s_i; \theta_a) R^s] \end{aligned}$$

where the superscript s denotes a quantity belonging to the s-th example. Now the term $\nabla_{\theta_a} \log p(j_{1:i}|h_i; \theta_a)$ can be computed by standard backpropagation.

Although the above estimation of $\nabla_{\theta_a} J_2(\theta_a)$ is unbiased, it may have very high variance. One widely used remedy to reduce the variance is to subtract a *baseline* value b^s_i from the reward R^s, such that the approximated gradient becomes

$$\nabla_{\theta_a} J_2(\theta_a) \approx \frac{1}{S} \sum_{s=1}^{S} \sum_{i=1}^{N} [\nabla_{\theta_a} \log p(j^s_{1:i}|h^s_i; \theta)(R^s - b^s_i)]$$

It is shown (Williams, 1992; Zaremba and Sutskever, 2015) that any number b^s_i will yield an unbiased estimation. Here, we adopt the strategy of Mnih et al. (2014) that $b^s_i = w_b h^s_i + c_b$ and the parameter $\theta_b = \{w_b, c_b\}$ is learned by minimizing $(R^s - b^s_i)^2$. Now the final objective to minimize is

$$J(\theta_m, \theta_a, \theta_b) = J_1(\theta_m) - J_2(\theta_a) + \sum_{s=1}^{S} \sum_{i=1}^{N} (R^s - b^s_i)^2,$$

which is fully differentiable and can be solved by standard backpropagation.

2.3 Inference

During inference, we can either use sampling or greedy evaluation by selecting the most probable jumping step suggested by the jump softmax and follow that path. In the our experiments, we will adopt the sampling scheme.

3 Experimental Results

In this section, we present our empirical studies to understand the efficiency of the proposed model in reading text. The tasks under experimentation are: synthetic number prediction, sentiment analysis, news topic classification and automatic question answering. Those, except the first one, are representative tasks in text reading involving different sizes of datasets and various levels of text processing, from character to word and to sentence. Table 1 summarizes the statistics of the dataset in our experiments.

To exclude the potential impact of advanced models, we restrict our comparison between the vanilla LSTM (Hochreiter and Schmidhuber, 1997) and our model, which is referred to as LSTM-Jump. In a nutshell, we show that, while achieving the same or even better testing accuracy, our model is up to 6 times and 66 times faster than the baseline LSTM model in real and synthetic

[1] The i-th jumping step is usually *not* x_i.

[2] In the general case, one may receive (discounted) intermediate rewards after each jump. But in our case, we only consider final reward. It is equivalent to a special case that all intermediate rewards are identical and without discount.

Task	Dataset	Level	Vocab	AvgLen	#train	#valid	#test	#class
Number Prediction	synthetic	word	100	100 words	1M	10K	10K	100

Q/A	Children Book Test-CN	sentence	53,185	20 sentences	120,769	2,000	2,500	10

Table 1: Task and dataset statistics.

datasets, respectively, as we are able to selectively skip a large fraction of text.

In fact, the proposed model can be readily extended to other recurrent neural networks with sophisticated mechanisms such as attention and/or hierarchical structure to achieve higher accuracy than those presented below. However, this is orthogonal to the main focus of this work and would be left as an interesting future work.

General Experiment Settings We use the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 in all experiments. We also apply gradient clipping to all the trainable variables with the threshold of 1.0. The dropout rate between the LSTM layers is 0.2 and the embedding dropout rate is 0.1. We repeat the notations N, K, R defined previously in Table 2, so readers can easily refer to when looking at Tables 4,5,6 and 7. While K is fixed during both training and testing, we would fix R and N at training but vary their values during test to see the impact of parameter changes. Note that N is essentially a constraint which can be relaxed. Yet we prefer to enforce this constraint here to let the model learn to read fewer tokens. Finally, the reported test time is measured by running one pass of the whole test set instance by instance, and the speedup is over the base LSTM model. The code is written with TensorFlow.[3]

Notation	Meaning
N	number of jumps allowed
K	maximum size of jumping
R	number of tokens read before a jump

Table 2: Notations referred to in experiments.

3.1 Number Prediction with a Synthetic Dataset

We first test whether LSTM-Jump is indeed able to learn how to jump if a *very clear* jumping signal is given in the text. The input of the task is a sequence of L positive integers $x_{0:T-1}$ and the output is simply x_{x_0}. That is, the output is chosen from the input sequence, with index determined by x_0 . Here are two examples to illustrate the idea:

$$\text{input1} : \underline{4}, 5, 1, 7, \underline{6}, 2. \quad \text{output1} : 6$$

$$\text{input2} : \underline{2}, 4, \underline{9}, 4, 5, 6. \quad \text{output2} : 9$$

One can see that x_0 is essentially the oracle jumping signal, i.e. the indicator of how many steps the reading should jump to get the exact output and obviously, the remaining number of the sequence are useless. After reading the first token, a "smart" network should be able to learn from the training examples to jump to the output position, skipping the rest.

We generate 1 million training and 10,000 validation examples with the rule above, each with sequence length $T = 100$. We also impose $1 \leq x_0 < T$ to ensure the index is valid. We find that directly training the LSTM-Jump with full sequence is unlikely to converge, therefore, we adopt a curriculum training scheme. More specifically, we generate sequences with lengths $\{10, 20, 30, 40, 50, 60, 70, 80, 90, 100\}$ and train the model starting from the shortest. Whenever the training accuracy reaches a threshold, we shift to longer sequences. We also train an LSTM with the same curriculum training scheme. The training stops when the validation accuracy is larger than 98%. We choose such stopping criterion simply because it is the highest that both models can achieve.[4] All the networks are single layered, with hidden size 512, embedding size 32 and batch size 100. During testing, we generate sequences of lengths 10, 100 and 1000 with the same rule, each having 10,000 examples. As the training size is large enough, we do not have to worry about overfitting so dropout is not applied. In fact, we find that the training, validation and testing accuracies are almost the same.

[3] https://www.tensorflow.org/

[4] In fact, our model can get higher but we stick to 98% for ease of comparison.

Seq length	LSTM-Jump	LSTM	Speedup
Test accuracy			
10	**98%**	96%	n/a
100	**98%**	96%	n/a
1000	**90%**	80%	n/a
Test time (Avg tokens read)			
10	**13.5s (2.1)**	18.9s (10)	1.40x
100	**13.9s (2.2)**	120.4s (100)	8.66x
1000	**18.9s (3.0)**	1250s (1000)	**66.14x**

Table 3: Testing accuracy and time of synthetic number prediction problem. The jumping level is number.

The results of LSTM and our method, LSTM-Jump, are shown in Table 3. The first observation is that LSTM-Jump is faster than LSTM; the longer the sequence is, the more significant speedup LSTM-Jump can gain. This is because the well-trained LSTM-Jump is aware of the jumping signal at the first token and hence can directly jump to the output position to make prediction, while LSTM is agnostic to the signal and has to read the whole sequence. As a result, the reading speed of LSTM-Jump is hardly affected by the length of sequence, but that of LSTM is linear with respect to length. Besides, LSTM-Jump also outperforms LSTM in terms of test accuracy under all cases. This is not surprising either, as LSTM has to read a large amount of tokens that are potentially not helpful and could interfere with the prediction. In summary, the results indicate LSTM-Jump is able to learn to jump if the signal is clear.

3.2 Word Level Sentiment Analysis with Rotten Tomatoes and IMDB datasets

As LSTM-Jump has shown great speedups in the synthetic dataset, we would like to understand whether it could carry this benefit to real-world data, where "jumping" signal is not explicit. So in this section, we conduct sentiment analysis on two movie review datasets, both containing equal numbers of positive and negative reviews.

The first dataset is Rotten Tomatoes, which contains 10,662 documents. Since there is not a standard split, we randomly select around 80% for training, 10% for validation, and 10% for testing. The average and maximum lengths of the reviews are 22 and 56 words respectively, and we pad each of them to 60. We choose the pre-trained word2vec embeddings[5] (Mikolov et al., 2013) as our fixed word embedding that we do not update this matrix during training. Both LSTM-Jump and LSTM contain 2 layers, 256 hidden units and the batch size is 100. As the amount of training data is small, we slightly augment the data by sampling a continuous 50-word sequence in each padded reviews as one training sample. During training, we enforce LSTM-Jump to read 8 tokens before a jump ($R = 8$), and the maximum skipping tokens per jump is 10 ($K = 10$), while the number of jumps allowed is 3 ($N = 3$).

The testing result is reported in Table 4. In a nutshell, LSTM-Jump is always faster than LSTM under different combinations of R and N. At the same time, the accuracy is on par with that of LSTM. In particular, the combination of $(R, N) = (7, 4)$ even achieves slightly better accuracy than LSTM while having a 1.5x speedup.

Model	(R, N)	Accuracy	Time	Speedup
LSTM-Jump	(9, 2)	0.783	**6.3s**	**1.98x**
	(8, 3)	0.789	7.3s	1.71x
	(7, 4)	**0.793**	8.1s	1.54x
LSTM	n/a	0.791	12.5s	1x

Table 4: Testing time and accuracy on the Rotten Tomatoes review classification dataset. The maximum size of jumping K is set to 10 for all the settings. The jumping level is word.

The second dataset is IMDB (Maas et al., 2011),[6] which contains 25,000 training and 25,000 testing movie reviews, where the average length of text is 240 words, much longer than that of Rotten Tomatoes. We randomly set aside about 15% of training data as validation set. Both LSTM-Jump and LSTM has one layer and 128 hidden units, and the batch size is 50. Again, we use pretrained word2vec embeddings as initialization but they are updated during training. We either pad a short sequence to 400 words or randomly select a 400-word segment from a long sequence as a training example. During training, we set $R = 20, K = 40$ and $N = 5$.

As Table 5 shows, the result exhibits a similar trend as found in Rotten Tomatoes that LSTM-Jump is uniformly faster than LSTM under many settings. The various (R, N) combinations again demonstrate the trade-off between efficiency and accuracy. If one cares more about accuracy, then allowing LSTM-Jump to read and jump more

[5] https://code.google.com/archive/p/word2vec/

Model	(R, N)	Accuracy	Time	Speedup
LSTM-Jump	(80, 8)	**0.894**	769s	1.62x
	(80, 3)	0.892	764s	1.63x
	(70, 3)	0.889	673s	1.85x
	(50, 2)	0.887	585s	2.12x
	(100, 1)	0.880	**489s**	**2.54x**
LSTM	n/a	0.891	1243s	1x

Table 5: Testing time and accuracy on the IMDB sentiment analysis dataset. The maximum size of jumping K is set to 40 for all the settings. The jumping level is word.

times is a good choice. Otherwise, shrinking either one would bring a significant speedup though at the price of losing some accuracy. Nevertheless, the configuration with the highest accuracy still enjoys a 1.6x speedup compared to LSTM. With a slight loss of accuracy, LSTM-Jump can be 2.5x faster .

3.3 Character Level News Article Classification with AG dataset

We now present results on testing the character level jumping with a news article classification problem. The dataset contains four classes of topics (World, Sports, Business, Sci/Tech) from the AG's news corpus,[7] a collection of more than 1 million news articles. The data we use is the subset constructed by Zhang et al. (2015) for classification with character-level convolutional networks. There are 30,000 training and 1,900 testing examples for each class respectively, where 15% of training data is set aside as validation. The non-space alphabet under use are:

```
abcdefghijklmnopqrstuvwxyz0123456
789-,;.!?:/\|_@#$%&*~`'+-=<>()[]{}
```

Since the vocabulary size is small, we choose 16 as the embedding size. The initialized entries of the embedding matrix are drawn from a uniform distribution in $[-0.25, 0.25]$, which are progressively updated during training. Both LSTM-Jump and LSTM have 1 layer and 64 hidden units and the batch sizes are 20 and 100 respectively. The training sequence is again of length 400 that it is either padded from a short sequence or sampled from a long one. During training, we set $R = 30, K = 40$ and $N = 5$.

The result is summarized in Table 6. It is interesting to see that even with skipping, LSTM-Jump is not always faster than LSTM. This is mainly due to the fact that the embedding size and hidden layer are both much smaller than those used previously, and accordingly the processing of a token is much faster. In that case, other computation overhead such as calculating and sampling from the jump softmax might become a dominating factor of efficiency. By this cross-task comparison, we can see that the larger the hidden unit size of recurrent neural network and the embedding are, the more speedup LSTM-Jump can gain, which is also confirmed by the task below.

Model	(R, N)	Accuracy	Time	Speedup
LSTM-Jump	(50, 5)	0.854	102s	0.80x
	(40, 6)	0.874	98.1s	0.83x
	(40, 5)	0.889	83.0s	0.98x
	(30, 5)	0.885	**63.6s**	**1.28x**
	(30, 6)	**0.893**	74.2s	1.10x
LSTM	n/a	0.881	81.7s	1x

Table 6: Testing time and accuracy on the AG news classification dataset. The maximum size of jumping K is set to 40 for all the settings. The jumping level is character.

3.4 Sentence Level Automatic Question Answering with Children's Book Test dataset

The last task is automatic question answering, in which we aim to test the sentence level skimming of LSTM-Jump. We benchmark on the data set Children's Book Test (CBT) (Hill et al., 2015).[8] In each document, there are 20 contiguous sentences (context) extracted from a children's book followed by a query sentence. A word of the query is deleted and the task is to select the best fit for this position from 10 candidates. Originally, there are four types of tasks according to the part of speech of the missing word, from which, we choose the most difficult two, i.e., the name entity (NE) and common noun (CN) as our focus, since simple language models can already achieve human-level performance for the other two types .

The models, LSTM or LSTM-Jump, firstly read the whole query, then the context sentences and finally output the predicted word. While LSTM reads everything, our jumping model would decide how many context sentences should skip after reading one sentence. Whenever a model finishes reading, the context and query are encoded in its

[7] http://www.di.unipi.it/~gulli/AG_corpus_of_news_articles.html

[8] http://www.thespermwhale.com/jaseweston/babi/CBTest.tgz

hidden state h_{O}, and the best answer from the candidate words has the same index that maximizes the following:

$$\mathrm{softmax}(CWh_{\mathrm{O}}) \in \mathbb{R}^{10},$$

where $C \in \mathbb{R}^{10\times d}$ is the word embedding matrix of the 10 candidates and $W \in \mathbb{R}^{d\times \text{hidden\_size}}$ is a trainable weight variable. Using such bilinear form to select answer basically follows the idea of Chen et al. (2016), as it is shown to have good performance. The task is now distilled to a classification problem of 10 classes.

We either truncate or pad each context sentence, such that they all have length 20. The same preprocessing is applied to the query sentences except that the length is set as 30. For both models, the number of layers is 2, the number of hidden units is 256 and the batch size is 32. Pretrained word2vec embeddings are again used and they are not adjusted during training. The maximum number of context sentences LSTM-Jump can skip per time is $K = 5$ while the number of total jumping is limited to $N = 5$. We let the model jump after reading every sentence, so $R = 1$ (20 words).

The result is reported in Table 7. The performance of LSTM-Jump is superior to LSTM in terms of both accuracy and efficiency under all settings in our experiments. In particular, the fastest LSTM-Jump configuration achieves a remarkable 6x speedup over LSTM, while also having respectively 1.4% and 4.4% higher accuracy in Children's Book Test - Named Entity and Children's Book Test - Common Noun.

Model	(R, N)	Accuracy	Time	Speedup
Children's Book Test - Named Entity				
LSTM-Jump	(1, 5)	**0.468**	40.9s	3.04x
	(1, 3)	0.464	30.3s	4.11x
	(1, 1)	0.452	**19.9s**	**6.26x**
LSTM	n/a	0.438	124.5s	1x
Children's Book Test - Common Noun				
LSTM-Jump	(1, 5)	0.493	39.3s	3.09x
	(1, 3)	0.487	29.7s	4.09x
	(1, 1)	**0.497**	**19.8s**	**6.14x**
LSTM	n/a	0.453	121.5s	1x

Table 7: Testing time and accuracy on the Children's Book Test dataset. The maximum size of jumping K is set to 5 for all the settings. The jumping level is sentence.

The dominant performance of LSTM-Jump over LSTM might be interpreted as follows. After reading the query, both LSTM and LSTM-Jump know what the question is. However, LSTM still has to process the remaining 20 sentences and thus at the very end of the last sentence, the long dependency between the question and output might become weak that the prediction is hampered. On the contrary, the question can guide LSTM-Jump on how to read selectively and stop early when the answer is clear. Therefore, when it comes to the output stage, the "memory" is both fresh and uncluttered that a more accurate answer is likely to be picked.

In the following, we show two examples of how the model reads the context given a query (bold face sentences are those read by our model in the increasing order). XXXXX is the missing word we want to fill. Note that due to truncation, a few sentences might look uncompleted.

Example 1 In the first example, the exact answer appears in the context multiple times, which makes the task relatively easy, as long as the reader has captured their occurrences.

(a) *Query:* 'XXXXX!

(b) *Context:*

1. **said Big Klaus, and he ran off at once to Little Klaus.**
2. 'Where did you get so much money from?'
3. **'Oh, that was from my horse-skin.**
4. I sold it yesterday evening.'
5. 'That 's certainly a good price!'
6. said Big Klaus; and running home in great haste, he took an axe, knocked all his four
7. **'Skins!**
8. **skins!**
9. Who will buy skins?'
10. he cried through the streets.
11. All the shoemakers and tanners came running to ask him what he wanted for them.'
12. **A bushel of money for each,' said Big Klaus.**
13. 'Are you mad?'
14. **they all exclaimed.**
15. 'Do you think we have money by the bushel?'
16. 'Skins!
17. skins!
18. Who will buy skins?'
19. he cried again, and to all who asked him what they cost, he answered,' A bushel
20. 'He is making game of us,' they said; and the shoemakers seized their yard measures and

(c) *Candidates:* Klaus | Skins | game | haste | head | home | horses | money | price| streets

(d) *Answer:* Skins

The reading behavior might be interpreted as follows. The model tries to search for clues, and after reading sentence 8, it realizes that the most plausible answer is "Klaus" or "Skins", as they both appear twice. "Skins" is more likely to be the answer as it is followed by a "!". The model searches further to see if "Klaus!" is mentioned somewhere, but it only finds "Klaus" without "!" for the third time. After the last attempt at sentence 14, it is confident about the answer and stops to output with "Skins".

Example 2 In this example, the answer is illustrated by a word "nuisance" that does not show up in the context at all. Hence, to answer the query, the model has to understand the meaning of both the query and context and locate the synonym of "nuisance", which is not merely verbatim and thus much harder than the previous example. Nevertheless, our model is still able to make a right choice while reading much fewer sentences.

(a) *Query:* Yes, I call XXXXX a nuisance.

(b) *Context:*

1. **But to you and me it would have looked just as it did to Cousin Myra – a very discontented**
2. "I'm awfully glad to see you, Cousin Myra, "explained Frank carefully, "and your
3. **But Christmas is just a bore – a regular bore."**
4. **That was what Uncle Edgar called things that didn't interest him, so that Frank felt pretty sure of**
5. **Nevertheless, he wondered uncomfortably what made Cousin Myra smile so queerly.**
6. **"Why, how dreadful!"**
7. she said brightly.
8. "I thought all boys and girls looked upon Christmas as the very best time in the year."
9. "We don't, "said Frank gloomily.
10. **"It's just the same old thing year in and year out.**
11. We know just exactly what is going to happen.
12. We even know pretty well what presents we are going to get.
13. And Christmas Day itself is always the same.
14. We'll get up in the morning , and our stockings will be full of things, and half of
15. Then there 's dinner.
16. It 's always so poky.
17. And all the uncles and aunts come to dinner – just the same old crowd, every year, and
18. Aunt Desda always says, 'Why, Frankie, how you have grown!'
19. She knows I hate to be called Frankie.
20. And after dinner they'll sit round and talk the rest of the day, and that's all.

(c) *Candidates:* Christmas | boys | day | dinner | half | interest | rest | stockings | things | uncles

(d) *Answer:* Christmas

The reading behavior can be interpreted as follows. After reading the query, our model realizes that the answer should be something like a nuisance. Then it starts to process the text. Once it hits sentence 3, it may begin to consider "Christmas" as the answer, since "bore" is a synonym of "nuisance". Yet the model is not 100% sure, so it continues to read, very conservatively – it does not jump for the next three sentences. After that, the model gains more confidence on the answer "Christmas" and it makes a large jump to see if there is something that can turn over the current hypothesis. It turns out that the last-read sentence is still talking about Christmas with a negative voice. Therefore, the model stops to take "Christmas" as the output.

4 Related Work

Closely related to our work is the idea of learning visual attention with neural networks (Mnih et al., 2014; Ba et al., 2014; Sermanet et al., 2014), where a recurrent model is used to combine visual evidence at multiple fixations processed by a convolutional neural network. Similar to our approach, the model is trained end-to-end using the REINFORCE algorithm (Williams, 1992). However, a major difference between those work and ours is that we have to sample from discrete jumping distribution, while they can sample from continuous distribution such as Gaussian. The difference is mainly due to the inborn characteristics of text and image. In fact, as pointed out by Mnih et al. (2014), it was difficult to learn policies over more than 25 possible discrete locations.

This idea has recently been explored in the context of natural language processing applications, where the main goal is to filter irrelevant content using a small network (Choi et al., 2016). Perhaps the most closely related to our work is the concurrent work on learning to reason with reinforcement

learning (Shen et al., 2016). The key difference between our work and Shen et al. (2016) is that they focus on early stopping after multiple pass of data to ensure accuracy whereas our method focuses on selective reading with single pass to enable fast processing.

The concept of "hard" attention has also been used successfully in the context of making neural network predictions more interpretable (Lei et al., 2016). The key difference between our work and Lei et al. (2016)'s method is that our method optimizes for faster inference, and is more dynamic in its jumping. Likewise is the difference between our approach and the "soft" attention approach by (Bahdanau et al., 2014).

Our method belongs to adaptive computation of neural networks, whose idea is recently explored by (Graves, 2016; Jernite et al., 2016), where different amount of computations are allocated dynamically per time step. The main difference between our method and Graves; Jernite et al.'s methods is that our method can set the amount of computation to be exactly zero for many steps, thereby achieving faster scanning over texts. Even though our method requires policy gradient methods to train, which is a disadvantage compared to (Graves, 2016; Jernite et al., 2016), we do not find training with policy gradient methods problematic in our experiments.

At the high-level, our model can be viewed as a simplified trainable Turing machine, where the controller can move on the input tape. It is therefore related to the prior work on Neural Turing Machines (Graves et al., 2014) and especially its RL version (Zaremba and Sutskever, 2015). Compared to (Zaremba and Sutskever, 2015), the output tape in our method is more simple and reward signals in our problems are less sparse, which explains why our model is easy to train. It is worth noting that Zaremba and Sutskever report difficulty in using policy gradients to train their model.

Our method, by skipping irrelevant content, shortens the length of recurrent networks, thereby addressing the vanishing or exploding gradients in them (Hochreiter et al., 2001). The baseline method itself, Long Short Term Memory (Hochreiter and Schmidhuber, 1997), belongs to the same category of methods. In this category, there are several recent methods that try to achieve the same goal, such as having recurrent networks that operate in different frequency (Koutnik et al., 2014) or is organized in a hierarchical fashion (Chan et al., 2015; Chung et al., 2016).

Lastly, we should point out that we are among the recent efforts that deploy reinforcement learning to the field of natural language processing, some of which have achieved encouraging results in the realm of such as neural symbolic machine (Liang et al., 2017), machine reasoning (Shen et al., 2016) and sequence generation (Ranzato et al., 2015).

5 Conclusions

In this paper, we focus on learning how to skim text for fast reading. In particular, we propose a "jumping" model that after reading every few tokens, it decides how many tokens should be skipped by sampling from a softmax. Such jumping behavior is modeled as a discrete decision making process, which can be trained by reinforcement learning algorithm such as REINFORCE. In four different tasks with six datasets (one synthetic and five real), we test the efficiency of the proposed method on various levels of text jumping, from character to word and then to sentence. The results indicate our model is several times faster than, while the accuracy is on par with the baseline LSTM model.

Acknowledgments

The authors would like to thank the Google Brain Team, especially Zhifeng Chen and Yuan Yu for helpful discussion about the implementation of this model on Tensorflow. The first author also wants to thank Chen Liang, Hanxiao Liu, Yingtao Tian, Fish Tung, Chiyuan Zhang and Yu Zhang for their help during the project. Finally, the authors appreciate the invaluable feedback from anonymous reviewers.

An Algebra for Feature Extraction

Vivek Srikumar
School of Computing
University of Utah
svivek@cs.utah.edu

Abstract

Though feature extraction is a necessary first step in statistical NLP, it is often seen as a mere preprocessing step. Yet, it can dominate computation time, both during training, and especially at deployment. In this paper, we formalize feature extraction from an algebraic perspective. Our formalization allows us to define a message passing algorithm that can restructure feature templates to be more computationally efficient. We show via experiments on text chunking and relation extraction that this restructuring does indeed speed up feature extraction in practice by reducing redundant computation.

1 Introduction

Often, the first step in building statistical NLP models involves feature extraction. It is well understood that the right choice of features can substantially improve classifier performance. However, from the computational point of view, the process of feature extraction is typically treated, at best as the preprocessing step of caching featurized inputs over entire datasets, and at worst, as 'somebody else's problem'. While such approaches work for training, when trained models are deployed, the computational cost of feature extraction cannot be ignored.

In this paper, we present the first (to our knowledge) algebraic characterization of the process of feature extraction. We formalize feature extractors as arbitrary functions that map objects (words, sentences, etc) to a vector space and show that this set forms a commutative semiring with respect to feature addition and feature conjunction.

An immediate consequence of the semiring characterization is a computational one. Every semiring admits the *Generalized Distributive Law (GDL) Algorithm* (Aji and McEliece, 2000) that exploits the distributive property to provide computational speedups. Perhaps the most common manifestation of this algorithm in NLP is in the form of inference algorithms for factor graphs and Bayesian networks like the max-product, max-sum and sum-product algorithms (*e.g.* Goodman, 1999; Kschischang et al., 2001). When applied to feature extractors, the GDL algorithm can refactor a feature extractor into a faster one by reducing redundant computation. In this paper, we propose a junction tree construction to allow such refactoring. Since the refactoring is done at the feature template level, the actual computational savings grow as classifiers encounter more examples.

We demonstrate the practical utility of our approach by factorizing existing feature sets for text chunking and relation extraction. We show that, by reducing the number of operations performed, we can obtain significant savings in the time taken to extract features.

To summarize, the main contribution of this paper is the recognition that feature extractors form a commutative semiring over addition and conjunction. We demonstrate a practical consequence of this characterization in the form of a mechanism for automatically refactoring any feature extractor into a faster one. Finally, we show the empirical usefulness of our approach on relation extraction and text chunking tasks.

2 Problem Definition

Before formal definitions, let us first see a running example.

2.1 Motivating Example

Consider the frequently used unigram, bigram and trigram features. Each of these is a template that specifies a feature representation for a word. In

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1891–1900
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1173

fact, the `bigram` and `trigram` templates themselves are compositional by definition. A `bigram` is simply the conjunction of a word `w` and previous word, which we will denote as $\texttt{w}_{-1}$; *i.e.*, $\texttt{bigram} = \texttt{w}_{-1}\&\texttt{w}$. Similarity, a `trigram` is the conjunction of $\texttt{w}_{-2}$ and `bigram`.

These templates are a function that operate on inputs. Given a sentence, say *John ate alone*, and a target word, say *alone*, they will produce indicators for the strings $\texttt{w}$=*alone*, $\texttt{w}_{-1}$=*ate*&$\texttt{w}$=*alone* and $\texttt{w}_{-2}$=*John*&$\texttt{w}_{-1}$=*ate*&$\texttt{w}$=*alone* respectively. Equivalently, each template maps an input to a vector. Here, the three vectors will be basis vectors associated with the feature strings.

Observe that the function that extracts the target word (*i.e.*, `w`) has to be executed in all three feature templates. Similarly, $\texttt{w}_{-1}$ has to be extracted to compute both the bigrams and the trigrams. *Can we optimize feature computation by automatically detecting such repetitions?*

2.2 Definitions and Preliminaries

Let X be a set of inputs to a classification problem at hand; *e.g.*, X could be words, sentences, etc. Let $\mathcal{V}$ be a possibly infinite dimensional vector space that represents the feature space. Feature extractors are functions that map the input space X to the feature space $\mathcal{V}$ to produce feature vectors for inputs. Let $\mathcal{F}$ represent the set of feature functions, defined as the set $\{\texttt{f} : X \to \mathcal{V}\}$. We will use the typewriter font to denote feature functions like `w` and `bigram`.

To round up the definitions, we will name two special feature extractors in $\mathcal{F}$. The feature extractor $\mathbb{0}$ maps all inputs to the zero vector. The feature extractor $\mathbb{1}$ maps all inputs to a bias feature vector. Without loss of generality, we will designate the basis vector $i_0 \in \mathcal{V}$ as the bias feature vector.

In this paper, we are concerned about two generally well understood operators on feature functions – addition and conjunction. However, let us see formal definitions for completeness.

Feature Addition. Given two feature extractors $\texttt{f}_1, \texttt{f}_2 \in \mathcal{F}$, feature addition (denoted by $+$) produces a feature extractor $\texttt{f}_1 + \texttt{f}_2$ that adds up the images of $\texttt{f}_1$ and $\texttt{f}_2$. That is, for any example $x \in X$, we have

$$(\texttt{f}_1 + \texttt{f}_2)(x) = \texttt{f}_1(x) + \texttt{f}_2(x) \qquad (1)$$

For example, the feature extractor $\texttt{w} + \texttt{w}_{-1}$ will map the word *alone* to a vector that is one for the basis elements $\texttt{w}$=*alone* and $\texttt{w}_{-1}$=*went*. This vector is the sum of the indicator vectors produced by the two operands `w` and $\texttt{w}_{-1}$.

Feature Conjunction. Given two feature extractors $\texttt{f}_1, \texttt{f}_2 \in \mathcal{F}$, their conjunction (denoted by $\&$) can be interpreted as an extension of Boolean conjunction. Indicator features like `bigram` are predicates for certain observations. Conjoining indicator features for two predicates is equivalent to an indicator feature for the Boolean conjunction of the predicates. More generally, with feature extractors that produce real valued vectors, the conjunction will produce their tensor product. The equivalence of feature conjunctions to tensor products has been explored and exploited in recent literature for various NLP tasks (Lei et al., 2014; Srikumar and Manning, 2014; Gormley et al., 2015; Lei et al., 2015).

We can further generalize this with an additional observation that is crucial for the rest of this paper. We argue that the conjunction operator produces *symmetric tensor products* rather than general tensor products. To see why, consider the `bigram` example. Though we defined the `bigram` feature as the conjunction of $\texttt{w}_{-1}$ and `w`, their ordering is irrelevant from classification perspective – the eventual goal is to associate weights with this combination of features. This observation allows us to formally define the conjunction operator as:

$$(\texttt{f}_1\&\texttt{f}_2)(x) = \text{vec}\left(\texttt{f}_1(x) \odot \texttt{f}_2(x)\right) \qquad (2)$$

Here, $\text{vec}(\cdot)$ stands for vectorize, which simply converts the resulting tensor into a vector and $\odot$ denotes the symmetric tensor product, introduced by Ryan (1980, Proposition 1.1). A symmetric tensor product is defined to be the average of the tensor products of all possible permutations of the operands, and thus, unlike a simple tensor product, is invariant to permutation of is operands. Informally, if we think of a tensor as a mapping from an ordered sequence of keys to real numbers, then, symmetric tensor product can be thought of as a mapping from a *set* of keys to numbers.

3 An Algebra for Feature Extraction

In this section, we will see that the set of feature extractors $\mathcal{F}$ form a commutative semiring with respect to addition and conjunction. First, let us revisit the definition of a commutative semiring.

Definition 1. *A* commutative semiring *is an algebraic structure consisting of a set K and two bi-*

nary operations $\oplus$ and $\otimes$ (addition and multiplication respectively) such that:

S1. $(K, \oplus)$ *is a commutative monoid:* $\oplus$ *is associative and commutative, and the set* K *contains a unique additive identity* 0 *such that* $\forall x \in K$*, we have* $0 \oplus x = x \oplus 0 = x$.

S2. $(K, \otimes)$ *is a commutative monoid:* $\otimes$ *is associative and commutative, and the set* K *contains a unique multiplicative identity* 1 *such that* $\forall x \in K$*, we have* $1 \otimes x = x \otimes 1 = x$.

S3. Multiplication distributes over addition on both sides. That is, for any $x, y, z \in K$*, we have* $x \otimes (y \oplus z) = (x \otimes y) \oplus (x \otimes z)$ *and* $(x \oplus y) \otimes z = (x \otimes z) \oplus (y \otimes z)$.

S4. The additive identity is an annihilating element with respect to multiplication. That is, for any $x \in K$*, we have* $x \otimes 0 = 0 = 0 \otimes x$.

We refer the reader to Golan (2013) for a broad-ranging survey of semiring theory. We can now state and prove the main result of this paper.

Theorem 1. *Let* X *be any set and let* $\mathcal{F}$ *denote the set of feature extractors defined on the set. Then,* $(\mathcal{F}, +, \&)$ *is a commutative semiring.*

Proof. We will show that the properties of a commutative semiring hold for $(\mathcal{F}, +, \&)$ using the definitions of the operators from §2.2. Let $\mathtt{f}_1, \mathtt{f}_2$ and $\mathtt{f} \in \mathcal{F}$ be feature extractors.

S1. For any example $x \in X$, we have $(\mathtt{f}_1 + \mathtt{f}_2)(x) = \mathtt{f}_1(x) + \mathtt{f}_2(y)$. The right hand side denotes vector addition, which is associative and commutative. The $\mathbb{0}$ feature extractor is the additive identify because it produces the zero vector for any input. Thus, $(\mathcal{F}, +)$ is a commutative monoid.

S2. To show that the conjunction operator is associative over feature extractors, it suffices to observe that the tensor product (and hence the symmetric tensor product) is associative. Furthermore, the symmetric tensor product is commutative by definition, because it is invariant to permutation of its operands.
Finally, the bias feature extractor, $\mathbb{1}$, that maps all inputs to the bias vector i_0, is the multiplicative identity. To see this, consider the conjunction $\mathtt{f}\&\mathbb{1}$, applied to an input x:

$$\begin{aligned}(\mathtt{f}\&\mathbb{1})(x) &= \text{vec}(\mathtt{f}(x) \odot \mathbb{1}(x)) \\ &= \text{vec}(\mathtt{f}(x) \odot i_0)\end{aligned}$$

The product term within the $\text{vec}(\cdot)$ in the final expression is a symmetric tensor, defined by basis vectors that are sets of the form $\{i_0, i_0\}, \{i_1, i_0\}, \cdots$. Each basis $\{i_j, i_0\}$ is associated with a feature value $\mathtt{f}(x)_j$. Thus, the vectorized form of this tensor will contain the *same elements* as $\mathtt{f}(x)$, perhaps mapped to different bases. The mapping from $\mathtt{f}(x)$ to the final vector is independent of the input x because the bias feature extractor is independent of x. Without loss of generality, we can fix this mapping to be the identity mapping, thereby rendering the final vectorized form equal to $\mathtt{f}(x)$. That is, $\mathtt{f}\&\mathbb{1} = \mathtt{f}$.
Thus, $(\mathcal{F}, \&)$ is a commutative monoid.

S3. Since tensor products distribute over addition, we get the distributive property.

S4. By definition, conjoining with the $\mathbb{0}$ feature extractor annihilates all feature functions because $\mathbb{0}$ maps all inputs to the zero vector.

■

4 From Algebra to an Algorithm

The fact that feature extractors form a commutative semiring has a computational consequence. The *generalized distributive law (GDL) algorithm* (Aji and McEliece, 2000) exploits the properties of a commutative semiring to potentially reduce the computational effort for marginalizing sums of products. The GDL algorithm manifests itself as the Viterbi, Baum-Welch, Floyd-Warshall and belief propagation algorithms, and the Fast Fourier and Hadamard transforms. Each corresponds to a different commutative semiring and a specific associated marginalization problem.

Here, we briefly describe the general marginalization problem from Aji and McEliece (2000) to introduce notation and also highlight the analogies to inference in factor graphs. Let $x_1, x_2, \cdots, x_n$ denote a collection of variables that can take values from finite sets $A_1, A_2, \cdots, A_n$ respectively. Let boldface $\mathbf{x}$ denote the entire set of variables. These variables are akin to inference variables in factor graphs that may be assigned values or marginalized away.

Let $(K, \oplus, \otimes)$ denote a commutative semiring. Suppose α_i is a function that maps a subset of the variables $\{x_{i_1}, x_{i_2}, \cdots\}$ to the set K. The subset of variables that constitute the domain of α_i is called the *local domain* of the corresponding *local function*. Local domains and local functions are analogous to factors and factor potentials in a factor graph. With a collection of local domains, each associated with a function α_i, the "marginalize the

product" problem is that of computing:

$$\sum_{\mathbf{x}} \prod_{i} \alpha_i \left(x_{i_1}, x_{i_2}, \cdots\right) \tag{3}$$

Here, the sum and product use the semiring operators. The summation is over all possible valid assignments of the variables $\mathbf{x}$ over the cross product of the sets $A_1, A_2, \cdots, A_n$. This problem generalizes the familiar max-product or sum-product settings. Indeed, the GDL algorithm is a generalization of the message passing (Pearl, 2014) for efficiently computing marginals.

To make feature extraction efficient using the GDL algorithm, in the next section, we will define a marginalization problem in terms of the semiring operators by specifying the variables involved, the local domains and local functions. Instead of describing the algorithm in the general setting, we will instantiate it on the semiring at hand.

5 Marginalizing Feature Extractors

First, let us see why we can expect any benefit from the GDL algorithm by revisiting our running example (unigrams, bigrams and trigrams), written below using the semiring operations:

$$\mathtt{f} = \mathtt{w} + (\mathtt{w}_{-1} \& \mathtt{w}) + (\mathtt{w}_{-2} \& \mathtt{w}_{-1} \& \mathtt{w}) \tag{4}$$

When applied to a token, $\mathtt{f}$ performs two additions and three conjunctions. However, by applying the distributive property, we can refactor it as follows to reduce the number of operations:

$$\mathtt{f}' = (\mathbb{1} + (\mathbb{1} + \mathtt{w}_{-2}) \,\&\mathtt{w}_{-1}) \,\&\mathtt{w} \tag{5}$$

The refactored version $\mathtt{f}'$ – equivalent to the original one – only performs two additions and two conjunctions, offering a computational saving of one operation. This refactoring is done at the level of feature templates (*i.e.*, feature extractors); the actual savings are realized when the feature vectors are computed by applying this feature function to an input. Thus, the simplification, though seemingly modest at the template level, can lead to a substantial speed improvements when the features vectors are actually manifested from data.

The GDL algorithm instantiated with the feature extractor semiring, automates such factorization at a symbolic level. In the rest of this section, first (§5.1), we will write our problem as a marginalization problem, as in Equation (3). Then (§5.2), we will construct a junction tree to apply the message passing algorithm.

5.1 Canonicalizing Feature Extractors

To frame feature simplification as marginalization, we need to first write any feature extractor as a *canonical* sum of products that is amenable for factorization (*i.e.*, as in (3)). To do so, in this section, we will define: (a) the variables involved, (b) the local domains (*i.e.*, subsets of variables contributing to each product term), and, (c) a local function for each local domain (*i.e.*, the α_i's).

Variables. First, we write a feature extractor as a sum of products. Our running example (4) is already one. If we had an expression like $\mathtt{f}_1 \& (\mathtt{f}_2 + \mathtt{f}_3)$, we can expand it into $\mathtt{f}_1 \& \mathtt{f}_2 + \mathtt{f}_1 \& \mathtt{f}_3$. From the sum of products, we identify the *base feature extractors* (*i.e.*, ones not composed of other feature extractors) and define a variable x_i for each. In our example, we have $\mathtt{w}$, $\mathtt{w}_{-1}$ and $\mathtt{w}_{-2}$.

Next, recall from §4 that each variable x_i can take values from a finite set A_i. If a base feature extractor $\mathtt{f}_i$ corresponds to the variable x_i, then, we define x_i's domain to be the set $A_i = \{\mathbb{1}, \mathtt{f}_i\}$. That is, each variable can either be the bias feature extractor or the feature extractor associated with it. Our example gives three variables x_1, x_2, x_3 with domains $A_1 = \{\mathbb{1}, \mathtt{w}\}$, $A_2 = \{\mathbb{1}, \mathtt{w}_{-1}\}$, $A_3 = \{\mathbb{1}, \mathtt{w}_{-2}\}$ respectively.

Local domains. Local domains are subsets of the variables defined above. They are the domains of functions that constitute products in the canonical form of a feature extractor. We define the following local domains, each illustrated with the corresponding instantiation in our running example:

1. A singleton set for each variable: $\{x_1\}$, $\{x_2\}$, and $\{x_3\}$.
2. One local domain consisting of all the variables: The set $\{x_1, x_2, x_3\}$.
3. One local domain consisting of no variables: The empty set $\{\}$.
4. One local domain for each subset of base feature extractors that participate in at least two conjunctions in the sum-of-products (*i.e.*, the ones that can be factored away): Only $\{x_1, x_2\}$ in our example, because only $\mathtt{w}$ and $\mathtt{w}_{-1}$ participate in two conjunctions in (4).

Local functions. Each local domain is associated with a function that maps variable assignments to feature extractors. These functions (called local kernels by Aji and McEliece (2000)) are like potential functions in a factor graph. We define two kinds of local functions, driven by the goal of de-

signing a marginalization problem that pushes towards simpler feature functions.

1. We associate the *identity function* with all singleton local domains, and the constant function that returns the bias $\mathbb{1}$ with the empty domain $\{\}$.
2. With all other local domains, we associate an *indicator function*, denoted by z. For a local domain, z is an indicator for those assignments of the variables involved, whose conjunctions are present in any product term in sum-of-products. In our running example, the function $z(x_1, x_2)$ is the indicator for (x_1, x_2) belonging to the set $\{(\mathtt{w}, \mathbb{1}), (\mathtt{w}, \mathtt{w}_{-1})\}$, represented by the table:

x_1	x_2	$z(x_1, x_2)$
$\mathbb{1}$	$\mathbb{1}$	$\mathbb{0}$
$\mathbb{1}$	$\mathtt{w}_{-1}$	$\mathbb{0}$
$\mathtt{w}$	$\mathbb{1}$	$\mathbb{1}$
$\mathtt{w}$	$\mathtt{w}_{-1}$	$\mathbb{1}$

The indicator returns the semiring's multiplicative and additive identities. The value of z above for inputs $(\mathtt{w}, \mathbb{1})$ is $\mathbb{1}$ because the first term in (4) that defines the feature extractor contains $\mathtt{w}$, but not $\mathtt{w}_{-1}$. On the other hand, the input $(\mathbb{1}, \mathbb{1})$ is mapped to $\mathbb{0}$ because every product term contains either $\mathtt{w}$ or $\mathtt{w}_{-1}$. For the local domain $\{x_1, x_2, x_3\}$, the local function is the indicator for the set $\{(\mathtt{w}, \mathbb{1}, \mathbb{1}), (\mathtt{w}, \mathtt{w}_{-1}, \mathbb{1}), (\mathtt{w}, \mathtt{w}_{-1}, \mathtt{w}_{-2})\}$, corresponding to each product term.

In summary, for the running example we have:

Local domain	Local function
$\{x_1\}$	x_1
$\{x_2\}$	x_2
$\{x_3\}$	x_3
$\{x_1, x_2, x_3\}$	$z(x_1, x_2, x_3)$
$\{\}$	$\mathbb{1}$
$\{x_1, x_2\}$	$z(x_1, x_2)$

The procedure described here aims to convert *any* feature function into a canonical form that can be factorized using the GDL algorithm. Indeed, using local domains and functions specified above, any feature extractor can we written as a canonical sum of products as in (3). For example, using the table above, our running example is identical to

$$\sum_{x_1, x_2, x_3} z(x_1, x_2, x_3) \& z(x_1, x_2) \& x_1 \& x_2 \& x_3 \quad (6)$$

Here, the summation is over the cross product of the A_i's. The choice of the z functions ensures that only those conjunctions that were in the original feature extractor remain.

This section shows one approach for canonicalization; the local domains and functions are a design choice that may be optimized in future work. We should also point out that, while this process is notationally tedious, its actual computational cost is negligible, especially given that it is to be performed only once at the template level.

5.2 Simplifying feature extractors

As mentioned in §4, a commutative semiring can allow us to employ the GDL algorithm to efficiently compute a sum of products. Starting from a canonical sum-of-products expression such as the one in (6), this process is similar to variable elimination for Bayesian networks. The junction tree algorithm is a general scheme to avoid redundant computation in such networks (Cowell, 2006). To formalize this, we will first build a junction tree and then define the messages sent from the leaves to the root. The final message at the root will give us the simplified feature function.

Constructing a Junction Tree. First, we will construct a junction tree using the local domains from § 5.1. In any junction tree, the edges should satisfy the *running intersection property*: *i.e.*, if a variable x_i is in two nodes in the tree, then it should be in every node in the path connecting them. To build a junction tree, we will first create a graph whose nodes are the local domains. The edges of this graph connect pairs of nodes if the variables in one are a subset of the other. For simplicity, we will assume that our nodes are arranged in a lattice as shown in Figure 1, with edges connecting nodes in subsequent levels. For example, there is no edge connecting nodes `B` and `C`.

Every spanning tree of this lattice is a junction tree. Which one should we consider? Let us examine the properties that we need. First, the root of the tree should correspond to the empty local domain $\{\}$ because messages arriving at this node will accumulate all products. Second, as we will see, feature extractors farther from the root will appear in inner terms in the factorized form. That is, frequent or more expensive feature extractors should be incentivized to appear higher in the tree.

To capture these preferences, we frame the task of constructing the junction tree as a maximum spanning tree problem over the graph, with edge weights incorporating the preferences. One natural weighting function is the computational expense of the base feature extractors associated with that edge. For example, the weight associated with the edge connecting nodes `E` and `D` in the fig-

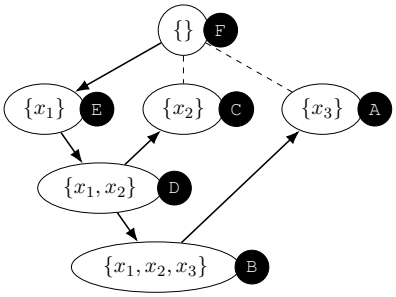

Figure 1: The junction tree for our running example. The process of constructing the junction tree is described in the text. Here, we show both the tree and the graph from which it is constructed; dashed lines show edges are not in the tree. Filled circles denote the names of the nodes. The local domain $\{x_1\}$ is connected to the empty local domain because the feature `w` corresponding to it is most frequent.

ure can be the average cost of the `w` and $\texttt{w}_{-1}$ feature extractors. If computational costs are unavailable, we can use the number times a feature extractor appears in the expression to be simplified. Under this criterion, in our example, edges connecting `E` to its neighbors will be weighted highest.

Once we have a spanning tree, we make the edges directed so that the empty set is the root. Figure 1 shows the junction tree obtained for our running example.

Message Passing for Feature Simplification. Given the junction tree, we can use a standard message passing scheme for factorization. The goal is to collect information at each node in the tree from its children all the way to the root.

Suppose v_i, v_j denote two nodes in the tree. Since nodes are associated with sets of variables, their intersections $v_i \cap v_j$ and differences $v_i \setminus v_j$ are defined. For example, in the example, $\texttt{A} \cap \texttt{B} = \{x_3\}$ and $\texttt{B} \setminus \texttt{D} = \{x_3\}$. We will denote children of a node v_i in the junction tree by $C(v_i)$.

The message from any node v_i to its parent v_j is a function that maps the variables $v_i \cap v_j$ to a feature extractor by marginalizing out all variables that are in v_i but not in v_j. Formally, we define the message μ_{ij} from a node v_i to a node v_j as:

$$\mu_{ij}\left(v_i \cap v_j\right) = \sum_{v_j \setminus v_i} \alpha_i\left(v_i\right) \prod_{v_k \in C(v_i)} \mu_{ki}\left(v_k \cap v_i\right). \quad (7)$$

Here, α_i is the local function at node v_i. To complete the formal definition of the algorithm, we note that by performing post-order traversal of the junction tree, we will accumulate all messages at the root of the tree, that corresponds to the empty set of variables. The incoming message at this node represents the factorized feature extractor.

Algorithm 1 briefly summarizes the entire simplification process. The proof of correctness of the algorithm follows from the fact that the range of all the local functions is a commutative semiring, namely the feature extractor semiring. We refer the reader to (Aji and McEliece, 2000, Appendix A) for details.

Algorithm 1 The Generalized Distributive Law Algorithm for simplifying a feature extractor `f`. See the text for details.

1: Convert `f` into a canonical sum of products representation (§ 5.1).
2: Construct a junction tree whose nodes are local domains.
3: **for** edge (v_j, v_i) in the post-order traversal of the tree **do**
4: Receive a message μ_{ij} at v_j using (7).
5: **end for**
6: **return** the incoming message at the root

Example run of message propagation. As an illustration, let us apply it to our running example.

1. The first message is from `A` to `B`. Since `A` has no children and its local function is the identity function, we have $\mu_{AB}(x) = x$. Similarly, we have $\mu_{CD}(x) = x$.
2. The message from `B` to `D` has to marginalize out the variable x_3. That is, we have $\mu_{BD}(x_1, x_2) = \sum_{x_3} z(x_1, x_2, x_3)\mu_{AB}(x_3)$. The summation is over the domain of x_3, namely $\{\mathbb{1}, \texttt{w}_{-2}\}$. By substituting for z and μ_{AB}, and simplifying, we get the message:

x_1	x_2	$\mu_{BD}(x_1, x_2)$
$\mathbb{1}$	$\mathbb{1}$	$\mathbb{0}$
$\mathbb{1}$	$\texttt{w}_{-1}$	$\mathbb{0}$
$\texttt{w}$	$\mathbb{1}$	$\mathbb{1}$
$\texttt{w}$	$\texttt{w}_{-1}$	$\mathbb{1} + \texttt{w}_{-2}$

3. The message from `D` to `E` marginalizes out the variable x_2 to give us $\mu_{DE}(x_1) = \sum_{x_2} z(x_1, x_2)\mu_{CD}(x_2)\mu_{BD}(x_1, x_2)$. Here, the summation is over the domain of x_2, namely $\{\mathbb{1}, \texttt{w}_{-1}\}$. We can simplify the message as:

x_1	$\mu_{DE}(x_1)$
$\mathbb{1}$	$\mathbb{0}$
$\texttt{w}$	$\mathbb{1} + (\mathbb{1} + \texttt{w}_{-2})\,\&\texttt{w}_{-1}$

4. Finally, the message from `E` to the root `F` marginalizes out the variable x_1 by summing over its domain $\{\mathbb{1}, \texttt{w}\}$ to give us the message $(\mathbb{1} + (\mathbb{1} + \texttt{w}_{-2})\,\&\texttt{w}_{-1})\,\&\texttt{w}$.

The message received at the root is the factorized feature extractor. Note that the final form is identical to (5) at the beginning of §5.

Discussion. An optimal refactoring algorithm would produce a feature extractor that is both correct and fastest. The algorithm above has the former guarantee. While it does reduce the number of operations performed, the closeness of the refac-

tored feature function to the fastest one depends on the heuristic used to weight edges for identifying the junction tree. Changing the heuristic can change the junction tree, thus changing the final factorized function. We found via experiments that using the number of times a feature extractor occurs in the sum-of-products to weight edges is promising. A formal study of optimality of factorization is an avenue of future research.

6 Experiments

We show the practical usefulness of feature function refactoring using text chunking and relation extraction. In both cases, the question we seek to evaluate empirically is: *Does the feature function refactoring algorithm improve feature extraction time?* We should point out that our goal is not to measure accuracy of prediction, but the efficiency of feature extraction. Indeed, we are guaranteed that refactoring will not change accuracy; factorized feature extractors produce the *same* feature vectors as the original ones.

In all experiments, we compare a feature extractor and its refactored variant. For the factorization, we incentivized the junction tree to factor out base feature extractors that occurred most frequently in the feature extractor. For both tasks, we use existing feature representations that we briefly describe. We refer the reader to the original work that developed the feature representations for further details. For both the original and the factorized feature extractors, we report (a) the number of additions and conjunctions at the template level, and, (b) the time for feature extraction on the entire dataset. For the time measurements, we report average times for the original and factorized feature extractors over five paired runs to average out variations in system load.[1]

6.1 Text Chunking

We use data from the CoNLL 2000 shared task (Tjong Kim Sang and Buchholz, 2000) of text chunking and the feature set described by Martins et al. (2011), consisting of the following templates extracted at each word: (1) Up to 3-grams of POS tags within a window of size ten centered at the word, (2) up to 3-grams of words, within a window of size six centered at the word, and (3) up to 2-grams of word shapes, within a window of size four centered at the word. In all, there are 96 feature templates.

[1]We performed all our experiments on a server with 128GB RAM and 24 CPU cores, each clocking at 2600 MHz.

Setting	Size		Average feature extraction time (ms)
	+	&	
Original	47	75	17776.6
Factorized	47	54	4294.2

Table 1: Comparison of the original and factorized feature extractors for the text chunking task. The time improvement is statistically significant using the paired t-test at $p < 0.01$.

Setting	Size		Average feature extraction time (ms)
	+	&	
Original	43	19	8173.0
Factorized	43	11	6276.4

Table 2: Comparison of the original and factorized feature extractors for the relation extraction task. We measured time using 3191 training mention pairs. The time improvement is statistically significant using the paired t-test at $p < 0.01$.

We factorized the feature representation using Algorithm 1. Table 1 reports the number of operations (addition and conjunction) in the templates in the original and factorized versions of the feature extractor. The table also reports feature extraction time taken from the entire training set of 8,936 sentences, corresponding to 211,727 tokens. First, we see that the factorization reduces the number of feature conjunction operations. Thus, to produce exactly the same feature vector, the factorized feature extractor does less work. The time results show that this computational gain is not merely a theoretical one; it also manifests itself practically.

6.2 Relation Extraction

Our second experiment is based on the task of relation extraction using the English section of the ACE 2005 corpus (Walker et al., 2006). The goal is to identify semantic relations between two entity mentions in text. We use the feature representation developed by Zhou et al. (2005) as part of an investigation of how various lexical, syntactic and semantic sources of information affect the relation extraction task. To this end, the feature set consists of word level information about mentions, their entity types, their relationships with chunks, path features from parse trees, and semantic features based on WordNet and various word lists. Given the complexity of the features, we do not describe them here and refer the reader to the original work for details. Note that compared to the chunking features, these features are more diverse in their computational costs.

We report the results of our experiments in Ta-

ble 2. As before, we see that the number of conjunction operations decreases after factorization. Curiously, however, despite the complexity of the feature set, the actual number of operations is smaller than text chunking. Due to this, we see a more modest, yet significant decrease in the time for feature extraction after factorization.

7 Related Work and Discussion

Simplifying Expressions. The problem of simplifying expressions with an eye on computational efficiency is the focus of logic synthesis (cf. Hachtel and Somenzi, 2006), albeit largely geared towards analyzing and verifying digital circuits. Logic synthesis is NP-hard in general. In our case, the hardness is hidden in the fact that our approach does not guarantee that we will find the smallest (or most efficient) factorization. The junction tree construction determines the factorization quality.

Semirings in NLP. Semirings abound in NLP, though primarily as devices to design efficient inference algorithms for various graphical models (*e.g.* Wainwright and Jordan, 2008; Sutton et al., 2012). Goodman (1999) synthesized various parsing algorithms in terms of semiring operations. Since then, we have seen several explorations of the interplay between weighted dynamic programs and semirings for inference in tasks such as parsing and machine translation (*e.g.* Eisner et al., 2005; Li and Eisner, 2009; Lopez, 2009; Gimpel and Smith, 2009). Allauzen et al. (2003) developed efficient algorithms for constructing statistical language models by exploiting the algebraic structure of the probability semiring.

Feature Extraction and Modeling Languages. Much work around features in NLP is aimed at improving classifier accuracy. There is some work on developing languages to better construct feature spaces (Cumby and Roth, 2002; Broda et al., 2013; Sammons et al., 2016), but they do not formalize feature extraction from an algebraic perspective. We expect that the algorithm proposed in this paper can be integrated into such feature construction languages, and also into libraries geared towards designing feature rich models (*e.g.* McCallum et al., 2009; Chang et al., 2015).

Representation vs. Speed. As the recent successes (Goodfellow et al., 2016) of distributed representations show, the representational capacity of a feature space is of primary importance. Indeed, several recent lines of work that use distributed representations have independently identified the connection between conjunctions (of features or factors in a factor graph) and tensor products (Lei et al., 2014; Srikumar and Manning, 2014; Gormley et al., 2015; Yu et al., 2015; Lei et al., 2015; Primadhanty et al., 2015). They typically impose sparsity or low-rank requirements to induce better representations for learning. In this paper, we use the connection between tensor products and conjunctions to prove algebraic properties of feature extractors, leading to speed improvements via factorization.

In this context, we note that in both our experiments, the number of conjunctions are reduced by factorization. We argue that this is an important saving because conjunctions can be a more expensive operation. This is especially true when dealing with dense feature representations, as is increasingly common with word vectors and neural networks, because conjunctions of dense feature vectors are tensor products, which can be slow.

Finally, while training classifiers can be time consuming, when trained classifiers are deployed, feature extraction will dominate computation time over the classifier's lifetime. However, the prediction step includes both feature extraction and computing inner products between features and weights. Many features may be associated with zero weights because of sparsity-inducing learning (*e.g.* Andrew and Gao, 2007; Martins et al., 2011; Strubell et al., 2015). Since these two aspects are orthogonal to each other, the factorization algorithm presented in this paper can be used to speed up extraction of those features that have non-zero weights.

8 Conclusion

In this paper, we studied the process of feature extraction using an algebraic lens. We showed that the set of feature extractors form a commutative semiring over addition and conjunction. We exploited this characterization to develop a factorization algorithm that simplifies feature extractors to be more computationally efficient. We demonstrated the practical value of the refactoring algorithm by speeding up feature extraction for text chunking and relation extraction tasks.

Abstract

Chunks (or phrases) once played a pivotal role in machine translation. By using a chunk rather than a word as the basic translation unit, local (intra-chunk) and global (inter-chunk) word orders and dependencies can be easily modeled. The chunk structure, despite its importance, has not been considered in the decoders used for neural machine translation (NMT). In this paper, we propose chunk-based decoders for NMT, each of which consists of a chunk-level decoder and a word-level decoder. The chunk-level decoder models global dependencies while the word-level decoder decides the local word order in a chunk. To output a target sentence, the chunk-level decoder generates a chunk representation containing global information, which the word-level decoder then uses as a basis to predict the words inside the chunk. Experimental results show that our proposed decoders can significantly improve translation performance in a WAT '16 English-to-Japanese translation task.

1 Introduction

Neural machine translation (NMT) performs end-to-end translation based on a simple encoder-decoder model (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014b) and has now overtaken the classical, complex statistical machine translation (SMT) in terms of performance and simplicity (Sennrich et al., 2016; Luong and Manning, 2016; Cromieres et al., 2016; Neubig, 2016). In NMT, an encoder first maps a source sequence into vector representations and a decoder then maps the vectors into a target sequence (§ 2). This simple framework allows researchers to incorporate the structure of the source sentence as in SMT by leveraging various architectures as the encoder (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014b; Eriguchi et al., 2016b). Most of the NMT models, however, still rely on a sequential decoder based on a recurrent neural network (RNN) due to the difficulty in capturing the structure of a target sentence that is unseen during translation.

En: I wanted to go home earlier.

Ja: 早く (early) 家へ (home) 帰っ (go back) て しまい たい と 思っ (feel) た 。

Figure 1: Translation from English to Japanese. The function words are underlined.

With the sequential decoder, however, there are two problems to be solved. First, it is difficult to model long-distance dependencies (Bahdanau et al., 2015). A hidden state h_t in an RNN is only conditioned by its previous output y_{t-1}, previous hidden state h_{t-1}, and current input x_t. This makes it difficult to capture the dependencies between an older output y_{t-N} if they are too far from the current output. This problem can become more serious when the target sequence becomes longer. For example, in Figure 1, when we translate the English sentence into the Japanese one, after the decoder predicts the content word "帰っ (go back)", it has to predict four function words "て (suffix)", "しまい (*perfect tense*)", "たい (*desire*)", and "と (to)" before predicting the next content word "思っ (feel)". In such a case, the decoder is required to capture the longer dependencies in a target sentence.

Another problem with the sequential decoder is that it is expected to cover multiple possible word orders simply by memorizing the local word se-

quences in the limited training data. This problem can be more serious in free word-order languages such as Czech, German, Japanese, and Turkish. In the case of the example in Figure 1, the order of the phrase "早く (early)" and the phrase "家へ (to home)" is flexible. This means that simply memorizing the word order in training data is not enough to train a model that can assign a high probability to a correct sentence regardless of its word order.

In the past, chunks (or phrases) were utilized to handle the above problems in statistical machine translation (SMT) (Watanabe et al., 2003; Koehn et al., 2003) and in example-based machine translation (EBMT) (Kim et al., 2010). By using a chunk rather than a word as the basic translation unit, one can treat a sentence as a shorter sequence. This makes it easy to capture the longer dependencies in a target sentence. The order of words in a chunk is relatively fixed while that in a sentence is much more flexible. Thus, modeling intra-chunk (local) word orders and inter-chunk (global) dependencies independently can help capture the difference of the flexibility between the word order and the chunk order in free word-order languages.

In this paper, we refine the original RNN decoder to consider chunk information in NMT. We propose three novel NMT models that capture and utilize the chunk structure in the target language (§ 3). Our focus is the hierarchical structure of a sentence: each sentence consists of chunks, and each chunk consists of words. To encourage an NMT model to capture the hierarchical structure, we start from a hierarchical RNN that consists of a chunk-level decoder and a word-level decoder (Model 1). Then, we improve the word-level decoder by introducing inter-chunk connections to capture the interaction between chunks (Model 2). Finally, we introduce a feedback mechanism to the chunk-level decoder to enhance the memory capacity of previous outputs (Model 3).

We evaluate the three models on the WAT '16 English-to-Japanese translation task (§ 4). The experimental results show that our best model outperforms the best single NMT model reported in WAT '16 (Eriguchi et al., 2016b).

Our contributions are twofold: (1) chunk information is introduced into NMT to improve translation performance, and (2) a novel hierarchical decoder is devised to model the properties of chunk structure in the encoder-decoder framework.

2 Preliminaries: Attention-based Neural Machine Translation

In this section, we briefly introduce the architecture of the attention-based NMT model (Bahdanau et al., 2015), which is the basis of our proposed models.

2.1 Neural Machine Translation

An NMT model usually consists of two connected neural networks: an encoder and a decoder. After the encoder maps a source sentence into a fixed-length vector, the decoder maps the vector into a target sentence. The implementation of the encoder can be a convolutional neural network (CNN) (Kalchbrenner and Blunsom, 2013), a long short-term memory (LSTM) (Sutskever et al., 2014; Luong and Manning, 2016), a gated recurrent unit (GRU) (Cho et al., 2014b; Bahdanau et al., 2015), or a Tree-LSTM (Eriguchi et al., 2016b). While various architectures are leveraged as an encoder to capture the structural information in the source language, most of the NMT models rely on a standard sequential network such as LSTM or GRU as the decoder.

Following (Bahdanau et al., 2015), we use GRU as the recurrent unit in this paper. A GRU unit computes its hidden state vector $\boldsymbol{h}_i$ given an input vector $\boldsymbol{x}_i$ and the previous hidden state $\boldsymbol{h}_{i-1}$:

$$\boldsymbol{h}_i = \mathrm{GRU}(\boldsymbol{h}_{i-1}, \boldsymbol{x}_i). \tag{1}$$

The function $\mathrm{GRU}(\cdot)$ is calculated as

$$\boldsymbol{r}_i = \sigma(\boldsymbol{W}_r \boldsymbol{x}_i + \boldsymbol{U}_r \boldsymbol{h}_{i-1} + \boldsymbol{b}_r), \tag{2}$$
$$\boldsymbol{z}_i = \sigma(\boldsymbol{W}_z \boldsymbol{x}_i + \boldsymbol{U}_z \boldsymbol{h}_{i-1} + \boldsymbol{b}_z), \tag{3}$$
$$\tilde{\boldsymbol{h}}_i = \tanh(\boldsymbol{W} \boldsymbol{x}_i + \boldsymbol{U}(\boldsymbol{r}_i \odot \boldsymbol{h}_{i-1} + \boldsymbol{b})), \tag{4}$$
$$\boldsymbol{h}_i = (\boldsymbol{1} - \boldsymbol{z}_i) \odot \tilde{\boldsymbol{h}}_i + \boldsymbol{z}_i \odot \boldsymbol{h}_{i-1}, \tag{5}$$

where vectors $\boldsymbol{r}_i$ and $\boldsymbol{z}_i$ are reset gate and update gate, respectively. While the former gate allows the model to forget the previous states, the latter gate decides how much the model updates its content. All the $\boldsymbol{W}$s and $\boldsymbol{U}$s, or the $\boldsymbol{b}$s above are trainable matrices or vectors. $\sigma(\cdot)$ and $\odot$ denote the sigmoid function and element-wise multiplication operator, respectively.

In this simple model, we train a GRU function that encodes a source sentence $\{x_1, \cdots, x_I\}$ into a single vector $\boldsymbol{h}_I$. At the same time, we jointly train another GRU function that decodes $\boldsymbol{h}_I$ to the target sentence $\{y_1, \cdots, y_J\}$. Here, the j-th word in the

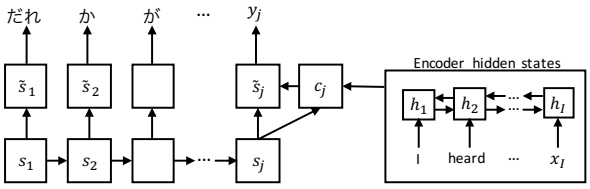

Figure 2: Standard word-based decoder.

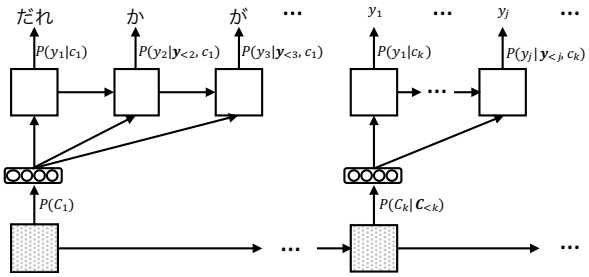

Figure 3: Chunk-based decoder. The top layer (word-level decoder) illustrates the first term in Eq. (15) and the bottom layer (chunk-level decoder) denotes the second term.

target sentence y_j can be predicted with this decoder GRU and a nonlinear function $g(\cdot)$ followed by a softmax layer, as

$$\boldsymbol{c} = \boldsymbol{h}_I, \tag{6}$$

$$\boldsymbol{s}_j = \text{GRU}(\boldsymbol{s}_{j-1}, [\boldsymbol{y}_{j-1}; \boldsymbol{c}]), \tag{7}$$

$$\tilde{\boldsymbol{s}}_j = g(\boldsymbol{y}_{j-1}, \boldsymbol{s}_j, \boldsymbol{c}), \tag{8}$$

$$P(y_j|\boldsymbol{y}_{<j}, \boldsymbol{x}) = \text{softmax}(\tilde{\boldsymbol{s}}_j), \tag{9}$$

where $\boldsymbol{c}$ is a context vector of the encoded sentence and $\boldsymbol{s}_j$ is a hidden state of the decoder GRU.

Following Bahdanau et al. (2015), we use a mini-batch stochastic gradient descent (SGD) algorithm with ADADELTA (Zeiler, 2012) to train the above two GRU functions (i.e., the encoder and the decoder) jointly. The objective is to minimize the cross-entropy loss of the training data $\boldsymbol{D}$, as

$$J = \sum_{(\boldsymbol{x},\boldsymbol{y})\in\boldsymbol{D}} -\log P(\boldsymbol{y}|\boldsymbol{x}). \tag{10}$$

2.2 Attention Mechanism for Neural Machine Translation

To use all the hidden states of the encoder and improve the translation performance of long sentences, Bahdanau et al. (2015) proposed using an attention mechanism. In the attention model, the context vector is not simply the last encoder state h_I but rather the weighted sum of all hidden states of the bidirectional GRU, as follows:

$$\boldsymbol{c}_j = \sum_{i=1}^{I} \alpha_{ji} \boldsymbol{h}_i. \tag{11}$$

Here, the weight α_{ji} decides how much a source word x_i contributes to the target word y_j. α_{ji} is computed by a feedforward layer and a softmax layer as

$$e_{ji} = \boldsymbol{v} \cdot \tanh(\boldsymbol{W}_e \boldsymbol{h}_i + \boldsymbol{U}_e \boldsymbol{s}_j + \boldsymbol{b}_e), \tag{12}$$

$$\alpha_{ji} = \frac{\exp(e_{ji})}{\sum_{j'=1}^{J} \exp(e_{j'i})}, \tag{13}$$

where $\boldsymbol{W}_e$, $\boldsymbol{U}_e$ are trainable matrices and the $\boldsymbol{v}$, $\boldsymbol{b}_e$ are trainable vectors.[1] In a decoder using the attention mechanism, the obtained context vector $\boldsymbol{c}_j$ in each time step replaces $\boldsymbol{c}$s in Eqs. (7) and (8). An illustration of the NMT model with the attention mechanism is shown in Figure 2.

The attention mechanism is expected to learn alignments between source and target words, and plays a similar role to the translation model in phrase-based SMT (Koehn et al., 2003).

3 Neural Machine Translation with Chunk-based Decoder

Taking non-sequential information such as chunks (or phrases) structure into consideration has proved helpful for SMT (Watanabe et al., 2003; Koehn et al., 2003) and EBMT (Kim et al., 2010). Here, we focus on two important properties of chunks (Abney, 1991): (1) The word order in a chunk is almost always fixed, and (2) A chunk consists of a few (typically one) content words surrounded by zero or more function words.

To fully utilize the above properties of a chunk, we propose modeling the intra-chunk and the inter-chunk dependencies independently with a "chunk-by-chunk" decoder (See Figure 3). In the standard word-by-word decoder described in § 2, a target word y_j in the target sentence $\boldsymbol{y}$ is predicted by taking the previous outputs $\boldsymbol{y}_{<j}$ and the source sentence $\boldsymbol{x}$ as input:

$$P(\boldsymbol{y}|\boldsymbol{x}) = \prod_{j=1}^{J} P(y_j|\boldsymbol{y}_{<j}, \boldsymbol{x}), \tag{14}$$

where J is the length of the target sentence. Not

[1] We choose this implementation following (Luong et al., 2015b), while (Bahdanau et al., 2015) use s_{j-1} instead of s_j in Eq. (12).

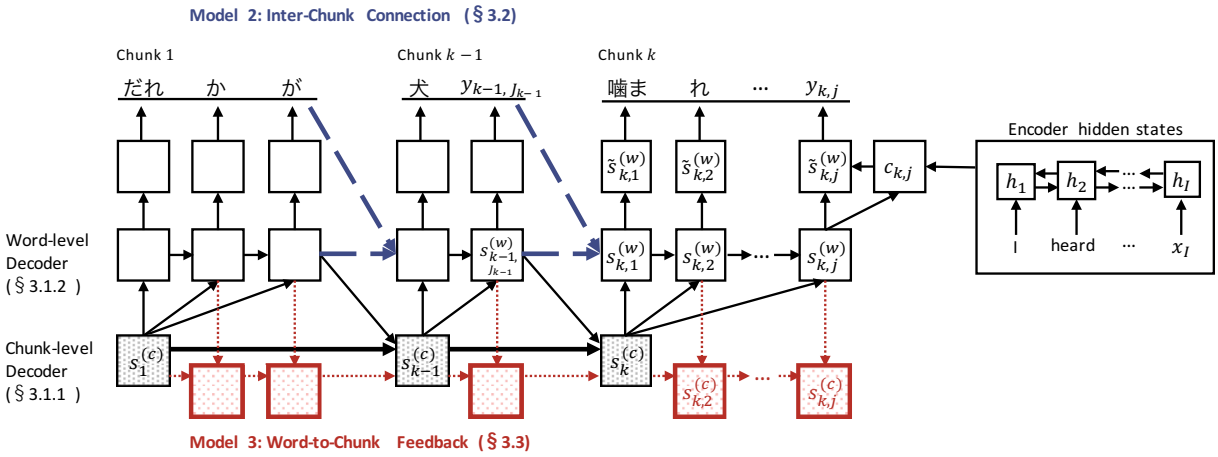

Figure 4: Proposed model: NMT with chunk-based decoder. A chunk-level decoder generates a chunk representation for each chunk while a word-level decoder uses the representation to predict each word. The solid lines in the figure illustrate Model 1. The dashed blue arrows in the word-level decoder denote the connections added in Model 2. The dotted red arrows in the chunk-level decoder denote the feedback states added in Model 3; the connections in the thick black arrows are replaced with the dotted red arrows.

assuming any structural information of the target language, the sequential decoder has to memorize long dependencies in a sequence. To release the model from the pressure of memorizing the long dependencies over a sentence, we redefine this problem as the combination of a word prediction problem and a chunk generation problem:

$$P(\boldsymbol{y}|\boldsymbol{x}) = \prod_{k=1}^{K} \left\{ P(c_k|\boldsymbol{c}_{<k}, \boldsymbol{x}) \prod_{j=1}^{J_k} P(y_j|\boldsymbol{y}_{<j}, c_k, \boldsymbol{x}) \right\}, \tag{15}$$

where K is the number of chunks in the target sentence and J_k is the length of the k-th chunk (see Figure 3). The first term represents the generation probability of a chunk c_k and the second term indicates the probability of a word y_j in the chunk. We model the former term as a chunk-level decoder and the latter term as a word-level decoder. As demonstrated later in § 4, both K and J_k are much shorter than the sentence length J, which is why our decoders do not have to capture the long dependencies like the standard decoder does.

In the above formulation, we model the information of words and their orders in a chunk. No matter which language we target, we can assume that a chunk usually consists of some content words and function words, and the word order in the chunk is almost always fixed (Abney, 1991). Although our idea can be used in several languages, the optimal network architecture could depend on the word order of the target language. In this work, we design models for languages in which content words are followed by function words, such as Japanese and Korean. The details of our models are described in the following sections.

3.1 Model 1: Basic Chunk-based Decoder

The model described in this section is the basis of our proposed decoders. It consists of two parts: a chunk-level decoder (§ 3.1.1) and a word-level decoder (§ 3.1.2). The part drawn in black solid lines in Figure 4 illustrates the architecture of Model 1.

3.1.1 Chunk-level Decoder

Our chunk-level decoder (see Figure 3) outputs a chunk representation. The chunk representation contains the information about words that should be predicted by the word-level decoder.

To generate the representation of the k-th chunk $\tilde{\boldsymbol{s}}_k^{(c)}$, the chunk-level decoder (see the bottom layer in Figure 4) takes the last states of the word-level decoder $\boldsymbol{s}_{k-1,J_{k-1}}^{(w)}$ and updates its hidden state $\boldsymbol{s}_k^{(c)}$ as:

$$\boldsymbol{s}_k^{(c)} = \mathrm{GRU}(\boldsymbol{s}_{k-1}^{(c)}, \boldsymbol{s}_{k-1,J_{k-1}}^{(w)}), \tag{16}$$

$$\tilde{\boldsymbol{s}}_k^{(c)} = \boldsymbol{W}_c \boldsymbol{s}_k^{(c)} + \boldsymbol{b}_c. \tag{17}$$

The obtained chunk representation $\tilde{\boldsymbol{s}}_k^{(c)}$ continues to be fed into the word-level decoder until it outputs all the words in the current chunk.

3.1.2 Word-level Decoder

Our word-level decoder (see Figure 4) differs from the standard sequential decoder described in § 2 in

that it takes the chunk representation $\tilde{s}_k^{(c)}$ as input:

$$\boldsymbol{s}_{k,j}^{(w)} = \mathrm{GRU}(\boldsymbol{s}_{k,j-1}^{(w)}, [\tilde{\boldsymbol{s}}_k^{(c)}; \boldsymbol{y}_{k,j-1}; \boldsymbol{c}_{k,j-1}]), \quad (18)$$

$$\tilde{\boldsymbol{s}}_{k,j}^{(w)} = g(\boldsymbol{y}_{k,j-1}, \boldsymbol{s}_{k,j}^{(w)}, \boldsymbol{c}_{k,j}), \quad (19)$$

$$P(y_{k,j}|\boldsymbol{y}_{<j}, \boldsymbol{x}) = \mathrm{softmax}(\tilde{\boldsymbol{s}}_{k,j}^{(w)}). \quad (20)$$

In a standard sequential decoder, the hidden state iterates over the length of a target sentence and then generates an end-of-sentence token. In other words, its hidden layers are required to memorize the long-term dependencies and orders in the target language. In contrast, in our word-level decoder, the hidden state iterates only over the length of a chunk and then generates an end-of-chunk token. Thus, our word-level decoder is released from the pressure of memorizing the long (inter-chunk) dependencies and can focus on learning the short (intra-chunk) dependencies.

3.2 Model 2: Inter-Chunk Connection

The second term in Eq. (15) only iterates over one chunk ($j = 1$ to J_k). This means that the last state and the last output of a chunk are not being fed into the word-level decoder at the next time step (see the black part in Figure 4). In other words, $\boldsymbol{s}_{k,1}^{(w)}$ in Eq. (18) is always initialized before generating the first word in a chunk. This may have a bad influence on the word-level decoder because it cannot access any previous information at the first word of each chunk.

To address this problem, we add new connections to Model 1 between the first state in a chunk and the last state in the previous chunk, as

$$\boldsymbol{s}_{k,1}^{(w)} = \mathrm{GRU}(\boldsymbol{s}_{k-1,J_{k-1}}^{(w)}, [\tilde{\boldsymbol{s}}_k^{(c)}; \boldsymbol{y}_{k-1,J_{k-1}}; \boldsymbol{c}_{k-1,J_{k-1}}]). \quad (21)$$

The dashed blue arrows in Figure 4 illustrate the added inter-chunk connections.

3.3 Model 3: Word-to-Chunk Feedback

The chunk-level decoder in Eq. (16) is only conditioned by $\boldsymbol{s}_{k-1,J_{k-1}}^{(w)}$, the last word state in each chunk (see the black part in Figure 4). This may affect the chunk-level decoder because it cannot memorize what kind of information has already been generated by the word-level decoder. The information about the words in a chunk should not be included in the representation of the next chunk; otherwise, it may generate the same chunks multiple times, or forget to translate some words in the source sentence.

To encourage the chunk-level decoder to memorize the information about the previous outputs more carefully, we add feedback states to our chunk-level decoder in Model 2. The feedback state in the chunk-level decoder is updated at every time step $j(> 1)$ in k-th chunk, as

$$\boldsymbol{s}_{k,j}^{(c)} = \mathrm{GRU}(\boldsymbol{s}_{k,j-1}^{(c)}, \boldsymbol{s}_{k,j}^{(w)}). \quad (22)$$

The red part in Figure 4 illustrate the added feedback states and their connections. The connections in the thick black arrows are replaced with the dotted red arrows in Model 3.

4 Experiments

4.1 Setup

Data To examine the effectiveness of our decoders, we chose Japanese, a free word-order language, as the target language. Japanese sentences are easy to break into well-defined chunks (called *bunsetsus* (Hashimoto, 1934) in Japanese). For example, the accuracy of *bunsetsu*-chunking on newspaper articles is reported to be over 99% (Murata et al., 2000; Yoshinaga and Kitsuregawa, 2014). The effect of chunking errors in training the decoder can be suppressed, which means we can accurately evaluate the potential of our method. We used the English-Japanese training corpus in the Asian Scientific Paper Excerpt Corpus (ASPEC) (Nakazawa et al., 2016), which was provided in WAT '16. To remove inaccurate translation pairs, we extracted the first two million out of the 3 million pairs following the setting that gave the best performances in WAT '15 (Neubig et al., 2015).

Preprocessings For Japanese sentences, we performed tokenization using KyTea 0.4.7[2] (Neubig et al., 2011). Then we performed *bunsetsu*-chunking with J.DepP 2015.10.05[3] (Yoshinaga and Kitsuregawa, 2009, 2010, 2014). Special end-of-chunk tokens were inserted at the end of the chunks. Our word-level decoders described in § 3 will stop generating words after each end-of-chunk token. For English sentences, we performed the same preprocessings described on the WAT '16 Website.[4] To suppress having possible

Table 2: Hyperparameters for training.

chunking errors affect the translation quality, we removed extremely long chunks from the training data. Specifically, among the 2 million preprocessed translation pairs, we excluded sentence pairs that matched any of following conditions: (1) The length of the source sentence or target sentence is larger than 64 (3% of whole data); (2) The maximum length of a chunk in the target sentence is larger than 8 (14% of whole data); and (3) The maximum number of chunks in the target sentence is larger than 20 (3% of whole data). Table 1 shows the details of the extracted data.

Postprocessing To perform unknown word replacement (Luong et al., 2015a), we built a bilingual English-Japanese dictionary from all of the three million translation pairs. The dictionary was extracted with the MGIZA++ 0.7.0[5] (Och and Ney, 2003; Gao and Vogel, 2008) word alignment tool by automatically extracting the alignments between English words and Japanese words.

Model Architecture Any encoder can be combined with our decoders. In this work, we adopted a single-layer bidirectional GRU (Cho et al., 2014b; Bahdanau et al., 2015) as the encoder to focus on confirming the impact of the proposed decoders. We used single layer GRUs for the word-level decoder and the chunk-level decoder. The vocabulary sizes were set to 40k for source side and 30k for target side, respectively. The conditional probability of each target word was computed with a deep-output (Pascanu et al., 2014) layer with maxout (Goodfellow et al., 2013) units following (Bahdanau et al., 2015). The maximum number of output chunks was set to 20 and the maximum length of a chunk was set to 8.

Training Details The models were optimized using ADADELTA following (Bahdanau et al., 2015). The hyperparameters of the training procedure were fixed to the values given in Table 2. Note that the learning rate was halved when the BLEU score on the development set did not increase for 30,000 batches. All the parameters were initialized randomly with Gaussian distribution. It took about a week to train each model with an NVIDIA TITAN X (Pascal) GPU.

Evaluation Following the WAT '16 evaluation procedure, we used BLEU (Papineni et al., 2002) and RIBES (Isozaki et al., 2010) to evaluate our models. The BLEU scores were calculated with `multi-bleu.pl` in Moses 2.1.1[6] (Koehn et al., 2007); RIBES scores were calculated with `RIBES.py` 1.03.1[7] (Isozaki et al., 2010). Following Cho et al. (2014a), we performed beam search[8] with length-normalized log-probability to decode target sentences. We saved the trained models that performed best on the development set during training and used them to evaluate the systems with the test set.

Baseline Systems The baseline systems and the important hyperparamters are listed in Table 3. Eriguchi et al. (2016a)'s baseline system (the first line in Table 3) was the best single (w/o ensembling) word-based NMT system that were reported in WAT '16. For a more fair evaluation, we also reimplemented a standard attention-based NMT system that uses exactly the same encoder, training procedure, and the hyperparameters as our proposed models, but has a word-based decoder. We trained this system on the training data without chunk segmentations (the second line in Table 3) and with chunk segmentations given by J.DepP (the third line in Table 3). The chunked corpus fed to the third system is exactly the same as the training data of our proposed systems (sixth to eighth lines in Table 3). In addition, we also include the Tree-to-Sequence models (Eriguchi et al., 2016a,b) (the fourth and fifth lines in Table 3) to compare the impact of capturing the structure in the source language and that in

		+ Word-to-chunk feedback (Model 3)	40k	30k	1024	1024	**37.26**	**82.23**	163.7

Table 3: The settings and results of the baseline systems and our systems. $|V_{src}|$ and $|V_{trg}|$ denote the vocabulary size of the source language and the target language, respectively. d_{emb} and d_{hid} are the dimension size of the word embeddings and hidden states, respectively. Only single NMT models (w/o ensembling) reported in WAT '16 are listed here. Full results are available on the WAT '16 Website.[10]

the target language. Note that all systems listed in Table 3, including our models, are single models without ensemble techniques.

4.2 Results

Proposed Models vs. Baselines Table 3 shows the experimental results on the ASPEC test set. We can observe that our best model (Model 3) outperformed all the single NMT models reported in WAT '16. The gain obtained by switching Word-based decoder to Chunk-based decoder ($+0.93$ BLEU and $+1.01$ RIBES) is larger than the gain obtained by switching word-based encoder to Tree-based encoder ($+0.27$ BLEU and $+0.06$ RIBES). This result shows that capturing the chunk structure in the target language is more effective than capturing the syntax structure in the source language. Compared with the character-based NMT model (Eriguchi et al., 2016a), our Model 3 performed better by $+5.74$ BLEU score and $+2.84$ RIBES score. One possible reason for this is that using a character-based model rather than a word-based model makes it more difficult to capture long-distance dependencies because the length of a target sequence becomes much longer in the character-based model.

Comparison between Baselines Among the five baselines, our reimplementation without chunk segmentations (the second line in Table 3) achieved the best BLEU score while the Eriguchi et al. (2016b)'s system (the fourth line in Table 3) achieved the best RIBES score. The most probable reasons for the superiority of our reimplementation over the Eriguchi et al. (2016a)'s word-based baseline (the first line in Table 3) is that the dimensions of word embeddings and hidden states in our systems are higher than theirs.

Feeding chunked training data to our baseline system (the third line in Table 3) instead of a normal data caused bad effects by -0.62 BLEU score and by -0.33 RIBES score. We evaluated the chunking ability of this system by comparing the positions of end-of-chunk tokens generated by this system with the chunk boundaries obtained by J.DepP. To our surprise, this word-based decoder could output chunk separations as accurate as our proposed Model 3 (both systems achieved F_1-score > 97). The results show that even a standard word-based decoder has the ability to predict chunk boundaries if they are given in training data. However, it is difficult for the word-based decoder to utilize the chunk information to improve the translation quality.

Decoding Speed Although the chunk-based decoder runs 2x slower than our word-based decoder, it is still practically acceptable (6 sentences per second). The character-based decoder (the fifth line in Table 3) is less time-consuming mainly because of its small vocabulary size ($|V_{trg}| = 3$k).

Chunk-level Evaluation To confirm that our models can capture local (intra-chunk) and global (inter-chunk) word orders well, we evaluated the translation quality at the chunk level. First, we performed *bunsetsu*-chunking on the reference translations in the test set. Then, for both reference translations and the outputs of our systems, we combined all the words in each chunk into a single token to regard a chunk as the basic translation unit instead of a word. Finally, we computed the chunk-based BLEU (C-BLEU) and RIBES

[9] Tree-to-Seq models are tested on CPUs instead of GPUs.

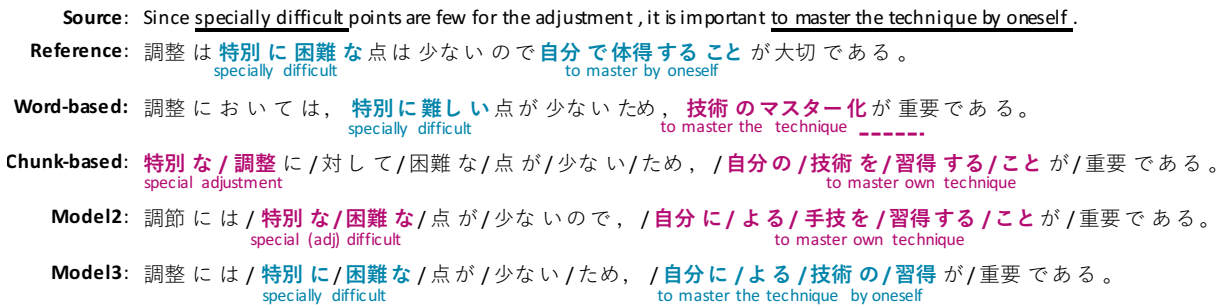

Figure 5: Translation examples. "/" denote chunk boundaries that are automatically determined by our decoders. Words colored blue and red respectively denote correct translations and wrong translations.

Decoder	C-BLEU	C-RIBES
Word-based (our implementation)	7.56	50.73
+ chunked training data via J.DepP	7.40	51.18
Proposed Chunk-based (Model 1)	7.59	50.47
+ Inter-chunk connection (Model 2)	7.78	51.48
+ Word-to-chunk feedback (Model 3)	**8.69**	**52.82**

Table 4: Chunk-based BLEU and RIBES with the systems using the word-based encoder.

(C-RIBES). The results are listed in Table 4. For the word-based decoder (the first line in Table 4), we performed *bunsetsu*-chunking by J.DepP on its outputs to obtain chunk boundaries. As another baseline (the second line in Table 4), we used the chunked sentences as training data instead of performing chunking after decoding. The results show that our models (Model 2 and Model 3) outperform the word-based decoders in both C-BLEU and C-RIBES. This indicates that our chunk-based decoders can produce more correct chunks in a more correct order than the word-based models.

Qualitative Analysis To clarify the qualitative difference between the word-based decoder and our chunk-based decoders, we show translation examples in Figure 5. Words in blue and red respectively denote correct translations and wrong translations. The word-based decoder (our implementation) has completely dropped the translation of "by oneself." On the other hand, Model 1 generated a slightly wrong translation "自分の技術を習得すること (to master own technique)." In addition, Model 1 has made another serious word-order error "特別な調整 (special adjustment)." These results suggest that Model 1 can capture longer dependencies in a long sequence than the word-based decoder. However, Model 1 is not good at modeling global word order because it cannot access enough information about previous outputs. The weakness of modeling word order was overcome in Model 2 thanks to the inter-chunk connections. However, Model 2 still suffered from the errors of function words: it still generates a wrong chunk "特別な (special)" instead of the correct one "特別に (specially)" and a wrong chunk "よる" instead of "より." Although these errors seem trivial, such mistakes with function words bring serious changes of sentence meaning. However, all of these problems have disappeared in Model 3. This phenomenon supports the importance of the feedback states to provide the decoder with a better ability to choose more accurate words in chunks.

5 Related Work

Much work has been done on using chunk (or phrase) structure to improve machine translation quality. The most notable work involved phrase-based SMT (Koehn et al., 2003), which has been the basis for a huge amount of work on SMT for more than ten years. Apart from this, Watanabe et al. (2003) proposed a chunk-based translation model that generates output sentences in a chunk-by-chunk manner. The chunk structure is effective not only for SMT but also for example-based machine translation (EBMT). Kim et al. (2010) proposed a chunk-based EBMT and showed that using chunk structures can help with finding better word alignments. Our work is different from theirs in that our models are based on NMT, but not SMT or EBMT. The decoders in the above studies can model the chunk structure by storing chunk pairs in a large table. In contrast, we do that by individually training a chunk generation model and a word prediction model with two RNNs.

While most of the NMT models focus on the conversion between sequential data, some works have tried to incorporate non-sequential informa-

tion into NMT (Eriguchi et al., 2016b; Su et al., 2017). Eriguchi et al. (2016b) use a Tree-based LSTM (Tai et al., 2015) to encode input sentence into context vectors. Given a syntactic tree of a source sentence, their tree-based encoder encodes words from the leaf nodes to the root nodes recursively. Su et al. (2017) proposed a lattice-based encoder that considers multiple tokenization results while encoding the input sentence. To prevent the tokenization errors from propagating to the whole NMT system, their attice-based encoder can utilize multiple tokenization results. These works focus on the encoding process and propose better encoders that can exploit the structures of the source language. In contrast, our work focuses on the decoding process to capture the structure of the target language. The encoders described above and our proposed decoders are complementary so they can be combined into a single network.

Considering that our Model 1 described in § 3.1 can be seen as a hierarchical RNN, our work is also related to previous studies that utilize multi-layer RNNs to capture hierarchical structures in data. Hierarchical RNNs are used for various NLP tasks such as machine translation (Luong and Manning, 2016), document modeling (Li et al., 2015; Lin et al., 2015), dialog generation (Serban et al., 2017), image captioning (Krause et al., 2016), and video captioning (Yu et al., 2016). In particular, Li et al. (2015) and Luong and Manning (2016) use hierarchical encoder-decoder models, but not for the purpose of learning syntactic structures of target sentences. Li et al. (2015) build hierarchical models at the sentence-word level to obtain better document representations. Luong and Manning (2016) build the word-character level to cope with the out-of-vocabulary problem. In contrast, we build a hierarchical models at the chunk-word level to explicitly capture the syntactic structure based on chunk segmentation.

In addition, the architecture of Model 3 is also related to stacked RNN, which has shown to be effective in improving the translation quality (Luong et al., 2015a; Sutskever et al., 2014). Although these architectures look similar to each other, there is a fundamental difference between the directions of the connection between two layers. A stacked RNN consists of multiple RNN layers that are connected from the input side to the output side at every time step. In contrast, our Model 3 has a different connection at each time step. Before it generates a chunk, there is a feed-forward connection from the chunk-level decoder to the word-level decoder. However, after generating a chunk representation, the connection is to be reversed to feed back the information from the word-level decoder to the chunk-level decoder. By switching the connections between two layers, our model can capture the chunk structure explicitly. This is the first work that proposes decoders for NMT that can capture plausible linguistic structures such as chunk.

Finally, we noticed that (Zhou et al., 2017) (which is accepted at the same time as this paper) have also proposed a chunk-based decoder for NMT. Their good experimental result on Chinese to English translation task also indicates the effectiveness of "chunk-by-chunk" decoders. Although their architecture is similar to our Model 2, there are several differences: (1) they adopt chunk-level attention instead of word-level attention; (2) their model predicts chunk tags (such as noun phrase), while ours only predicts chunk boundaries; and (3) they employ a boundary gate to decide the chunk boundaries, while we do that by simply having the model generate end-of-chunk tokens.

6 Conclusion

In this paper, we propose chunk-based decoders for NMT. As the attention mechanism in NMT plays a similar role to the translation model in phrase-based SMT, our chunk-based decoders are intended to capture the notion of chunks in chunk-based (or phrase-based) SMT. We utilize the chunk structure to efficiently capture long-distance dependencies and cope with the problem of free word-order languages such as Japanese. We designed three models that have hierarchical RNN-like architectures, each of which consists of a word-level decoder and a chunk-level decoder. We performed experiments on the WAT '16 English-to-Japanese translation task and found that our best model outperforms the strongest baselines by $+0.93$ BLEU score and by $+0.57$ RIBES score.

In future work, we will explore the optimal structures of chunk-based decoder for other free word-order languages such as Czech, German, and Turkish. In addition, we plan to combine our decoder with other encoders that capture language structure, such as a hierarchical RNN (Luong and Manning, 2016), a Tree-LSTM (Eriguchi et al., 2016b), or an order-free encoder, such as a CNN (Kalchbrenner and Blunsom, 2013).

Abstract

We introduce a Multi-modal Neural Machine Translation model in which a doubly-attentive decoder naturally incorporates *spatial* visual features obtained using pre-trained convolutional neural networks, bridging the gap between image description and translation. Our decoder learns to attend to source-language words and parts of an image independently by means of two *separate attention mechanisms* as it generates words in the target language. We find that our model can efficiently exploit not just back-translated in-domain multi-modal data but also large general-domain text-only MT corpora. We also report state-of-the-art results on the Multi30k data set.

1 Introduction

Neural Machine Translation (NMT) has been successfully tackled as a *sequence to sequence* learning problem (Kalchbrenner and Blunsom, 2013; Cho et al., 2014b; Sutskever et al., 2014) where each training example consists of one source and one target variable-length sequences, with no prior information on the alignment between the two.

In the context of NMT, Bahdanau et al. (2015) first proposed to use an *attention mechanism* in the decoder, which is trained to attend to the relevant source-language words as it generates each word of the target sentence. Similarly, Xu et al. (2015) proposed an attention-based model for the task of image description generation (IDG) where a model learns to attend to specific parts of an image representation (the source) as it generates its description (the target) in natural language.

We are inspired by recent successes in applying attention-based models to NMT and IDG. In this work, we propose an end-to-end attention-based multi-modal neural machine translation (MNMT) model which effectively incorporates *two independent attention mechanisms*, one over source-language words and the other over different areas of an image.

Our main contributions are:

- We propose a novel attention-based MNMT model which incorporates spatial visual features in a separate visual attention mechanism;
- We use a medium-sized, back-translated multi-modal in-domain data set and large general-domain text-only MT corpora to pre-train our models and show that our MNMT model can efficiently exploit both;
- We show that images bring useful information into an NMT model, e.g. in situations in which sentences describe objects illustrated in the image.

To the best of our knowledge, previous MNMT models in the literature that utilised spatial visual features did not significantly improve over a comparable model that used global visual features or even only textual features (Caglayan et al., 2016a; Calixto et al., 2016; Huang et al., 2016; Libovický et al., 2016; Specia et al., 2016). In this work, we wish to address this issue and propose an MNMT model that uses, in addition to an attention mechanism over the source-language words, an additional visual attention mechanism to incorporate spatial visual features, and still improves on simpler text-only and multi-modal attention-based NMT models.

The remainder of this paper is structured as follows. We first briefly revisit the attention-based NMT framework (§2) and expand it into an MNMT framework (§3). In §4, we introduce the

Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1175

datasets we use to train and evaluate our models, in §5 we discuss our experimental setup and analyse and discuss our results. Finally, in §6 we discuss relevant related work and in §7 we draw conclusions and provide avenues for future work.

2 Background and Notation

2.1 Attention-based NMT

In this section, we describe the attention-based NMT model introduced by Bahdanau et al. (2015). Given a source sequence $X = (x_1, x_2, \cdots, x_N)$ and its translation $Y = (y_1, y_2, \cdots, y_M)$, an NMT model aims to build a single neural network that translates X into Y by directly learning to model $p(Y \mid X)$. The entire network consists of one *encoder* and one *decoder* with one *attention mechanism*, typically implemented as two Recurrent Neural Networks (RNN) and one multilayer perceptron, respectively. Each x_i is a row index in a source lookup or word embedding matrix $\boldsymbol{E_x} \in \mathbb{R}^{|V_x| \times d_x}$, as well as each y_j being an index in a target lookup or word embedding matrix $\boldsymbol{E_y} \in \mathbb{R}^{|V_y| \times d_y}$, V_x and V_y are source and target vocabularies, and d_x and d_y are source and target word embeddings dimensionalities, respectively.

The encoder is a bi-directional RNN with GRU (Cho et al., 2014a), where a forward RNN $\overrightarrow{\Phi}_{\text{enc}}$ reads X word by word, from left to right, and generates a sequence of *forward annotation vectors* $(\overrightarrow{\boldsymbol{h}}_1, \overrightarrow{\boldsymbol{h}}_2, \cdots, \overrightarrow{\boldsymbol{h}}_N)$ at each encoder time step $i \in [1, N]$. Similarly, a backward RNN $\overleftarrow{\Phi}_{\text{enc}}$ reads X from right to left, word by word, and generates a sequence of *backward annotation vectors* $(\overleftarrow{\boldsymbol{h}}_N, \overleftarrow{\boldsymbol{h}}_{N-1}, \cdots, \overleftarrow{\boldsymbol{h}}_1)$. The final annotation vector is the concatenation of forward and backward vectors $\boldsymbol{h}_i = \left[\overrightarrow{\boldsymbol{h}_i}; \overleftarrow{\boldsymbol{h}_i}\right]$, and $C = (\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_N)$ is the set of source annotation vectors.

These annotation vectors are in turn used by the decoder, which is essentially a neural language model (LM) (Bengio et al., 2003) conditioned on the previously emitted words and the source sentence via an attention mechanism. A multilayer perceptron is used to initialise the decoder's hidden state $\boldsymbol{s}_0$ at time step $t = 0$, where the input to this network is the concatenation of the last forward and backward vectors $\left[\overrightarrow{\boldsymbol{h}_N}; \overleftarrow{\boldsymbol{h}_1}\right]$.

At each time step t of the decoder, a *time-dependent* source context vector $\boldsymbol{c}_t$ is computed based on the annotation vectors C and the decoder previous hidden state $\boldsymbol{s}_{t-1}$. This is part of the formulation of the *conditional GRU* and is described further in §2.2. In other words, the encoder is a bi-directional RNN with GRU and the decoder is an RNN with a conditional GRU.

Given a hidden state $\boldsymbol{s}_t$, the probabilities for the next target word are computed using one projection layer followed by a softmax layer as illustrated in eq. (1), where the matrices $\boldsymbol{L}_o$, $\boldsymbol{L}_s$, $\boldsymbol{L}_w$ and $\boldsymbol{L}_c$ are transformation matrices and $\boldsymbol{c}_t$ is a time-dependent source context vector generated by the conditional GRU.

2.2 Conditional GRU

The conditional GRU[1], illustrated in Figure 1, has three main components computed at each time step t of the decoder:

- REC_1 computes a hidden state proposal $\boldsymbol{s}'_t$ based on the previous hidden state $\boldsymbol{s}_{t-1}$ and the previously emitted word $\hat{y}_{t-1}$;
- ATT_{src}[2] is an attention mechanism over the hidden states of the source-language RNN and computes $\boldsymbol{c}_t$ using all source annotation vectors C and the hidden state proposal $\boldsymbol{s}'_t$;
- REC_2 computes the final hidden state $\boldsymbol{s}_t$ using the hidden state proposal $\boldsymbol{s}'_t$ and the time-dependent source context vector $\boldsymbol{c}_t$.

First, a single-layer feed-forward network is used to compute an *expected alignment* $e^{\text{src}}_{t,i}$ between each source annotation vector $\boldsymbol{h}_i$ and the target word $\hat{y}_t$ to be emitted at the current time step t, as shown in Equations (2) and (3):

$$e^{\text{src}}_{t,i} = (\boldsymbol{v}^{\text{src}}_a)^T \tanh(\boldsymbol{U}^{\text{src}}_a \boldsymbol{s}'_t + \boldsymbol{W}^{\text{src}}_a \boldsymbol{h}_i), \quad (2)$$

$$\alpha^{\text{src}}_{t,i} = \frac{\exp\left(e^{\text{src}}_{t,i}\right)}{\sum_{j=1}^{N} \exp\left(e^{\text{src}}_{t,j}\right)}, \quad (3)$$

where $\alpha^{\text{src}}_{t,i}$ is the normalised alignment matrix between each source annotation vector $\boldsymbol{h}_i$ and the word $\hat{y}_t$ to be emitted at time step t, and $\boldsymbol{v}^{\text{src}}_a$, $\boldsymbol{U}^{\text{src}}_a$ and $\boldsymbol{W}^{\text{src}}_a$ are model parameters.

Finally, a time-dependent source context vector $\boldsymbol{c}_t$ is computed as a weighted sum over the source annotation vectors, where each vector is weighted by the attention weight $\alpha^{\text{src}}_{t,i}$, as in eq. (4):

$$\boldsymbol{c}_t = \sum_{i=1}^{N} \alpha^{\text{src}}_{t,i} \boldsymbol{h}_i. \quad (4)$$

[1] https://github.com/nyu-dl/dl4mt-tutorial/blob/master/docs/cgru.pdf.

[2] ATT_{src} is named ATT in the original technical report.

$$p(y_t = k \mid \boldsymbol{y}_{<t}, \boldsymbol{c}_t) \propto \exp(\boldsymbol{L_o} \tanh(\boldsymbol{L_s} \boldsymbol{s}_t + \boldsymbol{L_w} \boldsymbol{E_y}[\hat{y}_{t-1}] + \boldsymbol{L_c} \boldsymbol{c}_t)). \quad (1)$$

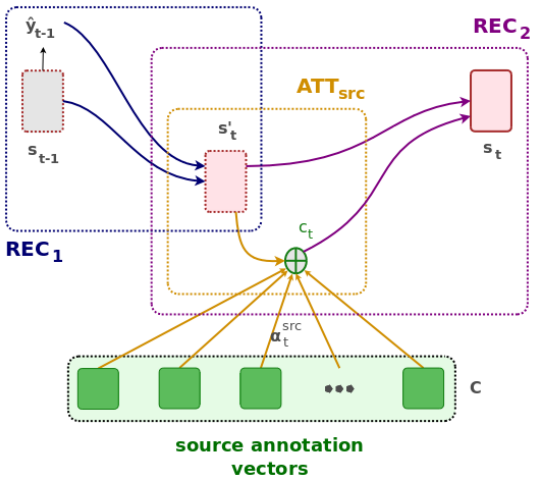

Figure 1: An illustration of the conditional GRU: the steps taken to compute the current hidden state $\boldsymbol{s}_t$ from the previous state $\boldsymbol{s}_{t-1}$, the previously emitted word $\hat{y}_{t-1}$, and the source annotation vectors C, including the candidate hidden state $\boldsymbol{s}'_t$ and the source-language attention vector $\boldsymbol{c}_t$.

3 Multi-modal NMT

Our MNMT model can be seen as an expansion of the attention-based NMT framework described in §2.1 with the addition of a *visual component* to incorporate spatial visual features.

We use publicly available pre-trained CNNs for image feature extraction. Specifically, we extract spatial image features for all images in our dataset using the 50-layer Residual network (ResNet-50) of He et al. (2015). These spatial features are the activations of the `res4f` layer, which can be seen as encoding an image in a 14×14 grid, where each of the entries in the grid is represented by a 1024D feature vector that only encodes information about that specific region of the image. We vectorise this 3-tensor into a 196×1024 matrix $A = (\boldsymbol{a}_1, \boldsymbol{a}_2, \cdots, \boldsymbol{a}_L), \boldsymbol{a}_l \in \mathbb{R}^{1024}$ where each of the L = 196 rows consists of a 1024D feature vector and each column, i.e. feature vector, represents one grid in the image.

3.1 NMT$_{\text{SRC+IMG}}$: decoder with two independent attention mechanisms

Model NMT$_{\text{SRC+IMG}}$ integrates two separate attention mechanisms over the source-language words and visual features in a single decoder RNN. Our doubly-attentive decoder RNN is conditioned on the previous hidden state of the decoder and the previously emitted word, as well as the source sentence and the image via two independent attention mechanisms, as illustrated in Figure 2.

We implement this idea expanding the conditional GRU described in §2.2 onto a *doubly-conditional* GRU. To that end, in addition to the source-language attention, we introduce a new attention mechanism ATT$_{\text{img}}$ to the original conditional GRU proposal. This visual attention computes a *time-dependent* image context vector $\boldsymbol{i}_t$ given a hidden state proposal $\boldsymbol{s}'_t$ and the image annotation vectors $A = (\boldsymbol{a}_1, \boldsymbol{a}_2, \cdots, \boldsymbol{a}_L)$ using the "soft" attention (Xu et al., 2015).

This attention mechanism is very similar to the source-language attention with the addition of a *gating scalar*, explained further below. First, a single-layer feed-forward network is used to compute an *expected alignment* $e^{\text{img}}_{t,l}$ between each image annotation vector $\boldsymbol{a}_l$ and the target word to be emitted at the current time step t, as in eqs. (5) and (6):

$$e^{\text{img}}_{t,l} = (\boldsymbol{v}^{\text{img}}_a)^T \tanh(\boldsymbol{U}^{\text{img}}_a \boldsymbol{s}'_t + \boldsymbol{W}^{\text{img}}_a \boldsymbol{a}_l), \quad (5)$$

$$\alpha^{\text{img}}_{t,l} = \frac{\exp(e^{\text{img}}_{t,l})}{\sum_{j=1}^{L} \exp(e^{\text{img}}_{t,j})}, \quad (6)$$

where $\alpha^{\text{img}}_{t,l}$ is the normalised alignment matrix between all the image patches $\boldsymbol{a}_l$ and the target word to be emitted at time step t, and $\boldsymbol{v}^{\text{img}}_a$, $\boldsymbol{U}^{\text{img}}_a$ and $\boldsymbol{W}^{\text{img}}_a$ are model parameters. Note that Equations (2) and (3), that compute the expected source alignment $e^{\text{src}}_{t,i}$ and the weight matrices $\alpha^{\text{src}}_{t,i}$, and eqs. (5) and (6) that compute the expected image alignment $e^{\text{img}}_{t,l}$ and the weight matrices $\alpha^{\text{img}}_{t,l}$, both compute similar statistics over the source and image annotations, respectively.

In eq. (7) we compute $\beta_t \in [0, 1]$, a gating scalar used to weight the expected importance of the image context vector in relation to the next target word at time step t:

$$\beta_t = \sigma(\boldsymbol{W}_\beta \boldsymbol{s}_{t-1} + \boldsymbol{b}_\beta), \quad (7)$$

where $\boldsymbol{W}_\beta$, $\boldsymbol{b}_\beta$ are model parameters. It is in turn used to compute the time-dependent image context vector $\boldsymbol{i}_t$ for the current decoder time step t, as in eq. (8):

$$\boldsymbol{i}_t = \beta_t \sum_{l=1}^{L} \alpha^{\text{img}}_{t,l} \boldsymbol{a}_l. \quad (8)$$

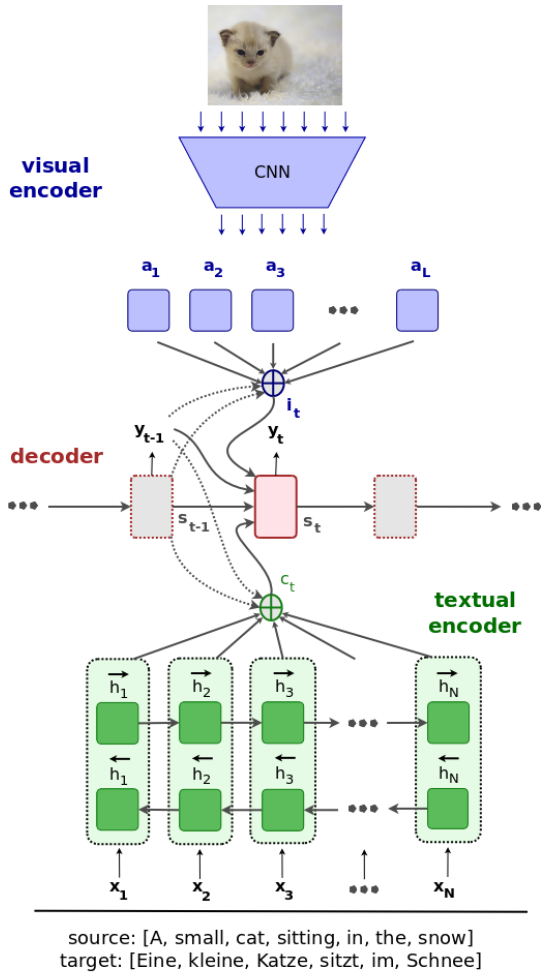

Figure 2: A doubly-attentive decoder learns to attend to image patches and source-language words independently when generating translations.

The only difference between Equations (4) (source context vector) and (8) (image context vector) is that the latter uses a gating scalar, whereas the former does not. We use β following Xu et al. (2015) who empirically found it to improve the variability of the image descriptions generated with their model.

Finally, we use the time-dependent image context vector $\boldsymbol{i}_t$ as an additional input to a modified version of REC$_2$ (§2.2), which now computes the final hidden state $\boldsymbol{s}_t$ using the hidden state proposal $\boldsymbol{s}'_t$, and the time-dependent source and image context vectors $\boldsymbol{c}_t$ and $\boldsymbol{i}_t$, as in eq. (9):

$$\begin{aligned}
\boldsymbol{z}_t &= \sigma(\boldsymbol{W}_z^{\text{src}}\boldsymbol{c}_t + \boldsymbol{W}_z^{\text{img}}\boldsymbol{i}_t + \boldsymbol{U}_z\boldsymbol{s}'_j),\\
\boldsymbol{r}_t &= \sigma(\boldsymbol{W}_r^{\text{src}}\boldsymbol{c}_t + \boldsymbol{W}_r^{\text{img}}\boldsymbol{i}_t + \boldsymbol{U}_r\boldsymbol{s}'_j),\\
\underline{\boldsymbol{s}}_t &= \tanh(\boldsymbol{W}^{\text{src}}\boldsymbol{c}_t + \boldsymbol{W}^{\text{img}}\boldsymbol{i}_t + \boldsymbol{r}_t \odot (\boldsymbol{U}\boldsymbol{s}'_t)),\\
\boldsymbol{s}_t &= (1 - \boldsymbol{z}_t) \odot \underline{\boldsymbol{s}}_t + \boldsymbol{z}_t \odot \boldsymbol{s}'_t. \qquad (9)
\end{aligned}$$

In Equation (10), the probabilities for the next target word are computed using the new multimodal hidden state $\boldsymbol{s}_t$, the previously emitted word $\hat{y}_{t-1}$, and the two context vectors $\boldsymbol{c}_t$ and $\boldsymbol{i}_t$, where $\boldsymbol{L}_o$, $\boldsymbol{L}_s$, $\boldsymbol{L}_w$, $\boldsymbol{L}_{cs}$ and $\boldsymbol{L}_{ci}$ are projection matrices and trained with the model.

4 Data

The Flickr30k data set contains 30k images and 5 descriptions in English for each image (Young et al., 2014). In this work, we use the Multi30k dataset (Elliott et al., 2016), which consists of two multilingual expansions of the original Flickr30k: one with translated data and another one with comparable data, henceforth referred to as M30k$_\text{T}$ and M30k$_\text{C}$, respectively.

For each of the 30k images in the Flickr30k, the M30k$_\text{T}$ has one of the English descriptions manually translated into German by a professional translator. Training, validation and test sets contain 29k, 1,014 and 1k images respectively, each accompanied by a sentence pair (the original English sentence and its translation into German). For each of the 30k images in the Flickr30k, the M30k$_\text{C}$ has five descriptions in German collected independently from the English descriptions. Training, validation and test sets contain 29k, 1,014 and 1k images respectively, each accompanied by five sentences in English and five sentences in German.

We use the entire M30k$_\text{T}$ training set for training our MNMT models, its validation set for model selection with BLEU (Papineni et al., 2002), and its test set for evaluation. In addition, since the amount of training data available is small, we build a back-translation model using the text-only NMT model described in §2.1 trained on the Multi30k$_\text{T}$ data set (German→English and English→German), without images. We use this model to back-translate the 145k German (English) descriptions in the Multi30k$_\text{C}$ into English (German) and include the triples (synthetic English description, German description, image) when translating into German, and the triples (synthetic German description, English description, image) when translating into English, as additional training data (Sennrich et al., 2016a).

We also use the WMT 2015 text-only parallel corpora available for the English–German language pair, consisting of about 4.3M sentence pairs (Bojar et al., 2015). These include the Eu-

$$p(y_t = k \mid \boldsymbol{y}_{<t}, C, A) \propto \exp(\boldsymbol{L_o} \tanh(\boldsymbol{L_s} \boldsymbol{s}_t + \boldsymbol{L_w} \boldsymbol{E_y}[\hat{y}_{t-1}] + \boldsymbol{L_{cs}} \boldsymbol{c}_t + \boldsymbol{L_{ci}} \boldsymbol{i}_t)). \quad (10)$$

roparl v7 (Koehn, 2005), News Commentary and Common Crawl corpora, which are concatenated and used for pre-training.

We use the scripts in the Moses SMT Toolkit (Koehn et al., 2007) to normalise and tokenize English and German descriptions, and we also convert space-separated tokens into subwords (Sennrich et al., 2016b). All models use a common vocabulary of $83,093$ English and $91,141$ German subword tokens. If sentences in English or German are longer than 80 tokens, they are discarded. We train models to translate from English into German, as well as for German into English, and report evaluation of cased, tokenized sentences with punctuation.

5 Experimental setup

Our encoder is a bidirectional RNN with GRU, one 1024D single-layer forward and one 1024D single-layer backward RNN. Source and target word embeddings are 620D each and trained jointly with the model. Word embeddings and other non-recurrent matrices are initialised by sampling from a Gaussian $\mathcal{N}(0, 0.01^2)$, recurrent matrices are random orthogonal and bias vectors are all initialised to zero.

Visual features are obtained by feeding images to the pre-trained ResNet-50 and using the activations of the `res4f` layer (He et al., 2015). We apply dropout with a probability of 0.5 in the encoder bidirectional RNN, the image features, the decoder RNN and before emitting a target word. We follow Gal and Ghahramani (2016) and apply dropout to the encoder bidirectional and the decoder RNN using one same mask in all time steps.

All models are trained using stochastic gradient descent with ADADELTA (Zeiler, 2012) with minibatches of size 80 (text-only NMT) or 40 (MNMT), where each training instance consists of one English sentence, one German sentence and one image (MNMT). We apply early stopping for model selection based on BLEU4, so that if a model does not improve on BLEU4 in the validation set for more than 20 epochs, training is halted.

The translation quality of our models is evaluated quantitatively in terms of BLEU4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), TER (Snover et al., 2006), and chrF3 (Popović, 2015).[3] We report statistical significance with approximate randomisation for the first three metrics with MultEval (Clark et al., 2011).

5.1 Baselines

We train a text-only phrase-based SMT (PBSMT) system and a text-only NMT model for comparison (English→German and German→English). Our PBSMT baseline is built with Moses and uses a 5–gram LM with modified Kneser-Ney smoothing (Kneser and Ney, 1995). It is trained on the English→German (German→English) descriptions of the M30k$_{\mathrm{T}}$, whereas its LM is trained on the German (English) descriptions only. We use minimum error rate training to tune the model with BLEU (Och, 2003). The text-only NMT baseline is the one described in §2.1 and is trained on the M30k$_{\mathrm{T}}$'s English–German descriptions, again in both language directions.

When translating into German, we also compare our model against two publicly available results obtained with multi-modal attention-based NMT models. The first model is Huang et al. (2016)'s best model trained on the same data, and the second is their best model using additional object detections, respectively models `m1` (image at head) and `m3` in the authors' paper.

5.2 Results

In Table 1, we show results for the two text-only baselines NMT and PBSMT, the multi-modal models of Huang et al. (2016), and our MNMT models trained on the M30k$_{\mathrm{T}}$ and pre-trained on the in-domain back-translated M30k$_{\mathrm{C}}$ and the general-domain text-only English-German MT corpora from WMT 2015. All models are trained to translate from English into German.

Training on M30k$_{\mathrm{T}}$ One main finding is that our model consistently outperforms the comparable model of Huang et al. (2016) when translating into German, with improvements of $+1.4$ BLEU and $+2.7$ METEOR. In fact, even when their model has access to more data our model still improves by $+0.9$ METEOR.

Moreover, we can also conclude from Table 1 that PBSMT performs better at recall-oriented

[3] We specifically compute character 6-gram F3, and additionally character precision and recall for comparison.

Table 1: BLEU4, METEOR, chrF3, character-level precision and recall (higher is better) and TER scores (lower is better) on the translated Multi30k ($M30k_T$) test set. Best text-only baselines results are underlined and best overall results appear in bold. We show Huang et al. (2016)'s improvements over the best text-only baseline in parentheses. Results are significantly better than the NMT baseline (†) and the SMT baseline (‡) with $p < 0.01$ (no pre-training) or $p < 0.05$ (when pre-training either on the back-translated $M30k_C$ or WMT'15 corpora).

metrics, i.e. METEOR and chrF3, whereas NMT is better at precision-oriented ones, i.e. BLEU4. This is somehow expected, since the attention mechanism in NMT (Bahdanau et al., 2015) does not explicitly take attention weights from previous time steps into account, an thus lacks the notion of source coverage as in SMT (Koehn et al., 2003; Tu et al., 2016). We note that these ideas are complementary and incorporating coverage into model $NMT_{SRC+IMG}$ could lead to more improvements, especially in recall-oriented metrics. Nonetheless, our doubly-attentive model shows consistent gains in both precision- and recall-oriented metrics in comparison to the text-only NMT baseline, i.e. it is significantly better according to BLEU4, METEOR and TER ($p < 0.01$), and it also improves chrF3 by $+2.1$. In comparison to the PBSMT baseline, our proposed model still significantly improves according to both BLEU4 and TER ($p < 0.01$), also increasing METEOR by $+0.7$ but with an associated p-value of $p = 0.071$, therefore not significant for $p < 0.05$. Although chrF3 is the only metric in which the PBSMT model scores best, the difference between our model and the latter is only 0.1, meaning that they are practically equivalent. We note that model $NMT_{SRC+IMG}$ consistently increases character recall in comparison to the text-only NMT baseline. Although it can happen at the expense of character precision, gains in recall are always much higher than any eventual loss in precision, leading to consistent improvements in chrF3.

In Table 2, we observe that when translating into English and training on the original $M30k_T$, model $NMT_{SRC+IMG}$ outperforms both baselines by a large margin, according to all four metrics evaluated. We also note that both model $NMT_{SRC+IMG}$'s character-level precision and re-

Table 2: BLEU4, METEOR, chrF3 (higher is better), and TER scores (lower is better) on the translated Multi30k (M30k_{T}) test set. Best text-only baselines results are underlined and best overall results appear in bold. Results are significantly better than the NMT baseline (†) and the SMT baseline (‡) with $p < 0.01$.

call are higher than those of the two baselines, in contrast to results obtained when translating from English into German. This suggests that model $\text{NMT}_{\text{SRC+IMG}}$ might better integrate the image features when translating into an "easier" language, i.e. a language with less morphology, although experiments involving more language pairs are necessary to confirm whether this is indeed the case.

Pre-training We now discuss results for models pre-trained using different data sets. We first pre-trained the two text-only baselines PBSMT and NMT, and our MNMT model on the back-translated M30k_{C}, a medium-sized in-domain image description data set (145k training instances), in both directions. We also pre-trained the same models on the English–German parallel sentences of much larger MT data sets, i.e. the concatenation of the Europarl (Koehn, 2005), Common Crawl and News Commentary corpora, used in WMT 2015 (∼4.3M parallel sentences). Model PBSMT (concat.) used the concatenation of the pre-training and training data for training, and model PBSMT (LM) used the general-domain German sentences as additional data to train the LM. From Tables 1 and 2, it is clear that model $\text{NMT}_{\text{SRC+IMG}}$ can learn from both in-domain, multi-modal pre-training data sets as well as text-only, general domain ones.

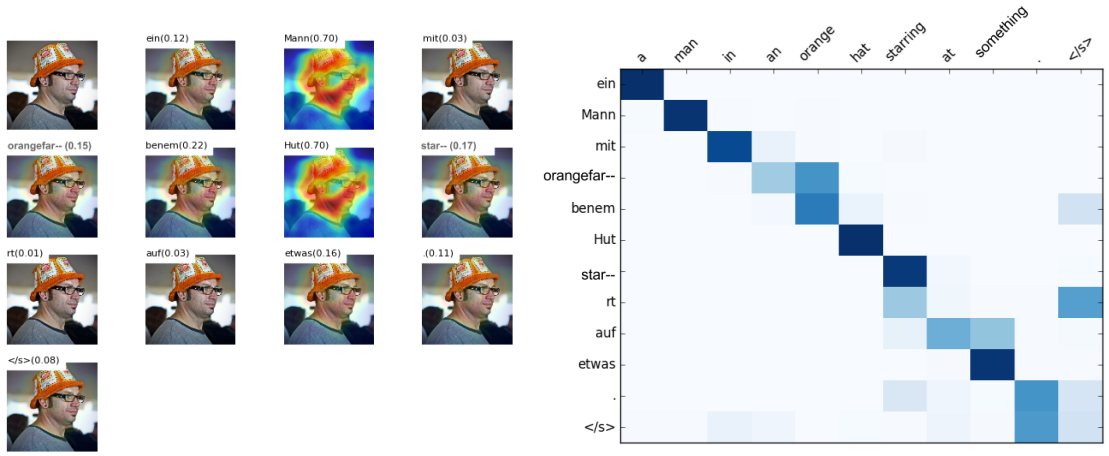
Pre-training on M30k_{C} When pre-training on the back-translated M30k_{C} and translating into German, the recall-oriented chrF3 shows a difference of 1.4 points between PBSMT and our model, mostly due to character recall; nonetheless, our model still improved by the same margin on the text-only NMT baseline. Our model still outperforms the PBSMT baseline according to BLEU4 and TER, and the text-only NMT baseline according to all metrics ($p < .05$).

When translating into English, model $\text{NMT}_{\text{SRC+IMG}}$ still consistently scores higher according to all metrics evaluated, although the differences between its translations and those obtained with the NMT baseline are no longer statistically significant ($p < 0.01$).

Pre-training on WMT 2015 corpora We also pre-trained our English–German models on the WMT 2015 corpora, which took 10 days, i.e. ∼6–7 epochs. Results show that model $\text{NMT}_{\text{SRC+IMG}}$ improves significantly over the NMT baseline according to BLEU4, and is consistently better than the PBSMT baseline according to all four metrics.[4] This is a strong indication that model $\text{NMT}_{\text{SRC+IMG}}$ can exploit the additional pre-training data efficiently, both general- and in-domain. While the PBSMT model is still competitive when using additional in-domain data—according to METEOR and chrF3— the same cannot be said when using general-domain pre-training corpora. From our experiments, NMT models in general, and especially model $\text{NMT}_{\text{SRC+IMG}}$, thrive when training and test domains are mixed, which is a very common real-world scenario.

Textual and visual attention In Figure 3, we visualise the visual and textual attention weights for an entry of the M30k_{T} test set. In the visual attention, the β gate (written in parentheses after each word) caused the image features to be used mostly to generate the words *Mann* (man) and *Hut* (hat), two highly visual terms in the sentence. We observe that in general visually grounded terms, e.g. Mann and Hut, usually have a high associated β value, whereas other less visual terms like *mit* (with) or *auf* (at) do not. That causes the model to use the image features when it is describing a visual concept in the sentence, which is an interest-

[4] In order for PBSMT models to remain competitive, we believe more advanced data selection techniques are needed, which are out of the scope of this work.



(a) Image–target word alignments.

(b) Source–target word alignments.

Figure 3: Visualisation of image– and source–target word alignments for the M30k$_{\text{T}}$ test set.

ing feature of our model. Interestingly, our model is very selective when choosing to use image features: it only assigned $\beta > 0.5$ for 20% of the outputted target words, and $\beta > 0.8$ to only 8%. A manual inspection of translations shows that these words are mostly concrete nouns with a strong visual appeal.

Lastly, using two independent attention mechanisms is a good compromise between model compactness and flexibility. While the attention-based NMT model baseline has ∼200M parameters, model NMT$_{\text{SRC+IMG}}$ has ∼213M, thus using just ∼6.6% more parameters than the latter.

6 Related work

Multi-modal MT was just recently addressed by the MT community by means of a shared task (Specia et al., 2016). However, there has been a considerable amount of work on natural language generation from non-textual inputs. Mao et al. (2014) introduced a multi-modal RNN that integrates text and visual features and applied it to the tasks of image description generation and image–sentence ranking. In their work, the authors incorporate global image features in a separate multi-modal layer that merges the RNN textual representations and the global image features. Vinyals et al. (2015) proposed an influential neural IDG model based on the sequence-to-sequence framework, which is trained end-to-end. Elliott et al. (2015) put forward a model to generate multilingual descriptions of images by learning and transferring features between two independent, non-attentive neural image description models.[5] Venugopalan et al. (2015) introduced a model trained end-to-end to generate textual descriptions of open-domain videos from the video frames based on the sequence-to-sequence framework. Finally, Xu et al. (2015) introduced the first attention-based IDG model where an attentive decoder learns to attend to different parts of an image as it generates its description in natural language.

In the context of NMT, Zoph and Knight (2016) introduced a multi-source attention-based NMT model trained to translate a pair of sentences in two different source languages into a target language, and reported considerable improvements over a single-source baseline. Dong et al. (2015) proposed a multi-task learning approach where a model is trained to translate from one source language into multiple target languages. Firat et al. (2016) put forward a multi-way model trained to translate between many different source and target languages. Instead of one attention mechanism per language pair as in Dong et al. (2015), which would lead to a quadratic number of attention mechanisms in relation to language pairs, they use a shared attention mechanism where each target language has one attention shared by all source languages. Luong et al. (2016) proposed a multi-task approach where they train a model using two tasks and a shared decoder: the main task is to translate from German into English and the sec-

[5] Although their model has not been devised with translation as its primary goal, theirs is one of the baselines of the first shared task in multi-modal MT in WMT 2016 (Specia et al., 2016).

ondary task is to generate English image descriptions. They show improvements in the main translation task when also training for the secondary image description task. Although not an NMT model, Hitschler et al. (2016) recently used image features to re-rank translations of image descriptions generated by an SMT model and reported significant improvements.

Although no purely neural multi-modal model to date significantly improves on both text-only NMT and SMT models (Specia et al., 2016), different research groups have proposed to include global and spatial visual features in re-ranking n-best lists generated by an SMT system or directly in an NMT framework with some success (Caglayan et al., 2016a; Calixto et al., 2016; Huang et al., 2016; Libovický et al., 2016; Shah et al., 2016). To the best of our knowledge, the best published results of a purely MNMT model are those of Huang et al. (2016), who proposed to use global visual features extracted with the VGG19 network (Simonyan and Zisserman, 2015) for an entire image, and also for regions of the image obtained using the RCNN of Girshick et al. (2014). Their best model improves over a strong text-only NMT baseline and is comparable to results obtained with an SMT model trained on the same data. For that reason, their models are used as baselines in our experiments whenever possible.

Our work differs from previous work in that, first, we propose attention-based MNMT models. This is an important difference since the use of attention in NMT has become standard and is the current state-of-the-art (Jean et al., 2015; Luong et al., 2015; Firat et al., 2016; Sennrich et al., 2016b). Second, we propose a *doubly-attentive model* where we effectively fuse two mono-modal attention mechanisms into one multi-modal decoder, training the entire model jointly and end-to-end. Additionally, we are interested in how to merge textual and visual representations into multi-modal representations when generating words in the target language, which differs substantially from text-only translation tasks even when these translate from many source languages and/or into many target languages (Dong et al., 2015; Firat et al., 2016; Zoph and Knight, 2016). To the best of our knowledge, we are among the first[6] to integrate multi-modal inputs in NMT via independent attention mechanisms.

Applications Initial experiments with model $\text{NMT}_{\text{SRC+IMG}}$ have been reported in Calixto et al. (2016). Additionally, $\text{NMT}_{\text{SRC+IMG}}$ has been applied to the machine translation of user-generated product listings from an e-commerce website, while also making use of the product images to improve translations (Calixto et al., 2017b,a).

7 Conclusions and Future Work

We have introduced a novel attention-based, multi-modal NMT model to incorporate spatial visual information into NMT. We have reported state-of-the-art results on the M30k_{T} test set, improving on previous multi-modal attention-based models. We have also showed that our model can be efficiently pre-trained on both medium-sized back-translated in-domain multi-modal data as well as also large general-domain text-only MT corpora, finding that it is able to exploit the additional data regardless of the domain. Our model also compares favourably to both NMT and PB-SMT baselines evaluated on the same training data. In the future, we will incorporate coverage into our model and study how to apply it to other Natural Language Processing tasks.

Abstract

While end-to-end neural machine translation (NMT) has made remarkable progress recently, it still suffers from the data scarcity problem for low-resource language pairs and domains. In this paper, we propose a method for zero-resource NMT by assuming that parallel sentences have close probabilities of generating a sentence in a third language. Based on the assumption, our method is able to train a source-to-target NMT model ("student") without parallel corpora available guided by an existing pivot-to-target NMT model ("teacher") on a source-pivot parallel corpus. Experimental results show that the proposed method significantly improves over a baseline pivot-based model by +3.0 BLEU points across various language pairs.

1 Introduction

Neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015), which directly models the translation process in an end-to-end way, has attracted intensive attention from the community. Although NMT has achieved state-of-the-art translation performance on resource-rich language pairs such as English-French and German-English (Luong et al., 2015; Jean et al., 2015; Wu et al., 2016; Johnson et al., 2016), it still suffers from the unavailability of large-scale parallel corpora for translating low-resource languages. Due to the large parameter space, neural models usually learn poorly from low-count events, resulting in a poor choice for low-resource language pairs. Zoph et al. (2016) indicate that NMT obtains much worse translation quality than a statistical machine translation (SMT) system on low-resource languages.

As a result, a number of authors have endeavored to explore methods for translating language pairs without parallel corpora available. These methods can be roughly divided into two broad categories: *multilingual* and *pivot-based*. Firat et al. (2016b) present a multi-way, multilingual model with shared attention to achieve zero-resource translation. They fine-tune the attention part using pseudo bilingual sentences for the zero-resource language pair. Another direction is to develop a universal NMT model in multilingual scenarios (Johnson et al., 2016; Ha et al., 2016). They use parallel corpora of multiple languages to train one single model, which is then able to translate a language pair without parallel corpora available. Although these approaches prove to be effective, the combination of multiple languages in modeling and training leads to increased complexity compared with standard NMT.

Another direction is to achieve source-to-target NMT without parallel data via a *pivot*, which is either text (Cheng et al., 2016a) or image (Nakayama and Nishida, 2016). Cheng et al. (2016a) propose a pivot-based method for zero-resource NMT: it first translates the source language to a pivot language, which is then translated to the target language. Nakayama and Nishida (2016) show that using multimedia information as pivot also benefits zero-resource translation. However, pivot-based approaches usually need to divide the decoding process into two steps, which is not only more computationally expensive, but also potentially suffers from the error propagation problem (Zhu et al., 2013).

In this paper, we propose a new method for zero-resource neural machine translation. Our

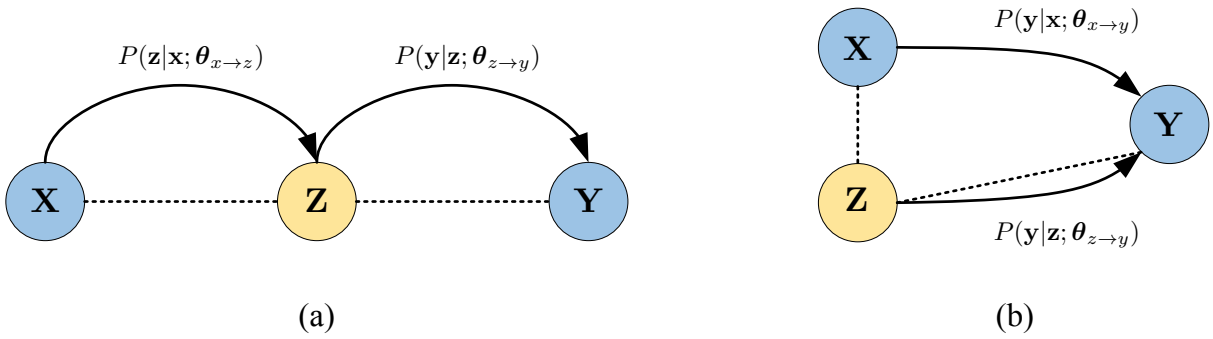

Figure 1: (a) The pivot-based approach and (b) the teacher-student approach to zero-resource neural machine translation. $\mathbf{X}$, $\mathbf{Y}$, and $\mathbf{Z}$ denote source, target, and pivot languages, respectively. We use a dashed line to denote that there is a parallel corpus available for the connected language pair. Solid lines with arrows represent translation directions. The pivot-based approach leverages a pivot to achieve indirect source-to-target translation: it first translates $\mathbf{x}$ into $\mathbf{z}$, which is then translated into $\mathbf{y}$. Our training algorithm is based on the translation equivalence assumption: if $\mathbf{x}$ is a translation of $\mathbf{z}$, then $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})$ should be close to $P(\mathbf{y}|\mathbf{z};\boldsymbol{\theta}_{z\to y})$. Our approach directly trains the intended source-to-target model $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})$ ("student") on a source-pivot parallel corpus, with the guidance of an existing pivot-to-target model $P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y})$ ("teacher").

method assumes that parallel sentences should have close probabilities of generating a sentence in a third language. To train a source-to-target NMT model without parallel corpora ("student"), we leverage an existing pivot-to-target NMT model ("teacher") to guide the learning process of the student model on a source-pivot parallel corpus. Compared with pivot-based approaches (Cheng et al., 2016a), our method allows direct parameter estimation of the intended NMT model, without the need to divide decoding into two steps. This strategy not only improves efficiency but also avoids error propagation in decoding. Experiments on the Europarl and WMT datasets show that our approach achieves significant improvements in terms of both translation quality and decoding efficiency over a baseline pivot-based approach to zero-resource NMT on Spanish-French and German-French translation tasks.

2 Background

Neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2015) advocates the use of neural networks to model the translation process in an end-to-end manner. As a data-driven approach, NMT treats parallel corpora as the major source for acquiring translation knowledge.

Let $\mathbf{x}$ be a source-language sentence and $\mathbf{y}$ be a target-language sentence. We use $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})$ to denote a source-to-target neural translation model, where $\boldsymbol{\theta}_{x\to y}$ is a set of model parameters. Given a source-target parallel corpus $D_{x,y}$, which is a set of parallel source-target sentences, the model parameters can be learned by maximizing the log-likelihood of the parallel corpus:

$$\hat{\boldsymbol{\theta}}_{x\to y} = \underset{\boldsymbol{\theta}_{x\to y}}{\operatorname{argmax}} \left\{ \sum_{\langle \mathbf{x},\mathbf{y}\rangle \in D_{x,y}} \log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y}) \right\}.$$

Given learned model parameters $\hat{\boldsymbol{\theta}}_{x\to y}$, the decision rule for finding the translation with the highest probability for a source sentence $\mathbf{x}$ is given by

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\operatorname{argmax}} \left\{ P(\mathbf{y}|\mathbf{x};\hat{\boldsymbol{\theta}}_{x\to y}) \right\}. \quad (1)$$

As a data-driven approach, NMT heavily relies on the availability of large-scale parallel corpora to deliver state-of-the-art translation performance (Wu et al., 2016; Johnson et al., 2016). Zoph et al. (2016) report that NMT obtains much lower BLEU scores than SMT if only small-scale parallel corpora are available. Therefore, the heavy dependence on the quantity of training data poses a severe challenge for NMT to translate zero-resource language pairs.

Simple and easy-to-implement, pivot-based methods have been widely used in SMT for

translating zero-resource language pairs (de Gispert and Mariño, 2006; Cohn and Lapata, 2007; Utiyama and Isahara, 2007; Wu and Wang, 2007; Bertoldi et al., 2008; Wu and Wang, 2009; Zahabi et al., 2013; Kholy et al., 2013). As pivot-based methods are agnostic to model structures, they have been adapted to NMT recently (Cheng et al., 2016a; Johnson et al., 2016).

Figure 1(a) illustrates the basic idea of pivot-based approaches to zero-resource NMT (Cheng et al., 2016a). Let $\mathbf{X}$, $\mathbf{Y}$, and $\mathbf{Z}$ denote source, target, and pivot languages. We use dashed lines to denote language pairs with parallel corpora available and solid lines with arrows to denote translation directions.

Intuitively, the source-to-target translation can be indirectly modeled by bridging two NMT models via a pivot:

$$\begin{aligned} & P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to z},\boldsymbol{\theta}_{z\to y}) \\ = & \sum_{\mathbf{z}} P(\mathbf{z}|\mathbf{x};\boldsymbol{\theta}_{x\to z})P(\mathbf{y}|\mathbf{z};\boldsymbol{\theta}_{z\to y}). \quad (2) \end{aligned}$$

As shown in Figure 1(a), pivot-based approaches assume that the source-pivot parallel corpus $D_{x,z}$ and the pivot-target parallel corpus $D_{z,y}$ are available. As it is impractical to enumerate all possible pivot sentences, the two NMT models are trained separately in practice:

$$\hat{\boldsymbol{\theta}}_{x\to z} = \underset{\theta_{x\to z}}{\operatorname{argmax}} \left\{ \sum_{\langle \mathbf{x},\mathbf{z}\rangle \in D_{x,z}} \log P(\mathbf{z}|\mathbf{x};\boldsymbol{\theta}_{x\to z}) \right\},$$

$$\hat{\boldsymbol{\theta}}_{z\to y} = \underset{\theta_{z\to y}}{\operatorname{argmax}} \left\{ \sum_{\langle \mathbf{z},\mathbf{y}\rangle \in D_{z,y}} \log P(\mathbf{y}|\mathbf{z};\boldsymbol{\theta}_{z\to y}) \right\}.$$

Due to the exponential search space of pivot sentences, the decoding process of translating an unseen source sentence $\mathbf{x}$ has to be divided into two steps:

$$\hat{\mathbf{z}} = \underset{\mathbf{z}}{\operatorname{argmax}} \left\{ P(\mathbf{z}|\mathbf{x};\hat{\boldsymbol{\theta}}_{x\to z}) \right\}, \quad (3)$$

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\operatorname{argmax}} \left\{ P(\mathbf{y}|\hat{\mathbf{z}};\hat{\boldsymbol{\theta}}_{z\to y}) \right\}. \quad (4)$$

The above two-step decoding process potentially suffers from the error propagation problem (Zhu et al., 2013): the translation errors made in the first step (i.e., source-to-pivot translation) will affect the second step (i.e., pivot-to-target translation).

Therefore, it is necessary to explore methods to directly model source-to-target translation without parallel corpora available.

3 Approach

3.1 Assumptions

In this work, we propose to directly model the intended source-to-target neural translation based on a teacher-student framework. The basic idea is to use a pre-trained pivot-to-target model ("teacher") to guide the learning process of a source-to-target model ("student") without training data available on a source-pivot parallel corpus. One advantage of our approach is that Equation (1) can be used as the decision rule for decoding, which avoids the error propagation problem faced by two-step decoding in pivot-based approaches.

As shown in Figure 1(b), we still assume that a source-pivot parallel corpus $D_{x,z}$ and a pivot-target parallel corpus $D_{z,y}$ are available. Unlike pivot-based approaches, we first use the pivot-target parallel corpus $D_{z,y}$ to obtain a **teacher model** $P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y})$, where $\hat{\boldsymbol{\theta}}_{z\to y}$ is a set of learned model parameters. Then, the teacher model "teaches" the **student model** $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})$ on the source-pivot parallel corpus $D_{x,z}$ based on the following assumptions.

Assumption 1 *If a source sentence* $\mathbf{x}$ *is a translation of a pivot sentence* $\mathbf{z}$*, then the probability of generating a target sentence* $\mathbf{y}$ *from* $\mathbf{x}$ *should be close to that from its counterpart* $\mathbf{z}$*.*

We can further introduce a word-level assumption:

Assumption 2 *If a source sentence* $\mathbf{x}$ *is a translation of a pivot sentence* $\mathbf{z}$*, then the probability of generating a target word* y *from* $\mathbf{x}$ *should be close to that from its counterpart* $\mathbf{z}$*, given the already obtained partial translation* $\mathbf{y}_{<j}$*.*

The two assumptions are empirically verified in our experiments (see Table 2). In the following subsections, we will introduce two approaches to zero-resource neural machine translation based on the two assumptions.

3.2 Sentence-Level Teaching

Given a source-pivot parallel corpus $D_{x,z}$, our training objective based on Assumption 1 is defined as follows:

$$\begin{aligned} & \mathcal{J}_{\text{SENT}}(\boldsymbol{\theta}_{x\to y}) \\ = & \sum_{\langle \mathbf{x},\mathbf{z}\rangle \in D_{x,z}} \text{KL}\Big(P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y}) \Big|\Big| P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})\Big), \quad (5) \end{aligned}$$

where the KL divergence sums over all possible target sentences:

$$\mathrm{KL}\Big(P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y})\Big|\Big|P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})\Big) = \sum_{\mathbf{y}} P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y}) \log \frac{P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y})}{P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})}. \quad (6)$$

As the teacher model parameters are fixed, the training objective can be equivalently written as

$$\mathcal{J}_{\mathrm{SENT}}(\boldsymbol{\theta}_{x\to y}) = -\sum_{\langle \mathbf{x},\mathbf{z}\rangle \in D_{x,z}} \mathbb{E}_{\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y}}\Big[\log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})\Big]. \quad (7)$$

In training, our goal is to find a set of source-to-target model parameters that minimizes the training objective:

$$\hat{\boldsymbol{\theta}}_{x\to y} = \operatorname*{argmin}_{\boldsymbol{\theta}_{x\to y}} \Big\{\mathcal{J}_{\mathrm{SENT}}(\boldsymbol{\theta}_{x\to y})\Big\}. \quad (8)$$

With learned source-to-target model parameters $\hat{\boldsymbol{\theta}}_{x\to y}$, we use the standard decision rule as shown in Equation (1) to find the translation $\hat{\mathbf{y}}$ for a source sentence $\mathbf{x}$.

However, a major difficulty faced by our approach is the intractability in calculating the gradients because of the exponential search space of target sentences. To address this problem, it is possible to construct a sub-space by either sampling (Shen et al., 2016), generating a k-best list (Cheng et al., 2016b) or mode approximation (Kim and Rush, 2016). Then, standard stochastic gradient descent algorithms can be used to optimize model parameters.

3.3 Word-Level Teaching

Instead of minimizing the KL divergence between the teacher and student models at the sentence level, we further define a training objective at the word level based on Assumption 2:

$$\mathcal{J}_{\mathrm{WORD}}(\boldsymbol{\theta}_{x\to y}) = \sum_{\langle \mathbf{x},\mathbf{z}\rangle \in D_{x,z}} \mathbb{E}_{\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y}}\Big[J(\mathbf{x},\mathbf{y},\mathbf{z},\hat{\boldsymbol{\theta}}_{z\to y},\boldsymbol{\theta}_{x\to y})\Big], \quad (9)$$

where

$$J(\mathbf{x},\mathbf{y},\mathbf{z},\hat{\boldsymbol{\theta}}_{z\to y},\boldsymbol{\theta}_{x\to y}) = \sum_{j=1}^{|\mathbf{y}|} \mathrm{KL}\Big(P(y|\mathbf{z},\mathbf{y}_{<j};\hat{\boldsymbol{\theta}}_{z\to y})\Big|\Big| P(y|\mathbf{x},\mathbf{y}_{<j};\boldsymbol{\theta}_{x\to y})\Big). \quad (10)$$

Equation (9) suggests that the teacher model $P(y|\mathbf{z},\mathbf{y}_{<j};\hat{\boldsymbol{\theta}}_{z\to y})$ "teaches" the student model $P(y|\mathbf{x},\mathbf{y}_{<j};\boldsymbol{\theta}_{x\to y})$ in a word-by-word way. Note that the KL-divergence between two models is defined at the word level:

$$\mathrm{KL}\Big(P(y|\mathbf{z},\mathbf{y}_{<j};\hat{\boldsymbol{\theta}}_{z\to y})\Big|\Big|P(y|\mathbf{x},\mathbf{y}_{<j};\boldsymbol{\theta}_{x\to y})\Big) = \sum_{y\in\mathcal{V}_y} P(y|\mathbf{z},\mathbf{y}_{<j};\hat{\boldsymbol{\theta}}_{z\to y}) \log \frac{P(y|\mathbf{z},\mathbf{y}_{<j};\hat{\boldsymbol{\theta}}_{z\to y})}{P(y|\mathbf{x},\mathbf{y}_{<j};\boldsymbol{\theta}_{x\to y})},$$

where $\mathcal{V}_y$ is the target vocabulary. As the parameters of the teacher model are fixed, the training objective can be equivalently written as:

$$\mathcal{J}_{\mathrm{WORD}}(\boldsymbol{\theta}_{x\to y}) = -\sum_{\langle \mathbf{x},\mathbf{z}\rangle \in D_{x,z}} \mathbb{E}_{\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y}}\Big[S(\mathbf{x},\mathbf{y},\mathbf{z},\hat{\boldsymbol{\theta}}_{z\to y},\boldsymbol{\theta}_{x\to y})\Big], \quad (11)$$

where

$$S(\mathbf{x},\mathbf{y},\mathbf{z},\hat{\boldsymbol{\theta}}_{z\to y},\boldsymbol{\theta}_{x\to y}) = \sum_{j=1}^{|\mathbf{y}|}\sum_{y\in\mathcal{V}_y} P(y|\mathbf{z},\mathbf{y}_{<j};\hat{\boldsymbol{\theta}}_{z\to y}) \times \log P(y|\mathbf{x},\mathbf{y}_{<j};\boldsymbol{\theta}_{x\to y}). \quad (12)$$

Therefore, our goal is to find a set of source-to-target model parameters that minimizes the training objective:

$$\hat{\boldsymbol{\theta}}_{x\to y} = \operatorname*{argmin}_{\boldsymbol{\theta}_{x\to y}} \Big\{\mathcal{J}_{\mathrm{WORD}}(\boldsymbol{\theta}_{x\to y})\Big\}. \quad (13)$$

We use similar approaches as described in Section 3.2 for approximating the full search space with sentence-level teaching. After obtaining $\hat{\boldsymbol{\theta}}_{x\to y}$, the same decision rule as shown in Equation (1) can be utilized to find the most probable target sentence $\hat{\mathbf{y}}$ for a source sentence $\mathbf{x}$.

4 Experiments

4.1 Setup

We evaluate our approach on the Europarl (Koehn, 2005) and WMT corpora. To compare with pivot-based methods, we use the same dataset as (Cheng et al., 2016a). All the sentences are tokenized by the `tokenize.perl` script. All the experiments treat English as the pivot language and French as the target language.

For the Europarl corpus, we evaluate our proposed methods on Spanish-French (Es-Fr) and German-French (De-Fr) translation tasks in a

Corpus	Direction	Train	Dev.	Test
Europarl	Es→ En	850K	2,000	2,000
	De→ En	840K	2,000	2,000
	En→ Fr	900K	2,000	2,000
WMT	Es→ En	6.78M	3,003	3,003
	En→ Fr	9.29M	3,003	3,003

Table 1: Data statistics. For the Europarl corpus, we evaluate our approach on Spanish-French (Es-Fr) and German-French (De-Fr) translation tasks. For the WMT corpus, we evaluate approach on the Spanish-French (Es-Fr) translation task. English is used as a pivot language in all experiments.

zero-resource scenario. To avoid the trilingual corpus constituted by the source-pivot and pivot-target corpora, we split the overlapping pivot sentences of the original source-pivot and pivot-target corpora into two equal parts and merge them separately with the non-overlapping parts for each language pair. The development and test sets are from WMT 2006 shared task.[1] The evaluation metric is case-insensitive BLEU (Papineni et al., 2002) as calculated by the `multi-bleu.perl` script. To deal with out-of-vocabulary words, we adopt byte pair encoding (BPE) (Sennrich et al., 2016) to split words into sub-words. The size of sub-words is set to 30K for each language.

For the WMT corpus, we evaluate our approach on a Spanish-French (Es-Fr) translation task with a zero-resource setting. We combine the following corpora to form the Es-En and En-Fr parallel corpora: Common Crawl, News Commentary, Europarl v7 and UN. All the sentences are tokenized by the `tokenize.perl` script. Newstest2011 serves as the development set and Newstest2012 and Newstest2013 serve as test sets. We use case-sensitive BLEU to evaluate translation results. BPE is also used to reduce the vocabulary size. The size of sub-words is set to 43K, 33K, 43K for Spanish, English and French, respectively. See Table 1 for detailed statistics for the Europarl and WMT corpora.

We leverage an open-source NMT toolkit *dl4mt* implemented by Theano [2] for all the experiments and compare our approach with state-of-the-art multilingual methods (Firat et al., 2016b) and pivot-based methods (Cheng et al., 2016a). Two variations of our framework are used in the experiments:

1. Sentence-Level Teaching: for simplicity, we use the mode as suggested in (Kim and Rush, 2016) to approximate the target sentence space in calculating the expected gradients with respect to the expectation in Equation (7). We run beam search on the pivot sentence with the teacher model and choose the highest-scoring target sentence as the mode. Beam size with $k = 1$ (greedy decoding) and $k = 5$ are investigated in our experiments, denoted as *sent-greedy* and *sent-beam*, respectively.[3]

2. Word-Level Teaching: we use the same mode approximation approach as in sentence-level teaching to approximate the expectation in Equation 12, denoted as *word-greedy* (beam search with $k = 1$) and *word-beam* (beam search with $k = 5$) respectively. Besides, Monte Carlo estimation by sampling from the teacher model is also investigated since it introduces more diverse data, denoted as *word-sampling*.

4.2 Assumptions Verification

To verify the assumptions in Section 3.1, we train a source-to-target translation model $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})$ and a pivot-to-target translation model $P(\mathbf{y}|\mathbf{z};\boldsymbol{\theta}_{z\to y})$ using the trilingual Europarl corpus. Then, we measure the sentence-level and word-level KL divergence from the source-to-target model $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}_{x\to y})$ at different iterations to the trained pivot-to-target model $P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y})$ by caculating $\mathcal{J}_{\text{SENT}}$ (Equation (5)) and $\mathcal{J}_{\text{WORD}}$

[1] http://www.statmt.org/wmt07/shared-task.html

[2] *dl4mt-tutorial*: https://github.com/nyu-dl

[3] We can also adopt sampling and k-best list for approximation. Random sampling brings a large variance (Sutskever et al., 2014; Ranzato et al., 2015; He et al., 2016) for sentence-level teaching. For k-best list, we renormalize the probabilities

$$P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y}) \sim \frac{P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y})^{\alpha}}{\sum_{\mathbf{y}\in\mathcal{Y}_k} P(\mathbf{y}|\mathbf{z};\hat{\boldsymbol{\theta}}_{z\to y})^{\alpha}},$$

where $\mathcal{Y}_k$ is the k-best list from beam search of the teacher model and α is a hyperparameter controling the sharpness of the distribution (Och, 2003). We set $k = 5$ and $\alpha = 5\times10^{-3}$. The results on test set for Eureparl Corpus are 32.24 BLEU over Spanish-French translation and 24.91 BLEU over German-French translation, which are slightly better than the sent-beam method. However, considering the traing time and the memory consumption, we think mode approximation is already a good way to approximate the target sentence space for sentence-level teaching.

	Approx.	Iterations				
		0	2w	4w	6w	8w
$\mathcal{J}_{\text{SENT}}$	greedy	313.0	73.1	61.5	56.8	55.1
	beam	323.5	73.1	60.7	55.4	54.0
$\mathcal{J}_{\text{WORD}}$	greedy	274.0	51.5	43.1	39.4	38.8
	beam	288.7	52.7	43.3	39.2	38.4
	sampling	268.6	53.8	46.6	42.8	42.4

Table 2: Verification of sentence-level and word-level assumptions by evaluating approximated KL divergence from the source-to-target model to the pivot-to-target model over training iterations of the source-to-target model. The pivot-to-target model is trained and kept fixed.

	Method	Es→ Fr	De→ Fr
Cheng et al. (2016a)	pivot	29.79	23.70
	hard	29.93	23.88
	soft	30.57	23.79
	likelihood	32.59	25.93

	word-sampling	33.86	27.03

Table 3: Comparison with previous work on Spanish-French and German-French translation tasks from the Europarl corpus. English is treated as the pivot language. The likelihood method uses 100K parallel source-target sentences, which are not available for other methods.

(Equation (9)) on 2,000 parallel source-pivot sentences from the development set of WMT 2006 shared task.

Table 2 shows the results. The source-to-target model is randomly initialized at iteration 0. We find that $\mathcal{J}_{\text{SENT}}$ and $\mathcal{J}_{\text{WORD}}$ decrease over time, suggesting that the source-to-target and pivot-to-target models do have small KL divergence at both sentence and word levels.

4.3 Results on the Europarl Corpus

Table 3 gives BLEU scores on the Europarl corpus of our best performing sentence-level method (sent-beam) and word-level method (word-sampling) compared with pivot-based methods (Cheng et al., 2016a). We use the same data preprocessing as (Cheng et al., 2016a). We find that both the sent-beam and word-sampling methods outperform the pivot-based approaches in a zero-resource scenario across language pairs. Our word-sampling method improves over the best performing zero-resource pivot-based method (soft) on Spanish-French translation by +3.29 BLEU points and German-French translation by +3.24 BLEU points. In addition, the word-sampling mothod surprisingly obtains improvement over the likelihood method, which leverages a source-target parallel corpus. The

Method	Es→ Fr		De→ Fr	
	dev	test	dev	test
sent-greedy	31.00	31.05	22.34	21.88
sent-beam	31.57	31.64	24.95	24.39
word-greedy	31.37	31.92	24.72	25.15
word-beam	30.81	31.21	24.64	24.19
word-sampling	33.65	33.86	26.99	27.03

Table 4: Comparison of our proposed methods on Spanish-French and German-French translation tasks from the Europarl corpus. English is treated as the pivot language.

significant improvements can be explained by the error propagation problem of pivot-based methods that translation error of the source-to-pivot translation process is propagated to the pivot-to-target translation process.

Table 4 shows BLEU scores on the Europarl corpus of our proposed methods. For sentence-level approaches, the sent-beam method outperforms the sent-greedy method by +0.59 BLEU points over Spanish-French translation and +2.51 BLEU points over German-French translation on the test set. The results are in line with our observation in Table 2 that sentence-level KL divergence by beam approximation is smaller than that by greedy approximation. However, as the

Our zero-resource NMT system						
	word-sampling	6.78M	9.29M	-	28.06	27.03

Table 5: Comparison with previous work on Spanish-French translation in a zero-resource scenario over the WMT corpus. The BLEU scores are case sensitive. †: the method depends on two-step decoding.

time complexity grows linearly with the number of beams k, the better performance is achieved at the expense of search time.

For word-level experiments, we observe that the word-sampling method performs much better than the other two methods: +1.94 BLEU points on Spanish-French translation and +1.88 BLEU points on German-French translation over the word-greedy method; +2.65 BLEU points on Spanish-French translation and +2.84 BLEU points on German-French translation over the word-beam method. Although Table 2 shows that word-level KL divergence approximated by sampling is larger than that by greedy or beam, sampling approximation introduces more data diversity for training, which dominates the effect of KL divergence difference.

We plot validation loss[4] and BLEU scores over iterations on the German-French translation task in Figure 2. We observe that word-level models tend to have lower validation loss compared with sentence-level methods. Generally, models with lower validation loss tend to have higher BLEU. Our results indicate that this is not necessarily the case: the sent-beam method converges to +0.31 BLEU points on the validation set with +13 validation loss compared with the word-beam method. Kim and Rush (2016) claim a similar observation in data distillation for NMT and provide an explanation that student distributions are more peaked for sentence-level methods. This is indeed the case in our result: on German-French translation task the argmax for the sent-beam student model (on average) approximately accounts for 3.49% of the total probability mass, while the corresponding number is 1.25% for the word-beam student model and 2.60% for the teacher model.

4.4 Results on the WMT Corpus

The word-sampling method obtains the best performance in our five proposed approaches according to experiments on the Europarl corpus. To further verify this approach, we conduct ex-

[4] *Validation loss*: the average negative log-likelihood of sentence pairs on the validation set.

groundtruth	source	Os sentáis al volante en la costa oeste , en San Francisco , y vuestra misión es llegar los primeros a Nueva York .
	pivot	You get in the car on the west coast , in San Francisco , and your task is to be the first one to reach New York .
	target	Vous vous asseyez derrière le volant sur la côte ouest à San Francisco et votre mission est d' arriver le premier à New York .
pivot	pivot	You 'll feel at *the west coast in San Francisco , and your* mission *is to* get *the first* to *New York .* [BLEU: 33.93]
	target	*Vous vous* sentirez comme chez vous *à San Francisco , et votre mission est d'* obtenir *le premier à New York .* [BLEU: 44.52]
likelihood	pivot	You feel at *the west coast , in San Francisco , and your* mission *is to* reach *the first* to *New York .* [BLEU: 47.22]
	target	*Vous vous* sentez à *la côte ouest , à San Francisco , et votre mission est d'* atteindre *le premier à New York .* [BLEU: 49.44]
word-sampling	target	*Vous vous* sentez au *volant sur la côte ouest , à San Francisco et votre mission est d' arriver le premier à New York .* [BLEU: 78.78]

Table 6: Examples and corresponding sentence BLEU scores of translations using the pivot and likelihood methods in (Cheng et al., 2016a) and the proposed word-sampling method. We observe that our approach generates better translations than the methods in (Cheng et al., 2016a). We italicize *correct translation segments* which are no short than 2-grams.

periments on the large scale WMT corpus for Spanish-French translation. Table 5 shows the results of our word-sampling method in comparison with other state-of-the-art baselines. Cheng et al. (2016a) use the same datasets and the same preprocessing as ours. Firat et al. (2016b) utilize a much larger training set.[5] Our method obtains significant improvement over the pivot baseline by +3.46 BLEU points on Newstest2012 and over many-to-one by +5.84 BLEU points on Newstest2013. Note that both methods depend on a source-pivot-target decoding path. Table 6 shows translation examples of the pivot and likelihood methods proposed in (Cheng et al., 2016a) and our proposed word-sampling method. For the pivot and likelihood methods, the Spainish sentence segment 'sentáis al volante' is lost when translated to English. Therefore, both methods miss this information in the translated French sentence. However, the word-sampling method generates 'volant sur', which partially translates 'sentáis al volante', resulting in improved translation quality of target-language sentence.

4.5 Results with Small Source-Pivot Data

The word-sampling method can also be applied to zero-resource NMT with a small source-pivot corpus. Specifically, the size of the source-pivot corpus is orders of magnitude smaller than that of the pivot-target corpus. This setting makes sense in applications. For example, there are significantly fewer Urdu-English corpora available than English-French corpora.

To fulfill this task, we combine our best performing word-sampling method with the initialization and parameter freezing strategy proposed in (Zoph et al., 2016). The Europarl corpus is used in the experiments. We set the size of German-English training data to 100K and use the same teacher model trained with 900K English-French sentences.

Table 7 gives the BLEU score of our method on German-French translation compared with three other methods. Note that our task is much harder than transfer learning (Zoph et al., 2016) since it depends on a parallel German-French corpus. Surprisingly, our method outperforms all other methods. We significantly improve the baseline pivot method by +5.63 BLEU points and the state-of-the-art transfer learning method by +0.56 BLEU points.

Method	Corpus			BLEU
	De-En	De-Fr	En-Fr	
MLE	×	√	×	19.30
transfer	×	√	√	22.39
pivot	√	×	√	17.32
Ours	√	×	√	22.95

Table 7: Comparison on German-French translation task from the Europarl corpus with 100K German-English sentences. English is regarded as the pivot language. Transfer represents the transfer learning method in (Zoph et al., 2016). 100K parallel German-French sentences are used for the MLE and transfer methods.

[5] Their training set does not include the Common Crawl corpus.

5 Related Work

Training NMT models in a zero-resource scenario by leveraging other languages has attracted intensive attention in recent years. Firat et al. (2016b) propose an approach which delivers the multi-way, multilingual NMT model proposed by (Firat et al., 2016a) to zero-resource translation. They use the multi-way NMT model trained by other language pairs to generate a pseudo parallel corpus and fine-tune the attention mechanism of the multi-way NMT model to enable zero-resource translation. Several authors propose a universal encoder-decoder network in multilingual scenarios to perform zero-shot learning (Johnson et al., 2016; Ha et al., 2016). This universal model extracts translation knowledge from multiple different languages, making zero-resource translation feasible without direct training.

Besides multilingual NMT, another important line of research is bridging source and target languages via a pivot language. This idea is widely used in SMT (de Gispert and Mariño, 2006; Cohn and Lapata, 2007; Utiyama and Isahara, 2007; Wu and Wang, 2007; Bertoldi et al., 2008; Wu and Wang, 2009; Zahabi et al., 2013; Kholy et al., 2013). Cheng et al. (2016a) propose pivot-based NMT by simultaneously improving source-to-pivot and pivot-to-target translation quality in order to improve source-to-target translation quality. Nakayama and Nishida (2016) achieve zero-resource machine translation by utilizing image as a pivot and training multimodal encoders to share common semantic representation.

Our work is also related to knowledge distillation, which trains a compact model to approximate the function learned by a larger, more complex model or an ensemble of models (Bucila et al., 2006; Ba and Caurana, 2014; Li et al., 2014; Hinton et al., 2015). Kim and Rush (2016) first introduce knowledge distillation in neural machine translation. They suggest to generate a pseudo corpus to train the student network. Compared with their work, we focus on zero-resource learning instead of model compression.

6 Conclusion

In this paper, we propose a novel framework to train the student model without parallel corpora under the guidance of the pre-trained teacher model on a source-pivot parallel corpus. We introduce sentence-level and word-level teaching to guide the learning process of the student model. Experiments on the Europarl and WMT corpora across languages show that our proposed word-level sampling method can significantly outperforms the state-of-the-art pivot-based methods and multilingual methods in terms of translation quality and decoding efficiency.

We also analyze zero-resource translation with small source-pivot data, and combine our word-level sampling method with initialization and parameter freezing suggested by (Zoph et al., 2016). The experiments on the Europarl corpus show that our approach obtains an significant improvement over the pivot-based baseline.

In the future, we plan to test our approach on more diverse language pairs, e.g., zero-resource Uyghur-English translation using Chinese as a pivot. It is also interesting to extend the teacher-student framework to other cross-lingual NLP applications as our method is transparent to architectures.

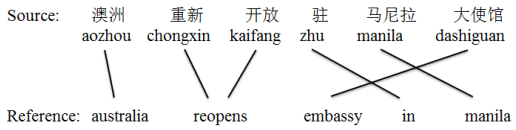
Abstract

Most neural machine translation (NMT) models are based on the sequential encoder-decoder framework, which makes no use of syntactic information. In this paper, we improve this model by explicitly incorporating source-side syntactic trees. More specifically, we propose (1) a *bidirectional tree encoder* which learns both sequential and tree structured representations; (2) a *tree-coverage model* that lets the attention depend on the source-side syntax. Experiments on Chinese-English translation demonstrate that our proposed models outperform the sequential attentional model as well as a stronger baseline with a bottom-up tree encoder and word coverage.[1]

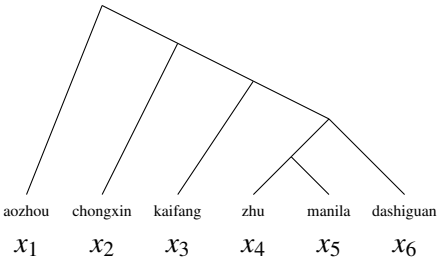
1 Introduction

Recently, neural machine translation (NMT) models (Sutskever et al., 2014; Bahdanau et al., 2015) have obtained state-of-the-art performance on many language pairs. Their success depends on the representation they use to bridge the source and target language sentences. However, this representation, a sequence of fixed-dimensional vectors, differs considerably from most theories about mental representations of sentences, and from traditional natural language processing pipelines, in which semantics is built up compositionally using a recursive syntactic structure.

Perhaps as evidence of this, current NMT models still suffer from syntactic errors such as attachment (Shi et al., 2016). We argue that instead of letting the NMT model rely solely on the implicit structure it learns during training (Cho et al., 2014a), we can improve its performance by augmenting it with explicit structural information and using this information throughout the model. This has two benefits.



(a) example sentence pair with alignments



(b) binarized source side tree

Figure 1: An example sentence pair (a), with its binarized source side tree (b). We use x_i to represent the i-th word in the source sentence. We will use this sentence pairs as the running example throughout this paper.

First, the explicit syntactic information will help the encoder generate better source side representations. Li et al. (2015) show that for tasks in which long-distance semantic dependencies matter, representations learned from recursive models using syntactic structures may be more powerful than those from sequential recurrent models. In the NMT case, given syntactic information, it will be easier for the encoder to incorporate long distance dependencies into better representations, which is especially important for the translation of long sentences.

Second, it becomes possible for the decoder to

use syntactic information to guide its reordering decisions better (especially for language pairs with significant reordering, like Chinese-English). Although the attention model (Bahdanau et al., 2015) and the coverage model (Tu et al., 2016; Mi et al., 2016) provide effective mechanisms to control the generation of translation, these mechanisms work at the word level and cannot capture phrasal cohesion between the two languages (Fox, 2002; Kim et al., 2017). With explicit syntactic structure, the decoder can generate the translation more in line with the source syntactic structure. For example, when translating the phrase *zhu manila dashiguan* in Figure 1, the tree structure indicates that *zhu* 'in' and *manila* form a syntactic unit, so that the model can avoid breaking this unit up to make an incorrect translation like "in embassy of manila" [2].

In this paper, we propose a novel encoder-decoder model that makes use of a precomputed source-side syntactic tree in both the encoder and decoder. In the encoder (§3.3), we improve the tree encoder of Eriguchi et al. (2016) by introducing a *bidirectional tree encoder*. For each source tree node (including the source words), we generate a representation containing information both from below (as with the original bottom-up encoder) and from above (using a top-down encoder). Thus, the annotation of each node summarizes the surrounding sequential context, as well as the entire syntactic context.

In the decoder (§3.4), we incorporate source syntactic tree structure into the attention model via an extension of the coverage model of Tu et al. (2016). With this *tree-coverage model*, we can better guide the generation phase of translation, for example, to learn a preference for phrasal cohesion (Fox, 2002). Moreover, with a tree encoder, the decoder may try to translate both a parent and a child node, even though they overlap; the tree-coverage model enables the decoder to learn to avoid this problem.

To demonstrate the effectiveness of the proposed model, we carry out experiments on Chinese-English translation. Our experiments show that: (1) our bidirectional tree encoder based NMT system achieves significant improvements over the standard attention-based NMT system, and (2) incorporating source tree structure into the attention model yields a further improvement.

[2] According to the source sentence, "embassy" belongs to "australia", not "manila".

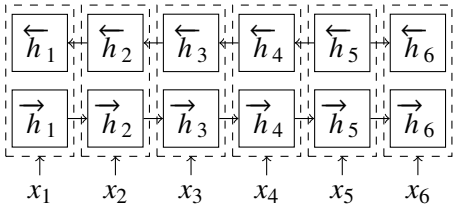

Figure 2: Illustration of the bidirectional sequential encoder. The dashed rectangle represents the annotation of word x_i.

In all, we demonstrate an improvement of +3.54 BLEU over a standard attentional NMT system, and +1.90 BLEU over a stronger NMT system with a Tree-LSTM encoder (Eriguchi et al., 2016) and a coverage model (Tu et al., 2016). To the best of our knowledge, this is the first work that uses source-side syntax in both the encoder and decoder of an NMT system.

2 Neural Machine Translation

Most NMT systems follow the encoder-decoder framework with attention, first proposed by Bahdanau et al. (2015). Given a source sentence $\mathbf{x} = x_1 \cdots x_i \cdots x_I$ and a target sentence $\mathbf{y} = y_1 \cdots y_j \cdots y_J$, NMT aims to directly model the translation probability:

$$P(\mathbf{y} \mid \mathbf{x}; \theta) = \prod_{1}^{J} P(y_j \mid \mathbf{y}_{<\mathbf{j}}, \mathbf{x}; \theta), \qquad (1)$$

where θ is a set of parameters and $y_{<j}$ is the sequence of previously generated target words. Here, we briefly describe the underlying framework of the encoder-decoder NMT system.

2.1 Encoder Model

Following Bahdanau et al. (2015), we use a bidirectional gated recurrent unit (GRU) (Cho et al., 2014b) to encode the source sentence, so that the annotation of each word contains a summary of both the preceding and following words. The bidirectional GRU consists of a forward and a backward GRU, as shown in Figure 2. The forward GRU reads the source sentence from left to right and calculates a sequence of forward hidden states $(\overrightarrow{h_1}, \ldots, \overrightarrow{h_I})$. The backward GRU scans the source sentence from right to left, resulting in a sequence of backward hidden states $(\overleftarrow{h_1}, \ldots, \overleftarrow{h_I})$. Thus

$$\begin{aligned} \overrightarrow{h_i} &= \mathrm{GRU}(\overrightarrow{h_{i-1}}, s_i) \\ \overleftarrow{h_i} &= \mathrm{GRU}(\overleftarrow{h_{i-1}}, s_i) \end{aligned} \qquad (2)$$

where s_i is the i-th source word's word embedding, and GRU is a gated recurrent unit; see the paper by Cho et al. (2014b) for a definition.

The *annotation* of each source word x_i is obtained by concatenating the forward and backward hidden states:

$$\overleftrightarrow{h_i} = \begin{bmatrix} \overrightarrow{h_i} \\ \overleftarrow{h_i} \end{bmatrix}.$$

The whole sequence of these annotations is used by the decoder.

2.2 Decoder Model

The decoder is a forward GRU predicting the translation $\mathbf{y}$ word by word. The probability of generating the j-th word y_j is:

$$P(y_j \mid \mathbf{y}_{<\mathbf{j}}, \mathbf{x}; \theta) = \text{softmax}(t_{j-1}, d_j, c_j) \quad (3)$$

where t_{j-1} is the word embedding of the $(j-1)$-th target word, d_j is the decoder's hidden state of time j, and c_j is the *context vector* at time j. The state d_j is computed as

$$d_j = \text{GRU}(d_{j-1}, t_{j-1}, c_j), \quad (4)$$

where GRU$(\cdot)$ is extended to more than two arguments by first concatenating all arguments except the first.

The attention mechanism computes the context vector c_i as a weighted sum of the source annotations,

$$c_j = \sum_{i=1}^{I} \alpha_{j,i} \overleftrightarrow{h_i} \quad (5)$$

where the attention weight $\alpha_{j,i}$ is

$$\alpha_{j,i} = \frac{\exp(e_{j,i})}{\sum_{i'=1}^{I} \exp(e_{j,i'})} \quad (6)$$

and

$$e_{j,i} = v_a^{\mathrm{T}} \tanh(W_a d_{j-1} + U_a \overleftrightarrow{h_i}) \quad (7)$$

where v_a, W_a and U_a are the weight matrices of the attention model, and $e_{j,i}$ is an attention model that scores how well d_{j-1} and $\overleftrightarrow{h_i}$ match.

With this strategy, the decoder can attend to the source annotations that are most relevant at a given time.

3 Tree Structure Enhanced Neural Machine Translation

Although syntax has shown its effectiveness in non-neural statistical machine translation (SMT) systems (Yamada and Knight, 2001; Koehn et al., 2003; Liu et al., 2006; Chiang, 2007), most proposed NMT models (a notable exception being that of Eriguchi et al. (2016)) process a sentence only as a sequence of words, and do not explicitly exploit the inherent structure of natural language sentences. In this section, we present models which directly incorporate source syntactic trees into the encoder-decoder framework.

3.1 Preliminaries

Like Eriguchi et al. (2016), we currently focus on source side syntactic trees, which can be computed prior to translation. Whereas Eriguchi et al. (2016) use HPSG trees, we use phrase-structure trees as in the Penn Chinese Treebank (Xue et al., 2005). Currently, we are only using the structure information from the tree without the syntactic labels. Thus our approach should be applicable to any syntactic grammar that provides such a tree structure (Figure 1(b)).

More formally, the encoder is given a source sentence $\mathbf{x} = x_1 \cdots x_I$ as well as a source tree whose leaves are labeled $x_1, \ldots, x_I$. We assume that this tree is strictly binary branching. For convenience, each node is assigned an index. The leaf nodes get indices $1, \ldots, I$, which is the same as their word indices. For any node with index k, let $p(k)$ denote the index of the node's parent (if it exists), and $L(k)$ and $R(k)$ denote the indices of the node's left and right children (if they exist).

3.2 Tree-GRU Encoder

We first describe tree encoders (Tai et al., 2015; Eriguchi et al., 2016), and then discuss our improvements.

Following Eriguchi et al. (2016), we build a tree encoder on top of the sequential encoder (as shown in Figure 3(a)). If node k is a leaf node, its hidden state is the annotation produced by the sequential encoder:

$$h_k^{\uparrow} = \overleftrightarrow{h_k}.$$

Thus, the encoder is able to capture both sequential context and syntactic context.

If node k is an interior node, its hidden state is the combination of its previously calculated left

child hidden state $h_{L(k)}$ and right child hidden state $h_{R(k)}$:

$$h_k^{\uparrow} = f(h_{L(k)}^{\uparrow}, h_{R(k)}^{\uparrow}) \tag{8}$$

where $f(\cdot)$ is a nonlinear function, originally a Tree-LSTM (Tai et al., 2015; Eriguchi et al., 2016).

The first improvement we make to the above tree encoder is that, to be consistent with the sequential encoder model, we use Tree-GRU units instead of Tree-LSTM units. Similar to Tree-LSTMs, the Tree-GRU has gating mechanisms to control the information flow inside the unit for every node without separate memory cells. Then, Eq. 8 is calculated by a Tree-GRU as follows:

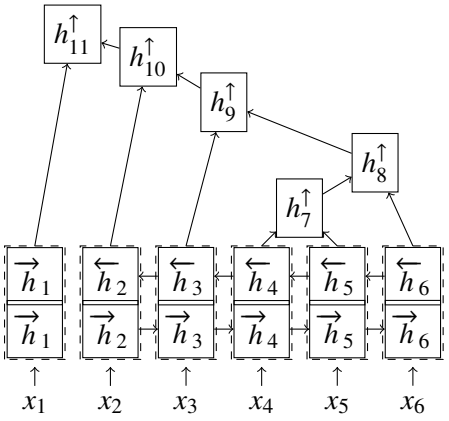
$$\begin{aligned}
r_L &= \sigma(U_L^{(rL)} h_{L(k)}^{\uparrow} + U_R^{(rL)} h_{R(k)}^{\uparrow} + b^{(rL)}) \\
r_R &= \sigma(U_L^{(rR)} h_{L(k)}^{\uparrow} + U_R^{(rR)} h_{R(k)}^{\uparrow} + b^{(rR)}) \\
z_L &= \sigma(U_L^{(zL)} h_{L(k)}^{\uparrow} + U_R^{(zL)} h_{R(k)}^{\uparrow} + b^{(zL)}) \\
z_R &= \sigma(U_L^{(zR)} h_{L(k)}^{\uparrow} + U_R^{(zR)} h_{R(k)}^{\uparrow} + b^{(zR)}) \\
z &= \sigma(U_L^{(z)} h_{L(k)}^{\uparrow} + U_R^{(z)} h_{R(k)}^{\uparrow} + b^{(z)}) \\
\tilde{h}_k^{\uparrow} &= \tanh\left(U_L(r_L \odot h_{L(k)}^{\uparrow}) + U_R(r_R \odot h_{R(k)}^{\uparrow})\right) \\
h_k^{\uparrow} &= z_L \odot h_{L(k)}^{\uparrow} + z_R \odot h_{R(k)}^{\uparrow} + z \odot \tilde{h}_k^{\uparrow}
\end{aligned}$$

where r_L, r_R are the reset gates and z_L, z_R are the update gates for the left and right children, and z is the update gate for the internal hidden state $\tilde{h}_k^{\uparrow}$. The $U^{(\cdot)}$ and $b^{(\cdot)}$ are the weight matrices and bias vectors.

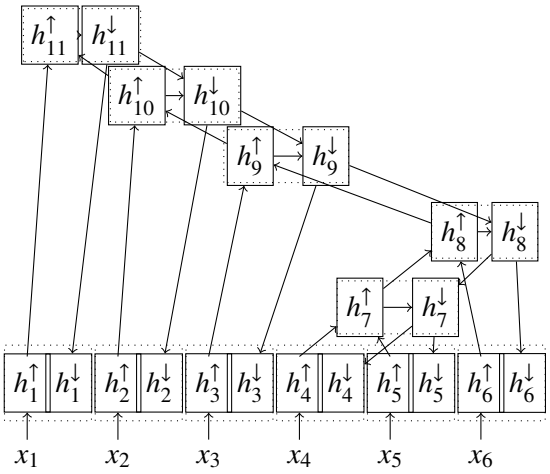
3.3 Bidirectional Tree Encoder

Although the bottom-up tree encoder can take advantage of syntactic structure, the learned representation of a node is based on its subtree only; it contains no information from higher up in the tree. In particular, the representation of leaf nodes is still the sequential one. Thus no syntactic information is fed into words. By analogy with the bidirectional sequential encoder, we propose a natural extension of the bottom-up tree encoder: the bidirectional tree encoder (Figure 3(b)).

Unlike the bottom-up tree encoder or the right-to-left sequential encoder, the top-down encoder by itself would have no lexical information as input. To address this issue, we feed the hidden states of the bottom-up encoder to the top-down encoder. In this way, the information of the whole syntactic tree is handed to the root node and propagated to its offspring by the top-down encoder.



(a) Tree-GRU Encoder



(b) Bidirectional Tree Encoder

Figure 3: Illustration of the proposed encoder models for the running example. The non-leaf nodes are assigned with index 7-11. The annotations $h_i^{\uparrow}$ of leaf nodes in (b) are identical to the annotations (dashed rectangles) of leaf nodes in (a). The dotted rectangles in (b) indicate the annotation produced by the bidirectional tree encoder.

In the top-down encoder, each hidden state has only one predecessor. In fact, the top-down path from root of a tree to any node can be viewed as a sequential recurrent neural network. We can calculate the hidden states of each node top-down using a standard sequential GRU.

First, the hidden state of the root node ρ is simply computed as follows:

$$h_{\rho}^{\downarrow} = \tanh\left(W h_{\rho}^{\uparrow} + b\right) \tag{9}$$

where W and b are a weight matrix and bias vector.

Then, other nodes are calculated by a GRU. For hidden state $h_k^{\downarrow}$:

$$h_k^{\downarrow} = \mathrm{GRU}(h_{p(k)}^{\downarrow}, h_k^{\uparrow}) \tag{10}$$

where $p(k)$ is the parent index of k. We replace the weight matrices W^r, U^r, W^z, U^z, W and U in the standard GRU with P^r_D, Q^r_D, P^z_D, Q^z_D, P_D, and Q_D, respectively. The subscript D is either L or R depending on whether node k is a left or right child, respectively.

Finally, the annotation of each node is obtained by concatenating its bottom-up hidden state and top-down hidden state:

$$h^{\updownarrow}_k = \begin{bmatrix} h^{\uparrow}_k \\ h^{\downarrow}_k \end{bmatrix}.$$

This allows the tree structure information flow from the root to the leaves (words). Thus, all the annotations are based on the full context of word sequence and syntactic tree structure.

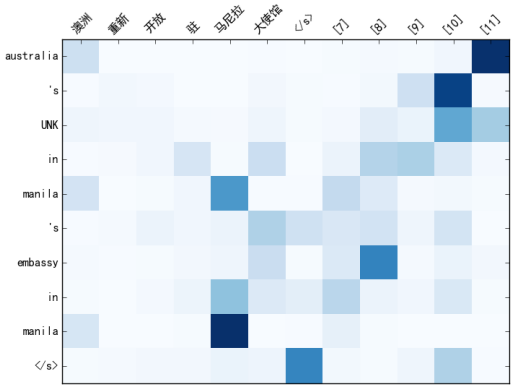
Kokkinos and Potamianos (2017) propose a similar bidirectional Tree-GRU for sentiment analysis, which differs from ours in several respects: in the bottom-up encoder, we use separate reset/update gates for left and right children, analogous to Tree-LSTMs (Tai et al., 2015); in the top-down encoder, we use separate weights for left and right children.

Teng and Zhang (2016) also propose a bidirectional Tree-LSTM encoder for classification tasks. They use a more complex head-lexicalization scheme to feed the top-down encoder. We will compare their model with ours in the experiments.

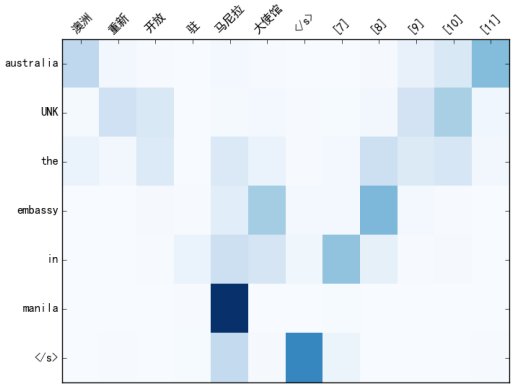
3.4 Tree-Coverage Model

We also extend the decoder to incorporate information about the source syntax into the attention model. We have observed two issues in translations produced using the tree encoder. First, a syntactic phrase in the source sentence is often incorrectly translated into discontinuous words in the output. Second, since the non-leaf node annotations contain more information than the leaf node annotations, the attention model prefers to attend to the non-leaf nodes, which may aggravate the over-translation problem (translating the same part of the sentence more than once).

As shown in Figure 4(a), almost all the non-leaf nodes are attended too many times during decoding. As a result, the Chinese phrase *zhu manila* is translated twice because the model attends to the node spanning *zhu manila* even though both words have already been translated; there is no mechanism to prevent this.



(a) Tree-GRU Encoder



(b) + Tree-Coverage Model

Figure 4: The attention heapmap plotting the attention weights during different translation steps, for translating the sentence in Figure 1(a). The nodes [7]-[11] correspond to non-leaf nodes indexed in Figure 3. Incorporating Tree-Coverage Model produces more concentrated alignments and alleviates the over-translation problem.

Inspired by the approaches of Cohn et al. (2016), Feng et al. (2016), Tu et al. (2016) and Mi et al. (2016), we propose to use prior knowledge to control the attention mechanism. In our case, the prior knowledge is the source syntactic information.

In particular, we build our model on top of the word coverage model proposed by Tu et al. (2016), which alleviate the problems of over-translation and under-translation (failing to translate part of a sentence). The word coverage model makes the attention at a given time step j dependent on the attention at previous time steps via *coverage vectors*:

$$C_{j,i} = \text{GRU}(C_{j-1,i}, \alpha_{j,i}, d_{j-1}, h_i). \quad (11)$$

The coverage vectors are, in turn, used to update the attention at the next time step, by a small modification to the calculation of $e_{j,i}$ in Eq. (7):

$$e_{j,i} = v_a^{\mathrm{T}} \tanh\left(W_a d_{j-1} + U_a h_i + V_a C_{j-1,i}\right). \quad (12)$$

The word coverage model could be interpreted as a control mechanism for the attention model. Like the standard attention model, this coverage model sees the source-sentence annotations as a bag of vectors; it knows nothing about word order, still less about syntactic structure.

For our model, we extend the word coverage model to coverage on the tree structure by adding a coverage vector for each node in the tree. We further incorporate source tree structure information into the calculation of the coverage vector by requiring each node's coverage vector to depend on its children's coverage vectors and attentions at the previous time step:

$$\begin{aligned} C_{j,i} = \mathrm{GRU}(&C_{j-1,i}, \alpha_{j,i}, d_{j-1}, h_i, \\ &C_{j-1,L(i)}, \alpha_{j,L(i)}, \\ &C_{j-1,R(i)}, \alpha_{j,R(i)}). \end{aligned} \quad (13)$$

Although both child and parent nodes of a subtree are helpful for translation, they may supply redundant information. With our mechanism, when the child node is used to produce a translation, the coverage vector of its parent node will reflect this fact, so that the decoder may avoid using the redundant information in the parent node. Figure 4(b) shows a heatmap of the attention of our tree structure enhanced attention model. The attention of non-leaf nodes becomes more concentrated and the over-translation of *zhu manila* is corrected.

4 Experiments

4.1 Data

We conduct experiments on the NIST Chinese-English translation task. The parallel training data consists of 1.6M sentence pairs extracted from LDC corpora,[3] with 46.6M Chinese words and 52.5M English words, respectively. We use NIST MT02 as development data, and NIST MT03–06 as test data. These data are mostly in the same genre (newswire), avoiding the extra consideration of domain adaptation. Table 1 shows the statistics of the data sets. The Chinese side of the corpora is word segmented using ICTCLAS.[4] We parse the Chinese sentences with the Berkeley Parser[5] (Petrov and Klein, 2007) and binarize the resulting trees following Zhang and Clark (2009). The English side of the corpora is lowercased and tokenized.

Data	Usage	Sents.
LDC	train	1.6M
MT02	dev	878
MT03	test	919
MT04	test	1,597
MT05	test	1,082
MT06	test	1,664

Table 1: Experiment data and statistics.

We filter out any translation pairs whose source sentences fail to be parsed. For efficient training, we also filter out the sentence pairs whose source or target lengths are longer than 50. We use a shortlist of the 30,000 most frequent words in each language to train our models, covering approximately 98.2% and 99.5% of the Chinese and English tokens, respectively. All out-of-vocabulary words are mapped to a special symbol `UNK`.

4.2 Model and Training Details

We compare our proposed models with several state-of-the-art NMT systems and techniques:

- **NMT**: the standard attentional NMT model (Bahdanau et al., 2015).
- **Tree-LSTM**: the attentional NMT model extended with the Tree-LSTM encoder (Eriguchi et al., 2016).
- **Coverage**: the attentional NMT model extended with word coverage (Tu et al., 2016).

We used the dl4mt implementation of the attentional model,[6] reimplementing the tree encoder and word coverage models. The word embedding dimension is 512. The hidden layer sizes of both forward and backward sequential encoder are 1024 (except where indicated). Since our Tree-GRU encoders are built on top of the bidirectional sequential encoder, the size of the hidden layer (in each direction) is 2048. For the coverage model, we set the size of coverage vectors to 50.

Table 2: BLEU scores of different systems. "Sequential", "Tree-LSTM", "Tree-GRU" and "Bidirectional" denote the encoder part for the standard sequential encoder, Tree-LSTM encoder, Tree-GRU encoder and the bidirectional tree encoder, respectively. "no", "word" and "tree" in column "Coverage" represents the decoder part for using no coverage (standard attention), word coverage (Tu et al., 2016) and our proposed tree-coverage model, respectively.

#	System	Coverage	MT02	MT03	MT04	MT05	MT06	Average
12′	Seq-LSTM	no	34.98	32.81	34.08	31.39	28.03	31.58(+0.82)
13′	SeqTree-LSTM	no	35.28	33.56	34.94	32.64	29.26	32.60(+1.84)

Table 3: BLEU scores of different systems based on LSTM. "Seq-LSTM" denotes both the encoder and decoder parts for the sequential model are based on LSTM; "SeqTree-LSTM" means using Tree-LSTM encoder on top of "Seq-LSTM".

We use Adadelta (Zeiler, 2012) for optimization using a mini-batch size of 32. All other settings are the same as in Bahdanau et al. (2015).

We use case insensitive 4-gram BLEU (Papineni et al., 2002) for evaluation, as calculated by `multi-bleu.perl` in the Moses toolkit.[7]

4.3 Tree Encoders

This set of experiments evaluates the effectiveness of our proposed tree encoders. Table 2, row 2 confirms the finding of Eriguchi et al. (2016) that a Tree-LSTM encoder helps, and row 3 shows that our Tree-GRU encoder gets a better result (+0.87 BLEU, v.s. row 2). To verify our assumption that model consistency is important for performance, we also conduct experiments to compare Tree-LSTM and Tree-GRU on top of LSTM-based encoder-decoder settings. Tree-Lstm with LSTM based sequential model can obtain 1.02 BLEU improvement(Table 3, row 13′), while Tree-LSTM with GRU based sequential model only gets 0.75 BLEU improvement. Although Tree-Lstm with LSTM based sequential model obtain a slightly better result(+0.22 BLEU, v.s. Table 2, row 3), it has more parameters(+1.6M) and takes 1.3 times longer for training.

Since the annotation size of our bidirectional tree encoder is twice of the Tree-LSTM encoder, we halved the size of the hidden layers in the sequential encoder to 512 in each direction, to make fair comparison. These results are shown in Table 4. Row 4′ shows that, even with the same annotation size, our bidirectional tree encoder works better than the original Tree-LSTM encoder (row 2). In fact, our halved-sized unidirectional Tree-GRU encoder (row 3′) also works better than the Tree-LSTM encoder (row 2) with half of its annotation size.

We also compared our bidirectional tree encoder with the head-lexicalization based bidirectional tree encoder proposed by Teng and Zhang (2016), which forms the input vector for each non-leaf node by a bottom-up head propagation mechanism (Table 4, row 14′). Our bidirectional tree encoder gives a better result, suggesting that head word information may not be as helpful for machine translation as it is for syntactic parsing.

When we set the hidden size back to 1024, we found that training the bidirectional tree encoder

[7] http://www.statmt.org/moses

#	Encoder	Coverage	MT02	MT03	MT04	MT05	MT06	Average
3′	Tree-GRU	no	34.92	32.79	34.16	32.03	28.75	31.93(+1.17)
4′	Bidirectional	no	35.02	32.64	35.04	32.50	29.72	32.48(+1.72)
14′	Bidirectional-head	no	34.66	33.17	34.78	31.70	28.47	32.03(+1.27)

Table 4: Experiments with 512 hidden units in each direction of the sequential encoder. The bidirectional tree encoder using head-lexicalization (Bidirectional-head), proposed by (Teng and Zhang, 2016), does not work as well as our simpler bidirectional tree encoder (Bidirectional).

was more difficult. Therefore, we adopted a two-phase training strategy: first, we train the parameters of the bottom-up encoder based NMT system; then, with the initialization of bottom-up encoder and random initialization of the top-down part and decoder, we train the bidirectional tree encoder based NMT system. Table 2, row 4 shows the results of this two-phase training: the bidirectional model (row 4) is 0.79 BLEU better than our unidirectional Tree-GRU (row 3).

4.4 Tree-Coverage Model

Rows 5–8 in Table 2 show that the word coverage model of Tu et al. (2016) consistently helps when used with our proposed tree encoders, with the bidirectional tree encoder remaining the best. However, the improvements of the tree encoder models are smaller than that of the baseline system. This may be caused by the fact that the word coverage model neglects the relationship among the trees, e.g. the relationship between children and parent nodes. Our tree-coverage model consistently improves performance further (rows 9–11).

Our best model combines our bidirectional tree encoder with our tree-coverage model (row 11), yielding a net improvement of +3.54 BLEU over the standard attentional model (row 1), and +1.90 BLEU over the stronger baseline that implements both the bottom-up tree encoder and coverage model from previous work (row 6).

As noted before, the original coverage model does not take word order into account. For comparison, we also implement an extension of the coverage model that lets each coverage vector also depend on those of its left and right neighbors at the previous time step. This model does not help; in fact, it reduces BLEU by about 0.2.

4.5 Analysis By Sentence Length

Following Bahdanau et al. (2015), we bin the development and test sentences by length and show BLEU scores for each bin in Figure 5. The proposed bidirectional tree encoder outperforms the sequential NMT system and the Tree-GRU encoder across all lengths. The improvements become larger for sentences longer than 20 words, and the biggest improvement is for sentences longer than 50 words. This provides some evidence for the importance of syntactic information for long sentences.

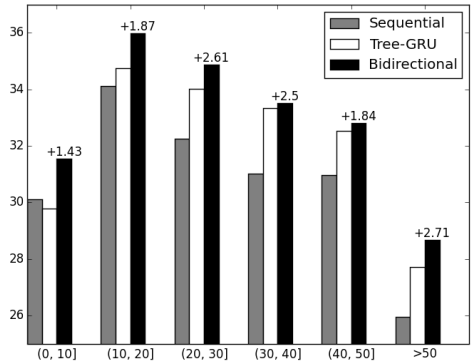

Figure 5: Performance of translations with respect to the lengths of the source sentences. "+" indicates the improvement over the baseline sequential model.

5 Related Work

Recently, many studies have focused on using explicit syntactic tree structure to help learn sentence representations for various sentence classification tasks. For example, Teng and Zhang (2016) and Kokkinos and Potamianos (2017) extend the bottom-up model to a bidirectional model for classification tasks, using Tree-LSTMs with head lexicalization and Tree-GRUs, respectively. We draw on some of these ideas and apply them to machine translation. We use the representation learnt from tree structures to enhance the original sequential model, and make use of these syntactic information during the generation phase.

In NMT systems, the attention model (Bahdanau et al., 2015) becomes a crucial part of the

decoder model. Cohn et al. (2016) and Feng et al. (2016) extend the attentional model to include structural biases from word based alignment models. Kim et al. (2017) incorporate richer structural distributions within deep networks to extend the attention model. Our contribution to the decoder model is to directly exploit structural information in the attention model combined with a coverage mechanism.

6 Conclusion

We have investigated the potential of using explicit source-side syntactic trees in NMT by proposing a novel syntax-aware encoder-decoder model. Our experiments have demonstrated that a top-down encoder is a useful enhancement for the original bottom-up tree encoder (Eriguchi et al., 2016); and incorporating syntactic structure information into the decoder can better control the translation. Our analysis suggests that the benefit of source-side syntax is especially strong for long sentences.

Our current work only uses the structure part of the syntactic tree, without the labels. For future work, it will be interesting to make use of node labels from the tree, or to use syntactic information on the target side, as well.

Abstract

The ambitious goal of this work is to develop a cross-lingual name tagging and linking framework for 282 languages that exist in Wikipedia. Given a document in any of these languages, our framework is able to identify name mentions, assign a coarse-grained or fine-grained type to each mention, and link it to an English Knowledge Base (KB) if it is linkable. We achieve this goal by performing a series of new KB mining methods: generating "silver-standard" annotations by transferring annotations from English to other languages through cross-lingual links and KB properties, refining annotations through self-training and topic selection, deriving language-specific morphology features from anchor links, and mining word translation pairs from cross-lingual links. Both name tagging and linking results for 282 languages are promising on Wikipedia data and on-Wikipedia data. All the data sets, resources and systems for 282 languages are made publicly available as a new benchmark [1].

1 Introduction

Information provided in languages which people can understand saves lives in crises. For example, language barrier was one of the main difficulties faced by humanitarian workers responding to the Ebola crisis in 2014. We propose to break language barriers by extracting information (e.g., entities) from a massive variety of languages and ground the information into an existing knowledge base which is accessible to a user in his/her own language (e.g., a reporter from the World Health Organization who speaks English only).

Wikipedia is a massively multi-lingual resource that currently hosts 295 languages and contains naturally annotated markups [2] and rich informational structures through crowd-sourcing for 35 million articles in 3 billion words. Name mentions in Wikipedia are often labeled as anchor links to their corresponding referent pages. Each entry in Wikipedia is also mapped to external knowledge bases such as DBpedia[3], YAGO (Mahdisoltani et al., 2015) and Freebase (Bollacker et al., 2008) that contain rich properties. Figure 1 shows an example of Wikipedia markups and KB properties. We leverage these markups for developing a language universal framework to automatically extract name mentions from documents in

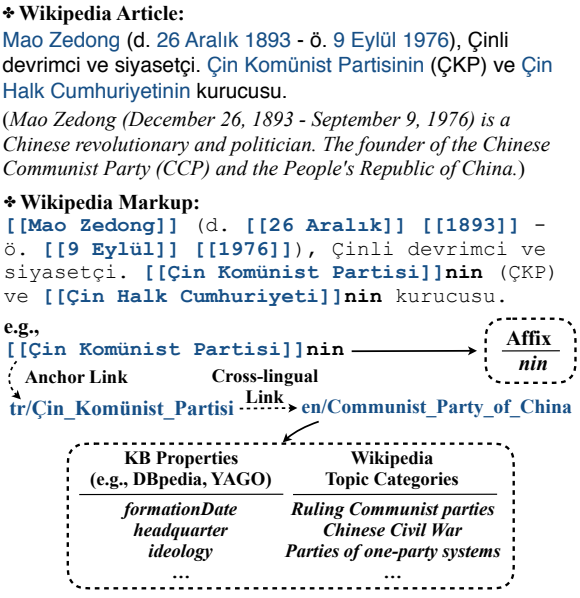

Figure 1: Examples of Wikipedia Markups and KB Properties

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1946–1958
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1178

282 languages, and link them to an English KB (Wikipedia in this work). The major challenges and our new solutions are summarized as follows.

Creating "Silver-standard" through cross-lingual entity transfer. The first step is to classify English Wikipedia entries into certain entity types and then propagate these labels to other languages. We exploit the English Abstract Meaning Representation (AMR) corpus (Banarescu et al., 2013) which includes both name tagging and linking annotations for fine-grained entity types to train an automatic classifier. Furthermore, we exploit each entry's properties in DBpedia as features and thus eliminate the need of language-specific features and resources such as part-of-speech tagging as in previous work (Section 2.2).

Refine annotations through self-training. The initial annotations obtained from above are too incomplete and inconsistent. Previous work used name string match to propagate labels. In contrast, we apply self-training to label other mentions without links in Wikipedia articles even if they have different surface forms from the linked mentions (Section 2.4).

Customize annotations through cross-lingual topic transfer. For the first time, we propose to customize name annotations for specific downstream applications. Again, we use a cross-lingual knowledge transfer strategy to leverage the widely available English corpora to choose entities with specific Wikipedia topic categories (Section 2.5).

Derive morphology analysis from Wikipedia markups. Another unique challenge for morphologically rich languages is to segment each token into its stemming form and affixes. Previous methods relied on either high-cost supervised learning (Roth et al., 2008; Mahmoudi et al., 2013; Ahlberg et al., 2015), or low-quality unsupervised learning (Grönroos et al., 2014; Ruokolainen et al., 2016). We exploit Wikipedia markups to automatically learn affixes as language-specific features (Section 2.3).

Mine word translations from cross-lingual links. Name translation is a crucial step to generate candidate entities in cross-lingual entity linking. Only a small percentage of names can be directly translated by matching against cross-lingual Wikipedia title pairs. Based on the observation that Wikipedia titles within any language tend to follow a consistent style and format, we propose an effective method to derive word translation pairs from these titles based on automatic alignment (Section 3.2).

2 Name Tagging

2.1 Overview

Our first step is to generate "silver-standard" name annotations from Wikipedia markups and train a universal name tagger. Figure 2 shows our overall procedure and the following subsections will elaborate each component.

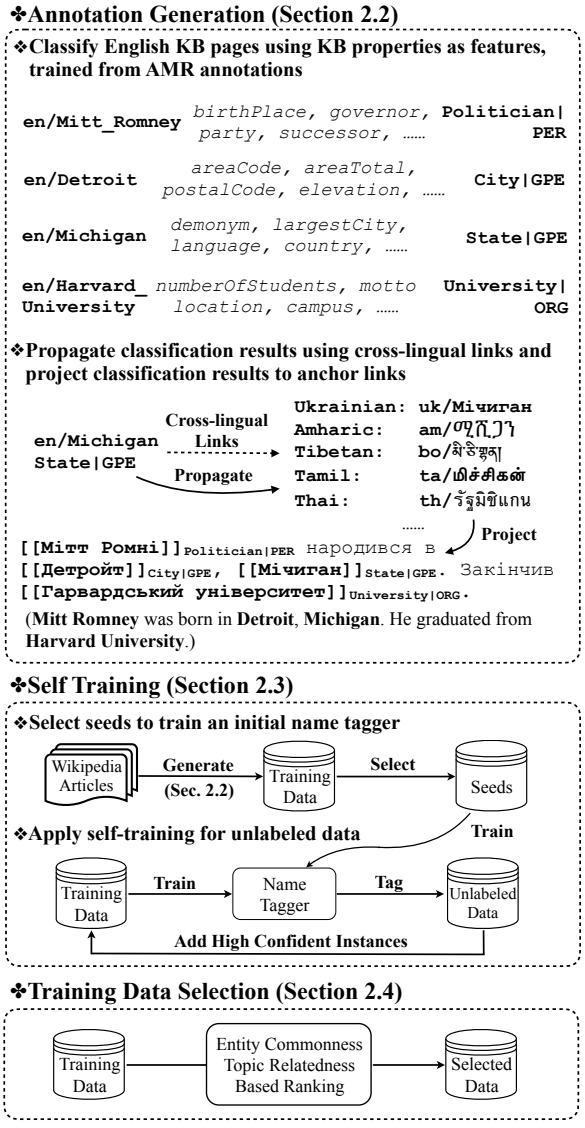

Figure 2: Name Tagging Annotation Generation and Training

2.2 Initial Annotation Generation

We start by assigning an entity type or "other" to each English Wikipedia entry. We utilize the AMR corpus where each entity name mention is manually labeled as one of 139 types

and linked to Wikipedia if it's linkable. In total we obtain 2,756 entity mentions, along with their AMR entity types, Wikipedia titles, YAGO entity types and DBpedia properties. For each pair of AMR entity type t^a and YAGO entity type t^y, we compute the Pointwise Mutual Information (PMI) (Ward Church and Hanks, 1990) of mapping t^a to t^y across all mentions in the AMR corpus. Therefore, each name mention is also assigned a list of YAGO entity types, ranked by their PMI scores with AMR types. In this way, our framework produces three levels of entity typing schemas with different granularity: 4 main types (Person (PER), Organization (ORG), Geo-political Entity (GPE), Location (LOC)), 139 types in AMR, and 9,154 types in YAGO.

Then we leverage an entity's properties in DBpedia as features for assigning types. For example, an entity with a birth date is likely to be a person, while an entity with a population property is likely to be a geo-political entity. Using all DBpedia entity properties as features (60,231 in total), we train Maximum Entropy models to assign types with three levels of granularity to all English Wikipedia pages. In total we obtained 10 million English pages labeled as entities of interest.

Nothman et al. (2013) manually annotated 4,853 English Wikipedia pages with 6 coarse-grained types (Person, Organization, Location, Other, Non-Entity, Disambiguation Page). Using this data set for training and testing, we achieved 96.0% F-score on this initial step, slightly better than their results (94.6% F-score).

Next, we propagate the label of each English Wikipedia page to all entity mentions in all languages in the entire Wikipedia through monolingual redirect links and cross-lingual links.

2.3 Learning Model and KB Derived Features

We use a typical neural network architecture that consists of Bi-directional Long Short-Term Memory and Conditional Random Fields (CRFs) network (Lample et al., 2016) as our underlying learning model for the name tagger for each language. In the following we will describe how we acquire linguistic features.

When a Wikipedia user tries to link an entity mention in a sentence to an existing page, she/he will mark the title (the entity's canonical form, without affixes) within the mention using brackets "`[[]]`", from which we can naturally derive a word's stem and affixes for free. For example, from the Wikipedia markups of the following Turkish sentence: "`Kıta Fransası, güneyde` **`[[Akdeniz]]den`** `kuzeyde [[Manş Denizi]] ve` **`[[Kuzey Denizi]]ne,`** `doğuda` **`[[Ren Nehri]]nden`** `batıda` **`[[Atlas Okyanusu]]na`** `kadar yayılan topraklarda yer alır.` *(Metropolitan France extends from the Mediterranean Sea to the English Channel and the North Sea, and from the Rhine to the Atlantic Ocean.)*", we can learn the following suffixes: "*den*", "*ne*", "*nden*" and "*na*". We use such affix lists to perform basic word stemming, and use them as additional features to determine name boundary and type. For example, "*den*" is a noun suffix which indicates ablative case in Turkish. `[[Akdeniz]]den` means "*from Mediterranean Sea*". Note that this approach can only perform morphology analysis for words whose stem forms and affixes are directly concatenated.

Table 1 summarizes name tagging features.

Features	Descriptions
Form	Lowercase forms of (w_{-1}, w_0, w_{+1})
Case	Case of w_0
Syllable	The first and the last character of w_0
Stem	Stems of (w_{-1}, w_0, w_{+1})
Affix	Affixes of (w_{-1}, w_0, w_{+1})
Gazetteer	Cross-lingual gazetteers learned from training data
Embeddings	Character embeddings and word embeddings [4]learned from training data

Table 1: Name Tagging Features

2.4 Self-Training to Enrich and Refine Labels

The name annotations acquired from the above procedure are far from complete to compete with manually labeled gold-standard data. For example, if a name mention appears multiple times in a Wikipedia article, only the first mention is labeled with an anchor link. We apply self-training to propagate and refine the labels.

We first train an initial name tagger using seeds selected from the labeled data. We adopt an idea from (Guo et al., 2014) which computes Normalized Pointwise Mutual Information (NPMI) (Bouma, 2009) between a tag and a token:

[4]For languages that don't have word segmentation, we consider each character as a token, and use character embeddings only.

$$NPMI(tag, token) = \frac{\ln \frac{p(tag,token)}{p(tag)p(token)}}{-\ln p(tag, token)} \quad (1)$$

Then we select the sentences in which all annotations satisfy $NPMI(tag, token) > \tau$ as seeds [5].

For all Wikipedia articles in a language, we cluster the unlabeled sentences into n clusters [6] by collecting sentences with low cross-entropy into the same cluster. Then we apply the initial tagger to the first unlabeled cluster, select the automatically labeled sentences with high confidence, add them back into the training data, and then re-train the tagger. This procedure is repeated n times until we scan through all unlabeled data.

2.5 Final Training Data Selection for Populous Languages

For some populous languages that have many millions of pages in Wikipedia, we obtain many sentences from self-training. In some emergent settings such as natural disasters it's important to train a system rapidly. Therefore we develop the following effective methods to rank and select high-quality annotated sentences.

Commonness: we prefer sentences that include common entities appearing frequently in Wikipedia. We rank names by their frequency and dynamically set the frequency threshold to select a list of common names. We first initialize the name frequency threshold S to 40. If the number of the sentences is more than a desired size D for training [7], we set the threshold $S = S + 5$, otherwise $S = S - 5$. We iteratively run the selection algorithm until the size of the training set reaches D for a certain S.

Topical Relatedness: Various criteria should be adopted for different scenarios. Our previous work on event extraction (Li et al., 2011) found that by carefully select 1/3 topically related training documents for a test set, we can achieve the same performance as a model trained from the entire training set. Using an emergent disaster setting as a use case, we prefer sentences that include entities related to disaster related topics. We run an English name tagger (Manning et al., 2014) and entity linker (Pan et al., 2015) on the Leidos corpus released by the DARPA LORELEI program [8]. The Leidos corpus consists of documents related to various disaster topics. Based on the linked Wikipedia pages, we rank the frequency of Wikipedia categories and select the top 1% categories (4,035 in total) for our experiments. Some top-ranked topic labels include "*International medical and health organizations*", "*Human rights organizations*", "*International development agencies*", "*Western Asian countries*", "*Southeast African countries*"and "*People in public health*". Then we select the annotated sentences including names (e.g., "*World Health Organization*") in all languages labeled with these topic labels to train the final model.

3 Cross-lingual Entity Linking

3.1 Overview

After we extract names from test documents in a source language, we translate them into English by automatically mined word translation pairs (Section 3.2), and then link translated English mentions to an external English KB (Section 3.3). The overall linking process is illustrated in Figure 3.

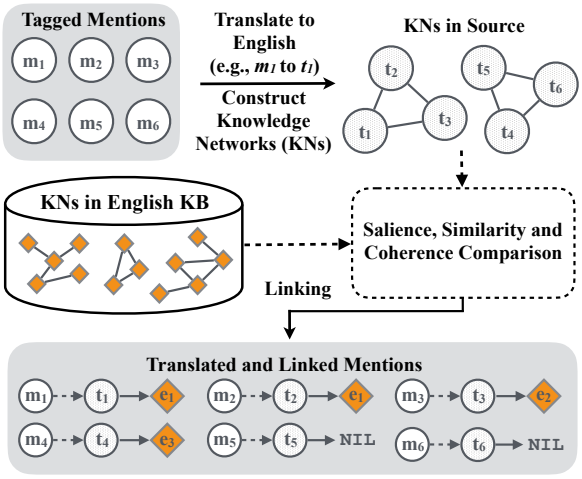

Figure 3: Cross-lingual Entity Linking Overview

3.2 Name Translation

The cross-lingual Wikipedia title pairs, generated through crowd-sourcing, generally follow a consistent style and format in each language. From Table 2 we can see that the order of modifier and head word keeps consistent in Turkish and English titles.

[5] $\tau = 0$ in our experiment.
[6] $n = 20$ in our experiment.
[7] D = 30,000 in our experiment.

Table 2: Word Translation Mining from Cross-lingual Wikipedia Title Pairs

For each name mention, we generate all possible combinations of continuous tokens. For example, no Wikipedia titles contain the Turkish name "*Pekin Teknoloji Enstitüsü (Beijing Institute of Technology)*". We generate the following 6 combinations: "*Pekin*", "*Teknoloji*", "*Enstitüsü*", "*Pekin Teknoloji*", "*Teknoloji Enstitüsü*" and "*Pekin Teknoloji Enstitüsü*", and then extract all cross-lingual Wikipedia title pairs containing each combination. Finally we run GIZA++ (Josef Och and Ney, 2003) to extract word for word translations from these title pairs, as shown in Table 2.

3.3 Entity Linking

Given a set of tagged name mentions $M = \{m_1, m_2, ..., m_n\}$, we first obtain their English translations $T = \{t_1, t_2, ..., t_n\}$ using the approach described above. Then we apply an unsupervised collective inference approach to link T to the KB, similar to our previous work (Pan et al., 2015). The only difference is that we construct knowledge networks (KNs) $g(t_i)$ for T based on their co-occurrence within a context window [9] instead of their AMR relations, because AMR parsing is not available for foreign languages. For each translated name mention t_i, an initial list of candidate entities $E(t_i) = \{e_1, e_2, ..., e_k\}$ is generated based on a surface form dictionary mined from KB properties (e.g., *redirects*, *names*, *aliases*). If no surface form can be matched then we determine the mention as unlinkable. Then we construct KNs $g(e_j)$ for each entity candidate e_j in t_i's entity candidate list $E(t_i)$. We compute the similarity between $g(t_i)$ and $g(e_j)$ based on three measures: salience, similarity and coherence, and select the candidate entity with the highest score.

4 Experiments

4.1 Performance on Wikipedia Data

We first conduct an evaluation using Wikipedia data as "silver-standard". For each language, we use 70% of the selected sentences for training and 30% for testing. For entity linking, we don't have ground truth for unlinkable mentions, so we only compute linking accuracy for linkable name mentions. Table 3 presents the overall performance for three coarse-grained entity types: PER, ORG and GPE/LOC, sorted by the number of name mentions. Figure 4 and Figure 5 summarize the performance, with some example languages marked for various ranges of data size.

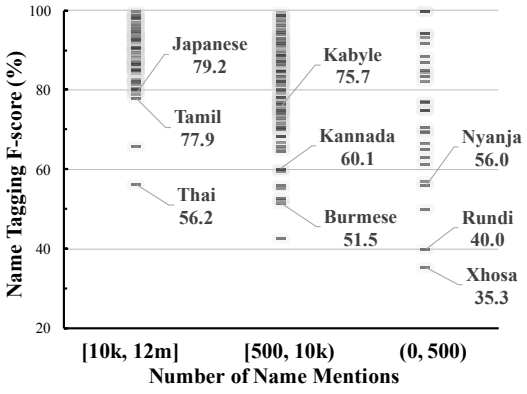

Figure 4: Summary of Name Tagging F-score (%) on Wikipedia Data

Not surprisingly, name tagging performs better for languages with more training mentions. The

[9] In our experiments, we use the previous four and next four name mentions as a context window.

F-score is generally higher than 80% when there are more than 10K mentions, and it significantly drops when there are less than 250 mentions. The languages with low name tagging performance can be categorized into three types: (1) the number of mentions is less than 2K, such as Atlantic-Congo (Wolof), Berber (Kabyle), Chadic (Hausa), Oceanic (Fijian), Hellenic (Greek), Igboid (Igbo), Mande (Bambara), Kartvelian (Georgian, Mingrelian), Timor-Babar (Tetum), Tupian (Guarani) and Iroquoian (Cherokee) language groups; Precision is generally higher than recall for most of these languages, because the small number of linked mentions is not enough to cover a wide variety of entities. (2) there is no space between words, including Chinese, Thai and Japanese; (3) they are not written in latin script, such as the Dravidian group (Tamil, Telugu, Kannada, Malayalam).

The training instances for various entity types are quite imbalanced for some languages. For example, Latin data includes 11% PER names, 84% GPE/LOC names and 5% ORG names. As a result, the performance of ORG is the lowest, while GPE and LOC achieve higher than 75% F-scores for most languages.

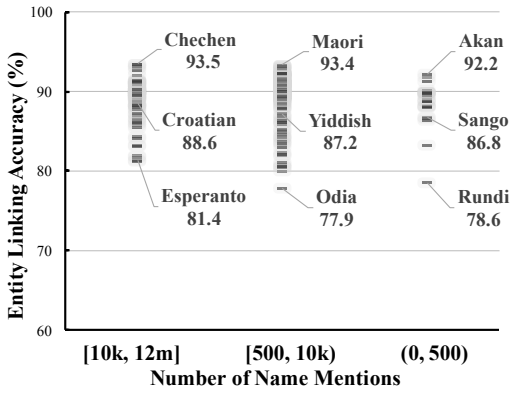

Figure 5: Summary of Entity Linking Accuracy (%) on Wikipedia Data

The linking accuracy is higher than 80% for most languages. Also note that since we don't have perfect annotations on Wikipedia data for any language, these results can be used to estimate how predictable our "silver-standard" data is, but they are not directly comparable to traditional name tagging results measured against gold-standard data annotated by human.

[10]The mapping to language names can be found at http://nlp.cs.rpi.edu/wikiann/mapping

4.2 Performance on Non-Wikipedia Data

In order to have more direct comparison with state-of-the-art name taggers trained from human annotated gold-standard data, we conduct experiments on non-Wikipedia data in 9 languages for which we have human annotated ground truths from the DARPA LORELEI program. Table 4 shows the data statistics. The documents are from news sources and discussion fora.

For fair comparison, we use the same learning method and feature set as described in Section 2.3 to train the models using gold-standard data. Therefore the results of our models trained from gold-standard data are slightly different from some previous work such as (Tsai et al., 2016), mainly due to different learning algorithms and different features sets. For example, the gazetteers we used are different from those in (Tsai et al., 2016), and we did not use brown clusters as additional features.

The name tagging results on LORELEI data set are presented in Table 5. We can see that our approach advances state-of-the-art language-independent methods (Zhang et al., 2016a; Tsai et al., 2016) on the same data sets for most languages, and achieves 6.5% - 17.6% lower F-scores than the models trained from manually annotated gold-standard documents that include thousands of name mentions. To fill in this gap, we would need to exploit more linguistic resources.

Mayfield et al. (2011) constructed a cross-lingual entity linking collection for 21 languages, which covers ground truth for the largest number of languages to date. Therefore we compare our approach with theirs that uses a supervised name transliteration model (McNamee et al., 2011). The entity linking results on non-NIL mentions are presented in Table 6. We can see that except Romanian, our approach outperforms or achieves comparable accuracy as their method on all languages, without using any additional resources or tools such as name transliteration.

4.3 Analysis

Impact of KB-derived Morphological Features

We measured the impact of our affix lists derived from Wikipedia markups on two morphologically-rich languages: Turkish and Uzbek. The morphol-

[11]McNamee et al. (2011) did not develop a model for Chinese even though Chinese data set was included in the collection.

Turkish	2,169	92.5	92.2
Urdu	1,093	70.7	**73.2**

Table 6: Entity Linking Accuracy (%) on Non-Wikipedia Data

ogy features contributed 11.1% and 7.1% absolute name tagging F-score gains to Turkish and Uzbek LORELEI data sets respectively.

Impact of Self-Training

Using Turkish as a case study, the learning curves of self-training on Wikipedia and non-Wikipedia test sets are shown in Figure 6. We can see that self-training provides significant improvement for both Wikipedia (6% absolute gain) and non-Wikipedia test data (12% absolute gain). As expected the learning curve on Wikipedia data is more smooth and converges more slowly than that of non-Wikipedia data. This indicates that when the training data is incomplete and noisy, the model can benefit from self-training through iterative label correction and propagation.

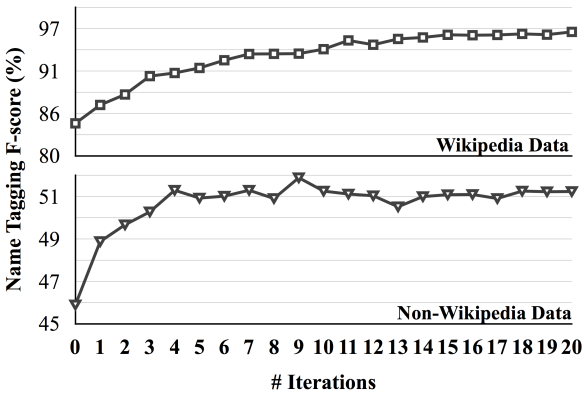

Figure 6: Learning Curve of Self-training

Impact of Topical Relatedness

We also found that the topical relatedness measure proposed in Section 2.5 not only significantly reduces the size of training data and thus speeds up the training process for many languages, but also consistently improves the quality. For example, the Turkish name tagger trained from the entire data set without topic selection yields 49.7% F-score on LORELEI data set, and the performance is improved to 51.5% after topic selection.

5 Related Work

Wikipedia markup based silver standard generation: Our work was mainly inspired from previous work that leveraged Wikipedia markups to train name taggers (Nothman et al., 2008; Dakka and Cucerzan, 2008; Mika et al., 2008; Ringland et al., 2009; Alotaibi and Lee, 2012; Nothman et al., 2013; Althobaiti et al., 2014). Most of these previous methods manually classified many English Wikipedia entries into pre-defined entity types. In contrast, our approach doesn't need any manual annotations or language-specific features, while generates both coarse-grained and fine-grained types.

Many fine-grained entity typing approaches (Fleischman and Hovy, 2002; Giuliano,

2009; Ekbal et al., 2010; Ling and Weld, 2012; Yosef et al., 2012; Nakashole et al., 2013; Gillick et al., 2014; Yogatama et al., 2015; Del Corro et al., 2015) also created annotations based on Wikipedia anchor links. Our framework performs both name identification and typing and takes advantage of richer structures in the KBs. Previous work on Arabic name tagging (Althobaiti et al., 2014) extracted entity titles as a gazetteer for stemming, and thus it cannot handle unknown names. We developed a new method to derive generalizable affixes for morphologically rich language based on Wikipedia markups.

Wikipedia as background features for IE: Wikipedia pages have been used as additional features to improve various Information Extraction (IE) tasks, including name tagging (Kazama and Torisawa, 2007), coreference resolution (Paolo Ponzetto and Strube, 2006), relation extraction (Chan and Roth, 2010) and event extraction (Hogue et al., 2014). Other automatic name annotation generation methods have been proposed, including KB driven distant supervision (An et al., 2003; Mintz et al., 2009; Ren et al., 2015) and cross-lingual projection (Li et al., 2012; Kim et al., 2012; Che et al., 2013; Wang et al., 2013; Wang and Manning, 2014; Zhang et al., 2016b).

Multi-lingual name tagging: Some recent research (Zhang et al., 2016a; Littell et al., 2016; Tsai et al., 2016) under the DARPA LORELEI program focused on developing name tagging techniques for low-resource languages. These approaches require English annotations for projection (Tsai et al., 2016), some input from a native speaker, either through manual annotations (Littell et al., 2016), or a linguistic survey (Zhang et al., 2016a). Without using any manual annotations, our name taggers outperform previous methods on the same data sets for many languages.

Multi-lingual entity linking: NIST TAC-KBP Tri-lingual entity linking (Ji et al., 2016) focused on three languages: English, Chinese and Spanish. (McNamee et al., 2011) extended it to 21 languages. But their methods required labeled data and name transliteration. We share the same goal as (Sil and Florian, 2016) to extend cross-lingual entity linking to all languages in Wikipedia. They exploited Wikipedia links to train a supervised linker. We mine reliable word translations from cross-lingual Wikipedia titles, which enables us to adopt unsupervised English entity linking techniques such as (Pan et al., 2015) to directly link translated English name mentions to English KB.

Efforts to save annotation cost for name tagging: Some previous work including (Ji and Grishman, 2006; Richman and Schone, 2008; Althobaiti et al., 2013) exploited semi-supervised methods to save annotation cost. We observed that self-training can provide further gains when the training data contains certain amount of noise.

6 Conclusions and Future Work

We developed a simple yet effective framework that can extract names from 282 languages and link them to an English KB. This framework follows a fully automatic training and testing pipeline, without the needs of any manual annotations or knowledge from native speakers. We evaluated our framework on both Wikipedia articles and external formal and informal texts and obtained promising results. To the best of our knowledge, our multilingual name tagging and linking framework is applied to the largest number of languages. We release the following resources for each of these 282 languages: "silver-standard" name tagging and linking annotations with multiple levels of granularity, morphology analyzer if it's a morphologically-rich language, and an end-to-end name tagging and linking system. In this work, we treat all languages independently when training their corresponding name taggers. In the future, we will explore the topological structure of related languages and exploit cross-lingual knowledge transfer to enhance the quality of extraction and linking. The general idea of deriving noisy annotations from KB properties can also be extended to other IE tasks such as relation extraction.

Abstract

Word embeddings are well known to capture linguistic regularities of the language on which they are trained. Researchers also observe that these regularities can transfer across languages. However, previous endeavors to connect separate monolingual word embeddings typically require cross-lingual signals as supervision, either in the form of parallel corpus or seed lexicon. In this work, we show that such cross-lingual connection can actually be established without any form of supervision. We achieve this end by formulating the problem as a natural adversarial game, and investigating techniques that are crucial to successful training. We carry out evaluation on the unsupervised bilingual lexicon induction task. Even though this task appears intrinsically cross-lingual, we are able to demonstrate encouraging performance without any cross-lingual clues.

1 Introduction

As word is the basic unit of a language, the betterment of its representation has significant impact on various natural language processing tasks. Continuous word representations, commonly known as word embeddings, have formed the basis for numerous neural network models since their advent. Their popularity results from the performance boost they bring, which should in turn be attributed to the linguistic regularities they capture (Mikolov et al., 2013b).

Soon following the success on monolingual tasks, the potential of word embeddings for cross-lingual natural language processing has attracted much attention. In their pioneering work, Mikolov et al. (2013a) observe that word embeddings trained separately on monolingual corpora exhibit isomorphic structure across languages, as illustrated in Figure 1. This interesting finding is in line with research on human cognition (Youn et al., 2016). It also means a linear transformation may be established to connect word embedding spaces, allowing word feature transfer. This has far-reaching implication on low-resource scenarios (Daumé III and Jagarlamudi, 2011; Irvine and Callison-Burch, 2013), because word embeddings only require plain text to train, which is the most abundant form of linguistic resource.

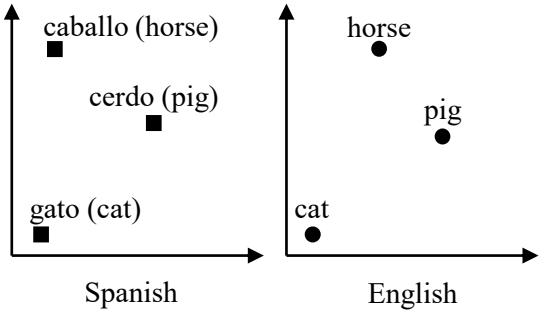

Figure 1: Illustrative monolingual word embeddings of Spanish and English, adapted from (Mikolov et al., 2013a). Although trained independently, the two sets of embeddings exhibit approximate isomorphism.

However, connecting separate word embedding spaces typically requires supervision from cross-lingual signals. For example, Mikolov et al. (2013a) use five thousand seed word translation pairs to train the linear transformation. In a recent study, Vulić and Korhonen (2016) show that at least hundreds of seed word translation pairs are needed for the model to generalize. This is unfortunate for low-resource languages and domains,

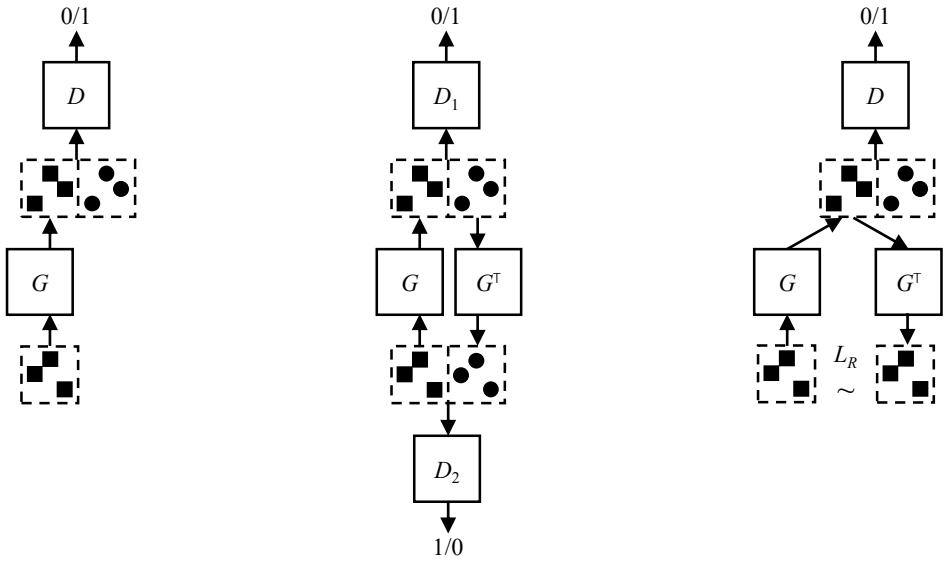

Figure 2: (a) The unidirectional transformation model directly inspired by the adversarial game: The generator G tries to transform source word embeddings (squares) to make them seem like target ones (dots), while the discriminator D tries to classify whether the input embeddings are generated by G or real samples from the target embedding distribution. (b) The bidirectional transformation model. Two generators with tied weights perform transformation between languages. Two separate discriminators are responsible for each language. (c) The adversarial autoencoder model. The generator aims to make the transformed embeddings not only indistinguishable by the discriminator, but also recoverable as measured by the reconstruction loss L_R.

because data encoding cross-lingual equivalence is often expensive to obtain.

In this work, we aim to entirely eliminate the need for cross-lingual supervision. Our approach draws inspiration from recent advances in generative adversarial networks (Goodfellow et al., 2014). We first formulate our task in a fashion that naturally admits an adversarial game. Then we propose three models that implement the game, and explore techniques to ensure the success of training. Finally, our evaluation on the bilingual lexicon induction task reveals encouraging performance, even though this task appears formidable without any cross-lingual supervision.

2 Models

In order to induce a bilingual lexicon, we start from two sets of monolingual word embeddings with dimensionality d. They are trained separately on two languages. Our goal is to learn a mapping function $f : \mathbb{R}^d \rightarrow \mathbb{R}^d$ so that for a source word embedding x, $f(x)$ lies close to the embedding of its target language translation y. The learned mapping function can then be used to translate each source word x by finding the nearest target embedding to $f(x)$.

We consider x to be drawn from a distribution p_x, and similarly $y \sim p_y$. The key intuition here is to find the mapping function to make $f(x)$ seem to follow the distribution p_y, for all $x \sim p_x$. From this point of view, we design an adversarial game as illustrated in Figure 2(a): The generator G implements the mapping function f, trying to make $f(x)$ passable as target word embeddings, while the discriminator D is a binary classifier striving to distinguish between fake target word embeddings $f(x) \sim p_{f(x)}$ and real ones $y \sim p_y$. This intuition can be formalized as the minimax game $\min_G \max_D V(D, G)$ with value function

$$\begin{aligned} & V(D,G) \\ =& \mathbb{E}_{y\sim p_y}\left[\log D(y)\right] + \\ & \mathbb{E}_{x\sim p_x}\left[\log\left(1 - D\left(G\left(x\right)\right)\right)\right]. \end{aligned} \tag{1}$$

Theoretical analysis reveals that adversarial training tries to minimize the Jensen-Shannon divergence $\text{JSD}\left(p_y || p_{f(x)}\right)$ (Goodfellow et al., 2014). Importantly, the minimization happens at the distribution level, without requiring word

translation pairs to supervise training.

2.1 Model 1: Unidirectional Transformation

The first model directly implements the adversarial game, as shown in Figure 2(a). As hinted by the isomorphism shown in Figure 1, previous works typically choose the mapping function f to be a linear map (Mikolov et al., 2013a; Dinu et al., 2015; Lazaridou et al., 2015). We therefore parametrize the generator as a transformation matrix $G \in \mathbb{R}^{d \times d}$. We also tried non-linear maps parametrized by neural networks, without success. In fact, if the generator is given sufficient capacity, it can in principle learn a constant mapping function to a target word embedding, which makes the discriminator impossible to distinguish, much like the "mode collapse" problem widely observed in the image domain (Radford et al., 2015; Salimans et al., 2016). We therefore believe it is crucial to grant the generator with suitable capacity.

As a generic binary classifier, a standard feed-forward neural network with one hidden layer is used to parametrize the discriminator D, and its loss function is the usual cross-entropy loss, as in the value function (1):

$$L_D = -\log D(y) - \log(1 - D(Gx)). \quad (2)$$

For simplicity, here we write the loss with a mini-batch size of 1; in our experiments we use 128.

The generator loss is given by

$$L_G = -\log D(Gx). \quad (3)$$

In line with previous work (Goodfellow et al., 2014), we find this loss easier to minimize than the original form $\log(1 - D(Gx))$.

Orthogonal Constraint

The above model is very difficult to train. One possible reason is that the parameter search space $\mathbb{R}^{d \times d}$ for the generator may still be too large. Previous works have attempted to constrain the transformation matrix to be orthogonal (Xing et al., 2015; Zhang et al., 2016b; Artetxe et al., 2016). An orthogonal transformation is also theoretically appealing for its self-consistency (Smith et al., 2017) and numerical stability. However, using constrained optimization for our purpose is cumbersome, so we opt for an orthogonal parametrization (Mhammedi et al., 2016) of the generator instead.

2.2 Model 2: Bidirectional Transformation

The orthogonal parametrization is still quite slow. We can relax the orthogonal constraint and only require the transformation to be self-consistent (Smith et al., 2017): If G transforms the source word embedding space into the target language space, its transpose $G^\top$ should transform the target language space back to the source. This can be implemented by two unidirectional models with a tied generator, as illustrated in Figure 2(b). Two separate discriminators are used, with the same cross-entropy loss as Equation (2) used by Model 1. The generator loss is given by

$$L_G = -\log D_1(Gx) - \log D_2\left(G^\top x\right). \quad (4)$$

2.3 Model 3: Adversarial Autoencoder

As another way to relax the orthogonal constraint, we introduce the adversarial autoencoder (Makhzani et al., 2015), depicted in Figure 2(c). After the generator G transforms a source word embedding x into a target language representation Gx, we should be able to reconstruct the source word embedding x by mapping back with $G^\top$. We therefore introduce the reconstruction loss measured by cosine similarity:

$$L_R = -\cos\left(x, G^\top Gx\right). \quad (5)$$

Note that this loss will be minimized if G is orthogonal. With this term included, the loss function for the generator becomes

$$L_G = -\log D(Gx) - \lambda \cos\left(x, G^\top Gx\right), \quad (6)$$

where λ is a hyperparameter that balances the two terms. $\lambda = 0$ recovers the unidirectional transformation model, while larger λ should enforce a stricter orthogonal constraint.

3 Training Techniques

Generative adversarial networks are notoriously difficult to train, and investigation into stabler training remains a research frontier (Radford et al., 2015; Salimans et al., 2016; Arjovsky and Bottou, 2017). We contribute in this aspect by reporting techniques that are crucial to successful training for our task.

3.1 Regularizing the Discriminator

Recently, it has been suggested to inject noise into the input to the discriminator (Sønderby et al.,

2016; Arjovsky and Bottou, 2017). The noise is typically additive Gaussian. Here we explore more possibilities, with the following types of noise, injected into the input and hidden layer:

- Multiplicative Bernoulli noise (dropout) (Srivastava et al., 2014): $\epsilon \sim \text{Bernoulli}\,(p)$.
- Additive Gaussian noise: $\epsilon \sim \mathcal{N}\left(0, \sigma^2\right)$.
- Multiplicative Gaussian noise: $\epsilon \sim \mathcal{N}\left(1, \sigma^2\right)$.

As noise injection is a form of regularization (Bishop, 1995; Van der Maaten et al., 2013; Wager et al., 2013), we also try l_2 regularization, and directly restricting the hidden layer size to combat overfitting. Our findings include:

- Without regularization, it is not impossible for the optimizer to find a satisfactory parameter configuration, but the hidden layer size has to be tuned carefully. This indicates that a balance of capacity between the generator and discriminator is needed.
- All forms of regularization help training by allowing us to liberally set the hidden layer size to a relatively large value.
- Among the types of regularization, multiplicative Gaussian injected into the input is the most effective, and additive Gaussian is similar. On top of input noise, hidden layer noise helps slightly.

In the following experiments, we inject multiplicative Gaussian into the input and hidden layer of the discriminator with $\sigma = 0.5$.

3.2 Model Selection

From a typical training trajectory shown in Figure 3, we observe that training is not convergent. In fact, simply using the model saved at the end of training gives poor performance. Therefore we need a mechanism to select a good model. We observe there are sharp drops of the generator loss L_G, and find they correspond to good models, as the discriminator gets confused at these points with its classification accuracy (D accuracy) dropping simultaneously. Interestingly, the reconstruction loss L_R and the value of $\left\|G^\top G - I\right\|_F$ exhibit synchronous drops, even if we use the unidirectional transformation model ($\lambda = 0$). This means a good transformation matrix is indeed nearly orthogonal, and justifies our encouragement of G towards orthogonality. With this finding, we can train for sufficient steps and save the model with the lowest generator loss.

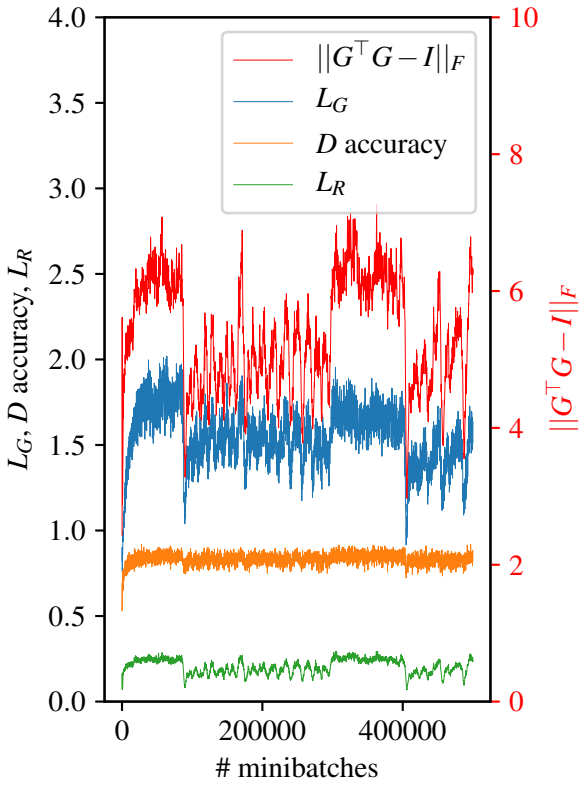

Figure 3: A typical training trajectory of the adversarial autoencoder model with $\lambda = 1$. The values are averages within each minibatch.

As we aim to find the cross-lingual transformation without supervision, it would be ideal to determine hyperparameters without a validation set. The sharp drops can also be indicative in this case. If a hyperparameter configuration is poor, those values will oscillate without a clear drop. Although this criterion is somewhat subjective, we find it to be quite feasible in practice.

3.3 Other Training Details

Our approach takes monolingual word embeddings as input. We train the CBOW model (Mikolov et al., 2013b) with default hyperparameters in `word2vec`.[1] The embedding dimension d is 50 unless stated otherwise. Before feeding them into our system, we normalize the word embeddings to unit length. When sampling words for adversarial training, we penalize frequent words in a way similar to (Mikolov et al., 2013b). G is

[1] https://code.google.com/archive/p/word2vec

initialized with a random orthogonal matrix. The hidden layer size of D is 500. Adversarial training involves alternate gradient update of the generator and discriminator, which we implement with a simpler variant algorithm described in (Nowozin et al., 2016). Adam (Kingma and Ba, 2014) is used as the optimizer, with default hyperparameters. For the adversarial autoencoder model, $\lambda = 1$ generally works well, but $\lambda = 10$ appears stabler for the low-resource Turkish-English setting.

4 Experiments

We evaluate the quality of the cross-lingual embedding transformation on the bilingual lexicon induction task. After a source word embedding is transformed into the target space, its M nearest target embeddings (in terms of cosine similarity) are retrieved, and compared against the entry in a ground truth bilingual lexicon. Performance is measured by top-M accuracy (Vulić and Moens, 2013): If any of the M translations is found in the ground truth bilingual lexicon, the source word is considered to be handled correctly, and the accuracy is calculated as the percentage of correctly translated source words. We generally report the harshest top-1 accuracy, unless when comparing with published figures in Section 4.4.

Baselines

Almost all approaches to bilingual lexicon induction from non-parallel data depend on seed lexica. An exception is decipherment (Dou and Knight, 2012; Dou et al., 2015), and we use it as our baseline. The decipherment approach is not based on distributional semantics, but rather views the source language as a cipher for the target language, and attempts to learn a statistical model to decipher the source language. We run the MonoGiza system as recommended by the toolkit.[2] It can also utilize monolingual embeddings (Dou et al., 2015); in this case, we use the same embeddings as the input to our approach.

Sharing the underlying spirit with our approach, related methods also build upon monolingual word embeddings and find transformation to link different languages. Although they need seed word translation pairs to train and thus not directly comparable, we report their performance with 50 and 100 seeds for reference. These methods are:

- Translation matrix (`TM`) (Mikolov et al., 2013a): the pioneer of this type of methods mentioned in the introduction, using linear transformation. We use a publicly available implementation.[3]

- Isometric alignment (`IA`) (Zhang et al., 2016b): an extension of `TM` by augmenting its learning objective with the isometric (orthogonal) constraint. Although Zhang et al. (2016b) had subsequent steps for their POS tagging task, it could be used for bilingual lexicon induction as well.

We ensure the same input embeddings for these methods and ours.

The seed word translation pairs are obtained as follows. First, we ask Google Translate[4] to translate the source language vocabulary. Then the target translations are queried again and translated back to the source language, and those that do not match the original source words are discarded. This helps to ensure the translation quality. Finally, the translations are discarded if they fall out of our target language vocabulary.

4.1 Experiments on Chinese-English

Data

For this set of experiments, the data for training word embeddings comes from Wikipedia comparable corpora.[5] Following (Vulić and Moens, 2013), we retain only nouns with at least 1,000 occurrences. For the Chinese side, we first use OpenCC[6] to normalize characters to be simplified, and then perform Chinese word segmentation and POS tagging with THULAC.[7] The preprocessing of the English side involves tokenization, POS tagging, lemmatization, and lowercasing, which we carry out with the NLTK toolkit.[8] The statistics of the final training data is given in Table 1, along with the other experimental settings.

As the ground truth bilingual lexicon for evaluation, we use Chinese-English Translation Lexicon Version 3.0 (LDC2002L27).

Overall Performance

Table 2 lists the performance of the MonoGiza baseline and our four variants of adversarial training. MonoGiza obtains low performance, likely due to the harsh evaluation protocol (cf. Section 4.4). Providing it with syntactic information can help (Dou and Knight, 2013), but in a low-resource scenario with zero cross-lingual information, parsers are likely to be inaccurate or even unavailable.

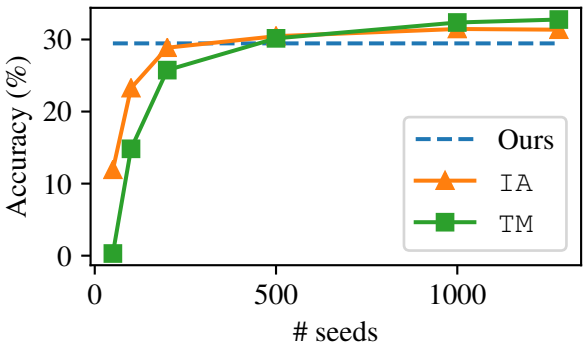

Figure 4: Top-1 accuracies of our approach, isometric alignment (IA), and translation matrix (TM), with the number of seeds varying in {50, 100, 200, 500, 1000, 1280}.

The unidirectional transformation model attains reasonable accuracy if trained successfully, but it is rather sensitive to hyperparameters and initialization. This training difficulty motivates our orthogonal constraint. But imposing a strict orthogonal constraint hurts performance. It is also about 20 times slower even though we utilize orthogonal parametrization instead of constrained optimization. The last two models represent different relaxations of the orthogonal constraint, and the adversarial autoencoder model achieves the best performance. We therefore use it in our following experiments. Table 3 lists some word translation examples given by the adversarial autoencoder model.

Comparison With Seed-Based Methods

In this section, we investigate how many seeds TM and IA require to attain the performance level of our approach. There are a total of 1,280 seed translation pairs for Chinese-English, which are removed from the test set during the evaluation for this experiment. We use the most frequent S pairs for TM and IA.

Figure 4 shows the accuracies with respect to

method	# seeds	es-en	it-en	ja-zh	tr-en
MonoGiza w/o embeddings	0	0.35	0.30	0.04	0.00
MonoGiza w/ embeddings	0	1.19	0.27	0.23	0.09

Ours	0	71.97	58.60	43.02	17.18

Table 4: Top-1 accuracies (%) of the MonoGiza baseline and our approach on Spanish-English, Italian-English, Japanese-Chinese, and Turkish-English. The results for translation matrix (TM) and isometric alignment (IA) using 50 and 100 seeds are also listed.

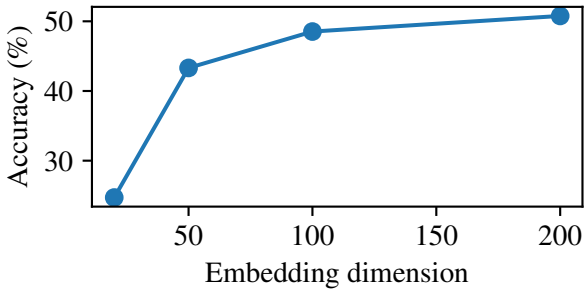

Figure 5: Top-1 accuracies of our approach with respect to the input embedding dimensions in {20, 50, 100, 200}.

S. When the seeds are few, the seed-based methods exhibit clear performance degradation. In this case, we also observe the importance of the orthogonal constraint from the superiority of IA to TM, which supports our introduction of this constraint as we attempt zero supervision. Finally, in line with the finding in (Vulić and Korhonen, 2016), hundreds of seeds are needed for TM to generalize. Only then do seed-based methods catch up with our approach, and the performance difference is marginal even when more seeds are provided.

Effect of Embedding Dimension

As our approach takes monolingual word embeddings as input, it is conceivable that their quality significantly affects how well the two spaces can be connected by a linear map. We look into this aspect by varying the embedding dimension d in Figure 5. As the dimension increases, the accuracy improves and gradually levels off. This indicates that too low a dimension hampers the encoding of linguistic information drawn from the corpus, and it is advisable to use a sufficiently large dimension.

4.2 Experiments on Other Language Pairs

Data

We also induce bilingual lexica from Wikipedia comparable corpora for the following language pairs: Spanish-English, Italian-English, Japanese-Chinese, and Turkish-English. For Spanish-English and Italian-English, we choose to use TreeTagger[9] for preprocessing, as in (Vulić and Moens, 2013). For the Japanese corpus, we use MeCab[10] for word segmentation and POS tagging. For Turkish, we utilize the preprocessing tools (tokenization and POS tagging) provided in LORELEI Language Packs (Strassel and Tracey, 2016), and its English side is preprocessed by NLTK. Unlike the other language pairs, the frequency cutoff threshold for Turkish-English is 100, as the amount of data is relatively small.

The ground truth bilingual lexica for Spanish-English and Italian-English are obtained from Open Multilingual WordNet[11] through NLTK. For Japanese-Chinese, we use an in-house lexicon. For Turkish-English, we build a set of ground truth translation pairs in the same way as how we obtain seed word translation pairs from Google Translate, described above.

Results

As shown in Table 4, the MonoGiza baseline still does not work well on these language pairs, while our approach achieves much better performance. The accuracies are particularly high for Spanish-English and Italian-English, likely because they are closely related languages, and their embedding spaces may exhibit stronger isomorphism. The

performance on Japanese-Chinese is lower, on a comparable level with Chinese-English (cf. Table 2), and these languages are relatively distantly related. Turkish-English represents a low-resource scenario, and therefore the lexical semantic structure may be insufficiently captured by the embeddings. The agglutinative nature of Turkish can also add to the challenge.

4.3 Large-Scale Settings

We experiment with large-scale Chinese-English data from two sources: the whole Wikipedia dump and Gigaword (LDC2011T13 and LDC2011T07). We also simplify preprocessing by removing the noun restriction and the lemmatization step (cf. preprocessing decisions for the above experiments).

Although large-scale data may benefit the training of embeddings, it poses a greater challenge to bilingual lexicon induction. First, the degree of non-parallelism tends to increase. Second, with cruder preprocessing, the noise in the corpora may take its toll. Finally, but probably most importantly, the vocabularies expand dramatically compared to previous settings (see Table 1). This means a word translation has to be retrieved from a much larger pool of candidates.

For these reasons, we consider the performance of our approach presented in Table 5 to be encouraging. The imbalanced sizes of the Chinese and English Wikipedia do not seem to cause a problem for the structural isomorphism needed by our method. MonoGiza does not scale to such large vocabularies, as it already takes days to train in our Italian-English setting. In contrast, our approach is immune from scalability issues by working with embeddings provided by word2vec, which is well known for its fast speed. With the network configuration used in our experiments, the adversarial autoencoder model takes about two hours to train for 500k minibatches on a single CPU.

4.4 Comparison With (Cao et al., 2016)

In order to compare with the recent method by Cao et al. (2016), which also uses zero cross-lingual signal to connect monolingual embeddings, we replicate their French-English experiment to test our approach.[12] This experimental setting has important differences from the above ones, mostly in the evaluation protocol. Apart from using top-5 accuracy as the evaluation metric, the ground truth bilingual lexicon is obtained by performing word alignment on a parallel corpus. We find this automatically constructed bilingual lexicon to be noisier than the ones we use for the other language pairs; it often lists tens of translations for a source word. This lenient evaluation protocol should explain MonoGiza's higher numbers in Table 6 than what we report in the other experiments. In this setting, our approach is able to considerably outperform both MonoGiza and the method by Cao et al. (2016).

5 Related Work

5.1 Cross-Lingual Word Embeddings for Bilingual Lexicon Induction

Inducing bilingual lexica from non-parallel data is a long-standing cross-lingual task. Except for the decipherment approach, traditional statistical methods all require cross-lingual signals (Rapp, 1999; Koehn and Knight, 2002; Fung and Cheung, 2004; Gaussier et al., 2004; Haghighi et al., 2008; Vulić et al., 2011; Vulić and Moens, 2013).

Recent advances in cross-lingual word embeddings (Vulić and Korhonen, 2016; Upadhyay et al.,

[12] As a confirmation, we ran MonoGiza in this setting and obtained comparable performance as reported.

2016) have rekindled interest in bilingual lexicon induction. Like their traditional counterparts, these embedding-based methods require cross-lingual signals encoded in parallel data, aligned at document level (Vulić and Moens, 2015), sentence level (Zou et al., 2013; Chandar A P et al., 2014; Hermann and Blunsom, 2014; Kočiský et al., 2014; Gouws et al., 2015; Luong et al., 2015; Coulmance et al., 2015; Oshikiri et al., 2016), or word level (i.e. seed lexicon) (Gouws and Søgaard, 2015; Wick et al., 2016; Duong et al., 2016; Shi et al., 2015; Mikolov et al., 2013a; Dinu et al., 2015; Lazaridou et al., 2015; Faruqui and Dyer, 2014; Lu et al., 2015; Ammar et al., 2016; Zhang et al., 2016a, 2017; Smith et al., 2017). In contrast, our work completely removes the need for cross-lingual signals to connect monolingual word embeddings, trained on non-parallel text corpora.

As one of our baselines, the method by Cao et al. (2016) also does not require cross-lingual signals to train bilingual word embeddings. It modifies the objective for training embeddings, whereas our approach uses monolingual embeddings trained beforehand and held fixed. More importantly, its learning mechanism is substantially different from ours. It encourages word embeddings from different languages to lie in the shared semantic space by matching the mean and variance of the hidden states, assumed to follow a Gaussian distribution, which is hard to justify. Our approach does not make any assumptions and directly matches the mapped source embedding distribution with the target distribution by adversarial training.

A recent work also attempts adversarial training for cross-lingual embedding transformation (Barone, 2016). The model architectures are similar to ours, but the reported results are not positive. We tried the publicly available code on our data, but the results were not positive, either. Therefore, we attribute the outcome to the difference in the loss and training techniques, but not the model architectures or data.

5.2 Adversarial Training

Generative adversarial networks are originally proposed for generating realistic images as an implicit generative model, but the adversarial training technique for matching distributions is generalizable to much more tasks, including natural language processing. For example, Ganin et al. (2016) address domain adaptation by adversarially training features to be domain invariant, and test on sentiment classification. Chen et al. (2016) extend this idea to cross-lingual sentiment classification. Our research deals with unsupervised bilingual lexicon induction based on word embeddings, and therefore works with word embedding distributions, which are more interpretable than the neural feature space of classifiers in the above works.

In the field of neural machine translation, a recent work (He et al., 2016) proposes dual learning, which also involves a two-agent game and therefore bears conceptual resemblance to the adversarial training idea. The framework is carried out with reinforcement learning, and thus differs greatly in implementation from adversarial training.

6 Conclusion

In this work, we demonstrate the feasibility of connecting word embeddings of different languages without any cross-lingual signal. This is achieved by matching the distributions of the transformed source language embeddings and target ones via adversarial training. The success of our approach signifies the existence of universal lexical semantic structure across languages. Our work also opens up opportunities for the processing of extremely low-resource languages and domains that lack parallel data completely.

Our work is likely to benefit from advances in techniques that further stabilize adversarial training. Future work also includes investigating other divergences that adversarial training can minimize (Nowozin et al., 2016), and broader mathematical tools that match distributions (Mohamed and Lakshminarayanan, 2016).

Abstract

Word-level language detection is necessary for analyzing code-switched text, where multiple languages could be mixed within a sentence. Existing models are restricted to code-switching between two specific languages and fail in real-world scenarios as text input rarely has a priori information on the languages used. We present a novel unsupervised word-level language detection technique for code-switched text for an arbitrarily large number of languages, which does not require any manually annotated training data. Our experiments with tweets in seven languages show a 74% relative error reduction in word-level labeling with respect to competitive baselines. We then use this system to conduct a large-scale quantitative analysis of code-switching patterns on Twitter, both global as well as region-specific, with 58M tweets.

1 Introduction

In stable multilingual societies, communication often features fluid alteration between two or more languages – a phenomenon known as *code-switching*[1] (Gumperz, 1982; Myers-Scotton, 1993). It has been studied extensively in linguistics, primarily as a speech phenomenon (Poplack, 1980; Gumperz, 1982; Myers-Scotton, 1993; Milroy and Muysken, 1995; Auer, 2013). However, the growing popularity of computer mediated communication, particularly social media, has resulted in language data in the text form which exhibits code-switching, among other speech-like characteristics (Crystal, 2001; Herring, 2003; Danet and Herring, 2007; Cardenas-Claros and Isharyanti, 2009). With the large amount of online content generated by multilingual users around the globe, it becomes necessary to design techniques to analyze mixed language, which can help not only in developing end-user applications, but also in conducting fundamental sociolinguistic studies.

Language detection (LD) is a prerequisite to several NLP techniques. Most state-of-the-art LD systems detect a single language for an entire document or sentence. Such methods often fail to detect code-switching, which can occur within a sentence. In recent times, there has been some effort to build word-level LD for code-switching between a specific pair of languages (Nguyen and Dogruöz, 2013; Elfardy et al., 2013; Solorio et al., 2014; Barman et al., 2014). However, usually user-generated text (e.g., on social media) has no prior information of the languages being used. Further, as several previous social-media based studies on multilingualism have pointed out (Kim et al., 2014; Manley, 2012), lack of general word-level LD has been a bottleneck in studying code-switching patterns in multilingual societies.

This paper proposes a novel technique for word-level LD that generalizes to an arbitrarily large set of languages. The method does not require a priori information on the specific languages (potentially more than two) being mixed in an input text as long as the languages are from a fixed (arbitrarily large) set. Training is done without any manually annotated data, while achieving accuracies comparable to language-restricted systems trained

* This work was done when the authors were affiliated with Microsoft Research.

[1] This paper uses the terms 'code-switching' and 'code-mixing' interchangeably.

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1971–1982
Vancouver, Canada, July 30 - August 4, 2017.

with large amounts of labeled data. With a word-level LD accuracy of 96.3% on seven languages, this technique enabled us to analyze patterns of code-switching on Twitter, which is the second key contribution of this paper. To the best of our knowledge, this is the first quantitative study of its kind, particularly at such a large-scale.

2 Related Work

In this section, we will briefly survey the language detection techniques (see Hughes et al. (2006) and Garg et al. (2014) for comprehensive surveys), and sociolinguistic studies on multilingualism (see Nguyen et al. (2016) for a detailed survey) that were enabled by these techniques.

Early work on LD (Cavnar and Trenkle, 1994; Dunning, 1994) focused on detecting a single language for an entire document. These obtained high accuracies on well-formed text (e.g., news articles), which led to LD being considered solved (McNamee, 2005). However, there has been renewed interest with the amount of user-generated content on the web. Such text poses unique challenges such as short length, misspelling, idiomatic expressions and acronyms (Carter et al., 2013; Goldszmidt et al., 2013). Xia et al. (2009), Tromp and Pechenizkiy (2011) and Lui and Baldwin (2012) created LD systems for monolingual sentences, web pages and tweets. Zhang et al. (2016) built an unsupervised model to detect the majority language in a document. There has also been document-level LD that assigns multiple language to each document (Prager, 1999; Lui et al., 2014). However, documents were synthetically generated, restricted to inter-sentential language mixing. Also, these models do not fragment the document based on language, making language-specific analysis impossible.

Document-level or sentence-level LD does not identify code-switching accurately, which can occur within a sentence. Word-level LD systems attempt to remedy this problem. Most work has been restricted to cases where two languages, known a priori, is to be detected in the input i.e, *binary LD at the word-level*. There has been work on Dutch-Turkish (Nguyen and Dogruöz, 2013), English-Bengali (Das and Gambäck, 2014) and Standard and dialectal Arabic (Elfardy et al., 2013). King and Abney (2013) address word-level LD for bilingual documents in 30 language pairs, where the language pair is known a priori. The features for word-level LD proposed by Al-Badrashiny and Diab (2016) are language-independent, however, at any given time, the model is only trained to tag a specific language pair. There have also been two shared task series on word-level LD: FIRE (Roy et al., 2013; Choudhury et al., 2014; Sequiera et al., 2015) focused on Indian languages and the EMNLP Code-Switching Workshop (Solorio et al., 2014; Molina et al., 2016). These pairwise LD methods vary from dictionary-based to completely supervised and semi-supervised. None tackle the imminent lack of annotated data required for scaling to more than one language pair.

There has been little research on word-level LD that is not restricted to two languages. Hammarström (2007) proposed a model for multilingual LD for short texts like queries. Gella et al. (2014) designed an algorithm for word-level LD across 28 languages. Jurgens et al. (2017) use an encoder-decoder architecture for word-level LD that supports dialectal variation and code-switching. However, these studies experiment with synthetically created multilingual data, constrained either by the number of language switches permitted or to phrase-level code-switching, and are not equipped to handle the challenges posed by real-world code-switching.

Using tweet-level LD systems like the CompactLanguageDetector[2], there have been studies on multilingualism in specific cities like London (Manley, 2012) and Manchester (Bailey et al., 2013). These studies, as well as Bergsma et al. (2012), observe that existing LD systems fail on code-switched text. Kim et al. (2014) studied the linguistic behavior of bilingual Twitter users from Qatar, Switzerland and Québec, and also acknowledge that code-switching could not be studied due to the absence of appropriate LD tools.

Using word-level LD for English-Hindi (Gella et al., 2013), Bali et al. 2014 observed that as much as 17% of Indian Facebook posts had code-switching, and Rudra et al. (2016) showed that the native language is strongly preferred for expressing negative sentiment by English-Hindi bilinguals on Twitter. However, without accurate multilingual word-level LD, there have been no large-scale studies on the extent and distribution of code-switching across various communities.

3 Generalized Word-level LD

We present *Generalized Word-Level Language Detection*, or GWLD, where:

- The number of supported languages can be arbitrarily large
- Any number of the supported languages can be mixed within a single input
- The languages in the input do not need to be known a priori
- Any number of language switches are allowed in the input.
- No manual annotation is required for training

Formalizing our model, let $\mathbf{w} = w_{i=1...n}$ be a natural language text consisting of a sequence of words, w_1 to w_n. For our current work, we define words to be whitespace-separated tokens (details in Sec 5). Let $\mathcal{L} = \{l_1, l_2, \ldots, l_k\}$ be a set of k natural languages. We assume that each w_i can be assigned to a unique language $l_j \in \mathcal{L}$.

We also define *universal tokens* like numbers, emoticons, URLs, emails and punctuation, which do not belong to any specific natural language. Certain strings of alphabetic characters representing generic interjections or sounds, such as `oh`, `awww`, `zzz` also fall in this category. For labeling these tokens, we use an auxiliary set of labels, $\mathcal{X}_\mathcal{L} = \{xl_1, xl_2, \ldots, xl_k\}$. Labeling each universal token with a specific language l_i (using xl_i) instead of generically labeling all such tokens xl allows preserving linguistic context when a memoryless model like Hidden Markov Models (HMM) are used for tagging. Further, various NLP tasks on might require the input text, including these universal tokens, to be split by language.

For input $\mathbf{w}$, let the output from the LD system be $\mathbf{y} = y_{i=1...n}$, a sequence of labels, where $y_i \in \mathcal{L} \cup \mathcal{X}_\mathcal{L}$. $y_i = l_j$ if and only if, in the context of $\mathbf{w}$, w_i is a word from l_j. If w_i is a *universal token*, $y_i = xl_j$, when $y_{i-1} = l_j$ or $y_{i-1} = xl_j$. If w_1 is a *universal token*, $y_1 = xl_j$, where l_j is the label of the first token $\in \mathcal{L}$ in the input.

Fig. 1 shows a few examples of labeled code-switched tweets. Named entities (NE) are assigned labels according to the convention used by King and Abney (2013).

4 Method

Word-level LD is essentially a sequence labeling task. We use a Hidden Markov Model (HMM), though any other sequence labeling technique, e.g., CRFs, can be used as well.

The intuition behind the model architecture is simple – a person who is familiar with k languages can easily recognize (and also understand) the words when any of those languages are code-switched, even if s/he has never seen any mixed language text before. Analogously, *is it possible that monolingual language models, when combined, can identify code-switched text accurately?*

Imagine we have k HMMs, where the ith HMM has two states l_i and xl_i. Each state can label a word. The HMMs are independent, but they are tied to a common start state s and end state e, forming a word-level LD model for monolingual text in one of the k languages. Now, we make transitions from $l_i \rightarrow l_j$ possible, where $i \neq j$. This HMM, shown in Fig. 2, is capable of generating and consequently, labeling code-switched text between any of the k languages. The solid and dotted lines show monolingual transitions and the added code-switching transitions respectively. Fig. 2 depicts three languages, however, the number of languages can be arbitrarily large.

Obtaining word-level annotated monolingual and code-switched data is expensive and nearly infeasible for a large number of languages. Instead, we automatically create weakly-labeled monolingual text (set $\mathcal{W}$) and use it to initialize the HMM parameters. We then use Baum-Welch reestimation on unlabeled data (set $\mathcal{U}$) that has monolingual and code-switched text in their natural distribution. Sec. 5 discusses creation of $\mathcal{W}$ and $\mathcal{U}$.

4.1 Structure, Initialization and Learning

The structure of the HMM shown in Fig. 2 can be formally described using:

- Set of states, $\mathcal{S} = s \cup \mathcal{L} \cup \mathcal{X}_\mathcal{L} \cup e$
- Set of observations, $\mathcal{O}$
- Emission matrix ($|\mathcal{S}| \times |\mathcal{O}|$)
- Transition matrix ($|\mathcal{S}| \times |\mathcal{S}|$)

$\mathcal{O}$ consists of all seen events in the data, and a special symbol unk for all unseen events. We define an event as a token n-gram and we experimented with $n = 1$ to 3. It is important to mention that the n-grams do not spread over language states. We also use special start and end symbols, which are observed at states s and e respectively. Elements of $\mathcal{O}$ are effectively what the states of the HMM 'emit' or generate during decoding.

Ex(1): no\$l_2$ me\$l_2$ lebante\$l_2$ ahorita\$l_2$ cuz\$l_1$ I\$l_1$ felt\$l_1$ como\$l_2$ si\$l_2$ me\$l_2$ kemara\$l_2$ por\$l_2$ dentro\$l_2$!\$xl_2$:o\$xl_2$ Then\$l_1$ I\$l_1$ started\$l_1$ getting\$l_1$ all\$l_1$ red\$l_1$,\$xl_1$ I\$l_1$ think\$l_1$ im\$l_1$ allergic\$l_1$ a\$l_2$ algo\$l_2$

Figure 1: Examples of code-switched tweets and the corresponding language labels. l_1 = English, l_2 = Spanish, l_3 = Dutch, l_4 = Turkish. Usernames have been anonymized.

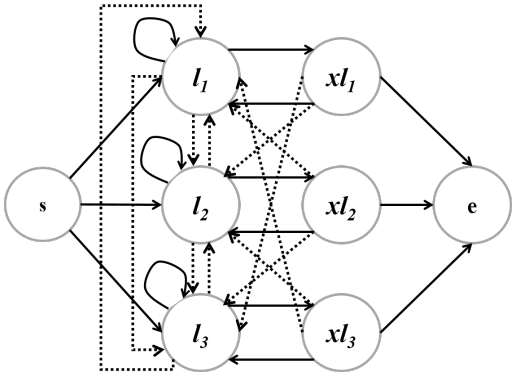

Figure 2: GWLD Hidden Markov Model. $s \rightarrow xl_i$ and $l_i \rightarrow e$ transitions omitted for clarity.

For any input, the HMM always starts in the state s. The parameters to be learned are the transition and emission matrices.

We initialize these matrices using $\mathcal{W}$. The trigram, bigram and unigram word counts from the data for each language in $\mathcal{W}$ are used to create language models (LM) with modified Kneser-Ney smoothing (Chen and Goodman, 1999). The emission values for state l_i are initialized with the respective LM probabilities for all seen n-grams. We also assign a small probability to unk. The emissions for the xl_i state are initialized using the counts of *universal tokens* for the language l_i in $\mathcal{W}$. These are identified using the preprocessing techniques discussed in Sec. 5.1.

Possible transitions for each monolingual HMM are $l_i \rightarrow l_i$, $l_i \rightarrow xl_i$ and $xl_i \rightarrow l_i$. We do not have the $xl_i \rightarrow xl_i$ transition, because preprocessing (Sec. 5.1) concatenates successive *universal tokens* into a single token. This does not change the output as the tokens can easily be separated after LD, but is a useful simplification for the model. The transition values for l_i are initialized by the probability of transitions between words and *universal tokens* in the text from $\mathcal{W}$.

As stated earlier, the model supports code-switching by the addition of transitions $l_i \rightarrow l_j$, and $xl_i \rightarrow l_j$, for all $i \neq j$. For each state l_i, there are $2k - 2$ new transitions (Fig. 2). We initialize these news edges with a small probability π, before normalizing transitions for each state. π, which we call the code-switch probability, is a hyperparameter tuned on a validation set.

Starting with the initialized matrices, we reestimate the transition and emission matrices using the EM-like *Baum-Welch* algorithm (Welch, 2003) over the large set of unlabeled text $\mathcal{U}$.

4.2 Decoding

The input to the trained model is first preprocessed as described in Sec. 5.1 (tokenization and identification of *universal tokens*). The Viterbi algorithm is then used with the HMM parameters to perform word-level LD. When an unknown n-gram, is encountered, its emission probability is estimated by recursively backing off to $(n-1)$-gram, until we find a known n-gram. If the unigram, i.e., the token, is also unknown, then the observation of the symbol unk is used instead.

5 Dataset Creation

The data for both training and testing comes primarily from Twitter because of its public API, and studies have shown the presence of code-switching in social media (Crystal, 2001; Herring, 2003; Danet and Herring, 2007; Cardenas-Claros and Isharyanti, 2009; Bali et al., 2014).

Our experiments use monolingual and code-switched tweets in seven languages – Dutch (*nl*), English (*en*), French (*fr*), German (*de*), Portuguese (*pt*), Spanish (*es*) and Turkish (*tr*). These form the set $\mathcal{L}$. The choice of languages is motivated by several factors. First, LD is non-trivial as all these languages use the Latin script. Second, a large volume of tweets are generated in these languages.

Third, there is annotated code-switched data available in *nl-tr* and *en-es*, which can be used for validation and testing. Lastly, we know that certain pairs of these languages are code-switched often.

5.1 Collection and Preprocessing

Using the Twitter API (Twitter, 2013), we collected tweets over May-July 2015. We selected tweets identified by Twitter LD API (Twitter, 2015) as one of the languages in $\mathcal{L}$. We also removed non-Latin script tweets.

As preprocessing, each tweet is first tokenized using *ark-twitter* (Gimpel et al., 2011) and URLs, hashtags and user mentions are identified using regular expressions. We also identify emoticons, punctuation, digits, special characters, and some universal interjections and abbreviations (such as `RT`, `aww`) as *universal tokens*. We use an existing dictionary (Chittaranjan et al., 2014) for the latter. Let the set of tweets after preprocessing be $\mathcal{T}$.

5.2 Sets $\mathcal{W}$ and $\mathcal{U}$

We use the CoverSet algorithm (Gella et al., 2014) on each tweet in $\mathcal{T}$. It obtains a confidence score for a word w_i belonging to a language l_j using a Naive Bayes classifier trained on Wikipedia. These scores are used to find the minimal set of languages are required to label all the input words. If CoverSet detects the tweet as monolingual (i.e., one language can label all words) and the identified language is the same as the Twitter LD label, the tweet is added to the weakly-labeled set $\mathcal{W}$. These tweets are almost certainly monolingual, as CoverSet has very high recall (and low precision) for detecting code-switching. As these are not manually labeled, we call them *weakly-labeled*. $\mathcal{W}$ contains 100K tweets in each language (700K in total).

From $\mathcal{T}$, we randomly select 100K tweets in each of the seven languages based on the Twitter LD API labels. These tweets do not have word-level language labels and may be code-switched or have an incorrect Twitter language label. We use these as unlabeled data, the set $\mathcal{U}$.

5.3 Validation and Test Sets

We curate two word-level gold-standard datasets for validation and testing. These sets contain monolingual tweets in each of the seven languages as well as code-switched tweets from certain language pairs, based on the availability of real-world data. However, it must be noted that GWLD can detect code-switching between more than two languages. The language-wise distribution is shown in Table 1. Including *universal tokens*, the validation and test set contain 33981 and 58221 tokens respectively. The annotated tweets will be made available for public use.

L1-L2	Tweets	L1 Tokens	L2 Tokens
nl	100 (100)	965 (1099)	–
fr	100 (102)	1085 (1045)	–
pt	100 (100)	1080 (967)	–
de	101 (100)	1078 (890)	–
tr	100 (100)	939 (879)	–
es	100 (100)	1067 (1119)	–
en	100 (100)	1161 (1006)	–

fr-en	50 (48)	428 (370)	224 (227)
pt-en	53 (53)	463 (513)	278 (242)
de-en	49 (50)	417 (459)	293 (292)
tr-en	50 (50)	347 (336)	238 (209)
es-en	3013 (52)	8510 (355)	16356 (395)
nl-tr	735 (728)	5895 (8590)	5293 (8140)

Table 1: Test Set Statistics (Validation Set in parentheses). Rows in gray show existing datasets.

For *es-en*, we use the word-level annotated test set from the code-switching shared task on language detection (Solorio et al., 2014). We ignore the tokens labeled NE, Ambiguous and Mixed during our system evaluation (Sec. 6), as they do not fall in the scope of this work. The words labeled 'Other' were marked as xl_i where l_i is *en* or *es*, based on the context. We also use existing *nl-tr* validation and test sets (Nguyen and Dogruöz, 2013), which contain posts from a web forum.

For the other language pairs, we created our own validation and test sets, as none already exist. We randomly selected tweets for which CoverSet identified code-switching with high confidence. We gave 215 of these to six annotators for word-level annotation. It is difficult to find annotators who know all seven languages; elaborate guidelines were provided on using online machine translation, dictionaries and search engines for the task. Four out of the six annotators had high inter-annotator agreement – the agreement on $L1$ (language that the majority of the words in the tweet belong to) was 0.93, $L2$ (the other language, whenever present) was 0.8 and whether the tweet is code-switched was 0.84. We did not find any instances of code-switching between more than two

Systems	*Acc*	L_1L_2Acc	*IsMix*

languages, which is rare in general. We distributed 3000 tweets between the four annotators (monolingual and code-switched tweets from COVERSET). Disagreements were settled between the annotators and a linguist. A subset of the annotated tweets form the validation and test sets (Table 1), and were removed from $\mathcal{W}$ and $\mathcal{U}$.

6 Experiments and Results

We compare GWLD with three existing systems: LINGUINI (Prager, 1999), LANGID (Lui and Baldwin, 2012), and POLYGLOT (Lui et al., 2014). None of these perform word-level LD, however, LANGID and POLYGLOT return a list of languages with confidence scores for the input. Since code-switching with more than two languages is absent in our dataset, we consider up to two language labels. We define the tweet to be monolingual if the difference between the confidence values for the top two languages is greater than a parameter δ. Otherwise, it is assumed to be code-switched with the top two languages. δ is tuned independently for the two LD systems on the validation set by maximizing the metric L_1L_2 *Accuracy* (Sec. 6.2). Inspired by Gella et al. (2013), we also compare with dictionary-based word-level LD baselines.

6.1 Dictionary-based Baselines

For each language, we build a lexicon of all the words and their frequencies found in $\mathcal{W}$ for that language. Let the lexicon for language $l_i \in \mathcal{L}$ be lex_i. Let $f(lex_i, w_j)$ be the frequency of w_j in lex_i. We define the following baselines:

MAXFREQ: For each w_j in $\mathbf{w}$, MAXFREQ returns lex_i that has the maximum frequency for that token. Therefore, the language label for w_j is $y_j = l_{[\arg\max_i f(lex_i, w_j)]}$. If the token is not found in any lexicon, y_j is assigned the value of y_{j-1}.

MINCOVER: We find the smallest subset $mincov(\mathbf{w}) \subset \mathcal{L}$, such that for all w_j in input $\mathbf{w}$, we have at least one language $l_i \in mincov(\mathbf{w})$ with $f(lex_i, w_j) > 0$. If there is no such language, then w_j is not considered while computing $mincov(\mathbf{w})$. Once $mincov(\mathbf{w})$ is obtained, labels y_i are computed using the MAXFREQ strategy, where the set of languages is restricted to $mincov(\mathbf{w})$ instead of $\mathcal{L}$. Note that $mincov(\mathbf{w})$ need not be unique for $\mathbf{w}$; in such cases, we choose the $mincov(\mathbf{w})$ which maximizes the sum of lexical frequencies based on MAXFREQ labels.

6.2 Metrics

We define the *Accuracy* (*Acc*) of an LD system as the fraction of words in the test set that are labeled correctly. Since the existing LD systems do not label languages at word-level, we also define:

IsMix is the fraction of tweets that are correctly identified as either monolingual or code-mixed.

L_1L_2 *Accuracy* (L_1L_2Acc) is the mean accuracy of detecting language(s) at tweet-level. For monolingual tweets, this accuracy is 1 if the gold standard label is detected by the LD system, else 0. For code-switched tweets, the accuracy is 1 if both languages are detected, 0.5 if one language is detected, and 0 otherwise. L_1L_2Acc is the average over all test set tweets.

6.3 Results

We use these metrics to assess performance on the test set for the baselines, existing LD systems and GWLD (Table 2). *Initial* refers to the HMM model estimated from $\mathcal{W}$ and *Reestimated* refers to the final model after Baum-Welch reestimation. The parameter π is tuned on the validation set using grid search. *Reestimated* GWLD has the best accuracy of 0.963 and performs significantly better than all the other systems for all metrics. Reesimatation improves the word-level *Acc* for L1 from 0.89 to 0.97 and for L2 from 0.43 to 0.82. LINGUINI and POLYGLOT likely have low L_1L_2Acc because they are trained on synthetically-created documents with no word-level code-switching.

Since our test set contains pre-existing annotations for *en-es* (Solorio et al., 2014) and *nl-tr* (Nguyen and Dogruöz, 2013), we compare with state-of-the-art results on those datasets. On *en-es* tokens, Al-Badrashiny and Diab (2016) reports an $F1$-score of 0.964; GWLD obtains 0.978. Nguyen and Dogruöz (2013) report 0.976 *Acc* on the *nl-tr*

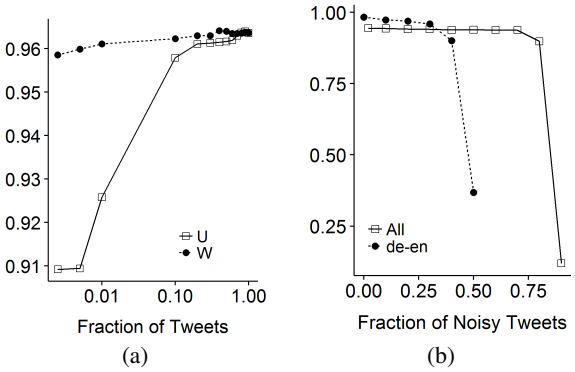

Figure 3: Acc versus Dataset Parameters

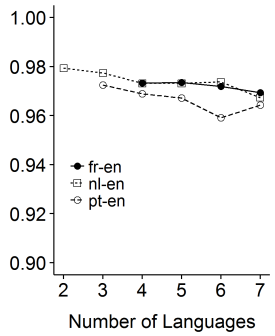

Figure 4: Acc versus Number of Languages

test set. We obtain a less competitive 0.936. However, when errors between *nl-en* are ignored as most of these are *en* words with *nl* gold-standard labels (convention followed by the dataset creators), the revised Acc is 0.963. Notably, unlike GWLD, both these models use large amounts of annotated data for training and are restricted to detecting only two languages.

Error Analysis: GWLD sometimes detects languages that are not present in the tweet, which account for a sizable fraction (39%) of all word-level errors. Not detecting a language switch causes 8% of the errors. Most other errors are caused by named entities, single-letter tokens, unseen words and the *nl-en* annotation convention in the test set from Nguyen and Dogruöz (2013).

6.4 Robustness of GWLD

We test the robustness of GWLD by varying the size of the weakly-labeled set, the unlabeled dataset and the number of languages the model is trained to support.

6.4.1 Size of $\mathcal{W}$ and $\mathcal{U}$

The variation of Acc with the size of $\mathcal{W}$ is shown in Figure 3a. Even with 0.25% of the set (250 tweets for each $l_i \in \mathcal{L}$), the model has accuracy of nearly 0.96. A slow rise in accuracy is observed as the number of tweets in $\mathcal{W}$ is increased. We also experiment with varying the size of $\mathcal{U}$. In Figure 3a, we see that with 0.25% of U (around 1,400 randomly sampled tweets), the accuracy on the test set is lower than 0.91. This quickly increases with 10% of $\mathcal{U}$. Thus, GWLD achieves Acc comparable to existing systems with very little weakly-labeled data (just 250 tweets per language, which are easily procurable for most languages) and around 50,000 unlabeled tweets.

L1-L2	Acc	$IsCM$	GWLD-Acc
nl-en	0.979	0.943	0.967
fr-en	0.982	0.948	0.969
pt-en	0.977	0.952	0.964
de-en	0.984	0.956	0.975
tr-en	0.985	0.984	0.983
es-en	0.954	0.929	0.978
nl-tr	0.975	0.907	0.936

Table 3: Statistics for Pairwise (col. 2 and 3) and GWLD Systems

6.4.2 Noise in $\mathcal{W}$

Since a small, but pure, $\mathcal{W}$ gives high accuracy (Sec. 6.4.1), we evaluate how artificially introduced noise affects Acc. The noise introduced into the $\mathcal{W}$ of each language comes uniformly from the other six languages. Figure 3b shows how increasing fractions of noise slowly degrades accuracy, with a steep drop to 0.11 accuracy at 90% noise, where the tweets from each incorrect language outnumber the correct language tweets. We test this with a pairwise model as well, as noise from a single language might have greater effect. The accuracy falls to 0.36 at 50% noise (Fig. 3b). At this point, $\mathcal{W}$ has an equal number of tweets from each language and is essentially useless.

6.4.3 Number of languages

Pairwise Models: Table 3 details two performance metrics (defined in Sec. 5.2) for our model trained on only two languages and the corresponding 7-language GWLD Acc for that language pair.

Incremental Addition of Languages: We test Acc while incrementally adding languages to the model in a random order (*nl-en-pt-fr-de-es-tr*). Figure 4 shows the variation in Acc for *nl-en*, *pt-en* and *fr-en* as more languages are added to the

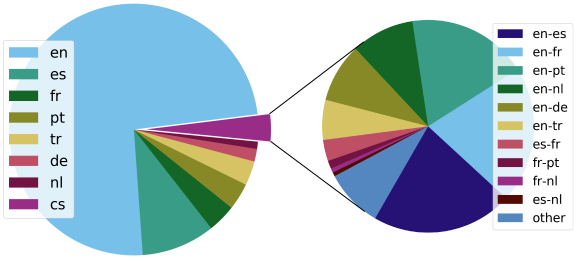

Figure 5: Worldwide distribution of monolingual and CS tweets (left and right charts respectively)

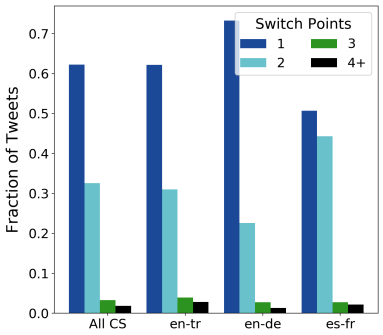

Figure 6: Worldwide CS point distribution

model. Although there is a slight degradation, in absolute terms, the accuracy remains very high.

7 Code-Switching on Twitter

The high accuracy and fast processing speed (the current multithreaded implementation labels 2.5M tweets per hour) of GWLD enables us to conduct large-scale and reliable studies of CS patterns on Twitter for the 7 languages. In this paper, we conduct two such studies. The first study analyzes 50M tweets from across the world to understand the extent and broad patterns of switching among these languages. In the second study, we analyze 8M tweets from 24 cities to gain insights into geography-specific CS patterns.

7.1 Worldwide Code-Switching Trends

We collected 50 million unique tweets that were identified by the Twitter LD API as one of the 7 languages. We place this constraint to avoid tweets from unsupported languages during analysis. Figure 5 shows the overall language distribution, including the CS language-pair distribution. Approximately 96.5% of the tweets are monolingual, a majority of which are *en* (74%).

Around 3.5% of all tweets are code-switched. Globally, *en-es*, *en-fr* and *en-pt* are the three most commonly mixed pairs accounting for 21.5%, 20.8% and 18.4% of all CS tweets in our data respectively. Interestingly, 85.4% of the CS tweets have *en* as one of the languages; *fr* is the next most popularly mixed language, with *fr-es* (3.2%), *fr-pt* (1.2%) and *fr-nl* (0.6%) as the top three observed pairs. Although around 1% of CS tweets were detected as containing more than two languages, these likely have low precision because of language overdetection as discussed in Sec. 6.3.

Figure 6 shows the fraction of *code-switch points*, i.e., how many times the language changes in a CS tweet, for all the languages, as well as for three language pairs with to highlight different trends. Most CS tweets have one CS-point, which implies that the tweet begins with one language, and then ends with another. Such tweets are very frequent for *en-de* where we observe that usually the tweets state the same fact in both *en* and *de*. This so-called *translation function* (Begum et al., 2016) of CS is probably adopted for reaching out to a wider and global audience. In contrast, *es-fr* tweets have fewer tweets with single and far more with two CS-point than average. Tweets with two CS-points typically imply the inclusion of a short phrase or chunk from another language. *en-tr* tweets have the highest number of CS-points, implying rampant and fluid switching between the two languages at all structural levels.

7.2 City-Specific Code-Switching Trends

Cosmopolitan cities are melting pots of cultures, which make them excellent locations for studying multilingualism and language interaction, including CS (Bailey et al., 2013). We collected tweets from 24 populous and highly cosmopolitan cities from Europe, North America and South America, where the primarily spoken language is one of the 7 languages detectable by GWLD. Around 8M tweets were collected from these cities.

Table 4 shows the top and bottom 6 cities, ranked by the fraction of CS tweets from that city. The total number of tweets analyzed and the top two CS pairs, along with their fractions (of CS tweets from that city) are also reported. More details can be found in the supplementary material. It is interesting to note that the 6 cities with lowest CS tweet fractions have *en* as the major language, whereas the 6 cities with highest CS fractions are from non-English (Turkish, Spanish and French) speaking geographies. In fact, the Pearson's cor-

Cities with highest fraction of CS tweet			Cities with lowest fraction of CS tweets		
City	Tweets	CS-fraction (CS pairs)	City	Tweets	CS-fraction (CS pairs)
Istanbul	351K	.12 (*en-tr* .53, *nl-tr* .13)	Houston	588K	.01 (*en-es* .22, *en-fr* .21)
Québec City	108K	.08 (*en-fr* .45, *es-fr* .23)	San Francisco	532K	.02 (*en-es* .26, *en-fr* .19)
Paris	158K	.07 (*en-fr* .43, *fr-pt* .21)	NYC	690K	.02 (*en-es* .21, *en-fr* .19)
Mexico City	332K	.07 (*en-es* .54, *es-fr* .14)	Miami	290K	.02 (*en-es* .33, *en-pt* .20)
Brussels	100K	.06 (*en-fr* .37, *es-fr* .15)	London	492K	.02 (*en-fr* .26, *en-pt* .17)
Madrid	147K	.06 (*en-es* .43, *es-fr* .32)	San Diego	432K	.02 (*en-es* .29, *en-fr* .14)

Table 4: Top (left) and bottom (right) six cities according to the fraction of CS tweets.

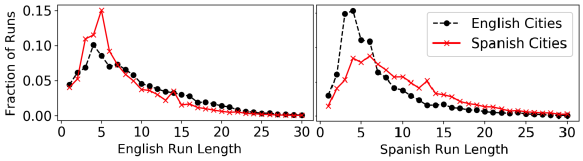

Figure 7: *en-es* Run Length

relation between the fraction of monolingual English tweets and CS tweets for these 24 cities is -0.85. Further, from Table 4 one can also observe that for non-English speaking geographies, the majority language is most commonly mixed with English, followed by French (Spanish, if French is the majority language). Istanbul is an exception, where Dutch is the second most commonly mixed language with Turkish, presumably because of the large Turkish immigrant population in Netherlands resulting in a sizeable Turkish-Dutch bilingual diaspora (Doğruöz and Backus, 2009; Nguyen and Dogruöz, 2013).

Is there a difference in the way speakers mix a pair of languages, say *en* and *es*, in *en*-speaking goegraphies like San Diego, Miami, Houston and New York City, and *es*-speaking geographies like Madrid, Barcelona, Buenos Aires and Mexico City? Indeed, as shown in Fig. 7, the distribution of the lengths of *en* and *es* runs (contiguous sequence of words in a single language beginning and ending with either a CS-point or beginning/end of a tweet) in *en-es* CS tweets is significantly different in *en*-speaking and *es*-speaking geographies. *en* runs are longer in *en*-speaking cities and vice versa, showing that the second language is likely used in short phrases.

8 Conclusion and Future Work

We present GWLD, a system for word-level language detection for an arbitrarily large set of languages that is completely unsupervised. Our results on monolingual and code-switched tweets in seven Latin script languages show a high 0.963 accuracy, significantly out-performing existing systems. Using GWLD, we conducted a large-scale study of CS trends among these languages, both globally and in specific cities.

One of the primary observations of this study is that while code-switching on Twitter is common worldwide (3.5%), it is much more common in non-English speaking cities like Istanbul (12%) where 90% of the population speak Turkish. On the other hand, while a third of the population of Houston speaks Spanish and almost everybody English, only 1% of the tweets from the city are code-switched. All the trends indicate a global dominance of English, which might be because Twitter is primarily a medium for broadcast, and English tweets have a wider audience. Bergsma et al. (2012) show that "[On Twitter] bilinguals bridge between monolinguals with English as a hub, while monolinguals tend not to directly follow each other." Androutsopoulos (2006) argues that due to linguistic non-homogenity of online public spaces, languages like *en*, *fr* and *de* are typically preferred for communication, even though in private spaces, "bilingual talk" differs considerably in terms of distribution and CS patterns.

As future directions, we plan to extend GWLD to several other languages and conduct similar sociolinguistic studies on CS patterns including not only more languages and geographies, but also other aspects like topic and sentiment.

Acknowledgments

We would like to thank Prof. Shambavi Pradeep and her students from BMS College of Engineering for assisting with data annotation. We are also grateful to Ashutosh Baheti and Silvana Hartmann from Microsoft Research (Bangalore, India) for help with data organization and error analysis.

Abstract

Global constraints and reranking have not been used in cognates detection research to date. We propose methods for using global constraints by performing rescoring of the score matrices produced by state of the art cognates detection systems. Using global constraints to perform rescoring is complementary to state of the art methods for performing cognates detection and results in significant performance improvements beyond current state of the art performance on publicly available datasets with different language pairs and various conditions such as different levels of baseline state of the art performance and different data size conditions, including with more realistic large data size conditions than have been evaluated with in the past.

1 Introduction

This paper presents an effective method for using global constraints to improve performance for cognates detection. Cognates detection is the task of identifying words across languages that have a common origin. Automatic cognates detection is important to linguists because cognates are needed to determine how languages evolved. Cognates are used for protolanguage reconstruction (Hall and Klein, 2011; Bouchard-Côté et al., 2013). Cognates are important for cross-language dictionary look-up and can also improve the quality of machine translation, word alignment, and bilingual lexicon induction (Simard et al., 1993; Kondrak et al., 2003).

A word is traditionally only considered cognate with another if both words proceed from the same ancestor. Nonetheless, in line with the conventions of previous research in computational linguistics, we set a broader definition. We use the word 'cognate' to denote, as in (Kondrak, 2001): "...words in different languages that are similar in form and meaning, without making a distinction between borrowed and genetically related words; for example, English 'sprint' and the Japanese borrowing 'supurinto' are considered cognate, even though these two languages are unrelated." These broader criteria are motivated by the ways scientists develop and use cognate identification algorithms in natural language processing (NLP) systems. For cross-lingual applications, the advantage of such technology is the ability to identify words for which similarity in meaning can be accurately inferred from similarity in form; it does not matter if the similarity in form is from strict genetic relationship or later borrowing (Mericli and Bloodgood, 2012).

Cognates detection has received a lot of attention in the literature. The research of the use of statistical learning methods to build systems that can automatically perform cognates detection has yielded many interesting and creative approaches for gaining traction on this challenging task. Currently, the highest-performing state of the art systems detect cognates based on the combination of multiple sources of information. Some of the most indicative sources of information discovered to date are word context information, phonetic information, word frequency information, temporal information in the form of word frequency distributions across parallel time periods, and word burstiness information. See section 3 for fuller explanations of each of these sources of information that state of the art systems currently use. Scores for all pairs of words from language L1 x language L2 are generated by generating component scores based on these sources of information and then combining them in an appropriate manner. Simple methods of combination are giving equal weight-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1983–1992
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1181

ing for each score, while state of the art performance is obtained by learning an optimal set of weights from a small seed set of known cognates. Once the full matrix of scores is generated, the word pairs with the highest scores are predicted as being cognates.

The methods we propose in the current paper consume as input the final score matrix that state of the art methods create. We test if our methods can improve performance by generating new rescored matrices by rescoring all of the pairs of words by taking into account global constraints that apply to cognates detection. Thus, our methods are complementary to previous methods for creating cognates detection systems. Using global constraints and performing rescoring to improve cognates detection has not been explored yet. We find that rescoring based on global constraints improves performance significantly beyond current state of the art levels.

The cognates detection task is an interesting task to apply our methods to for a few reasons:

- It's a challenging unsolved task where ongoing research is frequently reported in the literature trying to improve performance;
- There is significant room for improvement in performance;
- It has a global structure in its output classifications since if a word lemma[1] w_i from language L1 is cognate with a word lemma w_j from language L2, then w_i is not cognate with any other word lemma from L2 different from w_j and w_j is not cognate with any other word lemma w_k from L1.
- There are multiple standard datasets freely and publicly available that have been worked on with which to compare results.
- Different datasets and language pairs yield initial score matrices with very different qualities. Some of the score matrices built using the existing state of the art best approaches yield performance that is quite low (11-point interpolated average precision of only approximately 16%) while some of these score matrices for other language pairs and data sets have state of the art score matrices that are already able to achieve 11-point interpolated average precision of 57%.

Although we are not aware of work using global constraints to perform rescoring to improve cognates detection, there are related methodologies for reranking in different settings. Methodologically related work includes past work in structured prediction and reranking (Collins, 2002; Collins and Roark, 2004; Collins and Koo, 2005; Taskar et al., 2005a,b). Note that in these past works, there are many instances with structured outputs that can be used as training data to learn a structured prediction model. For example, a seminal application in the past was using online training with structured perceptrons to learn improved systems for performing various syntactic analyses and tagging of sentences such as POS tagging and base noun phrase chunking (Collins, 2002). Note that in those settings the unit at which there are structural constraints is a sentence. Also note that there are many sentences available so that online training methods such as discriminative training of structured perceptrons can be used to learn structured predictors effectively in those settings. In contrast, for the cognates setting the unit at which there are structural constraints is the entire set of cognates for a language pair and there is only one such unit in existence (for a given language pair). We call this a single overarching global structure to make the distinction clear. The method we present in this paper deals with a single overarching global structure on the predictions of all instances in the *entire* problem space for a task. For this type of setting, there is only a *single* global structure in existence, contrasted with the situation of there being many sentences each imposing a global structure on the tagging decisions for that individual sentence. Hence, previous structured prediction methods that require numerous instances each having a structured output on which to train parameters via methods such as perceptron training are inapplicable to the cognates setting. In this paper we present methods for rescoring effectively in settings with a single overarching global structure and show their applicability to improving the performance of cognates detection. Still, we note that philosophically our method builds on previous structured prediction methods since in both cases there is a similar intuition in that we're

[1] A lemma is a base form of a word. For example, in English the words 'baked' and 'baking' would both map to the lemma 'bake'. Lemmatizing software exists for many languages and lemmatization is a standard preprocessing task conducted before cognates detection.

using higher-level structural properties to inform and accordingly alter our system's predictions of values for subitems within a structure.

In section 2 we present our methods for performing rescoring of matrices based on global constraints such as those that apply for cognates detection. The key intuition behind our approach is that the scoring of word pairs for cognateness ought not be made independently as is currently done, but rather that global constraints ought to be taken into account to inform and potentially alter system scores for word pairs based on the scores of other word pairs. In section 3 we provide results of experiments testing the proposed methods on the cognates detection task on multiple datasets with multiple language pairs under multiple conditions. We show that the new methods complement and effectively improve performance over state of the art performance achieved by combining the major research breakthroughs that have taken place in cognates detection research to date. Complete precision-recall curves are provided that show the full range of performance improvements over the current state of the art that are achieved. Summary measurements of performance improvements, depending on the language pair and dataset, range from 6.73 absolute MaxF1 percentage points to 16.75 absolute MaxF1 percentage points and from 5.58 absolute 11-point interpolated average precision percentage points to 17.19 absolute 11-point interpolated average precision percentage points. Section 4 discusses the results and possible extensions of the method. Section 5 wraps up with the main conclusions.

2 Algorithm

While our focus in this paper is on using global constraints to improve cognates detection, we believe that our method is useful more generally. We therefore abstract out some of the specifics of cognates detection and present our algorithm more generally in this section, with the hope that it will be able to be used in the future for other applications in addition to cognates detection. None of our abstraction harms understanding of our method's applicability to cognates detection and the fact that the method may be more widely beneficial does not in any way detract from the utility we show it has for improving cognates detection.

A common setting is where one has a set $X = \{x_1, x_2, ..., x_n\}$ and a set $Y = \{y_1, y_2, ..., y_n\}$ where the task is to extract (x, y) pairs such that (x, y) are in some relation R. Here are examples:

- X might be a set of states and Y might be a set of cities and the relation R might be "is the capital of";
- X might be a set of images and Y might be a set of people's names and the relation R might be "is a picture of";
- X might be a set of English words and Y might be a set of French words and the relation R might be "is cognate with".

A common way these problems are approached is that a model is trained that can score each pair (x, y) and those pairs with scores above a threshold are extracted. We propose that often the relation will have a tendency, or a hard constraint, to satisfy particular properties and that this ought to be utilized to improve the quality of the extracted pairs.

The approach we put forward is to re-score each (x, y) pair by utilizing scores generated for other pairs and our knowledge of properties of the relation being extracted. In this paper, we present and evaluate methods for improving the scores of each (x, y) pair for the case when the relation is known to be one-to-one and discuss extensions to other situations.

The current approach is to generate a matrix of scores for each candidate pair as follows:

$$Score_{X,Y} = \begin{bmatrix} s_{x_1,y_1} & \cdots & s_{x_1,y_n} \\ \vdots & \ddots & \vdots \\ s_{x_n,y_1} & \cdots & s_{x_n,y_n} \end{bmatrix}. \quad (1)$$

Then those pairs with scores above a threshold are predicted as being in the relation. We now describe methods for sharpening the scores in the matrix by utilizing the fact that there is an overarching global structure on the predictions.

2.1 Reverse Rank

We know that if $(x_i, y_j) \in R$, then $(x_k, y_j) \notin R$ for $k \neq i$ when R is 1-to-1. We define $reverse\_rank(x_i, y_j) = |\{x_k \in X | s_{x_k,y_j} \geq s_{x_i,y_j}\}|$. Intuitively, a high reverse rank means that there are lots of other elements of X that score better to y_j than x_i does; this could be evidence that (x_i, y_j) is not in R and ought to have a lower score. Alternatively, if there are very few or no other elements of X that score better to y_j than x_i does this

could be evidence that (x_i, y_j) is in R and ought to have a higher score. In accord with this intuition, we use reverse rank as the basis for rescaling our scores as follows:

$$score_{RR}(x_i, y_j) = \frac{s_{x_i,y_j}}{reverse\_rank(x_i, y_j)}. \quad (2)$$

2.2 Forward Rank

Analogous to reverse rank, another basis we can use for adjusting scores is the forward rank. We define $forward\_rank(x_i, y_j) = |\{y_k \in Y | s_{x_i,y_k} \geq s_{x_i,y_j}\}|$. We then scale the scores analogously to how we did with reverse ranks via an inverse linear function.[2]

2.3 Combining Reverse Rank and Forward Rank

For combining reverse rank and forward rank, we present results of experiments doing it two ways. The first is a 1-step approach:

$$score_{RR\_FR\_1step}(x_i, y_j) = \frac{s_{x_i,y_j}}{product}, \quad (3)$$

where

$$\begin{aligned} product = & reverse\_rank(x_i, y_j) \times \\ & forward\_rank(x_i, y_j). \end{aligned} \quad (4)$$

The second combination method involves first computing the reverse rank and re-adjusting every score based on the reverse ranks. Then in a second step the new scores are used to compute forward ranks and then those scores are adjusted based on the forward ranks. We refer to this method as RR_FR_2step.

2.4 Maximum Assignment

If one makes the assumption that all elements in X and Y are present and have their partner element in the other set present with no extra elements and the sets are not too large, then it is interesting to compute what the 'maximal assignment' would be using the Hungarian Algorithm to optimize:

$$\begin{aligned} \max_{Z \in X \times Y} \quad & \sum_{(x,y) \in Z} score(x, y) \\ \text{s.t.} \quad & (x_i, y_j) \in Z \Rightarrow (x_k, y_j) \notin Z, \forall k \neq i \\ & (x_i, y_j) \in Z \Rightarrow (x_i, y_k) \notin Z, \forall k \neq j. \end{aligned} \quad (5)$$

We do this on datasets where the assumptions hold and see how close our methods get to the Hungarian maximal assignment at similar points of the precision-recall curves. For our larger datasets where the assumptions don't hold, the Hungarian either can't complete due to limited computational resources or it functioned poorly in comparison with the performance of our reverse rank and forward rank combination methods.

3 Experiments

Our goal is to test whether using the global structure algorithms we described in section 2 can significantly boost performance for cognates detection. To test this hypothesis, our first step is to implement a system that uses state of the art research results to generate the initial score matrices as a current state of the art system would currently do for this task. To that end, we implemented a baseline state of the art system that uses the information sources that previous research has found to be helpful for this task such as phonetic information, word context information, temporal context information, word frequency information, and word burstiness information (Kondrak, 2001; Mann and Yarowsky, 2001; Schafer and Yarowsky, 2002; Klementiev and Roth, 2006; Irvine and Callison-Burch, 2013). Consistent with past work (Irvine and Callison-Burch, 2013), we use supervised training to learn the weights for combining the various information sources. The system combines the sources of information by using weights learned by an SVM (Support Vector Machine) on a small seed training set of cognates[3] to optimize performance. This baseline system obtains state of the art performance on cognates detection. Using this state of the art system as our baseline, we investigated how much we could improve performance beyond current state of the art levels by applying the rescoring algorithm we described in section 2. We performed experiments on three language pairs: French-English, German-English, and Spanish-English, with different text corpora used as training and test data. The different language pairs and datasets have different levels of performance in terms of their baseline current state of the art score matrices. In the

[2] For both reverse rank and forward rank we also experimented with exponential decay and step functions, but found that simple division by the ranks worked as well or better than any of those more complicated methods.

[3] The small seed set was randomly selected and less than 20% in all cases. It was not used for testing. Note that using this data to optimize performance of the baseline system makes our baseline even stronger and makes it even harder for our new rescoring method to achieve larger improvements.

next few subsections, we describe our experimental details.

3.1 Lemmatization

We used morphological analyzers to convert the words in text corpora to lemma form. For English, we used the NLTK WordNetLemmatizer (Bird et al., 2009). For French, German, and Spanish we used the TreeTagger (Schmid, 1994).

3.2 Word Context Information

We used the Google N-Gram corpus (Michel et al., 2010). For English we used the English 2012 Google 5-gram corpus, for French we used the French 2012 Google 5-gram corpus, for German we used the German 2012 Google 5-gram corpus, and for Spanish we used the Spanish 2012 Google 5-gram corpus. From these corpora we compute word context similarity scores across languages using Rapp's method (Rapp, 1995, 1999). The intuition behind this method is that cognates are more likely to occur in correlating context windows and this statistic inferred from large amounts of data captures this correlation.

3.3 Frequency Information

The intuition is that over large amounts of data cognates should have similar relative frequencies. We compute our relative frequencies by using the same corpora mentioned in the previous subsection.

3.4 Temporal Information

The intuition is that cognates will have similar temporal distributions (Klementiev and Roth, 2006). To compute the temporal similarity we use newspaper data and convert it to simple daily word counts. For each word in the corpora the word counts create a time series vector. The Fourier transform is computed on the time series vectors. Spearman rank correlation is computed on the transform vectors. For English we used the English Gigaword Fifth Edition[4]. For French we used French Gigaword Third Edition[5]. For Spanish we used Spanish Gigaword First Edition[6]. The German news corpora were obtained by web crawling `http://www.tagesspiegel.de/` and extracting the news articles.

[4]Linguistic Data Consortium Catalog No. LDC2011T07
[5]Linguistic Data Consortium Catalog No. LDC2011T10
[6]Linguistic Data Consortium Catalog No. LDC2006T12

3.5 Word Burstiness

The intuition is that cognates will have similar burstiness measures (Church and Gale, 1995). For word burstiness we used the same corpora as for the temporal corpora.

3.6 Phonetic Information

The intuition is that cognates will have correspondences in how they are pronounced. For this, we compute a measurement based on Normalized Edit Distance (NED).

3.7 Combining Information Sources

We combine the information sources by using a linear Support Vector Machine to learn weights for each of the information sources from a small seed training set of cognates. So our final score assigned to a candidate cognate pair (x, y) is:

$$score(x, y) = \sum_{m \in metrics} w_m score_m(x, y), \quad (6)$$

where $metrics$ is the set of measurements such as phonetic similarity measurements, word burstiness similarity, relative frequency similarity, etc. that were explained in subsections 3.2 through 3.6; w_m is the learned weight for metric m; and $score_m(x, y)$ is the score assigned to the pair (x, y) by metric m.

The scores such assigned represent a state of the art approach for filling in the matrix identified in equation 1. At this point the matrix of scores would be used to predict cognates. We now turn to evaluation of the use of the global constraint rescoring methods from section 2 for improving performance beyond the state of the art levels.

3.8 Using Global Constraints to Rescore

For our cognates data we used the French-English pairs from (Bergsma and Kondrak, 2007) and the German-English and Spanish-English pairs from (Beinborn et al., 2013). Figure 1 shows the precision-recall[7] curves for

[7]Precision and recall are the standard measures used for systems that perform search. Precision is the percentage of predicted cognates that are indeed cognate. Recall is the percentage of cognates that are predicted as cognate. We vary the threshold that determines cognateness to generate all points along the Precision-Recall curve. We start with a very high threshold enabling precision of 100% and lower the threshold until recall of 100% is reached. In particular, we sort the test examples by score in descending order and then go down the list of scores in order to complete the entire precision-recall curve.

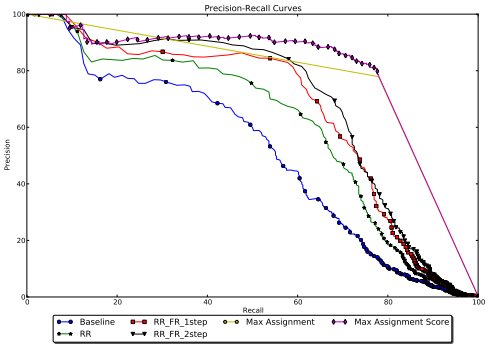

Figure 1: Precision-Recall Curves for French-English. Baseline denotes state of the art performance.

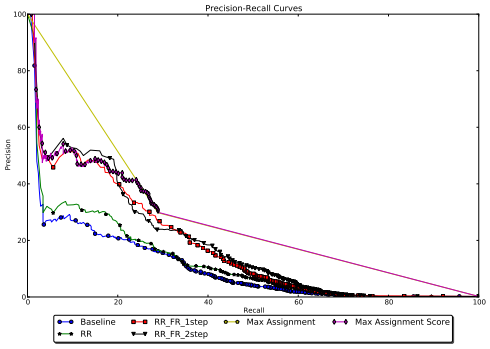

Figure 2: Precision-Recall Curves for German-English. Baseline denotes state of the art performance.

French-English, Figure 2 shows the performance for German-English, and Figure 3 shows the performance for Spanish-English. Note that state of the art performance (denoted in the figures as Baseline) has very different performance across the three datasets, but in all cases the systems from section 2 that incorporate global constraints and perform rescoring greatly exceed current state of the art performance levels. The Max Assignment is really just the single point that the Hungarian finds. We drew lines connecting it, but keep in mind those lines are just connecting the single point to the endpoints. Max Assignment Score traces the precision-recall curve back from the Max Assignment by steadily increasing the threshold so that only points in the maximum assignment set with scores above the increasing threshold are predicted as cognate.

For the non-max assignment curves, it is sometimes helpful to compute a single metric summarizing important aspects of the full curve. For this purpose, maxF1 and 11-point interpolated average precision are often used. MaxF1 is the F1 measure (i.e., harmonic mean of precision and recall) at the point on the precision-recall curve where F1 is highest. The interpolated precision p_{interp} at a given recall level r is defined as the highest precision level found for any recall level $r' \geq r$:

$$p_{interp}(r) = max_{r' \geq r} p(r'). \quad (7)$$

The 11-point interpolated average precision (11-point IAP) is then the average of the p_{interp} at $r = 0.0, 0.1, ..., 1.0$. Table 1 shows these performance measures for French-English, Table 2

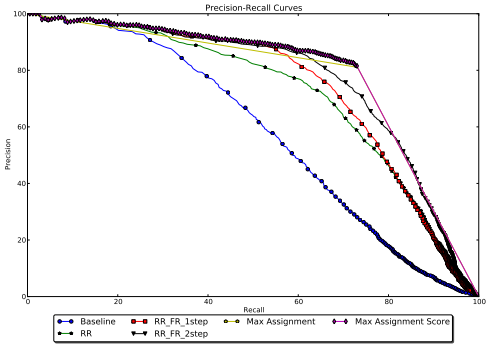

Figure 3: Precision-Recall Curves for Spanish-English. Baseline denotes state of the art performance.

shows the results for German-English, and Table 3 show the results for Spanish-English. In all cases, using global structure greatly improves upon the state of the art baseline performance. In (Bergsma and Kondrak, 2007), for French-English data a result of 66.5 11-point IAP is reported for a situation where word alignments from a bitext are available and a result of 77.7 11-point IAP is reported for a situation where translation pairs are available in large quantities. The setting considered in the current paper is much more challenging since it does not use bilingual dictionaries or word alignments from bitexts. The setting in the current paper is the one mentioned as future work on page 663 of (Bergsma and Kondrak, 2007): "In particular, we plan to investigate approaches that do not re-

quire the bilingual dictionaries or bitexts to generate training data."

Note that the evaluation thus far is a bit artificial for real cognates detection because in a real setting you wouldn't only be selecting matches for relatively small subsets of words that are guaranteed to have a cognate on the other side. Such was the case for our evaluation where the French-English set had approx. 600 cognate pairs, the German-English set had approx. 1000 pairs, and the Spanish-English set had approx. 3000 pairs. In a real setting, the system would have to consider words that don't have a cognate match in the other language and not only words that were hand-selected and guaranteed to have cognates. We are not aware of others evaluating according to this much more difficult condition, but we think it is important to consider especially given the potential impacts it could have on the global structure methods we've put forward. Therefore, we run a second set of evaluations where we take the ten thousand most common words in our corpora for each of our languages, which contain many of the cognates from the standard test sets and we add in any remaining words from the standard test sets that didn't make it into the top ten thousand. We then repeat each of the experiments under this much more challenging condition. With approx. ten thousand squared candidates, i.e., approx. 100 million candidates, to consider for cognateness, this is a large data condition. The Hungarian didn't run to completion on two of the datasets due to limited computational resources. On French-English it completed, but achieved poorer performance than any of the other methods. This makes sense as it is designed when there really is a bipartite matching to be found like in the artificial yet standard cognates evaluation that was just presented. When confronted with large amounts of words that create a much denser space and have no match at all on the other side the all or nothing assignments of the Hungarian are not ideal. The reverse rank and forward rank rescoring methods are still quite effective in improving performance although not by as much as they did in the small data results from above.

METHOD	MAX F1	11-POINT IAP

Figure 4 shows the full precision-recall curves for French-English for the large data condition, Figure 5 shows the curves for German-English for the large data condition, and Figure 6 shows the results for Spanish-English for the large data condition.

Tables 4 through 6 show the summary metrics for the three language pairs for the large data experiments. We can see that the reverse rank and forward rank methods of taking into account the global structure of interactions among predictions is still helpful, providing large improvements in performance even in this challenging large data condition over strong state of the art baselines that

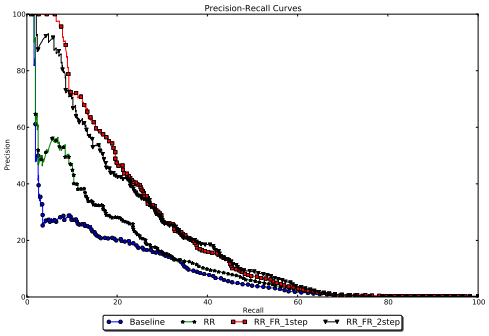

Figure 5: Precision-Recall Curves for German-English (large data). Note that Baseline denotes state of the art performance.

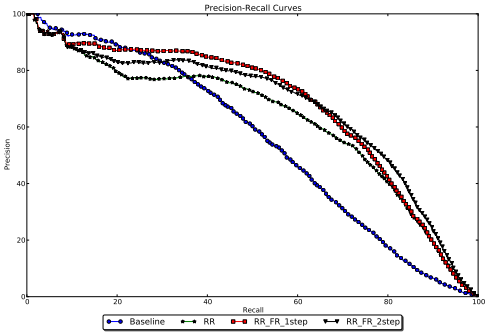

Figure 6: Precision-Recall Curves for Spanish-English (large data). Note that Baseline denotes state of the art performance.

make cognate predictions independently of each other and don't do any rescoring based on global constraints.

4 Discussion

We believe that this work opens up new avenues for further exploration. A few of these include the following:

- investigating the utility of applying and extending the method to other applications such as Information Extraction applications, many of which have similar global constraints as cognates detection;
- investigating how to handle other forms of global structure including tendencies that are not necessarily hard constraints;
- developing more theory to more precisely understand some of the nuances of using global structure when it's applicable and making connections with other areas of machine learning such as semi-supervised learning, active learning, etc.; and
- investigating how to have a machine *learn* that global structure exists and *learn* what form of global structure exists.

5 Conclusions

Cognates detection is an interesting and challenging task. Previous work has yielded state of the art approaches that create a matrix of scores for all word pairs based on optimized weighted combinations of component scores computed on the basis of various helpful sources of information such as phonetic information, word context information, temporal context information, word frequency information, and word burstiness information. However, when assigning a score to a word pair, the current state of the art methods do not take into account scores assigned to other word pairs. We proposed a method for rescoring the matrix that cur-

rent state of the art methods produce by taking into account the scores assigned to other word pairs. The methods presented in this paper are complementary to existing state of the art methods, easy to implement, computationally efficient, and practically effective in improving performance by large amounts. Experimental results reveal that the new methods significantly improve state of the art performance in multiple cognates detection experiments conducted on standard freely and publicly available datasets with different language pairs and various conditions such as different levels of baseline performance and different data size conditions, including with more realistic large data size conditions than have been evaluated with in the past.

Abstract

We present a novel cross-lingual transfer method for paradigm completion, the task of mapping a lemma to its inflected forms, using a neural encoder-decoder model, the state of the art for the monolingual task. We use labeled data from a high-resource language to increase performance on a low-resource language. In experiments on 21 language pairs from four different language families, we obtain up to 58% higher accuracy than without transfer and show that even zero-shot and one-shot learning are possible. We further find that the degree of language relatedness strongly influences the ability to transfer morphological knowledge.

1 Introduction

Low-resource natural language processing (NLP) remains an open problem for many tasks of interest. Furthermore, for most languages in the world, high-cost linguistic annotation and resource creation are unlikely to be undertaken in the near future. In the case of morphology, out of the 7000 currently spoken (Lewis, 2009) languages, only about 200 have computer-readable annotations (Sylak-Glassman et al., 2015) – although morphology is easy to annotate compared to syntax and semantics. *Transfer learning* is one solution to this problem: it exploits annotations in a high-resource language to train a system for a low-resource language. In this work, we present a method for cross-lingual transfer of inflectional morphology using an encoder-decoder recurrent neural network (RNN). This allows for the development of tools for computational morphology with limited annotated data.

In many languages, individual lexical entries may be realized as distinct inflections of a single lemma depending on the syntactic context. For example, the 3SgPresInd of the English verbal lemma *to bring* is *brings*. In morphologically rich languages, a lemma can have hundreds of individual forms. Thus, both generation and analysis of such morphological inflections are active areas of research in NLP and morphological processing has been shown to be a boon to several other down-stream applications, e.g., machine translation (Dyer et al., 2008), speech recognition (Creutz et al., 2007), parsing (Seeker and Çetinoğlu, 2015), keyword spotting (Narasimhan et al., 2014) and word embeddings (Cotterell et al., 2016b), *inter alia*. In this work, we focus on paradigm completion, a form of morphological generation that maps a given lemma to a target inflection, e.g., (*bring*, Past) $\mapsto$ *brought* (with Past being the target tag).

	Present Indicative		Past Indicative

2	*sueñas*	*soñáis*	*soñaste*	*soñasteis*
3	*sueña*	*sueñan*	*soñó*	*soñaron*

Table 1: Partial inflection table for the Spanish verb *soñar*.

RNN sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015) are the state of the art for paradigm completion (Faruqui et al., 2016; Kann and Schütze, 2016a; Cotterell et al., 2016a). However, these models require a large amount of data to achieve competitive performance; this makes them unsuitable for out-of-the-box application to paradigm completion in the low-resource scenario. To mitigate this, we consider transfer learning: we train an end-to-end neural system jointly with limited data from a low-resource language and a larger amount of data from a high-resource language. This technique allows

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 1993–2003
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1182

the model to apply knowledge distilled from the high-resource training data to the low-resource language as needed.

We conduct experiments on 21 language pairs from four language families, emulating a low-resource setting. Our results demonstrate successful transfer of morphological knowledge. We show improvements in accuracy and edit distance of up to 58% (accuracy) and 4.62 (edit distance) over the same model with only in-domain language data on the paradigm completion task. We further obtain up to 44% (resp. 14%) improvement in accuracy for the one-shot (resp. zero-shot) setting, i.e., one (resp. zero) in-domain language sample per target tag. We also show that the effectiveness of morphological transfer depends on language relatedness, measured by lexical similarity.

2 Inflectional Morphology and Paradigm Completion

Many languages exhibit inflectional morphology, i.e., the form of an individual lexical entry mutates to show properties such as person, number or case. The citation form of a lexical entry is referred to as the **lemma** and the collection of its possible inflections as its **paradigm**. Tab. 1 shows an example of a partial paradigm; we display several forms for the Spanish verbal lemma *soñar*. We may index the entries of a paradigm by a **morphological tag**, e.g., the 2SgPresInd form *sueñas* in Tab. 1. In generation, the speaker must select an entry of the paradigm given the form's context. In general, the presence of rich inflectional morphology is problematic for NLP systems as it greatly increases the token-type ratio and, thus, word form sparsity.

An important task in inflectional morphology is **paradigm completion** (Durrett and DeNero, 2013; Ahlberg et al., 2014; Nicolai et al., 2015; Cotterell et al., 2015; Faruqui et al., 2016). Its goal is to map a lemma to all individual inflections, e.g., $(\textit{soñar}, \textsf{1SgPresInd}) \mapsto \textit{sueño}$. There are good solutions for paradigm completion when a large amount of annotated training data is available (Cotterell et al., 2016a).[1] In this work, we address the low-resource setting, a yet unsolved challenge.

[1]The SIGMORPHON 2016 shared task (Cotterell et al., 2016a) on morphological reinflection, a harder generalization of paradigm completion, found that $\geq 98\%$ accuracy can be achieved in many languages with neural sequence-to-sequence models, improving the state of the art by 10%.

2.1 Transferring Inflectional Morphology

In comparison to other NLP annotations, e.g., part-of-speech (POS) and named entities, morphological inflection is especially challenging for transfer learning: we can define a universal set of POS tags (Petrov et al., 2012) or of entity types (e.g., coarse-grained types like *person* and *location* or fine-grained types (Yaghoobzadeh and Schütze, 2015)), but inflection is much more language-specific. It is infeasible to transfer morphological knowledge from Chinese to Portuguese as Chinese does not use inflected word forms. Transferring named entity recognition, however, among Chinese and European languages works well (Wang and Manning, 2014a). But even transferring inflectional paradigms from morphologically rich Arabic to Portuguese seems difficult as the inflections often mark dissimilar subcategories. In contrast, transferring morphological knowledge from Spanish to Portuguese, two languages with similar conjugations and 89% lexical similarity, appears promising. Thus, we conjecture that transfer of inflectional morphology is only viable among *related languages*.

2.2 Formalization of the Task

We now offer a formal treatment of the cross-lingual paradigm completion task and develop our notation. Let Σ_ℓ be a discrete alphabet for language ℓ and let $\mathcal{T}_\ell$ be a set of morphological tags for ℓ. Given a lemma w_ℓ in ℓ, the morphological paradigm (inflectional table) π can be formalized as a set of pairs

$$\pi(w_\ell) = \Big\{ \big(f_k[w_\ell], t_k\big) \Big\}_{k \in T(w_\ell)} \quad (1)$$

where $f_k[w_\ell] \in \Sigma_\ell^+$ is an inflected form, $t_k \in \mathcal{T}_\ell$ is its morphological tag and $T(w_\ell)$ is the set of slots in the paradigm; e.g., a Spanish paradigm is:

$$\pi(\text{soñar}) = \Big\{ \big(\textit{sueño}, \textsf{1SgPresInd}\big), \ldots, \big(\textit{soñaran}, \textsf{3PlPastSbj}\big) \Big\}$$

Paradigm completion consists of predicting missing slots in the paradigm $\pi(w_\ell)$ of a given lemma w_ℓ.

In cross-lingual paradigm completion, we consider a *high-resource source language* ℓ_s (lots of training data available) and a *low-resource target language* ℓ_t (little training data available). We denote the source training examples as $\mathcal{D}_s$ (with $|\mathcal{D}_s| = n_s$) and the target training examples as

$\mathcal{D}_t$ (with $|\mathcal{D}_t| = n_t$). The goal of cross-lingual paradigm completion is to populate paradigms in the low-resource target language with the help of data from the high-resource source language, using only few in-domain examples.

3 Cross-Lingual Transfer as Multi-Task Learning

We describe our probability model for morphological transfer using terminology from multi-task learning (Caruana, 1997; Collobert et al., 2011). We consider two tasks, training a paradigm completor (i) for a high-resource language and (ii) for a low-resource language. We want to train jointly, so we reap the benefits of having related languages. Thus, we define the log-likelihood as

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{(k,w_{\ell_t})\in\mathcal{D}_t} \log p_{\boldsymbol{\theta}}\left(f_k[w_{\ell_t}] \mid w_{\ell_t}, t_k, \lambda_{\ell_t}\right) \quad (2)$$
$$+ \sum_{(k,w_{\ell_s})\in\mathcal{D}_s} \log p_{\boldsymbol{\theta}}(f_k[w_{\ell_s}] \mid w_{\ell_s}, t_k, \lambda_{\ell_s})$$

where we tie parameters $\boldsymbol{\theta}$ for the two languages together to allow the transfer of morphological knowledge between languages. The λs are special language tags, cf. Sec. 3.2. Each probability distribution $p_{\boldsymbol{\theta}}$ defines a distribution over all possible realizations of an inflected form, i.e., a distribution over Σ^*. For example, consider the related Romance languages Spanish and French; focusing on one term from each of the summands in Eq. (2) (the past participle of the translation of *to visit* in each language), we arrive at

$$\mathcal{L}_{\text{visit}}(\boldsymbol{\theta}) = \log p_{\boldsymbol{\theta}}(\textit{visitado} \mid \textit{visitar}, \textsf{PastPart}, \textsf{ES})$$
$$+ \log p_{\boldsymbol{\theta}}(\textit{visité} \mid \textit{visiter}, \textsf{PastPart}, \textsf{FR}) \quad (3)$$

Our *cross-lingual* setting forces both transductions to share part of the parameter vector $\boldsymbol{\theta}$, to represent morphological regularities between the two languages in a common embedding space and, thus, to enable morphological transfer. This is no different from *monolingual* multi-task settings, e.g., jointly training a parser and tagger for transfer of syntax.

Based on recent advances in neural transducers, we parameterize each distribution as an encoder-decoder RNN, as in (Kann and Schütze, 2016b). In their setup, the RNN encodes the input and predicts the forms in a *single* language. In contrast, we force the network to predict *two or more* languages.

3.1 Encoder-Decoder RNN

We parameterize the distribution $p_{\boldsymbol{\theta}}$ as an encoder-decoder gated RNN (GRU) with attention (Bahdanau et al., 2015), the state-of-the-art solution for the monolingual case (Kann and Schütze, 2016b). A bidirectional gated RNN encodes the input sequence (Cho et al., 2014) – the concatenation of (i) the language tag, (ii) the morphological tag of the form to be generated and (iii) the characters of the input word – represented by embeddings. The input to the decoder consists of concatenations of $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$, the forward and backward hidden states of the encoder. The decoder, a unidirectional RNN, uses attention: it computes a weight α_i for each h_i. Each weight reflects the importance given to that input position. Using the attention weights, the probability of the output sequence given the input sequence is:

$$p(y \mid x_1, \ldots, x_{|X|}) = \prod_{t=1}^{|Y|} g(y_{t-1}, s_t, c_t) \quad (4)$$

where $y = (y_1, \ldots, y_{|Y|})$ is the output sequence (a sequence of $|Y|$ characters), $x = (x_1, \ldots x_{|X|})$ is the input sequence (a sequence of $|X|$ characters), g is a non-linear function, s_t is the hidden state of the decoder and c_t is the sum of the encoder states h_i, weighted by attention weights $\alpha_i(s_{t-1})$ which depend on the decoder state:

$$c_t = \sum_{i=1}^{|X|} \alpha_i(s_{t-1}) h_i \quad (5)$$

Fig. 1 shows the encoder-decoder. See Bahdanau et al. (2015) for further details.

3.2 Input Format

Each source form is represented as a sequence of characters; each character is represented as an embedding. In the same way, each source tag is represented as a sequence of subtags, and each subtag is represented as an embedding. More formally, we define the alphabet $\Sigma = \cup_{\ell\in L}\Sigma_\ell$ as the set of characters in the languages in L, with L being the set of languages in the given experiment. Next, we define $\mathcal{S}$ as the set of subtags that occur as part of the set of morphological tags $\mathcal{T} = \cup_{\ell\in L}\mathcal{T}_\ell$; e.g., if 1SgPresInd $\in \mathcal{T}$, then 1, Sg, Pres, Ind $\in \mathcal{S}$. Note that the set of subtags $\mathcal{S}$ is defined as attributes from the UniMorph schema (Sylak-Glassman, 2016) and, thus, is universal across languages; the schema is

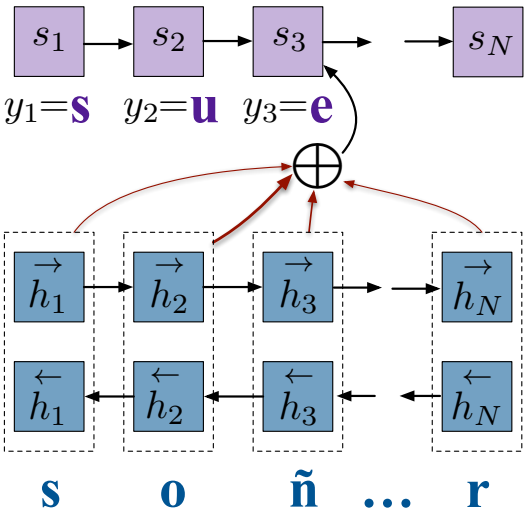

Figure 1: Encoder-decoder RNN for paradigm completion. The lemma *soñar* is mapped to a target form (e.g., *sueña*). For brevity, language and target tags are omitted from the input. Thickness of red arrows symbolizes the degree to which the model attends to the corresponding hidden state of the encoder.

derived from research in linguistic typology.[2] The format of the input to our system is $\mathcal{S}^+\Sigma^+$. The output format is Σ^+. Both input and output are padded with distinguished BOW and EOW symbols.

What we have described is the representation of Kann and Schütze (2016b). In addition, we preprend a symbol $\lambda \in L$ to the input string (e.g., λ = Es, also represented by an embedding), so the RNN can handle multiple languages simultaneously and generalize over them. Thus, our final input is of the form $\lambda\mathcal{S}^+\Sigma^+$.

4 Languages and Language Families

To verify the applicability of our method to a wide range of languages, we perform experiments on example languages from several different families.

Romance languages, a subfamily of Indo-European, are widely spoken, e.g., in Europe and Latin America. Derived from the common ancestor Vulgar Latin (Harris and Vincent, 2003), they share large parts of their lexicon and inflectional morphology; we expect knowledge among them to be easily transferable.

[2]Note that while the subtag set is universal, *which* subtags a language actually uses is language-specific; e.g., Spanish does not mark animacy as Russian does. We contrast this with the universal POS set (Petrov et al., 2012), where it is more likely that we see all 17 tags in most languages.

	PT	CA	IT	FR
similarity to ES	89%	85%	82%	75%

Table 2: Lexical similarities for Romance (Lewis, 2009).

We experiment on Catalan, French, Italian, Portuguese and Spanish. Tab. 2 shows that Spanish – which takes the role of the low-resource language in our experiments – is closely related with the other four, with Portuguese being most similar. We hypothesize that the transferability of morphological knowledge between source and target corresponds to the degree of lexical similarity; thus, we expect Portuguese and Catalan to be more beneficial for Spanish than Italian and French.

The Indo-European **Slavic language family** has its origin in eastern-central Europe (Corbett and Comrie, 2003). We experiment on Bulgarian, Macedonian, Russian and Ukrainian (Cyrillic script) and on Czech, Polish and Slovene (Latin script). Macedonian and Ukranian are low-resource languages, so we assign them the low-resource role. For Romance and for Uralic, we experiment with groups containing three or four source languages. To arrive at a comparable experimental setup for Slavic, we run two experiments, each with three source and one target language: (i) from Russian, Bulgarian and Czech to Macedonian; and (ii) from Russian, Polish and Slovene to Ukrainian.

We hope that the paradigm completor learns similar embeddings for, say, the characters "e" in Polish and "є" in Ukrainian. Thus, the use of two scripts in Slavic allows us to explore transfer across different alphabets.

We further consider a non-Indo-European language family, the **Uralic languages**. We experiment on the three most commonly spoken languages – Finnish, Estonian and Hungarian (Abondolo, 2015) – as well as Northern Sami, a language used in Northern Scandinavia. While Finnish and Estonian are closely related (both are members of the Finnic subfamily), Hungarian is a more distant cousin. Estonian and Northern Sami are low-resource languages, so we assign them the low-resource role, resulting in two groups of experiments: (i) Finnish, Hungarian and Estonian to Northern Sami; (ii) Finnish, Hungarian and Northern Sami to Estonian.

Arabic (baseline) is a Semitic language (part of the Afro-Asiatic family (Hetzron, 2013)) that is

spoken in North Africa, the Arabian Peninsula and other parts of the Middle East. It is unrelated to all other languages used in this work. Both in terms of form (new words are mainly built using a templatic system) and categories (it has tags such as construct state), Arabic is very different. Thus, we do not expect it to support morphological knowledge transfer and use it as a baseline for all target languages.

5 Experiments

We run four experiments on 21 distinct pairings of languages to show the feasibility of morphological transfer and analyze our method. We first discuss details common to all experiments.

We keep **hyperparameters** during all experiments (and for all languages) fixed to the following values. Encoder and decoder RNNs each have 100 hidden units and the size of all subtag, character and language embeddings is 300. For training we use ADADELTA (Zeiler, 2012) with minibatch size 20. All models are trained for 300 epochs. Following Le et al. (2015), we initialize all weights in the encoder, decoder and the embeddings except for the GRU weights in the decoder to the identity matrix. Biases are initialized to zero.

Evaluation metrics: (i) 1-best accuracy: the percentage of predictions that match the true answer exactly; (ii) average edit distance between prediction and true answer. The two metrics differ in that accuracy gives no partial credit and incorrect answers may be drastically different from the annotated form without incurring additional penalty. In contrast, edit distance gives partial credit for forms that are closer to the true answer.

5.1 Exp. 1: Transfer Learning for Paradigm Completion

In this experiment, we investigate to what extent our model transfers morphological knowledge from a high-resource source language to a low-resource target language. We experimentally answer three questions. (i) Is transfer learning possible for morphology? (ii) How much annotated data do we need in the low-resource target language? (iii) How closely related must the two languages be to achieve good results?

Data. Based on complete inflection tables from unimorph.org (Kirov et al., 2016), we create datasets as follows. Each training set consists of 12,000 samples in the high-resource source language and $n_t \in \{50, 200\}$ samples in the low-resource target language. We create target language dev and test sets of sizes 1600 and 10,000, respectively.[3] For Romance and Arabic, we create learning curves for $n_t \in \{100, 400, 800, 1600, 3200, 6400, 12000\}$. Due to the data available to us, we use *only* verbs for the Romance and Uralic language families, but nouns, verbs and adjectives for the Slavic language family and Arabic. Lemmata and inflections are randomly selected from all available paradigms.

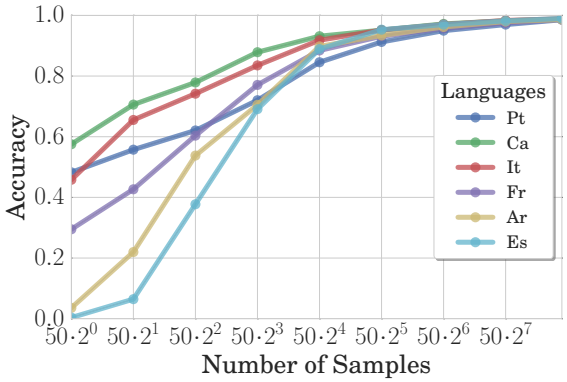

Figure 2: Learning curves showing the accuracy on Spanish test when training on language $\lambda \in \{$PT, CA, IT, FR, AR, ES$\}$. Except for λ=ES, each model is trained on 12,000 samples from λ and "Number of Samples" (x-axis) of Spanish.

Results and Discussion. Tab. 3 shows the effectiveness of transfer learning. There are *two* baselines. (i) "0": no transfer, i.e., we consider only in-domain data; (ii) "AR": Arabic, which is unrelated to all target languages.

With the exception of the 200 sample case of ET→SME, cross-lingual transfer is always better than the two baselines; the maximum improvement is 0.58 (0.58 vs. 0.00) in accuracy for the 50 sample case of CA→ES. More closely related source languages improve performance more than distant ones. French, the Romance language least similar to Spanish, performs worst for →ES. For the target language Macedonian, Bulgarian provides most benefit. This can again be explained by similarity: Bulgarian is closer to Macedonian than the other languages in this group. The best result for Ukrainian is RU→UK. Unlike Polish and Slowenian, Russian is the only language in this group that uses the same script as Ukrainian, showing

[3] For Estonian, we use 7094 (not 12,000) train and 5000 (not 10,000) test samples as more data is unavailable.

Table 3: Accuracy (acc; the higher the better; indicated by ↑) and edit distance (ED; the lower the better; indicated by ↓) of cross-lingual transfer learning for paradigm completion. The target language is indicated by "→", e.g., it is Spanish for "→ES". Sources are indicated in the row "source"; "0" is the monolingual case. Except for Estonian, we train on $n_s = 12{,}000$ source samples and $n_t \in \{50, 200\}$ target samples (as indicated by the row). There are *two* baselines in the table. (i) "0": no transfer, i.e., we consider only in-domain data; (ii) "AR": the Semitic language Arabic is unrelated to all target languages and functions as a dummy language that is unlikely to provide relevant information. All languages are denoted using the official codes (SME=Northern Sami).

the importance of the alphabet for transfer. Still, the results also demonstrate that transfer works across alphabets (although not as well); this suggests that similar embeddings for similar characters have been learned. Finnish is the language that is closest to Estonian and it again performs best as a source language for Estonian. For Northern Sami, transfer works least well, probably because the distance between sources and target is largest in this case. The distance of the Sami languages from the Finnic (Estonian, Finnish) and Ugric (Hungarian) languages is much larger than the distances within Romance and within Slavic. However, even for Northern Sami, the worst performing language, adding an additional language is still always beneficial compared to the monolingual baseline.

Learning curves for Romance and Arabic further support our finding that language similarity is important. In Fig. 2, knowledge is transferred to Spanish, and a baseline – a model trained *only* on Spanish data – shows the accuracy obtained without any transfer learning. Here, Catalan and Italian help the most, followed by Portuguese, French and, finally, Arabic. This corresponds to the order of lexical similarity with Spanish, except for the performance of Portuguese (cf. Tab. 2). A possible explanation is the potentially confusing overlap of lemmata between the two languages – cf. discussion in the next subsection. That the transfer learning setup improves performance for the unrelated language Arabic as source is at first surprising. However, adding new samples to a small training set helps prevent overfitting (e.g., rote memorization) even if the source is a morphologically unrelated language; effectively acting as a regularizer.

Following (Kann and Schütze, 2016b) we did not use standard regularizers. To verify that the effect of Arabic is mainly a regularization effect, we ran a small monolingual experiment on ES (200 setting) with dropout 0.5 (Srivastava et al., 2014). The resulting accuracy is 0.57, very similar to the comparable Arabic number of 0.54 in the table. The accuracy for dropout and 50 ES samples stays at 0.00, showing that in extreme low-resource settings an unrelated language might be preferable to a standard regularizer.

Error Analysis for Romance. Even for only 50 Spanish instances, many inflections are correctly produced in transfer. For, e.g., (*criar*, 3PlFutSbj) ↦ *criaren*, model outputs are: fr: *criaren*, ca: *criaren*, es: *crntaron*, it: *criaren*, ar: *ecriren*, pt: *criaren* (all correct except for the two baselines). Many errors involve accents, e.g., (*contrastar*, 2PlFutInd) ↦ *contrastaréis*; model outputs are: fr: *contrastareis*, ca: *contrastareis*, es: *conterarían*, it: *contrastareis*, ar: *contastarías*, pt: *contrastareis*. Some inflected forms are produced incorrectly by all systems, mainly because they apply the inflectional rules of the source language directly to the target. Finally, the output of the model trained on Portuguese contains a class of errors that are unlike those of other systems. Example: (*contraatacar*, 1SgCond) ↦ *contraatacaría* with the following solutions: fr: *contratacaríam*, ca: *contraatacaría*, es: *concarnar*, it: *contratacé*, ar: *cuntataría* and pt: *contra-atacaría*. The Portuguese model inserts "-" because Portuguese train data contains *contraatacar* and "-" appears in its inflected form. Thus, it seems that shared lemmata between the high-resource source language and the low-resource target language hurt our model's performance.[4] An

[4]To investigate this in more detail we retrain the Portuguese model with 50 Spanish samples, but exclude all lemmata that appear in Spanish train/dev/test, resulting in only 3695

		PT	CA	IT	CA&PT	CA&IT

	ED ↓	7.18	**1.95**	1.99	3.12	4.27	7.50

Table 5: Results for one-shot and zero-shot transfer learning. Formatting is the same as for Tab. 3. We still use $n_s = 12000$ source samples. In the one-shot (resp. zero-shot) case, we observe *exactly one form* (resp. *zero forms*) for each tag in the target language at training time.

example for the generally improved performance across languages for 200 Spanish training samples is (*contrastar*, 2PIIndFut) ↦ *contrastaréis*: all models now produce the correct form.

5.2 Exp. 2: Multiple Source Languages

We now want to investigate the effect of multiple source languages.

Data. Our experimental setup is similar to §5.1: we use the same dev, test and low-resource train sets as before. However, we limit this experiment to the Romance language family and the high-resource train data consists of samples from *two different* source languages at once. Choosing those which have the highest accuracies on their own, we experiment with the following pairs: CA&PT, as well as CA&IT. In order to keep all experiments easily comparable, we use *half* of each source language's data, again ending up with a total of 12,000 high-resource samples.

Results and Discussion. Results are shown in Tab. 4. Training on two source languages improves over training on a single one. Increases in accuracy are minor, but edit distance is reduced by up to 0.13 (50 low-resource samples) and 0.08 (200 low-resource samples). That using data from multiple languages is beneficial might be due to a weaker tendency of the final model to adapt wrong rules from the source language, since different alternatives are presented during training.

5.3 Exp. 3: Zero-Shot/One-Shot Transfer

In §5.1, we investigated the relationship between in-domain (target) training set size and performance. Here, we look at the extreme case of training set sizes 1 (one-shot) and 0 (zero-shot) for a tag. We train our model on *a single* sample for *half* of the tags appearing in the low-resource language, i.e., if $\mathcal{T}_\ell$ is the set of morphological tags for the target language, train set size is $|\mathcal{T}_\ell|/2$. As before, we add 12,000 source samples.

We report *one-shot accuracy* (resp. *zero-shot accuracy*), i.e., the accuracy for samples with a tag that has been seen once (resp. never) during training. Note that the model has seen the *individual subtags* each tag is composed of.[5]

Data. Now, we use the same dev, test and high-resource train sets as in §5.1. However, the low-resource data is created in the way specified above. To remove a potentially confounding variable, we impose the condition that no two training samples belong to the same lemma.

Results and Discussion. Tab. 5 shows that the Spanish and Arabic systems do not learn anything useful for either half of the tags. This is not surprising as there is not enough Spanish data for the system to generalize well and Arabic does not contribute exploitable information. The systems trained on French and Italian, in contrast, get a non-zero accuracy for the zero-shot case as well as 0.13 and 0.23, respectively, in the one-shot case. This shows that a single training example is sometimes sufficient for successful generation although generalization to tags never observed is rarely possible. Catalan and Portuguese show the best performance in both settings; this is intuitive since they are the languages closest to the target (cf. Tab. 2). In fact, adding Portuguese to the training data yields an absolute increase in accuracy of 0.44 (0.44 vs. 0.00) for one-shot and 0.14 (0.14 vs. 0.00) for zero-shot with corresponding improvements in edit distance.

Overall, this experiment shows that with transfer learning from a closely related language the per-

training samples. Accuracy on test *increases* by 0.09 despite the reduced size of the training set.

[5] It is very unlikely that due to random selection a subtag will not be in train; this case did not occur in our experiments.

formance of zero-shot morphological generation improves over the monolingual approach, and, in the one-shot setting, it is possible to generate the right form nearly half the time.

5.4 Exp. 4: True Transfer vs. Other Effects

We would like to separate the effects of regularization that we saw for Arabic from true transfer.

To this end, we generate a random cipher (i.e., a function $\gamma : \Sigma \cup \mathcal{S} \mapsto \Sigma \cup \mathcal{S}$) and apply it to all word forms and morphological tags of the high-resource train set; target language data are not changed. Ciphering makes it harder to learn true "linguistic" transfer of morphology. Consider the simplest case of transfer: an identical mapping in two languages, e.g., (*visitar*, 1SgPresInd) $\mapsto$ *visito* in both Portuguese and Spanish. If we transform Portuguese using the cipher γ(iostv...) = kltqa..., then *visito* becomes *aktkql* in Portuguese and its tag becomes similarly unrecognizable as being identical to the Spanish tag 1SgPresInd. Our intuition is that ciphering will disrupt transfer of morphology.[6] On the other hand, the regularization effect we observed with Arabic should still be effective.

Data. We use the Portuguese-Spanish and Arabic-Spanish data from §5.1. We generate a random cipher and apply it to morphological tags and word forms for Portuguese and Arabic. The language tags are kept unchanged. Spanish is also not changed. For comparability with Tab. 3, we use the same dev and test sets as before.

Results and Discussion. Tab. 6 shows that performance of PT→ES drops a lot: from 0.48 to 0.09 for 50 samples and from 0.62 to 0.54 for 200 samples. This is because there are no overt similarities between the two languages left after applying the cipher, e.g., the two previously identical forms *visito* are now different.

The impact of ciphering on AR→ES varies: slightly improved in one case (0.54 vs. 0.56), slightly worse in three cases. We also apply the cipher to the tags and Arabic and Spanish share subtags, e.g., Sg. Just the knowledge that something is a subtag is helpful because subtags must not be generated as part of the output. We can explain the tendency of ciphering to decrease performance on AR→ES by the "masking" of common subtags.

[6]Note that ciphered input is much harder than transfer between two alphabets (Latin/Cyrillic) because it creates ambiguous input. In the example, Spanish "i" is totally different from Portuguese "i" (which is really "k"), but the model must use the same representation.

		0→ES	PT→ES		AR→ES	
			orig	ciph	orig	ciph
50	acc ↑	0.00	0.48	0.09	0.04	0.02
	ED ↓	5.42	0.85	3.25	4.06	4.62
200	acc ↑	0.38	0.62	0.54	0.54	0.56
	ED ↓	1.37	0.57	0.95	0.87	0.93

Table 6: Results for ciphering. "0→ES" and "orig" are original results, copied from Tab. 3; "ciph" is the result after the cipher has been applied.

For 200 samples and ciphering, there is no clear difference in performance between Portuguese and Arabic. However, for 50 samples and ciphering, Portuguese (0.09) seems to perform better than Arabic (0.02) in accuracy. Portuguese uses suffixation for inflection whereas Arabic is templatic and inflectional changes are not limited to the end of the word. This difference is not affected by ciphering. Perhaps even ciphered Portugese lets the model learn better that the beginnings of words just need to be copied. For 200 samples, the Spanish dataset may be large enough, so that ciphered Portuguese no longer helps in this regard.

Comparing no transfer with transfer from a ciphered language to Spanish, we see large performance gains, at least for the 200 sample case: 0.38 (0→ES) vs. 0.54 (PT→ES) and 0.56 (AR→ES). This is evidence that our conjecture is correct that the baseline Arabic mainly acts as a regularizer that prevents the model from memorizing the training set and therefore improves performance. So performance improves even though no true transfer of morphological knowledge takes place.

6 Related Work

Cross-lingual transfer learning has been used for many tasks, e.g., automatic speech recognition (Huang et al., 2013), parsing (Cohen et al., 2011; Søgaard, 2011; Naseem et al., 2012; Ammar et al., 2016), language modeling (Tsvetkov et al., 2016), entity recognition (Wang and Manning, 2014b) and machine translation (Johnson et al., 2016; Ha et al., 2016).

One straightforward method is to translate datasets and then train a monolingual model (Fortuna and Shawe-Taylor, 2005; Olsson et al., 2005). Also, aligned corpora have been used to project information from annotations in one language to another (Yarowsky et al., 2001; Padó and Lapata, 2005). The drawback is that machine translation

errors cause errors in the target. Therefore, alternative methods have been proposed, e.g., to port a model trained on the source language to the target language (Shi et al., 2010).

In the realm of morphology, Buys and Botha (2016) recently adapted methods for the training of POS taggers to learn weakly supervised morphological taggers with the help of parallel text. Snyder and Barzilay (2008a, 2008b) developed a non-parametric Bayesian model for morphological segmentation. They performed identification of cross-lingual abstract morphemes and segmentation simultaneously and reported, similar to us, best results for related languages.

Work on **paradigm completion** has recently been encouraged by the SIGMORPHON 2016 shared task on morphological reinflection (Cotterell et al., 2016a). Some work first applies an unsupervised alignment model to source and target string pairs and then learns a string-to-string mapping (Durrett and DeNero, 2013; Nicolai et al., 2015), using, e.g., a semi-Markov conditional random field (Sarawagi and Cohen, 2004). Encoder-decoder RNNs (Aharoni et al., 2016; Faruqui et al., 2016; Kann and Schütze, 2016b), a method which our work further develops for the cross-lingual scenario, define the current state of the art.

Encoder-decoder RNNs were developed in parallel by Cho et al. (2014) and Sutskever et al. (2014) for machine translation and extended by Bahdanau et al. (2015) with an attention mechanism, supporting better generalization. They have been applied to NLP tasks like speech recognition (Graves and Schmidhuber, 2005; Graves et al., 2013), parsing (Vinyals et al., 2015) and segmentation (Kann et al., 2016).

More recently, a number of papers have used encoder-decoder RNNs in *multitask and transfer learning settings*; this is mainly work in machine translation: (Dong et al., 2015; Zoph and Knight, 2016; Chu et al., 2017; Johnson et al., 2016; Luong et al., 2016; Firat et al., 2016; Ha et al., 2016), *inter alia*. Each of these papers has both similarities and differences with our approach. (i) Most train several distinct models whereas we train a *single model* on input augmented with an explicit encoding of the language (similar to (Johnson et al., 2016)). (ii) Let k and m be the number of different input and output languages. We address the case $k \in \{1, 2, 3\}$ and $m = k$. Other work has addressed cases with $k > 3$ or $m > 3$; this would be an interesting avenue of future research for paradigm completion. (iii) Whereas training RNNs in machine translation is hard, we only experienced one difficult issue in our experiments (due to the low-resource setting): regularization. (iv) Some work is word- or subword-based, our work is character-based. The same way that similar word embeddings are learned for the inputs *cow* and *vache* (French for "cow") in machine translation, we expect similar embeddings to be learned for similar Cyrillic/Latin characters. (v) Similar to work in machine translation, we show that zero-shot (and, by extension, one-shot) learning is possible.

(Ha et al., 2016) (which was developed in parallel to our transfer model although we did not prepublish our paper on arxiv) is most similar to our work. Whereas Ha et al. (2016) address machine translation, we focus on the task of paradigm completion in low-resource settings and establish the state of the art for this problem.

7 Conclusion

We presented a cross-lingual transfer learning method for paradigm completion, based on an RNN encoder-decoder model. Our experiments showed that information from a high-resource language can be leveraged for paradigm completion in a related low-resource language. Our analysis indicated that the degree to which the source language data helps for a certain target language depends on their relatedness. Our method led to significant improvements in settings with limited training data – up to 58% absolute improvement in accuracy – and, thus, enables the use of state-of-the-art models for paradigm completion in low-resource languages.

8 Future Work

In the future, we want to develop methods to make better use of languages with different alphabets or morphosyntactic features, in order to increase the applicability of our knowledge transfer method.

Acknowledgments

We would like to thank the anonymous reviewers for their insightful comments. We are grateful to Siemens and Volkswagenstiftung for their generous support. This research would not have been possible without the organizers of the SIGMORPHON shared task, especially John Sylak-Glassman and Christo Kirov, who created the resources we use.

Abstract

We present a neural model for morphological inflection generation which employs a hard attention mechanism, inspired by the nearly-monotonic alignment commonly found between the characters in a word and the characters in its inflection. We evaluate the model on three previously studied morphological inflection generation datasets and show that it provides state of the art results in various setups compared to previous neural and non-neural approaches. Finally we present an analysis of the continuous representations learned by both the hard and soft attention (Bahdanau et al., 2015) models for the task, shedding some light on the features such models extract.

1 Introduction

Morphological inflection generation involves generating a target word (e.g. "härtestem", the German word for "hardest"), given a source word (e.g. "hart", the German word for "hard") and the morpho-syntactic attributes of the target (POS=adjective, gender=masculine, type=superlative, etc.).

The task is important for many down-stream NLP tasks such as machine translation, especially for dealing with data sparsity in morphologically rich languages where a lemma can be inflected into many different word forms. Several studies have shown that translating into lemmas in the target language and then applying inflection generation as a post-processing step is beneficial for phrase-based machine translation (Minkov et al., 2007; Toutanova et al., 2008; Clifton and Sarkar, 2011; Fraser et al., 2012; Chahuneau et al., 2013) and more recently for neural machine translation (García-Martínez et al., 2016).

The task was traditionally tackled with hand engineered finite state transducers (FST) (Koskenniemi, 1983; Kaplan and Kay, 1994) which rely on expert knowledge, or using trainable weighted finite state transducers (Mohri et al., 1997; Eisner, 2002) which combine expert knowledge with data-driven parameter tuning. Many other machine-learning based methods (Yarowsky and Wicentowski, 2000; Dreyer and Eisner, 2011; Durrett and DeNero, 2013; Hulden et al., 2014; Ahlberg et al., 2015; Nicolai et al., 2015) were proposed for the task, although with specific assumptions about the set of possible processes that are needed to create the output sequence.

More recently, the task was modeled as neural sequence-to-sequence learning over character sequences with impressive results (Faruqui et al., 2016). The vanilla encoder-decoder models as used by Faruqui et al. compress the input sequence to a single, fixed-sized continuous representation. Instead, the soft-attention based sequence to sequence learning paradigm (Bahdanau et al., 2015) allows directly conditioning on the entire input sequence representation, and was utilized for morphological inflection generation with great success (Kann and Schütze, 2016b,a).

However, the neural sequence-to-sequence models require large training sets in order to perform well: their performance on the relatively small CELEX dataset is inferior to the latent variable WFST model of Dreyer et al. (2008). Interestingly, the neural WFST model by Rastogi et al. (2016) also suffered from the same issue on the CELEX dataset, and surpassed the latent variable model only when given twice as much data to train on.

We propose a model which handles the above issues by directly modeling an almost monotonic

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 2004–2015
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1183

alignment between the input and output character sequences, which is commonly found in the morphological inflection generation task (e.g. in languages with concatenative morphology). The model consists of an encoder-decoder neural network with a dedicated control mechanism: in each step, the model attends to a *single* input state and either writes a symbol to the output sequence or advances the attention pointer to the next state from the bi-directionally encoded sequence, as described visually in Figure 1.

This modeling suits the natural monotonic alignment between the input and output, as the network learns to attend to the relevant inputs before writing the output which they are aligned to. The encoder is a bi-directional RNN, where each character in the input word is represented using a concatenation of a forward RNN and a backward RNN states over the word's characters. The combination of the bi-directional encoder and the controllable hard attention mechanism enables to condition the output on the entire input sequence. Moreover, since each character representation is aware of the neighboring characters, non-monotone relations are also captured, which is important in cases where segments in the output word are a result of long range dependencies in the input word. The recurrent nature of the decoder, together with a dedicated feedback connection that passes the last prediction to the next decoder step explicitly, enables the model to also condition the current output on all the previous outputs at each prediction step.

The hard attention mechanism allows the network to jointly align and transduce while using a focused representation at each step, rather then the weighted sum of representations used in the soft attention model. This makes our model Resolution Preserving (Kalchbrenner et al., 2016) while also keeping decoding time linear in the output sequence length rather than multiplicative in the input and output lengths as in the soft-attention model. In contrast to previous sequence-to-sequence work, we do not require the training procedure to also learn the alignment. Instead, we use a simple training procedure which relies on independently learned character-level alignments, from which we derive gold transduction+control sequences. The network can then be trained using straightforward cross-entropy loss.

To evaluate our model, we perform extensive experiments on three previously studied morphological inflection generation datasets: the CELEX dataset (Baayen et al., 1993), the Wiktionary dataset (Durrett and DeNero, 2013) and the SIGMORPHON2016 dataset (Cotterell et al., 2016). We show that while our model is on par with or better than the previous neural and non-neural state-of-the-art approaches, it also performs significantly better with very small training sets, being the first neural model to surpass the performance of the weighted FST model with latent variables which was specifically tailored for the task by Dreyer et al. (2008). Finally, we analyze and compare our model and the soft attention model, showing how they function very similarly with respect to the alignments and representations they learn, in spite of our model being much simpler. This analysis also sheds light on the representations such models learn for the morphological inflection generation task, showing how they encode specific features like a symbol's type and the symbol's location in a sequence.

To summarize, our contributions in this paper are three-fold:

1. We present a hard attention model for nearly-monotonic sequence to sequence learning, as common in the morphological inflection setting.

2. We evaluate the model on the task of morphological inflection generation, establishing a new state of the art on three previously-studied datasets for the task.

3. We perform an analysis and comparison of our model and the soft-attention model, shedding light on the features such models extract for the inflection generation task.

2 The Hard Attention Model

2.1 Motivation

We would like to transduce an input sequence, $x_{1:n} \in \Sigma_x^*$ into an output sequence, $y_{1:m} \in \Sigma_y^*$, where Σ_x and Σ_y are the input and output vocabularies, respectively. Imagine a machine with read-only random access to the encoding of the input sequence, and a single pointer that determines the current read location. We can then model sequence transduction as a series of pointer movement and write operations. If we assume the alignment is monotone, the machine can be simpli-

fied: the memory can be read in sequential order, where the pointer movement is controlled by a single "move forward" operation (step) which we add to the output vocabulary. We implement this behavior using an encoder-decoder neural network, with a control mechanism which determines in each step of the decoder whether to write an output symbol or promote the attention pointer the next element of the encoded input.

2.2 Model Definition

In prediction time, we seek the output sequence $y_{1:m} \in \Sigma_y^*$, for which:

$$y_{1:m} = \arg\max_{y' \in \Sigma_y^*} p(y'|x_{1:n}, f) \quad (1)$$

Where $x \in \Sigma_x^*$ is the input sequence and $f = \{f_1, \ldots, f_l\}$ is a set of attributes influencing the transduction task (in the inflection generation task these would be the desired morpho-syntactic attributes of the output sequence). Given a nearly-monotonic alignment between the input and the output, we replace the search for a sequence of letters with a sequence of actions $s_{1:q} \in \Sigma_s^*$, where $\Sigma_s = \Sigma_y \cup \{step\}$. This sequence is a series of step and write actions required to go from $x_{1:n}$ to $y_{1:m}$ according to the monotonic alignment between them (we will elaborate on the deterministic process of getting $s_{1:q}$ from a monotonic alignment between $x_{1:n}$ to $y_{1:m}$ in section 2.4). In this case we define: [1]

$$\begin{aligned} s_{1:q} &= \arg\max_{s' \in \Sigma_s^*} p(s'|x_{1:n}, f) \\ &= \arg\max_{s' \in \Sigma_s^*} \prod_{s'_i \in s'} p(s'_i|s'_1 \ldots s'_{i-1}, x_{1:n}, f) \end{aligned} \quad (2)$$

which we can estimate using a neural network:

$$s_{1:q} = \arg\max_{s' \in \Sigma_s^*} \text{NN}(x_{1:n}, f, \Theta) \quad (3)$$

where the network's parameters Θ are learned using a set of training examples. We will now describe the network architecture.

[1] We note that our model (Eq. 2) solves a different objective than (Eq 1), as it searches for the *best derivation* and not *the best sequence*. In order to accurately solve (1) we would need to marginalize over the different derivations leading to the same sequence, which is computationally challenging. However, as we see in the experiments section, the best-derivation approximation is effective in practice.

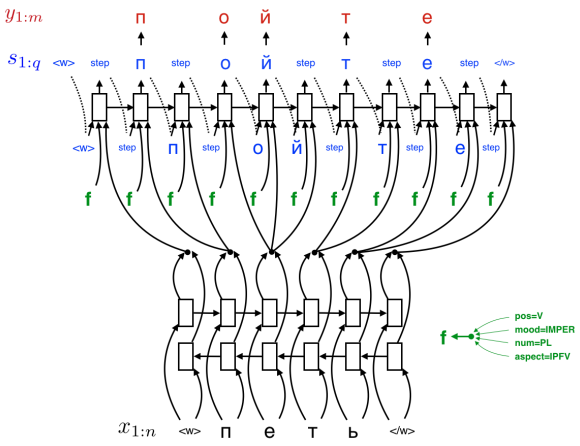

Figure 1: The hard attention network architecture. A round tip expresses concatenation of the inputs it receives. The attention is promoted to the next input element once a step action is predicted.

2.3 Network Architecture

Notation We use bold letters for vectors and matrices. We treat LSTM as a parameterized function $\mathbf{LSTM}_\theta(\mathbf{x}_1 \ldots \mathbf{x}_n)$ mapping a sequence of input vectors $\mathbf{x}_1 \ldots \mathbf{x}_n$ to a an output vector $\mathbf{h}_n$. The equations for the LSTM variant we use are detailed in the supplementary material of this paper.

Encoder For every element in the input sequence: $x_{1:n} = x_1 \ldots x_n$, we take the corresponding embedding: $\mathbf{e}_{x_1} \ldots \mathbf{e}_{x_n}$, where: $\mathbf{e}_{x_i} \in \mathbb{R}^E$. These embeddings are parameters of the model which will be learned during training. We then feed the embeddings into a bi-directional LSTM encoder (Graves and Schmidhuber, 2005) which results in a sequence of vectors: $\mathbf{x}_{1:n} = \mathbf{x}_1 \ldots \mathbf{x}_n$, where each vector $\mathbf{x}_i \in \mathbb{R}^{2H}$ is a concatenation of: $\mathbf{LSTM}_{\mathbf{forward}}(\mathbf{e}_{x_1}, \mathbf{e}_{x_2}, \ldots \mathbf{e}_{x_i})$ and $\mathbf{LSTM}_{\mathbf{backward}}(\mathbf{e}_{x_n}, \mathbf{e}_{x_{n-1}} \ldots \mathbf{e}_{x_i})$, the forward LSTM and the backward LSTM outputs when fed with $\mathbf{e}_{x_i}$.

Decoder Once the input sequence is encoded, we feed the decoder RNN, $\mathbf{LSTM}_{\mathbf{dec}}$, with three inputs at each step:

1. The current attended input, $\mathbf{x}_a \in \mathbb{R}^{2H}$, initialized with the first element of the encoded sequence, $\mathbf{x}_1$.
2. A set of embeddings for the attributes that influence the generation process, concatenated to a single vector: $\mathbf{f} = [\mathbf{f}_1 \ldots \mathbf{f}_l] \in \mathbb{R}^{F \cdot l}$.
3. $\mathbf{s}_{i-1} \in \mathbb{R}^E$, which is an embedding for the

predicted output symbol in the previous decoder step.

Those three inputs are concatenated into a single vector $\mathbf{z}_i = [\mathbf{x}_a, \mathbf{f}, \mathbf{s}_{i-1}] \in \mathbb{R}^{2H+F\cdot l+E}$, which is fed into the decoder, providing the decoder output vector: $\mathbf{LSTM_{dec}}(\mathbf{z}_1 \dots \mathbf{z}_i) \in \mathbb{R}^H$. Finally, to model the distribution over the possible actions, we project the decoder output to a vector of $|\Sigma_s|$ elements, followed by a softmax layer:

$$p(s_i = c) = softmax_c(\mathbf{W} \cdot \mathbf{LSTM_{dec}}(\mathbf{z}_1 \dots \mathbf{z}_i) + \mathbf{b}) \quad (4)$$

Control Mechanism When the most probable action is *step*, the attention is promoted so $\mathbf{x}_a$ contains the next encoded input representation to be used in the next step of the decoder. The process is demonstrated visually in Figure 1.

2.4 Training the Model

For every example: $(x_{1:n}, y_{1:m}, f)$ in the training data, we should produce a sequence of step and write actions $s_{1:q}$ to be predicted by the decoder. The sequence is dependent on the alignment between the input and the output: ideally, the network will attend to all the input characters aligned to an output character before writing it. While recent work in sequence transduction advocate jointly training the alignment and the decoding mechanisms (Bahdanau et al., 2015; Yu et al., 2016), we instead show that in our case it is worthwhile to decouple these stages and learn a hard alignment beforehand, using it to guide the training of the encoder-decoder network and enabling the use of correct alignments for the attention mechanism from the beginning of the network training phase. Thus, our training procedure consists of three stages: learning hard alignments, deriving oracle actions from the alignments, and learning a neural transduction model given the oracle actions.

Learning Hard Alignments We use the character alignment model of Sudoh et al. (2013), based on a Chinese Restaurant Process which weights single alignments (character-to-character) in proportion to how many times such an alignment has been seen elsewhere out of all possible alignments. The aligner implementation we used produces either 0-to-1, 1-to-0 or 1-to-1 alignments.

Deriving Oracle Actions We infer the sequence of actions $s_{1:q}$ from the alignments by the deterministic procedure described in Algorithm 1. An example of an alignment with the resulting oracle action sequence is shown in Figure 2, where a_4 is a 0-to-1 alignment and the rest are 1-to-1 alignments.

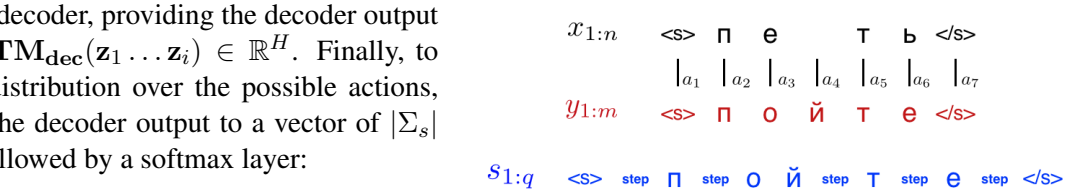

Figure 2: Top: an alignment between a lemma $x_{1:n}$ and an inflection $y_{1:m}$ as predicted by the aligner. Bottom: $s_{1:q}$, the sequence of actions to be predicted by the network, as produced by Algorithm 1 for the given alignment.

Algorithm 1 Generates the oracle action sequence $s_{1:q}$ from the alignment between $x_{1:n}$ and $y_{1:m}$

Require: a, the list of either 1-to-1, 1-to-0 or 0-to-1 alignments between $x_{1:n}$ and $y_{1:m}$

```
Initialize s as an empty sequence
for each a_i = (x_{a_i}, y_{a_i}) ∈ a do
    if a_i is a 1-to-0 alignment then
        s.append(step)
    else
        s.append(y_{a_i})
        if a_{i+1} is not a 0-to-1 alignment then
        s.append(step)
return s
```

This procedure makes sure that all the source input elements aligned to an output element are read (using the step action) before writing it.

Learning a Neural Transduction Model The network is trained to mimic the actions of the oracle, and at inference time, it will predict the actions according to the input. We train it using a conventional cross-entropy loss function per example:

$$\mathcal{L}(x_{1:n}, y_{1:m}, f, \Theta) = -\sum_{s_j \in s_{1:q}} \log softmax_{s_j}(\mathbf{d}),$$
$$\mathbf{d} = \mathbf{W} \cdot \mathbf{LSTM_{dec}}(\mathbf{z}_1 \dots \mathbf{z}_i) + \mathbf{b} \quad (5)$$

Transition System An alternative view of our model is that of a *transition system* with ADVANCE and WRITE(CH) actions, where the oracle is derived from a given hard alignment, the input is encoded using a biRNN, and the next action is determined by an RNN over the previous inputs and actions.

3 Experiments

We perform extensive experiments with three previously studied morphological inflection generation datasets to evaluate our hard attention model in various settings. In all experiments we compare our hard attention model to the best performing neural and non-neural models which were previously published on those datasets, and to our implementation of the global (soft) attention model presented by Luong et al. (2015) which we train with identical hyper-parameters as our hard-attention model. The implementation details for our models are described in the supplementary material section of this paper. The source code and data for our models is available on github.[2]

CELEX Our first evaluation is on a very small dataset, to see if our model indeed avoids the tendency to overfit with small training sets. We report exact match accuracy on the German inflection generation dataset compiled by Dreyer et al. (2008) from the CELEX database (Baayen et al., 1993). The dataset includes only 500 training examples for each of the four inflection types: 13SIA→13SKE, 2PIE→13PKE, 2PKE→z, and rP→pA which we refer to as 13SIA, 2PIE, 2PKE and rP, respectively.[3] We first compare our model to three competitive models from the literature that reported results on this dataset: the Morphological Encoder-Decoder (MED) of Kann and Schütze (2016a) which is based on the soft-attention model of Bahdanau et al. (2015), the neural-weighted FST of Rastogi et al. (2016) which uses stacked bi-directional LSTM's to weigh its arcs (NWFST), and the model of Dreyer et al. (2008) which uses a weighted FST with latent-variables structured particularly for morphological string transduction tasks (LAT). Following previous reports on this dataset, we use the same data splits as Dreyer et al. (2008), dividing the data for each inflection type into five folds, each consisting of 500 training, 1000 development and 1000 test examples. We train a separate model for each fold and report exact match accuracy, averaged over the five folds.

Wiktionary To neutralize the negative effect of very small training sets on the performance of the different learning approaches, we also evaluate our model on the dataset created by Durrett and DeNero (2013), which contains up to 360k training examples per language. It was built by extracting Finnish, German and Spanish inflection tables from Wiktionary, used in order to evaluate their system based on string alignments and a semi-CRF sequence classifier with linguistically inspired features, which we use a baseline. We also used the dataset expansion made by Nicolai et al. (2015) to include French and Dutch inflections as well. Their system also performs an align-and-transduce approach, extracting rules from the aligned training set and applying them in inference time with a proprietary character sequence classifier. In addition to those systems we also compare to the results of the recent neural approach of Faruqui et al. (2016), which did not use an attention mechanism, and Yu et al. (2016), which coupled the alignment and transduction tasks.

SIGMORPHON As different languages show different morphological phenomena, we also experiment with how our model copes with these various phenomena using the morphological inflection dataset from the SIGMORPHON2016 shared task (Cotterell et al., 2016). Here the training data consists of ten languages, with five morphological system types (detailed in Table 3): Russian (RU), German (DE), Spanish (ES), Georgian (GE), Finnish (FI), Turkish (TU), Arabic (AR), Navajo (NA), Hungarian (HU) and Maltese (MA) with roughly 12,800 training and 1600 development examples per language. We compare our model to two soft attention baselines on this dataset: MED (Kann and Schütze, 2016b), which was the best participating system in the shared task, and our implementation of the global (soft) attention model presented by Luong et al. (2015).

4 Results

In all experiments, for both the hard and soft attention models we implemented, we report results using an ensemble of 5 models with different random initializations by using majority voting on the final sequences the models predicted, as proposed by Kann and Schütze (2016a). This was done to perform fair comparison to the models of Kann and Schütze (2016a,b); Faruqui et al. (2016) which we compare to, that also perform a similar ensem-

bling technique.

On the low resource setting (CELEX), our hard attention model significantly outperforms both the recent neural models of Kann and Schütze (2016a) (MED) and Rastogi et al. (2016) (NWFST) and the morphologically aware latent variable model of Dreyer et al. (2008) (LAT), as detailed in Table 1. In addition, it significantly outperforms our implementation of the soft attention model (Soft). It is also, to our knowledge, the first model that surpassed in overall accuracy the latent variable model on this dataset. We attribute our advantage over the soft attention models to the ability of the hard attention control mechanism to harness the monotonic alignments found in the data. The advantage over the FST models may be explained by our conditioning on the entire output history which is not available in those models. Figure 3 plots the train-set and dev-set accuracies of the soft and hard attention models as a function of the training epoch. While both models perform similarly on the train-set (with the soft attention model fitting it slightly faster), the hard attention model performs significantly better on the dev-set. This shows the soft attention model's tendency to overfit on the small dataset, as it is not enforcing the monotonic assumption of the hard attention model.

On the large training set experiments (Wiktionary), our model is the best performing model on German verbs, Finnish nouns/adjectives and Dutch verbs, resulting in the highest reported average accuracy across all inflection types when compared to the four previous neural and non-neural state of the art baselines, as detailed in Table 2. This shows the robustness of our model also with large amounts of training examples, and the advantage the hard attention mechanism provides over the encoder-decoder approach of Faruqui et al. (2016) which does not employ an attention mechanism. Our model is also significantly more accurate than the model of Yu et al. (2016), which shows the advantage of using independently learned alignments to guide the network's attention from the beginning of the training process. While our soft-attention implementation outperformed the models of Yu et al. (2016) and Durrett and DeNero (2013), it still performed inferiorly to the hard attention model.

As can be seen in Table 3, on the SIGMORPHON 2016 dataset our model performs

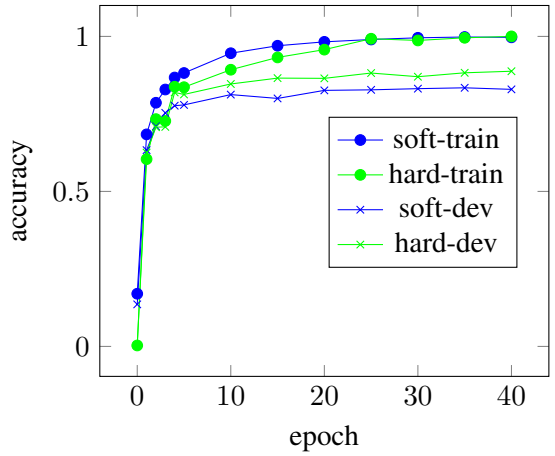

Figure 3: Learning curves for the soft and hard attention models on the first fold of the CELEX dataset

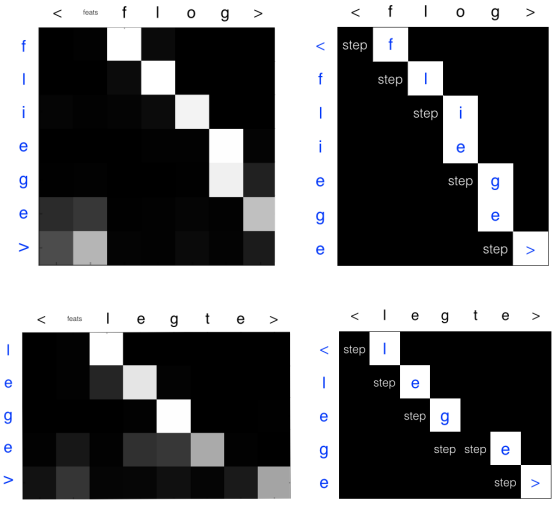

Figure 4: A comparison of the alignments as predicted by the soft attention (left) and the hard attention (right) models on examples from CELEX.

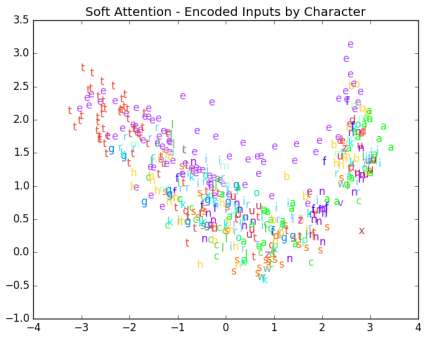
better than both soft-attention baselines for the suffixing+stem-change languages (Russian, German and Spanish) and is slightly less accurate than our implementation of the soft attention model on the rest of the languages, which is now the best performing model on this dataset to our knowledge. We explain this by looking at the languages from a linguistic typology point of view, as detailed in Cotterell et al. (2016). Since Russian, German and Spanish employ a suffixing morphology with internal stem changes, they are more suitable for monotonic alignment as the transformations they need to model are the addition of suffixes and changing characters in the stem. The rest of the languages in the dataset employ more context sensitive morphological phenomena like vowel harmony and consonant harmony, which require to model long range dependencies in the input sequence which better suits the soft attention mechanism. While our implementation of the soft attention model and MED are very similar modelwise, we hypothesize that our soft attention model results are better due to the fact that we trained the model for 100 epochs and picked the best performing model on the development set, while the MED system was trained for a fixed amount of 20 epochs (although trained on more data – both train and development sets).

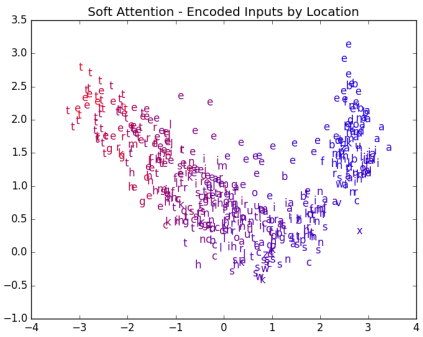
5 Analysis

The Learned Alignments In order to see if the alignments predicted by our model fit the monotonic alignment structure found in the data, and whether are they more suitable for the task when compared to the alignments found by the soft attention model, we examined alignment predictions of the two models on examples from the development portion of the CELEX dataset, as depicted in Figure 4. First, we notice the alignments found by the soft attention model are also monotonic, supporting our modeling approach for the task. Figure 4 (bottom-right) also shows how the hard-attention model performs deletion (legte→lege) by predicting a sequence of two step operations. Another notable morphological transformation is the one-to-many alignment, found in the top example: flog→fliege, where the model needs to transform a character in the input, *o*, to two characters in the output, *ie*. This is performed by two consecutive *write* operations after the *step* operation of the relevant character to be replaced. Notice that in this case, the soft attention model performs a different alignment by aligning the character *i* to *o* and the character *g* to the sequence *eg*, which is not the expected alignment in this case from a linguistic point of view.

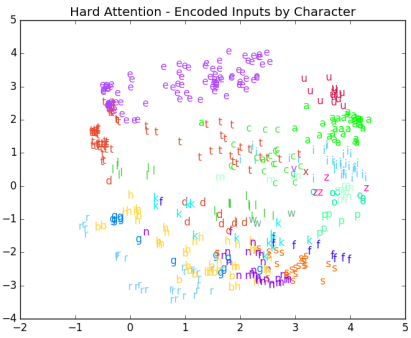
The Learned Representations How does the soft-attention model manage to learn nearly-perfect monotonic alignments? Perhaps the the network learns to encode the sequential position as part of its encoding of an input element? More generally, what information is encoded by the soft and hard alignment encoders? We selected 500 random encoded characters-in-context from input



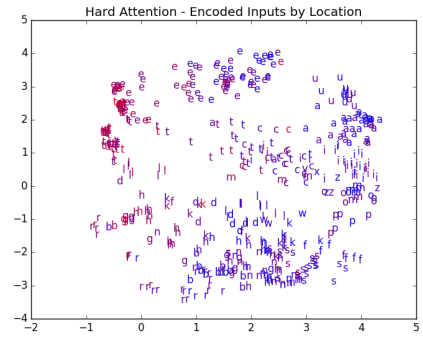
(a) Colors indicate which character is encoded.



(c) Colors indicate the character's position.



(b) Colors indicate which character is encoded.



(d) Colors indicate the character's position.

Figure 5: SVD dimension reduction to 2D of 500 character representations in context from the encoder, for both the soft attention (top) and hard attention (bottom) models.

words in the CELEX development set, where every encoded representation is a vector in $\mathbb{R}^{200}$. Since those vectors are outputs from the bi-LSTM encoders of the models, every vector of this form carries information of the specific character with its entire context. We project these encodings into 2-D using SVD and plot them twice, each time using a different coloring scheme. We first color each point according to the character it represents (Figures 5a, 5b). In the second coloring scheme (Figures 5c, 5d), each point is colored according to the character's sequential position in the word it came from, blue indicating positions near the beginning of the word, and red positions near its end.

While both models tend to cluster representations for similar characters together (Figures 5a, 5b), the hard attention model tends to have much more isolated character clusters. Figures 5c, 5d show that both models also tend to learn representations which are sensitive to the position of the character, although it seems that here the soft attention model is more sensitive to this information as its coloring forms a nearly-perfect red-to-blue transition on the X axis. This may be explained by the soft-attention mechanism encouraging the encoder to encode positional information in the input representations, which may help it to predict better attention scores, and to avoid collisions when computing the weighted sum of representations for the context vector. In contrast, our hard-attention model has other means of obtaining the position information in the decoder using the step actions, and for that reason it does not encode it as strongly in the representations of the inputs. This behavior may allow it to perform well even with fewer examples, as the location information is represented more explicitly in the model using the step actions.

6 Related Work

Many previous works on inflection generation used machine learning methods (Yarowsky and Wicentowski, 2000; Dreyer and Eisner, 2011; Durrett and DeNero, 2013; Hulden et al., 2014; Ahlberg et al., 2015; Nicolai et al., 2015) with assumptions about the set of possible processes needed to create the output word. Our work was mainly inspired by Faruqui et al. (2016) which trained an independent encoder-decoder neural

network for every inflection type in the training data, alleviating the need for feature engineering. Kann and Schütze (2016b,a) tackled the task with a *single* soft attention model (Bahdanau et al., 2015) for all inflection types, which resulted in the best submission at the SIGMORPHON 2016 shared task (Cotterell et al., 2016). In another closely related work, Rastogi et al. (2016) model the task with a WFST in which the arc weights are learned by optimizing a global loss function over all the possible paths in the state graph, while modeling contextual features with bi-directional LSTMS. This is similar to our approach, where instead of learning to mimic a single greedy alignment as we do, they sum over all possible alignments. While not committing to a single greedy alignment could in theory be beneficial, we see in Table 1 that—at least for the low resource scenario—our greedy approach is more effective in practice. Another recent work (Kann et al., 2016) proposed performing neural multi-source morphological reinflection, generating an inflection from several source forms of a word.

Previous works on neural sequence transduction include the RNN Transducer (Graves, 2012) which uses two independent RNN's over monotonically aligned sequences to predict a distribution over the possible output symbols in each step, including a null symbol to model the alignment. Yu et al. (2016) improved this by replacing the null symbol with a dedicated learned transition probability. Both models are trained using a forward-backward approach, marginalizing over all possible alignments. Our model differs from the above by learning the alignments independently, thus enabling a dependency between the encoder and decoder. While providing better results than Yu et al. (2016), this also simplifies the model training using a simple cross-entropy loss. A recent work by Raffel et al. (2017) jointly learns the hard monotonic alignments and transduction while maintaining the dependency between the encoder and the decoder. Jaitly et al. (2015) proposed the Neural Transducer model, which is also trained on external alignments. They divide the input into blocks of a constant size and perform soft attention separately on each block. Lu et al. (2016) used a combination of an RNN encoder with a CRF layer to model the dependencies in the output sequence. An interesting comparison between "traditional" sequence transduction models (Bisani and Ney, 2008; Jiampojamarn et al., 2010; Novak et al., 2012) and encoder-decoder neural networks for monotone string transduction tasks was done by Schnober et al. (2016), showing that in many cases there is no clear advantage to one approach over the other.

Regarding task-specific improvements to the attention mechanism, a line of work on attention-based speech recognition (Chorowski et al., 2015; Bahdanau et al., 2016) proposed adding location awareness by using the previous attention weights when computing the next ones, and preventing the model from attending on too many or too few inputs using "sharpening" and "smoothing" techniques on the attention weight distributions. Cohn et al. (2016) offered several changes to the attention score computation to encourage well-known modeling biases found in traditional machine translation models like word fertility, position and alignment symmetry. Regarding the utilization of independent alignment models for training attention-based networks, Mi et al. (2016) showed that the distance between the attention-infused alignments and the ones learned by an independent alignment model can be added to the networks' training objective, resulting in an improved translation and alignment quality.

7 Conclusion

We presented a hard attention model for morphological inflection generation. The model employs an explicit alignment which is used to train a neural network to perform transduction by decoding with a hard attention mechanism. Our model performs better than previous neural and non-neural approaches on various morphological inflection generation datasets, while staying competitive with dedicated models even with very few training examples. It is also computationally appealing as it enables linear time decoding while staying resolution preserving, i.e. not requiring to compress the input sequence to a single fixed-sized vector. Future work may include applying our model to other nearly-monotonic align-and-transduce tasks like abstractive summarization, transliteration or machine translation.

Supplementary Material

Training Details, Implementation and Hyper Parameters

To train our models, we used the train portion of the datasets as-is and evaluated on the test portion the model which performed best on the development portion of the dataset, without conducting any specific pre-processing steps on the data. We train the models for a maximum of 100 epochs over the training set. To avoid long training time, we trained the model for 20 epochs for datasets larger than 50k examples, and for 5 epochs for datasets larger than 200k examples. The models were implemented using the python bindings of the dynet toolkit.[4]

We trained the network by optimizing the expected output sequence likelihood using cross-entropy loss as mentioned in equation 5. For optimization we used ADADELTA (Zeiler, 2012) without regularization. We updated the weights after every example (i.e. mini-batches of size 1). We used the dynet toolkit implementation of an LSTM network with two layers for all models, each having 100 entries in both the encoder and decoder. The character embeddings were also vectors with 100 entries for the CELEX experiments, and with 300 entries for the SIGMORPHON and Wiktionary experiments.

The morpho-syntactic attribute embeddings were vectors of 20 entries in all experiments. We did not use beam search while decoding for both the hard and soft attention models as it is significantly slower and did not show clear improvement in previous experiments we conducted. For the character level alignment process we use the implementation provided by the organizers of the SIGMORPHON2016 shared task.[5]

LSTM Equations

We used the LSTM variant implemented in the dynet toolkit, which corresponds to the following equations:

$$
\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{ix}\mathbf{x}_t + \mathbf{W}_{ih}\mathbf{h}_{t-1} + \mathbf{W}_{ic}\mathbf{c}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_{fx}\mathbf{x}_t + \mathbf{W}_{fh}\mathbf{f}_{t-1} + \mathbf{W}_{fc}\mathbf{c}_{t-1} + \mathbf{b}_f) \\
\widetilde{\mathbf{c}} &= \tanh(\mathbf{W}_{cx}\mathbf{x}_t + \mathbf{W}_{ch}\mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{c}_t &= \mathbf{c}_{t-1} \circ \mathbf{f}_t + \widetilde{\mathbf{c}} \circ \mathbf{i}_t \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{ox}\mathbf{x}_t + \mathbf{W}_{oh}\mathbf{h}_{t-1} + \mathbf{W}_{ox}\mathbf{c}_t + \mathbf{b}_o) \\
\mathbf{h}_t &= \tanh(\mathbf{c}_t) \circ \mathbf{o}_t
\end{aligned}
\tag{6}
$$

From Characters to Words to in Between: Do We Capture Morphology?

Clara Vania and **Adam Lopez**
Institute for Language, Cognition and Computation
School of Informatics
University of Edinburgh
c.vania@ed.ac.uk, alopez@inf.ed.ac.uk

Abstract

Words can be represented by composing the representations of subword units such as word segments, characters, and/or character n-grams. While such representations are effective and may capture the morphological regularities of words, they have not been systematically compared, and it is not understood how they interact with different morphological typologies. On a language modeling task, we present experiments that systematically vary (1) the basic unit of representation, (2) the composition of these representations, and (3) the morphological typology of the language modeled. Our results extend previous findings that character representations are effective across typologies, and we find that a previously unstudied combination of character trigram representations composed with bi-LSTMs outperforms most others. But we also find room for improvement: none of the character-level models match the predictive accuracy of a model with access to true morphological analyses, even when learned from an order of magnitude more data.

1 Introduction

Continuous representations of words learned by neural networks are central to many NLP tasks (Cho et al., 2014; Chen and Manning, 2014; Dyer et al., 2015). However, directly mapping a finite set of word types to a continuous representation has well-known limitations. First, it makes a closed vocabulary assumption, enabling only generic out-of-vocabulary handling. Second, it cannot exploit systematic functional relationships in learning. For example, *cat* and *cats* stand in the same relationship as *dog* and *dogs*. While this relationship might be discovered for these specific frequent words, it does not help us learn that the same relationship also holds for the much rarer words *sloth* and *sloths*.

These functional relationships reflect the fact that words are composed from smaller units of meaning, or morphemes. For instance, *cats* consists of two morphemes, *cat* and *-s*, with the latter shared by the words *dogs* and *tarsiers*. Modeling this effect is crucial for languages with rich morphology, where vocabulary sizes are larger, many more words are rare, and many more such functional relationships exist. Hence, some models produce word representations as a function of subword units obtained from morphological segmentation or analysis (Luong et al., 2013; Botha and Blunsom, 2014; Cotterell and Schütze, 2015). A downside of these models is that they depend on morphological segmenters or analyzers.

Morphemes typically have similar orthographic representations across words. For example, the morpheme *-s* is realized as *-es* in *finches*. Since this variation is limited, the general relationship between morphology and orthography can be exploited by composing the representations of characters (Ling et al., 2015; Kim et al., 2016), character n-grams (Sperr et al., 2013; Wieting et al., 2016; Bojanowski et al., 2016; Botha and Blunsom, 2014), bytes (Plank et al., 2016; Gillick et al., 2016), or combinations thereof (Santos and Zadrozny, 2014; Qiu et al., 2014). These models are compact, can represent rare and unknown words, and do not require morphological analyzers. They raise a provocative question: Does NLP benefit from models of morphology, or can they be replaced entirely by models of characters?

The relative merits of word, subword. and character-level models are not fully understood because each new model has been compared on

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 2016–2027
Vancouver, Canada, July 30 - August 4, 2017.
https://doi.org/10.18653/v1/P17-1184

different tasks and datasets, and often compared against word-level models. A number of questions remain open:

1. How do representations based on morphemes compare with those based on characters?
2. What is the best way to compose subword representations?
3. Do character-level models capture morphology in terms of predictive utility?
4. How do different representations interact with languages of different morphological typologies?

The last question is raised by Bender (2013): languages are typologically diverse, and the behavior of a model on one language may not generalize to others. Character-level models implicitly assume concatenative morphology, but many widely-spoken languages feature non-concatenative morphology, and it is unclear how such models will behave on these languages.

To answer these questions, we performed a systematic comparison across different models for the simple and ubiquitous task of language modeling. We present experiments that vary (1) the type of subword unit; (2) the composition function; and (3) morphological typology. To understand the extent to which character-level models capture true morphological regularities, we present oracle experiments using human morphological annotations instead of automatic morphological segments. Our results show that:

1. For most languages, character-level representations outperform the standard word representations. Most interestingly, a previously unstudied combination of character trigrams composed with bi-LSTMs performs best on the majority of languages.
2. Bi-LSTMs and CNNs are more effective composition functions than addition.
3. Character-level models learn functional relationships between orthographically similar words, but don't (yet) match the predictive accuracy of models with access to true morphological analyses.
4. Character-level models are effective across a range of morphological typologies, but orthography influences their effectiveness.

word	`tries`
morphemes	`try+s`
morphs	`tri+es`
morph. analysis	`try+VB+3rd+SG+Pres`

Table 1: The morphemes, morphs, and morphological analysis of *tries*.

2 Morphological Typology

A **morpheme** is the smallest unit of meaning in a word. Some morphemes express core meaning (**roots**), while others express one or more dependent **features** of the core meaning, such as person, gender, or aspect. A **morphological analysis** identifies the lemma and features of a word. A **morph** is the surface realization of a morpheme (Morley, 2000), which may vary from word to word. These distinctions are shown in Table 1.

Morphological typology classifies languages based on the processes by which morphemes are composed to form words. While most languages will exhibit a variety of such processes, for any given language, some processes are much more frequent than others, and we will broadly identify our experimental languages with these processes.

When morphemes are combined sequentially, the morphology is **concatenative**. However, morphemes can also be composed by **non-concatenative** processes. We consider four broad categories of both concatenative and non-concatenative processes in our experiments.

Fusional languages realize multiple features in a single concatenated morpheme. For example, English verbs can express number, person, and tense in a single morpheme:

wanted (English)
want + *ed*
want + `VB+1st+SG+Past`

Agglutinative languages assign one feature per morpheme. Morphemes are concatenated to form a word and the morpheme boundaries are clear. For example (Haspelmath, 2010):

okursam (Turkish)
oku+r+sa+m
"read"+`AOR+COND+1SG`

Root and Pattern Morphology forms words by inserting consonants and vowels of dependent morphemes into a consonantal root based on a given pattern. For example, the Arabic root *ktb* ("write") produces (Roark and Sproat, 2007):

katab "wrote" (Arabic)

takaatab "wrote to each other" (Arabic)

Reduplication is a process where a word form is produced by repeating part or all of the root to express new features. For example:

anak "child" (Indonesian)
anak-anak "children" (Indonesian)
buah "fruit" (Indonesian)
buah-buahan "various fruits" (Indonesian)

3 Representation Models

We compare ten different models, varying subword units and composition functions that have commonly been used in recent work, but evaluated on various different tasks (Table 2). Given word w, we compute its representation $\mathbf{w}$ as:

$$\mathbf{w} = f(\mathbf{W}_s, \sigma(w)) \quad (1)$$

where σ is a deterministic function that returns a sequence of subword units; $\mathbf{W}_s$ is a parameter matrix of representations for the vocabulary of subword units; and f is a composition function which takes $\sigma(w)$ and $\mathbf{W}_s$ as input and returns $\mathbf{w}$. All of the representations that we consider take this form, varying only in f and σ.

3.1 Subword Units

We consider four variants of σ in Equation 1, each returning a different type of subword unit: character, character trigram, or one of two types of morph. Morphs are obtained from Morfessor (Smit et al., 2014) or a word segmentation based on Byte Pair Encoding (BPE; Gage (1994)), which has been shown to be effective for handling rare words in neural machine translation (Sennrich et al., 2016). BPE works by iteratively replacing frequent pairs of characters with a single unused character. For Morfessor, we use default parameters while for BPE we set the number of merge operations to 10,000.[1] When we segment into character trigrams, we consider all trigrams in the word, including those covering notional beginning and end of word characters, as in Sperr et al. (2013). Example output of σ is shown in Table 3.

3.2 Composition Functions

We use three variants of f in Eq. 1. The first constructs the representation $\mathbf{w}$ of word w by adding the representations of its subwords $s_1, \ldots, s_n = \sigma(w)$, where the representation of s_i is vector $\mathbf{s}_i$.

$$\mathbf{w} = \sum_{i=1}^{n} \mathbf{s}_i \quad (2)$$

The only subword unit that we don't compose by addition is characters, since this will produce the same representation for many different words.

Our second composition function is a bidirectional long-short-term memory (**bi-LSTM**), which we adapt based on its use in the character-level model of Ling et al. (2015) and its widespread use in NLP generally. Given $\mathbf{s}_i$ and the previous LSTM hidden state $\mathbf{h}_{i-1}$, an LSTM (Hochreiter and Schmidhuber, 1997) computes the following outputs for the subword at position i:

$$\mathbf{h}_i = LSTM(\mathbf{s}_i, \mathbf{h}_{i-1}) \quad (3)$$

$$\hat{s}_{i+1} = g(\mathbf{V}^T \cdot \mathbf{h}_i) \quad (4)$$

where $\hat{s}_{i+1}$ is the predicted target subword, g is the softmax function and $\mathbf{V}$ is a weight matrix.

A bi-LSTM (Graves et al., 2005) combines the final state of an LSTM over the input sequence with one over the reversed input sequence. Given the hidden state produced from the final input of the forward LSTM, $\mathbf{h}_n^{fw}$ and the hidden state produced from the final input of the backward LSTM $\mathbf{h}_0^{bw}$, we compute the word representation as:

$$\mathbf{w}_t = \mathbf{W}_f \cdot \mathbf{h}_n^{fw} + \mathbf{W}_b \cdot \mathbf{h}_0^{bw} + \mathbf{b} \quad (5)$$

where $\mathbf{W}_f$, $\mathbf{W}_b$, and $\mathbf{b}$ are parameter matrices and $\mathbf{h}_n^{fw}$ and $\mathbf{h}_0^{bw}$ are forward and backward LSTM states, respectively.

The third composition function is a convolutional neural network (**CNN**) with highway layers, as in Kim et al. (2016). Let $c_1, \ldots, c_k$ be the sequence of characters of word w. The character embedding matrix is $\mathbf{C} \in \mathbb{R}^{d \times k}$, where the i-th column corresponds to the embeddings of c_i. We first apply a narrow convolution between $\mathbf{C}$ and a filter $\mathbf{F} \in \mathbb{R}^{d \times n}$ of width n to obtain a feature map $\mathbf{f} \in \mathbf{R}^{k-n+1}$. In particular, the computation of the j-th element of $\mathbf{f}$ is defined as

$$\mathbf{f}[j] = tanh(\langle \mathbf{C}[*, j : j+n-1], \mathbf{F} \rangle + b) \quad (6)$$

where $\langle A, B \rangle = \mathtt{Tr}(\mathbf{A}\mathbf{B}^T)$ is the Frobenius inner product and b is a bias. The CNN model applies filters of varying width, representing features

[1] BPE takes a single parameter: the number of merge operations. We tried different parameter values (1k, 10k, 100k) and manually examined the resulting segmentation on the English dataset. Qualitatively, 10k gave the most plausible segmentation and we used this setting across all languages.

of character n-grams. We then calculate the max-over-time of each feature map.

$$y_j = \max_j \mathbf{f}[j] \tag{7}$$

and concatenate them to derive the word representation $\mathbf{w}_t = [y_1, \ldots, y_m]$, where m is the number of filters applied. Highway layers allow some dimensions of $\mathbf{w}_t$ to be carried or transformed. Since it can learn character n-grams directly, we only use the CNN with character input.

3.3 Language Model

We use language models (LM) because they are simple and fundamental to many NLP applications. Given a sequence of text $s = w_1, \ldots, w_T$, our LM computes the probability of s as:

$$P(w_1, \ldots, w_T) = \prod_{t=1}^{T} P(y_t | w_1, \ldots, w_{t-1}) \tag{8}$$

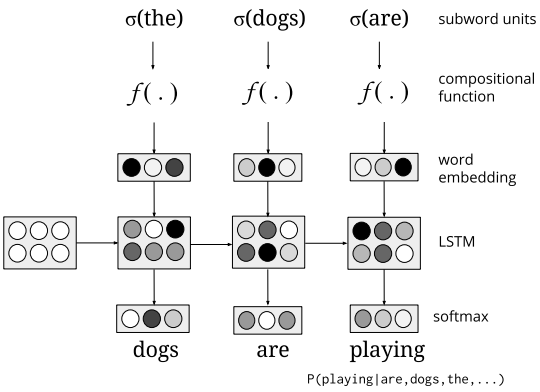

Figure 1: Our LSTM-LM architecture.

where $y_t = w_t$ if w_t is in the output vocabulary and $y_t = \texttt{UNK}$ otherwise.

Our language model is an LSTM variant of recurrent neural network language (RNN) LM (Mikolov et al., 2010). At time step t, it receives input w_t and predicts y_{t+1}. Using Eq. 1, it first computes representation $\mathbf{w}_t$ of w_t. Given this representation and previous state $\mathbf{h}_{t-1}$, it produces a new state $\mathbf{h}_t$ and predicts y_{t+1}:

$$\mathbf{h}_t = LSTM(\mathbf{w}_t, \mathbf{h}_{t-1}) \tag{9}$$

$$\hat{y}_{t+1} = g(\mathbf{V}^T \cdot \mathbf{h}_t) \tag{10}$$

where g is a softmax function over the vocabulary yielding the probability in Equation 8. Note that this design means that we can *predict* only words

Typology	Languages	#tokens	#types

Reduplication	Indonesian	1.2M	76.5K
	Malaysian	1.2M	77.7K

Table 4: Statistics of our datasets.

from a finite output vocabulary, so our models differ only in their representation of context words. This design makes it possible to compare language models using perplexity, since they have the same event space, though open vocabulary word prediction is an interesting direction for future work.

The complete architecture of our system is shown in Figure 1, showing segmentation function σ and composition function f from Equation 1.

4 Experiments

We perform experiments on ten languages (Table 4). We use datasets from Ling et al. (2015) for English and Turkish. For Czech and Russian we use Universal Dependencies (UD) v1.3 (Nivre et al., 2015). For other languages, we use preprocessed Wikipedia data (Al-Rfou et al., 2013).[2] For each dataset, we use approximately 1.2M tokens to train, and approximately 150K tokens each for development and testing. Preprocessing involves lowercasing (except for character models) and removing hyperlinks.

To ensure that we compared models and not implementations, we reimplemented all models in a single framework using Tensorflow (Abadi et al., 2015).[3] We use a common setup for all experiments based on that of Ling et al. (2015), Kim et al. (2016), and Miyamoto and Cho (2016). In preliminary experiments, we confirmed that our models produced similar patterns of perplexities for the reimplemented word and character LSTM models of Ling et al. (2015). Even following detailed discussion with Ling (p.c.), we were unable to reproduce their perplexities exactly—our English reimplementation gives lower perplexities; our Turkish higher—but we do reproduce their general result that character bi-LSTMs outperform word models. We suspect that different preprocessing and the stochastic learning explains differences in perplexities. Our final model with bi-LSTMs composition follows Miyamoto and Cho (2016) as it gives us the same perplexity results for our preliminary experiments on the Penn Treebank dataset (Marcus et al., 1993), preprocessed by Mikolov et al. (2010).

4.1 Training and Evaluation

Our LSTM-LM uses two hidden layers with 200 hidden units and representation vectors for words, characters, and morphs all have dimension 200. All parameters are initialized uniformly at random from -0.1 to 0.1, trained by stochastic gradient descent with mini-batch size of 32, time steps of 20, for 50 epochs. To avoid overfitting, we apply dropout with probability 0.5 on the input-to-hidden layer and all of the LSTM cells (including those in the bi-LSTM, if used). For all models which do not use bi-LSTM composition, we start with a learning rate of 1.0 and decrease it by half if the validation perplexity does not decrease by 0.1 after 3 epochs. For models with bi-LSTMs composition, we use a constant learning rate of 0.2 and stop training when validation perplexity does not improve after 3 epochs. For the character CNN model, we use the same settings as the *small model* of Kim et al. (2016).

To make our results comparable to Ling et al. (2015), for each language we limit the output vocabulary to the most frequent 5,000 training words plus an unknown word token. To learn to predict unknown words, we follow Ling et al. (2015): in training, words that occur only once are stochastically replaced with the unknown token with probability 0.5. To evaluate the models, we compute perplexity on the test data.

5 Results and Analysis

Table 5 presents our main results. In six of ten languages, character-trigram representations composed with bi-LSTMs achieve the lowest perplexities. As far as we know, this particular model has not been tested before, though it is similar

[2]The Arabic and Hebrew dataset are unvocalized. Japanese mixes Kanji, Katakana, Hiragana, and Latin characters (for foreign words). Hence, a Japanese character can correspond to a character, syllable, or word. The preprocessed dataset is already word-segmented.

[3]Our implementation of these models can be found at https://github.com/claravania/subword-lstm-lm

Table 5: Language model perplexities on test. The best model for each language is highlighted in **bold** and the improvement of this model over the word-level model is shown in the final column.

to (but more general than) the model of Sperr et al. (2013). We can see that the performance of character, character trigrams, and BPE are very competitive. Composition by bi-LSTMs or CNN is more effective than addition, except for Turkish. We also observe that BPE always outperforms Morfessor, even for the agglutinative languages. We now turn to a more detailed analysis by morphological typology.

Fusional languages. For these languages, character trigrams composed with bi-LSTMs outperformed all other models, particularly for Czech and Russian (up to 20%), which is unsurprising since both are morphologically richer than English.

Agglutinative languages. We observe different results for each language. For Finnish, character trigrams composed with bi-LSTMs achieves the best perplexity. Surprisingly, for Turkish character trigrams composed via addition is best and addition also performs quite well for other representations, potentially useful since the addition function is simpler and faster than bi-LSTMs. We suspect that this is due to the fact that Turkish morphemes are reasonably short, hence well-approximated by character trigrams. For Japanese, we improvements from character models are more modest than in other languages.

Root and Pattern. For these languages, character trigrams composed with bi-LSTMs also achieve the best perplexity. We had wondered whether CNNs would be more effective for root-and-pattern morphology, but since these data are unvocalized, it is more likely that non-concatenative effects are minimized, though we do still find morphological variants with consonantal inflections that behave more like concatenation. For example, *maktab* (root:*ktb*) is written as *mktb*. We suspect this makes character trigrams quite effective since they match the tri-consonantal root patterns among words which share the same root.

Reduplication. For Indonesian, BPE morphs composed with bi-LSTMs model obtain the best perplexity. For Malay, the character CNN outperforms other models. However, these improvements are small compared to other languages. This likely reflects that Indonesian and Malay are only moderately inflected, where inflection involves both concatenative and non-concatenative processes.

5.1 Effects of Morphological Analysis

In the experiments above, we used unsupervised morphological *segmentation* as a proxy for morphological *analysis* (Table 3). However, as discussed in Section 2, this is quite approximate, so it is natural to wonder what would happen if we had the true morphological analysis. If character-level models are powerful enough to capture the effects of morphology, then they should have the predictive accuracy of a model with access to this analysis. To find out, we conducted an oracle experiment using the human-annotated morphological analyses provided in the UD datasets for Czech and Russian, the only languages in our set for which these analyses were available. In these experiments we treat the lemma and each morphological feature as a subword unit.

The results (Table 6) show that bi-LSTM composition of these representations outperforms all

Languages	Addition	bi-LSTM
Czech	51.8	**30.07**
Russian	41.82	**26.44**

Table 6: Perplexity results using hand-annotated morphological analyses (cf. Table 5).

other models for both languages. These results demonstrate that neither character representations nor unsupervised segmentation is a perfect replacement for manual morphological analysis, at least in terms of predictive accuracy. In light of character-level results, they imply that current unsupervised morphological analyzers are poor substitutes for real morphological analysis.

However, we can obtain much more unannotated than annotated data, and we might guess that the character-level models would outperform those based on morphological analyses if trained on larger data. To test this, we ran experiments that varied the training data size on three representation models: word, character-trigram bi-LSTM, and character CNN. Since we want to see how much training data is needed to reach perplexity obtained using annotated data, we use the same output vocabulary derived from the original training. While this makes it possible to compare perplexities across models, it is unfavorable to the models trained on larger data, which may focus on other words. This is a limitation of our experimental setup, but does allow us to draw some tentative conclusions. As shown in Table 7, a character-level model trained on an order of magnitude more data still does not match the predictive accuracy of a model with access to morphological analysis.

5.2 Automatic Morphological Analysis

The oracle experiments show promising results if we have annotated data. But these annotations are expensive, so we also investigated the use of automatic morphological analysis. We obtained analyses for Arabic with the MADAMIRA (Pasha et al., 2014).[4] As in the experiment using annotations, we treated each morphological feature as a subword unit. The resulting perplexities of **71.94** and **42.85** for addition and bi-LSTMs, respectively, are worse than those obtained with character trigrams (**39.87**), though it approaches the best perplexities.

[4]We only experimented with Arabic since MADAMIRA disambiguates words in contexts; most other analyzers we found did not do this, and would require additional work to add disambiguation.

#tokens	word	char trigram bi-LSTM	char CNN
1M	39.69	32.34	35.15
2M	37.59	36.44	35.58
3M	36.71	35.60	35.75
4M	35.89	32.68	35.93
5M	35.20	34.80	37.02
10M	35.60	35.82	39.09

Table 7: Perplexity results on the Czech development data, varying training data size. Perplexity using ~1M tokens annotated data is **28.83**.

5.3 Targeted Perplexity Results

A difficulty in interpreting the results of Table 5 with respect to specific morphological processes is that perplexity is measured for all words. But these processes do not apply to all words, so it may be that the effects of specific morphological processes are washed out. To get a clearer picture, we measured perplexity for only specific subsets of words in our test data: specifically, given target word w_i, we measure perplexity of word w_{i+1}. In other words, we analyze the perplexities *when the inflected words of interest are in the most recent history*, exploiting the recency bias of our LSTM-LM. This is the perplexity most likely to be strongly affected by different representations, since we do not vary representations of the predicted word itself.

We look at several cases: nouns and verbs in Czech and Russian, where word classes can be identified from annotations, and reduplication in Indonesian, which we can identify mostly automatically. For each analysis, we also distinguish between *frequent* cases, where the inflected word occurs more than ten times in the training data, and *rare* cases, where it occurs fewer than ten times. We compare only bi-LSTM models.

For Czech and Russian, we again use the UD annotation to identify words of interest. The results (Table 8), show that manual morphological analysis uniformly outperforms other subword models, with an especially strong effect for Czech nouns, suggesting that other models do not capture useful predictive properties of a morphological analysis. We do however note that character trigrams achieve low perplexities in most cases, similar to overall results (Table 5). We also observe that the subword models are more effective for rare words.

Inflection	Model	all	frequent	rare
Czech nouns	word	61.21	56.84	72.96
	characters	51.01	47.94	59.01

	morph. analysis	**31.38**	**31.30**	**31.50**
Russian verbs	word	56.45	47.65	69.46
	characters	45.00	40.86	50.60
	char-trigrams	42.55	39.05	47.17
	BPE	54.58	47.81	64.12
	morph. analysis	**41.31**	**39.8**	**43.18**

Table 8: Average perplexities of words that occur after nouns and verbs. Frequent words occur more than ten times in the training data; rare words occur fewer times than this. The best perplexity is in **bold** while the second best is underlined.

For Indonesian, we exploit the fact that the hyphen symbol '-' typically separates the first and second occurrence of a reduplicated morpheme, as in the examples of Section 2. We use the presence of word tokens containing hyphens to estimate the percentage of those exhibiting reduplication. As shown in Table 9, the numbers are quite low.

Table 10 shows results for reduplication. In contrast with the overall results, the BPE bi-LSTM model has the worst perplexities, while character bi-LSTM has the best, suggesting that these models are more effective for reduplication.

Looking more closely at BPE segmentation of reduplicated words, we found that only 6 of 252 reduplicated words have a correct word segmentation, with the reduplicated morpheme often combining differently with the notional start-of-word or hyphen character. One the other hand BPE correctly learns 8 out of 9 Indonesian prefixes and 4 out of 7 Indonesian suffixes.[5] This analysis supports our intuition that the improvement from BPE might come from its modeling of concatenative morphology.

5.4 Qualitative Analysis

Table 11 presents nearest neighbors under cosine similarity for in-vocabulary, rare, and out-of-vocabulary (OOV) words.[6] For frequent words, standard word embeddings are clearly superior for lexical meaning. Character and morph representations tend to find words that are orthographically similar, suggesting that they are better at modeling dependent than root morphemes. The same pattern holds for rare and OOV words. We suspect that the subword models outperform words on language modeling because they exploit affixes to signal word class. We also noticed similar patterns in Japanese.

We analyze reduplication by querying reduplicated words to find their nearest neighbors using the BPE bi-LSTM model. If the model were sensitive to reduplication, we would expect to see morphological variants of the query word among its nearest neighbors. However, from Table 12, this is not so. With the partially reduplicated query *berlembah-lembah*, we do not find the lemma *lembah*.

Language	type-level (%)	token-level (%)
Indonesian	1.10	2.60
Malay	1.29	2.89

Table 9: Percentage of full reduplication on the type and token level.

Model	all	frequent	rare
word	101.71	91.71	156.98
characters	**99.21**	**91.35**	**137.42**
BPE	117.2	108.86	156.81

Table 10: Average perplexities of words that occur after reduplicated words in the test set.

6 Conclusion

We presented a systematic comparison of word representation models with different levels of morphological awareness, across languages with different morphological typologies. Our results confirm previous findings that character-level models are effective for many languages, but these models do not match the predictive accuracy of model with explicit knowledge of morphology, even after we increase the training data size by ten times. Moreover, our qualitative analysis suggests that they learn orthographic similarity of affixes, and lose the meaning of root morphemes.

Although morphological analyses are available

[5] We use Indonesian affixes listed in Larasati et al. (2011)

in limited quantities, our results suggest that there might be utility in semi-supervised learning from partially annotated data. Across languages with different typologies, our experiments show that the subword unit models are most effective on agglutinative languages. However, these results do not generalize to all languages, since factors such as morphology and orthography affect the utility of these representations. We plan to explore these effects in future work.

Abstract

Skip-Gram Negative Sampling (SGNS) word embedding model, well known by its implementation in "word2vec" software, is usually optimized by stochastic gradient descent. However, the optimization of SGNS objective can be viewed as a problem of searching for a good matrix with the low-rank constraint. The most standard way to solve this type of problems is to apply Riemannian optimization framework to optimize the SGNS objective over the manifold of required low-rank matrices. In this paper, we propose an algorithm that optimizes SGNS objective using Riemannian optimization and demonstrates its superiority over popular competitors, such as the original method to train SGNS and SVD over SPPMI matrix.

1 Introduction

In this paper, we consider the problem of embedding words into a low-dimensional space in order to measure the semantic similarity between them. As an example, how to find whether the word "table" is semantically more similar to the word "stool" than to the word "sky"? That is achieved by constructing a low-dimensional vector representation for each word and measuring similarity between the words as the similarity between the corresponding vectors.

One of the most popular word embedding models (Mikolov et al., 2013) is a discriminative neural network that optimizes Skip-Gram Negative Sampling (SGNS) objective (see Equation 3). It aims at predicting whether two words can be found close to each other within a text. As shown in Section 2, the process of word embeddings training using SGNS can be divided into two general steps with clear objectives:

Step 1. Search for a low-rank matrix X that provides a good SGNS objective value;

Step 2. Search for a good low-rank representation $X = WC^\top$ in terms of linguistic metrics, where W is a matrix of word embeddings and C is a matrix of so-called context embeddings.

Unfortunately, most previous approaches mixed these two steps into a single one, what entails a not completely correct formulation of the optimization problem. For example, popular approaches to train embeddings (including the original "word2vec" implementation) do not take into account that the objective from Step 1 depends only on the product $X = WC^\top$: instead of straightforward computing of the derivative w.r.t. X, these methods are explicitly based on the derivatives w.r.t. W and C, what complicates the optimization procedure. Moreover, such approaches do not take into account that parametrization $WC^\top$ of matrix X is non-unique and Step 2 is required. Indeed, for any invertible matrix S, we have

$$X = W_1 C_1^\top = W_1 S S^{-1} C_1^\top = W_2 C_2^\top,$$

therefore, solutions $W_1 C_1^\top$ and $W_2 C_2^\top$ are equally good in terms of the SGNS objective but entail different cosine similarities between embeddings and, as a result, different performance in terms of linguistic metrics (see Section 4.2 for details).

A successful attempt to follow the above described steps, which outperforms the original SGNS optimization approach in terms of various linguistic tasks, was proposed in (Levy and Goldberg, 2014). In order to obtain a low-rank matrix X on Step 1, the method reduces the dimensionality of Shifted Positive Pointwise Mutual Informa-

tion (SPPMI) matrix via Singular Value Decomposition (SVD). On Step 2, it computes embeddings W and C via a simple formula that depends on the factors obtained by SVD. However, this method has one important limitation: SVD provides a solution to a surrogate optimization problem, which has no direct relation to the SGNS objective. In fact, SVD minimizes the Mean Squared Error (MSE) between X and SPPMI matrix, what does not lead to minimization of SGNS objective in general (see Section 6.1 and Section 4.2 in (Levy and Goldberg, 2014) for details).

These issues bring us to the main idea of our paper: while keeping the low-rank matrix search setup on Step 1, optimize the original SGNS objective directly. This leads to an optimization problem over matrix X with the low-rank constraint, which is often (Mishra et al., 2014) solved by applying *Riemannian optimization* framework (Udriste, 1994). In our paper, we use the projector-splitting algorithm (Lubich and Oseledets, 2014), which is easy to implement and has low computational complexity. Of course, Step 2 may be improved as well, but we regard this as a direction of future work.

As a result, our approach achieves the significant improvement in terms of SGNS optimization on Step 1 and, moreover, the improvement on Step 1 entails the improvement on Step 2 in terms of linguistic metrics. That is why, the proposed two-step decomposition of the problem makes sense, what, most importantly, opens the way to applying even more advanced approaches based on it (e.g., more advanced Riemannian optimization techniques for Step 1 or a more sophisticated treatment of Step 2).

To summarize, the main contributions of our paper are:

- We reformulated the problem of SGNS word embedding learning as a two-step procedure with clear objectives;
- For Step 1, we developed an algorithm based on Riemannian optimization framework that optimizes SGNS objective over low-rank matrix X directly;
- Our algorithm outperforms state-of-the-art competitors in terms of SGNS objective and the semantic similarity linguistic metric (Levy and Goldberg, 2014; Mikolov et al., 2013; Schnabel et al., 2015).

2 Problem Setting

2.1 Skip-Gram Negative Sampling

In this paper, we consider the Skip-Gram Negative Sampling (SGNS) word embedding model (Mikolov et al., 2013), which is a probabilistic discriminative model. Assume we have a text corpus given as a sequence of words $w_1, \dots, w_n$, where n may be larger than 10^{12} and $w_i \in V_W$ belongs to a vocabulary of words V_W. A *context* $c \in V_C$ of the word w_i is a word from set $\{w_{i-L}, ..., w_{i-1}, w_{i+1}, ..., w_{i+L}\}$ for some fixed window size L. Let $\mathbf{w}, \mathbf{c} \in \mathbb{R}^d$ be the *word embeddings* of word w and context c, respectively. Assume they are specified by the following mappings:

$$\mathcal{W} : V_W \to \mathbb{R}^d, \quad \mathcal{C} : V_C \to \mathbb{R}^d.$$

The ultimate goal of SGNS word embedding training is to fit good mappings $\mathcal{W}$ and $\mathcal{C}$.

Let D be a multiset of all word-context pairs observed in the corpus. In the SGNS model, the probability that word-context pair (w, c) is observed in the corpus is modeled as a following dsitribution:

$$P\left(\#(w,c) \neq 0 | w, c\right) = \\ = \sigma(\langle \mathbf{w}, \mathbf{c} \rangle) = \frac{1}{1 + \exp(-\langle \mathbf{w}, \mathbf{c} \rangle)}, \tag{1}$$

where $\#(w, c)$ is the number of times the pair (w, c) appears in D and $\langle \mathbf{x}, \mathbf{y} \rangle$ is the scalar product of vectors $\mathbf{x}$ and $\mathbf{y}$. Number d is a hyperparameter that adjusts the flexibility of the model. It usually takes values from tens to hundreds.

In order to collect a training set, we take all pairs (w, c) from D as positive examples and k randomly generated pairs (w, c) as negative ones. The number of times the word w and the context c appear in D can be computed as

$$\#(w) = \sum_{c \in V_c} \#(w, c),$$

$$\#(c) = \sum_{w \in V_w} \#(w, c)$$

accordingly. Then negative examples are generated from the distribution defined by $\#(c)$ counters:

$$P_D(c) = \frac{\#(c)}{|D|}.$$

In this way, we have a model maximizing the following logarithmic likelihood objective for all word-context pairs (w, c):

$$l_{wc} = \#(w,c)(\log \sigma(\langle \mathbf{w}, \mathbf{c} \rangle) + \\ + k \cdot \mathbb{E}_{c' \sim P_D} \log \sigma(-\langle \mathbf{w}, \mathbf{c}' \rangle)). \quad (2)$$

In order to maximize the objective over all observations for each pair (w, c), we arrive at the following SGNS optimization problem over all possible mappings $\mathcal{W}$ and $\mathcal{C}$:

$$l = \sum_{w \in V_W} \sum_{c \in V_C} (\#(w,c)(\log \sigma(\langle \mathbf{w}, \mathbf{c} \rangle) + \\ + k \cdot \mathbb{E}_{c' \sim P_D} \log \sigma(-\langle \mathbf{w}, \mathbf{c}' \rangle))) \to \max_{\mathcal{W}, \mathcal{C}}. \quad (3)$$

Usually, this optimization is done via the stochastic gradient descent procedure that is performed during passing through the corpus (Mikolov et al., 2013; Rong, 2014).

2.2 Optimization over Low-Rank Matrices

Relying on the prospect proposed in (Levy and Goldberg, 2014), let us show that the optimization problem given by (3) can be considered as a problem of searching for a matrix that maximizes a certain objective function and has the rank-d constraint (Step 1 in the scheme described in Section 1).

2.2.1 SGNS Loss Function

As shown in (Levy and Goldberg, 2014), the logarithmic likelihood (3) can be represented as the sum of $l_{w,c}(\mathbf{w}, \mathbf{c})$ over all pairs (w, c), where $l_{w,c}(\mathbf{w}, \mathbf{c})$ has the following form:

$$l_{w,c}(\mathbf{w}, \mathbf{c}) = \#(w,c) \log \sigma(\langle \mathbf{w}, \mathbf{c} \rangle) + \\ + k \frac{\#(w)\#(c)}{|D|} \log \sigma(-\langle \mathbf{w}, \mathbf{c} \rangle). \quad (4)$$

A crucial observation is that this loss function depends only on the scalar product $\langle \mathbf{w}, \mathbf{c} \rangle$ but not on embeddings $\mathbf{w}$ and $\mathbf{c}$ separately:

$$l_{w,c}(\mathbf{w}, \mathbf{c}) = f_{w,c}(x_{w,c}),$$

where

$$f_{w,c}(x_{w,c}) = a_{w,c} \log \sigma(x_{w,c}) + b_{w,c} \log \sigma(-x_{w,c}),$$

and $x_{w,c}$ is the scalar product $\langle \mathbf{w}, \mathbf{c} \rangle$, and

$$a_{w,c} = \#(w,c), \quad b_{w,c} = k \frac{\#(w)\#(c)}{|D|}$$

are constants.

2.2.2 Matrix Notation

Denote $|V_W|$ as n and $|V_C|$ as m. Let $W \in \mathbb{R}^{n \times d}$ and $C \in \mathbb{R}^{m \times d}$ be matrices, where each row $\mathbf{w} \in \mathbb{R}^d$ of matrix W is the word embedding of the corresponding word w and each row $\mathbf{c} \in \mathbb{R}^d$ of matrix C is the context embedding of the corresponding context c. Then the elements of the product of these matrices

$$X = WC^\top$$

are the scalar products $x_{w,c}$ of all pairs (w, c):

$$X = (x_{w,c}), \quad w \in V_W, c \in V_C.$$

Note that this matrix has rank d, because X equals to the product of two matrices with sizes $(n \times d)$ and $(d \times m)$. Now we can write SGNS objective given by (3) as a function of X:

$$F(X) = \sum_{w \in V_W} \sum_{c \in V_C} f_{w,c}(x_{w,c}), \quad F : \mathbb{R}^{n \times m} \to \mathbb{R}. \quad (5)$$

This arrives us at the following proposition:

Proposition 1 *SGNS optimization problem given by (3) can be rewritten in the following constrained form:*

$$\begin{aligned} &\underset{X \in \mathbb{R}^{n \times m}}{\textit{maximize}} && F(X), \\ &\textit{subject to} && X \in \mathcal{M}_d, \end{aligned} \quad (6)$$

where $\mathcal{M}_d$ is the manifold (Udriste, 1994) of all matrices in $\mathbb{R}^{n \times m}$ with rank d:

$$\mathcal{M}_d = \{X \in \mathbb{R}^{n \times m} : \textit{rank}(X) = d\}.$$

The key idea of this paper is to solve the optimization problem given by (6) via the framework of Riemannian optimization, which we introduce in Section 3.

Important to note that this prospect does not suppose the optimization over parameters W and C directly. This entails the optimization in the space with $((n + m - d) \cdot d)$ degrees of freedom (Mukherjee et al., 2015) instead of $((n+m) \cdot d)$, what simplifies the optimization process (see Section 5 for the experimental results).

2.3 Computing Embeddings from a Low-Rank Solution

Once X is found, we need to recover W and C such that $X = WC^\top$ (Step 2 in the scheme described in Section 1). This problem does not

have a unique solution, since if (W, C) satisfy this equation, then WS^{-1} and $CS^{\top}$ satisfy it as well for any non-singular matrix S. Moreover, different solutions may achieve different values of the linguistic metrics (see Section 4.2 for details). While our paper focuses on Step 1, we use, for Step 2, a heuristic approach that was proposed in (Levy et al., 2015) and it shows good results in practice. We compute SVD of X in the form

$$X = U\Sigma V^{\top},$$

where U and V have orthonormal columns, and Σ is the diagonal matrix, and use

$$W = U\sqrt{\Sigma}, \quad C = V\sqrt{\Sigma}$$

as matrices of embeddings.

A simple justification of this solution is the following: we need to map words into vectors in a way that similar words would have similar embeddings in terms of cosine similarities:

$$\cos(\mathbf{w}_1, \mathbf{w}_2) = \frac{\langle \mathbf{w}_1, \mathbf{w}_2 \rangle}{\|\mathbf{w}_1\| \cdot \|\mathbf{w}_2\|}.$$

It is reasonable to assume that two words are similar, if they share contexts. Therefore, we can estimate the similarity of two words w_1, w_2 as

$$s(w_1, w_2) = \sum_{c \in V_C} x_{w_1,c} \cdot x_{w_2,c},$$

what is the element of the matrix $XX^{\top}$ with indices (w_1, w_2). Note that

$$XX^{\top} = U\Sigma V^{\top} V \Sigma U^{\top} = U\Sigma^2 U^{\top}.$$

If we choose $W = U\Sigma$, we exactly obtain $\langle \mathbf{w_1}, \mathbf{w_2} \rangle = s(w_1, w_2)$, since $WW^{\top} = XX^{\top}$ in this case. That is, the cosine similarity of the embeddings $\mathbf{w_1}, \mathbf{w_2}$ coincides with the intuitive similarity $s(w_1, w_2)$. However, scaling by $\sqrt{\Sigma}$ instead of Σ was shown in (Levy et al., 2015) to be a better solution in experiments.

3 Proposed Method

3.1 Riemannian Optimization

3.1.1 General Scheme

The main idea of Riemannian optimization (Udriste, 1994) is to consider (6) as a constrained optimization problem. Assume we have an approximated solution X_i on a current step of the optimization process, where i is the step number. In order to improve X_i, the next step of the standard gradient ascent outputs the point

$$X_i + \nabla F(X_i),$$

where $\nabla F(X_i)$ is the gradient of objective F at the point X_i. Note that the gradient $\nabla F(X_i)$ can be naturally considered as a matrix in $\mathbb{R}^{n \times m}$. Point $X_i + \nabla F(X_i)$ leaves the manifold $\mathcal{M}_d$, because its rank is generally greater than d. That is why Riemannian optimization methods map point $X_i + \nabla F(X_i)$ back to manifold $\mathcal{M}_d$. The standard Riemannian gradient method first projects the gradient step onto the tangent space at the current point X_i and then *retracts* it back to the manifold:

$$X_{i+1} = R\left(P_{\mathcal{T}_M}(X_i + \nabla F(X_i))\right),$$

where R is the *retraction* operator, and $P_{\mathcal{T}_M}$ is the projection onto the tangent space.

Although the optimization problem is non-convex, Riemannian optimization methods show good performance on it. Theoretical properties and convergence guarantees of such methods are discussed in (Wei et al., 2016) more thoroughly.

3.1.2 Projector-Splitting Algorithm

In our paper, we use a simplified version of such approach that retracts point $X_i + \nabla F(X_i)$ directly to the manifold and does not require projection onto the tangent space $P_{\mathcal{T}_M}$ as illustrated in Figure 1:

$$X_{i+1} = R(X_i + \nabla F(X_i)).$$

Intuitively, retractor R finds a rank-d matrix on the manifold $\mathcal{M}_d$ that is similar to high-rank matrix $X_i + \nabla F(X_i)$ in terms of Frobenius norm. How can we do it? The most straightforward way to reduce the rank of $X_i + \nabla F(X_i)$ is to perform the SVD, which keeps d largest singular values of it:

$$\begin{aligned} &1\text{: } U_{i+1}, S_{i+1}, V_{i+1}^{\top} \leftarrow \text{SVD}(X_i + \nabla F(X_i)), \\ &2\text{: } X_{i+1} \leftarrow U_{i+1} S_{i+1} V_{i+1}^{\top}. \end{aligned} \tag{7}$$

However, it is computationally expensive. Instead of this approach, we use the projector-splitting method (Lubich and Oseledets, 2014), which is a second-order retraction onto the manifold (for details, see the review (Absil and Oseledets, 2015)). Its practical implementation is

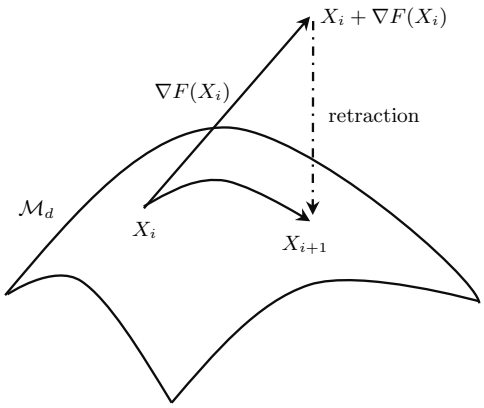

Figure 1: Geometric interpretation of one step of projector-splitting optimization procedure: the gradient step an the retraction of the high-rank matrix $X_i + \nabla F(X_i)$ to the manifold of low-rank matrices $\mathcal{M}_d$.

also quite intuitive: instead of computing the full SVD of $X_i + \nabla F(X_i)$ according to the gradient projection method, we use just one step of the block power numerical method (Bentbib and Kanber, 2015) which computes the SVD, what reduces the computational complexity.

Let us keep the current point in the following factorized form:

$$X_i = U_i S_i V_i^\top, \tag{8}$$

where matrices $U_i \in \mathbb{R}^{n \times d}$ and $V_i \in \mathbb{R}^{m \times d}$ have d orthonormal columns and $S_i \in \mathbb{R}^{d \times d}$. Then we need to perform two QR-decompositions to retract point $X_i + \nabla F(X_i)$ back to the manifold:

$$1: U_{i+1}, S_{i+1} \leftarrow \text{QR}\left((X_i + \nabla F(X_i))V_i\right),$$

$$2: V_{i+1}, S_{i+1}^\top \leftarrow \text{QR}\left((X_i + \nabla F(X_i))^\top U_{i+1}\right),$$

$$3: X_{i+1} \leftarrow U_{i+1} S_{i+1} V_{i+1}^\top.$$

In this way, we always keep the solution $X_{i+1} = U_{i+1} S_{i+1} V_{i+1}^\top$ on the manifold $\mathcal{M}_d$ and in the form (8).

What is important, we only need to compute $\nabla F(X_i)$, so the gradients with respect to U, S and V are never computed explicitly, thus avoiding the subtle case where S is close to singular (so-called singular (critical) point on the manifold). Indeed, the gradient with respect to U (while keeping the orthogonality constraints) can be written (Koch and Lubich, 2007) as:

$$\frac{\partial F}{\partial U} = \frac{\partial F}{\partial X} V S^{-1},$$

which means that the gradient will be large if S is close to singular. The projector-splitting scheme is free from this problem.

3.2 Algorithm

In case of SGNS objective given by (5), an element of gradient ∇F has the form:

$$(\nabla F(X))_{w,c} = \frac{\partial f_{w,c}(x_{w,c})}{\partial x_{w,c}} =$$

$$= \#(w,c) \cdot \sigma\left(-x_{w,c}\right) - k \frac{\#(w)\#(c)}{|D|} \cdot \sigma\left(x_{w,c}\right).$$

To make the method more flexible in terms of convergence properties, we additionally use $\lambda \in \mathbb{R}$, which is a step size parameter. In this case, retractor R returns $X_i + \lambda \nabla F(X_i)$ instead of $X_i + \nabla F(X_i)$ onto the manifold.

The whole optimization procedure is summarized in Algorithm 1.

4 Experimental Setup

4.1 Training Models

We compare our method ("RO-SGNS" in the tables) performance to two baselines: SGNS embeddings optimized via Stochastic Gradient Descent, implemented in the original "word2vec", ("SGD-SGNS" in the tables) (Mikolov et al., 2013) and embeddings obtained by SVD over SPPMI matrix ("SVD-SPPMI" in the tables) (Levy and Goldberg, 2014). We have also experimented with the blockwise alternating optimization over factors W and C, but the results are almost the same to SGD results, that is why we do not to include them into the paper. The source code of our experiments is available online[1].

The models were trained on English Wikipedia "enwik9" corpus[2], which was previously used in most papers on this topic. Like in previous studies, we counted only the words which occur more than 200 times in the training corpus (Levy and Goldberg, 2014; Mikolov et al., 2013). As a result, we obtained a vocabulary of 24292 unique tokens (set of words V_W and set of contexts V_C are equal). The size of the context window was set to 5 for all experiments, as it was done in (Levy and Goldberg, 2014; Mikolov et al., 2013). We conduct three series of experiments: for dimensionality $d = 100$, $d = 200$, and $d = 500$.

[1] https://github.com/AlexGrinch/ro_sgns
[2] http://mattmahoney.net/dc/textdata

Algorithm 1 Riemannian Optimization for SGNS

Require: Dimentionality d, initialization W_0 and C_0, step size λ, gradient function $\nabla F : \mathbb{R}^{n \times m} \to \mathbb{R}^{n \times m}$, number of iterations K

Ensure: Factor $W \in \mathbb{R}^{n \times d}$

$X_0 \leftarrow W_0 C_0^\top$ # get an initial point at the manifold

$U_0, S_0, V_0^\top \leftarrow \text{SVD}(X_0)$ # compute the first point satisfying the low-rank constraint

for $i \leftarrow 1, \dots, K$ **do**

  $U_i, S_i \leftarrow \text{QR}\left((X_{i-1} + \lambda \nabla F(X_{i-1}))V_{i-1}\right)$ # perform one step of the block power method

  $V_i, S_i^\top \leftarrow \text{QR}\left((X_{i-1} + \lambda \nabla F(X_{i-1}))^\top U_i\right)$

  $X_i \leftarrow U_i S_i V_i^\top$ # update the point at the manifold

end for

$U, \Sigma, V^\top \leftarrow \text{SVD}(X_K)$

$W \leftarrow U\sqrt{\Sigma}$ # compute word embeddings

return W

Optimization step size is chosen to be small enough to avoid huge gradient values. However, thorough choice of λ does not result in a significant difference in performance (this parameter was tuned on the training data only, the exact values used in experiments are reported below).

4.2 Evaluation

We evaluate word embeddings via the word similarity task. We use the following popular datasets for this purpose: "wordsim-353" ((Finkelstein et al., 2001); 3 datasets), "simlex-999" (Hill et al., 2016) and "men" (Bruni et al., 2014). Original "wordsim-353" dataset is a mixture of the word pairs for both word similarity and word relatedness tasks. This dataset was split (Agirre et al., 2009) into two intersecting parts: "wordsim-sim" ("ws-sim" in the tables) and "wordsim-rel" ("ws-rel" in the tables) to separate the words from different tasks. In our experiments, we use both of them on a par with the full version of "wordsim-353" ("ws-full" in the tables). Each dataset contains word pairs together with assessor-assigned similarity scores for each pair. As a quality measure, we use Spearman's correlation between these human ratings and cosine similarities for each pair. We call this quality metric *linguistic* in our paper.

5 Results of Experiments

First of all, we compare the value of SGNS objective obtained by the methods. The comparison is demonstrated in Table 1.

We see that SGD-SGNS and SVD-SPPMI methods provide quite similar results, however, the proposed method obtains significantly better SGNS values, what proves the feasibility of using Riemannian optimization framework in SGNS optimization problem. It is interesting to note that SVD-SPPMI method, which does not optimize SGNS objective directly, obtains better results than SGD-SGNS method, which aims at optimizing SGNS. This fact additionally confirms the idea described in Section 2.2.2 that the independent optimization over parameters W and C may decrease the performance.

	$d = 100$	$d = 200$	$d = 500$
SGD-SGNS	-1.68	-1.67	-1.63
SVD-SPPMI	-1.65	-1.65	-1.62
RO-SGNS	$\mathbf{-1.44}$	$\mathbf{-1.43}$	$\mathbf{-1.41}$

Table 1: Comparison of SGNS values (multiplied by 10^{-9}) obtained by the models. Larger is better.

However, the target performance measure of embedding models is the correlation between semantic similarity and human assessment (Section 4.2). Table 2 presents the comparison of the methods in terms of it. We see that our method outperforms the competitors on all datasets except for "men" dataset where it obtains slightly worse results. Moreover, it is important that the higher dimension entails higher performance gain of our method in comparison to the competitors.

To understand how our model improves or degrades the performance in comparison to the baseline, we found several words, whose neighbors in terms of cosine distance change significantly. Table 3 demonstrates neighbors of the words "five", "he" and "main" for both SVD-SPPMI and RO-SGNS models. A neighbor is marked bold if we suppose that it has similar semantic meaning to the

Dim. d	Algorithm	ws-sim	ws-rel	ws-full	simlex	men

Table 4: Examples of the semantic neighbors from 11th to 20th obtained for the word "usa" by all three methods. Top-10 neighbors for all three methods are exact names of states.

source word. First of all, we notice that our model produces much better neighbors of the words describing digits or numbers (see word "five" as an example). Similar situation happens for many other words, e.g. in case of "main" — the nearest neighbors contain 4 similar words for our model instead of 2 in case of SVD-SPPMI. The neighbourhood of "he" contains less semantically similar words in case of our model. However, it filters out irrelevant words, such as "promptly" and "dumbledore".

Table 4 contains the nearest words to the word "usa" from 11th to 20th. We marked names of USA states bold and did not represent top-10 nearest words as they are exactly names of states for all three models. Some non-bold words are arguably relevant as they present large USA cities ("akron", "burbank", "madison") or geographical regions of several states ("midwest", "northeast", "southwest"), but there are also some completely irrelevant words ("uk", "cities", "places") presented by first two models.

Our experiments show that the optimal number of iterations K in the optimization procedure and step size λ depend on the particular value of d. For $d = 100$, we have $K = 7, \lambda = 5 \cdot 10^{-5}$, for $d = 200$, we have $K = 8, \lambda = 5 \cdot 10^{-5}$, and for $d = 500$, we have $K = 2, \lambda = 10^{-4}$. Moreover, the best results were obtained when SVD-SPPMI embeddings were used as an initialization of Riemannian optimization process.

Figure 2 illustrates how the correlation between semantic similarity and human assessment scores changes through iterations of our method. Optimal value of K is the same for both whole testing set and its 10-fold subsets chosen for cross-validation. The idea to stop optimization procedure on some iteration is also discussed in (Lai et al., 2015).

Training of the same dimensional models ($d = 500$) on English Wikipedia corpus using SGD-SGNS, SVD-SPPMI, RO-SGNS took 20 minutes, 10 minutes and 70 minutes respectively. Our method works slower, but not significantly. Moreover, since we were not focused on the code efficiency optimization, this time can be reduced.

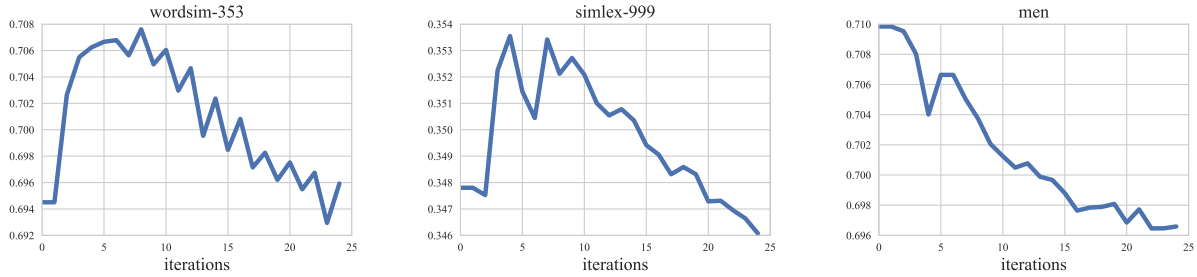

Figure 2: Illustration of why it is important to choose the optimal iteration and stop optimization procedure after it. The graphs show semantic similarity metric in dependence on the iteration of optimization procedure. The embeddings obtained by SVD-SPPMI method were used as initialization. Parameters: $d = 200$, $\lambda = 5 \cdot 10^{-5}$.

6 Related Work

6.1 Word Embeddings

Skip-Gram Negative Sampling was introduced in (Mikolov et al., 2013). The "negative sampling" approach is thoroughly described in (Goldberg and Levy, 2014), and the learning method is explained in (Rong, 2014). There are several open-source implementations of SGNS neural network, which is widely known as "word2vec". [1][2]

As shown in Section 2.2, Skip-Gram Negative Sampling optimization can be reformulated as a problem of searching for a low-rank matrix. In order to be able to use out-of-the-box SVD for this task, the authors of (Levy and Goldberg, 2014) used the surrogate version of SGNS as the objective function. There are two general assumptions made in their algorithm that distinguish it from the SGNS optimization:

1. SVD optimizes Mean Squared Error (MSE) objective instead of SGNS loss function.

2. In order to avoid infinite elements in SPMI matrix, it is transformed in ad-hoc manner (SPPMI matrix) before applying SVD.

This makes the objective not interpretable in terms of the original task (3). As mentioned in (Levy and Goldberg, 2014), SGNS objective weighs different (w, c) pairs differently, unlike the SVD, which works with the same weight for all pairs and may entail the performance fall. The comprehensive explanation of the relation between SGNS and SVD-SPPMI methods is provided in (Keerthi et al., 2015). (Lai et al., 2015; Levy et al., 2015) give a good overview of highly practical methods to improve these word embedding models.

6.2 Riemannian Optimization

An introduction to optimization over Riemannian manifolds can be found in (Udriste, 1994). The overview of retractions of high rank matrices to low-rank manifolds is provided in (Absil and Oseledets, 2015). The projector-splitting algorithm was introduced in (Lubich and Oseledets, 2014), and also was mentioned in (Absil and Oseledets, 2015) as "Lie-Trotter retraction".

Riemannian optimization is succesfully applied to various data science problems: for example, matrix completion (Vandereycken, 2013), large-scale recommender systems (Tan et al., 2014), and tensor completion (Kressner et al., 2014).

7 Conclusions

In our paper, we proposed the general two-step scheme of training SGNS word embedding model and introduced the algorithm that performs the search of a solution in the low-rank form via Riemannian optimization framework. We also demonstrated the superiority of our method by providing experimental comparison to existing state-of-the-art approaches.

Possible direction of future work is to apply more advanced optimization techniques to the Step 1 of the scheme proposed in Section 1 and to explore the Step 2 — obtaining embeddings with a given low-rank matrix.

Abstract

We present a deep neural architecture that parses sentences into three semantic dependency graph formalisms. By using efficient, nearly arc-factored inference and a bidirectional-LSTM composed with a multi-layer perceptron, our base system is able to significantly improve the state of the art for semantic dependency parsing, without using hand-engineered features or syntax. We then explore two multitask learning approaches—one that shares parameters across formalisms, and one that uses higher-order structures to predict the graphs jointly. We find that both approaches improve performance across formalisms on average, achieving a new state of the art. Our code is open-source and available at https://github.com/Noahs-ARK/NeurboParser.

1 Introduction

Labeled directed graphs are a natural and flexible representation for semantics (Copestake et al., 2005; Baker et al., 2007; Surdeanu et al., 2008; Banarescu et al., 2013, *inter alia*). Their generality over trees, for instance, allows them to represent relational semantics while handling phenomena like coreference and coordination. Even syntactic formalisms are moving toward graphs (de Marneffe et al., 2014). However, full semantic graphs can be expensive to annotate, and efforts are fragmented across competing semantic theories, leading to a limited number of annotations in any one formalism. This makes learning to parse more difficult, especially for powerful but data-hungry machine learning techniques like neural networks.

In this work, we hypothesize that the overlap among theories and their corresponding representations can be exploited using multitask learning (Caruana, 1997), allowing us to learn from more data. We use the 2015 SemEval shared task on Broad-Coverage Semantic Dependency Parsing (**SDP**; Oepen et al., 2015) as our testbed. The shared task provides an English-language corpus with parallel annotations for three semantic graph representations, described in §2. Though the shared task was designed in part to encourage comparison between the formalisms, we are the first to treat SDP as a multitask learning problem.

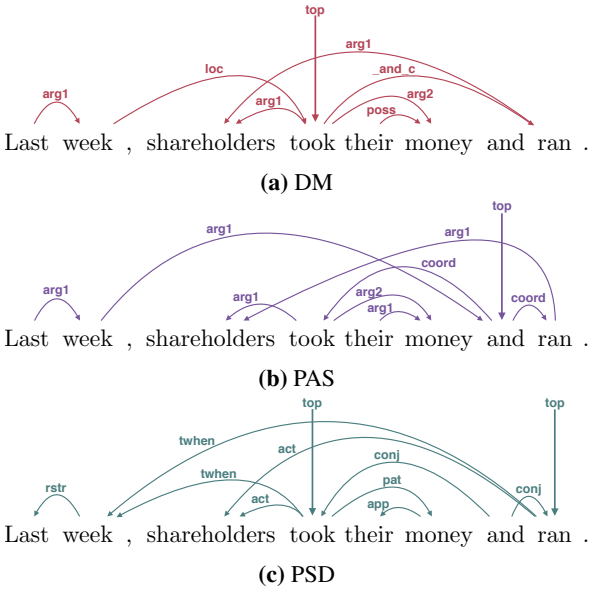

Figure 1: An example sentence annotated with the three semantic formalisms of the broad-coverage semantic dependency parsing shared tasks.

As a strong baseline, we introduce a new system that parses each formalism separately (§3). It uses a bidirectional-LSTM composed with a multi-layer perceptron to score arcs and predicates, and has efficient, nearly arc-factored inference. Experiments show it significantly improves on state-of-the-art methods (§3.4).

We then present two multitask extensions (§4.2

and §4.3), with a parameterization and factorization that implicitly models the relationship between multiple formalisms. Experiments show that both techniques improve over our basic model, with an additional (but smaller) improvement when they are combined (§4.5). Our analysis shows that the improvement in unlabeled F_1 is greater for the two formalisms that are more structurally similar, and suggests directions for future work. Finally, we survey related work (§5), and summarize our contributions and findings (§6).

2 Broad-Coverage Semantic Dependency Parsing (SDP)

First defined in a SemEval 2014 shared task (Oepen et al., 2014), and then extended by Oepen et al. (2015), the broad-coverage semantic depency parsing (**SDP**) task is centered around three semantic formalisms whose annotations have been converted into bilexical dependencies. See Figure 1 for an example. The formalisms come from varied linguistic traditions, but all three aim to capture predicate-argument relations between content-bearing words in a sentence.

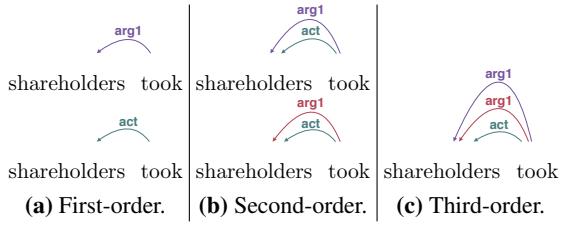
While at first glance similar to syntactic dependencies, semantic dependencies have distinct goals and characteristics, more akin to semantic role labeling (SRL; Gildea and Jurafsky, 2002) or the abstract meaning representation (AMR; Banarescu et al., 2013). They abstract over different syntactic realizations of the same or similar meaning (e.g., *"She gave me the ball."* vs. *"She gave the ball to me."*). Conversely, they attempt to distinguish between different senses even when realized in similar syntactic forms (e.g., *"I baked in the kitchen."* vs. *"I baked in the sun."*).

Structurally, they are labeled directed graphs whose vertices are tokens in the sentence. This is in contrast to AMR whose vertices are abstract concepts, with no explicit alignment to tokens, which makes parsing more difficult (Flanigan et al., 2014). Their arc labels encode broadly-applicable semantic relations rather than being tailored to any specific downstream application or ontology.[1] They are not necessarily trees, because a token may be an argument of more than one predicate (e.g., in *"John wants to eat,"* John is both the wanter and the would-be eater). Their analyses may optionally leave out non–content-bearing tokens, such as punctuation or the infinitival *"to,"* or prepositions that simply mark the type of relation holding between other words. But when restricted to content-bearing tokens (including adjectives, adverbs, etc.), the subgraph is connected. In this sense, SDP provides a *whole-sentence* analysis. This is in contrast to PropBank-style SRL, which gives an analysis of only verbal and nominal predicates (Palmer et al., 2005). Semantic dependency graphs also tend to have higher levels of nonprojectivity than syntactic trees (Oepen et al., 2014). Sentences with graphs containing cycles have been removed from the dataset by the organizers, so all remaining graphs are directed acyclic graphs. Table 1 summarizes some of the dataset's high-level statistics.

Formalisms. Following the SemEval shared tasks, we consider three formalisms. The **DM** (DELPH-IN MRS) representation comes from DeepBank (Flickinger et al., 2012), which are manually-corrected parses from the LinGO English Resource Grammar (Copestake and Flickinger, 2000). LinGO is a head-driven phrase structure grammar (HPSG; Pollard and Sag, 1994) with minimal recursion semantics (Copestake et al., 2005). The **PAS** (Predicate-Argument Structures) representation is extracted from the Enju Treebank, which consists of automatic parses from the Enju HPSG parser (Miyao, 2006). PAS annotations are also available for the Penn Chinese Treebank (Xue et al., 2005). The **PSD** (Prague Semantic Dependencies) representation is extracted from the tectogrammatical layer of the Prague Czech-English Dependency Treebank (Hajič et al., 2012). PSD annotations are also available for a Czech translation of the WSJ Corpus. In this work, we train and evaluate only on English annotations.

Of the three, PAS follows syntax most closely, and prior work has found it the easiest to predict. PSD has the largest set of labels, and parsers

[1] This may make another disambiguation step necessary to use these representations in a downstream task, but there is evidence that modeling semantic composition separately from grounding in any ontology is an effective way to achieve broad coverage (Kwiatkowski et al., 2013).



(a) First-order. **(b)** Second-order. **(c)** Third-order.

Figure 2: Examples of local structures. We refer to the number of arcs that a structure contains as its **order**.

have significantly lower performance on it (Oepen et al., 2015).

3 Single-Task SDP

Here we introduce our basic model, in which training and prediction for each formalism is kept completely separate. We also lay out basic notation, which will be reused for our multitask extensions.

3.1 Problem Formulation

The output of semantic dependency parsing is a labeled directed graph (see Figure 1). Each arc has a label from a predefined set $\mathcal{L}$, indicating the semantic relation of the child to the head. Given input sentence x, let $\mathcal{Y}(x)$ be the set of possible semantic graphs over x. The graph we seek maximizes a score function S:

$$\hat{y} = \arg\max_{y \in \mathcal{Y}(x)} S(x, y), \tag{1}$$

We decompose S into a sum of local scores s for **local structures** (or "parts") p in the graph:

$$S(x, y) = \sum_{p \in y} s(p). \tag{2}$$

For notational simplicity, we omit the dependence of s on x. See Figure 2a for examples of local structures. s is a parameterized function, whose parameters (denoted Θ and suppressed here for clarity) will be learned from the training data (§3.3). Since we search over every possible labeled graph (i.e., considering each labeled arc for each pair of words), our approach can be considered a **graph-based** (or **all-pairs**) method. The models presented in this work all share this common graph-based approach, differing only in the set of structures they score and in the parameterization of the scoring function s. This approach also underlies state-of-the-art approaches to SDP (Martins and Almeida, 2014).

3.2 Basic Model

Our basic model is inspired by recent successes in neural arc-factored graph-based dependency parsing (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017; Kuncoro et al., 2016). It borrows heavily from the neural arc-scoring architectures in those works, but decodes with a different algorithm under slightly different constraints.

3.2.1 Basic Structures

Our basic model factors over three types of structures (p in Equation 2):

- predicate, indicating a predicate word, denoted $i{\rightarrow}\cdot$;
- unlabeled arc, representing the existence of an arc from a predicate to an argument, denoted $i{\rightarrow}j$;
- labeled arc, an arc labeled with a semantic role, denoted $i \xrightarrow{\ell} j$.

Here i and j are word indices in a given sentence, and ℓ indicates the arc label. This list corresponds to the most basic structures used by Martins and Almeida (2014). Selecting an output y corresponds precisely to selecting which instantiations of these structures are included.

To ensure the internal consistency of predictions, the following constraints are enforced during decoding:

- $i{\rightarrow}\cdot$ if and only if there exists at least one j such that $i{\rightarrow}j$;
- If $i{\rightarrow}j$, then there must be exactly one label ℓ such that $i \xrightarrow{\ell} j$. Conversely, if not $i{\rightarrow}j$, then there must not exist any $i \xrightarrow{\ell} j$;

We also enforce a **determinism** constraint (Flanigan et al., 2014): certain labels must not appear on more than one arc emanating from the same token. The set of deterministic labels is decided based on their appearance in the training set. Notably, we do not enforce that the predicted graph is connected or spanning. If not for the predicate and determinism constraints, our model would be **arc-factored**, and decoding could be done for each i, j pair independently. Our structures do overlap though, and we employ AD^3 (Martins et al., 2011) to find the highest-scoring internally consistent semantic graph. AD^3 is an approximate discrete optimization algorithm based on dual decomposition. It can be used to decode factor graphs over discrete variables when scored structures overlap, as is the case here.

3.2.2 Basic Scoring

Similarly to Kiperwasser and Goldberg (2016), our model learns representations of tokens in a sentence using a bi-directional LSTM (BiLSTM). Each different type of structure (predicate, unlabeled arc, labeled arc) then shares these same BiLSTM representations, feeding them into a multilayer perceptron (MLP) which is specific to the structure type. We present the architecture slightly differently from prior work, to make the transition to the multitask scenario (§4) smoother. In our presentation, we separate the model into a function ϕ that represents the input (corresponding to the BiLSTM and the initial layers of the MLPs), and a function ψ that represents the output (corresponding to the final layers of the MLPs), with the scores given by their inner product.[2]

Distributed input representations. Long short-term memory networks (LSTMs) are a variant of recurrent neural networks (RNNs) designed to alleviate the vanishing gradient problem in RNNs (Hochreiter and Schmidhuber, 1997). A bi-directional LSTM (BiLSTM) runs over the sequence in both directions (Schuster and Paliwal, 1997; Graves, 2012).

Given an input sentence x and its corresponding part-of-speech tag sequence, each token is mapped to a concatenation of its word embedding vector and POS tag vector. Two LSTMs are then run in opposite directions over the input vector sequence, outputting the concatenation of the two hidden vectors at each position i: $\mathbf{h}_i = \left[\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i\right]$ (we omit $\mathbf{h}_i$'s dependence on x and its own parameters). $\mathbf{h}_i$ can be thought of as an encoder that contextualizes each token conditioning on all of its context, without any Markov assumption. $\mathbf{h}$'s parameters are learned jointly with the rest of the model (§3.3); we refer the readers to Cho (2015) for technical details.

The input representation ϕ of a predicate structure depends on the representation of one word:

$$\phi(i{\rightarrow}\cdot) = \tanh\left(\mathbf{C}_{\text{pred}}\mathbf{h}_i + \mathbf{b}_{\text{pred}}\right). \quad (3a)$$

[2]For clarity, we present single-layer BiLSTMs and MLPs, while in practice we use two layers for both.

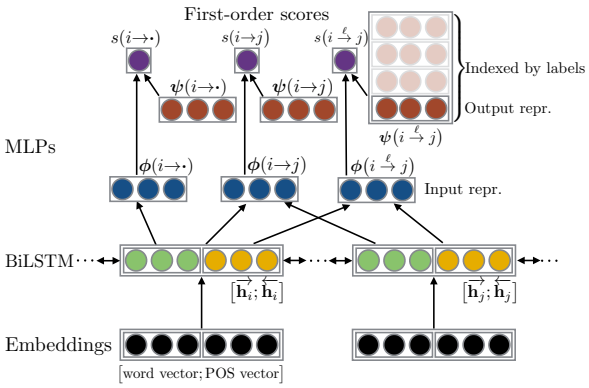


Figure 3: Illustration of the architecture of the basic model. i and j denote the indices of tokens in the given sentence. The figure depicts single-layer BiLSTM and MLPs, while in practice we use two layers for both.

For unlabeled arc and labeled arc structures, it depends on both the head and the modifier (but not the label, which is captured in the distributed output representation):

$$\phi(i{\rightarrow}j) = \tanh\left(\mathbf{C}_{\text{UA}}\left[\mathbf{h}_i; \mathbf{h}_j\right] + \mathbf{b}_{\text{UA}}\right), \quad (3b)$$

$$\phi(i \overset{\ell}{\rightarrow} j) = \tanh\left(\mathbf{C}_{\text{LA}}\left[\mathbf{h}_i; \mathbf{h}_j\right] + \mathbf{b}_{\text{LA}}\right). \quad (3c)$$

Distributed output representations. NLP researchers have found that embedding discrete output labels into a low dimensional real space is an effective way to capture commonalities among them (Srikumar and Manning, 2014; Hermann et al., 2014; FitzGerald et al., 2015, *inter alia*). In neural language models (Bengio et al., 2003; Mnih and Hinton, 2007, *inter alia*) the weights of the output layer could also be regarded as an output embedding.

We associate each first-order structure p with a d-dimensional real vector $\psi(p)$ which does not depend on particular words in p. Predicates and unlabeled arcs are each mapped to a single vector:

$$\psi(i{\rightarrow}\cdot) = \psi_{\text{pred}}, \quad (4a)$$

$$\psi(i{\rightarrow}j) = \psi_{\text{UA}}, \quad (4b)$$

and each label gets a vector:

$$\psi(i \overset{\ell}{\rightarrow} j) = \psi_{\text{LA}}(\ell). \quad (4c)$$

Scoring. Finally, we use an inner product to score first-order structures:

$$s(p) = \phi(p) \cdot \psi(p). \quad (5)$$

Figure 3 illustrates our basic model's architecture.

3.3 Learning

The parameters of the model are learned using a max-margin objective. Informally, the goal is to learn parameters for the score function so that the gold parse is scored over every incorrect parse with a margin proportional to the cost of the incorrect parse. More formally, let $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$ be the training set consisting of N pairs of sentence x_i and its gold parse y_i. Training is then the following ℓ_2-regularized empirical risk minimization problem:

$$\min_{\Theta} \frac{\lambda}{2}\|\Theta\|^2 + \frac{1}{N}\sum_{i=1}^{N} L(x_i, y_i; \Theta), \qquad (6)$$

where Θ is all parameters in the model, and L is the structured hinge loss:

$$L(x_i, y_i; \Theta) = \max_{y \in \mathcal{Y}(x_i)} \{S(x_i, y) + c(y, y_i)\} - S(x_i, y_i). \qquad (7)$$

c is a weighted Hamming distance that trades off between precision and recall (Taskar et al., 2004). Following Martins and Almeida (2014), we encourage recall over precision by using the costs 0.6 for false negative arc predictions and 0.4 for false positives.

3.4 Experiments

We evaluate our basic model on the English dataset from SemEval 2015 Task 18 closed track.[3] We split as in previous work (Almeida and Martins, 2015; Du et al., 2015), resulting in 33,964 training sentences from §00–19 of the WSJ corpus, 1,692 development sentences from §20, 1,410 sentences from §21 as in-domain test data, and 1,849 sentences sampled from the Brown Corpus as out-of-domain test data.

The *closed* track differs from the *open* and *gold* tracks in that it does not allow access to any syntactic analyses. In the open track, additional machine generated syntactic parses are provided, while the gold-track gives access to various gold-standard syntactic analyses. Our model is evaluated with closed track data; it does not have access to any syntactic analyses during training or test.

We refer the readers to §4.4 for implementation details, including training procedures, hyper-parameters, pruning techniques, etc..

	BASIC	**89.4**	**92.2**	**77.6**	**87.4**
ood	Du et al., 2015	81.8	87.2	73.3	81.7
	A&M, 2015	81.8	86.9	74.8	82.0
	BASIC	**84.5**	**88.3**	**75.3**	**83.6**

Table 2: Labeled parsing performance (F_1 score) on both in-domain (id) and out-of-domain (ood) test data. The last column shows the micro-average over the three tasks. Bold font indicates best performance without syntax. Underlines indicate statistical significance with Bonferroni (1936) correction compared to the best baseline system.[4]

Empirical results. As our model uses no explicit syntactic information, the most comparable models to ours are two state-of-the-art closed track systems due to Du et al. (2015) and Almeida and Martins (2015). Du et al. (2015) rely on graph-tree transformation techniques proposed by Du et al. (2014), and apply a voting ensemble to well-studied tree-oriented parsers. Closely related to ours is Almeida and Martins (2015), who used rich, hand-engineered second-order features and AD^3 for inference.

Table 2 compares our basic model to both baseline systems (labeled F_1 score) on SemEval 2015 Task 18 test data. Scores of those systems are repeated from the official evaluation results. Our basic model significantly outperforms the best published results with a 1.1% absolute improvement on the in-domain test set and 1.6% on the out-of-domain test set.

4 Multitask SDP

We introduce two extensions to our single-task model, both of which use training data for all three formalisms to improve performance on each formalism's parsing task. We describe a first-order model, where representation functions are enhanced by parameter sharing while inference is kept separate for each task (§4.2). We then introduce a model with cross-task higher-order structures that uses joint inference *across* different tasks (§4.3). Both multitask models use AD^3 for decoding, and are trained with the same margin-based objective, as in our single-task model.

4.1 Problem Formulation

We will use an additional superscript $t \in \mathcal{T}$ to distinguish the three tasks (e.g., $y^{(t)}$, $\boldsymbol{\phi}^{(t)}$), where $\mathcal{T} = \{\text{DM}, \text{PAS}, \text{PSD}\}$. Our task is now to predict three graphs $\{y^{(t)}\}_{t\in\mathcal{T}}$ for a given input sentence x. Multitask SDP can also be understood as parsing x into a single unified *multigraph* $y = \bigcup_{t\in\mathcal{T}} y^{(t)}$. Similarly to Equations 1–2, we decompose y's score $S(x, y)$ into a sum of local scores for local structures in y, and we seek a multigraph $\hat{y}$ that maximizes $S(x, y)$.

4.2 Multitask SDP with Parameter Sharing

A common approach when using BiLSTMs for multitask learning is to share the BiLSTM part of the model across tasks, while training specialized classifiers for each task (Søgaard and Goldberg, 2016). In this spirit, we let each task keep its own specialized MLPs, and explore two variants of our model that share parameters at the BiLSTM level.

The first variant consists of a set of task-specific BiLSTM encoders as well as a common one that is shared across all tasks. We denote it FREDA. FREDA uses a neural generalization of "frustratingly easy" domain adaptation (Daumé III, 2007; Kim et al., 2016), where one augments domain-specific features with a shared set of features to capture global patterns. Formally, let $\{\mathbf{h}^{(t)}\}_{t\in\mathcal{T}}$ denote the three task-specific encoders. We introduce another encoder $\widetilde{\mathbf{h}}$ that is shared across all tasks. Then a new set of input functions $\{\boldsymbol{\phi}^{(t)}\}_{t\in\mathcal{T}}$ can be defined as in Equations 3a–3c, for example:

$$\boldsymbol{\phi}^{(t)}(i \overset{\ell}{\rightarrow} j) = \tanh\big(\mathbf{C}^{(t)}_{\text{LA}}\big[\mathbf{h}^{(t)}_i; \mathbf{h}^{(t)}_j; \widetilde{\mathbf{h}}_i; \widetilde{\mathbf{h}}_j\big] + \mathbf{b}^{(t)}_{\text{LA}}\big). \quad (8)$$

The predicate and unlabeled arc versions are analogous. The output representations $\{\boldsymbol{\psi}^{(t)}\}$ remain task-specific, and the score is still the inner product between the input representation and the output representation.

The second variant, which we call SHARED, uses *only* the shared encoder $\widetilde{\mathbf{h}}$, and doesn't use task-specific encoders $\{\mathbf{h}^{(t)}\}$. It can be understood as a special case of FREDA where the dimensions of the task-specific encoders are 0.

4.3 Multitask SDP with Cross-Task Structures

In syntactic parsing, higher-order structures have commonly been used to model interactions between multiple adjacent arcs in the same dependency tree (Carreras, 2007; Smith and Eisner, 2008; Martins et al., 2009; Zhang et al., 2014, *inter alia*). Lluís et al. (2013), in contrast, used second-order structures to jointly model syntactic dependencies and semantic roles. Similarly, we use higher-order structures *across* tasks instead of *within* tasks. In this work, we look at interactions between arcs that share the same head and modifier.[5] See Figures 2b and 2c for examples of higher-order cross-task structures.

Higher-order structure scoring. Borrowing from Lei et al. (2014), we introduce a low-rank tensor scoring strategy that, given a higher-order structure p, models interactions between the first-order structures (i.e., arcs) p is made up of. This approach builds on and extends the parameter sharing techniques in §4.2. It can either follow FREDA or SHARED to get the input representations for first-order structures.

We first introduce basic tensor notation. The **order** of a tensor is the number of its dimensions. The **outer product** of two vectors forms a second-order tensor (matrix) where $[\mathbf{u} \otimes \mathbf{v}]_{i,j} = u_i v_j$. We denote the **inner product** of two tensors of the same dimensions by $\langle \cdot, \cdot \rangle$, which first takes their element-wise product, then sums all the elements in the resulting tensor.

For example, let p be a labeled third-order structure, including one labeled arc from each of the three different tasks: $p = \{p^{(t)}\}_{t\in\mathcal{T}}$. Intuitively, $s(p)$ should capture every pairwise interaction between the three input and three output representations of p. Formally, we want the score function to include a parameter for each term in the outer product of the representation vectors: $s(p) =$

$$\left\langle \mathcal{W}, \bigotimes_{t\in\mathcal{T}} \left(\boldsymbol{\phi}^{(t)}\left(p^{(t)}\right) \otimes \boldsymbol{\psi}^{(t)}\left(p^{(t)}\right)\right)\right\rangle, \quad (9)$$

where $\mathcal{W}$ is a sixth-order tensor of parameters.[6]

With typical dimensions of representation vectors, this leads to an unreasonably large number of

[5] In the future we hope to model structures over larger motifs, both across and within tasks, to potentially capture when an arc in one formalism corresponds to a path in another formalism, for example.

[6] This is, of course, not the only way to model interactions between several representations. For instance, one could concatenate them and feed them into another MLP. Our preliminary experiments in this direction suggested that it may be less effective given a similar number of parameters, but we did not run full experiments.

parameters. Following Lei et al. (2014), we upper-bound the rank of $\mathcal{W}$ by r to limit the number of parameters (r is a hyperparameter, decided empirically). Using the fact that a tensor of rank at most r can be decomposed into a sum of r rank-1 tensors (Hitchcock, 1927), we reparameterize $\mathcal{W}$ to enforce the low-rank constraint by construction:

$$\mathcal{W} = \sum_{j=1}^{r} \bigotimes_{t \in \mathcal{T}} \left(\left[\mathbf{U}_{\text{LA}}^{(t)} \right]_{j,:} \otimes \left[\mathbf{V}_{\text{LA}}^{(t)} \right]_{j,:} \right), \quad (10)$$

where $\mathbf{U}_{\text{LA}}^{(t)}, \mathbf{V}_{\text{LA}}^{(t)} \in \mathbb{R}^{r \times d}$ are now our parameters. $[\cdot]_{j,:}$ denotes the jth row of a matrix. Substituting this back into Equation 9 and rearranging, the score function $s(p)$ can then be rewritten as:

$$\sum_{j=1}^{r} \prod_{t \in \mathcal{T}} \left[\mathbf{U}_{\text{LA}}^{(t)} \boldsymbol{\phi}^{(t)} \left(p^{(t)} \right) \right]_j \left[\mathbf{V}_{\text{LA}}^{(t)} \boldsymbol{\psi}^{(t)} \left(p^{(t)} \right) \right]_j . \quad (11)$$

We refer readers to Kolda and Bader (2009) for mathematical details.

For labeled higher-order structures our parameters consist of the set of six matrices, $\{\mathbf{U}_{\text{LA}}^{(t)}\} \cup \{\mathbf{V}_{\text{LA}}^{(t)}\}$. These parameters are shared between second-order and third-order labeled structures. Labeled *second-order* structures are scored as Equation 11, but with the product extending over only the two relevant tasks. Concretely, only four of the representation functions are used rather than all six, along with the four corresponding matrices from $\{\mathbf{U}_{\text{LA}}^{(t)}\} \cup \{\mathbf{V}_{\text{LA}}^{(t)}\}$. *Unlabeled* cross-task structures are scored analogously, reusing the same representations, but with a separate set of parameter matrices $\{\mathbf{U}_{\text{UA}}^{(t)}\} \cup \{\mathbf{V}_{\text{UA}}^{(t)}\}$.

Note that we are not doing tensor factorization; we are learning $\mathbf{U}_{\text{LA}}^{(t)}, \mathbf{V}_{\text{LA}}^{(t)}, \mathbf{U}_{\text{UA}}^{(t)}$, and $\mathbf{V}_{\text{UA}}^{(t)}$ directly, and $\mathcal{W}$ is never explicitly instantiated.

Inference and learning. Given a sentence, we use AD^3 to jointly decode all three formalisms.[7] The training objective used for learning is the sum of the losses for individual tasks.

4.4 Implementation Details

Each input token is mapped to a concatenation of three real vectors: a pre-trained word vector; a randomly-initialized word vector; and a randomly-initialized POS tag vector.[8] All three are updated during training. We use 100-dimensional `GloVe` (Pennington et al., 2014) vectors trained over Wikipedia and Gigaword as pre-trained word embeddings. To deal with out-of-vocabulary words, we apply word dropout (Iyyer et al., 2015) and randomly replace a word w with a special unk-symbol with probability $\frac{\alpha}{1+\#(w)}$, where $\#(w)$ is the count of w in the training set.

Hyperparameter	Value
Pre-trained word embedding dimension	100
Randomly-initialized word embedding dimension	25
POS tag embedding dimension	25
Dimensions of representations ϕ and ψ	100
MLP layers	2
BiLSTM layers	2
BiLSTM dimensions	200
Rank of tensor r	100
α for word dropout	0.25

Table 3: Hyperparameters used in the experiments.

Models are trained for up to 30 epochs with Adam (Kingma and Ba, 2015), with $\beta_1 = \beta_2 = 0.9$, and initial learning rate $\eta_0 = 10^{-3}$. The learning rate η is annealed at a rate of 0.5 every 10 epochs (Dozat and Manning, 2017). We apply early-stopping based on the labeled F_1 score on the development set.[9] We set the maximum number of iterations of AD^3 to 500 and round decisions when it doesn't converge. We clip the ℓ_2 norm of gradients to 1 (Graves, 2013; Sutskever et al., 2014), and we do not use mini-batches. Randomly initialized parameters are sampled from a uniform distribution over $\left[-\sqrt{6/(d_\text{r}+d_\text{c})}, \sqrt{6/(d_\text{r}+d_\text{c})}\right]$, where d_r and d_c are the number of the rows and columns in the matrix, respectively. An ℓ_2 penalty of $\lambda = 10^{-6}$ is applied to all weights. Other hyperparameters are summarized in Table 3.

We use the same pruner as Martins and Almeida (2014), where a first-order feature-rich unlabeled pruning model is trained for each task, and arcs with posterior probability below 10^{-4} are discarded. We further prune labeled structures that appear less than 30 times in the training set. In the development set, about 10% of the arcs remain after pruning, with a recall of around 99%.

[7] Joint inference comes at a cost; our third-order model is able to decode roughly 5.2 sentences (i.e., 15.5 task-specific graphs) per second on a single Xeon E5-2690 2.60GHz CPU.

[8] There are minor differences in the part-of-speech data provided with the three formalisms. For the basic models, we use the POS tags provided with the respective dataset; for the multitask models, we use the (automatic) POS tags provided with DM.

[9] Micro-averaged labeled F_1 for the multitask models.

4.5 Experiments

Experimental settings. We compare four multitask variants to the basic model, as well as the two baseline systems introduced in §3.4.

- SHARED1 is a first-order model. It uses a single shared BiLSTM encoder, and keeps the inference separate for each task.
- FREDA1 is a first-order model based on "frustratingly easy" parameter sharing. It uses a shared encoder as well as task-specific ones. The inference is kept separate for each task.
- SHARED3 is a third-order model. It follows SHARED1 and uses a single shared BiLSTM encoder, but additionally employs cross-task structures and inference.
- FREDA3 is also a third-order model. It combines FREDA1 and SHARED3 by using both "frustratingly easy" parameter sharing and cross-task structures and inference.

In addition, we also examine the effects of syntax by comparing our models to the state-of-the-art open track system (Almeida and Martins, 2015).[10]

Main results overview. Table 4a compares our models to the best published results (labeled F_1 score) on SemEval 2015 Task 18 in-domain test set. Our basic model improves over all closed track entries in all formalisms. It is even with the best open track system for DM and PSD, but improves on PAS and on average, without making use of any syntax. Three of our four multitask variants further improve over our basic model; SHARED1's differences are statistically insignificant. Our best models (SHARED3, FREDA3) outperform the previous state-of-the-art closed track system by 1.7% absolute F_1, and the best open track system by 0.9%, without the use of syntax.

We observe similar trends on the out-of-domain test set (Table 4b), with the exception that, on PSD, our best-performing model's improvement over the open-track system of Almeida and Martins (2015) is not statistically significant.

The extent to which we might benefit from syntactic information remains unclear. With automatically generated syntactic parses, Almeida and Martins (2015) manage to obtain more than 1% absolute improvements over their closed track entry, which is consistent with the extensive evaluation by Zhang et al. (2016), but we leave the incorporation of syntactic trees to future work. Syntactic parsing could be treated as yet another output task, as explored in Lluís et al. (2013) and in the transition-based frameworks of Henderson et al. (2013) and Swayamdipta et al. (2016).

[10] Kanerva et al. (2015) was the winner of the gold track, which overall saw higher performance than the closed and open tracks. Since gold-standard syntactic analyses are not available in most realistic scenarios, we do not include it in this comparison.

Effects of structural overlap. We hypothesized that the overlap between formalisms would enable multitask learning to be effective; in this section we investigate in more detail how structural overlap affected performance. By looking at *undirected* overlap between unlabeled arcs, we discover that modeling only arcs in the same direction may have been a design mistake.

DM and PAS are more structurally similar to each other than either is to PSD. Table 5 compares the structural similarities between the three for-

	Undirected			Directed		
	DM	**PAS**	**PSD**	**DM**	**PAS**	**PSD**
DM	-	67.2	56.8	-	64.2	26.1

Table 6: Unlabeled (UF) and labeled (LF) parsing performance of FREDA1 and FREDA3 on the development set of SemEval 2015 Task 18.

malisms in unlabeled F_1 score (each formalism's gold-standard unlabeled graph is used as a prediction of each other formalism's gold-standard unlabeled graph). All three formalisms have more than 50% overlap when ignoring arcs' directions, but considering direction, PSD is clearly different; PSD reverses the direction about half of the time it shares an edge with another formalism. A concrete example can be found in Figure 1, where DM and PAS both have an arc from *"Last"* to *"week,"* while PSD has an arc from *"week"* to *"Last."*

We can compare FREDA3 to FREDA1 to isolate the effect of modeling higher-order structures. Table 6 shows performance on the development data in both unlabeled and labeled F_1. We can see that FREDA3's unlabeled performance improves on DM and PAS, but *degrades* on PSD. This supports our hypothesis, and suggests that in future work, a more careful selection of structures to model might lead to further improvements.

5 Related Work

We note two important strands of related work.

Graph-based parsing. Graph-based parsing was originally invented to handle non-projective syntax (McDonald et al., 2005; Koo et al., 2010; Martins et al., 2013, *inter alia*), but has been adapted to semantic parsing (Flanigan et al., 2014; Martins and Almeida, 2014; Thomson et al., 2014; Kuhlmann, 2014, *inter alia*). Local structure scoring was traditionally done with linear models over hand-engineered features, but lately, various forms of representation learning have been explored to learn feature combinations (Lei et al., 2014; Taub-Tabib et al., 2015; Pei et al., 2015, *inter alia*). Our work is perhaps closest to those who used BiLSTMs to encode inputs (Kiperwasser and Goldberg, 2016; Kuncoro et al., 2016; Wang and Chang, 2016; Dozat and Manning, 2017; Ma and Hovy, 2016).

Multitask learning in NLP. There have been many efforts in NLP to use joint learning to replace pipelines, motivated by concerns about cascading errors. Collobert and Weston (2008) proposed sharing the same word representation while solving multiple NLP tasks. Zhang and Weiss (2016) use a continuous stacking model for POS tagging and parsing. Ammar et al. (2016) and Guo et al. (2016) explored parameter sharing for multilingual parsing. Johansson (2013) and Kshirsagar et al. (2015) applied ideas from domain adaptation to multitask learning. Successes in multitask learning have been enabled by advances in representation learning as well as earlier explorations of parameter sharing (Ando and Zhang, 2005; Blitzer et al., 2006; Daumé III, 2007).

6 Conclusion

We showed two orthogonal ways to apply deep multitask learning to graph-based parsing. The first shares parameters when encoding tokens in the input with recurrent neural networks, and the second introduces interactions between output structures across formalisms. Without using syntactic parsing, these approaches outperform even state-of-the-art semantic dependency parsing systems that use syntax. Because our techniques apply to labeled directed graphs in general, they can easily be extended to incorporate more formalisms, semantic or otherwise. In future work we hope to explore cross-task scoring and inference for tasks where parallel annotations are not available. Our code is open-source and available at `https://github.com/Noahs-ARK/NeurboParser`.

Abstract

Sememes are minimum semantic units of word meanings, and the meaning of each word sense is typically composed by several sememes. Since sememes are not explicit for each word, people manually annotate word sememes and form linguistic common-sense knowledge bases. In this paper, we present that, word sememe information can improve word representation learning (WRL), which maps words into a low-dimensional semantic space and serves as a fundamental step for many NLP tasks. The key idea is to utilize word sememes to capture exact meanings of a word within specific contexts accurately. More specifically, we follow the framework of Skip-gram and present three sememe-encoded models to learn representations of sememes, senses and words, where we apply the attention scheme to detect word senses in various contexts. We conduct experiments on two tasks including word similarity and word analogy, and our models significantly outperform baselines. The results indicate that WRL can benefit from sememes via the attention scheme, and also confirm our models being capable of correctly modeling sememe information.

1 Introduction

Sememes are defined as minimum semantic units of word meanings, and there exists a limited close set of sememes to compose the semantic meanings of an open set of concepts (i.e. word sense). However, sememes are not explicit for each word. Hence, people manually annotate word sememes and build linguistic common-sense knowledge bases.

HowNet (Dong and Dong, 2003) is one of such knowledge bases, which annotates each concept in Chinese with one or more relevant sememes. Different from WordNet (Miller, 1995), the philosophy of HowNet emphasizes the significance of `part` and `attribute` represented by sememes. HowNet has been widely utilized in word similarity computation (Liu and Li, 2002) and sentiment analysis (Xianghua et al., 2013), and in section 3.2 we will give a detailed introduction to sememes, senses and words in HowNet.

In this paper, we aim to incorporate word sememes into word representation learning (WRL) and learn improved word embeddings in a low-dimensional semantic space. WRL is a fundamental and critical step in many NLP tasks such as language modeling (Bengio et al., 2003) and neural machine translation (Sutskever et al., 2014).

There have been a lot of researches for learning word representations, among which word2vec (Mikolov et al., 2013) achieves a nice balance between effectiveness and efficiency. In word2vec, each word corresponds to one single embedding, ignoring the polysemy of most words. To address this issue, (Huang et al., 2012) introduces a multi-prototype model for WRL, conducting unsupervised word sense induction and embeddings according to context clusters. (Chen et al., 2014) further utilizes the `synset` information in WordNet to instruct word sense representation learning.

From these previous studies, we conclude that word sense disambiguation are critical for WRL, and we believe that the sememe annotation of word senses in HowNet can provide necessary semantic regularization for the both tasks. To explore its feasibility, we propose a novel **S**ememe-**E**ncoded **W**ord **R**epresentation **L**earning

(SE-WRL) model, which detects word senses and learns representations simultaneously. More specifically, this framework regards each word sense as a combination of its sememes, and iteratively performs word sense disambiguation according to their contexts and learn representations of sememes, senses and words by extending Skip-gram in word2vec (Mikolov et al., 2013). In this framework, an attention-based method is proposed to select appropriate word senses according to contexts automatically. To take full advantages of sememes, we propose three different learning and attention strategies for SE-WRL.

In experiments, we evaluate our framework on two tasks including word similarity and word analogy, and further conduct case studies on sememe, sense and word representations. The evaluation results show that our models outperform other baselines significantly, especially on word analogy. This indicates that our models can build better knowledge representations with the help of sememe information, and also implies the potential of our models on word sense disambiguation.

The key contributions of this work are concluded as follows: (1) To the best of our knowledge, this is the first work to utilize sememes in HowNet to improve word representation learning. (2) We successfully apply the attention scheme to detect word senses and learn representations according to contexts with the favor of the sememe annotation in HowNet. (3) We conduct extensive experiments and verify the effectiveness of incorporating word sememes for improved WRL.

2 Related Work

2.1 Word Representation

Recent years have witnessed the great thrive in word representation learning. It is simple and straightforward to represent words using one-hot representations, but it usually struggles with the data sparsity issue and the neglect of semantic relations between words.

To address these issues, (Rumelhart et al., 1988) proposes the idea of distributed representation which projects all words into a continuous low-dimensional semantic space, considering each word as a vector. Distributed word representations are powerful and have been widely utilized in many NLP tasks, including neural language models (Bengio et al., 2003; Mikolov et al., 2010), machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), parsing (Chen and Manning, 2014) and text classification (Zhang et al., 2015). Word distributed representations are capable of encoding semantic meanings in vector space, serving as the fundamental and essential inputs of many NLP tasks.

There are large amounts of efforts devoted to learning better word representations. As the exponential growth of text corpora, model efficiency becomes an important issue. (Mikolov et al., 2013) proposes two models, CBOW and Skip-gram, achieving a good balance between effectiveness and efficiency. These models assume that the meanings of words can be well reflected by their contexts, and learn word representations by maximizing the predictive probabilities between words and their contexts. (Pennington et al., 2014) further utilizes matrix factorization on word affinity matrix to learn word representations. However, these models merely arrange only one vector for each word, regardless of the fact that many words have multiple senses. (Huang et al., 2012; Tian et al., 2014) utilize multi-prototype vector models to learn word representations and build distinct vectors for each word sense. (Neelakantan et al., 2015) presents an extension to Skip-gram model for learning non-parametric multiple embeddings per word. (Rothe and Schütze, 2015) also utilizes an Autoencoder to jointly learn word, sense and synset representations in the same semantic space.

This paper, for the first time, jointly learns representations of sememes, senses and words. The sememe annotation in HowNet provides useful semantic regularization for WRL. Moreover, the unified representations incorporated with sememes also provide us more explicit explanations of both word and sense embeddings.

2.2 Word Sense Disambiguation and Representation Learning

Word sense disambiguation (WSD) aims to identify word senses or meanings in a certain context computationally. There are mainly two approaches for WSD, namely the supervised methods and the knowledge-based methods. Supervised methods usually take the surrounding words or senses as features and use classifiers like SVM for word sense disambiguation (Lee et al., 2004), which are intensively limited to the time-consuming human annotation of training data.

On contrary, knowledge-based methods utilize

large external knowledge resources such as knowledge bases or dictionaries to suggest possible senses for a word. (Banerjee and Pedersen, 2002) exploits the rich hierarchy of semantic relations in WordNet (Miller, 1995) for an adapted dictionary-based WSD algorithm. (Bordes et al., 2011) introduces `synset` information in WordNet to WRL. (Chen et al., 2014) considers synsets in WordNet as different word senses, and jointly conducts word sense disambiguation and word / sense representation learning. (Guo et al., 2014) considers bilingual datasets to learn sense-specific word representations. Moreover, (Jauhar et al., 2015) proposes two approaches to learn sense-specific word representations that are grounded to ontologies. (Pilehvar and Collier, 2016) utilizes personalized PageRank to learn de-conflated semantic representations of words.

In this paper, we follow the knowledge-based approach and automatically detect word senses according to the contexts with the favor of sememe information in HowNet. To the best of our knowledge, this is the first attempt to apply attention-based models to encode sememe information for word representation learning.

3 Methodology

In this section, we present our framework Sememe-Encoded WRL (SE-WRL) that considers sememe information for word sense disambiguation and representation learning. Specifically, we learn our models on a large-scale text corpus with the semantic regularization of the sememe annotation in HowNet and obtain sememe, sense and word embeddings for evaluation tasks.

In the following sections, we first introduce HowNet and the structures of sememes, senses and words. Then we discuss the conventional WRL model Skip-gram that we utilize for the sememe-encoded framework. Finally, we propose three sememe-encoded models in details.

3.1 Sememes, Senses and Words in HowNet

In this section, we first introduce the arrangement of sememes, senses and words in HowNet. HowNet annotates precise senses to each word, and for each sense, HowNet annotates the significance of parts and attributes represented by sememes.

Fig. 1 gives an example of sememes, senses and words in HowNet. The first layer represents the **word** "apple". The word "apple" actually has two main **senses** shown on the second layer: one is a sort of juicy fruit (*apple*), and another is a famous computer brand (*Apple brand*). The third and following layers are those **sememes** explaining each sense. For instance, the first sense *Apple brand* indicates a computer brand, and thus has sememes `computer`, `bring` and `SpeBrand`.

From Fig. 1 we can find that, sememes of many senses in HowNet are annotated with various relations, such as *define* and *modifier*, and form complicated hierarchical structures. In this paper, for simplicity, we only consider all annotated sememes of each sense as a sememe set without considering their internal structure. HowNet assumes the limited annotated sememes can well represent senses and words in the real-world scenario, and thus sememes are expected to be useful for both WSD and WRL.

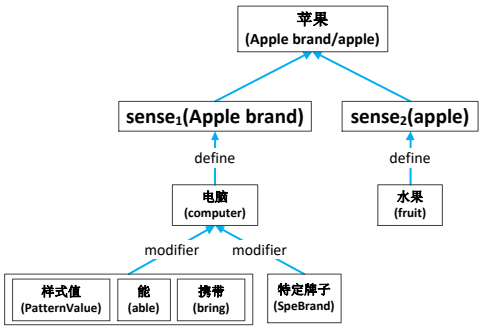

Figure 1: Examples of sememes, senses and words.

We introduce the notions utilized in the following sections as follows. We define the overall sememe, sense and word sets used in training as X, S and W respectively. For each $w \in W$, there are possible multiple senses $s_i^{(w)} \in S^{(w)}$ where $S^{(w)}$ represents the sense set of w. Each sense $s_i^{(w)}$ consists of several sememes $x_j^{(s_i)} \in X_i^{(w)}$. For each target word w in a sequential plain text, $C(w)$ represents its context word set.

3.2 Conventional Skip-gram Model

We directly utilize the widely-used model Skip-gram to implement our SE-WRL model, because Skip-gram has well balanced effectiveness as well as efficiency (Mikolov et al., 2013). The standard skip-gram model assumes that word embeddings should relate to their context words. It aims at

maximizing the predictive probability of context words conditioned on the target word w. Formally, we utilize a sliding window to select the context word set $C(w)$. For a word sequence $H = \{w_1, \cdots, w_n\}$, Skip-gram model intends to maximize:

$$L(H) = \sum_{i=K}^{n-K} \log \Pr(w_{i-K}, \cdots, w_{i+K}|w_i), \quad (1)$$

where K is the size of sliding window. $\Pr(w_{i-K}, \cdots, w_{i+K}|w_i)$ represents the predictive probability of context words conditioned on the target word w_i, formalized by the following softmax function:

$$\begin{aligned}\Pr(w_{i-K}, \cdots, w_{i+K}|w_i) &= \prod_{w_c \in C(w_i)} \Pr(w_c|w_i) \\ &= \prod_{w_c \in C(w_i)} \frac{\exp(\mathbf{w}_c^\top \cdot \mathbf{w}_i)}{\sum_{w'_i \in W} \exp(\mathbf{w}_c^\top \cdot \mathbf{w}'_i)},\end{aligned} \quad (2)$$

in which $\mathbf{w}_c$ and $\mathbf{w}_i$ stand for embeddings of context word $w_c \in C(w_i)$ and target word w_i respectively. We can also follow the strategies of hierarchical softmax and negative sampling proposed in (Mikolov et al., 2013) to accelerate the calculation of softmax.

3.3 SE-WRL Model

In this section, we introduce the SE-WRL models with three different strategies to utilize sememe information, including Simple Sememe Aggregation Model (SSA), Sememe Attention over Context Model (SAC) and Sememe Attention over Target Model (SAT).

3.3.1 Simple Sememe Aggregation Model

The Simple Sememe Aggregation Model (SSA) is a straightforward idea based on Skip-gram model. For each word, SSA considers all sememes in all senses of the word together, and represents the target word using the average of all its sememe embeddings. Formally, we have:

$$\mathbf{w} = \frac{1}{m} \sum_{s_i^{(w)} \in S^{(w)}} \sum_{x_j^{(s_i)} \in X_i^{(w)}} \mathbf{x}_j^{(s_i)}, \quad (3)$$

which means the word embedding of w is composed by the average of all its sememe embeddings. Here, m stands for the overall number of sememes belonging to w.

This model simply follows the assumption that, the semantic meaning of a word is composed of the semantic units, i.e., sememes. As compared to the conventional Skip-gram model, since sememes are shared by multiple words, this model can utilize sememe information to encode latent semantic correlations between words. In this case, similar words that share the same sememes may finally obtain similar representations.

3.3.2 Sememe Attention over Context Model

The SSA Model replaces the target word embedding with the aggregated sememe embeddings to encode sememe information into word representation learning. However, each word in SSA model still has only one single representation in different contexts, which cannot deal with polysemy of most words. It is intuitive that we should construct distinct embeddings for a target word according to specific contexts, with the favor of word sense annotation in HowNet.

To address this issue, we come up with the Sememe Attention over Context Model (SAC). SAC utilizes the attention scheme to automatically select appropriate senses for context words according to the target word. That is, SAC conducts word sense disambiguation for context words to learn better representations of target words. The structure of the SAC model is shown in Fig. 2.

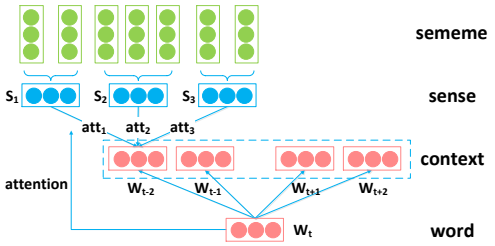

Figure 2: Sememe Attention over Context Model.

More specifically, we utilize the original word embedding for target word w, but use sememe embeddings to represent context word w_c instead of original context word embeddings. Suppose a word typically demonstrates some specific senses in one sentence. Here we employ the target word embedding as an attention to select the most appropriate senses to make up context word embeddings. We formalize the context word embedding

$\mathbf{w}_c$ as follows:

$$\mathbf{w}_c = \sum_{j=1}^{|S^{(w_c)}|} att(s_j^{(w_c)}) \cdot \mathbf{s}_j^{(w_c)}, \quad (4)$$

where $\mathbf{s}_j^{(w_c)}$ stands for the j-th sense embedding of w_c, and $att(s_j^{(w_c)})$ represents the attention score of the j-th sense with respect to the target word w, defined as follows:

$$att(s_j^{(w_c)}) = \frac{\exp(\mathbf{w} \cdot \hat{\mathbf{s}}_j^{(w_c)})}{\sum_{k=1}^{|S^{(w_c)}|} \exp(\mathbf{w} \cdot \hat{\mathbf{s}}_k^{(w_c)})}. \quad (5)$$

Note that, when calculating attention, we use the average of sememe embeddings to represent each sense $s_j^{(w_c)}$:

$$\hat{\mathbf{s}}_j^{(w_c)} = \frac{1}{|X_j^{(w_c)}|} \sum_{k=1}^{|X_j^{(w_c)}|} \mathbf{x}_k^{(s_j)}. \quad (6)$$

The attention strategy assumes that the more relevant a context word sense embedding is to the target word $\mathbf{w}$, the more this sense should be considered when building context word embeddings. With the favor of attention scheme, we can represent each context word as a particular distribution over its sense. This can be regarded as soft WSD. As shown in experiments, it will help learn better word representations.

3.3.3 Sememe Attention over Target Model

The Sememe Attention over Context Model can flexibly select appropriate senses and sememes for context words according to the target word. The process can also be applied to select appropriate senses for the target word, by taking context words as attention. Hence, we propose the Sememe Attention over Target Model (SAT) as shown in Fig. 3.

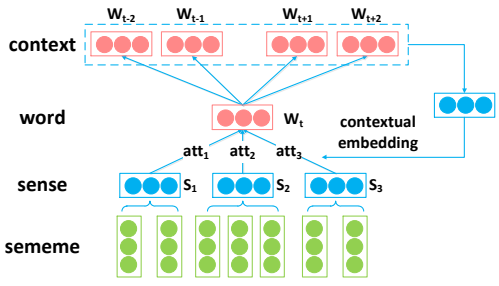

Figure 3: Sememe Attention over Target Model.

Different from SAC model, SAT learns the original word embeddings for context words, but sememe embeddings for target words. We apply context words as attention over multiple senses of the target word w to build the embedding of w, formalized as follows:

$$\mathbf{w} = \sum_{j=1}^{|S^{(w)}|} att(s_j^{(w)}) \cdot \mathbf{s}_j^{(w)}, \quad (7)$$

where $\mathbf{s}_j^{(w)}$ stands for the j-th sense embedding of w, and the context-based attention is defined as follows:

$$att(s_j^{(w)}) = \frac{\exp(\mathbf{w}'_c \cdot \hat{\mathbf{s}}_j^{(w)})}{\sum_{k=1}^{|S^{(w)}|} \exp(\mathbf{w}'_c \cdot \hat{\mathbf{s}}_k^{(w)})}, \quad (8)$$

where, similar to Eq. (6), we also use the average of sememe embeddings to represent each sense $s_j^{(w)}$. Here, $\mathbf{w}'_c$ is the context embedding, consisting of a constrained window of word embeddings in $C(w_i)$. We have:

$$\mathbf{w}'_c = \frac{1}{2K'} \sum_{k=i-K'}^{k=i+K'} \mathbf{w}_k, \quad k \neq i. \quad (9)$$

Note that, since in experiment we find the sense selection of the target word only relies on more limited context words for calculating attention, hence we select a smaller K' as compared to K.

Recall that, SAC only uses one target word as attention to select senses of context words, but SAT uses several context words together as attention to select appropriate senses of target words. Hence SAT is expected to conduct more reliable WSD and result in more accurate word representations, which will be explored in experiments.

4 Experiments

In this section, we evaluate the effectiveness of our SE-WRL[1] models on two tasks including word similarity and word analogy, which are two classical evaluation tasks mainly focusing on evaluating the quality of learned word representations. We also explore the potential of our models in word sense disambiguation with case study, showing the power of our attention-based models.

[1] https://github.com/thunlp/SE-WRL

4.1 Dataset

We use the web pages in Sogou-T[2] as the text corpus to learn WRL models. Sogou-T is provided by a Chinese commercial search engine, which contains 2.7 billion words in total.

We also utilize the sememe annotation in HowNet. The number of distinct sememes used in this paper is $1,889$. The average senses for each word are about 2.4, while the average sememes for each sense are about 1.6. Throughout the Sogou-T corpus, we find that 42.2% of words have multiple senses. This indicates the significance of WSD.

For evaluation, we choose wordsim-240 and wordsim-297[3] to evaluate the performance of word similarity computation. The two datasets both contain frequently-used Chinese word pairs with similarity scores annotated manually. We choose the Chinese Word Analogy dataset proposed by (Chen et al., 2015) to evaluate the performance of word analogy inference, that is, $\mathbf{w}(\text{“king”}) - \mathbf{w}(\text{“man”}) \simeq \mathbf{w}(\text{“queen”}) - \mathbf{w}(\text{“woman”})$.

4.2 Experimental Settings

We evaluate three SE-WRL models including S-SA, SAC and SAT on all tasks. As for baselines, we consider three conventional WRL models including Skip-gram, CBOW and GloVe. For Skip-gram and CBOW, we directly use the code released by Google (Mikolov et al., 2013). GloVe is proposed by (Pennington et al., 2014), which seeks the advantages of the WRL models based on statistics and those based on prediction. Moreover, we propose another model, Maximum Selection over Target Model (MST), for further comparison inspired by (Chen et al., 2014). It represents the current word embeddings with only the most probable sense according to the contexts, instead of viewing a word as a particular distribution over all its senses similar to that of SAT.

For a fair comparison, we train these models with the same experimental settings and with their best parameters. As for the parameter settings, we set the context window size $K = 8$ as the upper bound, and during training, the window size is dynamically selected ranging from 1 to 8 randomly. We set the dimensions of word, sense and sememe embeddings to be the same 200. For learning rate α, its initial value is 0.025 and will descend through iterations. We set the number of negative samples to be 25. We also set a lower bound of word frequency as 50, and in the training set, those words less frequent than this bound will be filtered out. For SAT, we set $K' = 2$.

4.3 Word Similarity

The task of word similarity aims to evaluate the quality of word representations by comparing the similarity ranks of word pairs computed by WRL models with the ranks given by dataset. WRL models typically compute word similarities according to their distances in the semantic space.

4.3.1 Evaluation Protocol

In experiments, we choose the cosine similarity between two word embeddings to rank word pairs. For evaluation, we compute the Spearman correlation between the ranks of models and the ranks of human judgments.

Model	Wordsim-240	Wordsim-297
CBOW	57.7	61.1
GloVe	59.8	58.7
Skip-gram	58.5	63.3
SSA	58.9	64.0
SAC	59.0	63.1
MST	59.2	62.8
SAT	**63.2**	**65.6**

Table 1: Evaluation results of word similarity computation.

4.3.2 Experiment Results

Table 1 shows the results of these models for word similarity computation. From the results we can observe that:

(1) Our SAT model outperforms other models, including all baselines, on both two test sets. This indicates that, by utilizing sememe annotation properly, our model can better capture the semantic relations of words, and learn more accurate word embeddings.

(2) The SSA model represents a word with the average of its sememe embeddings. In general, S-SA model performs slightly better than baselines, which tentatively proves that sememe information is helpful. The reason is that words which share common sememe embeddings will benefit from each other. Especially, those words with lower frequency, which cannot be learned sufficiently using conventional WRL models, in contrast, can

Model	Accuracy				Mean Rank			
	Capital	City	Relationship	All	Capital	City	Relationship	All
CBOW	49.8	85.7	**86.0**	64.2	36.98	1.23	62.64	37.62
GloVe	57.3	74.3	81.6	65.8	19.09	1.71	3.58	12.63
Skip-gram	66.8	93.7	76.8	73.4	137.19	1.07	2.95	83.51
SSA	62.3	93.7	81.6	71.9	45.74	1.06	3.33	28.52
SAC	61.6	95.4	77.9	70.8	19.08	1.02	**2.18**	12.18
MST	65.7	95.4	82.7	74.5	50.29	1.05	2.48	31.05
SAT	**83.2**	**98.9**	82.4	**85.3**	**14.42**	**1.01**	2.63	**9.48**

Table 2: Evaluation results of word analogy inference.

obtain better word embeddings from SSA simply because their sememe embeddings can be trained sufficiently through other words.

(3) The SAT model performs much better than SSA and SAC. This indicates that SAT can obtain more precise sense distribution of a word. The reason has been mentioned above that, different from SAC using only one target word as attention for WSD, SAT adopts richer contextual information as attention for WSD.

(4) SAT works better than MST, and we can conclude that a soft disambiguation over senses prevents inevitable errors when selecting only one most-probable sense. The result makes sense because, for many words, their various senses are not always entirely different from each other, but share some common elements. In some contexts, a single sense may not convey the exact meaning of this word.

4.4 Word Analogy

Word analogy inference is another widely-used task to evaluate the quality of WRL models (Mikolov et al., 2013).

4.4.1 Evaluation Protocol

The dataset proposed by (Chen et al., 2015) consists of $1,124$ analogies, which contains three analogy types: (1) capitals of countries (Capital), 677 groups; (2) states/provinces of cities (City), 175 groups; (3) family words (Relationship), 272 groups. Given an analogy group of words (w_1, w_2, w_3, w_4), WRL models usually get $\mathbf{w}_2 - \mathbf{w}_1 + \mathbf{w}_3$ equal to $\mathbf{w}_4$. Hence for word analogy inference, we suppose w_4 is missing, and WRL models will rank all candidate words according to their scores as follows:

$$R(w) = \cos(\mathbf{w}_2 - \mathbf{w}_1 + \mathbf{w}_3, \mathbf{w}), \qquad (10)$$

and select the top-ranked word as the answer.

For word analogy inference, we consider two evaluation metrics: (1) **Accuracy**. For each analogy group, a WRL model selects the top-ranked word $w = \arg\max_w R(w)$, which is judged as positive if $w = w_4$. The percentage of positive samples is regarded as the accuracy score for this WRL model. (2) **Mean Rank**. For each analogy group, a WRL model will assign a rank for the gold standard word w_4 according to the scores computed by Eq. (10). We use the mean rank of all gold standard words as the evaluation metric.

4.4.2 Experiment Results

Table 2 shows the evaluation results of these models for word analogy inference. From the table, we can observe that:

(1) The SAT model performs best among all models, and the superiority is more significant than that on word similarity computation. This indicates that SAT will enhance the modeling of implicit relations between word embeddings in the semantic space. The reason is that sememes annotated to word senses have encoded these word relations. For example, `capital` and `Cuba` are two sememes of the word "Havana", which provide explicit semantic relations between the words "Cuba" and "Havana".

(2) The SAT model does well on both classes of Capital and City, because some words in these classes have low frequencies, while their sememes occur so many times that sememe embeddings can be learned sufficiently. With these sememe embeddings, these low-frequent words can be learned more efficiently by SAT.

(3) It seems that CBOW works better than SAT on Relationship class. Whereas for the mean rank, CBOW gets the worst results, which indicates the performance of CBOW is unstable. On the contrary, although the accuracy of SAT is a bit lower than that of CBOW, SAT seldom gives an outrageous prediction. In most wrong cas-

Word: 苹果(“Apple brand/apple”) sense1: *Apple brand* (computer, PatternValue, able, bring, SpeBrand) sense2: *duct* (fruit)		
苹果 素有果中王美称（**Apple** is always famous as the king of fruits） **苹果** 电脑无法正常启动（The **Apple brand** computer can not startup normally）	*Apple brand*: 0.28 *Apple brand*: 0.87	*apple*: 0.72 *apple*: 0.13
Word: 扩散(“proliferate/metastasize”) sense1: *proliferate* (disperse) sense2: *metastasize* (disperse, disease)		
防止疫情**扩散**（Prevent epidemic from **metastasizing**） 不**扩散** 核武器条约（Treaty on the Non-**Proliferation** of Nuclear Weapons）	*proliferate*: 0.06 *proliferate*: 0.68	*metastasize*: 0.94 *metastasize*: 0.32
Word: 队伍(“contingent/troops”) sense1: *contingent* (community) sense2: *troops* (army)		
八支**队伍** 进入第二阶段团体赛（Eight **contingents** enter the second stage of team competition）	*contingent*: 0.90	*troops*: 0.10
公安基层**队伍** 组织建设（Construct the organization of public security’s **troops** in grass-roots unit）	*contingent*: 0.15	*troops*: 0.85

Table 3: Examples of sememes, senses and words in context with attention.

es, SAT predicts the word “grandfather” instead of “grandmother”, which is not completely nonsense, because in HowNet the words “grandmother”, “grandfather”, “grandma” and some other similar words share four common sememes while only one sememe of them are different. These similar sememes make the attention process less discriminative with each other. But for the wrong cases of CBOW, we find that many mistakes are about words with low frequencies, such as “stepdaughter” which occurs merely for 358 times. Considering sememes may relieve this problem.

4.5 Case study

The above experiments verify the effectiveness of our models for WRL. Here we show some examples of sememes, senses and words for case study.

4.5.1 Word Sense Disambiguation

To demonstrate the validity of Sememe Attention, we select three attention results in training set, as shown in Table 3. In this table, the first rows of three examples are word-sense-sememe structures of each word. For instance, in the third example, the word has two senses, *contingent* and *troops*; *contingent* has one sememe `community`, while *troops* has one sememe `army`. The three examples all indicate that our models can estimate appropriate distributions of senses for a word given a context.

4.5.2 Effect of Context Words for Attention

We demonstrate the effect of context words for attention in Table. 4. The word “Havana” consists of four sememes, among which two sememes `capital` and `Cuba` describe distinct attributes of the word from different aspects.

Word Sememe	哈瓦那(“Havana”) 国都(`capital`)	 古巴(`Cuba`)
古巴(“Cuba”)	0.39	0.42
俄罗斯(“Russia”)	0.39	-0.09
雪茄(“cigar”)	0.00	0.36

Table 4: Sememe weight for computing attention.

Here, we list three different context words “Cuba”, “Russia” and “cigar”. Given the context word “Cuba”, both sememes get high weights, indicating their contributions to the meaning of “Havana” in this context. The context word “Russia” is more relevant to the sememe `capital`. When the context word is “cigar”, the sememe `Cuba` has more influence, because cigar is a famous specialty of Cuba. From these examples, we can conclude that our Sememe Attention can accurately capture the word meanings in complicated contexts.

5 Conclusion and Future Work

In this paper, we propose a novel method to model sememe information for learning better word representations. Specifically, we utilize sememe information to represent various senses of each word and propose Sememe Attention to select appropriate senses in contexts automatically. We evaluate our models on word similarity and word analogy, and results show the advantages of our Sememe-Encoded WRL models. We also analyze several cases in WSD and WRL, which confirms our models are capable of selecting appropriate word senses with the favor of sememe attention.

We will explore the following research directions in future: (1) The sememe information in HowNet is annotated with hierarchical structure

and relations, which have not been considered in our framework. We will explore to utilize these annotations for better WRL. (2) We believe the idea of sememes is universal and could be well-functioned beyond languages. We will explore the effectiveness of sememe information for WRL in other languages.

Abstract

Previous work has modeled the compositionality of words by creating character-level models of meaning, reducing problems of sparsity for rare words. However, in many writing systems compositionality has an effect even on the character-level: the meaning of a character is derived by the sum of its parts. In this paper, we model this effect by creating embeddings for characters based on their visual characteristics, creating an image for the character and running it through a convolutional neural network to produce a visual character embedding. Experiments on a text classification task demonstrate that such model allows for better processing of instances with rare characters in languages such as Chinese, Japanese, and Korean. Additionally, qualitative analyses demonstrate that our proposed model learns to focus on the parts of characters that carry semantic content, resulting in embeddings that are coherent in visual space.

1 Introduction

Compositionality—the fact that the meaning of a complex expression is determined by its structure and the meanings of its constituents—is a hallmark of every natural language (Frege and Austin, 1980; Szabó, 2010). Recently, neural models have provided a powerful tool for learning how to compose words together into a meaning representation of whole sentences for many downstream tasks. This is done using models of various levels of sophistication, from simpler bag-of-words (Iyyer et al., 2015) and linear recurrent neural network (RNN) models (Sutskever et al., 2014; Kiros et al., 2015), to more sophisticated models using tree-structured (Socher et al., 2013) or convolutional networks (Kalchbrenner et al., 2014).

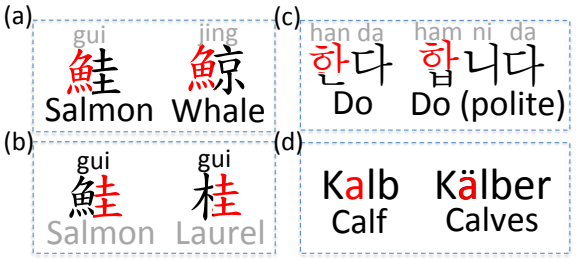

Figure 1: Examples of character-level compositionality in (a, b) Chinese, (c) Korean, and (d) German. The red part of the characters are shared, and affects the pronunciation (top) or meaning (bottom).

In fact, a growing body of evidence shows that it is essential to look below the word-level and consider compositionality within words themselves. For example, several works have proposed models that represent words by composing together the characters into a representation of the word itself (Ling et al., 2015; Zhang et al., 2015; Dhingra et al., 2016). Additionally, for languages with productive word formation (such as agglutination and compounding), models calculating morphology-sensitive word representations have been found effective (Luong et al., 2013; Botha and Blunsom, 2014). These models help to learn more robust representations for *rare words* by exploiting morphological patterns, as opposed to models that operate purely on the lexical level as the atomic units.

For many languages, compositionality stops at the character-level: characters are atomic units of meaning or pronunciation in the language, and no further decomposition can be done.[1] However, for other languages, character-level compositionality, where a character's meaning or pronunciation can

[1]In English, for example, this is largely the case.

Table 1: By-category statistics for the Wikipedia dataset. Note that Food is the abbreviation for "Food and Culture" and Religion is the abbreviation for "Religion and Belief".

be derived from the sum of its parts, is very much a reality. Perhaps the most compelling example of compositionality of sub-character units can be found in logographic writing systems such as the Han and Kanji characters used in Chinese and Japanese, respectively.[2] As shown on the left side of Fig. 1, each part of a Chinese character (called a "radical") potentially contributes to the meaning (i.e., Fig. 1(a)) or pronunciation (i.e., Fig. 1(b)) of the overall character. This is similar to how English characters combine into the meaning or pronunciation of an English word. Even in languages with phonemic orthographies, where each character corresponds to a pronunciation instead of a meaning, there are cases where composition occurs. Fig. 1(c) and (d) show the examples of Korean and German, respectively, where morphological inflection can cause single characters to make changes where some but not all of the component parts are shared.

In this paper, we investigate the feasibility of modeling the *compositionality of characters* in a way similar to how humans do: by visually observing the character and using the features of its shape to learn a representation encoding its meaning. Our method is relatively simple, and generalizable to a wide variety of languages: we first transform each character from its Unicode representation to a rendering of its shape as an image, then calculate a representation of the image using Convolutional Neural Networks (CNNs) (Cun et al., 1990). These features then serve as inputs to a down-stream processing task and trained in an end-to-end manner, which first calculates a loss function, then back-propagates the loss back to the CNN.

[2]Other prominent examples are largely for extinct languages: Egyptian hieroglyphics, Mayan glyphs, and Sumerian cuneiform scripts (Daniels and Bright, 1996).

As demonstrated by our motivating examples in Fig. 1, in logographic languages character-level semantic or phonetic similarity is often indicated by visual cues; we conjecture that CNNs can appropriately model these visual patterns. Consequently, characters with similar visual appearances will be biased to have similar embeddings, allowing our model to handle *rare characters* effectively, just as character-level models have been effective for rare words.

To evaluate our model's ability to learn representations, particularly for rare characters, we perform experiments on a downstream task of classifying Wikipedia titles for three Asian languages: Chinese, Japanese, and Korean. We show that our proposed framework outperforms a baseline model that uses standard character embeddings for instances containing rare characters. A qualitative analysis of the characteristics of the learned embeddings of our model demonstrates that visually similar characters share similar embeddings. We also show that the learned representations are particularly effective under low-resource scenarios and *complementary* with standard character embeddings; combining the two representations through three different fusion methods (Snoek et al., 2005; Karpathy et al., 2014) leads to consistent improvements over the strongest baseline without visual features.

2 Dataset

Before delving into the details of our model, we first describe a dataset we constructed to examine the ability of our model to capture the compositional characteristics of characters. Specifically, the dataset must satisfy two desiderata: (1) it must be necessary to fully utilize each character in the input in order to achieve high accuracy, and (2) there must be enough regularity and com-

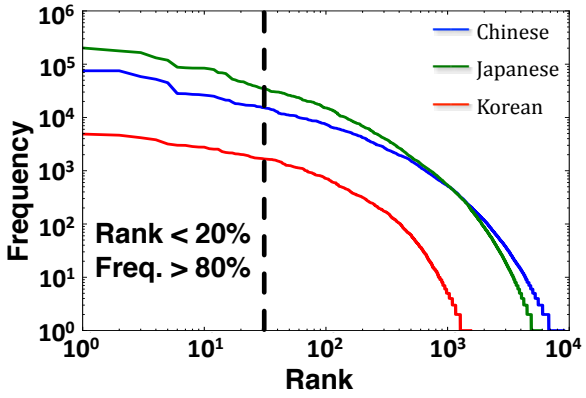

Figure 2: The character rank-frequency distribution of the corpora we considered in this paper. All three languages have a long-tail distribution.

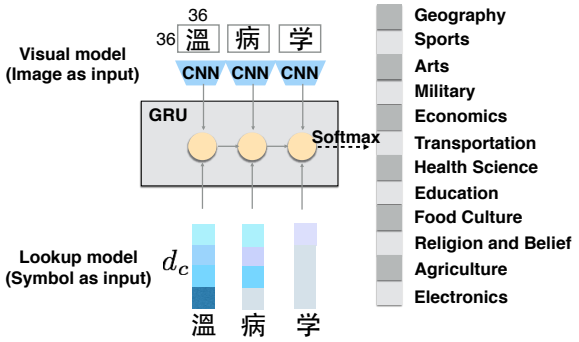

Figure 3: An illustration of two models, our proposed VISUAL model at the top and the baseline LOOKUP model at the bottom using the same RNN architecture. A string of characters (e.g. "温病学"), each converted into a 36x36 image, serves as input of our VISUAL model. d_c is the dimension of the character embedding for the LOOKUP model.

positionality in the characters of the language. To satisfy these desiderata, we create a text classification dataset where the input is a Wikipedia article title in Chinese, Japanese, or Korean, and the output is the category to which the article belongs.[3] This satisfies (1), because Wikipedia titles are short and thus each character in the title will be important to our decision about its category. It also satisfies (2), because Chinese, Japanese, and Korean have writing systems with large numbers of characters that decompose regularly as shown in Fig. 1. While this task in itself is novel, it is similar to previous work in named entity type inference using Wikipedia (Toral and Munoz, 2006; Kazama and Torisawa, 2007; Ratinov and Roth, 2009), which has proven useful for downstream named entity recognition systems.

2.1 Dataset Collection

As the labels we would like to predict, we use 12 different main categories from the Wikipedia web page: Geography, Sports, Arts, Military, Economics, Transportation, Health Science, Education, Food Culture, Religion and Belief, Agriculture and Electronics. Wikipedia has a hierarchical structure, where each of these main categories has a number of subcategories, and each subcategory has its own subcategories, etc. We traverse this hierarchical structure, adding each main category tag to all of its descendants in this subcategory tree structure. In the case that a particular article is the descendant of multiple main categories, we favor the main category that minimizes the depth of the article in the tree (e.g., if an article is two steps away from Sports and three steps away from Arts, it will receive the "Sports" label). We also perform some rudimentary filtering, removing pages that match the regular expression ".*:.*", which catches special pages such as "title:agriculture".

[3]The link to the dataset and the crawling scripts – https://github.com/frederick0329/Wikipedia_title_dataset

2.2 Statistics

For Chinese, Japanese, and Korean, respectively, the number of articles is 593k/810k/46.6k, and the average length and standard deviation of the title is 6.25±3.96/8.60±5.58/6.10±3.71. As shown in Fig. 2, the character rank-frequency distributions of all three languages follows the 80/20 rule (Newman, 2005) (i.e., top 20% ranked characters that appear more than 80% of total frequencies), demonstrating that the characters in these languages belong to a long tail distribution.

We further split the dataset into training, validation, and testing sets with a 6:2:2 ratio. The category distribution for each language can be seen in Tab. 1. Chinese has two varieties of characters, traditional and simplified, and the dataset is a mix of the two. Hence, we transform this dataset into two separate sets, one completely simplified and the other completely traditional using the Chinese text converter provided with Mac OS.

3 Model

Our overall model for the classification task follows the encoder model by Sutskever et al. (2014).

Layer#	3-layer CNN Configuration

12	ReLu

Table 2: Architecture of the CNN used in the experiments. All the convolutional layers have 32 3×3 filters.

We calculate character representations, use a RNN to combine the character representations into a sentence representation, and then add a softmax layer after that to predict the probability for each class. As shown in Fig. 2.1, the baseline model, which we call it the LOOKUP model, calculates the representation for each character by looking it up in a character embedding matrix. Our proposed model, the VISUAL model instead learns the representation of each character from its visual appearance via CNN.

LOOKUP model Given a character vocabulary C, for the LOOKUP model as in the bottom part of Fig. 2.1, the input to the network is a stream of characters $c_1, c_2, ...c_N$, where $c_n \in C$. Each character is represented by a 1-of-$|C|$ (one-hot) encoding. This one-hot vector is then multiplied by the lookup matrix $T_C \in \mathbf{R}^{|C| \times d_c}$, where d_c is the dimension of the character embedding. The randomly initialized character embeddings were optimized with classification loss.

VISUAL model The proposed method aims to learn a representation that includes image information, allowing for better parameter sharing among characters, particularly characters that are less common. Different from the LOOKUP model, each character is first transformed into a 36-by-36 image based on its Unicode encoding as shown in the upper part of Fig 2.1. We then pass the image through a CNN to get the embedding for the image. The parameters for the CNN are learned through backpropagation from the classification loss. Because we are training embeddings based on this classification loss, we expect that the CNN will focus on parts of the image that contain semantic information useful for category classification, a hypothesis that we examine in the experiments (see Section 5.5).

In more detail, the specific structure of the CNN that we utilize consists of three convolution layers where each convolution layer is followed by the max pooling and ReLU nonlinear activation layers. The configurations of each layer are listed in Tab. 2. The output vector for the image embeddings also has size d_c which is the same as the LOOKUP model.

Encoder and Classifier For both the LOOKUP and the VISUAL models, we adopt an RNN encoder using Gated Recurrent Units (GRUs) (Chung et al., 2014). Each of the GRU units processes the character embeddings sequentially. At the end of the sequence, the incremental GRU computation results in a hidden state e embedding the sentence. The encoded sentence embedding is passed through a linear layer whose output is the same size as the number of classes. We use a softmax layer to compute the posterior class probabilities:

$$P(y = j|e) = \frac{\exp(w_j^T e + b_j)}{\sum_{i=1}^{L} \exp(w_i^T e + b_i)} \quad (1)$$

To train the model, we use cross-entropy loss between predicted and true targets:

$$J = \frac{1}{B} \sum_{i=1}^{B} \sum_{j=1}^{L} -t_{i,j} \log(p_{i,j}) \quad (2)$$

where $t_{i,j} \in \{0, 1\}$ represents the ground truth label of the j-th class in the i-th Wikipedia page title. B is the batch size and L is the number of categories.

4 Fusion-based Models

One thing to note is that the LOOKUP and the VISUAL models have their own advantages. The LOOKUP model learns embedding that captures the semantics of each character symbol without sharing information with each other. In contrast, the proposed VISUAL model directly learns embedding from visual information, which naturally shares information between visually similar characters. This characteristic gives the VISUAL

Table 3: The classification results of the LOOKUP / VISUAL models for different percentages of full training size.

model the ability to generalize better to rare characters, but also has the potential disadvantage of introducing noise for characters with similar appearances but different meanings.

With the complementary nature of these two models in mind, we further combine the two embeddings to achieve better performances. We adopt three fusion schemes, early fusion, late fusion (described by Snoek et al. (2005) and Karpathy et al. (2014)), and fallback fusion, a method specific to this paper.

Early Fusion Early fusion works by concatenating the two varieties of embeddings before feeding them into the RNN. In order to ensure that the dimensions of the RNN are the same after concatenation, the concatenated vector is fed through a hidden layer to reduce the size from $2 \times d_c$ to d_c. The whole model is then fine-tuned with training data.

Late Fusion Instead of learning a joint representation like early fusion, late fusion averages the model predictions. Specifically, it takes the output of the softmax layers from both models and averages the probabilities to create a final distribution used to make the prediction.

Fallback Fusion Our final fallback fusion method hypothesizes that our VISUAL model does better with instances which contain more rare characters. First, in order to quantify the overall rareness of an instance consisting of multiple characters, we calculate the average training set frequency of the characters therein. The fallback fusion method uses the VISUAL model to predict testing instances with average character frequency below or equal to a threshold (here we use 0.0 frequency as cutoff, which means all characters in the instance do not appear in the training set), and uses the LOOKUP model to predict the rest of the instances.

5 Experiments and Results

In this section, we compare our proposed VISUAL model with the baseline LOOKUP model through three different sets of experiments. First, we examine whether our model is capable of classifying text and achieving similar performance as the baseline model. Next, we examine the hypothesis that our model will outperform the baseline model when dealing with low frequency characters. Finally, we examine the fusion methods described in Section 4.

5.1 Experimental Configurations

The dimension of the embeddings and batch size for both models are set to $d_c = 128$ and $B = 400$, respectively. We build our proposed model using Torch (Collobert et al., 2002), and use Adam (Kingma and Ba, 2014) with a learning rate $\eta = 0.001$ for stochastic optimization. The length of each instance is cut off or padded to 10 characters for batch training.

5.2 Comparison with the Baseline Model

In this experiment, we examine whether our VISUAL model achieves similar performance with the baseline LOOKUP model in classification accuracy.

The results in Tab. 3 show that the baseline model performs 1-2% better across four datasets; this is due to the fact that the LOOKUP model can directly learn character embeddings that capture the semantics of each character symbol for frequent characters. In contrast, the VISUAL model learns embeddings from visual information, which constraints characters that has similar appearance to have similar embeddings. This is an advantage for rare characters, but a disadvantage for high frequency characters because being similar in appearance does not always lead to similar semantics.

To demonstrate that this is in fact the case, besides looking at the overall classification accuracy, we also examine the performance on classifying low frequency instances which are sorted according to the average training set frequency of the characters therein. Tab. 4 and Fig. 4 both show that our model performs better in the 100 lowest frequency instances (the intersection point of the two models). More specifically, take Fig. 4(a)' as example, the solid (proposed) line is higher than the dashed (baseline) line up to 10^2, indicating that the proposed model outperforms the baseline for the

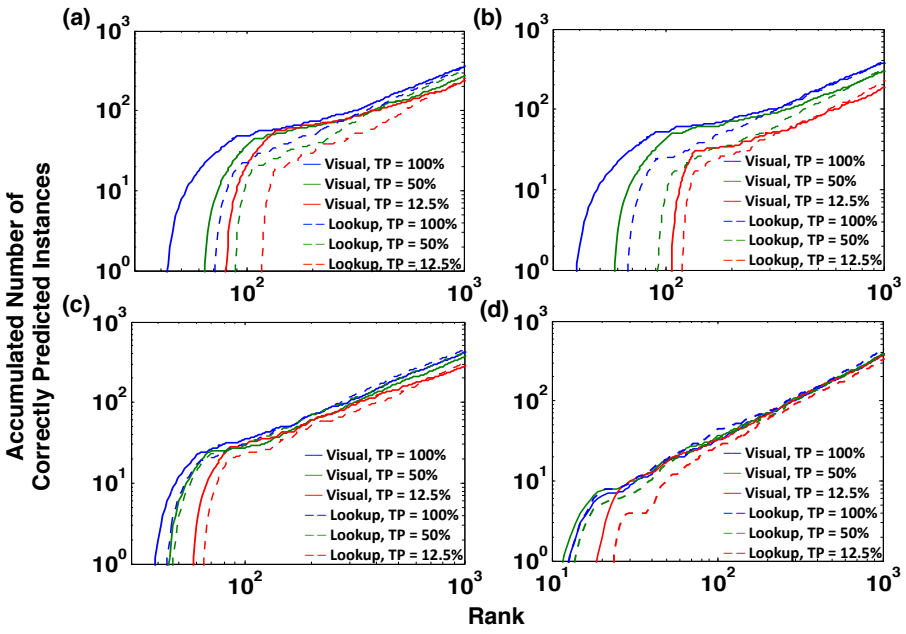

Figure 4: Experiments on different training sizes for four different datasets. More specifically, we consider three different training data size percentages (TPs) (100%, 50%, and 12.5%) and four datasets: (a) traditional Chinese, (b) simplified Chinese, (c) Japanese, and (d) Korean. We calculate the accumulated number of correctly predicted instances for the VISUAL model (solid lines) and the LOOKUP model (dashed lines). This figure is a log-log plot, where x-axis shows rarity (rarest to the left), y-axis shows cumulative correctly classified instances up to this rank; a perfect classifier will result in a diagonal line.

first 100 instances. Lines depart the x-axis when the model classifies its first instance correctly, and the LOOKUP model did not correctly classify any of the first 80 rarest instances, resulting in it crossing later than the proposed model. This confirms that the VISUAL model can share visual information among characters and help to classify low frequency instances.

For training time, visual features take significantly more time, as expected. VISUAL is 30x slower than LOOKUP, although they are equivalent at test time. For space, images of Chinese characters took 36MB to store for 8985 characters.

5.3 Experiments on Different Training Sizes

In our second experiment, we consider two smaller training sizes (i.e., 50% and 12.5% of the full training size) indicated by green and red lines in Fig. 4. We performed this experiment under the hypothesis that because the proposed method was more robust to infrequent characters, the proposed model may perform better in low-resourced scenarios. If this is the case, the intersection point of the two models will shift right because of the increase of the number of instances with low average character frequency.

Lookup/Visual	100	1000	10000
zh_trad	0.22/**0.49**	0.35/0.35	**0.40**/0.39
zh_simp	0.25/**0.53**	**0.39**/0.37	**0.41**/0.40
ja	0.30/**0.35**	**0.45**/0.41	**0.44**/0.41
ko	**0.44**/0.33	**0.44**/0.33	**0.48**/0.42

Table 4: Classification results for the LOOKUP / VISUAL of the k lowest frequency instances across four datasets. The 100 lowest frequency instances for traditional and simplified Chinese and Korean were both significant (p-value < 0.05). Those for Japanese were not (p-value = 0.13); likely because there was less variety than Chinese and more data than Korean.

As we can see in Fig. 4, the intersection point for 100% training data lies between the intersection point for 50% training data and 12.5%. This disagrees with our hypothesis; this is likely because while the number of low-frequency characters increases, smaller amounts of data also adversely impact the ability of CNN to learn useful visual features, and thus there is not a clear gain nor loss when using the proposed method.

As a more extreme test of the ability of our proposed framework to deal with the unseen char-

late	**0.5658**	**0.5685**	**0.5029**	**0.4869**
fall	0.5507	0.5547	0.4914	0.4766

Table 5: Experiment results for three different fusion methods across 4 datasets. The late fusion model was better (p-value < 0.001) across four datasets.

acters in the test set, we use traditional Chinese as our training data and simplified Chinese as our testing data. The model was able to achieve around 40% classification accuracy when we use the full training set, compared to 55%, which is achieved by the model trained on simplified Chinese. This result demonstrates that the model is able to transfer between similar scripts, similarly to how most Chinese speakers can guess the meaning of the text, even if it is written in the other script.

5.4 Experiment on Different Fusion Methods

Results of different fusion methods can be found in Tab. 5. The results show that late fusion gives the best performance among all the fusion schemes combining the LOOKUP model and the proposed VISUAL model. Early fusion achieves small improvements for all languages except Japanese, where it displays a slight drop. Unsurprisingly, fallback fusion performs better than the LOOKUP model and the VISUAL model alone, since it directly targets the weakness of the LOOKUP model (e.g., rare characters) and replaces the results with the VISUAL model. These results show that simple integration, no matter which schemes we use, is beneficial, demonstrating that both methods are capturing complementary information.

5.5 Visualization of Character Embeddings

Finally, we qualitatively examine what is learned by our proposed model in two ways. First, we visualize which parts of the image are most important to the VISUAL model's embedding calculation. Second, we show the 6-nearest neighbor results for characters using both the LOOKUP and the VISUAL embeddings.

Figure 5: Examples of how much each part of the character contributes to its embedding (the darker the more). Two characters are shown per radical to emphasize that characters with same radical have similar patterns.

Emphasis of the VISUAL Model In order to delve deeper into what the VISUAL model has learned, we measure a modified version of the occlusion sensitivity proposed by Zeiler and Fergus (2014) by masking the original character image in four ways, and examine the importance of each part of the character to the model's calculated representations. Specifically, we leave only the upper half, bottom half, left half, or right half of the image, and mask the remainder with white pixels since Chinese characters are usually formed by combining two radicals vertically or horizontally. We run these four images forward through the CNN part of the model and calculate the L_2 distance between the masked image embeddings with the full image embedding. The larger the distance, the more the masked part of the character contributes to the original embedding. The contribution of each part (e.g. the L_2 distance) is represented as a heat map, and then it is normalized to adjust the opacity of the character strokes for better visualization. The value of each corner of the heatmap is calculated by adding the two L_2 distances that contribute to this corner.

The visualization is shown in Fig. 5. The meaning of each Chinese character in English is shown below the Chinese character. The opacity of the character strokes represent how much the corresponding parts contribute to the original embedding (the darker the more). In general, the darker part of the character is related to its semantics. For example, "金" means gold in Chinese, which is

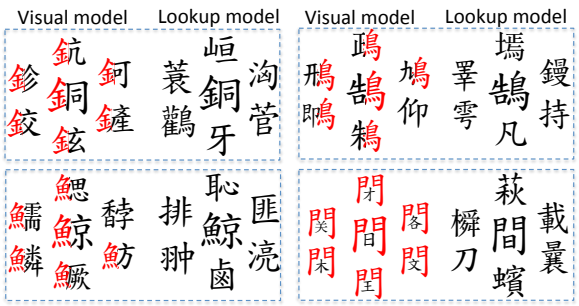

Figure 6: Visualization of the Chinese traditional characters by finding the 6-nearest neighbors of the query (i.e., center) characters. The highlighted red indicates the radical along with the meaning of the characters.

highlighted in both "鐵" (Iron) and "銅" (Bronze). We can also find similar results for other examples shown in Fig. 5. Fig. 5 also demonstrated that our model captures the compositionality of Chinese characters, both meaning of sub-character units and their structure (e.g. the semantic content tends to be structurally localized on one side of a Chinese character).

K-nearest neighbors Finally, to illustrate the difference of the learned embeddings between the two models, we display 6-nearest neighbors (L_2 distance) for selected characters in Fig. 6. As can be seen, the VISUAL embedding for characters with similar appearances are close to each other. In addition, similarity in the radical part indicates semantic similarity between the characters. For example, the characters with radical "鳥" all refer to different type of birds.

The LOOKUP embedding do not show such feature, as it learns the embedding individually for each symbol and relies heavily on the training set and the task. In fact, the characters shown in Fig. 6 for the LOOKUP model do not exhibit semantic similarity either. There are two potential explanations for this: First, the category classification task that we utilized do not rely heavily on the fine-grained semantics of each character, and thus the LOOKUP model was able to perform well without exactly capturing the semantics of each character precisely. Second, the Wikipedia dataset contains a large number of names and location and the characters therein might not have the same semantic meaning used in daily vocabulary.

6 Related Work

Methods that utilize neural networks to learn distributed representations of words or characters have been widely developed. However, word2vec (Mikolov et al., 2013), for example, requires storing an extremely large table of vectors for all word types. For example, due to the size of word types in twitter tweets, work has been done to generate vector representations of tweets at character-level (Dhingra et al., 2016).

There is also work done in understanding mathematical expressions with a convolutional network for text and layout recognition by using an attention-based neural machine translation system (Deng et al., 2016). They tested on real-world rendered mathematical expressions paired with LaTeX markup and show the system is effective at generating accurate markup. Other than that, there are several works that combine visual information with text in improving machine translation (Sutskever et al., 2014), visual question answering, caption generation (Xu et al., 2015), etc. These works extract image representations from a pre-trained CNN (Zhu et al., 2016; Wang et al., 2016).

Unrelated to images, CNNs have also been used for text classification (Kim, 2014; Zhang et al., 2015). These models look at the sequential dependencies at the word or character-level and achieve the state-of-the-art results. These works inspire us to use CNN to extract features from image and serve as the input to the RNN. Our model is able to directly back-propagate the gradient all the way through the CNN, which generates visual embeddings, in a way such that the embedding can contain both semantic and visual information.

Several techniques for reducing the rare words effects have been introduced in the literature, including spelling expansion (Habash, 2008), dictionary term expansion (Habash, 2008), proper name transliteration (Daumé and Jagarlamudi, 2011), treating words as a sequence of characters (Luong and Manning, 2016), subword units (Sennrich et al., 2015), and reading text as bytes (Gillick et al., 2015). However, most of these techniques still have no mechanism for handling low frequency characters, which are the target of this work.

Finally, there are works on improving embeddings with radicals, which explicitly splits Chinese characters into radicals based on a dictionary

of what radicals are included in which characters (Li et al., 2015; Shi et al., 2015; Yin et al., 2016). The motivation of this method is similar to ours, but is only applicable to Chinese, in contrast to the method in this paper, which works on any language for which we can render text.

7 Conclusion and Future Work

In this paper, we proposed a new framework that utilizes appearance of characters, convolutional neural networks, recurrent neural networks to learn embeddings that are compositional in the component parts of the characters. More specifically, we collected a Wikipedia dataset, which consists of short titles of three different languages and satisfies the compositionality in the characters of the language. Next, we proposed an end-to-end model that learns visual embeddings for characters using CNN and showed that the features extracted from the CNN include both visual and semantic information. Furthermore, we showed that our VISUAL model outperforms the LOOKUP baseline model in low frequency instances. Additionally, by examining the character embeddings visually, we found that our VISUAL model is able to learn visually related embeddings.

In summary, we tackled the problem of rare characters by using embeddings learned from images. In the future, we hope to further generalize this method to other tasks such as pronunciation estimation, which can take advantage of the fact that pronunciation information is encoded in parts of the characters as demonstrated in Fig. 1, or machine translation, which could benefit from a wholistic view that considers both semantics and pronunciation. We also hope to apply the model to other languages with complicated compositional writing systems, potentially including historical texts such as hieroglyphics or cuneiform.

Abstract

Previous studies on Chinese semantic role labeling (SRL) have concentrated on a single semantically annotated corpus. But the training data of single corpus is often limited. Whereas the other existing semantically annotated corpora for Chinese SRL are scattered across different annotation frameworks. But still, Data sparsity remains a bottleneck. This situation calls for larger training datasets, or effective approaches which can take advantage of highly heterogeneous data. In this paper, we focus mainly on the latter, that is, to improve Chinese SRL by using heterogeneous corpora together. We propose a novel progressive learning model which augments the Progressive Neural Network with Gated Recurrent Adapters. The model can accommodate heterogeneous inputs and effectively transfer knowledge between them. We also release a new corpus, Chinese SemBank, for Chinese SRL[1]. Experiments on CPB 1.0 show that our model outperforms state-of-the-art methods.

1 Introduction

Semantic role labeling (SRL) is one of the fundamental tasks in natural language processing because of its important role in information extraction (Bastianelli et al., 2013), statistical machine translation (Aziz et al., 2016; Xiong et al., 2012), and so on.

However, state-of-the-art performance of Chinese SRL is still far from satisfactory. And data sparsity has been a bottleneck which can not be ignored. For English, the most commonly used benchmark dataset PropBank (Xue and Palmer, 2003) has about 54,900 sentences. But for Chinese, there are only 10,364 sentences in Chinese PropBank 1.0 (CPB) (with about 35,700 propositions) (Xue, 2008).

(They, to, system, made, revise .)

Figure 1: Sentences from (**a**) CPB and (**b**) our heterogeneous dataset. In CPB, each predicate (e.g., 修改) has a specific set of core roles given with numbers (e.g., *Arg0*). While our dataset uses a different semantic role set, and all roles are non-predicate-specific.

To mitigate the data sparsity, models incorporating heterogeneous resources have been introduced to improve Chinese SRL performance (Wang et al., 2015; Guo et al., 2016; Li et al., 2016). The heterogeneous resources introduced by these models include other semantically annotated corpora with annotation schema different to that used in PropBank, and even of a different language. The challenge here lies in the fact that those newly introduced resources are heterogeneous in nature, without sharing the same tagging schema, semantic role set, syntactic tag set and domain. For example, Wang et al. (2015) introduced a heterogeneous dataset, Chinese NetBank, by pretraining word embeddings. Specifically, they learn an LSTM RNN model based on NetBank first, then initialize a new model with the

pretrained embeddings obtained from NetBank, and then train it on CPB. Chinese NetBank (Yulin, 2007) is also a corpus annotated with semantic roles, but using a very different role set and annotation schema. Wang's method can inherit knowledge acquired from other resources conveniently, but only at word representation level, missing more generalized semantic meanings in higher hidden layers. Li (2016) proposed a two-pass training approach to use corpora of two languages, but a few non-common roles are ignored in the first pass. Guo et al. (2016) proposed a unified neural network model for SRL and *relation classification* (RC). It can learn two tasks at the same time, but cannot filter out harmful features learned in incompatible tasks.

Recently, *Progressive Neural Networks* (PNN) model was proposed by Rusu et al. (2016) to transfer learned reinforcement learning policies from one game to another, or from simulation to the real robot. PNN "freezes" learned parameters once starting to learn a new task, and it uses lateral connections, namely adapter, to access previously learned features.

Inspired by the PNN model, we propose a progressive learning model to Chinese semantic role labeling in this paper. Especially, we extend the model with Gated Recurrent Adapters (GRA). Since the standard PNN takes pixels as input, policies as output, it is not suitable for SRL task we focus in this context. Moreover, to handle long sentences in the corpus, we enhance adapters with internal memories, and gates to keep the gradient stable. The contributions of this paper are threefold:

1. We reconstruct PNN columns with bidirectional LSTMs to introduce heterogeneous corpora to improve Chinese SRL. The architecture can also be applied to a wider range of NLP tasks, like event extraction and relation classification, etc.

2. We further extend the model with GRA to remember and take advantage of what has been transferred, thus improve the performance on long sentences.

3. We also release a new corpus, Chinese SemBank, which was annotated with the schema different to that used in CPB. We hope that it will be helpful for future work on SRL tasks.

Subjective roles: agent(施事), co-agent(同事), experiencer(当事) , indirect experiencer(接事)
Objective roles: patient(受事), relative(系事), dative(与事) , result(结果), content(内容), target(对象)
Space roles: a point of departure(起点) , a point of arrival(终点) , path(路径), direction(方向), location(处所)
Time roles: start time(起始), end time(结束), time point(时点) , duration(时段)
Comparison roles: comparison subject(比较主体), comparison object(比较对象) , comparison range(比较范围), comparison thing(比较项目) , comparison result(比较结果)
Others: instrument(工具) , material(材料) , manner(方式) , quantity(物量) , range(范围) , reason(原因) , purpose(目的)

Table 1: Semantic roles in Chinese SemBank

We use our new corpus as a heterogeneous resource, and evaluate the proposed model on the benchmark dataset CPB 1.0. The experiment shows that our approach achieves 79.67% F1 score, significantly outperforms existing state-of-the-art systems by a large margin (Section 5).

2 Heterogeneous Corpora for Chinese SRL

In this paper, we provide a new SRL corpus Chinese SemBank (CSB) and use it as an example of heterogeneous data in our experiments. In this section, we first briefly introduce the corpus, then compare it to existing corpora.

Sentences in CSB are from various sources including online articles and news. The vision of this project is to build a very large and complete Chinese semantic corpus in the future. Currently, it only focuses on the predicate-argument structures in a sentence without annotation of the temporal relations and coreference. CBS is different with respect to commonly used dataset CPB in the following aspects:

- In terms of predicate, CSB takes wider range of predicates into account. We not only annotated common verbs, but also nominal verbs, as NomBank does, and state words. Whereas

CPB only annotate common verbs as predicates.

- In terms of semantic roles, CSB has a more fine-grained semantic role set. There are 31 roles defined in five types (as Table. 1 shows). Whereas in CPB, there are totally 23 roles, including core roles and non-core roles.

- CSB does not have any pre-defined frames for predicates because all roles are set to be non-predicate-specific. The reason for not defining frames is that frames may lead inconsistencies in labels. For example, according to Chinese verb formation theory (Sun et al., 2009), in CPB, an *agent* of a verb is often marked as its *Arg0*, but not all *Arg0* are agents. Therefore, roles are defined for predicates with similar syntactic and semantic regularities, rather than single predicate.

Two direct benefits of using stand-alone non-predicate-specific roles are: First, meanings of all semantic roles can be directly inferred from their labels. For instance, roles of things that people are telling (谈) or looking (看) are labeled as 内容/*content*, because verbs like 谈 and 看 are often followed by an object. Second, we can easily annotate sentences with new predicates without defining new frame files.

Other Corpora for Chinese SRL Other popular semantic role labeling corpora include Chinese NomBank (Xue, 2006), Peking University Chinese NetBank (Yulin, 2007). NomBank, often used as a complement to PropBank, annotates nominal predicates and semantic roles according to the similar semantic schema as PropBank does. Peking University Chinese NetBank was created by adding a semantic layer to Peking University Chinese TreeBank (Zhou et al., 1997). It only uses non-predicate-specific roles as we do. And its role set is smaller, which has 20 roles.

3 Challenges in Inheriting Knowledge from Heterogeneous Corpora

Although there are a lot of annotated corpora for Chinese SRL as we mentioned in the previous section, most of them are quite small as compared to that in English. *Data sparsity* remains a bottleneck. This situation calls for larger training dataset, or effective approaches which can take advantage of very heterogeneous datasets. In this paper, we focus on the second problem, that is, *to improve Chinese SRL by using heterogeneous corpora together within one model*.

We will consider the combination of the standard benchmark, CPB 1.0 dataset (Xue and Palmer, 2003), with the new corpus, CSB, because there are a lot of differences between them, as we discussed in Section 2. Consequently, a number of challenges arise for this task. Now we describe them as below.

Inheriting from Different Schema and Role Sets. CPB was annotated with PropBank-style frames and roles, whereas Chinese FrameNet uses its own frames and roles. And our dataset has no frame files and use different role set. Therefore, it is hard to find explicit mapping or hierarchical relationships among their role sets, or decide which system is better, especially when there are more than two resources.

Inheriting from Different Domain/Genre. The datasets mentioned above are composed of sentences from various sources, including news and stories, etc. However, it is well known that adding data in very different genre to training data may hurt parser performance (Bikel, 2004). Therefore, we also need to deal with domain adaptation problem when using heterogeneous data. In other words, the proposed approach should be robust to harmful features learned on incompatible datasets. It can also accommodate potentially different model structures and inputs in the procedure of knowledge fusion.

Inheriting from Different Syntactic Annotation. Unlikes English, previous works (Ding and Chang, 2009; Sun et al., 2009) on Chinese SRL task often use both correct segmentation and part-of-speech tagging, and even treebank gold-standard parses (Xue, 2008) as their features. But some corpora like CPB and NetBank do not share the same PoS tag set, or do not have correct PoS tagging and gold treebank parses at all, like CSB. And in real application scenarios, it is more convenient to use automatic PoS tagging instead of gold-standard tagging on large datasets, as they can be obtained quickly. So to deal with the absence of syntactic features, we adopt automatic PoS tagging when training on CSB in this work.

Some previous techniques, such as finetuning after pretraining (Wang et al., 2015; Li et al., 2016) and multi-task learning (Guo et al., 2016), have

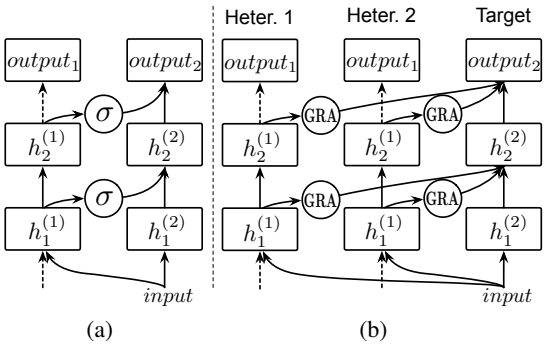

Figure 2: Depiction of the standard Progressive Neural Network architecture (a) and ours PNN GRA model (b). Our model uses Gated Recurrent Adapters (GRA), instead of sigmoid adapters to access previous knowledge in previous columns learned on heterogeneous data. If there are more than one heterogeneous resources available, more columns can be added on the left.

been used to deal with these challenges. Though they can also leverage knowledge from different domains, they have following drawbacks: finetuning cannot avoid catastrophic forgetting because learned parameters, whether embeddings or other hidden weights, will be tuned after the model has been initialized; And multi-task learning cannot ignore previously learned harmful features because some features are learned in shared layers, although it avoids forgetting by randomly selecting a task to learn at each iteration. Therefore, to solve the above-mentioned challenges, we further introduce progressive learning which we believe is more suitable for the task.

4 Progressive Learning Approach

We propose a progressive learning approach which is ideal for combining heterogeneous SRL data for multiple reasons. First, it can accommodate dissimilar inputs with different schema, syntactic information and domain, because it allow models for heterogeneous resources to be extremely different, such as different network structures, different width, and different learning rates, etc. Second, it is immune to forgetting by freezing learned weights and can leverage prior knowledge via lateral connections. Third, the lateral connections can be extended with recurrent structure and gate mechanism to handle with forgetting problem over long distance.

Our model is mainly inspired by Rusu et al. (2016). They proposed *progressive neural networks* for a wide variety of reinforcement learning tasks (e.g. Atari games and robot simulation). In their cases, inputs are pixels, outputs are learned policies. And each column, consisting of simple layers and convolutional layers, is trained to solve a particular Markov Decision Process. But in our case, inputs are sentences annotated using different syntactic tagsets and outputs are semantic role sequences. So we change the structure of columns to recurrent neural networks with LSTM, similar to the model proposed by Wang et al. (2015). Below we first introduce basic progressive neural network architecture, then describe our model, PNN with gated recurrent adapters.

4.1 Progressive Neural Networks

Fig. 2a is an illustration of the basic progressive neural network model. It starts with single column (a neural network), in which there are L hidden layers and the output for ith layer ($i \leq L$) with n_i units is $h_i^1 \in \mathbb{R}^{n_i}$. Θ^1 denotes the parameters to be learned in the first column. When switching to a second corpus, it "freezes" the parameter Θ^1 and randomly initialize a new column with parameters Θ^2 and several lateral connections between two columns so that layer h_i^2 can receive input from both h_{i-1}^2 and h_{i-1}^1. In this straightforward manner, progressive neural networks can make use of columns with any structures or to compile lateral connections in an ensemble setting. To be more general, we calculate the output of ith layer in kth column h_i^k by:

$$h_i^k = f(W_i^k h_{i-1}^k + \sum_{j<k} U_i^{(k:j)} h_{i-1}^j) \qquad (1)$$

where $W_i^k \in \mathbb{R}^{n_i^k \times n_{i-1}^k}$ is the weight matrix of layer i of column k, $U_i^{(k:j)} \in \mathbb{R}^{n_i^k \times n_{i-1}^j}$ are the lateral connections to transfer information from layer $i-1$ of column j to layer i of column k, h_0 is the input of the network. f can be any activation function, such as element-wise non-linearity. Bias term was omitted in the equation.

Adapters. With implicit assumption that there is some "overlap" between the first task and the second task, pretrain-and-finetune learning paradigm is effective, as only slight adjustment to parameters is needed to learn new features. Progressive networks also have ability to transfer knowledge from previous tasks to improve convergence

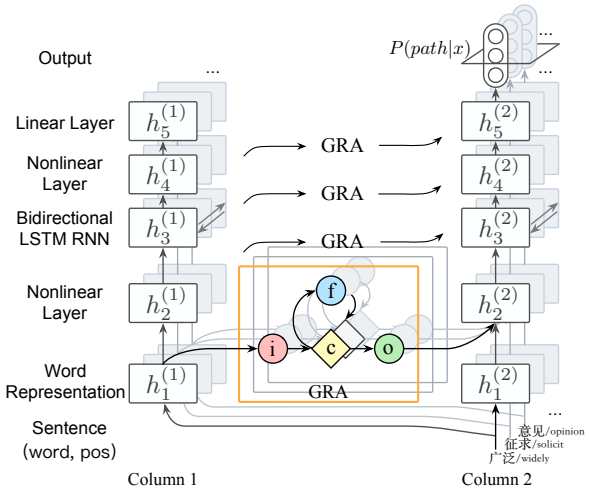

Figure 3: Each column is a stacked bidirectional LSTM RNN model. Two columns are connected by GRAs. There are three gates in each GRA: g_i, g_f, and g_o. The input gate g_i and the forget gate g_f can also be coupled as one uniform gate, that is $g_i = 1 - g_f$.

speed. On the one hand, the model reuse previously learned features from left columns via lateral connections (i.e., *adapters*). On the other hand, new features can be learned by adding more columns incrementally. Moreover, when the "overlap" between two tasks is small, lateral connections can filter out harmful features by sigmoid functions. So in practice, the output of adapters can also be calculated by

$$a_i^{(k:j)} = \sigma(A_i^{(k:j)} \alpha_{i-1}^j h_{i-1}^j) \quad (2)$$

where $A_i^{(k:j)}$ is a matrix to be learned. We treat Equation 2 as one of baseline settings in experiments.

4.2 PNN with Gated Recurrent Adapter for Chinese SRL

We reconstruct PNN with bidirectional LSTM to solve SRL problems. Our model is illustrated in Fig. 3.

First, each column in the PNN architecture is a stacked bidirectional LSTM RNN, rather than convolutional neural networks, because inputs are sentences not pixels, and bi-LSTM RNN has proved powerful for Chinese SRL (Wang et al., 2015).

Second, we enhance the adapter with recurrent structure and gate mechanism, because the simple Multi-Layer Perceptron (MLP) adapters have a limitation: their weights are learned word after word independently. For tasks like transferring reinforcement learning policies, this is enough because there are little dependencies among actions. But in NLP domain, things are different. Therefore, we add internal memory to adapters to help them remember what has been inherited from heterogeneous resource.

Third, to keep gradient stable and balance between long-term and short-term memory, we introduce gate mechanism which has been widely used in RNN models. Intuitively, we call the new adapter *Gated Recurrent Adapter* (GRA).

Formally, let $h_{i-1}^{(<k)} = [h_{i-1}^1, ..., h_{i-1}^j, ..., h_{i-1}^{k-1}]$ be the outputs of $i-1$ layers from the first column to the $(k-1)$th column. The dimensionality of them is $n_{i-1}^{(<k)} = [n_{i-1}^1, ..., n_{i-1}^{k-1}]$. $a^{(<k)}$ is the outputs of $k-1$ adapters with dimension $m^{(<k)} = [m^1, ..., m^{k-1}]$. The output vector is multiplied by a learned matrix W_a initialized by random small values before going to GRAs. Its role is to adjust for the different scales of the different inputs and reduce the dimensionality. Formally, the candidate outputs is

$$\hat{a}_t = f(W_a^j h_t^j + U_a^j a_{t-1}^j) \quad (3)$$

where a_{t-1} is the output of the adapter at the previous time-step. U_a is a weight matrix to learn. The output of an adapter a_t^j of layer i at time t can be formalized as follows,

$$g_i = \sigma(W_i^j h_t^j + U_i^j a_{t-1}^j) \quad (4)$$
$$g_f = \sigma(W_f^j h_t^j + U_f^j a_{t-1}^j) \quad (5)$$
$$g_o = \sigma(W_o^j h_t^j + U_o^j a_{t-1}^j) \quad (6)$$
$$\tilde{a}_t = g_i \odot \hat{a}_t + g_f \odot \tilde{a}_{t-1}^j \quad (7)$$
$$a_t = g_o \odot f(\tilde{a}_{t-1}) \quad (8)$$

where $h^j \in \mathbb{R}^{m_{i-1}^j \times n_{i-1}^j}$ is the outputs of previous layers, $W_f, W_o, W_a \in \mathbb{R}^{m_{i-1} \times n_{i-1}}$, $U_f, U_o, U_a \in \mathbb{R}^{m_{i-1} \times d_{i-1}}$ are parameters to learn. d_{i-1} is the dimension of the inner memory in adapters. $\tilde{a}_t$ represents the inner state of the adapter. f is an activation function, like *tanh*. The input gate and the forget gate can be coupled as a uniform gate, that is $g_i = 1 - g_f$ to alleviate the problem of information redundancy and reduce the possibility of overfitting (Greff et al., 2015).

Finally, we calculate the output of the next layer i of column k by

$$h_i^k = f(W_i^k concat[a^{(<k)}, h_{i-1}^k]) \quad (9)$$

where $W_i \in \mathbb{R}^{n_i^{(k)} \times \sum m_{i-1}^{(<k)}}$ is the parameters in ith layer.

4.3 Training Criteria

We adopt the sentence tagging approach as Wang et al. (2015) did, because words in a sentence may closely be related with each other, independently labeling each word is inappropriate. Sentence tagging approach only consider valid transition paths of tags when calculating the cost. For example, when using IOBES tagging schema, tag transition from *I-Arg0* to *B-Arg0* is invalid, and transition from *I-Arg0* to *I-Arg1* is also invalid because the type of the role changed *inside* the semantic chunk. For each task (column), the log likelihood of sentence x and its correct path y is

$$\log p(y|x,\Theta) = \log \frac{\exp \sum_t^N o_{t,y_t}}{\sum_z \exp \sum_t^{N_i} o_{t,z_t}} \quad (10)$$

where N is the number of words, $o_t \in \mathbb{R}^M$ is the output of the last layer at time t. $y_t = k$ means the tth word has the kth semantic role label. z ranges from all the valid paths of tags.

The negative log likelihood of the whole training set D is

$$J(\Theta) = \sum_{(x,y)\in D} \log p(y|x,\Theta) \quad (11)$$

We minimize $J(\Theta)$ using stochastic gradient descent to learn network parameters Θ. When testing, the best prediction of a sentence can be found using Viterbi algorithm.

5 Experiments

5.1 Experiment Settings

To compare our approach with others, we designed four experimental setups:

(1) A simple LSTM setup on CSB and CPB with automatic PoS tagging. Since CPB is about two times as large as the new corpus, we need to know whether CSB can be used for training good semantic parsers and how much information can be learned from CSB by machine. So we conduct this experiment to provide two baselines for CSB and CPB respectively. In this setup we train and evaluate a one-column LSTM model on CSB.

(2) A simple LSTM setup on CPB with pretrained word embedding on CSB (marked as bi-LSTM+CSB embedding). Previous work found that using pretrained word embeddings can improve performance (Wang et al., 2015) on Chinese SRL. So we conduct this experiment to compare with the method using embeddings trained on large-scale unlabeled data like Gigaword [2], and NetBank.

(3) A two-column finetuning setup where we pretrain the first column on CSB and finetune both two columns on CPB. Clearly, finetuning is a traditional method for continual learning scenarios. But the disadvantage of it is that learned features will be gradually forgotten when the model is adapting new tasks. To assess this empirically, we design this experiment. The model uses the same network structure as PNN does, but it does not "freeze" parameters in the first column when tuning two columns.

(4) A progressive network setup where we train column 1 on CSB, then train column 2 and adapters on CPB. We conduct this experiment to evaluate the proposed model and compare it to all previous methods. To further analyze effectiveness of the new adapter structure, we also conduct an experiment for progressive nets with GRA.

We apply grid-search technique to explore hyper-parameters including learning rates and width of layers.

Preprocessing. We follow the same data setting as previous work (Xue, 2008; Sun et al., 2009), which divided CPB dataset[3] into three parts: 648 files, from `chtb_081.fid` to `chtb_899.fid`, are the training set; 40 files, from `chtb_041.fid` to `chtb_080.fid`, are the development set; 72 files, from `chtb_001.fid` to `chtb_040.fid`, and `chtb_900.fid` to `chtb_931.fid`, are used as the test set.

We also divide shuffled CSB corpus into three sets with similar partition ratios. Currently, there are 10634 sentences in CSB. So 8900 samples are used as training set, 500 samples as development set and the rest 965 samples as test set. We use Stanford Parser[4] for PoS tagging.

5.2 Results

Performance on Chinese SemBank Table 2 gives the results of Experiment 1. We see that precision on CPB with automatic PoS tagging is

[2] https://code.google.com/p/word2vec/
[3] https://catalog.ldc.upenn.edu/LDC2005T23
[4] http://nlp.stanford.edu/software/lex-parser.shtml

Corpus	Pr.(%)	Rec.(%)	F1(%)
1. CSB	75.80	73.45	74.61
2. CPB	76.75	73.03	74.84

Table 2: Results of Chinese SRL tested on CPB and CSB with automatic PoS tagging, using standard LSTM RNN model (Experiment 1).

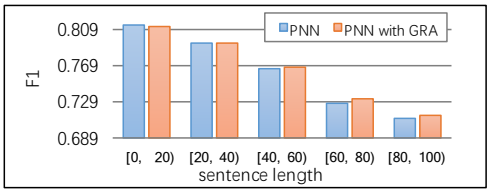

Figure 4: Performance of PNN models with and without GRAs over sentence length. For sentences shorter than 40 words, there is no big difference. But for longer sentences (≥40 words), PNN with GRA model performs significantly better.

about 0.9 percentage point higher than that on CSB, while recall is about 0.4 percentage point lower, and the gap between F1 scores on CPB and CSB is not significant, which is only about 0.3 percentage point, although the size of CSB is smaller. We can explain this by two reasons. First, CSB does not have predicate-specific roles which may lead to inconsistency, as we explained in Section 3. Thus, it might be easier to learn by machine. Second, there are underlying similarities between them: both of them annotate predicate-argument structures. So when there is sufficient training data, difference between scores on testing sets is not very likely to be huge.

Overall, the results indicated that the new annotated corpus CSB is not a bad choice for training semantic parser even when this does not involve larger training sets.

Compare to Methods without Using Heterogeneous Data Table 3 summarizes the SRL performance of previous benchmark methods and our experiments described above. Collobert and Weston only conducted their experiments on English corpus, but we notice that their approach has been implemented and tested on CPB by Wang et al. (2015), so we also put their result here for comparison. We can make several observations from these results. Our approach significantly outperforms Sha et al. (2016) by a large margin (Wilcoxon Signed Rank Test, $p < 0.05$), even without using GRA. This result can prove the ability of our model to capture underlying similarities between heterogeneous SRL resources.

Compare to Methods Using Heterogeneous Resources The results of methods using external language resources are also presented in Table 3. Not surprisingly, we see that the overall best F1 score, 79.67%, is achieved by the progressive nets with the GRAs. Furthermore, as shown in Fig. 4, PNN with GRA performs better on longer sentences, which is consistent with our expectation. Without GRA, the F1 drops 0.37% percentage point to 79.30, confirming that gated recurrent adapter structure is more suitable for our task because it can remember what has been transferred in previous time steps.

Compared to progressive learning methods, finetuning method does not perform well even with the same network structure (Two-column finetuning), but it is still better than simply pretraining word embeddings (bi-LSTM+CSB embedding). This confirms the effectiveness of multi-column learning structure which add capacity to the model by adding new columns. Therefore, as can be seen, our PNN model achieves 79.30% F1 score, outperforming finetuning by 0.88% percentage point, and pretraining embeddings by even larger margin.

To sum up, not only network structures but also learning methods (finetuning/multitask/progressive) can influence the performance of knowledge transfer. According to the results, our PNN approach is more effective than others because it is immune to forgetting and robust to harmful features, and GRA is more suitable for our task than simple adapters.

6 Related Work

6.1 Chinese Semantic Role Labeling

The concept of Semantic Role Labeling is first proposed by Gildea and Jurafsky(2002). Previous work on Chinese SRL mainly focused on how to improve SRL on single corpus. Approaches falls into two categories: feature-based machine learning approaches and neural-network-based approaches. Using feature-based method, Sun and Jurafsky (2004) did the preliminary work and achieved promising results without using any large

Table 3: Result comparison on CPB dataset. Compared to learning with single corpus using bi-LSTM model (77.09%), learning with CSB can improve the performance by at list 0.59%. Also the best score (79.67%) was achieved by the PNN GRA model.

annotated corpus. After CPB was built by Xue and Palmer (2003), more complete and systematic research on Chinese SRL were done (Xue and Palmer, 2005; Chen et al., 2006; Ding and Chang, 2009; Yang et al., 2014).

Neural network methods do not rely on handcrafted features. For Chinese SRL, Wang et al. (2015) proposed bidirectional a LSTM RNN model. And based on their work, Sha (2016) proposed quadratic optimization method as a post-processing module and further improved the result.

6.2 Learning with Heterogeneous Data

In this paper, we mainly focus on learning with heterogeneous semantic resource for Chinese SRL. Wang et al. (2015) introduced heterogeneous data by using pretrained embeddings at initialization and achieved promising results. Guo et al. (2016) proposed a multitask learning method with a unified neural network model to learn SRL and relation classification task together and also achieved improvement.

Different from previous work, we proposed a progressive neural network model with gated recurrent adapters to leverage knowledge from heterogeneous semantic data. Compared with previous methods, this approach is more constructive, rather than destructive, because it uses lateral connections to access previously learned features which are fixed when learning new tasks. And by introducing gated recurrent adapters, we further enhance our model to deal with long sentences and achieve state-of-the-art performance on Chinese PropBank.

7 Conclusion and Future Work

In this paper, we proposed a progressive neural network model with gated recurrent adapters to leverage heterogeneous corpus for Chinese SRL. Unlike previous methods like finetuning, ours leverage prior knowledge via lateral connections. Experiments have shown that our model yields better performance on CPB than all baseline models. Moreover, we proposed novel gated recurrent adapter to handle transfer on long sentences, The experiment has proved the effectiveness of the new adapter structure.

We believe that progressive learning with heterogeneous data is a promising avenue to pursue. So in the future, we might try to combine more heterogeneous semantic data for other tasks like event extraction and relation classification, etc.

We also release the new corpus Chinese SemBank for Chinese SRL. We hope that it will be helpful in providing common benchmarks for future work on Chinese SRL tasks.

Revisiting Recurrent Networks for Paraphrastic Sentence Embeddings

John Wieting **Kevin Gimpel**
Toyota Technological Institute at Chicago, Chicago, IL, 60637, USA
{jwieting,kgimpel}@ttic.edu

Abstract

We consider the problem of learning general-purpose, paraphrastic sentence embeddings, revisiting the setting of Wieting et al. (2016b). While they found LSTM recurrent networks to underperform word averaging, we present several developments that together produce the opposite conclusion. These include training on sentence pairs rather than phrase pairs, averaging states to represent sequences, and regularizing aggressively. These improve LSTMs in both transfer learning and supervised settings. We also introduce a new recurrent architecture, the GATED RECURRENT AVERAGING NETWORK, that is inspired by averaging and LSTMs while outperforming them both. We analyze our learned models, finding evidence of preferences for particular parts of speech and dependency relations. [1]

1 Introduction

Modeling sentential compositionality is a fundamental aspect of natural language semantics. Researchers have proposed a broad range of compositional functional architectures (Mitchell and Lapata, 2008; Socher et al., 2011; Kalchbrenner et al., 2014) and evaluated them on a large variety of applications. Our goal is to learn a general-purpose sentence embedding function that can be used unmodified for measuring semantic textual similarity (STS) (Agirre et al., 2012) and can also serve as a useful initialization for downstream tasks. We wish to learn this embedding function such that sentences with high semantic similarity have high cosine similarity in the embedding space. In particular, we focus on the setting of Wieting et al. (2016b), in which models are trained on noisy paraphrase pairs and evaluated on both STS and supervised semantic tasks.

Surprisingly, Wieting et al. found that simple embedding functions—those based on averaging word vectors—outperform more powerful architectures based on long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997). In this paper, we revisit their experimental setting and present several techniques that together improve the performance of the LSTM to be superior to word averaging.

We first change data sources: rather than train on noisy phrase pairs from the Paraphrase Database (PPDB; Ganitkevitch et al., 2013), we use noisy *sentence* pairs obtained automatically by aligning Simple English to standard English Wikipedia (Coster and Kauchak, 2011). Even though this data was intended for use by text simplification systems, we find it to be efficient and effective for learning sentence embeddings, outperforming much larger sets of examples from PPDB.

We then show how we can modify and regularize the LSTM to further improve its performance. The main modification is to simply average the hidden states instead of using the final one. For regularization, we experiment with two kinds of dropout and also with randomly scrambling the words in each input sequence. We find that these techniques help in the transfer learning setting and on two supervised semantic similarity datasets as well. Further gains are obtained on the supervised tasks by initializing with our models from the transfer setting.

Inspired by the strong performance of both averaging and LSTMs, we introduce a novel recurrent neural network architecture which we call

[1] Trained models and code are available at http://ttic.uchicago.edu/~wieting.

the GATED RECURRENT AVERAGING NETWORK (GRAN). The GRAN outperforms averaging and the LSTM in both the transfer and supervised learning settings, forming a promising new recurrent architecture for semantic modeling.

2 Related Work

Modeling sentential compositionality has received a great deal of attention in recent years. A comprehensive survey is beyond the scope of this paper, but we mention popular functional families: neural bag-of-words models (Kalchbrenner et al., 2014), deep averaging networks (DANs) (Iyyer et al., 2015), recursive neural networks using syntactic parses (Socher et al., 2011, 2012, 2013; İrsoy and Cardie, 2014), convolutional neural networks (Kalchbrenner et al., 2014; Kim, 2014; Hu et al., 2014), and recurrent neural networks using long short-term memory (Tai et al., 2015; Ling et al., 2015; Liu et al., 2015). Simple operations based on vector addition and multiplication typically serve as strong baselines (Mitchell and Lapata, 2008, 2010; Blacoe and Lapata, 2012).

Most work cited above uses a supervised learning framework, so the composition function is learned discriminatively for a particular task. In this paper, we are primarily interested in creating general purpose, domain independent embeddings for word sequences. Several others have pursued this goal (Socher et al., 2011; Le and Mikolov, 2014; Pham et al., 2015; Kiros et al., 2015; Hill et al., 2016; Arora et al., 2017; Pagliardini et al., 2017), though usually with the intent to extract useful features for supervised sentence tasks rather than to capture semantic similarity.

An exception is the work of Wieting et al. (2016b). We closely follow their experimental setup and directly address some outstanding questions in their experimental results. Here we briefly summarize their main findings and their attempts at explaining them. They made the surprising discovery that word averaging outperforms LSTMs by a wide margin in the transfer learning setting. They proposed several hypotheses for why this occurs. They first considered that the LSTM was unable to adapt to the differences in sequence length between phrases in training and sentences in test. This was ruled out by showing that neither model showed any strong correlation between sequence length and performance on the test data.

They next examined whether the LSTM was overfitting on the training data, but then showed that both models achieve similar values of the training objective and similar performance on *in-domain* held-out test sets. Lastly, they considered whether their hyperparameters were inadequately tuned, but extensive hyperparameter tuning did not change the story. Therefore, the reason for the performance gap, and how to correct it, was left as an open problem. This paper takes steps toward addressing that problem.

3 Models and Training

3.1 Models

Our goal is to embed a word sequence s into a fixed-length vector. We focus on three compositional models in this paper, all of which use words as the smallest unit of compositionality. We denote the tth word in s as s_t, and we denote its word embedding by x_t.

Our first two models have been well-studied in prior work, so we describe them briefly. The first, which we call AVG, simply averages the embeddings x_t of all words in s. The only parameters learned in this model are those in the word embeddings themselves, which are stored in the word embedding matrix W_w. This model was found by Wieting et al. (2016b) to perform very strongly for semantic similarity tasks.

Our second model uses a long short-term memory (LSTM) recurrent neural network (Hochreiter and Schmidhuber, 1997) to embed s. We use the LSTM variant from Gers et al. (2003) including its "peephole" connections. We consider two ways to obtain a sentence embedding from the LSTM. The first uses the final hidden vector, which we denote h_{-1}. The second, denoted LSTMAVG, averages all hidden vectors of the LSTM. In both variants, the learnable parameters include both the LSTM parameters W_c and the word embeddings W_w.

Inspired by the success of the two models above, we propose a third model, which we call the GATED RECURRENT AVERAGING NETWORK (GRAN). The GATED RECURRENT AVERAGING NETWORK combines the benefits of AVG and LSTMs. In fact it reduces to AVG if the output of the gate is all ones. We first use an LSTM to generate a hidden vector, h_t, for each word s_t in s. Then we use h_t to compute a gate that will be elementwise-multiplied with x_t, resulting in a new, gated hidden vector a_t for each step t:

$$a_t = x_t \odot \sigma(W_x x_t + W_h h_t + b) \quad (1)$$

where W_x and W_h are parameter matrices, b is a parameter vector, and σ is the elementwise logistic sigmoid function. After all a_t have been generated for a sentence, they are averaged to produce the embedding for that sentence. This model includes as learnable parameters those of the LSTM, the word embeddings, and the additional parameters in Eq. (1). For both the LSTM and GRAN models, we use W_c to denote the "compositional" parameters, i.e., all parameters other than the word embeddings.

The motivation for the GRAN is that we are contextualizing the word embeddings prior to averaging. The gate can be seen as an attention, attending to the prior context of the sentence.[2]

We also experiment with four other variations of this model, though they generally were more complex and showed inferior performance. In the first, GRAN-2, the gate is applied to h_t (rather than x_t) to produce a_t, and then these a_t are averaged as before.

GRAN-3 and GRAN-4 use two gates: one applied to x_t and one applied to a_{t-1}. We tried two different ways of computing these gates: for each gate i, $\sigma(W_{x_i}x_t + W_{h_i}h_t + b_i)$ (GRAN-3) or $\sigma(W_{x_i}x_t + W_{h_i}h_t + W_{a_i}a_{t-1} + b_i)$ (GRAN-4). The sum of these two terms comprised a_t. In this model, the last average hidden state, a_{-1}, was used as the sentence embedding after dividing it by the length of the sequence. In these models, we are additionally keeping a running average of the embeddings that is being modified by the context at every time step. In GRAN-4, this running average is also considered when producing the contextualized word embedding.

Lastly, we experimented with a fifth GRAN, GRAN-5, in which we use two gates, calculated by $\sigma(W_{x_i}x_t + W_{h_i}h_t + b_i)$ for each gate i. The first is applied to x_t and the second is applied to h_t. The output of these gates is then summed. Therefore GRAN-5 can be reduced to either word-averaging or averaging LSTM states, depending on the behavior of the gates. If the first gate is all ones and the second all zeros throughout the sequence, the model is equivalent to word-averaging. Conversely, if the first gate is all zeros and the second is all ones throughout the sequence, the model is equivalent to averaging the LSTM states. Further analysis of these models is included in Section 4.

[2]We tried a variant of this model without the gate. We obtain a_t from $f(W_x x_t + W_h h_t + b)$, where f is a nonlinearity, tuned over tanh and ReLU. The performance of the model is significantly worse than the GRAN in all experiments.

3.2 Training

We follow the training procedure of Wieting et al. (2015) and Wieting et al. (2016b), described below. The training data consists of a set S of phrase or sentence pairs $\langle s_1, s_2 \rangle$ from either the Paraphrase Database (PPDB; Ganitkevitch et al., 2013) or the aligned Wikipedia sentences (Coster and Kauchak, 2011) where s_1 and s_2 are assumed to be paraphrases. We optimize a margin-based loss:

$$\min_{W_c, W_w} \frac{1}{|S|} \Bigg(\sum_{\langle s_1, s_2 \rangle \in S} \max(0, \delta - \cos(g(s_1), g(s_2)) + \cos(g(s_1), g(t_1))) + \max(0, \delta - \cos(g(s_1), g(s_2)) + \cos(g(s_2), g(t_2))) \Bigg) + \lambda_c \left\| W_c \right\|^2 + \lambda_w \left\| W_{w_{initial}} - W_w \right\|^2 \tag{2}$$

where g is the model in use (e.g., AVG or LSTM), δ is the margin, λ_c and λ_w are regularization parameters, $W_{w_{initial}}$ is the initial word embedding matrix, and t_1 and t_2 are carefully-selected negative examples taken from a mini-batch during optimization. The intuition is that we want the two phrases to be more similar to each other ($\cos(g(s_1), g(s_2))$) than either is to their respective negative examples t_1 and t_2, by a margin of at least δ.

3.2.1 Selecting Negative Examples

To select t_1 and t_2 in Eq. (2), we simply choose the most similar phrase in some set of phrases (other than those in the given phrase pair). For simplicity we use the mini-batch for this set, but it could be a different set. That is, we choose t_1 for a given $\langle s_1, s_2 \rangle$ as follows:

$$t_1 = \operatorname*{argmax}_{t : \langle t, \cdot \rangle \in S_b \setminus \{\langle s_1, s_2 \rangle\}} \cos(g(s_1), g(t))$$

where $S_b \subseteq S$ is the current mini-batch. That is, we want to choose a negative example t_i that is similar to s_i according to the current model. The downside is that we may occasionally choose a phrase t_i that is actually a true paraphrase of s_i.

4 Experiments

Our experiments are designed to address the empirical question posed by Wieting et al. (2016b): why do LSTMs underperform AVG for transfer

learning? In Sections 4.1.2-4.2, we make progress on this question by presenting methods that bridge the gap between the two models in the transfer setting. We then apply these same techniques to improve performance in the supervised setting, described in Section 4.3. In both settings we also evaluate our novel GRAN architecture, finding it to consistently outperform both AVG and the LSTM.

4.1 Transfer Learning

4.1.1 Datasets and Tasks

We train on large sets of noisy paraphrase pairs and evaluate on a diverse set of 22 textual similarity datasets, including all datasets from every SemEval semantic textual similarity (STS) task from 2012 to 2015. We also evaluate on the SemEval 2015 Twitter task (Xu et al., 2015) and the SemEval 2014 SICK Semantic Relatedness task (Marelli et al., 2014). Given two sentences, the aim of the STS tasks is to predict their similarity on a 0-5 scale, where 0 indicates the sentences are on different topics and 5 indicates that they are completely equivalent. We report the average Pearson's r over these 22 sentence similarity tasks.

Each STS task consists of 4-6 datasets covering a wide variety of domains, including newswire, tweets, glosses, machine translation outputs, web forums, news headlines, image and video captions, among others. Further details are provided in the official task descriptions (Agirre et al., 2012, 2013, 2014, 2015).

4.1.2 Experiments with Data Sources

We first investigate how different sources of training data affect the results. We try two data sources. The first is phrase pairs from the Paraphrase Database (PPDB). PPDB comes in different sizes (S, M, L, XL, XXL, and XXXL), where each larger size subsumes all smaller ones. The pairs in PPDB are sorted by a confidence measure and so the smaller sets contain higher precision paraphrases. PPDB is derived automatically from naturally-occurring bilingual text, and versions of PPDB have been released for many languages without the need for any manual annotation (Ganitkevitch and Callison-Burch, 2014).

The second source of data is a set of sentence pairs automatically extracted from Simple English Wikipedia and English Wikipedia articles by Coster and Kauchak (2011). This data was extracted for developing text simplification systems, where each instance pairs a simple and complex sentence representing approximately the same information. Though the data was obtained for simplification, we use it as a source of training data for learning paraphrastic sentence embeddings. The dataset, which we call SimpWiki, consists of 167,689 sentence pairs.

	AVG	LSTM	LSTMAVG
PPDB	67.7	54.2	64.2
SimpWiki	68.4	59.3	67.5

Table 1: Test results on SemEval semantic textual similarity datasets (Pearson's $r \times 100$) when training on different sources of data: phrase pairs from PPDB or simple-to-standard English Wikipedia sentence pairs from Coster and Kauchak (2011).

To ensure a fair comparison, we select a sample of pairs from PPDB XL such that the number of tokens is approximately the same as the number of tokens in the SimpWiki sentences.[3]

We use PARAGRAM-SL999 embeddings (Wieting et al., 2015) to initialize the word embedding matrix (W_w) for all models. For all experiments, we fix the mini-batch size to 100, and λ_c to 0. We tune the margin δ over $\{0.4, 0.6, 0.8\}$ and λ_w over $\{10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}, 10^{-8}, 0\}$. We train AVG for 7 epochs, and the LSTM for 3, since it converges much faster and does not benefit from 7 epochs. For optimization we use Adam (Kingma and Ba, 2015) with a learning rate of 0.001. We use the 2016 STS tasks (Agirre et al., 2016) for model selection, where we average the Pearson's r over its 5 datasets. We refer to this type of model selection as *test*. For evaluation, we report the average Pearson's r over the 22 other sentence similarity tasks.

The results are shown in Table 1. We first note that, when training on PPDB, we find the same result as Wieting et al. (2016b): AVG outperforms the LSTM by more than 13 points. However, when training both on sentence pairs, the gap shrinks to about 9 points. It appears that part of the inferior performance for the LSTM in prior work was due to training on phrase pairs rather than on sentence pairs. The AVG model also benefits from training on sentences, but not nearly as much as the LSTM.[4]

[3]The PPDB data consists of 1,341,188 phrase pairs and contains 3 more tokens than the SimpWiki data.

[4]We experimented with adding EOS tags at the end of training and test sentences, SOS tags at the start of train-

Our hypothesis explaining this result is that in PPDB, the phrase pairs are short fragments of text which are not necessarily constituents or phrases in any syntactic sense. Therefore, the sentences in the STS test sets are quite different from the fragments seen during training. We hypothesize that while word-averaging is relatively unaffected by this difference, the recurrent models are much more sensitive to overall characteristics of the word sequences, and the difference between train and test matters much more.

These results also suggest that the SimpWiki data, even though it was developed for text simplification, may be useful for other researchers working on semantic textual similarity tasks.

4.1.3 Experiments with LSTM Variations

We next compare LSTM and LSTMAVG. The latter consists of averaging the hidden vectors of the LSTM rather than using the final hidden vector as in prior work (Wieting et al., 2016b). We hypothesize that the LSTM may put more emphasis on the words at the end of the sentence than those at the beginning. By averaging the hidden states, the impact of all words in the sequence is better taken into account. Averaging also makes the LSTM more like AVG, which we know to perform strongly in this setting.

The results on AVG and the LSTM models are shown in Table 1. When training on PPDB, moving from LSTM to LSTMAVG improves performance by 10 points, closing most of the gap with AVG. We also find that LSTMAVG improves by moving from PPDB to SimpWiki, though in both cases it still lags behind AVG.

4.2 Experiments with Regularization

We next experiment with various forms of regularization. Previous work (Wieting et al., 2016b,a) only used L_2 regularization. Wieting et al. (2016b) also regularized the word embeddings back to their initial values. Here we use L_2 regularization as well as several additional regularization methods we describe below.

We try two forms of dropout. The first is just standard dropout (Srivastava et al., 2014) on the word embeddings. The second is "word dropout", which drops out entire word embeddings with some probability (Iyyer et al., 2015).

We also experiment with scrambling the inputs. For a given mini-batch, we go through each sentence pair and, with some probability, we shuffle the words in each sentence in the pair. When scrambling a sentence pair, we always shuffle both sentences in the pair. We do this before selecting negative examples for the mini-batch. The motivation for scrambling is to make it more difficult for the LSTM to memorize the sequences in the training data, forcing it to focus more on the identities of the words and less on word order. Hence it will be expected to behave more like the word averaging model.[5]

We also experiment with combining scrambling and dropout. In this setting, we tune over scrambling with either word dropout or dropout.

The settings for these experiments are largely the same as those of the previous section with the exception that we tune λ_w over a smaller set of values: $\{10^{-5}, 0\}$. When using L_2 regularization, we tune λ_c over $\{10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}\}$. When using dropout, we tune the dropout rate over $\{0.2, 0.4, 0.6\}$. When using scrambling, we tune the scrambling rate over $\{0.25, 0.5, 0.75\}$. We also include a bidirectional model ("Bi") for both LSTMAVG and the GATED RECURRENT AVERAGING NETWORK. We tune over two ways to combine the forward and backward hidden states; the first simply adds them together and the second uses a single feedforward layer with a $\tanh$ activation.

We try two approaches for model selection. The first, *test* , is the same as was done in Section 4.1.2, where we use the average Pearson's r on the 5 2016 STS datasets. The second tunes based on the average Pearson's r of all 22 datasets in our evaluation. We refer to this as *oracle*.

The results are shown in Table 2. They show that dropping entire word embeddings and scram-

ing and test sentences, adding both, and adding neither. We treated adding these tags as hyperparameters and tuned over these four settings along with the other hyperparameters in the original experiment. Interestingly, we found that adding these tags, especially EOS, had a large effect on the LSTM when training on SimpWiki, improving performance by 6 points. When training on PPDB, adding EOS tags only improved performance by 1.6 points.

The addition of the tags had a smaller effect on LSTMAVG. Adding EOS tags improved performance by 0.3 points on SimpWiki and adding SOS tags on PPDB improved performance by 0.9 points.

[5] We also tried some variations on scrambling that did not yield significant improvements: scrambling after obtaining the negative examples, partially scrambling by performing n swaps where n comes from a Poisson distribution with a tunable λ, and scrambling individual sentences with some probability instead of always scrambling both in the pair.

Model	Regularization	Oracle	2016 STS

GRAN-2	68.8	68.1
GRAN-3	69.0	67.2
GRAN-4	68.6	68.1
GRAN-5	66.1	64.8
BiGRAN	**69.7**	68.4

Table 3: Results on SemEval textual similarity datasets (Pearson's $r \times 100$) for the GRAN architectures. The first row, marked as (no reg.) is the GRAN without any regularization. The other rows show the result of the various GRAN models using dropout and scrambling.

bling input sequences is very effective in improving the result of the LSTM, while neither type of dropout improves AVG. Moreover, averaging the hidden states of the LSTM is the most effective modification to the LSTM in improving performance. All of these modifications can be combined to significantly improve the LSTM, finally allowing it to overtake AVG.

In Table 3, we compare the various GRAN architectures. We find that the GRAN provides a small improvement over the best LSTM configuration, possibly because of its similarity to AVG. It also outperforms the other GRAN models, despite being the simplest.

In Table 4, we show results on all individual STS evaluation datasets after using STS 2016 for model selection (unidirectional models only). The LSTMAVG and GATED RECURRENT AVERAGING NETWORK are more closely correlated in performance, in terms of Spearman's ρ and Pearson'r r, than either is to AVG. But they do differ significantly in some datasets, most notably in those comparing machine translation output with its reference. Interestingly, both the LSTMAVG and GATED RECURRENT AVERAGING NETWORK significantly outperform AVG in the datasets focused on comparing glosses like *OnWN* and *FNWN*. Upon examination, we found that these datasets, especially 2013 *OnWN*, contain examples of low similarity with high word overlap. For example, the pair ⟨*the act of preserving or protecting something.*, *the act of decreasing or reducing something.*⟩ from 2013 *OnWN* has a gold similarity score of 0.4. It appears that AVG was fooled by the high amount of word overlap in such pairs, while the other two models were better able to recognize the semantic differences.

4.3 Supervised Text Similarity

We also investigate if these techniques can improve LSTM performance on supervised semantic textual similarity tasks. We evaluate on two supervised datasets. For the first, we start with the 20 SemEval STS datasets from 2012-2015 and then use 40% of each dataset for training, 10% for validation, and the remaining 50% for testing. There are 4,481 examples in training, 1,207 in validation, and 6,060 in the test set. The second is the SICK 2014 dataset, using its standard training, validation, and test sets. There are 4,500 sentence pairs

in the training set, 500 in the development set, and 4,927 in the test set. The SICK task is an easier learning problem since the training examples are all drawn from the same distribution, and they are mostly shorter and use simpler language. As these are supervised tasks, the sentence pairs in the training set contain manually-annotated semantic similarity scores.

We minimize the loss function[6] from Tai et al. (2015). Given a score for a sentence pair in the range $[1, K]$, where K is an integer, with sentence representations h_L and h_R, and model parameters θ, they first compute:

$$h_\times = h_L \odot h_R, \;\; h_+ = |h_L - h_R|,$$
$$h_s = \sigma\left(W^{(\times)} h_\times + W^{(+)} h_+ + b^{(h)}\right),$$
$$\hat{p}_\theta = \text{softmax}\left(W^{(p)} h_s + b^{(p)}\right),$$
$$\hat{y} = r^T \hat{p}_\theta,$$

where $r^T = [1\ 2\ \ldots\ K]$. They then define a sparse target distribution p that satisfies $y = r^T p$:

$$p_i = \begin{cases} y - \lfloor y \rfloor, & i = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & i = \lfloor y \rfloor \\ 0 & \text{otherwise} \end{cases}$$

for $1 \leq i \leq K$. Then they use the following loss, the regularized KL-divergence between p and $\hat{p}_\theta$:

$$J(\theta) = \frac{1}{m} \sum_{k=1}^{m} \text{KL}\left(p^{(k)} \,\middle\|\, \hat{p}_\theta^{(k)}\right),$$

where m is the number of training pairs.

We experiment with the LSTM, LSTMAVG, and AVG models with dropout, word dropout, and scrambling tuning over the same hyperparameter as in Section 4.2. We again regularize the word embeddings back to their initial state, tuning λ_w over $\{10^{-5}, 0\}$. We used the validation set for each respective dataset for model selection.

The results are shown in Table 5. The GATED RECURRENT AVERAGING NETWORK has the best performance on both datasets. Dropout helps the word-averaging model in the STS task, unlike in the transfer learning setting. The LSTM benefits slightly from dropout, scrambling, and averaging on their own individually with the exception of word dropout on both datasets and averaging on the SICK dataset. However, when combined, these modifications are able to significantly improve the performance of the LSTM, bringing it much closer in performance to AVG. This experiment indicates that these modifications when training LSTMs are beneficial outside the transfer learning setting, and can potentially be used to improve performance for the broad range of problems that use LSTMs to model sentences.

[6]This objective function has been shown to perform very strongly on text similarity tasks, significantly better than squared or absolute error.

Model	Regularization	STS	SICK	Avg.
AVG	none	79.2	85.2	82.2
	dropout	80.7	84.5	82.6
	word dropout	79.3	81.8	80.6
LSTM	none	68.4	80.9	74.7
	dropout	69.6	81.3	75.5
	word dropout	68.0	76.4	72.2
	scrambling	74.2	84.4	79.3
	dropout, scrambling	75.0	84.2	79.6

	dropout, scrambling	76.5	84.0	80.3
GRAN	none	79.7	85.2	82.5
	dropout	79.7	84.6	82.2
	word dropout	77.3	83.0	80.2
	scrambling	81.4	**85.3**	**83.4**
	dropout, scrambling	**81.6**	85.1	**83.4**

Table 5: Results from supervised training on the STS and SICK datasets (Pearson's $r \times 100$). The last column is the average result on the two datasets.

Model	STS	SICK	Avg.
GRAN	**81.6**	85.3	**83.5**
GRAN-2	77.4	85.1	81.3
GRAN-3	81.3	85.4	83.4
GRAN-4	80.1	**85.5**	82.8
GRAN-5	70.9	83.0	77.0

Table 6: Results from supervised training on the STS and SICK datasets (Pearson's $r \times 100$) for the GRAN architectures. The last column is the average result on the two datasets.

In Table 6 we compare the various GRAN architectures under the same settings as the previous experiment. We find that the GRAN still has the best overall performance.

We also experiment with initializing the supervised models using our pretrained sentence model parameters, for the AVG model (no regularization), LSTMAVG (dropout, scrambling), and GATED RECURRENT AVERAGING NETWORK (dropout, scrambling) models from Table 2 and Table 3. We both initialize and then regularize back to these initial values, referring to this setting as "universal".[7]

[7]In these experiments, we tuned λ_w over $\{10, 1, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}, 10^{-8}, 0\}$

#	Sentence 1	Sentence 2	LAVG	AVG	Gold
1	the lamb is looking at the camera.	a cat looking at the camera.	**3.42**	4.13	0.8
2	he also said shockey is "living the dream life of a new york athlete."	"jeremy's a good guy," barber said, adding:"jeremy is living the dream life of the new york athlete."	**3.55**	4.22	2.75
3	bloomberg chips in a billion	bloomberg gives $1.1 b to university	**3.99**	3.04	4.0
4	in other regions, the sharia is imposed.	in other areas, sharia law is being introduced by force.	**4.44**	3.72	4.75
5	three men in suits sitting at a table.	two women in the kitchen looking at a object.	3.33	**2.79**	0.0
6	we never got out of it in the first place!	where does the money come from in the first place?	4.00	**3.33**	0.8
7	two birds interacting in the grass.	two dogs play with each other outdoors.	3.44	**2.81**	0.2

Table 7: Illustrative sentence pairs from the STS datasets showing errors made by LSTMAVG and AVG. The last three columns show the gold similarity score, the similarity score of LSTMAVG, and the similarity score of AVG. Boldface indicates smaller error compared to gold scores.

Model	Regularization	STS	SICK
AVG	dropout	80.7	84.5
	dropout, universal	**82.9**	85.6
LSTMAVG	dropout, scrambling	76.5	84.0
	dropout, scrambling, universal	81.3	85.2
GRAN	dropout, scrambling	81.6	85.1
	dropout, scrambling, universal	82.7	**86.0**

Table 8: Impact of initializing and regularizing toward universal models (Pearson's $r \times 100$) in supervised training.

The results are shown in Table 8. Initializing and regularizing to the pretrained models significantly improves the performance for all three models, justifying our claim that these models serve a dual purpose: they can be used a black box semantic similarity function, and they possess rich knowledge that can be used to improve the performance of downstream tasks.

5 Analysis

5.1 Error Analysis

We analyze the predictions of AVG and the recurrent networks, represented by LSTMAVG, on the 20 STS datasets. We choose LSTMAVG as it correlates slightly less strongly with AVG than the GRAN on the results over all SemEval datasets used for evaluation. We scale the models' cosine similarities to lie within $[0, 5]$, then compare the predicted similarities of LSTMAVG and AVG to the gold similarities. We analyzed instances in which each model would tend to overestimate or underestimate the gold similarity relative to the other. These are illustrated in Table 7.

We find that AVG tends to overestimate the semantic similarity of a sentence pair, relative to LSTMAVG, when the two sentences have a lot of word or synonym overlap, but have either important differences in key semantic roles or where one sentence has significantly more content than the other. These phenomena are shown in examples 1 and 2 in Table 7. Conversely, AVG tends to underestimate similarity when there are one-word-to-multiword paraphrases between the two sentences as shown in examples 3 and 4.

LSTMAVG tends to overestimate similarity when the two inputs have similar sequences of syntactic categories, but the meanings of the sentences are different (examples 5, 6, and 7). Instances of LSTMAVG underestimating the similarity relative to AVG are relatively rare, and those that we found did not have any systematic patterns.

5.2 GRAN Gate Analysis

We also investigate what is learned by the gating function of the GATED RECURRENT AVERAGING NETWORK. We are interested to see whether its estimates of importance correlate with those of traditional syntactic and (shallow) semantic analysis.

We use the oracle trained GATED RECURRENT AVERAGING NETWORK from Table 3 and calculate the L_1 norm of the gate after embedding 10,000 sentences from English Wikipedia.[8] We also automatically tag and parse these sentences using the Stanford dependency parser (Manning et al., 2014). We then compute the average gate L_1 norms for particular part-of-speech tags, dependency arc labels, and their conjunction.

Table 9 shows the highest/lowest average norm tags and dependency labels. The network prefers nouns, especially proper nouns, as well as cardinal numbers, which is sensible as these are among the most discriminative features of a sentence.

Analyzing the dependency relations, we find

and λ_c over $\{10, 1, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, 0\}$.

[8] We selected only sentences of less than or equal to 15 tokens to ensure more accurate parsing.

POS		Dep. Label	
top 10	bot. 10	top 10	bot. 10
NNP	TO	number	possessive
NNPS	WDT	nn	cop
CD	POS	num	det
NNS	DT	acomp	auxpass
VBG	WP	appos	prep
NN	IN	pobj	cc
JJ	CC	vmod	mark
UH	PRP	dobj	aux
VBN	EX	amod	expl
JJS	WRB	conj	neg

Table 9: POS tags and dependency labels with highest and lowest average GATED RECURRENT AVERAGING NETWORK gate L_1 norms. The lists are ordered from highest norm to lowest in the top 10 columns, and lowest to highest in the bottom 10 columns.

Dep. Label	Weight
xcomp	170.6
acomp	167.1
root	157.4
amod	143.1
advmod	121.6

Table 10: Average L_1 norms for adjectives (JJ) with selected dependency labels.

that nouns in the object position tend to have higher weight than nouns in the subject position. This may relate to topic and focus; the object may be more likely to be the "new" information related by the sentence, which would then make it more likely to be matched by the other sentence in the paraphrase pair.

We find that the weights of adjectives depend on their position in the sentence, as shown in Table 10. The highest norms appear when an adjective is an xcomp, acomp, or root; this typically means it is residing in an object-like position in its clause. Adjectives that modify a noun (amod) have medium weight, and those that modify another adjective or verb (advmod) have low weight.

Dep. Label	Weight
pcomp	190.0
amod	178.3
xcomp	176.8
vmod	170.6
root	161.8
auxpass	125.4
prep	121.2

Table 11: Average L_1 norms for words with the tag VBG with selected dependency labels.

Lastly, we analyze words tagged as VBG, a highly ambiguous tag that can serve many syntactic roles in a sentence. As shown in Table 11, we find that when they are used to modify a noun (amod) or in the object position of a clause (xcomp, pcomp) they have high weight. Medium weight appears when used in verb phrases (root, vmod) and low weight when used as prepositions or auxiliary verbs (prep, auxpass).

6 Conclusion

We showed how to modify and regularize LSTMs to improve their performance for learning paraphrastic sentence embeddings in both transfer and supervised settings. We also introduced a new recurrent network, the GATED RECURRENT AVERAGING NETWORK, that improves upon both AVG and LSTMs for these tasks, and we release our code and trained models.

Furthermore, we analyzed the different errors produced by AVG and the recurrent methods and found that the recurrent methods were learning composition that wasn't being captured by AVG. We also investigated the GRAN in order to better understand the compositional phenomena it was learning by analyzing the L_1 norm of its gate over various inputs.

Future work will explore additional data sources, including from aligning different translations of novels (Barzilay and McKeown, 2001), aligning new articles of the same topic (Dolan et al., 2004), or even possibly using machine translation systems to translate bilingual text into paraphrastic sentence pairs. Our new techniques, combined with the promise of new data sources, offer a great deal of potential for improved universal paraphrastic sentence embeddings.

Abstract

Type-level word embeddings use the same set of parameters to represent all instances of a word regardless of its context, ignoring the inherent lexical ambiguity in language. Instead, we embed semantic concepts (or synsets) as defined in WordNet and represent a word token in a particular context by estimating a distribution over relevant semantic concepts. We use the new, context-sensitive embeddings in a model for predicting prepositional phrase (PP) attachments and jointly learn the concept embeddings and model parameters. We show that using context-sensitive embeddings improves the accuracy of the PP attachment model by 5.4% absolute points, which amounts to a 34.4% relative reduction in errors.

1 Introduction

Type-level word embeddings map a word type (i.e., a surface form) to a dense vector of real numbers such that similar word types have similar embeddings. When pre-trained on a large corpus of unlabeled text, they provide an effective mechanism for generalizing statistical models to words which do not appear in the labeled training data for a downstream task.

In accordance with standard terminology, we make the following distinction between types and tokens in this paper: By word types, we mean the surface form of the word, whereas by tokens we mean the instantiation of the surface form in a context. For example, the same word type *'pool'* occurs as two different tokens in the sentences *"He sat by the pool,"* and *"He played a game of pool."*

Most word embedding models define a single vector for each word type. However, a fundamental flaw in this design is their inability to distinguish between different meanings and abstractions of the same word. In the two sentences shown above, the word *'pool'* has different meanings, but the same representation is typically used for both of them. Similarly, the fact that *'pool'* and *'lake'* are both kinds of water bodies is not explicitly incorporated in most type-level embeddings. Furthermore, it has become a standard practice to tune pre-trained word embeddings as model parameters during training for an NLP task (e.g., Chen and Manning, 2014; Lample et al., 2016), potentially allowing the parameters of a frequent word in the labeled training data to drift away from related but rare words in the embedding space.

Previous work partially addresses these problems by estimating concept embeddings in WordNet (e.g., Rothe and Schütze, 2015), or improving word representations using information from knowledge graphs (e.g., Faruqui et al., 2015). However, it is still not clear how to use a lexical ontology to derive context-sensitive token embeddings.

In this work, we represent a word token in a given context by estimating a context-sensitive probability distribution over relevant concepts in WordNet (Miller, 1995) and use the expected value (i.e., weighted sum) of the concept embeddings as the token representation (see §2). We take a task-centric approach towards doing this, and learn the token representations jointly with the task-specific parameters. In addition to providing context-sensitive token embeddings, the proposed method implicitly regularizes the embeddings of related words by forcing related words to share similar concept embeddings. As a result, the representation of a rare word which does not appear in the training data for a downstream task benefits from all the updates to related words which share one or more concept embeddings.

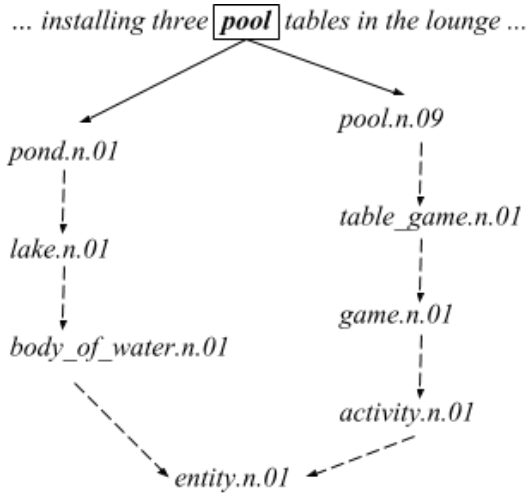

Figure 1: An example grounding for the word *'pool'*. Solid arrows represent possible senses and dashed arrows represent hypernym relations. Note that the same set of concepts are used to ground the word *'pool'* regardless of its context. Other WordNet senses for *'pool'* were removed from the figure for simplicity.

Our approach to context-sensitive embeddings assumes the availability of a lexical ontology. While this work relies on WordNet, and we exploit the order of senses given by WordNet, our model is, in principle applicable to any ontology, with appropriate modifications. In this work, we do not assume the inputs are sense tagged. We use the proposed embeddings to predict prepositional phrase (PP) attachments (see §3), a challenging problem which emphasizes the selectional preferences between words in the PP and each of the candidate head words. Our empirical results and detailed analysis (see §4) show that the proposed embeddings effectively use WordNet to improve the accuracy of PP attachment predictions.

2 WordNet-Grounded Context-Sensitive Token Embeddings

In this section, we focus on defining our context-sensitive token embeddings. We first describe our grounding of word types using WordNet concepts. Then, we describe our model of context-sensitive token-level embeddings as a weighted sum of WordNet concept embeddings.

2.1 WordNet Grounding

We use WordNet to map each word type to a set of synsets, including possible generalizations or abstractions. Among the labeled relations defined in WordNet between different synsets, we focus on the hypernymy relation to help model generalization and selectional preferences between words, which is especially important for predicting PP attachments (Resnik, 1993). To ground a word type, we identify the set of (direct and indirect) hypernyms of the WordNet senses of that word. A simplified grounding of the word 'pool' is illustrated in Figure 1. This grounding is key to our model of token embeddings, to be described in the following subsections.

2.2 Context-Sensitive Token Embeddings

Our goal is to define a context-sensitive model of token embeddings which can be used as a drop-in replacement for traditional type-level word embeddings.

Notation. Let $\mathit{Senses}(w)$ be the list of synsets defined as possible word senses of a given word type w in WordNet, and $\mathit{Hypernyms}(s)$ be the list of hypernyms for a synset s.[1] For example, according to Figure 1:

$$\mathit{Senses}(\text{pool}) = [\text{pond.n.01, pool.n.09}], \text{and}$$
$$\mathit{Hypernyms}(\text{pond.n.01}) = [\text{pond.n.01, lake.n.01,}$$
$$\text{body\_of\_water.n.01, entity.n.01}]$$

Each WordNet synset s is associated with a set of parameters $\mathbf{v}_s \in \mathbb{R}^n$ which represent its embedding. This parameterization is similar to that of Rothe and Schütze (2015).

Embedding model. Given a sequence of tokens $\boldsymbol{t}$ and their corresponding word types $\boldsymbol{w}$, let $\mathbf{u}_i \in \mathbb{R}^n$ be the embedding of the word token t_i at position i. Unlike most embedding models, the token embeddings $\mathbf{u}_i$ are not parameters. Rather, $\mathbf{u}_i$ is computed as the expected value of concept embeddings used to ground the word type w_i corresponding to the token t_i:

$$\mathbf{u}_i = \sum_{s \in \mathit{Senses}(w_i)} \sum_{s' \in \mathit{Hypernyms}(s)} p(s, s' \mid \boldsymbol{t}, \boldsymbol{w}, i)\, \mathbf{v}_{s'} \quad (1)$$

such that

$$\sum_{s \in \mathit{Senses}(w_i)} \sum_{s' \in \mathit{Hypernyms}(s)} p(s, s' \mid \boldsymbol{t}, \boldsymbol{w}, i) = 1$$

[1] For notational convenience, we assume that $s \in \mathit{Hypernyms}(s)$.

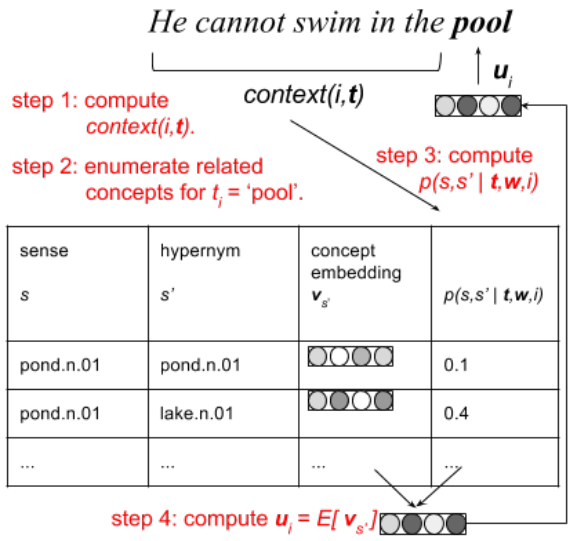

Figure 2: Steps for computing the context-sensitive token embedding for the word *'pool'*, as described in §2.2.

The distribution which governs the expectation over synset embeddings factorizes into two components:

$$p(s, s' \mid \boldsymbol{t}, \boldsymbol{w}, i) \propto \lambda_{w_i} \exp^{-\lambda_{w_i} \, rank(s, w_i)} \times MLP([\mathbf{v}_{s'}; context(i, \boldsymbol{t})]) \quad (2)$$

The first component, $\lambda_{w_i} \exp^{-\lambda_{w_i} \, rank(s,w_i)}$, is a sense prior which reflects the prominence of each word sense for a given word type. Here, we exploit[2] the fact that WordNet senses are ordered in descending order of their frequencies, obtained from sense tagged corpora, and parameterize the sense prior like an exponential distribution. $rank(s, w_i)$ denotes the rank of sense s for the word type w_i, thus $rank(s, w_i) = 0$ corresponds to s being the first sense of w_i. The scalar parameter (λ_{w_i}) controls the decay of the probability mass, which is learned along with the other parameters in the model. Note that sense priors are defined for each word type (w_i), and are shared across all tokens which have the same word type.

$MLP([\mathbf{v}_{s'}; context(i, \boldsymbol{t})])$, the second component, is what makes the token representations context-sensitive. It scores each concept in the WordNet grounding of w_i by feeding the concatenation of the concept embedding and a dense vector that summarizes the textual context into a multilayer perceptron (*MLP*) with two $tanh$ layers followed by a $softmax$ layer. This component is inspired by the soft attention often used in neural machine translation (Bahdanau et al., 2014).[3] The definition of the *context* function is dependent on the encoder used to encode the context. We describe a specific instantiation of this function in §3.

To summarize, Figure 2 illustrates how to compute the embedding of a word token $t_i = \textit{'pool'}$ in a given context:

1. compute a summary of the context $context(i, \boldsymbol{t})$,
2. enumerate related concepts for t_i,
3. compute $p(s, s' \mid \boldsymbol{t}, \boldsymbol{w}, i)$ for each pair (s, s'), and
4. compute $\mathbf{u}_i = \mathbb{E}[\mathbf{v}_{s'}]$.

In the following section, we describe our model for predicting PP attachments, including our definition for *context*.

3 PP Attachment

Disambiguating PP attachments is an important and challenging NLP problem. Since modeling hypernymy and selectional preferences is critical for successful prediction of PP attachments (Resnik, 1993), it is a good fit for evaluating our WordNet-grounded context-sensitive embeddings.

Figure 3, reproduced from Belinkov et al. (2014), illustrates an example of the PP attachment prediction problem. The accuracy of a competitive English dependency parser at predicting the head word of an ambiguous prepositional phrase is 88.5%, significantly lower than the overall unlabeled attachment accuracy of the same parser (94.2%).[4]

This section formally defines the problem of PP attachment disambiguation, describes our baseline model, then shows how to integrate the token-level embeddings in the model.

3.1 Problem Definition

We follow Belinkov et al. (2014)'s definition of the PP attachment problem. Given a preposition p and

[2]Note that for ontologies where such information is not available, our method is still applicable but without this component. We show the effect of using a uniform sense prior in §4.2.

[3]Although soft attention mechanism is typically used to explicitly represent the importance of each item in a sequence, it can also be applied to non-sequential items.

[4]See Table 2 in §4 for detailed results.

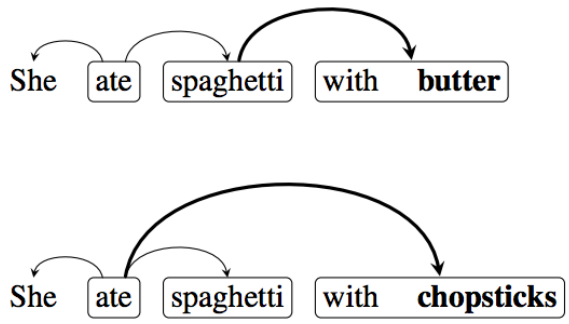

Figure 3: Two sentences illustrating the importance of lexicalization in PP attachment decisions. In the top sentence, the PP *'with butter'* attaches to the noun *'spaghetti'*. In the bottom sentence, the PP *'with chopsticks'* attaches to the verb *'ate'*. **Note:** This figure and caption have been reproduced from Belinkov et al. (2014).

its direct dependent d in the prepositional phrase (PP), our goal is to predict the correct head word for the PP among an ordered list of candidate head words $\boldsymbol{h}$. Each example in the train, validation, and test sets consists of an input tuple $\langle \boldsymbol{h}, p, d \rangle$ and an output index k to identify the correct head among the candidates in $\boldsymbol{h}$. Note that the order of words that form each $\langle \boldsymbol{h}, p, d \rangle$ is the same as that in the corresponding original sentence.

3.2 Model Definition

Both our proposed and baseline models for PP attachment use bidirectional RNN with LSTM cells (bi-LSTM) to encode the sequence $\boldsymbol{t} = \langle h_1, \ldots, h_K, p, d \rangle$.

We score each candidate head by feeding the concatenation of the output bi-LSTM vectors for the head h_k, the preposition p and the direct dependent d through an MLP, with a fully connected *tanh* layer to obtain a non-linear projection of the concatenation, followed by a fully-connected *softmax* layer:

$$p(h_k \text{is head}) = \mathit{MLP}_{\mathit{attach}}([\mathit{lstm\_out}(h_k); \mathit{lstm\_out}(p); \mathit{lstm\_out}(d)]) \quad (3)$$

To train the model, we use cross-entropy loss at the output layer for each candidate head in the training set. At test time, we predict the candidate head with the highest probability according to the model in Eq. 3, i.e.,

$$\hat{k} = \arg\max_k p(h_k \text{is head} = 1). \quad (4)$$

This model is inspired by the Head-Prep-Child-Ternary model of Belinkov et al. (2014). The main difference is that we replace the input features for each token with the output bi-RNN vectors.

We now describe the difference between the proposed and the baseline models. Generally, let $\mathit{lstm\_in}(t_i)$ and $\mathit{lstm\_out}(t_i)$ represent the input and output vectors of the bi-LSTM for each token $t_i \in \boldsymbol{t}$ in the sequence. The outputs at each timestep are obtained by concatenating those of the forward and backward LSTMs.

Baseline model. In the baseline model, we use type-level word embeddings to represent the input vector $\mathit{lstm\_in}(t_i)$ for a token t_i in the sequence. The word embedding parameters are initialized with pre-trained vectors, then tuned along with the parameters of the bi-LSTM and $\mathit{MLP}_{\mathit{attach}}$. We call this model **LSTM-PP**.

Proposed model. In the proposed model, we use token level word embedding as described in §2 as the input to the bi-LSTM, i.e., $\mathit{lstm\_in}(t_i) = \mathbf{u}_i$. The context used for the attention component is simply the hidden state from the previous timestep. However, since we use a bi-LSTM, the model essentially has two RNNs, and accordingly we have two context vectors, and associated attentions. That is, $\mathit{context}_f(i, \boldsymbol{t}) = \mathit{lstm\_in}(t_{i-1})$ for the forward RNN and $\mathit{context}_b(i, \boldsymbol{t}) = \mathit{lstm\_in}(t_{i+1})$ for the backward RNN. Consequently, each token gets two representations, one from each RNN. The synset embedding parameters are initialized with pre-trained vectors and tuned along with the sense decay (λ_w) and MLP parameters from Eq. 2, the parameters of the bi-LSTM and those of $\mathit{MLP}_{\mathit{attach}}$. We call this model **OntoLSTM-PP**.

4 Experiments

Dataset and evaluation. We used the English PP attachment dataset created and made available by Belinkov et al. (2014). The training and test splits contain 33,359 and 1951 labeled examples respectively. As explained in §3.1, the input for each example is 1) an ordered list of candidate head words, 2) the preposition, and 3) the direct

dependent of the preposition. The head words are either nouns or verbs and the dependent is always a noun. All examples in this dataset have at least two candidate head words. As discussed in Belinkov et al. (2014), this dataset is a more realistic PP attachment task than the RRR dataset (Ratnaparkhi et al., 1994). The RRR dataset is a binary classification task with exactly two head word candidates in all examples. The context for each example in the RRR dataset is also limited which defeats the purpose of our context-sensitive embeddings.

Model specifications and hyperparameters. For efficient implementation, we use mini-batch updates with the same number of senses and hypernyms for all examples, padding zeros and truncating senses and hypernyms as needed. For each word type, we use a maximum of S senses and H indirect hypernyms from WordNet. In our initial experiments on a held-out development set (10% of the training data), we found that values greater than $S = 3$ and $H = 5$ did not improve performance. We also used the development set to tune the number of layers in MLP_{attach} separately for the *OntoLSTM-PP* and *LSTM-PP*, and the number of layers in the attention MLP in *OntoLSTM-PP*. When a synset has multiple hypernym paths, we use the shortest one. Finally, words types which do not appear in WordNet are assumed to have one unique sense per word type with no hypernyms. Since the POS tag for each word is included in the dataset, we exclude WordNet synsets which are incompatible with the POS tag. The synset embedding parameters are initialized using the synset vectors obtained by running AutoExtend (Rothe and Schütze, 2015) on 100-dimensional GloVe (Pennington et al., 2014) vectors for WordNet 3.1. We refer to this embedding as *GloVe-extended*. Representation for the OOV word types in LSTM-PP and OOV synset types in *OntoLSTM-PP* were randomly drawn from a uniform 100-d distribution. Initial sense prior parameters (λ_w) were also drawn from a uniform 1-d distribution.

Baselines. In our experiments, we compare our proposed model, *OntoLSTM-PP* with three baselines – *LSTM-PP* initialized with GloVe embedding, *LSTM-PP* initialized with GloVe vectors retrofitted to WordNet using the approach of Faruqui et al. (2015) (henceforth referred to as *GloVe-retro*), and finally the best performing standalone PP attachment system from Belinkov et al. (2014), referred to as *HPCD (full)* in the paper. *HPCD (full)* is a neural network model that learns to compose the vector representations of each of the candidate heads with those of the preposition and the dependent, and predict attachments. The input representations are enriched using syntactic context information, POS, WordNet and VerbNet (Kipper et al., 2008) information and the distance of the head word from the PP is explicitly encoded in composition architecture. In contrast, we do not use syntactic context, VerbNet and distance information, and do not explicitly encode POS information.

4.1 PP Attachment Results

Table 1 shows that our proposed token level embedding scheme *OntoLSTM-PP* outperforms the better variant of our baseline *LSTM-PP* (with GloVe-retro intialization) by an absolute accuracy difference of 4.9%, or a relative error reduction of 32%. *OntoLSTM-PP* also outperforms *HPCD (full)*, the previous best result on this dataset.

Initializing the word embeddings with *GloVe-retro* (which uses WordNet as described in Faruqui et al. (2015)) instead of GloVe amounts to a small improvement, compared to the improvements obtained using *OntoLSTM-PP*. This result illustrates that our approach of dynamically choosing a context sensitive distribution over synsets is a more effective way of making use of WordNet.

Effect on dependency parsing. Following Belinkov et al. (2014), we used RBG parser (Lei et al., 2014), and modified it by adding a binary feature indicating the PP attachment predictions from our model.

We compare four ways to compute the additional binary features: 1) the predictions of the best standalone system *HPCD (full)* in Belinkov et al. (2014), 2) the predictions of our baseline model *LSTM-PP*, 3) the predictions of our improved model *OntoLSTM-PP*, and 4) the gold labels *Oracle PP*.

Table 2 shows the effect of using the PP attachment predictions as features within a dependency parser. We note there is a relatively small difference in unlabeled attachment accuracy for all dependencies (not only PP attachments), even when gold PP attachments are used as additional features to the parser. However, when gold PP attachment are used, we note a large potential improve-

System	Initialization	Embedding	Resources	Test Acc.
HPCD (full)	Syntactic-SG	Type	WordNet, VerbNet	88.7
LSTM-PP	GloVe	Type	-	84.3
LSTM-PP	GloVe-retro	Type	WordNet	84.8
OntoLSTM-PP	GloVe-extended	Token	WordNet	**89.7**

Table 1: Results on Belinkov et al. (2014)'s PPA test set. *HPCD (full)* is from the original paper, and it uses syntactic SkipGram. *GloVe-retro* is GloVe vectors retrofitted (Faruqui et al., 2015) to WordNet 3.1, and *GloVe-extended* refers to the synset embeddings obtained by running AutoExtend (Rothe and Schütze, 2015) on GloVe.

System	Full UAS	PPA Acc.
RBG	94.17	88.51
RBG + HPCD (full)	94.19	89.59
RBG + LSTM-PP	94.14	86.35
RBG + OntoLSTM-PP	94.30	90.11
RBG + Oracle PP	94.60	98.97

Table 2: Results from RBG dependency parser with features coming from various PP attachment predictors and oracle attachments.

ment of 10.46 points in PP attachment accuracies (between the PPA accuracy for *RBG* and *RBG + Oracle PP*), which confirms that adding PP predictions as features is an effective approach. Our proposed model *RBG + OntoLSTM-PP* recovers 15% of this potential improvement, while *RBG + HPCD (full)* recovers 10%, which illustrates that PP attachment remains a difficult problem with plenty of room for improvements even when using a dedicated model to predict PP attachments and using its predictions in a dependency parser.

We also note that, although we use the same predictions of the *HPCD (full)* model in Belinkov et al. (2014)[5], we report different results than Belinkov et al. (2014). For example, the unlabeled attachment score (UAS) of the baselines *RBG* and *RBG + HPCD (full)* are 94.17 and 94.19, respectively, in Table 2, compared to 93.96 and 94.05, respectively, in Belinkov et al. (2014). This is due to the use of different versions of the RBG parser.[6]

4.2 Analysis

In this subsection, we analyze different aspects of our model in order to develop a better understanding of its behavior.

Effect of context sensitivity and sense priors. We now show some results that indicate the relative strengths of two components of our context-sensitive token embedding model. The second row in Table 3 shows the test accuracy of a system trained without sense priors (that is, making $p(s|w_i)$ from Eq. 1 a uniform distribution), and the third row shows the effect of making the token representations context-insensitive by giving a similar attention score to all related concepts, essentially making them type level representations, but still grounded in WordNet. As it can be seen, removing context sensitivity has an adverse effect on the results. This illustrates the importance of the sense priors and the attention mechanism.

It is interesting that, even without sense priors and attention, the results with WordNet grounding is still higher than that of the two LSTM-PP systems in Table 1. This result illustrates the regularization behavior of sharing concept embeddings across multiple words, which is especially important for rare words.

Effect of training data size. Since *OntoLSTM-PP* uses external information, the gap between the model and *LSTM-PP* is expected to be more pronounced when the training data sizes are smaller. To test this hypothesis, we trained the two models with different amounts of training data and measured their accuracies on the test set. The plot is shown in Figure 4. As expected, the gap tends to be larger at smaller data sizes. Surprisingly, even with 2000 sentences in the training data set, *OntoLSTM-PP* outperforms *LSTM-PP* trained with the full data set. When both the models are trained with the full dataset, *LSTM-PP* reaches a training accuracy of 95.3%, whereas *OntoLSTM-PP* reaches 93.5%. The fact that *LSTM-PP* is overfitting the training data more, indicates the regular-

[5]The authors kindly provided their predictions for 1942 test examples (out of 1951 examples in the full test set). In Table 2, we use the same subset of 1942 test examples and will include a link to the subset in the final draft.

[6]We use the latest commit (SHA: e07f74) on the GitHub repository of the RGB parser.

ization capability of *OntoLSTM-PP*.

Qualitative analysis. To better understand the effect of WordNet grounding, we took a sample of 100 sentences from the test set whose PP attachments were correctly predicted by OntoLSTM-PP but not by LSTM-PP. A common pattern observed was that those sentences contained words not seen frequently in the training data. Figure 5 shows two such cases. In both cases, the weights assigned by OntoLSTM-PP to infrequent words are also shown. The word types *soapsuds* and *buoyancy* do not occur in the training data, but OntoLSTM-PP was able to leverage the parameters learned for the synsets that contributed to their token representations. Another important observation is that the word type *buoyancy* has four senses in WordNet (we consider the first three), none of which is the metaphorical sense that is applicable to *markets* as shown in the example here. Selecting a combination of relevant hypernyms from various senses may have helped OntoLSTM-PP make the right prediction. This shows the value of using hypernymy information from WordNet. Moreover, this indicates the strength of the hybrid nature of the model, that lets it augment ontological information with distributional information.

Parameter space. We note that the vocabulary sizes in OntoLSTM-PP and LSTM-PP are comparable as the synset types are shared across word types. In our experiments with the full PP attachment dataset, we learned embeddings for 18k synset types with OntoLSTM-PP and 11k word types with LSTM-PP. Since the biggest contribution to the parameter space comes from the embedding layer, the complexities of both the models are comparable.

5 Related Work

This work is related to various lines of research within the NLP community: dealing with synonymy and homonymy in word representations both in the context of distributed embeddings and more traditional vector spaces; hybrid models of distributional and knowledge based semantics; and selectional preferences and their relation with syntactic and semantic relations.

The need for going beyond a single vector per word-type has been well established for a while, and many efforts were focused on building multi-prototype vector space models of meaning (Reisinger and Mooney, 2010; Huang et al., 2012; Chen et al., 2014; Jauhar et al., 2015; Neelakantan et al., 2015; Arora et al., 2016, etc.). However, the target of all these approaches is obtaining multi-sense word vector spaces, either by incorporating sense tagged information or other kinds of external context. The number of vectors learned is still fixed, based on the preset number of senses. In contrast, our focus is on learning a context dependent distribution over those concept representations. Other work not necessarily related to multi-sense vectors, but still related to our work includes Belanger and Kakade (2015)'s work which proposed a Gaussian linear dynamical system for estimating token-level word embeddings, and Vilnis and McCallum (2015)'s work which proposed mapping each word type to a density instead of a point in a space to account for uncertainty in meaning. These approaches do not make use of lexical ontologies and are not amenable for joint training with a downstream NLP task.

Related to the idea of concept embeddings is Rothe and Schütze (2015) who estimated WordNet synset representations, given pre-trained type-level word embeddings. In contrast, our work focuses on estimating token-level word embeddings as context sensitive distributions of concept em-

The prepositions are shown in bold, LSTM-PP's predictions in red and OntoLSTM-PP's predictions in green. Words that are not candidate heads or dependents are shown in brackets.

beddings.

There is a large body of work that tried to improve word embeddings using external resources. Yu and Dredze (2014) extended the CBOW model (Mikolov et al., 2013) by adding an extra term in the training objective for generating words conditioned on similar words according to a lexicon. Jauhar et al. (2015) extended the skipgram model (Mikolov et al., 2013) by representing word senses as latent variables in the generation process, and used a structured prior based on the ontology. Faruqui et al. (2015) used belief propagation to update pre-trained word embeddings on a graph that encodes lexical relationships in the ontology. Similarly, Johansson and Pina (2015) improved word embeddings by representing each sense of the word in a way that reflects the topology of the semantic network they belong to, and then representing the words as convex combinations of their senses. In contrast to previous work that was aimed at improving *type level* word representations, we propose an approach for obtaining *context-sensitive* embeddings at the *token level*, while jointly optimizing the model parameters for the NLP task of interest.

Resnik (1993) showed the applicability of semantic classes and selectional preferences to resolving syntactic ambiguity. Zapirain et al. (2013) applied models of selectional preferences automatically learned from WordNet and distributional information, to the problem of semantic role labeling. Resnik (1993); Brill and Resnik (1994); Agirre (2008) and others have used WordNet information towards improving prepositional phrase attachment predictions.

6 Conclusion

In this paper, we proposed a grounding of lexical items which acknowledges the semantic ambiguity of word types using WordNet and a method to learn a context-sensitive distribution over their representations. We also showed how to integrate the proposed representation with recurrent neural networks for disambiguating prepositional phrase attachments, showing that the proposed WordNet-grounded context-sensitive token embeddings outperforms standard type-level embeddings for predicting PP attachments. We provided a detailed qualitative and quantitative analysis of the proposed model.

Implementation and code availability. The models are implemented using Keras (Chollet, 2015), and the functionality is available at `https://github.com/pdasigi/onto-lstm` in the form of Keras layers to make it easier to use the proposed embedding model in other NLP problems.

Future work. This approach may be extended to other NLP tasks that can benefit from using encoders that can access WordNet information. WordNet also has some drawbacks, and may not always have sufficient coverage given the task at hand. As we have shown in §4.2, our model can deal with missing WordNet information by augmenting it with distributional information. Moreover, the methods described in this paper can be extended to other kinds of structured knowledge sources like Freebase which may be more suitable for tasks like question answering.

Abstract

We present a method for populating fine-grained classes (e.g., *"1950s American jazz musicians"*) with instances (e.g., *Charles Mingus*). While state-of-the-art methods tend to treat class labels as single lexical units, the proposed method considers each of the individual modifiers in the class label relative to the head. An evaluation on the task of reconstructing Wikipedia category pages demonstrates a >10 point increase in AUC, over a strong baseline relying on widely-used Hearst patterns.

1 Introduction

The majority of approaches (Snow et al., 2006; Shwartz et al., 2016) for extracting IsA relations from text rely on lexical patterns as the primary signal of whether an instance belongs to a class. For example, observing a pattern like *"X such as Y"* is a strong indication that *Y* (e.g., *"Charles Mingus"*) is an instance of class *X* (e.g., *"musician"*) (Hearst, 1992).

Methods based on these "Hearst patterns" assume that class labels can be treated as atomic lexicalized units. This assumption has several significant weakness. First, in order to recognize an instance of a class, these pattern-based methods require that the entire class label be observed verbatim in text. The requirement is reasonable for class labels containing a single word, but in practice, there are many possible fine-grained classes: not only *"musicians"* but also *"1950s American jazz musicians"*. The probability that a given label will appear in its entirety within one of the expected patterns is very low, even in large amounts of text. Second, when class labels are treated as though they cannot be decomposed, every class label must be modeled independently, even those containing overlapping words (*"American jazz musician"*, *"French jazz musician"*). As a result, the number of meaning representations to be learned is exponential in the length of the class label, and quickly becomes intractable. Thus, compositional models of taxonomic relations are necessary for better language understanding.

1950s American jazz musicians
...seminal musicians *such as* **Charles Mingus** and George Russell...
...A virtuoso bassist and composer, **Mingus** irrevocably *changed the face of* jazz...
...**Mingus** truly *was a product of* America in all its historic complexities...
...**Mingus** *dominated the scene back in* the 1950s and 1960s...

Figure 1: We extract instances of fine-grained classes by considering each of the modifiers in the class label individually. This allows us to extract instances even when the full class label never appears in text.

We introduce a compositional approach for reasoning about fine-grained class labels. Our approach is based on the notion from formal semantics, in which modifiers (*"1950s"*) correspond to properties that differentiate instances of a subclass (*"1950s musicians"*) from instances of the superclass (*"musicians"*) (Heim and Kratzer, 1998). Our method consists of two stages: interpreting each modifier relative to the head (*"musicians active during 1950s"*), and using the interpretations to identify instances of the class from text (Figure 1). Our main contributions are: 1) a compositional method for IsA extraction, which in-

volves a novel application of noun-phrase paraphrasing methods to the task of semantic taxonomy induction and 2) the operationalization of a formal semantics framework to address two aspects of semantics that are often kept separate in NLP: assigning intrinsic "meaning" to a phrase, and reasoning about that phrase in a truth-theoretic context.

2 Related Work

Noun Phrase Interpretation. Compound noun phrases (*"jazz musician"*) communicate implicit semantic relations between modifiers and the head. Many efforts to provide semantic interpretations of such phrases rely on matching the compound to pre-defined patterns or semantic ontologies (Fares et al., 2015; Ó Séaghdha and Copestake, 2007; Tratz and Hovy, 2010; Surtani and Paul, 2015; Choi et al., 2015). Recently, interpretations may take the form of arbitrary natural language predicates (Hendrickx et al., 2013). Most approaches are supervised, comparing unseen noun compounds to the most similar phrase seen in training (Wijaya and Gianfortoni, 2011; Nulty and Costello, 2013; Van de Cruys et al., 2013). Other unsupervised approaches apply information extraction techniques to paraphrase noun compounds (Kim and Nakov, 2011; Xavier and Strube de Lima, 2014; Paşca, 2015). They focus exclusively on providing good paraphrases for an input noun compound. To our knowledge, ours is the first attempt to use these interpretations for the downstream task of IsA relation extraction.

IsA Relation Extraction. Most efforts to acquire taxonomic relations from text build on the seminal work of Hearst (1992), which observes that certain textual patterns–e.g., *"X and other Y"*–are high-precision indicators of whether X is a member of class Y. Recent work focuses on learning such patterns automatically from corpora (Snow et al., 2006; Shwartz et al., 2016). These IsA extraction techniques provide a key step for the more general task of knowledge base population. The "universal schema" approach (Riedel et al., 2013; Kirschnick et al., 2016; Verga et al., 2017), which infers relations using matrix factorization, often includes Hearst patterns as input features. Graphical (Bansal et al., 2014) and joint inference models (Movshovitz-Attias and Cohen, 2015) typically require Hearst patterns to define an inventory of possible classes. A separate line of work avoids Hearst patterns by instead exploiting semi-structured data from HTML markup (Wang and Cohen, 2009; Dalvi et al., 2012; Pasupat and Liang, 2014). These approaches all share the limitation that, in practice, in order for a class to be populated with instances, the entire class label has to have been observed verbatim in text. This requirement limits the ability to handle arbitrarily fine-grained classes. Our work addresses this limitation by modeling fine-grained class labels compositionally. Thus the proposed method can combine evidence from multiple sentences, and can perform IsA extraction without requiring any example instances of a given class.[1]

Taxonomy Construction. Previous work on the construction of a taxonomy of IsA relations (Flati et al., 2014; de Melo and Weikum, 2010; Kozareva and Hovy, 2010; Ponzetto and Strube, 2007; Ponzetto and Navigli, 2009) considers that task to be different than extracting a flat set of IsA relations from text in practice. Challenges specific to taxonomy construction include overall concept positioning and how to discover whether concepts are unrelated, subordinated or parallel to each other (Kozareva and Hovy, 2010); the need to refine and enrich the taxonomy (Flati et al., 2014); the difficulty in adding relevant IsA relations towards the top of the taxonomy (Ponzetto and Navigli, 2009); eliminating cycles and inconsistencies (Ponzetto and Navigli, 2009; Kozareva and Hovy, 2010). For practical purposes, these challenges are irrelevant when extracting flat IsA relations. Whereas Flati et al. (2014); Bizer et al. (2009); de Melo and Weikum (2010); Nastase and Strube (2013); Ponzetto and Strube (2007); Ponzetto and Navigli (2009); Hoffart et al. (2013) rely on data within human-curated resources, our work operates over unstructured text. Resources constructed in Bizer et al. (2009); Nastase and Strube (2013); Hoffart et al. (2013) contain not just a taxonomy of IsA relations,

[1] Pasupat and Liang (2014) also focuses on zero-shot IsA extraction, but exploits HTML document structure, rather than reasoning compositionally.

but also relation types other than IsA.

3 Modifiers as Functions

Formalization. In formal semantics, modification is modeled as function application. Specifically, let MH be a class label consisting of a head H, which we assume to be a common noun, preceded by a modifier M. We use $[\![\cdot]\!]$ to represent the "interpretation function" that maps a linguistic expression to its denotation in the world. The interpretation of a common noun is the set of entities[2] in the universe $\mathcal{U}$. They are denoted by the noun (Heim and Kratzer, 1998):

$$[\![H]\!] = \{e \in \mathcal{U} \mid e \text{ is a } H\} \quad (1)$$

The interpretation of a modifier M is a function that maps between sets of entities. That is, modifiers select a subset[3] of the input set:

$$[\![M]\!](H) = \{e \in H \mid e \text{ satisfies } M\} \quad (2)$$

This formalization leaves open how one decides whether or not "e satisfies M". This nontrivial, as the meaning of a modifier can vary depending on the class it is modifying: if e is a *"good student"*, e is not necessarily a *"good person"*, making it difficult to model whether "e satisfies *good*" in general. We therefore reframe the above equation, so that the decision of whether "e satisfies M" is made by calling a binary function ϕ_M, parameterized by the class H within which e is being considered:

$$[\![M]\!](H) = \{e \in H \mid \phi_M(H, e)\} \quad (3)$$

Conceptually, ϕ_M captures the core "meaning" of the modifier M, which is the set of properties that differentiate members of the output class MH from members of the more general input class H. This formal semantics framework has two important consequences. First, the modifier has an intrinsic "meaning". The properties entailed by the modifier are independent of the particular state of the world. This makes it possible to make inferences about *"1950s musician"* even if no 1950s musician have been observed. Second, the modifier is a function that can be applied in a truth-theoretic setting. That is, applying *"1950s"* to the set of *"musicians"* returns exactly the set of *"1950s musicians"*.

Computational Approaches. While the notion of modifiers as functions has been incorporated into computational models previously, prior work focuses on either assigning an intrinsic meaning to M or on operationalizing M in a truth-theoretic sense, but not on doing both simultaneously. For example, Young et al. (2014) focuses exclusively on the subset selection aspect of modification. That is, given a set of instances H and a modifier M, their method could return the subset MH. However, their method does not model the meaning of the modifier itself, so that, e.g., if there were no red cars in their model of the world, the phrase *"red cars"* would have no meaning. In contrast, Baroni and Zamparelli (2010) models the meaning of modifiers explicitly as functions that map between vector-space representations of nouns. However, their model focuses on similarity between class labels–e.g., to say that *"important routes"* is similar to *"major roads"*–and it is not obvious how the method could be operationalized in order to identify instances of those classes. A contribution of our work is to model the semantics of M intrinsically, but in a way that permits application in the model theoretic setting. We learn an explicit model of the "meaning" of a modifier M relative to a head H, represented as a distribution over properties that differentiate the members of the class MH from those of the class H. We then use this representation to identify the subset of instances of H, which constitute the subclass MH.

4 Learning Modifier Interpretations

4.1 Setup

For each modifier M, we would like to learn the function ϕ_M from Eq. 3. Doing so makes it possible, given H and an instance $e \in H$, to decide whether e has the properties required to be an instance of MH. In general, there is no systematic way to determine the implied relation between M and H, as modifiers can arguably express any semantic relation, given the right context (Weiskopf,

[2] We use "entities" and "instances" interchangeably;"entities" is standard terminology in linguistics.

[3] As does virtually all previous work in information extraction, we assume that modifiers are *subsective*, acknowledging the limitations (Kamp and Partee, 1995).

2007). We therefore model the semantic relation between M and H as a distribution over properties that could potentially define the subclass $MH \subseteq H$. We will refer to this distribution as a "property profile" for M relative to H. We make the assumption that relations between M and H that are discussed more often are more likely to capture the important properties of the subclass MH. This assumption is not perfect (Section 4.4) but has given good results for paraphrasing noun phrases (Nakov and Hearst, 2013; Paşca, 2015). Our method for learning property profiles is based on the unsupervised method proposed by Paşca (2015), which uses query logs as a source of common sense knowledge, and rewrites noun compounds by matching MH (*"American musicians"*) to queries of the form "$H(.*)M$" (*"musicians from America"*).

4.2 Inputs

We assume two inputs: 1) an IsA repository, $\mathcal{O}$, containing $\langle e, C\rangle$ tuples where C is a category and e is an instance of C, and 2) a fact repository, $\mathcal{D}$, containing $\langle s, p, o, w\rangle$ tuples where s and o are noun phrases, p is a predicate, and w is a confidence that p expresses a true relation between s and o. Both $\mathcal{O}$ and $\mathcal{D}$ are extracted from a sample of around 1 billion Web documents in English. The supplementary material gives additional details.

We instantiate $\mathcal{O}$ with an IsA repository constructed by applying Hearst patterns to the Web documents. Instances are represented as automatically-disambiguated entity mentions[4] which, when possible, are resolved to Wikipedia pages. Classes are represented as (non-disambiguated) natural language strings. We instantiate $\mathcal{D}$ with a large repository of facts extracted using in-house implementations of ReVerb (Fader et al., 2011) and OLLIE (Mausam et al., 2012). The predicates are extracted as natural language strings. Subjects and objects may be either disambiguated entity references or natural language strings. Every tuple is included in both the forward and the reverse direction. E.g. $\langle$*jazz, perform at, venue*$\rangle$ also appears as $\langle$*venue*, $\leftarrow$*perform at, jazz*$\rangle$, where $\leftarrow$ is a special character signifying inverted predicates. These inverted predicates simplify the following definitions. In total, $\mathcal{O}$ contains 1.1M tuples and $\mathcal{D}$ contains 30M tuples.

4.3 Building Property Profiles

Properties. Let I be a function that takes as input a noun phrase MH and returns a property profile for M relative to H. We define a "property" to be a tuple of a subject, predicate and object in which the subject position[5] is a wildcard, e.g. $\langle *, born\ in, America\rangle$. Any instance that fills the wildcard slot then "has" the property. We expand adjectival modifiers to encompass nominalized forms using a nominalization dictionary extracted from WordNet (Miller, 1995). If MH is *"American musician"* and we require a tuple to have the form $\langle H, p, M, w\rangle$, we will include tuples in which the third element is either *"American"* or *"America"*.

Relating M to H Directly. We first build property profiles by taking the predicate and object from any tuple in $\mathcal{D}$ in which the subject is the head and the object is the modifier:

$$I_1(MH) = \{\langle\langle p, M\rangle, w\rangle \mid \langle H, p, M, w\rangle \in \mathcal{D}\} \quad (4)$$

Relating M to an Instance of H. We also consider an extension in which, rather than requiring the subject to be the class label H, we require the subject to be an instance of H.

$$I_2(MH) = \{\langle\langle p, M\rangle, w\rangle \mid \langle e, H\rangle \in \mathcal{O} \wedge \langle e, p, M, w\rangle \in \mathcal{D}\} \quad (5)$$

Modifier Expansion. In practice, when building property profiles, we do not require that the object of the fact tuple match the modifier exactly, as suggested in Eq. 4 and 5. Instead, we follow Paşca (2015) and take advantage of facts involving distributionally similar modifiers. Specifically, rather than looking only at tuples in $\mathcal{D}$ in which the object matches M, we consider all tuples, but discount the weight proportionally to the similarity between M and the object of the tuple.

[4] "Entity mentions" may be individuals, like *"Barack Obama"*, but may also be concepts like *"jazz"*.

[5] Inverse predicates capture properties in which the wildcard is conceptually the object of the relation, but occupies the subject slot in the tuple. For example, $\langle$*venue*, $\leftarrow$*perform at, jazz*$\rangle$ captures that a *"jazz venue"* is a *"venue"* e such that *"jazz performed at e"*.

Good Property Profiles				Bad Property Profiles	
rice dish	French violinist	Led Zeppelin song	still life painter	child actor	risk manager
* serve with rice	* live in France	Led Zeppelin write *	* known for still life	* have child	* take risk
* include rice	* born in France	Led Zeppelin play *	* paint still life	* expect child	* be at risk
* consist of rice	* speak French	Led Zeppelin have *	still life be by *	* play child	* be aware of risk

Table 1: Example property profiles learned by observing predicates that relate instances of class H to modifier M (I_2). Results are similar when using the class label H directly (I_1). We spell out inverted predicates (Section 4.2) so wildcards (*) may appear as subjects or objects.

Thus, I_1 is computed as below:

$$I_1(MH) = \{\langle\langle p, M\rangle, w \times sim(M, N)\rangle \mid \langle H, p, N, w\rangle \in \mathcal{D}\} \quad (6)$$

where $sim(M, N)$ is the cosine similarity between M and N. I_2 is computed analogously. We compute sim using a vector space built from Web documents following Lin and Wu (2009); Pantel et al. (2009). We retain the 100 most similar phrases for each of ∼10M phrases, and consider all other similarities to be 0.

4.4 Analysis of Property Profiles

Table 1 provides examples of good and bad property profiles for several MHs. In general, frequent relations between M and H capture relevant properties of MH, but it is not always the case. To illustrate, the most frequently discussed relation between *"child"* and *"actor"* is that actors have children, but this property is not indicative of the meaning of *"child actor"*. Qualitatively, the top-ranked interpretations learned by using the head noun directly (I_1, Eq. 4) are very similar to those learned using instances of the head (I_2, Eq. 5). However, I_2 returns many more properties (10 on average per MH) than I_1 (just over 1 on average). Anecdotally, we see that I_2 captures more specific relations than does I_1. For example, for *"jazz musicians"*, both methods return *"* write jazz"* and *"* compose jazz"*, but I_2 additionally returns properties like *"* be major creative influence in jazz"*. We compare I_1 and I_2 quantitatively in Section 6. Importantly, we do see that both I_1 and I_2 are capable of learning head-specific property profiles for a modifier. Table 2 provides examples.

Class Label	Property Profile
American company	* based in America
American composer	* born in America
American novel	* written in America
jazz album	* features jazz
jazz composer	* writes jazz
jazz venue	jazz performed at *

Table 2: Head-specific property profiles learned by relating instances of H to the modifier M (I_2). Results are similar using I_1.

5 Class-Instance Identification

Instance finding. After finding properties that relate a modifier to a head, we turn to the task of identifying instances of fine-grained classes. That is, for a given modifier M, we want to instantiate the function ϕ_M from Eq. 3. In practice, rather than being a binary function that decides whether or not e is in class MH, our instantiation, $\hat{\phi}_M$, will return a real-valued score expressing the confidence that e is a member of MH. For notational convenience, let $\mathcal{D}(\langle s, p, o\rangle) = w$, if $\langle s, p, o, w\rangle \in \mathcal{D}$ and 0 otherwise. We define $\hat{\phi}_M$ as follows:

$$\hat{\phi}_M(H, e) = \sum_{\langle\langle p,o\rangle,\omega\rangle \in I(MH)} \omega \times \mathcal{D}(\langle e, p, o\rangle) \quad (7)$$

Applying M to H, then, is as in Eq. 3 except that instead of a discrete set, it returns a scored list of candidate instances:

$$[\![M]\!](H) = \{\langle e, \hat{\phi}_M(H, e)\rangle \mid \langle e, H\rangle \in \mathcal{O}\} \quad (8)$$

Ultimately, we need to identify instances of arbitrary class labels, which may contain multiple modifiers. Given a class label $C = M_1 \ldots M_k H$ that contains a head H preceded by modifiers $M_1 \ldots M_k$, we generate a list of candidate instances by finding all instances of H that have some property to support every modifier:

$$\bigcap_{i=1}^{k} \{\langle e, s(e)\rangle \mid \langle e, w\rangle \in [\![M_i]\!](H) \wedge w > 0\} \quad (9)$$

where $s(e)$ is the mean[6] of the scores assigned by each separate $\hat{\phi}_{M_i}$. From here on, we use **Mods** to refer to our method that generates lists of instances for a class using Eq. 8 and 9. When $\hat{\phi}_M$ (Eq. 7) is implemented using I_1, we use the name $\textbf{Mods}_H$ (for "heads"). When it is implemented using I_2, we use the name $\textbf{Mods}_I$ (for "instances").

Weakly Supervised Reranking. Eq. 8 uses a naive ranking in which the weight for $e \in MH$ is the product of how often e has been observed with some property and the weight of that property for the class MH. Thus, instances of H with overall higher counts in $\mathcal{D}$ receive high weights for every MH. We therefore train a simple logistic regression model to predict the likelihood that e belongs to MH. We use a small set of features[7], including the raw weight as computed in Eq. 7. For training, we sample $\langle e, C \rangle$ pairs from our IsA repository $\mathcal{O}$ as positive examples and random pairs that were not extracted by any Hearst pattern as negative examples. We frame the task as a binary prediction of whether $e \in C$, and use the model's confidence as the value of $\hat{\phi}_M$ in place of the function in Eq. 7.

6 Evaluation

6.1 Experimental Setup

Evaluation Sets. We evaluate our models on their ability to return correct instances for arbitrary class labels. As a source of evaluation data, we use Wikipedia category pages (e.g., http://en.wikipedia.org/wiki/Category:Pakistani_film_actresses). These are pages in which the title is the name of the category (*"pakistani film actresses"*) and the body is a manually curated list of links to other pages that fall under the category. We measure the precision and recall of each method for discovering the instances listed on these pages given the page title (henceforth "class label").

We collect the titles of all Wikipedia category pages, removing those in which the last word is capitalized or which contain fewer than three words. These heuristics are intended to retain compositional titles in which the head is a single common noun. We also remove any titles that contain links to sub-categories. This is to favor fine-grained classes (*"pakistani film actresses"*) over coarse-grained ones (*"film actresses"*). We perform heuristic modifier chunking in order to group together multiword modifiers (e.g., *"puerto rican"*); for details, see supplementary material. From the resulting list of class labels, we draw two samples of 100 labels each, enforcing that no H appear as the head of more than three class labels per sample. The first sample is chosen uniformly at random (denoted **UniformSet**). The second (**WeightedSet**) is weighted so that the probability of drawing $M_1 \ldots M_k H$ is proportional to the total number of class labels in which H appears as the head. These different evaluation sets[8] are intended to evaluate performance on the head versus the tail of class label distribution, since information retrieval methods often perform differently on different parts of the distribution. On average, there are 17 instances per category in UniformSet and 19 in WeightedSet. Table 3 gives examples of class labels.

Evaluation Set: Examples of Class Labels
UniformSet: 2008 california wildfires · australian army chaplains · australian boy bands · canadian military nurses · canberra urban places · cellular automaton rules · chinese rice dishes · coldplay concert tours · daniel libeskind designs · economic stimulus programs · german film critics · invasive amphibian species · latin political phrases · log flume rides · malayalam short stories · pakistani film actresses · puerto rican sculptors · string theory books
WeightedSet: ancient greek physicists · art deco sculptors · audio engineering schools · ballet training methods · bally pinball machines · british rhythmic gymnasts · calgary flames owners · canadian rock climbers · canon l-series lenses · emi classics artists · free password managers · georgetown university publications · grapefruit league venues · liz claiborne subsidiaries · miss usa 2000 delegates · new zealand illustrators · russian art critics

Table 3: Examples of class labels from evaluation sets.

Baselines. We implement two baselines using our IsA repository ($\mathcal{O}$ as defined in Section 4.1). Our simplest baseline ignores modifiers altogether, and simply assumes that any instance of H is an instance of MH, regardless of M. In this case the confidence value for

[6] Also tried minimum, but mean gave better results.
[7] Feature templates in supplementary material.
[8] Available at http://www.seas.upenn.edu/~nlp/resources/finegrained-class-eval.gz

$\langle e, MH \rangle$ is equivalent to that for $\langle e, H \rangle$. We refer to this baseline simply as **Baseline**. Our second, stronger baseline uses the IsA repository directly to identify instances of the fine-grained class $C = M_1 \dots M_k H$. That is, we consider e to be an instance of the class if $\langle e, C \rangle \in \mathcal{O}$, meaning the entire class label appeared in a source sentence matching some Hearst pattern. We refer to this baseline as **Hearst**. The weight used to rank the candidate instances is the confidence value assigned by the Hearst pattern extraction (Section 4.2).

Compositional Models. As a baseline compositional model, we augment the Hearst baseline via set intersection. Specifically, for a class $C = M_1 \dots M_k H$, if each of the $M_i H$ appears in $\mathcal{O}$ independently, we take the instances of C to be the intersection of the instances of each of the $M_i H$. We assign the weight of an instance e to be the sum of the weights associated with each independent modifier. We refer to this method as **Hearst**$\cap$. It is roughly equivalent to (Paşca, 2014). We contrast it with our proposed model, which recognizes instances of a fine-grained class by 1) assigning a meaning to each modifier in the form of a property profile and 2) checking whether a candidate instance exhibits these properties. We refer to the versions of our method as **Mods**$_H$ and **Mods**$_I$, as described in Section 5. When relevant, we use "raw" to refer to the version in which instances are ranked using raw weights and "RR" to refer to the version in which instances are ranked using logistic regression (Section 5). We also try using the proposed methods to extend rather than replace the Hearst baseline. We combine predictions by merging the ranked lists produced by each system: i.e. the score of an instance is the inverse of the sum of its ranks in each of the input lists. If an instance does not appear at all in an input list, its rank in that list is set to a large constant value. We refer to these combination systems as **Hearst+Mods**$_H$ and **Hearst+Mods**$_I$.

6.2 Results

Precision and Coverage. We first compare the methods in terms of their coverage, the number of class labels for which the method is able to find some instance, and their precision, to what extent the method is able to correctly rank true instances of the class above non-instances. We report total coverage, the number of labels for which the method returns any instance, and correct coverage, the number of labels for which the method returns a correct instance. For precision, we compute the average precision (AP) for each class label. AP ranges from 0 to 1, where 1 indicates that all positive instances were ranked above all negative instances. We report mean average precision (MAP), which is the mean of the APs across all the class labels. MAP is only computed over class labels for which the method returns something, meaning methods are not punished for returning empty lists.

Table 4 gives examples of instances returned for several class labels and Table 5 shows the precision and coverage for each of the methods. Figure 2 illustrates how the single mean AP score (as reported in Table 5) can misrepresent the relative precision of different methods. In combination, Table 5 and Figure 2 demonstrate that the proposed methods extract instances about as well as the baseline, whenever the baseline can extract anything at all; i.e. the proposed method does not cause a precision drop on classes covered by the baseline. In addition, there are many classes for which the baseline is not able to extract any instances, but the proposed method is. None of the methods can extract some of the gold instances, such as *"Dictator perpetuo"* and *"Furor Teutonicus"* of the gold class *"latin political phrases"*.

Table 5 also reveals that the reranking model (RR) consistently increases MAP for the proposed methods. Therefore, going forward, we only report results using the reranking model (i.e. Mods$_H$ and Mods$_I$ will refer to Mods$_H$ RR and Mods$_I$ RR, respectively).

Manual Re-Annotation. It possible that true instances of a class are missing from our Wikipedia reference set, and thus that our precision scores underestimate the actual precision of the systems. We therefore manually verify the top 10 predictions of each of the systems for a random sample of 25 class labels. We choose class labels for which Hearst was able to return at least one instance, in order to ensure reliable precision

Flemish still life painters: Clara Peeters · Willem Kalf · Jan Davidsz de Heem · *Pieter Claesz* · ~~Peter Paul Rubens~~ · Frans Snyders · Jan Brueghel the Elder · ~~Hans Memling~~ · ~~Pieter Bruegel the Elder~~ · ~~Caravaggio~~ · Abraham Brueghel

Mods_I RR	62 / 36	0.24	59 / 38	0.23

Table 5: Coverage and precision for populating Wikipedia category pages with instances. "Coverage" is the number of class labels (out of 100) for which at least one instance was returned, followed by the number for which at least one correct instance was returned. "MAP" is mean average precision. MAP does not punish methods for returning empty lists, thus favoring the baseline (see Figure 2).

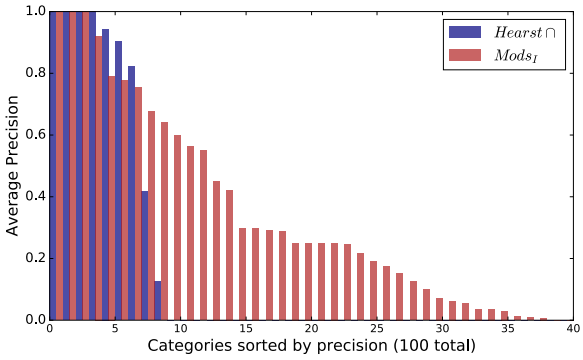

Figure 2: Distribution of AP over 100 class labels in WeightedSet. The proposed method (red) and the baseline method (blue) achieve high AP for the same number of classes, but Mods_I additionally finds instances for classes for which the baseline returns nothing.

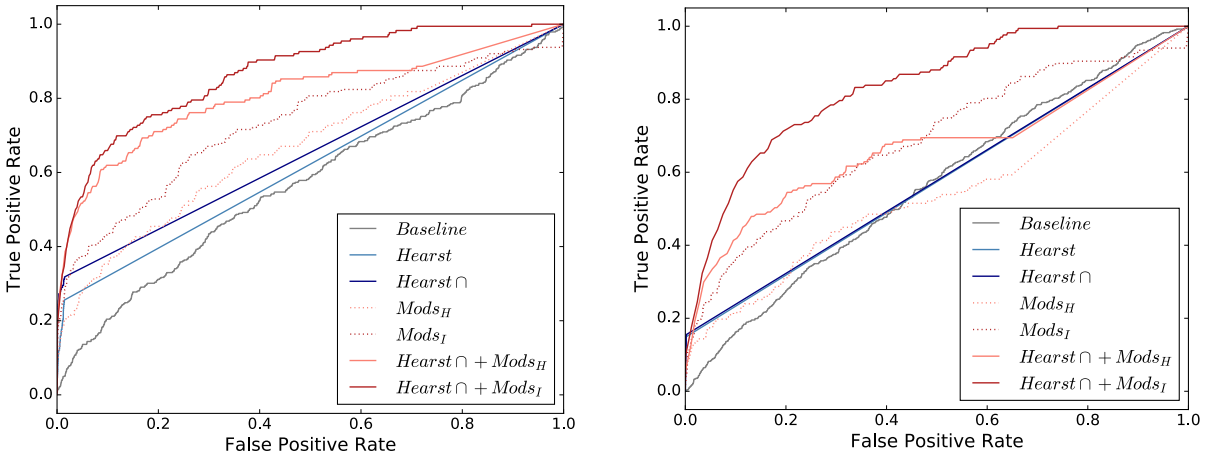
estimates. For each of these labels, we manually check the top 10 instances proposed by each method to determine whether each belongs to the class. Table 6 shows the precision scores for each method computed against the original Wikipedia list of instances and against our manually-augmented list of gold instances. The overall ordering of the systems does not change, but the precision scores increase notably after re-annotation. We continue to evaluate against the Wikipedia lists, but acknowledge that reported precision is likely an underestimate of true precision.

	Wikipedia	Gold
Hearst	0.56	0.79
Hearst∩	0.53	0.78
Mods_H	0.23	0.39
Mods_I	0.24	0.42
Hearst+Mods_H	0.43	0.63
Hearst+Mods_I	0.43	0.63

Table 6: P@10 before vs. after re-annotation; Wikipedia underestimates true precision.

	UniformSet		WeightedSet	
	AUC	Recall	AUC	Recall
Baseline	0.55	0.23	0.53	0.28
Hearst	0.56	0.03	0.52	0.02
Hearst∩	0.57	0.04	0.53	0.02
Mods_H	0.68	0.08	0.60	0.06
Mods_I	0.71	0.09	0.65	0.09
Hearst∩+Mods_H	0.70	0.09	0.61	0.08
Hearst∩+Mods_I	0.73	0.10	0.66	0.10

Table 7: Recall of instances on Wikipedia category pages, measured against the full set of instances from all pages in sample. AUC captures tradeoff between true and false positives.



(a) Uniform random sample (UniformSet).

(b) Weighted random sample (WeightedSet).

Figure 3: ROC curves for selected methods (Hearst in blue, proposed in red). Given a ranked list of instances, ROC curves plot true positives vs. false positives retained by setting various cutoffs. The curve becomes linear once all remaining instances have the same score (e.g., 0), as this makes it impossible to add true positives without also including all remaining false positives.

Precision-Recall Analysis. We next look at the precision-recall tradeoff in terms of the area under the curve (AUC) when each method attempts to rank the complete list of candidate instances. We take the union of all of the instances proposed by all of the methods (including the Baseline method which, given a class label $M_0 \ldots M_k H$, proposes every instance of the head H as a candidate). Then, for each method, we rank this full set of candidates such that any instance returned by the method is given the score the method assigns, and every other instance is scored as 0. Table 7 reports the AUC and recall. Figure 3 plots the full ROC curves. The requirement by Hearst that class labels appear in full in a single sentence results in very low recall, which translates into very low AUC when considering the full set of candidate instances. In comparison, the proposed compositional methods make use of a larger set of sentences, and provide non-zero scores for many more candidates, resulting in a >10 point increase in AUC on both UniformSet and WeightedSet (Table 7).

7 Conclusion

We have presented an approach to IsA extraction that takes advantage of the compositionality of natural language. Existing approaches often treat class labels as atomic units that must be observed in full in order to be populated with instances. As a result, current methods are not able to handle the infinite number of classes describable in natural language, most of which never appear in text. Our method reasons about each modifier in the label individually, in terms of the properties that it implies about the instances. This approach allows us to harness information that is spread across multiple sentences, significantly increasing the number of fine-grained classes that we are able to populate.

Acknowledgments

The paper incorporates suggestions on an earlier version from Susanne Riehemann. Ryan Doherty offered support in refining and accessing the fact repository used in the evaluation.

Abstract

We study the Maximum Subgraph problem in deep dependency parsing. We consider two restrictions to deep dependency graphs: (a) 1-endpoint-crossing and (b) pagenumber-2. Our main contribution is an exact algorithm that obtains maximum subgraphs satisfying both restrictions simultaneously in time $O(n^5)$. Moreover, ignoring one linguistically-rare structure descreases the complexity to $O(n^4)$. We also extend our quartic-time algorithm into a practical parser with a discriminative disambiguation model and evaluate its performance on four linguistic data sets used in semantic dependency parsing.

1 Introduction

Dependency parsing has long been studied as a central issue in developing syntactic or semantic analysis. Recently, some linguistic projects grounded on deep grammar formalisms, including CCG, LFG, and HPSG, draw attentions to rich syntactic and semantic dependency annotations that are not limited to trees (Hockenmaier and Steedman, 2007; Sun et al., 2014; Ivanova et al., 2012). Parsing for these *deep* dependency representations can be viewed as the search for Maximum Subgraphs (Kuhlmann and Jonsson, 2015). This is a natural extension of the Maximum Spanning Tree (MST) perspective (McDonald et al., 2005) for dependency tree parisng.

One main challenge of the Maximum Subgraph perspective is to design tracTable algorithms for certain graph classes that have good empirical coverage for linguistic annotations. Unfortunately, no previously defined class simultaneously has high coverage and low-degree polynomial parsing algorithms. For example, noncrossing dependency graphs can be found in time $O(n^3)$, but cover only 48.23% of sentences in CCGBank (Kuhlmann and Jonsson, 2015).

We study two well-motivated restrictions to deep dependency graphs: (a) 1-endpoint-crossing (1EC hereafter; Pitler et al., 2013) and (b) pagenumber is less than or equal to 2 (P2 hereafter; Kuhlmann and Jonsson, 2015). We will show that if the output dependency graphs are restricted to satisfy both restrictions, the Maximum Subgraph problem can be solved using dynamic programming in time $O(n^5)$. Moreover, if we ignore one linguistically-rare sub-problem, we can reduce the time complexity to $O(n^4)$. Though this new algorithm is a degenerated one, it has the same empirical coverage for various deep dependency annotations. We evaluate the coverage of our algorithms on four linguistic data sets: CCGBank, DeepBank, Enju HPSGBank and Prague Dependency TreeBank. They cover 95.68%, 97.67%, 97.28% and 97.53% of dependency graphs in the four corpora. The relatively satisfactory coverage makes it possible to parse with high accuracy.

Based on the quartic-time algorithm, we implement a parser with a discriminative disambiguation model. Our new parser can be taken as a graph-based parser which is complementary to transition-based (Henderson et al., 2013; Zhang et al., 2016) and factorization-based (Martins and Almeida, 2014; Du et al., 2015a) systems. We evaluate our parser on four data sets: those used in SemEval 2014 Task 8 (Oepen et al., 2014), and the dependency graphs extracted from CCGbank (Hockenmaier and Steedman, 2007). Evaluations indicate that our parser produces very accurate deep dependency analysis. It reaches state-of-the-art results on average produced by a transition-based system of Zhang et al.

The first two authors contribute equally.

(2016) and factorization-based systems (Martins and Almeida, 2014; Du et al., 2015a).

The implementation of our parser is available at http://www.icst.pku.edu.cn/lcwm/grass.

2 Background

Dependency parsing is the task of mapping a natural language sentence into a dependency graph. Previous work on dependency parsing mainly focused on tree-shaped representations. Recently, it is shown that data-driven parsing techniques are also applicable to generate more flexible deep dependency graphs (Du et al., 2014; Martins and Almeida, 2014; Du et al., 2015b,a; Zhang et al., 2016; Sun et al., 2017). Parsing for deep dependency representations can be viewed as the search for Maximum Subgraphs for a certain graph class $\mathcal{G}$ (Kuhlmann and Jonsson, 2015), a generalization of the MST perspective for tree parsing. In particular, we have the following optimization problem:

Given an arc-weighted graph $G = (V, A)$, find a subgraph $G' = (V, A' \subseteq A)$ with maximum total weight such that G' belongs to $\mathcal{G}$.

The choice of $\mathcal{G}$ determines the computational complexity of dependency parsing. For example, if $\mathcal{G}$ is the set of projective trees, the problem can be solved in time $O(|V|^3)$, and if $\mathcal{G}$ is the set of noncrossing dependency graphs, the complexity is $O(|V|^3)$. Unfortunately, no previously defined class simultaneously has high coverage on deep dependency annotations and low-degree polynomial decoding algorithms for practical parsing. In this paper, we study well-motivated restrictions: 1EC (Pitler et al., 2013) and P2 (Kuhlmann and Jonsson, 2015). We will show that relatively satisfactory coverage and parsing complexity can be obtained for graphs that satisfy both restrictions.

3 The 1EC, P2 Graphs

3.1 The 1EC Restriction

Pitler et al. (2013) introduced a very nice property for modelling non-projective dependency trees, i.e. 1EC. This property not only covers a large amount of tree annotations in natural language treebanks, but also allows the corresponding MST problem to bo solved in time of $O(n^4)$. The formal description of the 1EC property is adopted from (Pitler et al., 2013).

Definition 1. *Edges e_1 and e_2 cross if e_1 and e_2 have distinct endpoints and exactly one of the endpoints of e_1 lies between the endpoints of e_2.*

Definition 2. *A dependency graph is 1-Endpoint-Crossing if for any edge e, all edges that cross e share an endpoint p.*

Given a sentence $s = w_0 w_1 \cdots w_{n-1}$ of length n, the vertices, i.e. words, are indexed with integers, an arc from w_i to w_j as $a_{(i,j)}$, and the common endpoint, namely pencil point, of all edges crossed with $a_{(i,j)}$ or $a_{(j,i)}$ as $pt(i, j)$. We denote an edge as $e_{(i,j)}$, if we do not consider its direction.

3.2 The P2 Restriction

The term *pagenumber* is referred to as *planar* by some other authors, e.g. (Titov et al., 2009; Gómez-Rodríguez and Nivre, 2010; Pitler et al., 2013). We give the definition of related concepts as follows.

Definition 3. *A book is a particular kind of topological space that consists of a single line called the spine, together with a collection of one or more half-planes, called the pages, each having the spine as its boundary.*

Definition 4. *A book embedding of a finite graph G onto a book B satisfies three conditions: (1) every vertex of G is drawn as a point on the spine of B; (2) every edge of G is drawn as a curve that lies within a single page of B; (3) every page of B does not have any edge crossings.*

Empirically, a deep dependency graph is not very dense and can typically be embedded onto a very *thin* book. To measure the thickness of a graph, we can use its *pagenumber*.

Definition 5. *The book pagenumber of G is the minimum number of pages required for a book embedding of G.*

For sake of concision, we say a graph is "pagenumber-k", meaning that the pagenumber is at most k.

Theorem 1. *The pagenumber of* 1EC *graph may be greater than 2.*

Proof. The graph in Figure 1 gives an instance which is 1EC but the pagenumber of which is 3. There is a cycle, namely $a \to c \to e \to b \to d \to a$, consisting of odd number of edges. □

Pitler et al. (2013) proved that 1EC trees are a subclass of graphs whose pagenumber is at most 2. This property provides the foundation to the

PN≤ 2	1EC	EnjuBank	DeepBank	PCEDT	CCGBank

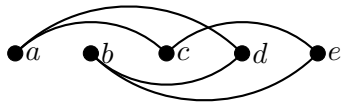

Figure 1: A 1EC graph whose pagenumber is 3.

success in designing dynamic programming algorithms for trees. Theorem 1 indicates that when we consider more general graph, the case is more complicated. In this paper, we study graphs that are constrained to be both 1EC and P2. We call them 1EC/P2 graphs.

3.3 Coverage on Linguistic Data

To show that the two restrictions above are well-motivated for describing linguistic data, we evaluate their empirical coverage on four deep dependency corpora (as defined in Section 5.2). These corpora are also used for training and evaluating our data-driven parsers. The coverage is evaluated using sentences in the training sets.

Table 1 shows the results. We can see that 1EC is also an empirical well-motivated restriction when it comes to deep dependency structures. The P2 property has an even better coverage. Unfortunately, it is a NP-hard problem to find optimal P2 graphs (Kuhlmann and Jonsson, 2015). Though theoretically a 1EC graph is not necessarily P2, the empirical evaluation demonstrates the high overlap of them on linguistic annotations. In particular, almost all 1EC deep dependency graphs are P2. The percentages of graphs satisfying both restrictions vary between 95.68% for CCGBank and 97.67% for DeepBank. The relatively satisfactory coverage enables accurate practical parsing.

4 The Algorithm

This section contains the main contribution of this paper: a polynomial time exact algorithm for solving the Maximum Subgraph problem for the class of 1EC/P2 graphs.

Theorem 2. *Take* 1EC/P2 *graphs as target subgraphs, the maximum subgraph problem can be solved in time* $O(|V|^5)$.

For sake of formal concision, we introduce the algorithm of which the goal is to calculate the maximum score of a subgraph. Extracting corresponding optimal graphs can be done in a number of ways. For example, we can maintain an auxiliary arc table which is populated parallel to the procedure of obtaining maximum scores.

Our algorithm is highly related to the following property: Every subgraph of a 1EC/P2 graph is also a 1EC/P2 graph. We therefore focus on maximal 1EC/P2 graphs, a particular type of 1EC/P2 graphs defined as follows.

Definition 6. *A maximal* 1EC/P2 *graph is a* 1EC/P2 *graph that cannot be extended by including one more edge.*

Our algorithm is a bottom-up dynamic programming algorithm. It defines different structures corresponding to different sub-problems, and visits all structures from bottom to top, finding the best combination of smaller structures to form a new structure. The key design is to make sure that it can produce all maximal 1EC/P2 graphs. During the search for maximal 1EC/P2 graphs, we can freely delete bad edges whose scores are negative. In particular, we figure out some edges, in each construction step, which can be created without violating either 1EC or P2 restriction. Assume the arc weight associated with $a_{(i,j)}$ is $w[i,j]$. Then we define a function SELECT(i,j) according to the comparison of 0 and $w[i,j]$ as well as $w[j,i]$. If $w[i,j] \geq 0$ (or $w[j,i] \geq 0$), we then *select* $a_{(i,j)}$ (or $a_{(j,i)}$) and add it to currently the best solution of a sub-problem. SELECT(i,j) returns $\max(\max(0, w[i,j]) + \max(0, w[j,i]))$. If we allow at most one arc between two nodes, SELECT(i,j) returns $\max(0, w[i,j], w[j,i])$.

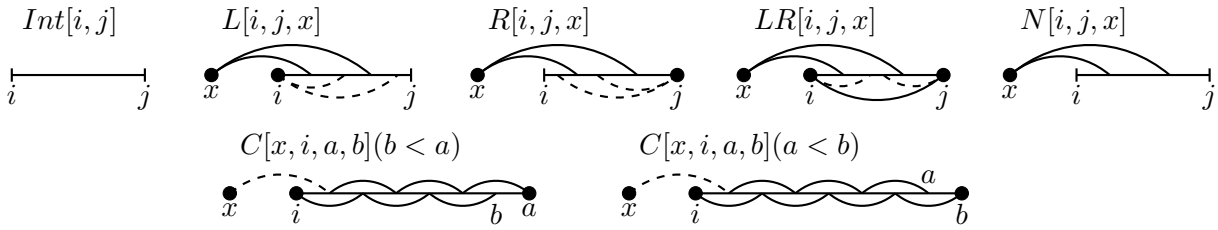

Figure 2: Graphic representations of sub-problems.

The graphical illustration of our algorithm uses undirected graphs[1]. In other words, we use $e_{(i,j)}$ to include the discussion about both $a_{(i,j)}$ and $a_{(j,i)}$.

4.1 Sub-problems

We consider six sub-problems when we construct a maximum dependency graph on a given (closed) interval $[i, k] \subseteq V$ of vertices. When we focus on the nodes strictly inside this interval, and we use an open interval (i, k) to exclude i and j. See Figure 2 for graphical visualization. The first five are adapted in concord with Pitler et al. (2013)'s solution for trees, and we introduce a new sub-problem, namely **C**. Because graphs allow for loops as well as disconnectedness, the sub-problems are simplified to some extent, while a special case of **LR** is now prominent. **C** is thus introduced to represent the special case. The sub-problems are explained as follows.

Int $Int[i, j]$ represents a partial analysis associated with an interval from i to j inclusively. $Int[i, j]$ may or may not contain edge $e_{(i,j)}$. To parse a given sentence is equivalent to solve the problem $Int[0, n-1]$.

L $L[i, j, x]$ represents a partial analysis associated with an interval from i to j inclusively as well as an external vertex x. $\forall p \in (i, j), pt(x, p) = i$. $L[i, j, x]$ can contain $e_{(i,j)}$ but disallows $e_{(x,i)}$ or $e_{(x,j)}$.

R $R[i, j, x]$ represents a partial analysis associated with an interval from i to j inclusively as well as an external vertex x. $\forall p \in (i, j), pt(x, p) = j$. $R[i, j, x]$ can contain $e_{(i,j)}$ but disallows $e_{(x,i)}$ or $e_{(x,j)}$.

LR $LR[i, j, x]$ represents a partial analysis associated with an interval from i to j inclusively as well as an external vertex x. $\forall p \in (i, j), pt(x, p) = i$ or j. $LR[i, j, x]$ must allow $e_{(i,j)}$ but disallows $e_{(x,i)}$ or $e_{(x,j)}$.

N $N[i, j, x]$ represents a partial analysis associated with an interval from i to j inclusively and an external vertex x. $\forall p \in (i, j), pt(x, p) \notin [i, j]$. $N[i, j, x]$ can contain $e_{(i,j)}$ but disallows $e_{(x,i)}$ or $e_{(x,j)}$.

C $C[x, i, a, b](a \neq b, a > i, b > i)$ represents a partial analysis associated with an interval from i to $max\{a, b\}$ inclusively and an external vertex x. Intuitively, **C** depicts a class of graphs constructed by upper- and lower-plane edges arranged in a staggered pattern. a stands for the last endpoint in the upper plane, and b the last endpoint in the lower plane.

We give a definition of **C**. There exists in $C[x, i, a, b]$ a series $\{s_1, \cdots, s_m\}$ that fulfills the following constraints:

1. $s_1 = i < s_2 < ... < s_m = \max\{a, b\}$.
2. $\exists e_{(x,s_2)}$.
3. $\forall k \in [1, m-2], \exists e_{(s_k, s_{k+2})}$.
4. $\forall k \in [1, m-2], \nexists e_{(l,r)} (s_k, s_{k+2}) \subset (l, r) \subset (s_1, s_m)$[2].
5. $\forall k \in [2, m-3]$, $e_{(s_k, s_{k+2})}$ crosses only with $e_{(s_{k-1}, s_{k+1})}$ and $e_{(s_{k+1}, s_{k+3})}$; $e_{(s_1, s_3)}$ crosses only with $e_{(s_2, s_4)}$ and $e_{(x,s_2)}$; $e_{(s_{m-2}, s_m)}$ crosses only with $e_{(s_{m-3}, s_{m-1})}$.
6. $e_{(x,s_{m-1})}, e_{(s_1,s_m)}, e_{(x,s_1)}, e_{(x,s_m)}$ are disallowed.
7. While $a < b$, the series can be written as $\{s_1 = i, \cdots, s_{m-1} = a, s_m = b\} (m \geq 5)$. While $b < a$, the series is $\{s_1, \cdots, s_{m-1} =$

[1] The *single-head* property does not hold. We currently do not consider other constraints of directions. So prediction of the direction of one edge does not affect prediction of other edges as well as their directions. The directions can be assigned *locally*, and our parser builds directed rather than undirected graphs in this way. Undirected graphs are only used to conveniently illustrate our algorithms. All experimental results in Section 5.2 consider directed dependencies in a standard way. We use the official evaluation tool provided by SDP2014 shared task. The numberic results reported in this paper are directly comparable to results in other papers.

[2] By "$(x, y) \subset (z, w)$," we mean $x \geq z, y < w$ or $x > z, y \leq w$.

$b, s_m = a\}(m \geq 4)$. We denote the two cases using the signs **C1** and **C2** respectively.

The distinction between **C1** and **C2** is whether there is one more edge below than above.

4.2 Decomposing an Int Sub-problem

Consider an $Int[i,j]$ sub-problem. Assume that $k(k \in (i,j))$ is the farthest vertex that is linked with i, and $l = pt(i,k)$. When $j - i > 1$, there must be such a k given that we consider maximal 1EC/P2 graphs. There are three cases.

Case 1: $l = j$**.** Vertex k divides the interval $[i,j]$ into two parts: $[i,k]$ and $[k,j]$. First notice that the edges linking (i,k) and j can only cross with $e_{(i,k)}$. Thus i or k can be the pencil points of those edges, which entails that interval $[i,k]$ is an **LR** in respect to external vertex j. Because there exist no edge from i to any node in (k,j), interval $[k,j]$ is an **Int**. The problem is eventually decomposed to: $LR[i,k,j] + Int[k,j] + \text{SELECT}[i,j]$.

Case 2: $l \in (k,j)$**.** In this case, we can freely add $e_{(i,l)}$ without violating either 1EC or P2 conditions. Therefore Case 2 does not lead to any maximal 1EC/P2 graph. Our algorithm does not need to explicitly handle this case, given that they can be derived from solutions to other cases.

Case 3: $l \in (i,k)$**.** Now assume that there is an edge from i to a vertex in (l,k). Consider the farthest vertex that is linked with l, say $p(p \in (k,j)$. We can freely add $e_{(i,p)}$ without violating the 1EC and P2 restrictions. Similar to Case 2, we do not explicitly deal with this case.

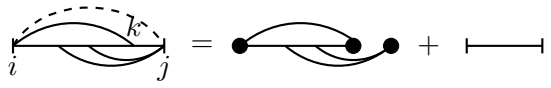
If there is no edge from i to any vertex in (l,k), then $[i,l]$, $[l,k]$, $[k,j]$ are **R**, **Int**, **L** respectively. Three external edges are $e_{(i,k)}$, $e_{(l,j)}$, and $e_{(i,j)}$. The decomposition is: $R[i,l,k]+Int[l,k]+L[k,j,l] + \text{SELECT}[l,j] + \text{SELECT}[i,j]$.

4.3 Decomposing an L Sub-problem

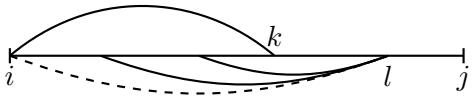
If there is no edge from x to any node in (i,j), the graph is reduced to $Int[i,j]$. If there is one, let k be the vertex farthest from i and adjacent to x. There are two different cases, as shown in Figure 4.

1. If there exists an edge from x to some node in (i,k), intervals $[i,k]$, $[k,j]$ are classified as **L**, **N** respectively. Two edges external to the interval: $e_{(x,k)}$, $e_{(i,j)}$. The decomposition is $L[i,k,x]+N[k,j,i]+\text{SELECT}[x,k]+\text{SELECT}[i,j]$.

Case 1: $l = j$



Case 2: $l \in (k,j)$



Case 3: $l \in (i,k)$

Does such a dashed edge exist?

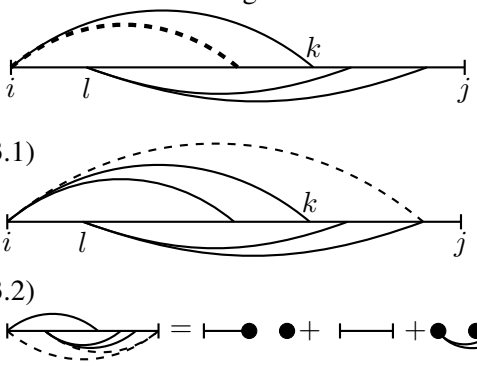


Figure 3: Decomposition for $Int[i,j]$, with $pt(i,k) = l$.

Does such a dashed edge exist?

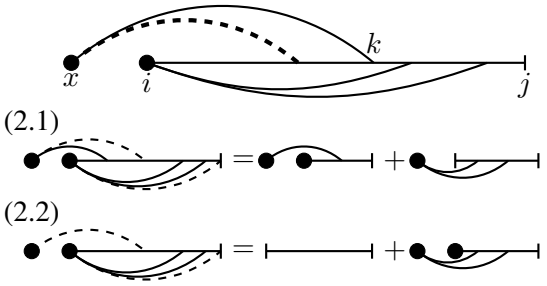

Figure 4: Decomposition for $L[i,j,x]$.

2. Otherwise, Intervals $[i,k]$, $[k,j]$ are classified as **Int**, **L** respectively. Two edges external to the interval: $e_{(x,k)}$, $e_{(i,j)}$. The decomposition is $Int[i,k] + L[k,j,i] + \text{SELECT}[x,k] + \text{SELECT}[i,j]$.

4.4 Decomposing an R Sub-problem

If there is no edge from x to (i,j), then the graph is reduced to $Int[i,j]$. If there is one, let k be the farthest vertex from j and adjacent to x. There are two different cases:

1. If there exist an edge from x to (k,j), Intervals $[i,k]$, $[k,j]$ are classified as **N**, **R** respectively. Two edges external to the interval: $e_{(x,k)}$, $e_{(i,j)}$. The decomposition

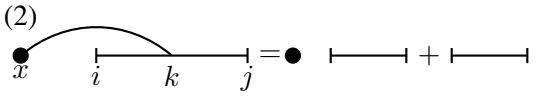

Figure 5: Decomposition for $N[i, j, x]$.

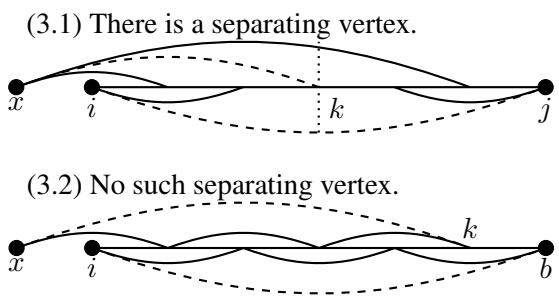

Figure 6: Decomposition for $LR[i, j, x]$.

is $N[i, k, j] + R[k, j, x] + \text{SELECT}[x, k] + \text{SELECT}[i, j]$.

2. Otherwise, Intervals $[i, k]$, $[k, j]$ are classified as **R**, **Int** respectively. Two edges external to the interval are $e_{(x,k)}$, $e_{(i,j)}$. The decomposition is $R[i, k, j] + Int[k, j] + \text{SELECT}[x, k] + \text{SELECT}[i, j]$.

The decomposition is similar to **L**, we thus do not give a graphical representation to save space.

4.5 Decomposing an N Sub-problem

If there is no edge from x to (i, j), then the graph is reduced to $Int[i, j]$. If there is one, let k be the farthest vertex from i and adjacent to x. By definition, $N[i, j, x]$ does not allow for $e_{(x,i)}$ or $e_{(x,j)}$. Thus $k \neq i$ or j. Intervals $[i, k]$, $[k, j]$ are classified as **N**, **Int** respectively. Two edges external to the interval are $e_{(x,k)}$, $e_{(i,j)}$. The decomposition is $N[i, k, x] + Int[k, j] + \text{SELECT}[x, k] + \text{SELECT}[i, j]$.

4.6 Decomposing an LR Sub-problem

If the pencil point of all edges from x to (i, j) is i, then the model is the same as $L[i, j, x]$. Similary, if the pencil point is j, then the model is the same as $R[i, j, x]$.

If some of the edges from x to (i, j) share a pencil point i, and the others share j, there are two different cases.

1. If there is a k which satisfies that within $[i, j]$, only $e_{(i,j)}$ crosses over k (i.e., $[i, j]$ can be divided along dashed line k into two), then, k divides $[i, j]$ into $[i, k]$ and $[k, j]$. Because k is not allowed to be pencil point, the two subintervals must be an **L** and an **R** in terms of external x, respectively. In addition, there are two edges, namely $e_{(x,k)}$ and $e_{(i,j)}$ not included by the subintervals. The problem is thus decomposed as $L[i, k, x] + R[k, j, x] + \text{SELECT}[x, k] + \text{SELECT}[i, j]$.

2. If there is no such k in concord with the condition in (1), it comes a much more difficult case for which we introduce sub-problem **C**. Here we put forward the conclusion:

Lemma 1. *Assume that $k(k \in (i, j))$ is the vertex that is adjacent to x and farthest from i. The decomposition for the second case is $C[x, i, k, j] + \text{SELECT}[x, k] + \text{SELECT}[i, j]$.*

Proof. The distinction between Case 1 and 2 implies the following property, which is essential, $\forall t \in (i, j), \exists e_{(pl,pr)}$ such that $t \in (pl, pr) \subset [i, j]$.

We can recursively generate a series of length n—$\{e_{(sl_k,sr_k)}\}$—in $LR[i, j, x]$ as follows.

$k = 1$ Let $sl_k = i, sr_k = \max\{p | p \in (i + 1, j) \text{ and } \exists e_{(i,p)}\}$;

$k > 1$ For sr_{k-1}, we denote all edges that cover it as $e_{(pl_1,pr_1)}, \cdots, e_{(pl_s,pr_s)}$. Note that there is at least one such edge. For any two edges in them, viz $e_{(pl_u,pr_u)}$ and $e_{(pl_v,pr_v)}$, $(pl_u, pr_u) \subset (pl_v, pr_v)$ or $(pl_v, pr_v) \subset (pl_u, pr_u)$. Otherwise, the P2 property no longer holds due to the interaction among $e_{(sl_{k-1},sr_{k-1})}$, $e_{(pl_u,pr_u)}$ and $e_{(pl_v,pr_v)}$. Assume (pl_w, pr_w) is the largest one, then we let $sl_k = pl_w, sr_k = pr_w$. When $sr_k = j$, recursion ends.

We are going to prove that if we delete two edges $e_{(x,sr_{n-1})}$ and $e_{(i,j)}$ from $LR[i, j, x]$, the series $\{sl_1, sl_2, sl_3, ..., sl_{n-2}, sl_{n-1}, sl_n, sr_{n-1}, sr_n\}$ satisfies each and all the conditions of **C1**.

Condition 1. Because $e_{(sl_n,sr_n)}$ covers sr_{n-1}, Condition 1 holds for $k = m-3, m-2$. Consider $k \leq m-4 = n-2$. Assume that $s_{k+1} < s_k$, then we have $e_{(s_{k+1},sr_{k+1})}$ is larger than $e_{(s_k,sr_{k+1})}$. This is impossible because we select the largest edge in every step.

Condition 2. The **LR** sub-problem we discussed now cannot be reduced to **L** nor **R**, so there must be two edges from x that respectively cross edges linked to i and j. We are going to prove that

the two edges must be $e_{(x,s_2)}$ and $e_{(x,sr_{n-1})}$. Assume that there is $e_{(x,p)}$, where $p \in (i,j)$, $p \neq s_2$ and $p \neq sr_{n-1}$. If $p \in (i,s_2)$, then $e_{(s_1,s_3)}$ crosses with $e_{(x,p)}$ and $e_{(s_2,s_4)}$ simultaneously. 1EC is violated. If $p \in (s_2, sr_{n-1})$, $e_{(x,p)}$ necessarily crosses with some edge $e_{(s_k,s_{k+2})}$. Furthermore, $i < s_k < s_{k+2} < j$. Thus 1EC is violated. If $p \in (sr_{n-1}, j)$, the situation is similar to $p \in (i, s_2)$.

Condition 3. $\forall k \in [1, n-2]$, $e_{(sl_k,sr_k)}$ and $e_{(sl_{k+1},sr_{k+1})}$ cross, $e_{(sl_{k+1},sr_{k+1})}$ and $e_{(sl_{k+2},sr_{k+2})}$ cross, so $sr_k \leq sl_{k+2}$. Otherwise the interaction of the three edges results in the violation of P2. If $sr_k < sl_{k+2}$, $e_{(sl_k,sr_k)}$ and $e_{(sl_{k+2},sr_{k+2})}$ share no common endpoint, violating 1EC. Therefore, $sr_k = sl_{k+2} = s_{k+2}$, and Condition 3 is satisfied.

We also reach proposition that $pt(s_k, s_{k+2}) = s_{k+1}$.

Condition 4. This condition is easy to verify because (s_k, s_{k+2}) is the largest with respective to sr_k.

Condition 5. Assume, that there is $e_{(pl,pr)}$ which intersects with $e_{(s_k,s_{k+2})}$, and at the same time satisfy the conditions: $e_{(pl,pr)} \notin \{e_{(s_t,s_{t+2})} | t \in [1, m-2]\} \cup \{e_{(x,s_2)}, e_{(x,sr_{n-1})}\}$. Since $pt(s_k, s_{k+2}) = s_{k+1}$, $pl = s_{k+1}$ or $pr = s_{k+1}$.

If $pl = s_{k+1}$, then $pl < sl_{k+2} < pr$, and in turn $k < m-2$. In addition, according to Condition 4, $(pl, pr) \subset (s_{k+1}, s_{k+3})$. So $pr < s_{k+3}$. If $k = m-3$ then $e_{(x,s_{n-1})}$ crosses with $e_{(pl,pr)}$ and $e_{(i,j)}$ simultaneously. 1EC is violated. If $k < m-3$ then $e_{(s_{k+2},s_{k+4})}$ cross with $e_{(pl,pr)}$, and $pr < s_{k+3} = pt(e_{(s_{k+2},s_{k+4})})$. Again 1EC is violated. If $pr = s_{k+1}$ The symmetry of our proof entails the violation of 1ec.

All in all, the assumption does not hold and thus satisfies Condition 5.

Condition 6. $e_{(x,s_1)}, e_{(x,s_m)}$ are disallowed due to definition of an **LR** problem. $e_{(x,s_{m-1})}, e_{(s_1,s_m)}$ are disallowed due to the decomposition.

Condition 7. Due to the existence of $e_{(x,s_2)}$ and $e_{(x,sr_{n-1})}$, there must be two edges: $e_{(x,p_1)}$ and $e_{(x,p_2)}$ that cross $e_{(i,s_2)}$ and $e_{(sr_{n-1},j)}$ respectively. There must be an odd number of edges in the series $\{e_{(sl_k,sr_k)}\}$, otherwise P2 is violated as the case shown in Figure 1. In summary, the last condition is satisfied and we have a **C1** structure in this **LR** sub-problem.

□

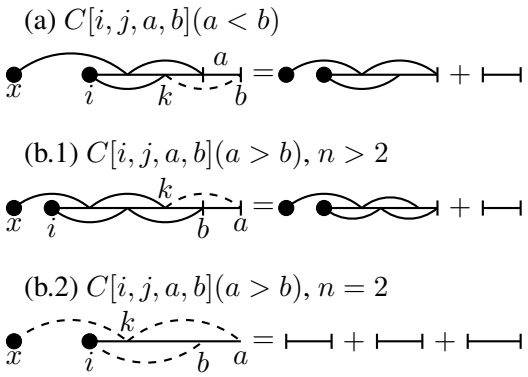

Figure 7: Decomposition for $C[x,i,a,b]$.

4.7 Decomposing a C Sub-problem

We illustrate the decomposition using the graphical representations shown in Figure 7. When $a < b$, since a is the *upper-plane* endpoint farthest to the right, and b is the *lower-plane* counterpart, in this case a precedes b (i.e., a is to the left of b).

Let $C[x,i,a,k]$ be a **C** in which the lower-plane endpoint k precedes a. Add $e_{(k,b)}$ gives a new **C** sub-problem with lower-plane endpoint preceded by the upper-plane one. The decomposition is then $C[x,i,a,k] + Int[a,b] + \text{SELECT}[k,b]$.

When $a > b$ and $n > 2$, the lower-plane endpoint b precedes a. In analogy, the case can be obtained by adding $e_{(k,a)}$ to $C[x,i,k,b]$. The decomposition: $C[x,i,k,b] + Int[b,a] + \text{SELECT}[k,a]$.

When $n = 2$, we reach the most fundamental case. Only 4 vertices are in the series, namely i,k,b,a. Moreover, there are three edges: $e_{(x,k)}$, $e_{(i,b)}$, $e_{(k,a)}$, and the interval [i,a] is divided by k,b into three parts. The decomposition is $Int[i,k] + Int[k,b] + Int[b,a] + \text{SELECT}[x,k] + \text{SELECT}[i,b] + \text{SELECT}[k,a]$.

4.8 Discussion

4.8.1 Soundness and Completeness

The algorithm is sound and complete with respective to 1EC/P2 graphs. We present our algorithms by detailing the decomposition rules. The completeness is obvious because we can decompose any 1EC/P2 graph from an **Int**, use our rules to reduce it into smaller sub-problems, and repeat this procedure. The decomposition rules are also construction rules. During constructing graphs by applying these rules, we never violate 1EC nor P2

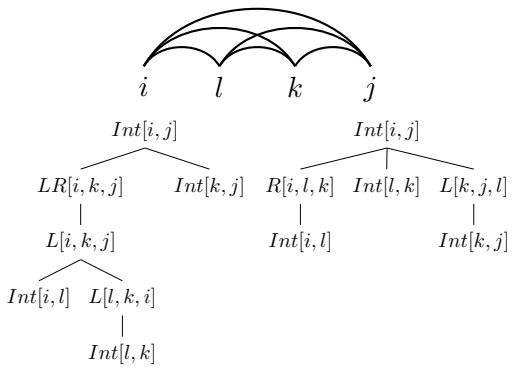

Figure 8: A maximal 1EC/P2 graph and its two derivations. For brevity, we elide the edges created in each derivation step.

restrictions. So our algorithm is sound.

4.8.2 Greedy Search during Construction

There is an important difference between our algorithm and Eisner-style MST algorithms (Eisner, 1996b; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010) for trees as well as Kuhlmann and Jonsson's Maximum Subgraph algorithm for noncrossing graphs. In each construction step, our algorithm allows multiple arcs to be constructed, but whether or not such arcs are added to the target graph depends on their arc-weights. In each step, we do greedy search and decide if adding an related arc according to local scores. If all arcs are assigned scores that are greater than 0, the output of our algorithm includes the most complicated 1EC/P2 graphs. That means adding one more arc voilates the 1EC or P2 restrictions. For all other aforementioned algorithms, in a single construction step, it is clear whether to add a new arc, and which one. There is no local search.

4.8.3 Spurious Ambiguity

To generate the same graph, even a maximal 1EC/P2 graph, we may have different derivations. Figure 8 is an example. This is similar to syntactic analysis licensed by Combinatory Categorial Grammar (CCG; Steedman, 1996, 2000). To derive one surface string, there usually exists multiple CCG derivations. A practice of CCG parsing is defining one particular derivation as the *standard* one, namely normal form (Eisner, 1996a). The spurious ambiguity in our algorithm does not affect the correctness of first-order parsing, because scores are assigned to individual dependencies, rather than derivation processes. There is no need to distinguish one special derivation here.

4.8.4 Complexity

The sub-problem **Int** is of size $O(n^2)$, each graph of which takes a calculating time of order $O(n^2)$. For sub-problems **L**, **R**, **LR**, and **N**, each has $O(n^3)$ elements, with a unit calculating time $O(n)$. **C** has $O(n^4)$ elements, with a unit calculating time $O(n)$. Therefore the full version algorithm runs in time of $O(n^5)$ with a space requirement of $O(n^4)$.

4.9 A Degenerated Version

We find that graphical structures involved in the **C** sub-problem, namely coupled staggered pattern, is extremely rare in linguistic analysis. If we ignore this special case, we get a degenerated version of dynamic programming algorithm. This algorithm can find a strict subset of 1EC/P2 graphs. We can improve efficiency without sacrificing *expressiveness* in terms of linguistic data. This degenerated version algorithm requires $O(n^4)$ time and $O(n^3)$ space.

5 Practical Parsing

5.1 Disambiguation

We extend our quartic-time parsing algorithm into a practical parser. In the context of data-driven parsing, this requires an extra disambiguation model. As with many other parsers, we employ a global linear model. Following Zhang et al. (2016)'s experience, we define rich features extracted from word, POS-tags and pseudo trees. For details we refer to the source code. To estimate parameters, we utilize the averaged perceptron algorithm (Collins, 2002).

5.2 Data

We conduct experiments on unlabeled parsing using four corpora: CCGBank (Hockenmaier and Steedman, 2007), DeepBank (Flickinger et al., 2012), Enju HPSGBank (EnjuBank; Miyao et al., 2004) and Prague Dependency TreeBank (PCEDT; Hajic et al., 2012), We use "standard" training, validation, and test splits to facilitate comparisons. Following previous experimental setup for CCG parsing, we use section 02-21 as training data, section 00 as the development data, and section 23 for testing. The other three data sets are from SemEval 2014 Task 8 (Oepen et al.,

Table 3: Parsing accuracy evaluated on the test sets.

2014), and the data splitting policy follows the shared task. All the four data sets are publicly available from LDC (Oepen et al., 2016).

Experiments for CCG-grounded analysis were performed using automatically assigned POS-tags that are generated by a symbol-refined HMM tagger (Huang et al., 2010). Experiments for the other three data sets used POS-tags provided by the shared task. We also use features extracted from pseudo trees. We utilize the Mate parser (Bohnet, 2010) to generate pseudo trees. The pre-processing for CCGBank, DeepBank and EnjuBank are exactly the same as in experiments reported in (Zhang et al., 2016).

5.3 Accuracy

We evaluate two parsing algorithms, the algorithm for noncrossing dependency graphs (Kuhlmann and Jonsson, 2015), i.e. pagenumber-1 (denoted as *P1*) graphs, and our quartic-time algorithm (denoted as *1ECP2*^{d}). Table 2 summerizes the accuracy obtained our parser. Same feature templates are applied for disambiguation. We can see that our new algorithm yields significant improvements on all data sets, as expected. Especially, due to the improved coverage, the recall is improved more.

5.4 Comparison with Other Parsers

Our new parser can be taken as a graph-based parser which employ a different architecture from transition-based and factorization-based (Martins and Almeida, 2014; Du et al., 2015a) systems. We compare our parser with the best reported systems in the other two architectures. *ZDSW* (Zhang et al., 2016) is transition-based parser while *MA* (Martins and Almeida, 2014) and DSW (Du et al., 2015a) are two factorization-based systems. All of them achieves state-of-the-art performance. All results on the test set is shown in Table 3. We can see that our parser, as a graph-based parser, is comparable to state-of-the-art transition-based and factorization-based parsers.

6 Conclusion and Future Work

In this paper, we explore the strength of the graph-based approach. In particular, we enhance the Maximum Subgraph model with new parsing algorithms for 1EC/P2 graphs. Our work indicates the importance of finding appropriate graph classes that on the one hand are linguistically expressive and on the other hand allow efficient search. Within tree-structured dependency parsing, higher-order factorization that conditions on wider syntactic contexts than arc-factored relationships have been proved very useful. The arc-factored model proposed in this paper may be enhanced with higher-order features too. We leave this for future investigation.

Abstract

We propose a sequence labeling framework with a secondary training objective, learning to predict surrounding words for every word in the dataset. This language modeling objective incentivises the system to learn general-purpose patterns of semantic and syntactic composition, which are also useful for improving accuracy on different sequence labeling tasks. The architecture was evaluated on a range of datasets, covering the tasks of error detection in learner texts, named entity recognition, chunking and POS-tagging. The novel language modeling objective provided consistent performance improvements on every benchmark, without requiring any additional annotated or unannotated data.

1 Introduction

Accurate and efficient sequence labeling models have a wide range of applications, including named entity recognition (NER), part-of-speech (POS) tagging, error detection and shallow parsing. Specialised approaches to sequence labeling often include extensive feature engineering, such as integrated gazetteers, capitalisation features, morphological information and POS tags. However, recent work has shown that neural network architectures are able to achieve comparable or improved performance, while automatically discovering useful features for a specific task and only requiring a sequence of tokens as input (Collobert et al., 2011; Irsoy and Cardie, 2014; Lample et al., 2016).

This feature discovery is usually driven by an objective function based on predicting the annotated labels for each word, without much incentive to learn more general language features from the available text. In many sequence labeling tasks, the relevant labels in the dataset are very sparse and most of the words contribute very little to the training process. For example, in the CoNLL 2003 NER dataset (Tjong Kim Sang and De Meulder, 2003) only 17% of the tokens represent an entity. This ratio is even lower for error detection, with only 14% of all tokens being annotated as an error in the FCE dataset (Yannakoudakis et al., 2011). The sequence labeling models are able to learn this bias in the label distribution without obtaining much additional information from words that have the majority label (O for outside of an entity; C for correct word). Therefore, we propose an additional training objective which allows the models to make more extensive use of the available data.

The task of language modeling offers an easily accessible objective – learning to predict the next word in the sequence requires only plain text as input, without relying on any particular annotation. Neural language modeling architectures also have many similarities to common sequence labeling frameworks: words are first mapped to distributed embeddings, followed by a recurrent neural network (RNN) module for composing word sequences into an informative context representation (Mikolov et al., 2010; Graves et al., 2013; Chelba et al., 2013). Compared to any sequence labeling dataset, the task of language modeling has a considerably larger and more varied set of possible options to predict, making better use of each available word and encouraging the model to learn more general language features for accurate composition.

In this paper, we propose a neural sequence labeling architecture that is also optimised as a language model, predicting surrounding words in the dataset in addition to assigning labels to each token. Specific sections of the network are op-

Proceedings of the 55th Annual Meeting of the Association for Computational Linguistics, pages 2121–2130

https://doi.org/10.18653/v1/P17-1194

timised as a forward- or backward-moving language model, while the label predictions are performed using context from both directions. This secondary unsupervised objective encourages the framework to learn richer features for semantic composition without requiring additional training data. We evaluate the sequence labeling model on 10 datasets from the fields of NER, POS-tagging, chunking and error detection in learner texts. Our experiments show that by including the unsupervised objective into the training process, the sequence labeling model achieves consistent performance improvements on all the benchmarks. This multitask training framework gives the largest improvements on error detection datasets, outperforming the previous state-of-the-art architecture.

2 Neural Sequence Labeling

We use the neural network model of Rei et al. (2016) as the baseline architecture for our sequence labeling experiments. The model takes as input one sentence, separated into tokens, and assigns a label to every token using a bidirectional LSTM.

The input tokens are first mapped to a sequence of distributed word embeddings $[x_1, x_2, x_3, ..., x_T]$. Two LSTM (Hochreiter and Schmidhuber, 1997) components, moving in opposite directions through the sentence, are then used for constructing context-dependent representations for every word. Each LSTM takes as input the hidden state from the previous time step, along with the word embedding from the current step, and outputs a new hidden state. The hidden representations from both directions are concatenated, in order to obtain a context-specific representation for each word that is conditioned on the whole sentence in both directions:

$$\overrightarrow{h_t} = LSTM(x_t, \overrightarrow{h_{t-1}}) \quad (1)$$

$$\overleftarrow{h_t} = LSTM(x_t, \overleftarrow{h_{t+1}}) \quad (2)$$

$$h_t = [\overrightarrow{h_t}; \overleftarrow{h_t}] \quad (3)$$

Next, the concatenated representation is passed through a feedforward layer, mapping the components into a joint space and allowing the model to learn features based on both context directions:

$$d_t = tanh(W_d h_t) \quad (4)$$

where W_d is a weight matrix and $tanh$ is used as the non-linear activation function.

In order to predict a label for each token, we use either a softmax or CRF output architecture. For softmax, the model directly predicts a normalised distribution over all possible labels for every word, conditioned on the vector d_t:

$$P(y_t|d_t) = softmax(W_o d_t) = \frac{e^{W_{o,k} d_t}}{\sum_{\tilde{k} \in K} e^{W_{o,\tilde{k}} d_t}} \quad (5)$$

where K is the set of all possible labels, and $W_{o,k}$ is the k-th row of output weight matrix W_o. The model is optimised by minimising categorical crossentropy, which is equivalent to minimising the negative log-probability of the correct labels:

$$E = -\sum_{t=1}^{T} log(P(y_t|d_t)) \quad (6)$$

While this architecture returns predictions based on all words in the input, the labels are still predicted independently. For some tasks, such as named entity recognition with a BIO[1] scheme, there are strong dependencies between subsequent labels and it can be beneficial to explicitly model these connections. The output of the architecture can be modified to include a Conditional Random Field (CRF, Lafferty et al. (2001)), which allows the network to look for the most optimal path through all possible label sequences (Huang et al., 2015; Lample et al., 2016). The model is then optimised by maximising the score for the correct label sequence, while minimising the scores for all other sequences:

$$E = -s(y) + log \sum_{\tilde{y} \in \tilde{Y}} e^{s(\tilde{y})} \quad (7)$$

where $s(y)$ is the score for a given sequence y and Y is the set of all possible label sequences.

We also make use of the character-level component described by Rei et al. (2016), which builds an alternative representation for each word. The individual characters of a word are mapped to character embeddings and passed through a bidirectional LSTM. The last hidden states from both direction are concatenated and passed through a

[1] Each NER entity has sub-tags for Beginning, Inside and Outside

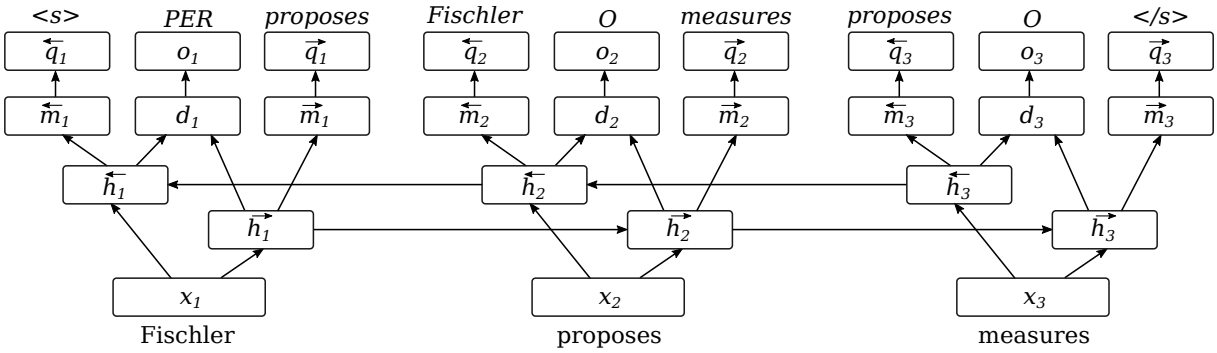

Figure 1: The unfolded network structure for a sequence labeling model with an additional language modeling objective, performing NER on the sentence *"Fischler proposes measures"*. The input tokens are shown at the bottom, the expected output labels are at the top. Arrows above variables indicate the directionality of the component (forward or backward).

nonlinear layer. The resulting vector representation is combined with a regular word embedding using a dynamic weighting mechanism that adaptively controls the balance between word-level and character-level features. This framework allows the model to learn character-based patterns and handle previously unseen words, while still taking full advantage of the word embeddings.

3 Language Modeling Objective

The sequence labeling model in Section 2 is only optimised based on the correct labels. While each token in the input does have a desired label, many of these contribute very little to the training process. For example, in the CoNLL 2003 NER dataset (Tjong Kim Sang and De Meulder, 2003) there are only 8 possible labels and 83% of the tokens have the label O, indicating that no named entity is detected. This ratio is even higher for error detection, with 86% of all tokens containing no errors in the FCE dataset (Yannakoudakis et al., 2011). The sequence labeling models are able to learn this bias in the label distribution without obtaining much additional information from the majority labels. Therefore, we propose a supplementary objective which would allow the models to make full use of the training data.

In addition to learning to predict labels for each word, we propose optimising specific sections of the architecture as language models. The task of predicting the next word will require the model to learn more general patterns of semantic and syntactic composition, which can then be reused in order to predict individual labels more accurately. This objective is also generalisable to any sequence labeling task and dataset, as it requires no additional annotated training data.

A straightforward modification of the sequence labeling model would add a second parallel output layer for each token, optimising it to predict the next word. However, the model has access to the full context on each side of the target token, and predicting information that is already explicit in the input would not incentivise the model to learn about composition and semantics. Therefore, we must design the loss objective so that only sections of the model that have not yet observed the next word are optimised to perform the prediction. We solve this by predicting the next word in the sequence only based on the hidden representation $\overrightarrow{h_t}$ from the forward-moving LSTM. Similarly, the previous word in the sequence is predicted based on $\overleftarrow{h_t}$ from the backward-moving LSTM. This architecture avoids the problem of giving the correct answer as an input to the language modeling component, while the full framework is still optimised to predict labels based on the whole sentence.

First, the hidden representations from forward- and backward-LSTMs are mapped to a new space using a non-linear layer:

$$\overrightarrow{m_t} = tanh(\overrightarrow{W}_m \overrightarrow{h_t}) \quad (8)$$

$$\overleftarrow{m_t} = tanh(\overleftarrow{W}_m \overleftarrow{h_t}) \quad (9)$$

where $\overrightarrow{W}_m$ and $\overleftarrow{W}_m$ are weight matrices. This separate transformation learns to extract features that are specific to language modeling, while the LSTM is optimised for both objectives. We also use the opportunity to map the representation to a smaller size – since language modeling is not the

main goal, we restrict the number of parameters available for this component, forcing the model to generalise more using fewer resources.

These representations are then passed through softmax layers in order to predict the preceding and following word:

$$P(w_{t+1}|\overrightarrow{m_t}) = softmax(\overrightarrow{W}_q\overrightarrow{m_t}) \quad (10)$$

$$P(w_{t-1}|\overleftarrow{m_t}) = softmax(\overleftarrow{W}_q\overleftarrow{m_t}) \quad (11)$$

The objective function for both components is then constructed as a regular language modeling objective, by calculating the negative log-likelihood of the next word in the sequence:

$$\overrightarrow{E} = -\sum_{t=1}^{T-1} log(P(w_{t+1}|\overrightarrow{m_t})) \quad (12)$$

$$\overleftarrow{E} = -\sum_{t=2}^{T} log(P(w_{t-1}|\overleftarrow{m_t})) \quad (13)$$

Finally, these additional objectives are combined with the training objective E from either Equation 6 or 7, resulting in a new cost function $\widetilde{E}$ for the sequence labeling model:

$$\widetilde{E} = E + \gamma(\overrightarrow{E} + \overleftarrow{E}) \quad (14)$$

where γ is a parameter that is used to control the importance of the language modeling objective in comparison to the sequence labeling objective.

Figure 1 shows a diagram of the unfolded neural architecture, when performing NER on a short sentence with 3 words. At each token position, the network is optimised to predict the previous word, the current label, and the next word in the sequence. The added language modeling objective encourages the system to learn richer feature representations that are then reused for sequence labeling. For example, $\overrightarrow{h_1}$ is optimised to predict *proposes* as the next word, indicating that the current word is a subject, possibly a named entity. In addition, $\overleftarrow{h_2}$ is optimised to predict *Fischler* as the previous word and these features are used as input to predict the *PER* tag at o_1.

The proposed architecture introduces 4 additional parameter matrices that are optimised during training: $\overrightarrow{W}_m$, $\overleftarrow{W}_m$, $\overrightarrow{W}_q$, and $\overleftarrow{W}_q$. However, the computational complexity and resource requirements of this model during sequence labeling are equal to the baseline from Section 2, since the language modeling components are ignored during testing and these additional weight matrices are not used. While our implementation uses a basic softmax as the output layer for the language modeling components, the efficiency during training could be further improved by integrating noise-contrastive estimation (NCE, Mnih and Teh (2012)) or hierarchical softmax (Morin and Bengio, 2005).

4 Evaluation Setup

The proposed architecture was evaluated on 10 different sequence labeling datasets, covering the tasks of error detection, NER, chunking, and POS-tagging. The word embeddings in the model were initialised with publicly available pretrained vectors, created using word2vec (Mikolov et al., 2013). For general-domain datasets we used 300-dimensional embeddings trained on Google News.[2] For biomedical datasets, the word embeddings were initialised with 200-dimensional vectors trained on PubMed and PMC.[3]

The neural network framework was implemented using Theano (Al-Rfou et al., 2016) and we make the code publicly available online.[4] For most of the hyperparameters, we follow the settings by Rei et al. (2016) in order to facilitate direct comparison with previous work. The LSTM hidden layers are set to size 200 in each direction for both word- and character-level components. All digits in the text were replaced with the character 0; any words that occurred only once in the training data were replaced by an OOV token. In order to reduce computational complexity in these experiments, the language modeling objective predicted only the 7,500 most frequent words, with an extra token covering all the other words.

Sentences were grouped into batches of size 64 and parameters were optimised using AdaDelta (Zeiler, 2012) with default learning rate 1.0. Training was stopped when performance on the development set had not improved for 7 epochs. Performance on the development set was also used to select the best model, which was then evaluated on the test set. In order to avoid any outlier results due to randomness in the model initialisa-

tion, each configuration was trained with 10 different random seeds and the averaged results are presented in this paper. We use previously established splits for training, development and testing on each of these datasets.

Based on development experiments, we found that error detection was the only task that did not benefit from having a CRF module at the output layer – since the labels are very sparse and the dataset contains only 2 possible labels, explicitly modeling state transitions does not improve performance on this task. Therefore, we use a softmax output for error detection experiments and CRF on all other datasets.

The publicly available sequence labeling system by Rei et al. (2016) is used as the baseline. During development we found that applying dropout (Srivastava et al., 2014) on word embeddings improves performance on nearly all datasets, compared to this baseline. Therefore, element-wise dropout was applied to each of the input embeddings with probability 0.5 during training, and the weights were multiplied by 0.5 during testing. In order to separate the effects of this modification from the newly proposed optimisation method, we report results for three different systems: 1) the publicly available baseline, 2) applying dropout on top of the baseline system, and 3) applying both dropout and the novel multitask objective from Section 3.

Based on development experiments we set the value of γ, which controls the importance of the language modeling objective, to 0.1 for all experiments throughout training. Since context prediction is not part of the main evaluation of sequence labeling systems, we expected the additional objective to mostly benefit early stages of training, whereas the model would later need to specialise only towards assigning labels. Therefore, we also performed experiments on the development data where the value of γ was gradually decreased, but found that a small static value performed comparably well or even better. These experiments indicate that the language modeling objective helps the network learn general-purpose features that are useful for sequence labeling even in the later stages of training.

5 Error Detection

We first evaluate the sequence labeling architectures on the task of error detection – given a sentence written by a language learner, the system needs to detect which tokens have been manually tagged by annotators as being an error. As the first benchmark, we use the publicly released First Certificate in English (FCE, Yannakoudakis et al. (2011)) dataset, containing 33,673 manually annotated sentences. The texts were written by learners during language examinations in response to prompts eliciting free-text answers and assessing mastery of the upper-intermediate proficiency level. In addition, we evaluate on the CoNLL 2014 shared task dataset (Ng et al., 2014), which has been converted to an error detection task. This contains 1,312 sentences, written by higher-proficiency learners on more technical topics. They have been manually corrected by two separate annotators, and we report results on each of these annotations. For both datasets we use the FCE training set for model optimisation and results on the CoNLL-14 dataset indicate out-of-domain performance. Rei and Yannakoudakis (2016) present results on these datasets using the same setup, along with evaluating the top shared task submissions on the task of error detection. As the main evaluation metric, we use the $F_{0.5}$ measure, which is consistent with previous work and was also adopted by the CoNLL-14 shared task.

Table 1 contains results for the three different sequence labeling architectures on the error detection datasets. We found that including the dropout actually decreases performance in the setting of

Table 2: Performance of alternative sequence labeling architectures on NER and chunking datasets, measured using CoNLL standard entity-level F_1 score.

error detection, which is likely due to the relatively small amount of error examples available in the dataset – it is better for the model to memorise them without introducing additional noise in the form of dropout. However, we did verify that dropout indeed gives an improvement in combination with the novel language modeling objective. Because the model is receiving additional information at every token, dropout is no longer obscuring the limited training data but instead helps with generalisation.

The bottom row shows the performance of the language modeling objective when added on top of the baseline model, along with dropout on word embeddings. This architecture outperforms the baseline on all benchmarks, increasing both precision and recall, and giving a 3.9% absolute improvement on the FCE test set. These results also improve over the previous best results by Rei and Yannakoudakis (2016) and Rei et al. (2016), when all systems are trained on the same FCE dataset. While the added components also require more computation time, the difference is not excessive – one training batch over the FCE dataset was processed in 112 seconds on the baseline system and 133 seconds using the language modeling objective.

Error detection is the task where introducing the additional cost objective gave the largest improvement in performance, for a few reasons:

1. This task has very sparse labels in the datasets, with error tokens very infrequent and far apart. Without the language modeling objective, the network has very little use for all the available words that contain no errors.

2. There are only two possible labels, correct and incorrect, which likely makes it more difficult for the model to learn feature detectors for many different error types. Language modeling uses a much larger number of possible labels, giving a more varied training signal.

3. Finally, the task of error detection is directly related to language modeling. By learning a better model of the overall text in the training corpus, the system can more easily detect any irregularities.

We also analysed the performance of the different architectures during training. Figure 2 shows the $F_{0.5}$ score on the development set for each model after every epoch over the training data. The baseline model peaks quickly, followed by a gradual drop in performance, which is likely due to overfitting on the available data. Dropout provides an effective regularisation method, slowing down the initial performance but preventing the model from overfitting. The added language modeling objective provides a substantial improvement – the system outperforms other configurations already in the early stages of training and the results are also sustained in the later epochs.

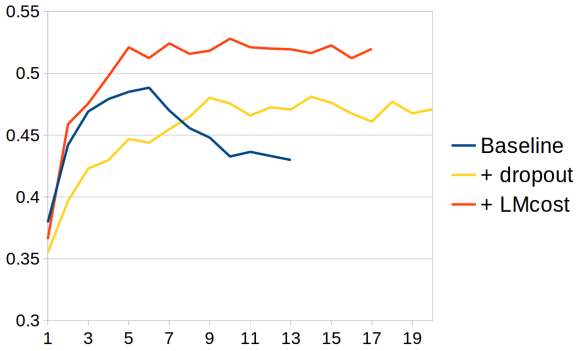

Figure 2: $F_{0.5}$ score on the FCE development set after each training epoch.

6 NER and Chunking

In the next experiments we evaluate the language modeling objective on named entity recognition and chunking. For general-domain NER, we use

+ LMcost	**98.89**	**98.81**	**97.48**	**97.43**	**96.62**	**96.21**	**96.14**	**95.88**

Table 3: Accuracy of different sequence labeling architectures on POS-tagging datasets.

the English section of the CoNLL 2003 corpus (Tjong Kim Sang and De Meulder, 2003), containing news stories from the Reuters Corpus. We also report results on two biomedical NER datasets: The BioCreative IV Chemical and Drug corpus (CHEMDNER, Krallinger et al. (2015)) of 10,000 abstracts, annotated for mentions of chemical and drug names, and the JNLPBA corpus (Kim et al., 2004) of 2,404 abstracts annotated for mentions of different cells and proteins. Finally, we use the CoNLL 2000 dataset (Tjong Kim Sang and Buchholz, 2000), created from the Wall Street Journal Sections 15-18 and 20 from the Penn Treebank, for evaluating sequence labeling on the task of chunking. The standard CoNLL entity-level F_1 score is used as the main evaluation metric.

Compared to error detection corpora, the labels are more balanced in these datasets. However, majority labels still exist: roughly 83% of the tokens in the NER datasets are tagged as "O", indicating that the word is not an entity, and the NP label covers 53% of tokens in the chunking data.

Table 2 contains results for evaluating the different architectures on NER and chunking. On these tasks, the application of dropout provides a consistent improvement – applying some variance onto the input embeddings results in more robust models for NER and chunking. The addition of the language modeling objective consistently further improves performance on all benchmarks.

While these results are comparable to the respective state-of-the-art results on most datasets, we did not fine-tune hyperparameters for any specific task, instead providing a controlled analysis of the language modeling objective in different settings. For JNLPBA, the system achieves 73.83% compared to 72.55% by Zhou and Su (2004) and 72.70% by Rei et al. (2016). On CoNLL-03, Lample et al. (2016) achieve a considerably higher result of 90.94%, possibly due to their use of specialised word embeddings and a custom version of LSTM. However, our system does outperform a similar architecture by Huang et al. (2015), achieving 86.26% compared to 84.26% F_1 score on the CoNLL-03 dataset.

Figure 3 shows F_1 on the CHEMDNER development set after every training epoch. Without dropout, performance peaks quickly and then trails off as the system overfits on the training set. Using dropout, the best performance is sustained throughout training and even slightly improved. Finally, adding the language modeling objective on top of dropout allows the system to consistently outperform the other architectures.

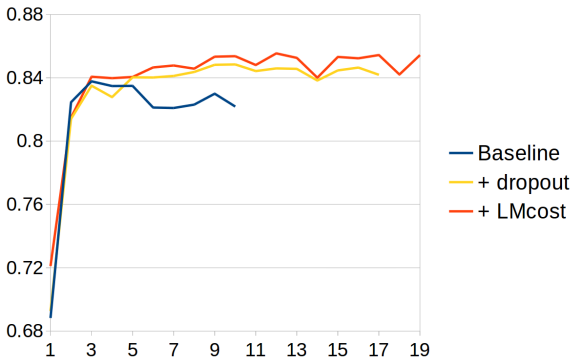

Figure 3: Entity-level F_1 score on the CHEMDNER development set after each training epoch.

7 POS tagging

We also evaluated the language modeling training objective on four POS-tagging datasets. The Penn Treebank POS-tag corpus (Marcus et al., 1993) contains texts from the Wall Street Journal and has been annotated with 48 different part-of-speech tags. In addition, we use the POS-annotated subset of the GENIA corpus (Ohta et al., 2002) containing 2,000 biomedical PubMed abstracts. Following Tsuruoka et al. (2005), we use the same 210-document test set. Finally, we also evaluate on the Finnish and Spanish sections of the Universal Dependencies v1.2 dataset (UD, Nivre et al. (2015)), in order to investigate performance on morphologically complex and Romance languages.

These datasets are somewhat more balanced in terms of label distributions, compared to error detection and NER, as no single label covers over 50% of the tokens. POS-tagging also offers a large variance of unique labels, with 48 labels in PTB and 42 in GENIA, and this can provide useful information to the models during training. The baseline performance on these datasets is also close to the upper bound, therefore we expect the language modeling objective to not provide much additional benefit.

The results of different sequence labeling architectures on POS-tagging can be seen in Table 3 and accuracy on the development set is shown in Figure 4. While the performance improvements are small, they are consistent across all domains, languages and datasets. Application of dropout again provides a more robust model, and the language modeling cost improves the performance further. Even though the labels already offer a varied training objective, learning to predict the surrounding words at the same time has provided the model with additional general-purpose features.

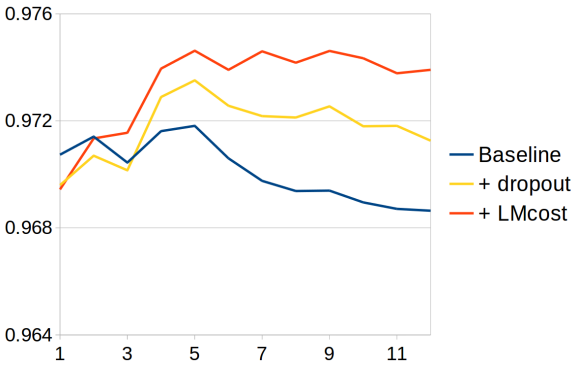

Figure 4: Token-level accuracy on the PTB-POS development set after each training epoch.

8 Related Work

Our work builds on previous research exploring multi-task learning in the context of different sequence labeling tasks. The idea of multi-task learning was described by Caruana (1998) and has since been extended to many language processing tasks using neural networks. For example, Collobert and Weston (2008) proposed a multi-task framework using weight-sharing between networks that are optimised for different supervised tasks.

Cheng et al. (2015) described a system for detecting out-of-vocabulary names by also predicting the next word in the sequence. While they use a regular recurrent architecture, we propose a language modeling objective that can be integrated with a bidirectional network, making it applicable to existing state-of-the-art sequence labeling frameworks.

Plank et al. (2016) described a related architecture for POS-tagging, predicting the frequency of each word together with the part-of-speech, and showed that this can improve tagging accuracy on low-frequency words. While predicting word frequency can be useful for POS-tagging, language modeling provides a more general training signal, allowing us to apply the model to many different sequence labeling tasks.

Recently, Augenstein and Søgaard (2017) explored multi-task learning for classifying keyphrase boundaries, by incorporating tasks such as semantic super-sense tagging and identification of multi-word expressions. Bingel and Søgaard (2017) also performed a systematic comparison of task relationships by combining different datasets through multi-task learning. Both of these approaches involve switching to auxiliary datasets, whereas our proposed language modeling objective requires no additional data.

9 Conclusion

We proposed a novel sequence labeling framework with a secondary objective – learning to predict surrounding words for each word in the dataset. One half of a bidirectional LSTM is trained as a forward-moving language model, whereas the other half is trained as a backward-moving language model. At the same time, both of these are also combined, in order to predict the most probable label for each word. This modification can be applied to several common sequence labeling architectures and requires no additional annotated or unannotated data.

The objective of learning to predict surrounding words provides an additional source of information during training. The model is incentivised to discover useful features in order to learn the language distribution and composition patterns in the training data. While language modeling is not the main goal of the system, this additional training objective leads to more accurate sequence labeling models on several different tasks.

The architecture was evaluated on a range of datasets, covering the tasks of error detection in

learner texts, named entity recognition, chunking and POS-tagging. We found that the additional language modeling objective provided consistent performance improvements on every benchmark. The largest benefit from the new architecture was observed on the task of error detection in learner writing. The label distribution in the original dataset is very sparse and unbalanced, making it a difficult task for the model to learn. The added language modeling objective allowed the system to take better advantage of the available training data, leading to 3.9% absolute improvement over the previous best architecture. The language modeling objective also provided consistent improvements on other sequence labeling tasks, such as named entity recognition, chunking and POS-tagging.

Future work could investigate the extension of this architecture to additional unannotated resources. Learning generalisable language features from large amounts of unlabeled in-domain text could provide sequence labeling models with additional benefit. While it is common to pre-train word embeddings on large-scale unannotated corpora, only limited research has been done towards useful methods for pre-training or co-training more advanced compositional modules.

Abstract

We have been developing an end-to-end math problem solving system that accepts natural language input. The current paper focuses on how we analyze the problem sentences to produce logical forms. We chose a hybrid approach combining a shallow syntactic analyzer and a manually-developed lexicalized grammar. A feature of the grammar is that it is extensively typed on the basis of a formal ontology for pre-university math. These types are helpful in semantic disambiguation inside and across sentences. Experimental results show that the hybrid system produces a well-formed logical form with 88% precision and 56% recall.

1 Introduction

Frege and Russell, the initiators of the mathematical logic, delved also into the exploration of a theory of natural language semantics (Frege, 1892; Russell, 1905). Since then, symbolic logic has been a fundamental tool and a source of inspiration in the study of language meaning. It suggests that the formalization of the two realms, mathematical reasoning and language meaning, is actually the two sides of the same coin – probably, we could not even conceive the idea of formalizing language meaning without *grounding it* onto mathematical reasoning. This point was first clarified by Tarski (1936; 1944) mainly on formal languages and then extended to natural languages by Davidson (1967). Montague (1970a; 1970b; 1973) further embodied it by putting forward a terrifyingly arrogant and attractive idea of seeing a natural language *as* a formal language.

The automation of end-to-end math problem solving thus has an outstanding status in the research themes in natural language processing. The conceptual basis has been laid down, which connects text to the truth (= answer) through reasoning. However, we have not seen a fully automated system that instantiates it end-to-end. We wish to add a piece to the big picture by materializing it.

> Define the two straight lines L_1 and L_2 on the xy-plane as L_1: $y = 0$ (x-axis) and L_2: $y = \sqrt{3}x$. Let P be a point on the xy-plane. Let Q be the point symmetric to P about the straight line L_1, and let R be the point symmetric to P about the straight line L_2. Answer the following questions:
>
> (1) Let (a, b) be the coordinates of P, then represent the coordinates of R using a and b.
>
> (2) Assuming that the distance between the two points Q and R is 2, find the locus C of P.
>
> (3) When the point P moves on C, find the maximum area of the triangle PQR and the coordinates of P that gives the maximum area.
>
> (Hokkaido Univ., 1999-Sci-3)

Figure 1: Example problem

Past studies have mainly targeted at primary school level arithmetic word problems (Bobrow, 1964; Charniak, 1969; Kushman et al., 2014; Hosseini et al., 2014; Shi et al., 2015; Roy and Roth, 2015; Zhou et al., 2015; Koncel-Kedziorski et al., 2015; Mitra and Baral, 2016; Upadhyay et al., 2016). In their nature, arithmetic questions are quantifier-free. Moreover they tend to include only $\wedge$ (and) as the logical connective. The main challenge in these works was to extract simple numerical relations (most typically equations) from a real-world scenario described in a text.

Seo et al. (2015) took SAT geometry questions as their benchmark. However, the nature of SAT geometry questions restricts the resulting formula's complexity. In §3, we will show that none of them includes $\forall$ (for all), $\vee$ (or) or $\rightarrow$ (implies). It suggests that this type of questions require little need to analyze the logical structure of the problems beyond conjunctions of predicates.

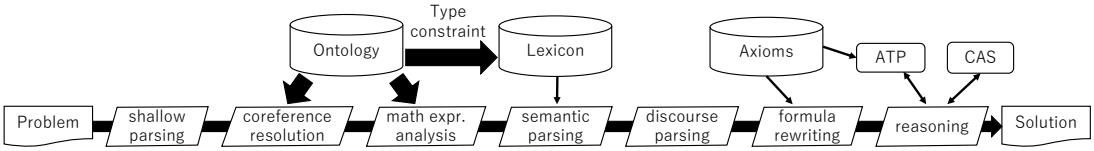

Figure 2: Overview of the end-to-end math problem solving system

We take pre-university math problems falling in the theory of real-closed fields (RCF) as our benchmark because of their variety and complexity. The subject areas include real and linear algebra, complex numbers, calculus, and geometry. Furthermore, many problems involve more than one subject: e.g., algebraic curves and calculus as in Fig. 1. Their logical forms include all the logical connectives, quantifiers, and λ-abstraction. Our goal is to recognize the complex logical structures precisely, including the scopes of the quantifiers and other logical operators.

In the rest of the paper, we first present an overview of an end-to-end problem solving system (§2) and analyze the complexity of the pre-university math benchmark in comparison with others (§3). Among the modules in the end-to-end system, we focus on the sentence-level semantic parsing component and describe an extensively-typed grammar (§4 and §5), an analyzer for the math expressions in the text (§6), and two semantic parsing techniques to fight against the scarcity of the training data (§7) and the complexity of the domain (§8). Experimental results show the effectiveness of the presented techniques as well as the complexity of the task through an in-depth analysis of the end-to-end problem solving results (§9).

2 End-to-end Math Problem Solving

Fig. 2 presents an overview of our end-to-end math problem solving system. A math problem text is firstly analyzed with a dependency parser. Anaphoric and coreferential expressions in the text are then identified and their antecedents are determined. We assume the math formulas in the problems are encoded in MathML presentation mark-up. A specialized parser processes each one of them to determine its syntactic category and semantic content. The semantic representation of each sentence is determined by a semantic parser based on Combinatory Categorial Grammar (CCG) (Steedman, 2001, 2012). The output from the CCG parser is a ranked list of sentence-level logical forms for each sentence.

Dataset	Succeeded		Failed	
	Success%	Avg. Time	Timeout	Other
DEV	75.3% (131/174)	10.5s	16.7%	8.1%
TEST	78.2% (172/220)	16.2s	15.0%	6.8%

Table 1: Performance of the reasoning module on *manually* formalized pre-university problems

After the sentence-level processing steps, we determine the logical relations among the sentence-level logical forms (discourse parsing) by a simple rule-based system. It produces a tree structure whose leaves are labeled with sentences and internal nodes with logical connectives. Free variables in the logical form are then bound by some quantifiers (or kept free) and their scopes are determined according to the logical structure of the problem. A semantic representation of a problem is obtained as a formula in a higher-order logic through these language analysis steps.

The logical representation is then rewritten using a set of axioms that define the meanings of the predicate and function symbols in the formula, such as `maximum` defined as follows:

$$\texttt{maximum}(x, S) \leftrightarrow x \in S \wedge \forall y(y \in S \rightarrow y \leq x),$$

as well as several logical rules such as β-reduction. We hope to obtain a representation of the initial problem expressed in a decidable math theory such as RCF through these equivalence-preserving rewriting. Once we find such a formula, we invoke a computer algebra system (CAS) or an automatic theorem prover (ATP) to derive the answer.

The reasoning module (i.e., the formula rewriting and the deduction with CAS and ATP) of the system has been extensively tested on a large collection of manually formalized pre-university math problems that includes more than 1,500 problems. It solves 70% of the them in the time limit of 10 minutes per problem. Table 1 shows the rate of successfully solved problems in the *manually* formalized version of the benchmark problems used in the current paper.

	Prob-lems	Avg. tokens	Avg. sents.	Uniq. words	Atoms	$\exists$	$\forall$	λ	$\wedge$	$\vee$	$\neg$	$\rightarrow$	Unique sketches

3 Profile of the Benchmark Data

Our benchmark problems, UNIV, were collected from the past entrance exams of seven top-ranked universities in Japan. In the exams held in odd numbered years from 1999 to 2013, we exhaustively selected the problems which are ultimately expressible in RCF. They occupied 40% of all the problems. We divided the problems into two sets: DEV for development (those from year 1999 to 2005) and TEST for test (those from year 2007 to 2013). DEV was used for the lexicon development and the tuning of the end-to-end system. The problem texts (both in English and Japanese) with MathML mark-up and manually translated logical forms are publicly available at https://github.com/torobomath.

The manually translated logical forms were formulated in a higher-order semantic language introduced later in the paper. The translation was done as faithfully as possible to the original wordings of the problems. They thus keep the inherent logical structures expressed in natural language.

Table 2 lists several statistics of the UNIV problems in the English version and their manual formalization. For comparison, the statistics of three other benchmarks are also listed. JOBS and GEOQUERY are collections of natural language queries against databases. They have been widely used as benchmarks for semantic parsing (e.g., Tang and Mooney, 2001; Zettlemoyer and Collins, 2005, 2007; Kwiatkowski et al., 2010, 2011; Liang et al., 2011). The queries are annotated with logical forms in Prolog. We converted them to equivalent higher-order formulas to collect comparable statistics. GEOMETRY is a collection of SAT geometry questions compiled by Seo et al. (2015). We formalized the GEOMETRY questions[1] in our semantic language in the same way as UNIV.

In Table 2, the first column lists the number of problems. The next three provide statistics of the problem texts: average number of words and sentences in a problem ('Avg. tokens' and 'Avg. sents'), and the number of unique words in the whole dataset.[2] They reveal that the sentences in UNIV are significantly longer than the others and more than three sentences have to be correctly processed for a problem.

The remaining columns provide the statistics about the logical complexities of the problems. 'Atoms' stands for the average number of the occurrences of predicates per problem. The next three columns list the number of variables bound by $\exists$, $\forall$, and λ. We count sequential occurrences of the same binder as one. The columns for $\wedge$, $\vee$, $\neg$, and $\rightarrow$ list the average number of them per problem.[3] We can see UNIV includes a wider variety of quantifiers and connectives than the others.

The final column lists the numbers of unique 'sketches' of the logical forms in the dataset. What

[1] Including *all* conditions expressed in the diagrams.

[2] All the math formulas in the texts were replaced with a special token "MATH" before counting words.

[3] $\wedge$ and $\vee$ was counted as operators with arbitrary arity. E.g., there is only one $\wedge$ in $A \wedge B \wedge C$.

we call 'sketch' here is a signature that encodes the overall structure of a logical form. Table 3 shows the top four most frequent sketches observed in the datasets. In a sketch, P stands for a (conjunction of) predicate(s) and f stands for a term. $\exists$, $\forall$, and λ stand for (immediately nested sequence of) the binders.

To obtain the sketch of a formula ϕ, we first replace all the predicate symbols in ϕ to P and function symbols and constants to f. We then eliminate all variables in ϕ and 'flatten' it by applying the following rewriting rules to the sub-formulas in ϕ in the bottom-up order:

$$f(..., f(\alpha_1, \alpha_2, ..., \alpha_n), ...) \Rightarrow f(..., \alpha_1, \alpha_2, ..., \alpha_n, ...)$$
$$P(..., f(\alpha_1, \alpha_2, ..., \alpha_n), ...) \Rightarrow P(..., \alpha_1, \alpha_2, ..., \alpha_n, ...)$$
$$\alpha \vee \alpha \vee \beta \Rightarrow \alpha \vee \beta, \quad \alpha \wedge \alpha \Rightarrow \alpha$$
$$\exists\exists\psi \Rightarrow \exists\psi, \quad \forall\forall\psi \Rightarrow \forall\psi, \quad \lambda\lambda\psi \Rightarrow \lambda\psi$$

Finally, we sort the arguments of Ps and fs and remove the duplicates among them. For instance, to obtain the sketch of the following formula:

$$\forall k \forall m \left(\begin{array}{c} \texttt{maximum}(m, \texttt{set}(\lambda e.(e < k))) \\ \rightarrow k - 1 \leq m \wedge m < k \end{array} \right),$$

we replace the predicate/function symbols as in:

$$\forall k \forall m \left(\begin{array}{c} P(m, f(\lambda e.P(e, k))) \\ \rightarrow P(f(k, f), m) \wedge P(m, k) \end{array} \right),$$

and then eliminate the variables to have:

$$\forall\forall(P(f(\lambda P)) \rightarrow P(f(f)) \wedge P),$$

and finally flatten it to:

$$\forall(P(\lambda P) \rightarrow P).$$

Table 3 shows that a wide variety of structures are found in UNIV while other data sets are dominated by a small number of structures. Table 4 presents some of less frequent sketches found in UNIV (DEV). In actuality, 67% of the unique sketches found in UNIV (DEV) occur only once in the dataset. These statistics suggest that the distribution of the logical structures found in UNIV, and math text in general, is very long-tailed.

4 A Type System for Pre-university Math

Our semantic language is a higher-order logic (lambda calculus) with parametric polymorphism. Table 5 presents the types in the language. The atomic types are defined so that they capture the selectional restriction of verbs and other argument-taking phrases as precisely as possible. For instance, an equation in real domain, e.g., $x^2 - 1 = 0$, can be regarded as a set of reals, i.e., $\{x \mid x^2 - 1 = 0\}$. However, we never say 'a solution of a set.' We thus discriminate an equation from a set in the type system even though the concept of equation is mathematically dispensable.

truth values	`Bool`
numbers	`Z` (integers), `Q` (rationals), `R` (reals), `C` (complex)
polynomials	`Poly`
single variable functions	`R2R` ($\mathbb{R} \rightarrow \mathbb{R}$), `C2C` ($\mathbb{C} \rightarrow \mathbb{C}$)
single variable equations	`EqnR` (in $\mathbb{R}$), `EqnC` (in $\mathbb{C}$)
points in 2D/3D space	`2d.Point`, `3d.Point`
geometric objects	`2d.Shape`, `3d.Shape`
vectors and matrices	`2d.Vector`, `3d.Vector`
matrices	`2d.Matrix`, `3d.Matrix`
angles	`2d.Angle`, `3d.Angle`
number sequences	`Seq`
cardinals and ordinals	`Card`, `Ord`
ratios among numbers	`Ratio`
limit values of functions	`LimitVal`
integer division	`QuoRem`
polymorphic containers	`SetOf`(α), `ListOf`(α)
polymorphic tuples	`Pair`(α, β), `Triple`(α, β, γ)

Table 5: Types defined in the semantic language

Entities of equation and set are built by constructor functions that take a higher-order term as the argument as in `eqn`($\lambda x.x^2 - 1$) and `set`($\lambda x.x^2 - 1$). Related concepts such as 'solution' and 'element' are defined by the axioms for corresponding function and predicate symbols:

$$\forall f \forall x(\texttt{solution}(x, \texttt{eqn}(f)) \leftrightarrow fx)$$
$$\forall s \forall x(\texttt{element}(x, \texttt{set}(s)) \leftrightarrow sx).$$

Distinction of cardinal numbers (`Card`) and ordinal numbers (`Ord`), and the introduction of 'integer division' type (`QuoRem`) are also linguistically motivated. The former is necessary to capture the difference between, e.g., 'k-th integer in $n_1, n_2, \ldots, n_m$' and 'k integers in $n_1, n_2, \ldots, n_m$.' An object of type `QuoRem` is conceptually a pair of integers that represent the quotient and the remainder of integer division. It is linguistically distinct from the type of `Pair(Z,Z)` because, e.g., in

> Select a pair of integers (n, m) and divide n by m. If the remainder (of ϕ) is zero, ...

the null (i.e., omitted) pronoun ϕ has 'the result of division n/m' as its antecedent but not (n, m).

Polymorphism is a mandatory part of the language. Especially, the semantics of plural noun

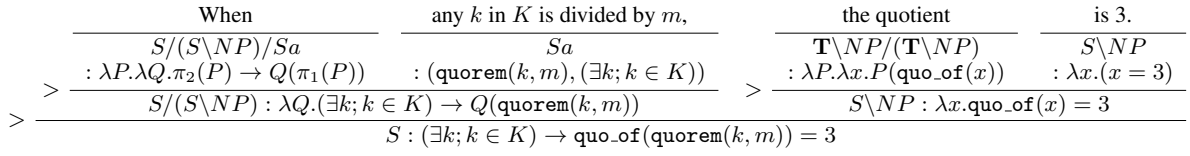

Figure 3: Sketch of the derivation tree for a sentence including an action verb and quantification

phrases is expressed by polymorphic lists and tuples: e.g., 'the radii of the circles C_1, C_2, and C_3' is of type `ListOf(R)` and 'the function f and its maximum value' is of type `Pair(R2R,R)`.

5 Lexicon and Grammar

5.1 Combinatory Categorial Grammar

An instance of CCG grammar consists of a *lexicon* and a small number of *combinatory rules*. A lexicon is a set of *lexical items*, each of which associates a word surface form with a syntactic category and a semantic function: e.g.,

$$\textit{sum} \;::\; \text{NP/PP} : \lambda x.\texttt{sum\_of}(x)$$
$$\textit{intersects} \;::\; \text{S}\backslash\text{NP/PP} : \lambda y.\lambda x.\texttt{intersect}(x, y)$$

A syntactic category is one of atomic categories, such as NP, PP, and S, or a complex category in the form of $\mathbf{X}/\mathbf{Y}$ or $\mathbf{X}\backslash\mathbf{Y}$, where $\mathbf{X}$ and $\mathbf{Y}$ are syntactic categories.

The syntactic categories and the semantic functions of constituents are combined by applying combinatory rules. The most fundamental rules are forward ($>$) and backward ($<$) application:

$$> \frac{\mathbf{X}/\mathbf{Y} : f \quad \mathbf{Y} : x}{\mathbf{X} : fx} \qquad < \frac{\mathbf{Y} : x \quad \mathbf{X}\backslash\mathbf{Y} : f}{\mathbf{X} : fx}$$

The atomic categories are further classified by *features* such as `num`(ber) and `case` of noun phrases. In the current paper, the features are written as in NP[`num=pl,case=acc`].

5.2 A Japanese CCG Grammar and Lexicon

We developed a Japanese CCG following the analysis of basic constructions by Bekki (2010) but significantly extending it by covering various phenomena related to copula verbs, action verbs, argument-taking nouns, appositions and so forth. The semantic functions are defined in the format of a higher-order version of dynamic predicate logic (Eijck and Stokhof, 2006). The dynamic property is necessary to analyze semantic phenomena related to quantifications, such as donkey anaphora. In the following examples, we use English instead of Japanese and the standard notation of higher-order logic for the sake of readability.

We added two atomic categories, Sn and Sa, to the commonly used S, NP, and N. Category Sn is assigned to a proposition expressed as a math formula, such as '$x > 0$'. Semantically it is of type `Bool` but syntactically it behaves both like a noun phrase and a sentence.

Category Sa is assigned to a sentence where the main verb is an action verb such as *add* and *rotate*. Such a sentence introduces the result of the action as a discourse entity (i.e., what can be an antecedent of coreferential expressions). The action verbs can also mediate quantification as in:

When any $k \in K$ is divided by m, the quotient is 3.
$\forall k(k \in K \rightarrow \texttt{quo\_of}(\texttt{quorem}(k,m)) = 3)$

where $\texttt{quorem}(k,m)$ represents the result of the division (i.e., the pair of the quotient and the remainder) and `quo_of` is a function that extracts the quotient from it. To handle such phenomena, we posit the semantic type of Sa as `Pair(`α`,Bool)` where the two components respectively bring the result of an action and the condition on it (including quantification). Fig. 3 presents a derivation tree for the above example.[4]

The atomic category NP, N, and Sa in our grammar have `type` feature. Its value is one of the types defined in the semantic language or a *type variable* when the entity type is underspecified. The lexical entry for '(an integer) *divides* (an integer)' and '(a set) *includes* (an element)' would thus have the following categories (other features than `type` are not shown):

$$\textit{divides} \;::\; \text{S}\backslash\text{NP[type=Z]/NP[type=Z]}$$
$$\textit{includes} \;::\; \text{S}\backslash\text{NP[type=SetOf}(\alpha)\text{]/NP[type=}\alpha\text{]}$$

When defining a lexical item, we don't have to explicitly specify the `type` features in most cases. They can be usually inferred from the definition of

[4] In Fig. 3, the semantic part is in the dynamic logic format as in our real grammar where the dynamic binding $(\exists x; \phi) \rightarrow \psi$ is interpreted as $\forall x(\phi \rightarrow \psi)$ in the standard predicate logic. Following our analysis of an analogous construction in Japanese, the null pronoun after 'the quotient' is filled by analysing the second clause as including a gap rather than filling it by zero-pronoun resolution.

the semantic function. In the above example, *divides* will have $\lambda y.\lambda x.(x|y)$ and *includes* will have $\lambda y.\lambda x.(y \in x)$ as their semantic functions. For both cases, the `type` feature of the NP arguments can be determined from the type definitions of the operators | and $\in$ in the ontology.

The lexicon currently includes 54,902 lexical items for 8,316 distinct surface forms, in which 5,094 lexical items for 1,287 surface forms are for function words and functional multi-word expressions. The number of unique categories in the lexicon is 10,635. When the `type` features are ignored, there are still 4,026 distinct categories.

6 Math Expression Analysis

The meaning of a math expression is composed with the semantic functions of surrounding words to produce a logical form. We dynamically generate lexical items for each math expression in a problem. Consider the following sentence including two 'equations':

If $a^2-4=0$, then $x^2+ax+1=0$ has a real solution.

The latter, $x^2+ax+1=0$, should receive a lexical item of a noun phrase, NP : $\texttt{eqn}(\lambda \texttt{x}.\texttt{x}^2 + \texttt{a} + 1)$, but the former, $a^2-4=0$, should receive category S since it denotes a proposition. Such disambiguation is not always possible without semantic analysis of the text. We thus generate more than one lexical item for ambiguous expressions and let the semantic parser make a choice.

To generate the lexical items, we first collect appositions to the math expressions, such as 'integer n and m' and 'equation $x^2 + a = 0$,' and use them as the type constraints on the variables and the compound expressions. Compound expressions are then parsed with an operator precedence parser (Aho et al., 2006). Overloaded operators, such as $+$ for numbers and vectors, are resolved using the type constrains whenever possible. Finally, we generate all possible interpretations of the expressions and select appropriate syntactic categories.

We have seen only three categories of math expressions: NP, Sn, and **T**/(**T**\NP). The last one is used for a NP with post-modification, as in:

$$\dfrac{\dfrac{n > 0}{\mathbf{T}/(\mathbf{T}\backslash NP) \;:\; \lambda P.(n > 0 \wedge P(n))} \quad \dfrac{\text{is an even number}}{S\backslash NP \;:\; \lambda x.(\texttt{even}(x))}}{S : n > 0 \wedge \texttt{even}(n)} \;>$$

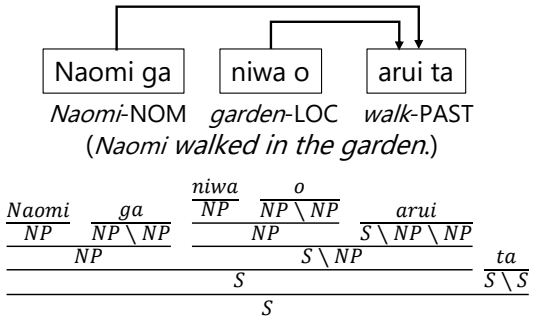

Figure 4: Bunsetsu dependency structure (top) and CCG derivation tree (bottom)

7 Two-step Semantic Parsing

Two central issues in parsing are the cost of the search and the accuracy of disambiguation. Supervised learning is commonly used to solve both. It is however very costly to create the training data by manually annotating a large number of sentences with CCG trees. Past studies have tried to bypass it by so-called weak supervision, where a parser is trained only with the logical form (e.g., Kwiatkowski et al. 2011) or even only with the answers to the queries (e.g., Liang et al. 2011).

Although the adaptation of such methods to the pre-university math data is an interesting future direction, we developed yet another approach based on a hybrid of shallow dependency parsing and the detailed CCG grammar. The syntactic structure of Japanese sentences has traditionally been analyzed based on the relations among word chunks called *bunsetsu*s. A bunsetsu consists of one or more content words followed by zero or more function words. The dependencies among bunsetsus mostly correspond to the predicate-argument and inter-clausal dependencies (Fig. 4). The dependency structure hence matches the overall structure of a CCG tree only leaving the details unspecified.

We derive a full CCG-tree by using a bunsetsu dependency tree as a constraint. We assume: (i) the fringe of each sub-tree in the dependency tree has a corresponding node in the CCG tree. We call such a node in the CCG tree 'a matching node.' We further assume: (ii) a matching node is combined with another CCG tree node whose span includes at least one word in the head bunsetsu of the matching node. Fig. 5 presents an example of a sentence consisting of four bunsetsus (rounded squares), each of which contains two words. In the figure, the i-th cell in the k-th row from the bottom is the CKY cell for the span from i-th to

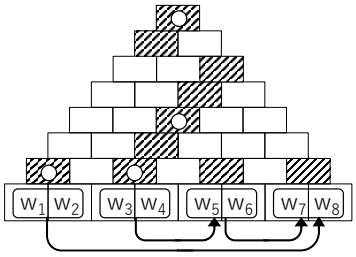

Figure 5: Restricted CKY parsing based on a shallow dependency structure

(i+k-1)-th words. Under the two assumptions, we only need to fill the hatched cells given the dependency structure shown below the CKY chart. The hatched cells with a white circle indicate the positions of the matching nodes.

Even under the constraint of a dependency tree, it is impractical to do exhaustive search. We use beam search based on a simple score function on the chart items that combines several features such as the number of atomic categories in the item. We also use N-best dependency trees to circumvent the dependency errors. The restricted CKY parsing is repeated on the N-best dependency trees until a CCG tree is obtained. Our hope is to reject a dependency error as violation of the syntactic and semantic constraints encoded in the CCG lexicon. In the experiment, we used a Japanese dependency parser developed by Kudo and Matsumoto (2002). We modified it to produce N-best outputs and used up to 20-best trees per sentence.

8 Global Type Coherency

The well-typedness of the logical form is usually guaranteed by the combinatory rules. However, they do not always guarantee the type coherency among the interpretations of the math expressions.

For instance, consider the following derivation:

$$> \frac{\dfrac{\text{if } x+y \in U,}{S/S : \lambda P.(\mathtt{add_R}(x,y) \in U \to P)} \quad \dfrac{\text{then } x+z \in V.}{S : \mathtt{add_V}(x,y) \in V}}{S : \mathtt{add_R}(x,y) \in U \to \mathtt{add_V}(x,z) \in V}$$

The $+$ symbol is interpreted as the addition of real numbers ($\mathtt{add_R}$) in the first clause but that of vectors ($\mathtt{add_V}$) in the second one. The logical form is not typable because the two occurrences of x must have different types. The forward application rule does not reject this derivation since the categories of the two clauses perfectly match the rule schema.

We can reject such inconsistency by doing type checking on the logical form at every step of the derivation. It is however quite time consuming because we cannot use dynamic programming any more and need to do type checking on numerous chart items. Furthermore, such type inconsistency may happen *across* sentences. Instead, we consider the *type environment* while parsing. A type environment, written as $\{v_1 : T_1, v_2 : T_2, \dots\}$, is a finite function from variables to type expressions. A pair $v : T$ means that the variable v must be of type T or its instance (e.g., $\mathtt{SetOf(R)}$ is an instance of $\mathtt{SetOf}(\alpha)$). For example, the logical form of the first clause of the above sentence is typable under $\{x:\mathtt{R}, y:\mathtt{R}, z:\alpha, U:\mathtt{SetOf(R)}, V:\beta\}$, but that of the second clause isn't. Please refer, e.g., to (Pierce, 2002) for the formal definitions. Two environments Γ_1 and Γ_2 are *unifiable* iff there exists a substitution σ that maps the type variables in Γ_1 and Γ_2 to some type expressions so that $\Gamma_1\sigma = \Gamma_2\sigma$ holds. We write $\Gamma_1 \sqcup \Gamma_2$ for the result of such substitution (i.e., unification) with the

Algorithm 1 Global type coherence check

	News+Math	59.3	65.3	66.9	68.3

Table 7: Fraction of sentences on which a CCG tree was obtained in top N dependency trees

most general σ (most general unifier, mgu).

We associate a type environment with each chart item and refine it through parsing. The type constraints implied in a discourse are accumulated in the environment and block the generation of incoherent derivations (Algorithm 1). Fig. 6 presents an example of a parsing result, in which the type constraints implied in the two clauses are unified at the root and the type of U is determined. When we apply a combinatory rule, we first check if the environments of the child chart items are unifiable. If so, we put the unified environment in the parent item and apply the unifier to the `type` features in the parent category. For instance, the forward application rule is revised as follows:

$$(X/Y, \Gamma_1) + (Y, \Gamma_2) \rightarrow (X\sigma, \Gamma_1 \sqcup \Gamma_2),$$

where σ is the mgu of Γ_1 and Γ_2 and $X\sigma$ means the application of σ to the `type` features in X.[5]

[5] To be precise, we also consider the type constraints induced through the unification of the *categories*. It can be seen in the derivation step for "n divides 12" in Fig. 6, where the new constraint n :Z is induced by the unification of NP[α] and NP[Z] and merged into the environment of the parent.

9 Experiments and Analysis

This section presents the overall performance of the current end-to-end system and demonstrates the effectiveness of the proposed parsing techniques. We also present an analysis of the failures.

Table 6 presents the result of end-to-end problem solving on the UNIV data. It shows the failure in the semantic parsing is a major bottleneck in the current system. Since a problem in UNIV includes more than three sentences on average, parsing a whole problem is quite a high bar for a semantic parser. It is however necessary to solve it by the nature of the task. Once a problem-level logical form was produced, the system yielded a correct solution for 44% of such problems in DEV and 36% in TEST.

Table 7 lists the fraction of the sentences on which the two-step parser produced a CCG tree within top-N dependency trees. We compared the results obtained with the dependency parser trained only on a news corpus (News) (Kurohashi and Nagao, 2003), which is annotated with bunsetsu level dependencies, and that trained additionally with a math problem corpus consisting of 6,000 sentences[6] (News+Math). The math problem corpus was developed according to the same annotation guideline for the news corpus. The attachment accuracy of the dependency parser was 84% on math problem text when trained only on the news corpus but improved to 94% by the addition of the math problem corpus. The performance gain by increasing N is more evident in the results with the News parser than that with the News+Math parser. It suggests the grammar properly rejected wrong dependency trees, which were ranked higher by the News parser. The effect of the additional training is very large at small Ns and still significant at $N = 20$. It means that we successfully boosted both the speed and the success rate of CCG parsing only with the shallow dependency annotation on in-domain data.

[6] No overlap with DEV and TEST sections of UNIV.

Dataset	Parsing w/ type env.	Typing failure (%)	Correct answer (%)
DEV	no	9.8%	21.8%
	yes	0.6%	27.6%
TEST	no	8.6%	8.6%
	yes	0.0%	11.4%

Table 8: Effect of parsing with type environment

Freq.	Reason for the parse failures (on TEST-2007)
17	Unknown usage of known content words
9	Unknown content words
8	Errors in coreference resolution
4	Missing math expression interpretaions
3	Unknown usage of known function words
3	Unknown function words
2	No correct dependency tree in 20-best

Table 9: Reasons for the parse failures

	Dataset	Precision	Recall
sentence-level	DEV-1999	83% (64/77)	72% (64/ 89)
	TEST-2007	88% (64/73)	56% (64/114)
problem-level	DEV-1999	75% (18/24)	45% (18/40)
	TEST-2007	50% (8/16)	15% (8/53)

Table 10: Accuracy of logical forms

Error type	DEV-1999	TEST-2007
Bind a variable or leave it free	6	2
Wrong math expr. interpretaion	6	1
Quantifier choice	0	3
Quantifier scope	1	1
Logical connective choice	1	1
Logical connective scope	1	0
Others	1	2

Table 11: Types of errors in the logical forms

Table 8 shows the effect of CCG parsing with type environments. The column headed 'Typing failure' is the fraction of the problems on which no logical form was obtained due to typing failure. Parsing with type environment eliminated almost all such failures and significantly improved the number of correct answers. The remaining type failure was due to beam thresholding where a necessary derivation fell out of the beam.

Table 9 lists the reasons for the parse failures on 1/4 of the TEST section (the problems taken from exams on 2007). In the table, "unknown usage" means a missing lexical item for a word already in the lexicon. "Unknown word" means no lexical item was defined for the word. Collecting unknown usages (especially that of a function word) is much harder than just compiling a list of words. Our experience in the lexicon development tells us that once we find a usage example, in the large majority of the cases, it is not difficult to write down its syntactic category and semantic function. Table 9 suggests that we can efficiently detect and collect unknown word usages through parsing failures on a large raw corpus of math problems.

Table 10 presents the accuracy of the sentence- and problem-level logical forms produced on the year 1999 subset of DEV and the year 2007 subset of TEST. Although the recall on the unseen test data is not as high as we hope, the high precision of the sentence-level logical forms is encouraging.

Table 11 provides the counts of the error types found in the wrong sentence-level logical forms produced on DEV-1999 and TEST-2007. It reveals the majority of the errors are related to the choice of quantifier ($\exists$, $\forall$, or free) and logical operators (e.g., $\rightarrow$ vs. $\leftrightarrow$) as well as the determination of their scopes. Meanwhile, we did not find an error related to the predicate-argument structure of a logical form. This fact and the results in Table 6 suggest that the selectional restrictions, encoded in the lexicon, properly rejected nonsensical predicate-argument relations. Our next step is to introduce a more sophisticated disambiguation model on top of the grammar, enjoying the properly confined search space.

10 Conclusion

We have explained why the task of end-to-end math problem solving matters for a practical theory of natural language semantics and introduced the semantic parsing of pre-university math problems as a novel benchmark. The statistics of the benchmark data revealed that it includes far more complex semantic structures than the other benchmarks. We also presented an overview of an end-to-end problem solving system and described two parsing techniques motivated by the scarcity of the annotated data and the need for the type coherency of the analysis. Experimental results demonstrated the effectiveness of the proposed techniques and showed the accuracy of the sentence-level logical form was 88% precision and 56% recall. Our future work includes the expansion of the lexicon with the aid of the semantic parser and the development of a disambiguation model for the binding and scoping structures.
