We propose two new classes of trees between projective trees and the set of all spanning trees. These two classes provide a closer approximation to the set of plausible natural language dependency trees: unlike projective trees, a word can have descendants in more than one interval; unlike spanning trees, these intervals cannot be nested in arbitrary ways. We introduce *gap inheritance*, a new structural property on trees, which provides a way to quantify the degree to which these intervals can be nested. Different levels of gap inheritance define each of these two classes (Section 3).

The *1-Inherit* class of trees (Section 4) has *exactly* the same empirical coverage (Table 1) of natural language sentences as the class of *mildly non-projective trees* (Bodirsky et al., 2005), yet the optimal scoring tree can be found in an order of magnitude less time (Section 4.1).

*Gap-minding trees* (the second class) have the

property that all edges into an interval of descendants come from the same node. Non-contiguous intervals are therefore *decoupled* given this single node, and thus an algorithm which uses only single intervals (as in projective parsing) can produce trees in which a node has descendants in multiple intervals (as in mildly non-projective parsing (Gómez-Rodríguez et al., 2011)). A procedure for finding the optimal scoring tree in this space is given in Section 5, which can be searched in yet another order of magnitude faster than the *I-Inherit* class.

Unlike the class of spanning trees, it is still tractable to find the optimal tree in these new spaces when higher order factors are included. An extension which finds the optimal scoring gap-minding tree with scores over pairs of adjacent edges (grandparent scoring) is given in Section 6. These gap-minding algorithms have been implemented in practice and empirical results are presented in Section 7.

## 2 Preliminaries

In this section, we review some relevant definitions from previous work that characterize degrees of non-projectivity. We also review how well these definitions cover empirical data from six languages: Arabic, Czech, Danish, Dutch, Portuguese, and Swedish. These are the six languages whose CoNLL-X shared task data are either available open source<sup>1</sup> or from the LDC<sup>2</sup>.

A *dependency tree* is a rooted, directed spanning tree that represents a set of dependencies between words in a sentence.<sup>3</sup> The tree has one artificial root node and vertices that correspond to the words in an input sentence  $w_1, w_2, \dots, w_n$ . There is an edge from  $h$  to  $m$  if  $m$  depends on (or modifies)  $h$ .

**Definition 1.** *The projection of a node is the set of words in the subtree rooted at it (including itself).*

A tree is *projective* if, for every node in the tree, that node’s projection forms a contiguous interval in the input sentence order.

A tree is *non-projective* if the above does not hold, i.e., there exists at least one word whose descendants

do not form a contiguous interval.

**Definition 2.** *A gap of a node  $v$  is a non-empty, maximal interval that does not contain any words in the projection of  $v$  but lies between words that are in the projection of  $v$ . The gap degree of a node is the number of gaps it has. The gap degree of a tree is the maximum of the gap degrees of its vertices. (Bodirsky et al., 2005)*

Note that a projective tree will have gap degree 0.

Two subtrees *interleave* if there are vertices  $l_1, r_1$  from one subtree and  $l_2, r_2$  from the other such that  $l_1 < l_2 < r_1 < r_2$ .

**Definition 3.** *A tree is well-nested if no two disjoint subtrees interleave (Bodirsky et al., 2005).*

**Definition 4.** *A mildly non-projective tree has gap degree at most one and is well-nested.*

Mildly non-projective trees are of both theoretical and practical interest, as they correspond to derivations in Lexicalized Tree Adjoining Grammar (Bodirsky et al., 2005) and cover the overwhelming majority of sentences found in treebanks for Czech and Danish (Kuhlmann and Nivre, 2006).

Table 1 shows the proportion of mildly non-projective sentences for Arabic, Czech, Danish, Dutch, Portuguese, and Swedish, ranging from 95.4% of Portuguese sentences to 99.9% of Arabic sentences.<sup>4</sup> This definition covers a substantially larger set of sentences than projectivity does — an assumption of projectivity covers only 63.6% (Dutch) to 90.2% (Swedish) of examples (Table 1).

## 3 Gap Inheritance

Empirically, natural language sentences seem to be mostly mildly non-projective trees, but mildly non-projective trees are quite expensive to parse ( $O(n^7)$  (Gómez-Rodríguez et al., 2011)). The parsing complexity comes from the fact that the definition allows two non-contiguous intervals of a projection to be tightly coupled, with an unbounded number of edges passing back and forth between the two intervals; however, this type of structure seems unusual

<sup>1</sup>[http://ilk.uvt.nl/conll/free\\_data.html](http://ilk.uvt.nl/conll/free_data.html)

<sup>2</sup>LDC catalogue numbers LDC2006E01 and LDC2006E02

<sup>3</sup>Trees are a reasonable assumption for most, but not all, linguistic structures. Parasitic gaps are an example in which a word perhaps should have multiple parents.

<sup>4</sup>While some of the treebank structures are ill-nested or have a larger gap degree because of annotation decisions, some linguistic constructions in German and Czech are ill-nested or require at least two gaps under any reasonable representation (Chen-Main and Joshi, 2010; Chen-Main and Joshi, 2012).

	Arabic		Czech		Danish		Dutch		Portuguese		Swedish		Parsing
Mildly non-proj	1458	(99.9)	72321	(99.5)	5175	(99.7)	12896	(96.6)	8650	(95.4)	10955	(99.2)	$O(n^7)$

Table 1: The number of sentences from the CoNLL-X training sets whose parse trees fall into each of the above classes. The two new classes of structures, *Mild+0-Inherit* and *Mild+1-Inherit*, have more coverage of empirical data than projective structures, yet can be parsed faster than mildly non-projective structures. Parsing times assume an edge-based factorization with no pruning of edges. The corresponding algorithms for Mild+1-Inherit and Mild+0-Inherit are in Sections 4 and 5.

for natural language. We therefore investigate if we can define further structural properties that are both appropriate for describing natural language trees and which admit more efficient parsing algorithms.

Let us first consider an example of a tree which both has gap degree at most one and satisfies well-nestedness, yet appears to be an unrealistic structure for a natural language syntactic tree. Consider a tree which is rooted at node  $x_{n+2}$ , which has one child, node  $x_{n+1}$ , whose projection is  $[x_1, x_{n+1}] \cup [x_{n+3}, x_{2n+2}]$ , with  $n$  children ( $x_1, \dots, x_n$ ), and each child  $x_i$  has a child at  $x_{2n-i+3}$ . This tree is well-nested, has gap degree 1, but all  $n$  of  $x_{n+1}$ 's children have edges into the other projection interval.

We introduce a further structural restriction in this section, and show that trees satisfying our new property can be parsed more efficiently with no drop in empirical coverage.

**Definition 5.** *A child is gap inheriting if its parent has gap degree 1 and it has descendants on both sides of its parent's gap. The inheritance degree of a node is the number of its children which inherit its gap. The inheritance degree of a tree is the maximum inheritance degree over all its nodes.*

Figure 1 gives examples of trees with varying degrees of gap inheritance. Each projection of a node with a gap is shown with two matching rectangles. If a child has a projection rectangle nested inside each of the parent's projection rectangles, then that child inherits the parent's gap. Figure 1(a) shows a mildly projective tree (with inheritance degree 2), with both node 2 and node 11 inheriting their parent (node 3)'s gap (note that both the dashed and dotted rectangles each show up inside both of the solid rectangles). Figure 1(b) shows a tree with inheritance degree 1:

there is now only one pair of rectangles (the dotted ones) which show up in both of the solid ones. Figure 1(c) shows a tree with inheritance degree 0: while there are gaps, each set of matching rectangles is contained within a single rectangle (projection interval) of its parent, i.e., the two dashed rectangles of node 2's projection are contained within the left interval of node 3; the two dotted rectangles of node 12's projection are contained within the right interval of node 3, etc.

We now ask:

1. How often does gap inheritance occur in the parses of natural language sentences found in treebanks?
2. Furthermore, how often are there *multiple* gap inheriting children of the same node (inheritance degree at least two)?

Table 1 shows what proportion of mildly non-projective trees have the added property of gap inheritance degree 0 (Mild+0-Inherit) or have gap inheritance degree 1 (Mild+1-Inherit). Over all six languages, there are *no* examples of multiple gap inheritance — Mild+1-Inherit has exactly the same empirical coverage as the unrestricted set of mildly non-projective trees.

## 4 Mild+1-Inherit Trees

There are some reasons from syntactic theory why we might expect at most one child to inherit its parent's gap. Traditional Government and Binding theories of syntax (Chomsky, 1981) assume that there is an underlying projective (phrase structure) tree, and that gaps primarily arise through movement of

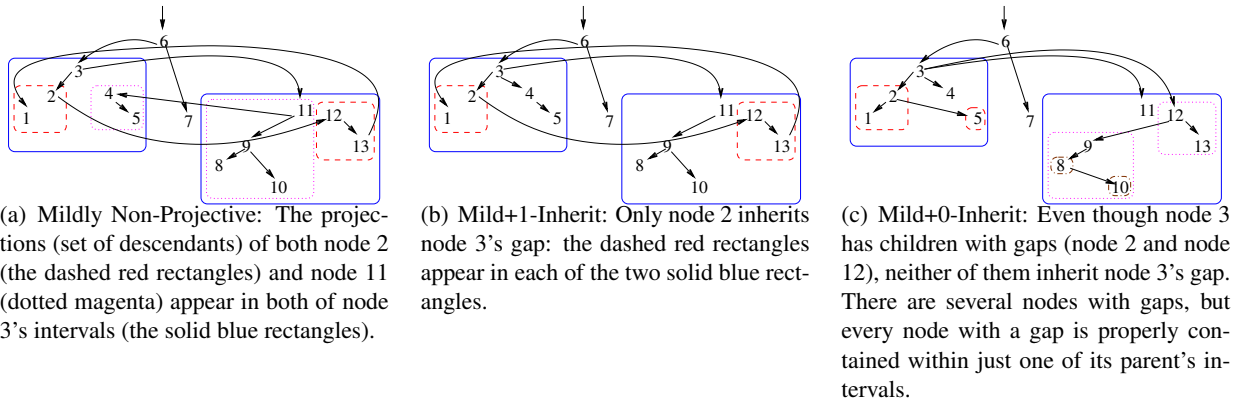

Figure 1: Rectangles that match in color and style indicate the two projection intervals of a node, separated by a gap. In all three trees, node 3's two projection intervals are shown in the two solid blue rectangles. The number of children which inherit its gap vary, however; in 1(a), two children have descendants within both sides; in 1(b) only one child has descendants on both sides; in 1(c), none of its children do.

subtrees (constituents). One of the fundamental assumptions of syntactic theory is that movement is upward in the phrase structure tree.<sup>5</sup>

Consider one movement operation and its effect on the gap degree of all other nodes in the tree: (a) it should have no effect on the gap degree of the nodes in the subtree itself, (b) it can create a gap for an ancestor node if it moves *out* of its projection interval, and (c) it can create a gap for a non-ancestor node if it moves *in* to its projection interval. Now consider which cases can lead to gap inheritance: in case (b), there is a single path from the ancestor to the root of the subtree, so the parent of the subtree will have no gap inheritance and any higher ancestors will have a single child inherit the gap created by this movement. In case (c), it is possible for there to be multiple children that inherit this newly created gap if multiple children had descendants on both sides. However, the assumption of upward movement in the phrase structure tree should rule out movement into the projection interval of a non-ancestor. Therefore, under these syntactic assumptions, we would expect at most one child to inherit a parent's gap.

<sup>5</sup>The Proper Binding Condition (Fiengo, 1977) asserts that a moved element leaves behind a *trace* (unpronounced element), which must be *c-commanded* (Reinhart, 1976) by the corresponding pronounced material in its final location. Informally, c-commanded means that the first node is descended from the lowest ancestor of the other that has more than one child.

#### 4.1 Parsing Mild+1-Inherit Trees

Finding the optimal Mild+1-Inherit tree can be done by bottom-up constructing the tree for each node and its descendants. We can maintain subtrees with two intervals (two endpoints each) and one root ( $O(n^5)$  space). Consider the most complicated possible case: a parent that has a gap, a (single) child which inherits the gap, and additional children. An example of this is seen with the parent node 3 in Figure 1(b).

This subtree can be constructed by first starting with the child spanning the gap, updating its root index to be the parent, and then expanding the interval indices to the left and right to include the other children. In each case, only one index needs to be updated at a time, so the optimal tree can be found in  $O(n^6)$  time. In the Figure 1(b) example, the subtree rooted at 3 would be built by starting with the intervals  $[1, 2] \cup [12, 13]$  rooted at 2, first adding the edge from 2 to 3 (so the root is updated to 3), then adding an edge from 3 to 4 to extend the left interval to  $[1, 5]$ , and then adding an edge from 3 to 11 to extend the right interval to  $[8, 13]$ . The subtree corresponds to the completed item  $[1, 5] \cup [8, 13]$  rooted at 3.

This procedure corresponds to Gómez-Rodríguez et al. (2011)'s  $O(n^7)$  algorithm for parsing mildly non-projective structures if the most expensive step (*Combine Shrinking Gap Centre*) is dropped; this step would only ever be needed if a parent node has

more than one child inheriting its gap.

This is also similar in spirit to the algorithm described in Satta and Schuler (1998) for parsing a restricted version of TAG, in which there are some limitations on adjunction operations into the spines of trees.<sup>6</sup> That algorithm has similar steps and items, with the root portion of the item replaced with a node in a phrase structure tree (which may be a non-terminal).

## 5 Gap-minding Trees

The algorithm in the previous section used  $O(n^5)$  space and  $O(n^6)$  time. While more efficient than parsing in the space of mildly projective trees, this is still probably not practically implementable. Part of the difficulty lies in the fact that gap inheritance causes the two non-contiguous projection intervals to be coupled.

**Definition 6.** *A tree is called gap-minding<sup>7</sup> if it has gap degree at most one, is well-nested, and has gap inheritance degree 0.*

Gap-minding trees still have good empirical coverage (between 90.4% for Dutch and 97.7% for Swedish). We now turn to the parsing of gap-minding trees and show how a few consequences of its definition allow us to use items ranging over only one interval.

In Figure 1(c), notice how each rectangle has edges incoming from *exactly one* node. This is not unique to this example; all projection intervals in a gap-minding tree have incoming edges from exactly one node outside the interval.

**Claim 1.** *Within a gap-minding tree, consider any node  $n$  with a gap (i.e.,  $n$ 's projection forms two non-contiguous intervals  $[x_i, x_j] \cup [x_k, x_l]$ ). Let  $p$  be the parent of  $n$ .*

1. *For each of the intervals of  $n$ 's projection:*

(a) *If the interval contains  $n$ , the only edge incoming to that interval is from  $p$  to  $n$ .*

<sup>6</sup>That algorithm has a running time of  $O(Gn^5)$ , where as written  $G$  would likely add a factor of  $n^2$  with bilinear selectional preferences; this can be lowered to  $n$  using the same technique as in Eisner and Satta (2000) for non-restricted TAG.

<sup>7</sup>The terminology is a nod to the London Underground but imagines parents admonishing children to mind the gap.

(b) *If the interval does not contain  $n$ , all edges incoming to that interval come from  $n$ .*

2. *For the gap interval  $([x_{j+1}, x_{k-1}])$ :*

(a) *If the interval contains  $p$ , then the only edge incoming is from  $p$ 's parent to  $p$*

(b) *If the interval does not contain  $p$ , then all edges incoming to that interval come from  $p$ .*

*As a consequence of the above,  $[x_i, x_j] \cup \{n\}$  forms a gap-minding tree rooted at  $n$ ,  $[x_k, x_l] \cup \{n\}$  also forms a gap-minding tree rooted at  $n$ , and  $[x_{j+1}, x_{k-1}] \cup \{p\}$  forms a gap-minding tree rooted at  $p$ .*

*Proof.* (Part 1): Assume there was a directed edge  $(x, y)$  such that  $y$  is inside a projection interval of  $n$  and  $x$  is not inside the same interval, and  $x \neq y \neq n$ .  $y$  is a descendant of  $n$  since it is contained in  $n$ 's projection. Since there is a directed edge from  $x$  to  $y$ ,  $x$  is  $y$ 's parent, and thus  $x$  must also be a descendant of  $n$  and therefore in another of  $n$ 's projection intervals. Since  $x$  and  $y$  are in different intervals, then whichever child of  $n$  that  $x$  and  $y$  are descended from would have inherited  $n$ 's gap, leading to a contradiction.

(Part 2): First, suppose there existed a set of nodes in  $n$ 's gap which were not descended from  $p$ . Then  $p$  has a gap over these nodes. ( $p$  clearly has descendants on each side of the gap, because all descendants of  $n$  are also descendants of  $p$ ).  $n$ ,  $p$ 's child, would then have descendants on both sides of  $p$ 's gap, which would violate the property of no gap inheritance. It is also not possible for there to be edges incoming from other descendants of  $p$  outside the gap, as that would imply another child of  $p$  being ill-nested with respect to  $n$ .  $\square$

From the above, we can build gap-minding trees using only single intervals, potentially with a single node outside of the interval. Our objective is to find the maximum scoring gap-minding tree, in which the score of a tree is the sum of the scores of its edges. Let  $\mathbf{Score}(\mathbf{p}, \mathbf{x})$  indicate the score of the directed edge from  $p$  to  $x$ .

Therefore, the main type of sub-problems we will use are:

1.  $\mathbf{C}[i, j, p]$ : The maximum score of any gap-minding tree, rooted at  $p$ , with vertices  $[i, j] \cup \{p\}$  ( $p$  may or may not be within  $[i, j]$ ).

This improves our space requirement, but not necessarily the time requirement. For example, if we built up the subtree in Figure 1(c) by concatenating the three intervals  $[1, 5]$  rooted at 3,  $[6, 7]$  rooted at 6, and  $[8, 13]$  rooted at 3, and add the edge  $6 \rightarrow 3$ , we would still need 6 indices to describe this operation (the four interval endpoints and the two roots), and so we have not yet improved the running time over the *Inherit-1* case.

By part 2, we can concatenate one interval of a child with its gap, knowing that the gap is entirely descended from the child's parent, and forget the concatenation split point between the parent's other descendants and this side of the child. This allows us to substitute all operations involving 6 indices with two operations involving just 5 indices. For example, in Figure 1(c), we could first merge  $[6, 7]$  rooted at 6 with  $[8, 13]$  rooted at 3 to create an interval  $[6, 13]$  and say that it is descended from 6, with the rightmost side descended from its child 3. That step required 5 indices. The following step would merge this concatenated interval ( $[6, 13]$  rooted at 6 and 3) with  $[1, 5]$  rooted at 3. This step also requires only 5 indices.

Our helper subtype we make use of is then:

2.  $\mathbf{D}[i, j, p, x, b]$ : The maximum score of any set of two gap-minding trees, one rooted at  $p$ , one rooted at  $x$ , with vertices  $[i, j] \cup \{p, x\}$  ( $x \notin [i, j]$ ,  $p$  may or may not be in  $[i, j]$ ), such that for some  $k$ , vertices  $[i, k]$  are in the tree rooted at  $p$  if  $b = \text{true}$  (and at  $x$  if  $b = \text{false}$ ), and vertices  $[k + 1, j]$  are in the tree rooted at  $x$  ( $p$ ).

Consider an optimum scoring gap-minding tree  $T$  rooted at  $p$  with vertices  $V = [i, j] \cup \{p\}$  and edges  $E$ , where  $E \neq \emptyset$ . The form of the dynamic program may depend on whether:

- $p$  is within  $(i, j)$  (**I**) or external to  $[i, j]$  (**E**)<sup>8</sup>

<sup>8</sup>In the discussion we will assume that  $p \neq i$  and  $p \neq j$ , since any optimum solution with  $V = [i, j] \cup \{i\}$  and a root at  $i$  will be equivalent to  $V = [i + 1, j] \cup \{i\}$  rooted at  $i$  (and similarly for  $p = j$ ).

We can exhaustively enumerate all possibilities for  $T$  by considering all valid combinations of the following binary cases:

- $p$  has a single child (**S**) or multiple children (**M**)
- $i$  and  $j$  are descended from the same child of  $p$  (**C**) or different children of  $p$  (**D**)

Note that case (**S/D**) is not possible:  $i$  and  $j$  cannot be descended from different children of  $p$  if  $p$  has only a single child. We therefore need to find the maximum scoring tree over the three cases of **S/C**, **M/C**, and **M/D**.

**Claim 2.** Let  $T$  be the optimum scoring gap-minding tree rooted at  $p$  with vertices  $V = [i, j] \cup \{p\}$ . Then  $T$  and its score are derived from one of the following:

**S/C** If  $p$  has a single child  $x$  in  $T$ , then if  $p \in (i, j)$  (**I**),  $T$ 's score is  $\mathbf{Score}(\mathbf{p}, \mathbf{x}) + \mathbf{C}[i, \mathbf{p} - \mathbf{1}, \mathbf{x}] + \mathbf{C}[\mathbf{p} + \mathbf{1}, \mathbf{j}, \mathbf{x}]$ ; if  $p \notin [i, j]$  (**E**),  $T$ 's score is  $\mathbf{Score}(\mathbf{p}, \mathbf{x}) + \mathbf{C}[i, \mathbf{j}, \mathbf{x}]$ .

**M/C** If  $p$  has multiple children in  $T$  and  $i$  and  $j$  are descended from the same child  $x$  in  $T$ , then there is a split point  $k$  such that  $T$ 's score is:  $\mathbf{Score}(\mathbf{p}, \mathbf{x}) + \mathbf{C}[i, \mathbf{k}, \mathbf{x}] + \mathbf{D}[\mathbf{k} + \mathbf{1}, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{T}]$  if  $x$  is on the left side of its own gap, and  $T$ 's score is:  $\mathbf{Score}(\mathbf{p}, \mathbf{x}) + \mathbf{C}[\mathbf{k}, \mathbf{j}, \mathbf{x}] + \mathbf{D}[\mathbf{i}, \mathbf{k} - \mathbf{1}, \mathbf{p}, \mathbf{x}, \mathbf{F}]$  if  $x$  is on the right side.

**M/D** If  $p$  has multiple children in  $T$  and  $i$  and  $j$  are descended from different children in  $T$ , then there is a split point  $k$  such that  $T$ 's score is  $\mathbf{C}[i, \mathbf{k}, \mathbf{p}] + \mathbf{C}[\mathbf{k} + \mathbf{1}, \mathbf{j}, \mathbf{p}]$ .

$T$  has the maximum score over each of the above cases, for all valid choices of  $x$  and  $k$ .

*Proof.* **Case S/C:** If  $p$  has exactly one child  $x$ , then the tree can be decomposed into the edge from  $p$  to  $x$  and the subtree rooted at  $x$ . If  $p$  is outside the interval, then the maximum scoring such tree is clearly  $\mathbf{Score}(\mathbf{p}, \mathbf{x}) + \mathbf{C}[i, \mathbf{j}, \mathbf{x}]$ . If  $p$  is inside, then  $x$  has a gap across  $p$ , and so using Claim 1, the maximum scoring tree rooted at  $p$  with a single child  $x$  has score of  $\mathbf{Score}(\mathbf{p}, \mathbf{x}) + \mathbf{C}[i, \mathbf{p} - \mathbf{1}, \mathbf{x}] + \mathbf{C}[\mathbf{p} + \mathbf{1}, \mathbf{j}, \mathbf{x}]$ .

**Case M/C:** If there are multiple children and the endpoints are descended from the same child  $x$ , then

the child  $x$  has to have gap degree 1.  $x$  itself is on either the left or right side of its gap. For the moment, assume  $x$  is in the left interval. By Claim 1, we can split up the score of the tree as the score of the edge from  $p$  to  $x$  ( $\text{Score}(\mathbf{p}, \mathbf{x})$ ), the score of the subtree corresponding to the projection of  $x$  to the left of its gap ( $\mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{x}]$ ), and the score of the subtrees rooted at  $p$  with its remaining children and the subtree rooted at  $x$  corresponding to the right side of  $x$ 's projection ( $\mathbf{D}[\mathbf{k} + 1, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{T}]$ ). The case in which  $x$  is on the right side of its gap is symmetric.

**Case M/D:** If there are multiple children and the endpoints are descended from different children of  $p$ , then there must exist a split point  $k$  that partitions the children of  $p$  into two non-empty sets, such that each child's projection is either entirely on the left or entirely on the right of the split point. We show one such split point to demonstrate that there always exists at least one. Let  $x$  be the child of  $p$  that  $i$  is descended from, and let  $x_l$  and  $x_r$  be  $x$ 's leftmost and right descendants, respectively.<sup>9</sup> Consider all the children of  $p$  (whose projections taken together partition  $[i, j] - \{p\}$ ). No child can have descendants both to the left of  $x_r$  and to the right of  $x_r$ , because otherwise that child and  $x$  would be *ill-nested*. Therefore we can split up the interval at  $x_r$  to have two gap-minding trees, both rooted at  $p$ . The score of  $T$  is then the sum of the scores of the best subtree rooted at  $p$  over  $[i, k]$  ( $\mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{p}]$ ) and the score of the best subtree rooted at  $p$  over  $[k + 1, j]$  ( $\mathbf{C}[\mathbf{k} + 1, \mathbf{j}, \mathbf{p}]$ ).

The above cases cover all non-empty gap-minding trees, so the maximum will be found.  $\square$

**Using Claim 2 to Devise an Algorithm** The above claim showed that any problem of type **C** can be decomposed into subproblems of types **C** and **D**. From the definition of **D**, any problem of type **D** can clearly be decomposed into two problems of type **C** — simply split the interval at the split point known to exist and assign  $p$  or  $x$  as the roots for each side of the interval, as prescribed by the boolean  $b$ :

$$\begin{aligned} \mathbf{D}(\mathbf{i}, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{T}) &= \max_{\mathbf{k}} \mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{p}] + \mathbf{C}[\mathbf{k} + 1, \mathbf{j}, \mathbf{x}] \\ \mathbf{D}(\mathbf{i}, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{F}) &= \max_{\mathbf{k}} \mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{x}] + \mathbf{C}[\mathbf{k} + 1, \mathbf{j}, \mathbf{p}] \end{aligned}$$

<sup>9</sup>Note that  $x_l = i$  by construction, and  $x_r \neq j$  (because the endpoints are descended from different children).

Algorithm 1 makes direct use of the above claims. Note that in every gap-minding tree referred to in the cases above, all vertices that were not the root formed a single interval. Algorithm 1 builds up trees in increasing sizes of  $[i, j] \cup \{p\}$ . The tree in  $\mathbf{C}[\mathbf{i}, \mathbf{j}, \mathbf{p}]$  corresponds to the maximum of four subroutines: SingleChild (**S/C**), EndpointsDiff (**M/D**), EndsFromLeftChild (**M/C**), and EndsFromRightChild (**M/C**). The **D** subproblems are filled in with the subroutine Max2Subtrees, which uses the above discussion. The maximum score of any gap-minding tree is then found in  $\mathbf{C}[1, \mathbf{n}, 0]$ , and the tree itself can be found using backpointers.

## 5.1 Runtime analysis

If the input is assumed to be the complete graph (any word can have any other word as its parent), then the above algorithm takes  $O(n^5)$  time. The most expensive steps are **M/C**, which take  $O(n^2)$  time to fill in each of the  $O(n^3)$  **C** cells. and solving a **D** subproblem, which takes  $O(n)$  time on each of the  $O(n^4)$  possible such problems.

**Pruning:** In practice, the set of edges considered ( $m$ ) is not necessarily  $O(n^2)$ . Many edges can be ruled out beforehand, either based on the distance in the sentence between the two words (Eisner and Smith, 2010), the predictions of a local ranker (Martins et al., 2009), or the marginals computed from a simpler parsing model (Carreras et al., 2008).

If we choose a pruning strategy such that each word has at most  $k$  potential parents (incoming edges), then the running time drops to  $O(kn^4)$ . The five indices in an **M/C** step were:  $i, j, k, p$ , and  $x$ . As there must be an edge from  $p$  to  $x$ , and  $x$  only has  $k$  possible parents, there are now only  $O(kn^4)$  valid such combinations. Similarly, each **D** subproblem (which ranges over  $i, j, k, p, x$ ) may only come into existence because of an edge from  $p$  to  $x$ , so again the runtime of these such steps drops to  $O(kn^4)$ .

## 6 Extension to Grandparent Factorizations

The ability to define slightly non-local features has been shown to improve parsing performance. In this section, we assume a *grandparent-factored* model, where the score of a tree is now the sum over scores of  $(g, p, c)$  triples, where  $(g, p)$  and  $(p, c)$  are both

directed edges in the tree. Let  $\text{Score}(\mathbf{g}, \mathbf{p}, \mathbf{c})$  indicate the score of this grandparent-parent-child triple. We now show how to extend the above algorithm to find the maximum scoring gap-minding tree with grandparent scoring.

Our two subproblems are now  $\mathbf{C}[\mathbf{i}, \mathbf{j}, \mathbf{p}, \mathbf{g}]$  and  $\mathbf{D}[\mathbf{i}, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{b}, \mathbf{g}]$ ; each subproblem has been augmented with an additional grandparent index  $g$ , which has the meaning that  $g$  is  $p$ 's parent. Note that  $g$  must be outside of the interval  $[i, j]$  (if it were not, a cycle would be introduced). Edge scores are now computed over  $(g, p, x)$  triples. In particular, claim 2 is modified:

**Claim 3.** *Let  $T$  be the optimum scoring gap-minding tree rooted at  $p$  with vertices  $V = [i, j] \cup \{p\}$ , where  $p \in (i, j)$  (**I**), with a grandparent index  $g$  ( $g \notin V$ ). Then  $T$  and its score are derived from one of the following:*

**S/C** *If  $p$  has a single child  $x$  in  $T$ , then if  $p \in (i, j)$  (**I**),  $T$ 's score is  $\text{Score}(\mathbf{g}, \mathbf{p}, \mathbf{x}) + \mathbf{C}[\mathbf{i}, \mathbf{p} - \mathbf{1}, \mathbf{x}, \mathbf{p}] + \mathbf{C}[\mathbf{p} + \mathbf{1}, \mathbf{j}, \mathbf{x}, \mathbf{p}]$ ; if  $p \notin [i, j]$  (**E**),  $T$ 's score is  $\text{Score}(\mathbf{g}, \mathbf{p}, \mathbf{x}) + \mathbf{C}[\mathbf{i}, \mathbf{j}, \mathbf{x}, \mathbf{p}]$ .*

**M/C** *If  $p$  has multiple children in  $T$  and  $i$  and  $j$  are descended from the same child  $x$  in  $T$ , then there is a split point  $k$  such that  $T$ 's score is:  $\text{Score}(\mathbf{g}, \mathbf{p}, \mathbf{x}) + \mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{x}, \mathbf{p}] + \mathbf{D}[\mathbf{k} + \mathbf{1}, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{T}, \mathbf{g}]$  if  $x$  is on the left side of its own gap, and  $T$ 's score is:  $\text{Score}(\mathbf{g}, \mathbf{p}, \mathbf{x}) + \mathbf{C}[\mathbf{k}, \mathbf{j}, \mathbf{x}, \mathbf{p}] + \mathbf{D}[\mathbf{i}, \mathbf{k} - \mathbf{1}, \mathbf{p}, \mathbf{x}, \mathbf{F}, \mathbf{g}]$  if  $x$  is on the right side.*

**M/D** *If  $p$  has multiple children in  $T$  and  $i$  and  $j$  are descended from different children in  $T$ , then there is a split point  $k$  such that  $T$ 's score is  $\mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{p}, \mathbf{g}] + \mathbf{C}[\mathbf{k} + \mathbf{1}, \mathbf{j}, \mathbf{p}, \mathbf{g}]$ .*

$T$  has the maximum score over each of the above cases, for all valid choices of  $x$  and  $k$ .

Note that for subproblems rooted at  $p$ ,  $g$  is the grandparent index, while for subproblems rooted at  $x$ ,  $p$  is the updated grandparent index. The **D** subproblems with the grandparent index are shown below:

$$\mathbf{D}(\mathbf{i}, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{T}, \mathbf{g}) = \max_{\mathbf{k}} \mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{p}, \mathbf{g}] + \mathbf{C}[\mathbf{k} + \mathbf{1}, \mathbf{j}, \mathbf{x}, \mathbf{p}]$$

$$\mathbf{D}(\mathbf{i}, \mathbf{j}, \mathbf{p}, \mathbf{x}, \mathbf{F}, \mathbf{g}) = \max_{\mathbf{k}} \mathbf{C}[\mathbf{i}, \mathbf{k}, \mathbf{x}, \mathbf{p}] + \mathbf{C}[\mathbf{k} + \mathbf{1}, \mathbf{j}, \mathbf{p}, \mathbf{g}] \text{ (Proj+Sib+Rearr).}$$

We have added another index which ranges over  $n$ , so without pruning, we have now increased the running time to  $O(n^6)$ . However, every step now includes both a  $g$  and a  $p$  (and often an  $x$ ), so there is at least one implied edge in every step. If pruning is done in such a way that each word has at most  $k$  parents, then each word's set of grandparent and parent possibilities is at most  $k^2$ . To run all of the **S/C** steps, we therefore need  $O(k^2 n^3)$  time; for all of the **M/C** steps,  $O(k^2 n^4)$  time; for all of the **M/D** steps,  $O(kn^4)$ ; for all of the **D** subproblems,  $O(k^2 n^4)$ . The overall running time is therefore  $O(k^2 n^4)$ , and we have shown that when edges are sufficiently pruned, grandparent factors add only an extra factor of  $k$ , and not a full extra factor of  $n$ .

## 7 Experiments

The space of projective trees is strictly contained within the space of gap-minding trees which is strictly contained within spanning trees. Which space is most appropriate for natural language parsing may depend on the particular language and the type and frequencies of non-projective structures found in it. In this section we compare the parsing accuracy across languages for a parser which uses either the Eisner algorithm (projective), MST (spanning trees), or MaxGapMindingTree (gap-minding trees) as its decoder for both training and inference.

We implemented both the basic gap-minding algorithm and the gap-minding algorithm with grandparent scoring as extensions to MSTParser<sup>10</sup>. MSTParser (McDonald et al., 2005b; McDonald et al., 2005a) uses the Margin Infused Relaxed Algorithm (Crammer and Singer, 2003) for discriminative training. Training requires a decoder which produces the highest scoring tree (in the space of valid trees) under the current model weights. This same decoder is then used to produce parses at test time. MSTParser comes packaged with the Eisner algorithm (for projective trees) and MST (for spanning trees). MSTParser also includes two second order models: one of which is a projective decoder that also scores siblings (Proj+Sib) and the other of which produces non-projective trees by rearranging edges after producing a projective tree (Proj+Sib+Rearr). We add a further decoder with

<sup>10</sup><http://sourceforge.net/projects/mstparser/>

the algorithm presented here for gap minding trees, and plan to make the extension publicly available. The gap-minding decoder has both an edge-factored implementation and a version which scores grandparents as well.<sup>11</sup>

The gap-minding algorithm is much more efficient when edges have been pruned so that each word has at most  $k$  potential parents. We use the weights from the trained MST models combined with the Matrix Tree Theorem (Smith and Smith, 2007; Koo et al., 2007; McDonald and Satta, 2007) to produce marginal probabilities of each edge. We wanted to be able to both achieve the running time bound and yet take advantage of the fact that the size of the set of reasonable parent choices is variable. We therefore use a hybrid pruning strategy: each word’s set of potential parents is the *smaller* of a) the top  $k$  parents (we chose  $k = 10$ ) or b) the set of parents whose probabilities are above a threshold (we chose  $th = .001$ ). The running time for the gap-minding algorithm is then  $O(kn^4)$ ; with the grandparent features the gap-minding running time is  $O(k^2n^4)$ .

The training and test sets for the six languages come from the CoNLL-X shared task.<sup>12</sup> We train the gap-minding algorithm on sentences of length at most 100<sup>13</sup> (the vast majority of sentences). The projective and MST models are trained on all sentences and are run without any pruning. The Czech training set is much larger than the others and so for Czech only the first 10,000 training sentences were used. Testing is on the full test set, with no length restrictions.

The results are shown in Table 2. The first three lines show the first order gap-minding decoder compared with the first order projective and MST de-

<sup>11</sup>The grandparent features used were identical to the features provided within MSTParser for the second-order sibling parsers, with one exception — many features are conjoined with a direction indicator, which in the projective case has only two possibilities. We replaced this two-way distinction with a six-way distinction of the six possible orders of the grandparent, parent, and child.

<sup>12</sup>MSTParser produces labeled dependencies on CoNLL formatted input. We replace all labels in the training set with a single dummy label to produce unlabeled dependency trees.

<sup>13</sup>Because of long training times, the gap-minding with grandparent models for Portuguese and Swedish were trained on only sentences up to 50 words.

	Ar	Cz	Da	Du	Pt	Sw
Proj.	78.0	80.0	88.2	79.8	87.4	86.9
MST	78.0	80.4	88.1	84.6	86.7	86.2
Gap-Mind	77.6	80.8	88.6	83.9	86.8	86.0
Proj+Sib	78.2	80.0	88.9	81.1	87.5	88.1
+Rearr	78.5	81.3	89.3	85.4	88.2	87.7
GM+Grand	78.3	82.1	89.1	84.6	87.7	88.5

Table 2: Unlabeled Attachment Scores on the CoNLL-X shared task test set.

coders. The gap-minding decoder does better than the projective decoder on Czech, Danish, and Dutch, the three languages with the most non-projectivity, even though it was at a competitive disadvantage in terms of both pruning and (on languages with very long sentences) training data. The gap-minding decoder with grandparent features is better than the projective decoder with sibling features on all six of the languages. On some languages, the local search decoder with siblings has the absolute highest accuracy in Table 2; on other languages (Czech and Swedish) the gap-minding+grandparents has the highest accuracy. While not directly comparable because of the difference in features, the promising performance of the gap-minding+grandparents decoder shows that the space of gap-minding trees is larger than the space of projective trees, yet unlike spanning trees, it is tractable to find the best tree with higher order features. It would be interesting to extend the gap-minding algorithm to include siblings as well.

## 8 Conclusion

Gap inheritance, a structural property on trees, has implications both for natural language syntax and for natural language parsing. We have shown that the mildly non-projective trees present in natural language treebanks *all* have zero or one children inherit each parent’s gap. We also showed that the assumption of 1 gap inheritance removes a factor of  $n$  from parsing time, and the further assumption of 0 gap inheritance removes yet another factor of  $n$ . The space of gap-minding trees provides a closer fit to naturally occurring linguistic structures than the space of projective trees, and unlike spanning trees, the inclusion of higher order factors does not substantially increase the difficulty of finding the maximum scoring tree in that space.

# Joint Entity and Event Coreference Resolution across Documents

Heeyoung Lee, Marta Recasens, Angel Chang, Mihai Surdeanu, Dan Jurafsky  
Stanford University, Stanford, CA 94305  
{heeyoung, recasens, angelx, mihais, jurafsky}@stanford.edu

## Abstract

We introduce a novel coreference resolution system that models entities and events jointly. Our iterative method cautiously constructs clusters of entity and event mentions using linear regression to model cluster merge operations. As clusters are built, information flows between entity and event clusters through features that model semantic role dependencies. Our system handles nominal and verbal events as well as entities, and our joint formulation allows information from event coreference to help entity coreference, and vice versa. In a cross-document domain with comparable documents, joint coreference resolution performs significantly better (over 3 CoNLL F1 points) than two strong baselines that resolve entities and events separately.

## 1 Introduction

Most coreference resolution systems focus on entities and tacitly assume a correspondence between entities and noun phrases (NPs). Focusing on NPs is a way to restrict the challenging problem of coreference resolution, but misses coreference relations like the one between *hanged* and *his suicide* in (1), and between *placed* and *put* in (2).

- (a) **One of the key suspected Mafia bosses arrested yesterday** has hanged himself.  
(b) Police said **Lo Presti** had hanged himself.  
(c) His suicide appeared to be related to clan feuds.
- (a) **The New Orleans Saints** placed Reggie Bush on the injured list on Wednesday.  
(b) **Saints** put Bush on I.R.

As (1c) shows, NPs can also refer to events, and so corefer with phrases other than NPs (Webber, 1988). By being anchored in spatio-temporal dimensions, events represent the most frequent referent of verbal elements. In addition to time and location, events are characterized by their participants or arguments, which often correspond with discourse entities. This two-way feedback between events and their arguments (or entities) is the core of our approach. Since arguments play a key role in describing an event, knowing that two arguments corefer is useful for finding coreference relations between events, and knowing that two events corefer is useful for finding coreference relations between entities. In (1), the coreference relation between *One of the key suspected Mafia bosses arrested yesterday* and *Lo Presti* can be found by knowing that their predicates (i.e., *has hanged* and *had hanged*) corefer. On the other hand, the coreference relations between the arguments *Saints* and *Bush* in (2) helps to determine the coreference relation between their predicates *placed* and *put*.

In this paper, we take a holistic approach to coreference. We annotate a corpus with cross-document coreference relations for nominal and verbal mentions. We focus on both intra and inter-document coreference because this scenario is at the same time more challenging and more relevant to real-world applications such as news aggregation. We use this corpus to train a model that jointly addresses references to both entities and events across documents. The contributions of this work are the following:

- We introduce a novel approach for entity and event coreference resolution. At the core of

our approach is an iterative algorithm that cautiously constructs clusters of entity and event mentions using linear regression to model cluster merge operations. Importantly, our model allows information to flow between clusters of both types through features that model context using semantic role dependencies.

- We annotate and release a new corpus with coreference relations between both entities and events across documents. The relations annotated are both intra and inter-document, which more accurately models real-world scenarios.
- We evaluate our cross-document coreference resolution system on this corpus and show that our joint approach significantly outperforms two strong baselines that resolve entities and events separately.

## 2 Related Work

Entity coreference resolution is a well studied problem with many successful techniques for identifying mention clusters (Ponzetto and Strube, 2006; Haghighi and Klein, 2009; Stoyanov et al., 2009; Haghighi and Klein, 2010; Raghunathan et al., 2010; Rahman and Ng, 2011, *inter alia*). Most of these techniques focus on matching compatible noun pairs using various syntactic and semantic features, with efforts targeted toward improving features and clustering models.

Prior work showed that models that jointly resolve mentions across multiple entities result in better performance than simply resolving mentions in a pairwise fashion (Denis and Baldridge, 2007; Poon and Domingos, 2008; Wick et al., 2008; Lee et al., 2011, *inter alia*). A natural extension is to perform coreference jointly across both entities and events. Yet there has been little attempt in this direction.

We know of only limited work that incorporates event-related information in entity coreference, typically by incorporating the verbs in context as features. For instance, Haghighi and Klein (2010) include the governor of the head of nominal mentions as features in their model. Rahman and Ng (2011) also used event-related information by looking at which semantic role the entity mentions can have and the verb pairs of their predicates. We confirm

that such features are useful but also show that the complementary features for verbal mentions lead to even better performance, especially when event and entity clusters are jointly modeled.

Compared to the extensive work on entity coreference, the related problem of event coreference remains relatively under-explored, with minimal work on how entity and event coreference can be considered jointly on an open domain. Early work on event coreference for MUC (Humphreys et al., 1997; Bagga and Baldwin, 1999) focused on scenario-specific events. More recently, there have been approaches that looked at event coreference for wider domains. Chen and Ji (2009) proposed using spectral graph clustering to cluster events. Bejan and Harabagiu (2010) proposed a nonparametric Bayesian model for open-domain event resolution. However, most of this prior work focused only on event coreference, whereas we address both entities and events with a single model. Humphreys et al. (1997) considered entities as well as events, but due to the lack of a corpus annotated with event coreference, their approach was only evaluated implicitly in the MUC-6 template filling task. To our knowledge, the only previous work that considered entity and event coreference resolution jointly is He (2007), but limited to the medical domain and focused on just five semantic categories.

## 3 Architecture

Following the intuition introduced in Section 1, our approach iteratively builds clusters of event and entity mentions jointly. As more information becomes available (e.g., finding out that two verbal mentions have arguments that belong to the same entity cluster), the features of both entity and event mentions are re-generated, which prompts future clustering operations. Our model follows a cautious (or “baby steps”) approach, which we previously showed to be successful for entity coreference resolution (Raghunathan et al., 2010; Lee et al., 2011). However, unlike our previous work, which used deterministic rules, in this paper we learn a coreference resolution model using linear regression. Algorithm 1 summarizes the flow of the proposed algorithm. We detail its steps next. We describe the training procedure in Section 4 and the features used in Section 5.

---

**Algorithm 1: Joint Coreference Resolution**

---

```
input : set of documents  $\mathcal{D}$ 
input : coreference model  $\Theta$ 
// clusters of mentions:
1  $\mathcal{E} = \{\}$ 
// clusters of documents:
2  $\mathcal{C} = \text{clusterDocuments}(\mathcal{D})$ 
3 foreach document cluster  $c$  in  $\mathcal{C}$  do
    // all mentions in one doc cluster:
4  $\mathcal{M} = \text{extractMentions}(c)$ 
    // singleton mention clusters:
5  $\mathcal{E}' = \text{buildSingletonClusters}(\mathcal{M})$ 
    // high-precision deterministic sieves:
6  $\mathcal{E}' = \text{applyHighPrecisionSieves}(\mathcal{E}')$ 
    // iterative event/entity coreference:
7 while  $\exists e_1, e_2 \in \mathcal{E}'$  s.t.  $\text{score}(e_1, e_2, \Theta) > 0.5$  do
8      $(e_1, e_2) = \arg \max_{e_1, e_2 \in \mathcal{E}'} \text{score}(e_1, e_2, \Theta)$ 
9      $\mathcal{E}' = \text{merge}(e_1, e_2, \mathcal{E}')$ 
    // pronoun sieve:
10  $\mathcal{E}' = \text{applyPronounSieve}(\mathcal{E}')$ 
    // append to global output:
11  $\mathcal{E} = \mathcal{E} + \mathcal{E}'$ 
output :  $\mathcal{E}$ 
```

---

### 3.1 Document Clustering

Our approach starts with several steps that reduce the search space for the actual coreference resolution task. The first is document clustering, which clusters the set of input documents ( $\mathcal{D}$ ) into a set of document clusters ( $\mathcal{C}$ ). In the subsequent steps we only cluster mentions that appear in the same document cluster. We found this to be very useful in practice because, in addition to reducing the search space, it provides a word sense disambiguation mechanism based on corpus-wide topics. For example, without document clustering, our algorithm may decide to cluster two mentions of the verb *hit*, but knowing that one belongs to a cluster containing earthquake reports and the other to a cluster with reports on criminal activities, this decision can be avoided.<sup>1</sup>

Any non-parametric clustering algorithm can be used in this step. In this paper, we used the algorithm proposed by Surdeanu et al. (2005). This algorithm is an Expectation Maximization (EM) variant where the initial points (and the number of clusters) are selected from the clusters generated by a hierarchical agglomerative clustering algorithm using ge-

---

<sup>1</sup>Since different mentions of the verb *say* in the same topic might refer to different events, they are only merged if they have coreferent arguments.

ometric heuristics. This algorithm performs well on our data. For example, in the training dataset, only two topics (handling different earthquake events) are incorrectly merged into the same cluster.

### 3.2 Mention Extraction

In this step (4 in Algorithm 1) we extract nominal, pronominal, and verbal mentions. We extract nominal and pronominal mentions using the mention identification component in the publicly downloadable Stanford coreference resolution system (Raghunathan et al., 2010; Lee et al., 2011). We consider as verbal mentions all words whose part of speech starts with VB, with the exception of some auxiliary/copulative verbs (*have*, *be* and *seem*). For each of the identified mentions we build a singleton cluster (step 5 in Algorithm 1).

Crucially, we do not make a formal distinction between entity and event mentions. This distinction is not trivial to implement (e.g., is the noun *earthquake* an entity or an event mention?) and an imperfect classification would negatively affect the following coreference resolution. Instead, we simply classify mentions into verbal or nominal, and use this distinction later during feature generation (Section 5). To compare event nouns (e.g., *development*) with verbal mentions, the “derivationally related form” relation in WordNet is used.

### 3.3 High-precision Entity Resolution Sieves

To further reduce the problem’s search space, in step 6 of Algorithm 1 we apply a set of high-precision filters from the Stanford coreference resolution system. This system is a collection of deterministic models (or “sieves”) for entity coreference resolution that incorporate lexical, syntactic, semantic, and discourse information. These sieves are applied from higher to lower precision. As clusters are built, information such as mention gender and number is propagated across mentions in the same cluster, which helps subsequent decisions. The Stanford system obtained the highest score at the CoNLL-2011 shared task on English coreference resolution.

For this step, we selected all the sieves from the Stanford system with the exception of the pronoun resolution sieve. All the remaining sieves (listed in Table 1) have high precision because they employ linguistic heuristics with little ambiguity, e.g.,

High-precision sieves
Discourse processing sieve
Exact string match sieve
Relaxed string match sieve
Precise constructs sieve (e.g., appositives)
Strict head match sieves
Proper head noun match sieve
Relaxed head matching sieve

Table 1: Deterministic sieves in step 6 of Algorithm 1.

one sieve clusters together two entity mentions only when they have the same head word. Note that all these heuristics were designed for within-document coreference. They work well in our context because we apply them in individual document clusters, where the one-sense-per-discourse principle still holds (Yarowsky, 1995).

Importantly, these sieves do not address verbal mentions. That is, all verbal mentions are still in singleton clusters after this step. Furthermore, none of these sieves use features that facilitate the joint resolution of nominal and verbal mentions (e.g., features from semantic role frames). All these limitations are addressed next.

### 3.4 Iterative Entity/Event Resolution

In this stage (steps 7 – 9 in Algorithm 1), we construct entity and event clusters using a cautious or “baby steps” approach. We use a single linear regressor ( $\Theta$ ) to model cluster merge operations between both verbal and nominal clusters. Intuitively, the linear regressor models the quality of the merge operation, i.e., a score larger than 0.5 indicates that more than half of the mention pairs introduced by this merge are correct. We discuss the training procedure that yields this scoring function in Section 4. In each iteration, we perform the merge operation that has the highest score. Once two clusters are merged (step 9) we regenerate all the mention features to reflect the current clusters. We stop when no merging operation with an overall benefit is found.

This iterative procedure is the core of our joint coreference resolution approach. This algorithm transparently merges both entity and event mentions and, importantly, allows information to flow between clusters of both types as merge operations take place. For example, assume that during iteration  $i$  we merge the two *hanged* verbs in the first

example in Section 1 (because they have the same lemma). Because of this merge, in iteration  $i + 1$  the nominal mentions *Lo Presti* and *One of the key suspected Mafia bosses* have the same semantic role for verbs assigned to the same cluster. This is a strong hint that these two nominal mentions belong to the same cluster. Indeed, the feature that models this structure received one of the highest weights in our linear regression model (see Section 7).

### 3.5 Pronoun Sieve

Our approach concludes with the pronominal coreference resolution sieve from the Stanford system. This sieve is necessary because our current resolution algorithm ignores mention ordering and distance (i.e., in step 7 we compare all clusters regardless of where their mentions appear in the text). As previous work has proved, the structure of the text is crucial for pronominal coreference (Hobbs, 1978). For this reason, we handle pronouns outside of the main algorithm block.

## 4 Training the Cluster Merging Model

Two observations drove our choice of model and training algorithm. First, modeling the merge operation as a classification task is not ideal, because only a few of the resulting clusters are entirely correct or incorrect. In practice, most of the clusters will contain some mention pairs that are correct and some that are not. Second, generating training data for the merging model is not trivial: a brute force approach that looks at all the possible combinations is exponential in the number of mentions. This is both impractical and unnecessary, as some of these combinations are unlikely to be seen in practice.

We address these observations with Algorithm 2. The algorithm uses gold coreference labels to train a linear regressor that models the quality of the clusters produced by merge operations. We define the quality score  $q$  of a new cluster as the percentage of new mention pairs (i.e., not present in either one of the clusters to be merged) that are correct:

$$q = \frac{links_{correct}}{links_{correct} + links_{incorrect}} \quad (1)$$

where  $links_{(in)correct}$  is the number of newly introduced (in)correct pairwise mention links when two clusters are merged.

---

**Algorithm 2:** Training Procedure

---

```
input : set of documents  $\mathcal{D}$ 
input : correct mention clusters  $\mathcal{G}$ 
1  $\mathcal{C} = \text{clusterDocuments}(\mathcal{D})$ 
  // linear regression coreference model:
2  $\Theta = \text{assignInitialWeights}(\mathcal{C}, \mathcal{G})$ 
  // repeat for T epochs:
3 for  $t = 1$  to  $T$  do
  // training data for linear regressor:
4  $\Gamma = \{\}$ 
5 foreach document cluster  $c$  in  $\mathcal{C}$  do
6    $\mathcal{M} = \text{extractMentions}(c)$ 
7    $\mathcal{E} = \text{buildSingletonClusters}(\mathcal{M})$ 
8    $\mathcal{E} = \text{applyHighPrecisionSieves}(\mathcal{E})$ 
  // gather training examples
  // as clusters are built:
9   while  $\exists e_1, e_2 \in \mathcal{E}$  s.t.  $\text{sco}(e_1, e_2, \Theta) > 0.5$  do
10    forall  $e'_1, e'_2 \in \mathcal{E}$  do
11       $q = \text{qualityOfMerge}(e'_1, e'_2, \mathcal{G})$ 
12       $\Gamma = \text{append}(e'_1, e'_2, q, \Gamma)$ 
13       $(e_1, e_2) = \arg \max_{e_1, e_2 \in \mathcal{E}} \text{sco}(e_1, e_2, \Theta)$ 
14       $\mathcal{E} = \text{merge}(e_1, e_2, \mathcal{E})$ 
  // train using data from last epoch:
15  $\Theta' = \text{trainLinearRegressor}(\Gamma)$ 
  // interpolate with older model:
16  $\Theta = \lambda\Theta + (1 - \lambda)\Theta'$ 
output :  $\Theta$ 
```

---

We address the potential explosion in training data size by considering only merge operations that are likely to be inspected by the algorithm as it runs. To achieve this, Algorithm 2 repeatedly runs the actual clustering algorithm (as given by the current model  $\Theta$ ) over the training dataset (steps 5 – 14).<sup>2</sup> When the algorithm iteratively constructs its clusters (steps 9 – 14), we generate training data from all possible cluster pairs available during a particular iteration (steps 10 – 12). For each pair, we compute its score using Equation 1 (step 11) and add it to the training corpus  $\Gamma$  (step 12). Note that this avoids inspecting many of the possible cluster combinations: once a cluster is built (e.g., during the previous iterations or by the deterministic sieves in step 8), we do not generate training data from its members, but rather treat it as an atomic unit. On the other hand, our approach generates more training data than on-line learning, which trains using only the actual decisions taken during inference in each iteration (i.e.,

---

<sup>2</sup>We skip the pronoun sieve here because it does not affect the decisions taken during the iterative resolution steps.

the pair  $(e_1, e_2)$  in step 13).

After each epoch we have a new training corpus  $\Gamma$ , which we use to train the new linear regression model  $\Theta'$  (step 15), which is then interpolated with the old one (step 16).

Our training procedure is similar in spirit to transformation based learning (TBL) (Brill, 1995). Similarly to TBL, our approach repeatedly applies the model over the training data and attempts to minimize the error rate of the current model. However, while TBL learns rules that directly minimize the current error rate, our approach achieves this indirectly, by incorporating the reduction in error rate in the score of the generated datums. This allows us to fit a linear regression to this task, which, as discussed before, is a better model for this task.

Just like any hill-climbing algorithm, our approach has the risk of converging to a local maximum. To mitigate this risk, we do not initialize our model  $\Theta$  with random weights, but rather use hints from the deterministic sieves. This procedure (listed in step 2) runs the high-precision sieves introduced in Section 3.3 and, just like the data generation loop in Algorithm 2, creates training examples from the clusters available after every merge operation. Since these deterministic models address only nominal clusters, at the end we generate training data for events by inspecting all the pairs of singleton verbal clusters. Using this data, we train the initial linear regression model.

We trained our model using L2 regularized linear regression with a regularization coefficient of 1.0. We did not tune the regularization coefficient. We ran the training algorithm for 10 epochs, although we observed minimal changes after three epochs. We tuned the interpolation weight ( $\lambda$ ) to a value of 0.7 using our development corpus.

## 5 Features

We list in Table 2 the features used by the linear regression model. As the table indicates, our feature set relies heavily on semantic roles, which were extracted using the SwiRL semantic role labeling (SRL) system (Surdeanu et al., 2007).<sup>3</sup> Because SwiRL addresses only verbal predicates, we extended it to handle nominal predicates. In this

---

<sup>3</sup><http://www.surdeanu.name/mihai/swirl/>

Feature Name	Applies to Entities (E) or Events (V)	Description and Example
Entity Heads	E	Cosine similarity of the head-word vectors of two clusters. The head-word vector stores the head words of all mentions in a cluster and their frequencies. For example, the vector for the three-mention cluster $\{\textit{Barack Obama, President Obama, US president}\}$ , is $\{\textit{Obama:2, president:1}\}$ .
Event Lemmas	V	Cosine similarity of the lemma vectors of two clusters. For example, the lemma vector for the cluster $\{\textit{murdered, murders, hitting}\}$ is $\{\textit{murder:2, hit:1}\}$ .
Links between Synonyms	E, V	The percentage of newly-introduced mention links after the merge that are WordNet synonyms (Fellbaum, 1998). For example, when merging the following two clusters, $\{\textit{hit, strike}\}$ and $\{\textit{strike, join, say}\}$ , two out of the six new links are between words that belong to the same WordNet synset: $(\textit{hit} - \textit{strike})$ and $(\textit{strike} - \textit{strike})$ .
Number of Coreferent Arguments or Predicates	E, V	The total number of shared arguments and predicates between mentions in the two clusters. We use the cluster IDs of the corresponding arguments/predicates to check for identity. For example, when comparing the event clusters $\{\textit{bought}\}$ and $\{\textit{acquired}\}$ , extracted from the sentences $[\textit{AMD}]_{\textit{Arg0}} \textit{bought} [\textit{ATI}]_{\textit{Arg1}}$ and $[\textit{AMD}]_{\textit{Arg0}} \textit{acquired} [\textit{ATI}]_{\textit{Arg1}}$ , the value of this feature is 2 because the two mentions share one $\textit{Arg0}$ and one $\textit{Arg1}$ argument (assuming that the clusters $\{\textit{AMD, AMD}\}$ and $\{\textit{ATI, ATI}\}$ were previously created). For entity clusters, this feature counts the number of coreferent predicates. In addition to PropBank-style roles, for event mentions we also include the closest left and right entity mentions in order to capture any arguments missed by the SRL system.
Coreferent Arguments in a Specific Role?	E, V	Indicator feature set to 1 if the two clusters have at least one coreferent argument in a given role. We generate one variant of this feature for each argument label, e.g., $\textit{Arg0}$ , $\textit{Arg1}$ , etc. For example, the value of this feature for $\textit{Arg0}$ for the clusters $\{\textit{bought}\}$ and $\{\textit{acquired}\}$ in the above example is 1.
Coreferent Predicate in a Specific Role?	E	Indicator feature set to 1 if the two clusters have at least one coreferent predicate for a given role. For example, for the clusters $\{\textit{the man}\}$ and $\{\textit{the person}\}$ , extracted from the sentences $\textit{helped} [\textit{the man}]_{\textit{Arg1}}$ and $\textit{helped} [\textit{the person}]_{\textit{Arg1}}$ , the value of this feature is 1 if the two $\textit{helped}$ verbs were previously clustered together.
2nd Order Similarity of Mention Words	E	Cosine similarity of vectors containing words that are distributionally similar to words in the cluster mentions. We built these vectors by extracting the top-ten most-similar words in Dekang Lin’s similarity thesaurus (Lin, 1998) for all the nouns/adjectives/verbs in a cluster. For example, for the singleton cluster $\{\textit{a new home}\}$ , we construct this vector by expanding $\textit{new}$ and $\textit{home}$ to: $\{\textit{new:1, original:1, old:1, existing:1, current:1, unique:1, modern:1, different:1, special:1, major:1, small:1, home:1, house:1, apartment:1, building:1, hotel:1, residence:1, office:1, mansion:1, school:1, restaurant:1, hospital:1}\}$ .
Number; Animacy; Gender; NE Label	E	Cosine similarity of number, gender, animacy, and NE label vectors. For example, the number and gender vectors for the two-mention cluster $\{\textit{systems, a pen}\}$ are $\textit{Number} = \{\textit{singular:1, plural:1}\}$ , $\textit{Gender} = \{\textit{neutral:2}\}$ .

Table 2: List of features used when comparing two clusters. If any of the two clusters contains a verbal mention we consider the merge an operation between event (V) clusters; otherwise it is a merge between entity (E) clusters. We append to all entity features the suffix `Proper` or `Common` based on the type of the head word of the first mention in each of the two clusters. We use the suffix `Proper` only if both head words are proper nouns.

paper we used a single heuristic: the possessor of a nominal event’s predicate is marked as its  $\textit{Arg0}$ , e.g., *Logan* is the  $\textit{Arg0}$  to *run* in *Logan’s run*.<sup>4</sup>

<sup>4</sup>A principled solution to this problem is to use an SRL system for nominal predicates trained using NomBank (Meyers et al., 2004). We will address this in future work.

We extracted named entity labels using the named entity recognizer from the Stanford CoreNLP suite.

## 6 Evaluation

### 6.1 Corpus

The training and test data sets were derived from the EventCorefBank (ECB) corpus<sup>5</sup> created by Bejan and Harabagiu (2010) to study event coreference since standard corpora such as OntoNotes (Pradhan et al., 2007) contain a small number of annotated event clusters. The ECB corpus consists of 482 documents from Google News clustered into 43 topics, where a topic is described as a seminal event. The reason for including comparable documents was to increase the number of cross-document coreference relations. Bejan and Harabagiu (2010) only annotated a selection of events.

For the purpose of our study, we extended the original corpus in two directions: (i) fully annotated sentences, and (ii) entity coreference relations. In addition, we removed relations other than coreference (e.g., subevent, purpose, related, etc.) that had been originally annotated. We revised and completed the original annotation by annotating every entity and event in the sentences that were (partially) annotated. The annotation was performed by four experts, using the Callisto annotation tool.<sup>6</sup> The annotation guidelines and the generated corpus are available here.<sup>7</sup>

Our annotation of the ECB corpus followed the OntoNotes (Pradhan et al., 2007) standard for coreference annotation, with a few extensions to handle events. For nouns, we annotated full NPs (with all modifiers), excluding appositive phrases and nominal predicates. Only premodifiers that were proper nouns or possessive phrases were annotated. For events, we annotated the semantic head of the verb phrase. We extended the OntoNotes guidelines by also annotating singletons (but we do not score them; see below), and by including all events mentions (not only those mentioned at least once with an NP). This required us to be specific with respect to:

<sup>5</sup><http://faculty.washington.edu/bejan/data/ECB1.0.tar.gz>

<sup>6</sup><http://callisto.mit.edu>

<sup>7</sup><http://nlp.stanford.edu/pubs/jcoref-corpus.zip>

	Training	Dev	Test	Total
# Topics	12	3	28	43
# Documents	112	39	331	482
# Entities	459	46	563	1068
# Entity Mentions	1723	259	3465	5447
# Events	300	30	444	774
# Event Mentions	751	140	1642	2533

Table 3: Corpus statistics.

⟨ENTITY COREFID="26"⟩ A publicist ⟨/ENTITY⟩ ⟨EVENT COREFID="4"⟩ says ⟨/EVENT⟩ ⟨ENTITY COREFID="23"⟩ Tara Reid ⟨/ENTITY⟩ has ⟨EVENT COREFID="3"⟩ checked ⟨/EVENT⟩ ⟨ENTITY COREFID="23"⟩ herself ⟨/ENTITY⟩ ⟨EVENT COREFID="3\*"⟩ into ⟨/EVENT⟩ ⟨ENTITY COREFID="28"⟩ rehab ⟨/ENTITY⟩.

Figure 1: Annotation example.

**Light verbs** Verbs such as *give* and *make* followed by a noun (e.g., *make an offer*) were not annotated, but the noun was.

**Phrasal verbs** We annotated the verb together with the preposition or adverb (e.g., *check in*).

**Idioms** They were annotated with all their elements (e.g., *booze it up*).

The first topic was annotated by all four annotators as burn-in. Afterwards, annotation disagreements were resolved between all annotators and the next three topics were annotated again by all four annotators to measure agreement. Following Passonneau (2004), we computed an inter-annotator agreement of  $\alpha = 0.55$  (Krippendorff, 2004) on these three topics, indicating moderate agreement among the annotators. Given the complexity of the task, we consider this to be a good score. For example, the average of the CoNLL F1 between any two annotators is 73.58, which is much higher than the system scores reported in the literature.

After annotating the four topics, disagreements were resolved again and all the documents in the four topics were corrected to match the consensus. The rest of the corpus was split between the four annotators, and each document was annotated by a single annotator. Figure 1 shows an example. Table 3 shows the corpus statistics, including the training, development (dev) and test set splits. The dev topics were used for tuning the interpolation parameter  $\lambda$  from Section 4.

Table 4: Performance of the two baselines and our model. We report scores for entity clusters, event clusters and the complete task using five metrics.

## 6.2 Evaluation

We use five coreference evaluation metrics widely used in the literature:

**MUC** (Vilain et al., 1995) Link-based metric which measures how many predicted and gold clusters need to be merged to cover the gold and predicted clusters, respectively.

**B<sup>3</sup>** (Bagga and Baldwin, 1998) Mention-based metric which measures the proportion of overlap between predicted and gold clusters for a given mention.

**CEAF** (Luo, 2005) Entity-based metric that, unlike  $B^3$ , enforces a one-to-one alignment between gold and predicted clusters. We employ the entity-based version of CEAF.

**BLANC** (Recasens and Hovy, 2011) Metric based on the Rand index (Rand, 1971) that considers both coreference and non-coreference links to address the imbalance between singleton and coreferent mentions.

**CoNLL F1** Average of MUC,  $B^3$ , and CEAF- $\phi_4$ . This was the official metric in the CoNLL-2011 shared task (Pradhan et al., 2011).

We followed the CoNLL-2011 evaluation methodology, that is, we removed all singleton clusters, and apposition/copular relations before scoring.

We evaluated the systems on three different settings: only on entity clusters, only on event clusters, and on the complete task, i.e., both entities and events. Note that the gold corpus separates clusters into entity and event clusters (see Table 3), but our

system does not make this distinction at runtime. In order to compute the entity-only and event-only scores in Table 4, we implemented the following procedure: (a) when scoring entity clusters, we removed all mentions that were found to be coreferent with at least one gold event mention and not coreferent with any gold entity mentions; and (b) we performed the opposite action when scoring event clusters. This procedure is necessary because our mention identification component is not perfect, i.e., it generates mentions that do not exist in the gold annotation. Furthermore, this procedure is conservative with respect to the clustering errors of our system, e.g., all spurious mentions that our system includes in a cluster with a gold entity mention are considered for the entity score, regardless of their gold type (event or entity).

## 6.3 Results

Table 4 compares the performance of our system against two strong baselines that resolve entities and events separately. Baseline 1 uses a modified Stanford coreference resolution system after our document clustering and mention identification steps. Because the original Stanford system implements only entity coreference, we extended it with an extra sieve that implements lemma matching for events. This additional sieve merges two verbal clusters (i.e., clusters that contain at least one verbal mention) or a verbal and a nominal cluster when at least two lemmas of mention head words are the same between clusters, e.g., *helped* and *the help*.

The second baseline adds two more sieves to Baseline 1. Both these sieves model entity and event

contextual information using semantic roles. The first sieve merges two nominal clusters when two mentions in the respective clusters have the same head words and two mentions (possibly with different heads) modify with the same role label two predicates that have the same lemma. For example, this sieve merges the clusters  $\{Obama, the\ president\}$  (seen in the text  $[Obama]_{Arg0}$  attended and  $[the\ president]_{Arg1}$  was elected) and  $\{Obama\}$  (seen in the text  $[Obama]_{Arg1}$  was elected), because they share a mention with the same head word (*Obama*) and two mentions modify with the same role (*Arg1*) predicates with the same lemma (*elect*). The second sieve implements the complementary action for event clusters. That is, it merges two verbal clusters when at least two mentions have the same lemma and at least two mentions have semantic arguments with the same role label and the same lemma.

## 7 Discussion

The first block in Table 4 indicates that lemma matching is a strong baseline for event resolution. Most of the event scores for Baseline 1 are actually higher than the corresponding entity scores, which were obtained using the highest ranked system at the CoNLL-2011 shared task (Lee et al., 2011). Adding contextual information using semantic roles (Baseline 2) helps both entities and events. The CoNLL F1 for Baseline 2 increases almost 3 points for entities and 1 point for events. This demonstrates that local syntactico-semantic context is important for coreference resolution even in a cross-document setting and that the current state-of-the-art in SRL can model this context accurately.

The best scores (almost unanimously) are obtained by the model proposed in this paper, which scores 3.4 CoNLL F1 points higher than Baseline 2 for entities, and 2.6 points higher for events. For the complete task, our approach scores 3.3 CoNLL F1 points higher than Baseline 2, and 6.1 points higher than Baseline 1. This demonstrates that a holistic approach to coreference resolution improves the resolution of both entities and events more than models that address aspects of the task separately. To further understand our experiments, we listed the top five entity/event features with the highest weights in our model in Table 5. The table indicates that six out of the ten features serve the purpose of passing infor-

Entity Feature	Weight
Entity Heads – Proper	1.10
Coreferent Predicate for <i>ArgM-LOC</i> – Common	0.45
Entity Heads – Common	0.36
Coreferent Predicate for <i>Arg0</i> – Proper	0.29
Coreferent Predicate for <i>Arg2</i> – Common	0.28

Event Feature	Weight
Event Lemmas	0.45
Coreferent Argument for <i>Arg1</i>	0.19
Links between Synonym	0.16
Coreferent Argument for <i>Arg2</i>	0.13
Number of Coreferent Arguments	0.07

Table 5: Top five features with the highest weights.

mation between entity and event clusters. For example, the “Coreferent Argument for *Arg1*” feature is triggered when two event clusters have *Arg1* arguments that already belong to the same entity cluster. This allows information from previous entity coreference operations to impact future merges of event clusters. This is the crux of our iterative approach to joint coreference resolution.

Finally, we performed an error analysis by manually evaluating 100 errors. We distinguished nine major types of errors. Their ratios together with a description and an example are given in Table 6.

This work demonstrates that an approach that jointly models entities and events is better for cross-document coreference resolution. However, our model can be improved. For example, document clustering and coreference resolution can be solved jointly, which we expect would improve both tasks. Furthermore, our iterative coreference resolution procedure (Algorithm 1) could be modified to account for mention ordering and distance, which would allow us to include pronominal resolution in our joint model, rather than addressing it with a separate deterministic sieve.

## 8 Conclusion

We have presented a holistic model for cross-document coreference resolution that jointly solves references to events and entities by handling both nominal and verbal mentions. Our joint resolution algorithm allows event coreference to help improve entity coreference, and vice versa. In addition, our iterative procedure, based on a linear regressor that models the quality of cluster merges, allows each

Error Type (Ratio)	Description
	Example
Pronoun resolution (36%)	The pronoun is incorrectly resolved by the pronominal sieve of the Stanford deterministic entity system. These errors include (only a small number of) event pronouns. <u>He</u> said <i>Timmons</i> aimed and missed <b>his</b> target.
Semantics beyond role frames (20%)	The semantics of the coreference relation cannot be captured by role frames or WordNet. Israeli forces on Tuesday killed <i>at least 40 people</i> ... The Israeli army said the UN school in the Jabaliya refugee camp was hit ... and that <b>the dead</b> included a number of Hamas militants.
Arguments of nominal events (17%)	The arguments of two nominal events are not detected and thus not coreferred. The attack on <i>the school</i> has caused widespread shock across Israel ... while Israeli forces on Tuesday killed at least 40 people during an attack on a <b>United Nations-run school in Gaza</b> .
Cascaded errors (7%)	Entities or events are not coreferred due to errors in a previous merge iteration in the same semantic frame. In the example below, we failed to link the two <i>die</i> verbs, which leads to the listed entity error. An Australian climber who survived two nights stuck on Mount Cook after seeing <i>his brother die</i> ... <b>Dr Mark Vinar, 43</b> , is presumed dead ...
Initial high-precision sieves (6%)	An error made by the initial high-precision entity resolution sieves is propagated to our model. <i>Timmons</i> told police he fired when he thought he saw someone in the other group reach for a <u>gun</u> ... 15-year-old <i>Timmons</i> was at the scene of the shooting and had a <b>gun</b> .
Phrasal verbs (6%)	The meaning of a phrasal verb is not captured. A relative unknown will <i>take over</i> the title role of Doctor Who ... But <b>the casting of Smith</b> is a stroke of genius.
Linear regression (4%)	Recall error made by the regression model when the features are otherwise correct. The Interior Department on Thursday <i>issued</i> “revised” regulations ... Interior Secretary Dirk Kempthorne <b>announced</b> major changes ...
Mention detection (3%)	The mention detection module detects a spurious mention. Police have arrested a man ... in the parking lot crosswalk at <u>Sam’s Club</u> in Bloomington.
SRL (1%)	The SRL system fails to label the semantic role. In this example, <i>jail</i> is detected as the ArgM-MNR of <i>hanged</i> instead of ArgM-LOC. A Mafia boss in Palermo <i>hanged</i> himself in <b>jail</b> .

Table 6: Error analysis. Mentions to be resolved are in **bold face**, correct antecedents are in *italics*, and our system’s predictions are underlined.

merging state to benefit from the previous merged entity and event mentions. This approach allows us to start with a set of high-precision coreference relations and gradually add new ones to increase recall.

The experimental evaluation shows that our coreference algorithm gives markedly better F1 for both entities and events, outperforming two strong baselines that handle entities and events separately, measured by all the standard measures: MUC,  $B^3$ , CEAF- $\phi_4$ , BLANC and the official CoNLL-2011 metric. This is noteworthy since each measure has been shown to place primary emphasis in evaluating a different aspect of the coreference resolution task.

Our system is tailored for cross-document coreference resolution on a corpus that contains news articles that repeatedly report on a smaller number of topics. This makes it particularly suitable for real-

world applications such as multi-document summarization and cross-document information extraction. We also release our labeled corpus to facilitate extensions and comparisons to our work.

# Joint Chinese Word Segmentation, POS Tagging and Parsing

Xian Qian      Yang Liu

qx, yangl@hlt.utdallas.edu

## Abstract

In this paper, we propose a novel decoding algorithm for discriminative joint Chinese word segmentation, part-of-speech (POS) tagging, and parsing. Previous work often used a pipeline method – Chinese word segmentation followed by POS tagging and parsing, which suffers from error propagation and is unable to leverage information in later modules for earlier components. In our approach, we train the three individual models separately during training, and incorporate them together in a unified framework during decoding. We extend the CYK parsing algorithm so that it can deal with word segmentation and POS tagging features. As far as we know, this is the first work on joint Chinese word segmentation, POS tagging and parsing. Our experimental results on Chinese Tree Bank 5 corpus show that our approach outperforms the state-of-the-art pipeline system.

## 1 Introduction

For Asian languages such as Japanese and Chinese that do not contain explicitly marked word boundaries, word segmentation is an important first step for many subsequent language processing tasks, such as POS tagging, parsing, semantic role labeling, and various applications. Previous studies for POS tagging and syntax parsing on these languages sometimes assume that gold standard word segmentation information is provided, which is not the real scenario. In a fully automatic system, a pipeline approach is often adopted, where raw sentences are

first segmented into word sequences, then POS tagging and parsing are performed. This kind of approach suffers from error propagation. For example, word segmentation errors will result in tagging and parsing errors. Additionally, early modules cannot use information from subsequent modules. Intuitively a joint model that performs the three tasks together should help the system make the best decisions.

In this paper, we propose a unified model for joint Chinese word segmentation, POS tagging, and parsing. Three sub-models are independently trained using the state-of-the-art methods. We do not use the joint inference algorithm for training because of the high complexity caused by the large amount of parameters. We use linear chain Conditional Random Fields (CRFs) (Lafferty et al., 2001) to train the word segmentation model and POS tagging model, and averaged perceptron (Collins, 2002) to learn the parsing model. During decoding, parameters of each sub-model are scaled to represent its importance in the joint model. Our decoding algorithm is an extension of CYK parsing. Initially, weights of all possible words together with their POS tags are calculated. When searching the parse tree, the word and POS tagging features are dynamically generated and the transition information of POS tagging is considered in the span merge operation.

Experiments are conducted on Chinese Tree Bank (CTB) 5 dataset, which is widely used for Chinese word segmentation, POS tagging and parsing. We compare our proposed joint model with the pipeline system, both built using the state-of-the-art sub-models. We also propose an evaluation metric to

calculate the bracket scores for parsing in the face of word segmentation errors. Our experimental results show that the joint model significantly outperforms the pipeline method based on the state-of-the-art sub-models.

## 2 Related Work

There is very limited previous work on joint Chinese word segmentation, POS tagging, and parsing. Previous joint models mainly focus on word segmentation and POS tagging task, such as the virtual nodes method (Qian et al., 2010), cascaded linear model (Jiang et al., 2008a), perceptron (Zhang and Clark, 2008), sub-word based stacked learning (Sun, 2011), reranking (Jiang et al., 2008b). These joint models showed about 0.2 – 1% F-score improvement over the pipeline method. Recently, joint tagging and dependency parsing has been studied as well (Li et al., 2011; Lee et al., 2011).

Previous research has showed that word segmentation has a great impact on parsing accuracy in the pipeline method (Harper and Huang, 2009). In (Jiang et al., 2009), additional data was used to improve Chinese word segmentation, which resulted in significant improvement on the parsing task using the pipeline framework. Joint segmentation and parsing was also investigated for Arabic (Green and Manning, 2010). A study that is closely related to ours is (Goldberg and Tsarfaty, 2008), where a single generative model was proposed for joint morphological segmentation and syntactic parsing for Hebrew. Different from that work, we use a discriminative model, which benefits from large amounts of features and is easier to deal with unknown words. Another main difference is that, besides segmentation and parsing, we also incorporate the POS tagging model into the CYK parsing framework.

## 3 Methods

For a given Chinese sentence, our task is to generate the word sequence, its POS tag sequence, and the parse tree (constituent parsing). A joint model is expected to make more optimal decisions than a pipeline approach; however, such a model will be too complex and it is difficult to estimate model parameters. Therefore we do not perform joint inference for training. Instead, we develop three individ-

ual models independently during training and perform joint decoding using them. In this section, we first describe the three sub-models and then the joint decoding algorithm.

### 3.1 Word Segmentation Model

Methods for Chinese word segmentation can be broadly categorized into character based and word based models. Previous studies showed that character-based models are more effective to detect out-of-vocabulary words while word-based models are more accurate to predict in-vocabulary words (Zhang et al., 2006). Here, we use order-0 semi-Markov model (Sarawagi and Cohen, 2004) to take advantages of both approaches.

More specifically, given a sentence  $\mathbf{x} = c_1, c_2, \dots, c_l$  (where  $c_i$  is the  $i^{th}$  Chinese character,  $l$  is the sentence length), the character-based model assigns each character with a word boundary tag. Here we use the *BCDIES* tag set, which achieved the best official performance (Zhao and Kit, 2008): *B*, *C*, *D*, *E* denote the first, second, third, and last character of a multi-character word respectively, *I* denotes the other characters, and *S* denotes the single character word. We use the same character-based feature templates as in the best official system, shown in Table 1 (1.1-1.3), including character unigram and bigram features, and transition features. Linear chain CRFs are used for training.

Feature templates in the word-based model are shown in Table 1 (1.4-1.6), including word features, sub-word features, and character bigrams within words. The word feature is activated if a predicted word  $w$  is in the vocabulary (i.e., appears in training data).  $\text{Subword}(w)$  is the longest in-vocabulary word within  $w$ . To use word features, we adopt a K-best reranking approach. The top K candidate segmentation results for each training sample are generated using the character-based model, and the gold segmentation is added if it is not in the candidate set. We use the Maximum Entropy (ME) model to learn the weights of word features such that the probability of the gold candidate is maximal.

A problem arises when combining the two models and using it in joint segmentation and parsing, since the linear chain used in the character-based model is incompatible with CYK parsing model and the word-based model due to the transition informa-

Character Level Feature Templates	
(1.1)	$c_{i-2}y_i, c_{i-1}y_i, c_iy_i, c_{i+1}y_i, c_{i+2}y_i$
(1.2)	$c_{i-1}c_iy_i, c_i c_{i+1}y_i, c_{i-1}c_{i+1}y_i$
(1.3)	$y_{i-1}y_i$
Word Level Feature Templates	
(1.4)	word $w$
(1.5)	subword( $w$ )
(1.6)	character bigrams within $w$

Table 1: Feature templates for word segmentation.  $c_i$  is the  $i^{th}$  character in the sentence,  $y_i$  is its label,  $w$  is a predicted word.

tion. Thus, we slightly modify the linear chain CRFs by fixing the weights of transition features during training and testing. That is, weights of impossible transition features (e.g.,  $B \rightarrow B$ ) are set to  $-\infty$ , and weights of the other transition features (e.g.,  $E \rightarrow B$ ) are set to 0. In this way, the transition feature could be neglected in testing for two reasons. First, all illegal label assignments are prohibited in prediction, since their weights are  $-\infty$ ; second, because weights of legal transition features are 0, they do not affect the prediction at all. In the following, transition features are excluded.

Now we can use order-0 semi Markov model as the hybrid model. We define the score of a word as the sum of the weights of all the features within the word. Formally, the score of a multi-character word  $w = c_i, \dots, c_j$  is defined as:

$$\begin{aligned}
score_{seg}(\mathbf{x}, i, j) &= \theta_{CRF} \cdot \mathbf{f}_{CRF}(\mathbf{x}, y_i = B) + \dots \\
&+ \theta_{CRF} \cdot \mathbf{f}_{CRF}(\mathbf{x}, y_j = E) + \theta_{ME} \cdot \mathbf{f}_{ME}(\mathbf{x}, i, j) \\
&\equiv \theta_{seg} \mathbf{f}_{seg}(\mathbf{x}, i, j)
\end{aligned} \tag{1}$$

where  $\mathbf{f}_{CRF}$  and  $\mathbf{f}_{ME}$  are the feature vectors in the character and word based models respectively, and  $\theta_{CRF}, \theta_{ME}$  are their corresponding weight vectors. For simplicity, we denote  $\theta_{seg} = \theta_{CRF \oplus ME}$ ,  $\mathbf{f}_{seg} = \mathbf{f}_{CRF \oplus ME}$ , where  $\theta_{CRF \oplus ME}$  means the concatenation of  $\theta_{CRF}$  and  $\theta_{ME}$ . Scores for single character words are defined similarly. These word scores will be used in the joint segmentation and parsing task Section 3.4.

### 3.2 POS Tagging Model

Though syntax parsing model can directly predict the POS tag itself, we choose not to use this, but use an independent POS tagger for two reasons. First,

there is a large amount of data with labeled POS tags but no syntax annotations, such as the People’s Daily corpus and SIGHAN bakeoff corpora (Jin and Chen, 2008). Such data can only be used to train POS taggers, but not for training the parsing model. Often using a larger training set will result in a better POS tagger. Second, the state-of-the-art POS tagging systems are often trained by sequence labeling models, not parsing models.

(2.1)	$w_{i-2}t_i, w_{i-1}t_i, w_it_i, w_{i+1}t_i, w_{i+2}t_i$
(2.2)	$w_{i-2}w_{i-1}t_i, w_{i-1}w_it_i, w_iw_{i+1}t_i, w_{i+1}w_{i+2}t_i, w_{i-1}w_{i+1}t_i$
(2.3)	$c_1(w_i)t_i, c_2(w_i)t_i, c_3(w_i)t_i, c_{-2}(w_i)t_i, c_{-1}(w_i)t_i$
(2.4)	$c_1(w_i)c_2(w_i)t_i, c_{-2}(w_i)c_{-1}(w_i)t_i$
(2.5)	$l(w_i)t_i$
(2.5)	$t_{i-1}t_i$

Table 2: Feature templates for POS tagging.  $w_i$  is the  $i^{th}$  word in the sentence,  $t_i$  is its POS tag. For a word  $w$ ,  $c_j(w)$  is its  $j^{th}$  character,  $c_{-j}(w)$  is the last  $j^{th}$  character, and  $l(w)$  is its length.

The POS tagging problem is to assign a POS tag  $t \in \mathcal{T}$  to each word in a sentence. We also use linear chain CRFs for POS tagging. Feature templates shown in Table 2 are the same as those in (Qian et al., 2010), which have been shown effective on CTB corpus. Three feature sets are considered: (i) word level features, including surrounding word unigrams, bigrams, and word length; (ii) character level features, such as the first and last characters in the words; (iii) transition features.

### 3.3 Parsing Model

We choose discriminative models for parsing since it is easy to handle unknown words by simply adding character level features. Online structured learning algorithms were demonstrated to be effective for training, such as stochastic optimization (Finkel et al., 2008). In this study, we use averaged perceptron algorithm for parameter estimation since it is easier to implement and has competitive performance.

A Context Free Grammar (CFG) consists of (i) a set of terminals; (ii) a set of nonterminals  $\{N^k\}$ ; (iii) a designated start symbol ROOT; and (iv) a set of rules,  $\{r = N^i \rightarrow \zeta^j\}$ , where  $\zeta^j$  is a sequence of terminals and nonterminals. In the parsing task, ter-

Figure 1: Parse tree binarization

minals are the words, and nonterminals are the POS tags and phrase types. In this paper, nonterminal is named **state** for short. A parse tree  $T$  of sentence  $\mathbf{x}$  can be factorized into several one-level subtrees, each corresponding to a rule  $r$ .

In practice, binarization of rules is necessary to obtain cubic parsing time. That is, the right hand side of each rule should contain no more than 2 s-tates. We used right branching binarization, as illustrated in Figure 1. We did not use parent annotation, since we found it degraded the performance in our experiments (shown in Section 4). We used the same preprocessing step as (Harper and Huang, 2009), collapsing all the allowed nonterminal-yield unary chains to single unary rules. Therefore, all spans in the binarized trees contain no more than one unary rules. To facilitate decoding, we unify the form of spans so that each span contains exactly one unary rule. This is done by adding identity unary rules ( $N \rightarrow N$ ) to spans that have no unary rule. These identity unary rules will be removed in evaluation. Hence, there are two states of a span: the top state  $\bar{N}$  and the bottom state  $\underline{N}$  that correspond to the left and right hand of the unary rule  $r^{unary} = \bar{N} \rightarrow \underline{N}$  respectively, as shown in Figure 2.

Table 3 lists the feature templates we use for parsing. There are 4 feature sets: (i) bottom state features  $\mathbf{f}_{bottom}(i, j, \mathbf{x}, \underline{N}_{i,j})$ , which depend on the bot-

Figure 2: Unary rule normalization. Nonterminal-yield unary chains are collapsed to single unary rules. Identity unary rules are added to spans that have no unary rule.

tom states; (ii) top state features  $\mathbf{f}_{top}(i, j, \mathbf{x}, \bar{N}_{i,j})$ ; (iii) unary rule features  $\mathbf{f}_{unary}(i, j, \mathbf{x}, r_{i,j}^{unary})$ , which extract the transition information from bottom s-tates to top states; (iv) binary rule features  $\mathbf{f}_{binary}(i, j, k, \mathbf{x}, r_{i,j,k}^{binary} = \underline{N}_{i,j} \rightarrow \bar{N}_{i,k-1} + \bar{N}_{k,r})$ , where  $\bar{N}_{i,k-1}, \bar{N}_{k,r}$  are the top states of the left and right children.

The score function for a sentence  $\mathbf{x}$  with parse tree  $T$  is defined as:

$$\begin{aligned}
 score(\mathbf{x}, T) = & \sum_{\underline{N}_{i,j} \in T} \theta_{bottom} \cdot \mathbf{f}_{bottom}(i, j, \mathbf{x}, \underline{N}_{i,j}) \\
 & + \sum_{\bar{N}_{i,j} \in T} \theta_{top} \cdot \mathbf{f}_{top}(i, j, \mathbf{x}, \bar{N}_{i,j}) \\
 & + \sum_{r_{i,j}^{unary} \in T} \theta_{unary} \cdot \mathbf{f}_{unary}(i, j, \mathbf{x}, r_{i,j}^{unary}) \\
 & + \sum_{r_{i,j,k}^{binary} \in T} \theta_{binary} \cdot \mathbf{f}_{binary}(i, j, \mathbf{x}, r_{i,j,k}^{binary})
 \end{aligned}$$

where  $\theta_{bottom}, \theta_{top}, \theta_{unary}, \theta_{binary}$  are the weight vectors of the four feature sets.

Given the training corpus  $\{(\mathbf{x}_i, \tilde{T}_i)\}$ , the learning task is to estimate the weight vectors so that for each sentence  $\mathbf{x}_i$ , the gold standard tree  $\tilde{T}_i$  achieves the maximal score among all the possible trees. The perceptron algorithm is guaranteed to find the solution if it exists.

### 3.4 Joint Decoding

The three models described above are separately trained to make parameter estimation feasible as well as optimize each individual component. In test-

Table 3: Feature templates for parsing, where X can be word, first and last character of word, first and last character bigram of word, POS tag.  $X_{l+a}/X_{r-a}$  denotes the first/last  $a^{\text{th}}$  X in the span, while  $X_{l-a}/X_{r+a}$  denotes the  $a^{\text{th}}$  X left/right to span.  $X_m$  is the first X of right child, and  $X_{m-1}$  is the last X of the left child.  $\text{len}$ ,  $\text{len}_l$ ,  $\text{len}_r$  denote the length of the span, left child and right child respectively.  $w_l$  is the length of word. ROOT/LEAF means the template can only generate the features for the root/initial span.

ing, we perform joint decoding to combine information from the three models. Parameters of word segmentation ( $\theta_{\text{seg}}$ ), POS tagging ( $\theta_{\text{pos}}$ ), and parsing models ( $\theta_{\text{parse}} = \theta_{\text{bottom} \oplus \text{top} \oplus \text{unary} \oplus \text{binary}}$ ) are scaled by three positive hyper-parameters  $\alpha$ ,  $\beta$ , and  $\gamma$  respectively, which control their contribution in the joint model. If  $\alpha \gg \beta \gg \gamma$ , then the joint model is equivalent to a pipeline model, in which there is no feedback from downstream models to upstream ones. For well tuned hyper-parameters, we expect that segmentation and POS tagging results can be improved by parsing information. The hyper-parameters are tuned on development data. In the following sections, for simplicity we drop  $\alpha, \beta, \gamma$ , and just use  $\theta_{\text{seg}}, \theta_{\text{pos}}, \theta_{\text{parse}}$  to represent the scaled parameters.

The basic idea of our decoding algorithm is to extend the CYK parsing algorithm so that it can deal with transition features in POS tagging and segmentation scores in word segmentation.

### 3.4.1 Algorithm

The joint decoding algorithm is shown in Algorithm 1. Given a sentence  $\mathbf{x} = c_1, \dots, c_l$ , Line 0 calculates the scores of all possible words in the sentence using Eq(1). There are  $l(l+1)/2$  word candidates in total.

Surrounding words are important features for

POS tagging and parsing; however, they are unavailable because segmentation is incomplete before parsing. Therefore, we adopt pseudo surrounding features by simply fixing the context words as the single most likely ones. Given a word candidate  $w_{i,j}$  from  $c_i$  to  $c_j$ , its previous word  $s'$  is the rightmost one in the best word sequence of  $c_1, \dots, c_{i-1}$ , which can be obtained by dynamic programming. Recursively, the second word left to  $w_{i,j}$  is the previous word of  $s'$ . The next word of  $w_{i,j}$  is defined similarly. In Line 1, we use bidirectional Viterbi decoding to obtain all the surrounding words. In the forward direction, the algorithm starts from the first character boundary to the last, and finds the best previous word for the  $i^{\text{th}}$  character boundary  $b_i$ . In the backward direction, the algorithm starts from right to left, and finds the best next word of each  $b_i$ .

In Line 2, for each word candidate, we can calculate the score of each POS tag using state features in the POS tagging model, since the context words are available now. The score function of word  $w_{i,j}$  with POS tag  $t$  is:

$$\begin{aligned} \text{score}_{\text{seg} \oplus \text{pos}}(\mathbf{x}, i, j, t) = \\ \text{score}_{\text{seg}}(\mathbf{x}, i, j) + \theta_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\mathbf{x}, w_{i,j}, t) \end{aligned} \quad (2)$$

In Line 3, POS tags of surrounding words can be obtained similarly using bidirectional decoding.

Table 4: Complexity Analysis of Algorithm 1.

That is, for  $w_{i,j}$  with POS tag  $t$ , we use Viterbi algorithm to search the optimal POS tags of its left and right words.

In Lines 4-9, each word was initialized as a basic span. A span structure in the joint model is a 6-tuple:  $S(i, j, \mathbf{w}, \mathbf{t}, \underline{N}, \overline{N})$ , where  $i, j$  are the boundary indices,  $\mathbf{w}, \mathbf{t}$  are the word sequence and POS sequence within the span respectively, and  $\underline{N}, \overline{N}$  are the bottom and top states. There are two types of surrounding n-grams: one is inside the span, for example, the first word of a span, which can be obtained from  $\mathbf{w}$ ; the other is outside the span, for example, the previous word of a span, which is obtained from the

pseudo context information. The score of a basic span depends on its corresponding word and POS pair score, and the weights of the active state and unary features.

To avoid enumerating the combination of the bottom and top states, initialization for each span is divided into 2 steps. In the first step, the score of every bottom state is calculated using bottom state features, and only the  $B$  best states are maintained (see Line 6-7). In the second step, top state features and unary rule features are used to get the score of each top state (Line 9), and only the top  $B$  states are preserved.

Similarly, there are two steps in the merge operation:  $S(i, j, \mathbf{w}, \mathbf{t}, \underline{N}, \overline{N}) = S_l(i, k, \mathbf{w}_l, \mathbf{t}_l, \underline{N}_l, \overline{N}_l) + S_r(k + 1, j, \mathbf{w}_r, \mathbf{t}_r, \underline{N}_r, \overline{N}_r)$ . The score of the bottom state  $\underline{N}$  is calculated using binary features  $\mathbf{f}_{binary}(\mathbf{x}, i, j, k, \mathbf{w}, \mathbf{t}, \underline{N} \rightarrow \overline{N}_r + \overline{N}_r)$ , bottom state features  $\mathbf{f}_{bottom}(\mathbf{x}, i, j, \mathbf{w}, \mathbf{t}, \underline{N})$ , and POS tag transition features that depend on the boundary POS tags of  $S_l$  and  $S_r$ . See Line 14 of Algorithm 1, where  $t_l^{last}$  and  $t_r^{first}$  are the POS tags of the last word in the left child span and the first word in the right child span respectively.

### 3.4.2 Complexity analysis

Given a sentence of length  $l$ , the complexity for each line of Algorithm 1 is listed in Table 4, where  $|\mathcal{T}|$  is the size of POS tag set,  $M$  is the number of states, and  $B$  is the beam size.

## 4 Experiments

### 4.1 Data

For comparison with other systems, we use the CTB5 corpus, which has been studied for Chinese word segmentation, POS tagging and parsing. We use the standard train/develop/test split of the data. Details are shown in Table 5.

	CTB files	# sent.	# words
Training	1-270 400-1151	18089	493,939
Develop	301-325	350	6,821
Test	271-300	348	8,008

Table 5: Training, development, and test data of CTB 5.

### 4.2 Evaluation Metric

We evaluate system performance on the individual tasks, as well as the joint tasks.<sup>1</sup> For word segmentation, three metrics are used for evaluation: precision (P), recall (R), and F-score (F) defined by  $2PR/(P+R)$ . Precision is the percentage of correct words in the system output. Recall is the percentage of words in gold standard annotations that are correctly predicted. For parsing, we use the standard parseval evaluation metrics: bracketing precision, recall and F-score.

<sup>1</sup>Note that the joint task refers to automatic segmentation and tagging/parsing. It can be achieved using a pipeline system or our joint decoding method.

For joint word segmentation and POS tagging, a word is correctly predicted if both the boundaries and the POS tag are correctly identified. For joint segmentation, POS tagging, and parsing task, when calculating the bracket scores using existing parseval tools, we need to consider possible word segmentation errors. To do this, we add the word boundary information in states – a bracket is correct only if its boundaries, label and word segmentation are all correct. One example is shown in Figure 3. Notice that identity unary rules are removed during evaluation. The basic spans are characters, not words, because the number of words in reference and prediction may be different. POS tags are removed since they do not affect the bracket scores. If the segmentation is perfect, then the bracket scores of the modified tree are exactly the same as the original tree. This is similar to evaluating parsing performance on speech transcripts with automatic sentence segmentation (Roark et al., 2006).

Figure 3: Boundary information is added to states to calculate the bracket scores in the face of word segmentation errors. Left: the original parse tree, Right: the converted parse tree. The numbers in the brackets are the indices of the character boundaries based on word segmentation.

### 4.3 Parameter Estimation

We train three submodels using the gold features, that is, POS tagger is trained using the perfect segmentation, and parser is trained using perfect segmentation and POS tags. Some studies reported that better performance may be achieved by training subsequent models using representative output of the preceding models (Che et al., 2009). Hence for comparison we trained another parser using automatically generated POS tags obtained from 10-fold cross validation, but did not find significant difference between these two parsers when testing on the perfectly segmented development dataset. Therefore

we use the parser trained with perfect POS tags for the joint task.

Three hyper-parameters,  $\alpha$ ,  $\beta$ , and  $\gamma$ , are tuned on development data using a heuristic search. Parameters that achieved the best joint parsing result are selected. In the search, we fixed  $\gamma = 1$  and varied  $\alpha$ ,  $\beta$ . First, we set  $\beta = 1$ , and enumerate  $\alpha = \frac{1}{4}, \frac{1}{2}, 1, 2, \dots$ , and choose the best  $\alpha^*$ . Then, we set  $\alpha = \alpha^*$  and vary  $\beta = \frac{1}{4}, \frac{1}{2}, 1, 2, \dots$ , and select the best  $\beta^*$ .

Table 6 lists the parameters we used for training the submodels, as well as the hyper-parameters for joint decoding.

Model	Parameter	Value
Character based word segmentor	Gaussian prior	0.01
	# Feature	3,875,802
Word based word segmentor	Gaussian prior	0.01
	# Feature	312,533
POS tagger	Gaussian prior	0.1
	# Feature	48,608,802
Parser	Iteration Number	10
	# Feature	49,369,843
Joint	Hyper-parameter $\alpha$	4
	Hyper-parameter $\beta$	0.5
	Hyper-parameter $\gamma$	1
	Beam Size B	20

Table 6: Parameters used in our system.

## 4.4 Experimental Results

In this section we first show that our sub-models are better than or comparable to state-of-the-art systems, and then the joint model is superior to the pipeline approach.

### 4.4.1 Evaluating Sub-models

Table 7 shows word segmentation results using our word segmentation submodel, in comparison to a few state-of-the-art systems. For our segmentor, we show results for two variants: one removes transition features as described in Section 3.1, the other uses CRFs to learn the weights of transition features. We can see that our system is competitive with all the others except Sun’s that used additional idiom resources. Our two word segmentors have similar performance. Since the one without transition features can be naturally integrated into the joint system, we use it in the following joint tasks.

System	P	R	F
(Jiang et al., 2008b)	-	-	97.74
(Jiang et al., 2008a)	-	-	97.85
(Kruengkrai et al., 2009)	97.46	98.29	97.87
(Zhang and Clark, 2010)	-	-	97.78
(Zhang and Clark, 2011)	-	-	97.78
(Sun, 2011)	-	-	98.17
Ours (w/o transition features)	97.45	98.24	97.85
Ours (with transition features)	97.44	98.23	97.84

Table 7: Word segmentation results.

For the POS tagging only task that takes gold standard word segmentation as input, we have two systems. One uses the linear chain CRFs as described in Section 3.2, the other is obtained using the parser described in Section 3.3 – the parser generates POS tag hypotheses when POS tag features are not used. The POS tagging accuracy is 95.53% and 95.10% using these two methods respectively. The better performance from the former system may be because the local label dependency is more helpful for POS tagging than the long distance dependencies that might be noisy. This result also confirms our choice of using an independent POS tagger for the sub-model, rather than relying on a parser for POS tagging. However, since there are no reported results for this setup, we demonstrate the competence of our POS tagger using the joint word segmentation and POS tagging task. Table 8 shows the performance of a few systems along with ours, all using the pipeline approach where automatic segmentation is followed by POS tagging. We can see that our POS tagger is comparable to the others.

System	P	R	F
(Jiang et al., 2008b)	-	-	93.37
(Jiang et al., 2008a)	-	-	93.41
(Kruengkrai et al., 2009)	93.28	94.07	93.67
(Zhang and Clark, 2010)	-	-	93.67
(Zhang and Clark, 2011)	-	-	93.67
(Sun, 2011)	-	-	94.02
Ours (pipeline)	93.10	93.96	93.53

Table 8: Results for the joint word segmentation and POS tagging task.

For parsing, Table 9 presents the parsing result on gold standard segmented sentence. Notice that the result of (Harper and Huang, 2009; Zhang and

Clark, 2011) are not directly comparable to ours, as they used a different data split. The best published system result on CTB5 is Petrov and Klein’s, which used PCFG with latent Variables. Our system performs better mainly because it benefits from a large amount of features.

System	LP	LR	F
(Petrov and Klein, 2007)	84.8	81.9	83.3
(Jiang et al., 2009)	-	-	82.35
(Harper and Huang, 2009)*	83.22	82.84	83.03
(Zhang and Clark, 2011)*	78.6	78.0	78.3
Ours	84.57	83.68	<b>84.13</b>
Ours (w/ parent annotation)	83.35	82.73	83.04
Ours (no POS tag feature)	83.49	82.97	83.23

Table 9: Parsing results using gold standard word segmentation.

For our parser, besides the model described in Section 3.3, we tried two variations: one does not use the automatic POS tag features, the other one is learned on the parent annotated training data. The results in Table 9 show that there is a performance degradation when using parent annotation. This may be due to the introduction of a large number of s-tates, resulting in sparse features. We also notice that with the help of the POS tag information, even automatically generated, the parser gained 0.9% improvement in F-score. This demonstrates the advantage of using a better independent POS tagger and incorporating it in parsing.

Finally Table 10 shows the results for the three tasks using our joint decoding method in comparison to the pipeline method. We can see that the joint model outperforms the pipeline one. This is mainly because of a better parsing module as well as joint decoding. In the table we also include results of (Jiang et al., 2009), which is the only reported joint parsing result we found using the same data split on CTB5. They achieved 80.28% parsing F-score using automatic word segmentation. Their adapted system Jiang09<sup>+</sup> leveraged additional corpus to improve Chinese word segmentation, resulting in an F-score of 81.07%. Our system has better performance than these.

System	Task	P	R	F
Jiang09	Parse	-	-	80.28
Jiang09 <sup>+</sup>	Parse	-	-	81.07
Ours Pipeline	Seg.	97.45	98.24	97.85
	POS	93.10	93.96	93.53
	Parse	81.87	81.65	81.76
Ours Joint	Seg.	97.56	98.36	97.96
	POS	93.43	94.20	93.81
	Parse	83.03	82.66	<b>82.85</b>

Table 10: Results for the joint segmentation, tagging, and parsing task using pipeline and joint models.

#### 4.5 Error Analysis

We compared the results from the pipeline and our joint decoding systems in order to understand the impact of the joint model on word segmentation and POS tagging. We notice that the joint model tend to generate more words than the pipeline model. For example, “巴尔一行” is one word in the pipeline model, but correctly segmented as two words “巴尔/一行” in the joint model. This tendency of segmentation also makes it fail to recognize some long words, especially OOV words. For example, “事实上” is segmented as “事实/上”. In the data set, we find that, the joint model corrected 10 missing boundaries over the pipeline method, and introduced 3 false positive segmentation errors.

For the analysis of POS tags, we only examined the words that are correctly segmented by both the pipeline and the joint models. Table 11 shows the increase and decrease of error patterns of the joint model over the pipeline POS tagger. An error pattern “X → Y” means that the word whose true tag is ‘X’ is assigned a tag ‘Y’. All the patterns are ranked in descending order of the reduction/increase of the error number. We can see that the joint model has a clear advantage in the disambiguation of {VV, NN} and {DEG, DEC}, which results in the overall improved performance. In contrast, the joint method performs worse on ambiguous POS pairs such as {NN, NR}. This observation is similar to those reported by (Li et al., 2011; Hatori et al., 2011).

## 5 Conclusion

In this paper, we proposed a new algorithm for joint Chinese word segmentation, POS tagging, and parsing. Our algorithm is an extension of the CYK

error pattern	#	↓	error pattern	#	↑
NN→VV	47	19	NN→NR	15	12
VV→NN	42	13	NR→NN	7	5
DEG→DEC	23	10	JJ→P	1	4
NN→JJ	29	8	NN→DT	2	4
DEC→DEG	11	4	P→VV	3	2
JJ→NN	12	4	AD→NN	1	2

Table 11: POS tagging error patterns. # means the error number of the corresponding pattern made by the pipeline tagging model. ↓ and ↑ mean the error number reduced or increased by the joint model.

parsing method. The sub-models are independently trained for the three tasks to reduce model complexity and optimize individual sub-models. Our experiments demonstrate the advantage of the joint models. In the future work, we will compare this joint model to the pipeline approach that uses multiple candidates or soft decisions in the early modules. We will also investigate methods for joint learning as well as ways to speed up the joint decoding algorithm.

## Abstract

In this paper, we propose a novel translation model (TM) based cross-lingual data selection model for language model (LM) adaptation in statistical machine translation (SMT), from word models to phrase models. Given a source sentence in the translation task, this model directly estimates the probability that a sentence in the target LM training corpus is similar. Compared with the traditional approaches which utilize the first pass translation hypotheses, cross-lingual data selection model avoids the problem of noisy proliferation. Furthermore, phrase TM based cross-lingual data selection model is more effective than the traditional approaches based on bag-of-words models and word-based TM, because it captures contextual information in modeling the selection of phrase as a whole. Experiments conducted on large-scale data sets demonstrate that our approach significantly outperforms the state-of-the-art approaches on both LM perplexity and SMT performance.

## 1 Introduction

Language model (LM) plays a critical role in statistical machine translation (SMT). It seems to be a universal truth that LM performance can always be improved by using more training data (Brants et al., 2007), but only if the training data is reasonably well-matched with the desired output (Moore and Lewis, 2010). It is also obvious that among the large training data the topics or domains of discussion will change (Eck et al., 2004), which causes the mismatch problems with the translation task. For

this reason, most researchers preferred to select similar training data from the large training corpus in the past few years (Eck et al., 2004; Zhao et al., 2004; Kim, 2005; Masskey and Sethy, 2010; Axelrod et al., 2011). This would empirically provide more accurate lexical probabilities, and thus better match the translation task at hand (Axelrod et al., 2011).

Many previous data selection approaches for LM adaptation in SMT depend on the first pass translation hypotheses (Eck et al., 2004; Zhao et al., 2004; Kim, 2005; Masskey and Sethy, 2010), they select the sentences which are similar to the translation hypotheses. These schemes are overall limited by the quality of the translation hypotheses (Tam et al., 2007 and 2008), and better initial translation hypotheses lead to better selected sentences (Zhao et al., 2004). However, while SMT has achieved a great deal of development in recent years, the translation hypotheses are still far from perfect (Wei and Pal, 2010), which have many noisy data. The noisy translation hypotheses mislead data selection process (Xu et al., 2001; Tam et al., 2006 and 2007; Wei and Pal, 2010), and thus take noisy data into the selected training data, which causes *noisy proliferation* and degrades the performance of adapted LM.

Furthermore, traditional approaches for LM adaptation are based on bag-of-words models and considered to be *context independent*, despite of their state-of-the-art performance, such as TF-IDF (Eck et al., 2004; Zhao et al., 2004; Hildebrand et al., 2005; Kim, 2005; Foster and Kuhn, 2007), centroid similarity (Masskey and Sethy, 2010), and cross-lingual similarity (CLS) (Ananthakrishnan et al., 2011a). They all perform at the word level, exact only ter-

m matching schemes, and do not take into account any contextual information when modeling the selection by single words in isolation, which degrade the quality of selected sentences.

In this paper, we argue that it is beneficial to model the data selection based on the source translation task directly and capture the contextual information for LM adaptation. To this end, we propose a more principled translation model (TM) based cross-lingual data selection model for LM adaptation, from word models to phrase models. We assume that the data selection should be performed by the cross-lingual model and at the phrase level. Given a source sentence in the translation task, this model directly estimates the probability before translation that a sentence in the target LM training corpus is similar. Therefore, it does not require the translation task to be pre-translation as in monolingual adaptation, and can address the problem of noisy proliferation.

To the best of our knowledge, this is the first extensive and empirical study of using phrase TM based cross-lingual data selection for LM adaptation. This model learns the transform probability of a multi-term phrase in a source sentence given a phrase in the target sentence of LM training corpus. Compared with bag-of-words models and word-based TM that account for selecting single words in isolation, this model performs at the phrase level and captures some *contextual information* in modeling the selection of phrase as a whole, thus it is potentially more effective. More precise data selection can be determined for phrases than for words. In this model, we propose a linear ranking model framework to further improve the performance, referred to the linear discriminant function (Duda et al., 2001; Collins, 2002; Gao et al., 2005) in pattern classification and information retrieval (IR), where different models are incorporated as features, as we will show in our experiments.

Unlike the general TM in SMT, we explore the use of TextRank algorithm (Mihalcea et al., 2004) to identify and eliminate unimportant words (e.g., non-topical words, common words) for corpus preprocessing, and construct TM by *important words*. This reduces the average number of words in cross-lingual data selection model, thus improving the efficiency. Moreover, TextRank utilizes the contex-

t information of words to assign term weights (Lee et al., 2008), which makes phrase TM based cross-lingual data selection model play its advantage of capturing the contextual information, thus further improving the performance.

The remainder of this paper is organized as follows. Section 2 introduces the related work of LM adaptation. Section 3 presents the framework of cross-lingual data selection for LM adaptation. Section 4 describes our proposed TM based cross-lingual data selection model: from word models to phrase models. In section 5 we present large-scale experiments and analyses, and followed by conclusions and future work in section 6.

## 2 Related Work

TF-IDF and cosine similarity have been widely used for LM adaptation (Eck et al., 2004; Zhao et al., 2004; Hildebrand et al., 2005; Kim, 2005; Foster and Kuhn, 2007). Masskey and Sethy (2010) selected the auxiliary data by computing centroid similarity score to the centroid of the in-domain data. The main idea of these methods is to select the sentences which are similar to the first pass translation hypotheses or in-domain corpus from the large LM training corpus, and estimate the bias LM for SMT system to improve the translation quality.

Tam et al. (2007 and 2008) proposed a bilingual-LSA model for LM adaptation. They integrated the LSA marginal into the target generic LM using marginal adaptation which minimizes the Kullback-Leibler divergence between the adapted LM and the generic LM. Ananthakrishnan et al. (2011a) proposed CLS to bias the count and probability of corresponding n-gram through weighting the LM training corpus. However, these two cross-lingual approaches focus on modify LM itself, which are different from data selection method for LM adaptation. In our comparable experiments, we apply CLS for the first time to the task of cross-lingual data selection for LM adaptation. Due to lack of smoothing measure for sparse vector representation in CLS, the similarity computation is not accurate which degrades the performance of adapted LM. To avoid this, we add smoothing measure like TF-IDF, called  $CLS_s$ , as we will discuss in the experiments.

Snover et al. (2008) used a word TM based CLIR

system (Xu et al., 2001) to select a subset of target documents comparable to the source document for adapting LM. Because of the data sparseness in the document state and it operated at the document level, this model selected large quantities of irrelevant text, which may degrade the adapted LM (Eck et al., 2004; Ananthakrishnan et al., 2011b). In our word TM based cross-lingual data selection model, we operate at the sentence level and add the smoothing mechanism by integrating with the background word frequency model, and these can significantly improve the performance. Axelrod et al. (2011) proposed a bilingual cross-entropy difference to select data from parallel corpus for domain adaptation which captures the contextual information slightly, and outperformed monolingual cross-entropy difference (Moore and Lewis, 2010), which first shows the advantage of bilingual data selection. However, its performance depends on the parallel in-domain corpus which is usually hard to find, and its application is assumed to be limited.

### 3 Cross-Lingual Data Selection for Language Model Adaptation

Our LM adaptation is an unsupervised similar training data selection guided by TM based cross-lingual data selection model. For the source sentences in the translation task, we estimate a new LM, the bias LM, from the corresponding target LM training sentences which are selected as the similar sentences. Since the size of the selected sentences is small, the corresponding bias LM is specific and more effective, giving high probabilities to those phrases that occur in the desired output translations.

Following the work of (Zhao et al., 2004; Snover et al., 2008), the generic LM  $P_g(w_i|h)$  and the bias LM  $P_b(w_i|h)$  are combined using linear interpolation as the adapted LM  $P_a(w_i|h)$ , which is shown to improve the performance over individual model,

$$P_a(w_i|h) = \mu P_g(w_i|h) + (1 - \mu)P_b(w_i|h) \quad (1)$$

where the interpolation factor  $\mu$  can be simply estimated using the Powell Search algorithm (Press et al., 1992) via cross-validation.

Our work focuses on TM based cross-lingual data selection model, from word model to phrase models, and the quality of this model is crucial to the performance of adapted LM.

## 4 Translation Model for Cross-Lingual Data Selection (CLTM)

Let  $Q = \mathbf{q}_1, \dots, \mathbf{q}_j$  be a source sentence in the translation task and  $S = \mathbf{w}_1, \dots, \mathbf{w}_i$  be a sentence in the general target LM training corpus, thus cross-lingual data selection model can be framed probabilistically as maximizing the  $P(S|Q)$ . By Bayes' rule,

$$P(S|Q) = \frac{P(S)P(Q|S)}{P(Q)} \quad (2)$$

where the prior probability  $P(S)$  can be viewed as uniform, and the  $P(Q)$  is constant across all sentences. Therefore, selecting a sentence to maximize  $P(S|Q)$  is equivalent to selecting a sentence that maximizes  $P(Q|S)$ .

### 4.1 Word-Based Translation Model for Cross-Lingual Data Selection (CLWTM)

#### 4.1.1 Cross-Lingual Sentence Selection Model

Following the work of (Xu et al., 2001; Snover et al., 2008), CLWTM can be described as

$$P(Q|S) = \prod_{q \in Q} P(q|S) \quad (3)$$

$$P(q|S) = \alpha P(q|C_q) + (1 - \alpha) \sum_{w \in S} P(q|w)P(w|S) \quad (4)$$

where  $\alpha$  is the interpolation weight empirically set as a constant<sup>1</sup>,  $P(q|w)$  is the word-based TM which is estimated by IBM Model 1 (Brown et al., 1993) from the parallel corpus,  $P(q|C_q)$  and  $P(w|S)$  are the un-smoothed background and sentence model, respectively, estimated using maximum likelihood estimation (MLE) as

$$P(q|C_q) = \frac{freq(q, C_q)}{|C_q|} \quad (5)$$

$$P(w|S) = \frac{freq(w, S)}{|S|} \quad (6)$$

where  $C_q$  refers to the translation task,  $freq(q, C_q)$  refers to the number of times  $q$  occurs in  $C_q$ ,  $freq(w, S)$  refers to the number of times  $w$  occurs in  $S$ , and  $|C_q|$  and  $|S|$  are the sizes of the translation task and the current target sentence, respectively.

<sup>1</sup>As in Xu et al. (2001), a value of 0.3 was used for  $\alpha$ .

### 4.1.2 Ranking Candidate Sentences

Because of the data sparseness in the sentence state which degrades the model, Equation (6) does not perform well in our data selection experiments. Inspired by the work of (Berger et al., 1999) in IR, we make the following smoothing mechanism:

$$P(q|S) = \alpha P(q|C_q) + (1 - \alpha) \sum_{w \in S} P(q|w) P_s(w|S) \quad (7)$$

$$P_s(w|S) = \beta P(w|C_s) + (1 - \beta) P(w|S) \quad (8)$$

$$P(w|C_s) = \frac{\text{freq}(w, C_s)}{|C_s|} \quad (9)$$

where  $P(w|C_s)$  is the un-smoothed background model, estimated using MLE as Equation (5),  $C_s$  refers to the LM training corpus and  $|C_s|$  refers to its size. Here,  $\beta$  is interpolation weight; notice that letting  $\beta = 0$  in Equation (8) reduces the model to the un-smoothed model in Equation (4).

## 4.2 Phrase-Based Translation Model for Cross-Lingual Data Selection (CLPTM)

### 4.2.1 Cross-Lingual Sentence Selection Model

The phrase-based TM (Koehn et al., 2003; Och and Ney, 2004) has shown superior performance compared to the word-based TM. In this paper, the goal of phrase-based TM is to transfer  $S$  into  $Q$ . Rather than transferring single words in isolation, the phrase model transfers one sequence of words into another sequence of words, thus incorporating contextual information. Inspired by the work of web search (Gao et al., 2010) and question retrieval in community question answer (Q&A) (Zhou et al., 2011), we assume the following generative process: first the sentence  $S$  is broken into  $K$  non-empty word sequences  $\mathbf{w}_1, \dots, \mathbf{w}_k$ , then each is transferred into a new non-empty word sequences  $\mathbf{q}_1, \dots, \mathbf{q}_k$ , and finally these phrases are permuted and concatenated to form the sentence  $Q$ , where  $q$  and  $w$  denote the phrases or consecutive sequence of words.

To formulate this generative process, let  $U$  denote the segmentation of  $S$  into  $K$  phrases  $\mathbf{w}_1, \dots, \mathbf{w}_k$ , and let  $V$  denote the  $K$  phrases  $\mathbf{q}_1, \dots, \mathbf{q}_k$ , we refer to these  $(\mathbf{w}_i, \mathbf{q}_i)$  pairs as bi-phrases. Finally, let  $M$  denote a permutation of  $K$  elements representing the final ranking step.

Next we place a probability distribution over rewrite pairs. Let  $B(S, Q)$  denote the set of  $U, V, M$  triples that transfer  $S$  into  $Q$ . Here we assume a uniform probability over segmentations, so the phrase-based selection probability can be formulated as

$$P(Q|S) \propto \sum_{\substack{(U,V,M) \in \\ B(S,Q)}} P(V|S, U) \cdot P(M|S, U, V) \quad (10)$$

Then, we use the maximum approximation to the sum:

$$P(Q|S) \approx \max_{\substack{(U,V,M) \in \\ B(S,Q)}} P(V|S, U) \cdot P(M|S, U, V) \quad (11)$$

Although we have defined a generative model for transferring  $S$  into  $Q$ , our goal is to calculate the ranking score function over existing  $Q$  and  $S$ . However, this model can not be used directly for sentence ranking because  $Q$  and  $S$  are often of different lengths, the length of  $S$  is almost 1.5 times to that of  $Q$  in our corpus, leaving many words in  $S$  unaligned to any word in  $Q$ . This is another key difference between our task and SMT. As pointed out by the previous work (Berger and Lafferty, 1999; Gao et al., 2010; Zhou et al., 2011), sentence-query selection requires a distillation of the sentence, while selection of natural language tolerates little being thrown away. Thus we restrict our attention to those *key sentence words* that form the distillation of  $S$ , do not consider the unaligned words in  $S$ , and assume that  $Q$  is transferred only from the key sentence words.

In this paper, the key sentence words are identified via word alignment. Let  $A = a_1 \dots a_J$  be the "hidden" word alignment, which describes a mapping from a term position  $j$  in  $Q$  to a word position  $a_j$  in  $S$ . We assume that the positions of the key sentence words are determined by the Viterbi alignment  $\hat{A}$ , which can be obtained using IBM Model 1 (Brown et al., 1993) as follows:

$$\begin{aligned} \hat{A} &= \arg \max_A P(Q, A|S) \\ &= \arg \max_A \left\{ P(J|I) \prod_{j=1}^J P(q_j|w_{a_j}) \right\} \\ &= \left[ \arg \max_{a_j} P(q_j|w_{a_j}) \right]_{j=1}^J \end{aligned} \quad (12)$$

Given  $\hat{A}$ , when scoring a given  $Q/S$  pair, we restrict our attention to those  $U, V, M$  triples that are consistent with  $\hat{A}$ , which we denote as  $B(S, Q, \hat{A})$ . Here, consistency requires that if two words are aligned in  $\hat{A}$ , then they must appear in the same bi-phrase  $(\mathbf{w}_i, \mathbf{q}_i)$ . Once the word alignment is fixed, the final permutation is uniquely determined, so we can safely discard that factor. Then Equation (11) can be written as

$$P(Q|S) \approx \max_{\substack{(U,V,M) \in \\ B(S,Q,\hat{A})}} P(V|S,U) \quad (13)$$

For the sole remaining factor  $P(V|S,U)$ , we assume that a segmented queried question  $V = \mathbf{q}_1, \dots, \mathbf{q}_k$  is generated from left to right by transferring each phrase  $\mathbf{w}_1, \dots, \mathbf{w}_k$  independently, as follows:

$$P(V|S,U) = \prod_{k=1}^K P(\mathbf{q}_k|\mathbf{w}_k) \quad (14)$$

where  $P(\mathbf{q}_k|\mathbf{w}_k)$  is a phrase translation probability computed from the parallel corpus, which can be estimated in two ways (Koehn et al., 2003; Och and Ney, 2004): relative frequency and lexical weighting, and has two format: phrase translation probability and lexical weight probability.

In order to find the maximum probability assignment  $P(Q|S)$  efficiently, we use a dynamic programming approach, somewhat similar to the monotone decoding algorithm described in the work (Och, 2002). We consider quantity  $\alpha_j$  as the maximal probability of the most likely sequence of phrases in  $S$  covering the first  $j$  words in  $Q$ , therefore the probability can be calculated using the following recursion:

step (1). Initialization:

$$\alpha_0 = 1 \quad (15)$$

step (2). Induction:

$$\alpha_j = \sum_{j' < j, \mathbf{q} = \mathbf{q}_{j'+1} \dots \mathbf{q}_j} \{ \alpha_{j'} P(\mathbf{q}|\mathbf{w}_{\mathbf{q}}) \} \quad (16)$$

step (3). Total:

$$P(Q|S) = \alpha_J \quad (17)$$

## 4.2.2 Ranking Candidate Sentences

However, directly using the phrase-based TM, computed in Equations (15) to (17), to rank the candidate sentences does not perform well. Inspired by the linear discriminant function (Duda et al., 2001; Collins, 2002; Gao et al., 2005) in pattern classification and IR, we therefore propose a linear ranking model framework for cross-lingual data selection model in which different models are incorporated as features.

We consider the linear ranking model as follows:

$$\begin{aligned} \text{Score}(Q, S) &= \lambda^T \cdot H(Q, S) \\ &= \sum_{n=1}^N \lambda_n h_n(Q, S) \end{aligned} \quad (18)$$

where the model has a set of  $N$  features, and each feature is an arbitrary function that maps  $(Q|S)$  to a real value, i.e.,  $H(Q, S) \in \mathbf{R}$ .  $\lambda_n$  for  $n = 1 \dots N$  is the corresponding parameters of each feature, and we optimize these parameters using the Powell Search algorithm (Press et al., 1992) via cross-validation.

The used features in the linear ranking model are as follows:

- Phrase translation feature (PT):  $h_{PT}(Q, S, A) = \log P(Q|S)$ , where  $P(Q|S)$  is computed using Equations (15) to (17), and  $P(\mathbf{q}_k|\mathbf{w}_k)$  is phrase translation probability.
- Inverted phrase translation feature (IPT):  $h_{IPT}(S, Q, A) = \log P(S|Q)$ , where  $P(S|Q)$  is computed using Equations (15) to (17), and  $P(\mathbf{w}_k|\mathbf{q}_k)$  is inverted phrase translation probability.
- Lexical weight feature (LW):  $h_{LW}(Q, S, A) = \log P(Q|S)$ , where  $P(Q|S)$  is computed using Equations (15) to (17), and  $P(\mathbf{q}_k|\mathbf{w}_k)$  is lexical weight probability.
- Inverted lexical weight feature (ILW):  $h_{ILW}(S, Q, A) = \log P(S|Q)$ , where  $P(S|Q)$  is computed using Equations (15) to (17), and  $P(\mathbf{w}_k|\mathbf{q}_k)$  is inverted lexical weight probability.
- Unaligned word penalty feature (UWP):  $h_{UWP}(Q, S, A)$ , which is defined as the ratio between the number of unaligned terms and the total number of terms in  $Q$ .

- Word-based translation feature (WT):  $h_{WT}(Q, S, A) = \log P(Q|S)$ , where  $P(Q|S)$  is the word-based TM defined by Equations (3) and (7).

### 4.3 Eliminating Unimportant Words (EUW)

To improve the efficiency of cross-lingual data selection process, we consider the translation task, the LM training corpus and the parallel corpus in our task are constructed by the key words or important words, and thus construct TM by the key words or important words, which is another key difference between our task and SMT. We identify and eliminate unimportant words, somewhat similar to Q&A retrieval (Lee et al., 2008; Zhou et al., 2011). Thus, the average number of words (the total word number in  $Q$  and  $S$ ) in cross-lingual sentence selection model would be minimized naturally, and the efficiency of cross-lingual data selection would be improved.

In this paper, we adopt a variant of TextRank algorithm (Mihalcea and Tarau, 2004), a graph-based ranking model for key word extraction which achieves state-of-the-art accuracy. It identifies and eliminates unimportant words from the corpus, and assumes that a word is unimportant if it holds a relatively low significance in the corpus. Compared with the traditional approaches, such as TF-IDF, TextRank utilizes the context information of words to assign term weights (Lee et al., 2008), so it further improves the performance of CLPTM, as we will show in the experiments.

Following the work of (Lee et al., 2008), the ranking algorithm proceeds as follows. First, all the words in a given document are added as vertices in a graph. Then edges are added between words (vertices) if the words co-occur in a fixed-sized window. The number of co-occurrences becomes the weight of an edge. When the graph is constructed, the score of each vertex is initialized as 1, and the PageRank based ranking algorithm is run on the graph iteratively until convergence. The TextRank score  $R_{w_i,D}^k$  of a word  $w_i$  in document  $D$  at  $k$ th iteration is defined as follows:

$$R_{w_i,D}^k = (1-d) + d \cdot \sum_{\forall j:(i,j) \in G} \frac{e_{i,j}}{\sum_{\forall l:(j,l) \in G} e_{j,l}} R_{w_j,D}^{k-1} \quad (19)$$

where  $d$  is a damping factor usually set as a constant

$t^2$ , and  $e_{i,j}$  is an edge weight between  $w_i$  and  $w_j$ .

In our experiments, we manually set the proportion to be removed as 25%, that is to say, 75% of total words in the documents would be remained as the important words.

## 5 Experiments

We measure the utility of our proposed LM adaptation approach in two ways: (a) comparing reference translations based perplexity of adapted LMs with the generic LM, and (b) comparing SMT performance of adapted LMs with the generic LM.

### 5.1 Corpus and Tasks

We conduct experiments on two Chinese-to-English translation tasks: IWSLT-07 (dialogue domain) and NIST-06 (news domain).

**IWSLT-07.** The bilingual training corpus comes from BTEC<sup>3</sup> and CJK<sup>4</sup> corpus, which contains 3.82K sentence pairs with 3.0M/3.1M Chinese/English words. The LM training corpus is from the English side of the parallel data (BTEC, CJK, and CWMT2008<sup>5</sup>), which consists of 1.34M sentences and 15.2M English words. The test set is IWSLT-07 test set which consists of 489 sentences, and the development set is IWSLT-05 test set which consists of 506 sentences.

**NIST-06.** The bilingual training corpus comes from Linguistic Data Consortium (LDC)<sup>6</sup>, which consists of 3.4M sentence pairs with 64M/70M Chinese/English words. The LM training corpus is from the English side of the parallel data as well as the English Gigaword corpus<sup>7</sup>, which consists of 11.3M sentences. The test set is 2006 NIST MT Evaluation test set which consists of 1664 sentences, and the development set is 2005 NIST MT Evaluation test set which consists of 1084 sentences.

<sup>2</sup>As in Lee et al. (2008), a value of 0.85 was used for  $d$ .

## 5.2 Perplexity Analysis

We randomly divide the development set into five subsets and conduct 5-fold cross-validation experiments. In each trial, we tune the parameter  $\mu$  in Equation (1) and parameter  $\lambda$  in Equation (18) with four of five subsets and then apply it to one remaining subset. The experiments reported below are those averaged over the five trials.

We estimate the generic 4-gram LM with the entire LM training corpus as the baseline. Then, we select the top- $N$  sentences which are similar to the development set, estimate the bias 4-gram LMs (with  $n$ -gram cutoffs tuned as above) with these selected sentences, and interpolate with the generic 4-gram LM as the adapted LMs. All the LMs are estimated by the SRILM toolkit (Stolcke, 2002). Perplexity is a metric of LM performance, and the lower perplexity value indicates the better performance. Therefore, we estimate the perplexity of adapted LMs according to English reference translations.

Figure 1 shows the perplexity of adapted LMs vs. the size of selected data. In this paper, we choose TF-IDF as the foundation of our solution since TF-IDF has gained the state-of-the-art performance for LM adaptation (Eck et al., 2004; Hildebrand et al., 2005; Kim, 2005; Foster and Kuhn, 2007). CLS refers to the cross-lingual similarity of (Ananthakrishnan et al., 2011a), and  $CLS_s$  is our proposed improved algorithm on CLS with optimization measure like TF-IDF.  $CLWTM(\beta = 0)$  refers to Snaver et al. (2008), which is the un-smooth ver-

Task	Method	Perplexity	Reduction
IWSLT-07	Baseline	524.1	–
	TF-IDF	471.4	10.06%
	CLS	475.7	9.23%
	$CLS_s$	468.9	10.53%
	$CLWTM(\beta = 0)$	463.5	11.56%
	<b>CLWTM</b>	<b>451.5</b>	<b>13.85%</b>
	<b>CLPTM(<math>l = 4</math>)</b>	<b>435.3</b>	<b>16.94%</b>
NIST-06	Baseline	398.3	–
	TF-IDF	346.2	13.08%
	CLS	351.6	11.72%
	$CLS_s$	340.9	14.41%
	$CLWTM(\beta = 0)$	341.1	14.36%
	<b>CLWTM</b>	<b>332.7</b>	<b>16.47%</b>
	<b>CLPTM(<math>l = 4</math>)</b>	<b>319.2</b>	<b>19.86%</b>

Table 1: English reference translations based perplexity of adapted LMs with different approaches on two test sets, with the top 8K sentences on IWSLT-07 and top 16K sentences on NIST-06, respectively.

sion of our proposed CLWTM in the document state.  $CLPTM(l = 4)$  is our proposed CLPTM with a maximum phrase length of four, and we score the target sentences by the highest scoring  $Q/S$  pair.

The results in Figure 1 indicate that English reference translations based perplexity of adapted LMs decreases consistently with increase of the size of selected top- $N$  sentences, and increases consistently after a certain size in all approaches. Therefore, proper size of similar sentences with the translation task makes the adapted LM perform well, but if too many noisy data are taken into the selected sentences, the performance becomes worse. Similar observations have been done by (Eck et al., 2004;

Task	#	Method	BLEU

Table 2: Comparison of SMT performance ( $p < 0.05$ ) with different approaches for LM adaptation on two test sets.

Axelrod et al., 2011). Furthermore, it is comforting that our approaches (CLWTM and CLPTM( $l = 4$ )) performs better and are more stable than other approaches.

According to the perplexity results in Figure 1, we select the top 8K sentences on IWSLT-07 and top 16K sentences on NIST-06 which are similar to the test set for adapting LM, respectively. Table 1 shows English reference translations based perplexity of adapted LMs on two test sets. Our approaches have significantly reduction in perplexity compared with other approaches, and the results indicate that adapted LMs are significantly better predictors of the corresponding translation task at hand than the generic LM. We use these adapted LMs for next translation experiments to show the detailed performance of selected training data for LM adaptation.

### 5.3 Translation Experiments

We carry out translation experiments on the test set by hierarchical phrase-based (HPB) SMT (Chiang, 2005 and 2007) system to demonstrate the utility of LM adaptation on improving SMT performance by BLEU score (Papineni et al., 2002). The generic LM and adapted LMs are estimated as above in perplexity analysis experiments. We use minimum error rate training (Och, 2003) to tune the feature weights of HPB for maximum BLEU score on the development set with several groups of different start weights.

Table 2 shows the main translation results on two

Task	Translation Hypotheses	BLEU
IWSLT-07	First Pass	34.14
	Second Pass	34.31
NIST-06	First Pass	29.78
	Second Pass	29.91

Table 3: The impact of noisy data in the translation hypotheses on the performance of LM adaptation.

test sets, and the improvements are statistically significant at the 95% confidence interval with respect to the baseline. From the comparison results, we get some clear trends:

(1) Cross-lingual data selection model outperforms the traditional approaches which utilize the first pass translation hypotheses (row 4 vs. row 2; row 11 vs. row 9), but the detailed impact of noisy data in the translation hypotheses on data selection will be shown in the next section (section 5.4).

(2) CLWTM significantly outperforms CLS<sub>s</sub> (row 6 vs. row 4; row 13 vs. row 11), we suspect that word-based TM makes more accurate cross-lingual data selection model than single cross-lingual projection (Ananthakrishnan et al., 2011a).

(3) Compared with (Snover et al., 2008), adding the smoothing mechanism in the sentence state for CLWTM significantly improves the performance (row 6 vs. row 5; row 13 vs. row 12).

(4) Phrase-based TM (CLPTM) significantly outperforms the state-of-the-art approaches based on bag-of-words models and word-based TM (row 7 vs. row 2, row 4, row 5 and row 6; row 14 vs. row 9, row 11, row 12 and row 13).

### 5.4 Impact of Noisy Data in the Translation Hypotheses

The experiment results in Table 2 indicate the second pass translation hypotheses (row 2 and row 9) made by TF-IDF are better than the first pass translation hypotheses (row 1 and row 8), so we consider that these translations have less noisy data. Thus, they were considered as the new translation hypotheses (the second pass) to select the similar sentences for LM adaptation by TF-IDF.

Table 3 shows the impact of noisy data in the translation hypotheses on the performance of adapted LMs. The observed improvement suggests that better initial translations which have less noisy data

Task	Phrase Length	BLEU
IWSLT-07	$l = 1$	34.33
	$l = 2$	34.44
	$l = 3$	34.49
	$l = 4$	34.49
NIST-06	$l = 1$	29.97
	$l = 2$	30.07
	$l = 3$	30.14
	$l = 4$	30.17

Table 4: The impact of phrase length in CLPTM on the performance of LM adaptation, and the maximum phrase length is four.

lead to better adapted LMs, and thereby better second iteration translations. Therefore, it is advisable to use cross-lingual data selection for LM adaptation in SMT, which can address the problem of noisy proliferation.

### 5.5 Impact of Phrase Length

The results in Table 4 show that longer phrases do yield some visible improvement up to the maximum length of four. This may suggest that some properties captured by longer phrases are also captured by other features. The performances when the phrase length is 1 are better than that of single word-based TM (row 6 and row 13 in Table 2), this suspect that the features in our linear ranking model are useful. However, it will be instructive to explore the methods of preserving the improvement generated by longer phrase when more features are incorporated in the future work.

### 5.6 Impact of Eliminating Unimportant Words

Table 5 shows the results of EUW by TextRank algorithm on the performance of CLTM for LM adaptation. Initial represents that we do not eliminate unimportant words. Average number represents the average number of words (the total word number in  $Q$  and  $S$ ) in cross-lingual data selection model. The average number is reduced when unimportant words are eliminated, from 19 to 12 on IWSLT-07 and from 37 to 24 on NIST-06, respectively. This makes the cross-lingual data selection process become more efficient. In CLWTM, the performance with EUW is basically the same with that of the initial state; but in CLPTM, EUW outperforms the initial state because TextRank algorithm utilizes the context infor-

Task	Method	Average Number	BLEU	
			CLWTM	CLPTM ( $l = 4$ )
IWSLT-07	Initial	19	34.31	34.47
	EUW	12	34.30	34.49
NIST-06	Initial	37	29.91	30.12
	EUW	24	29.93	30.17

Table 5: The impact of eliminating unimportant words by TextRank algorithm on the performance of CLTM for LM adaptation.

mation of words when assigning term weights, thus making CLPTM play its advantage of capturing the contextual information.

## 6 Conclusions and Future Work

In this paper, we propose a novel TM based cross-lingual data selection model for LM adaptation in SMT, from word models to phrase models, and aims to find the LM training corpus which are similar to the translation task at hand. Unlike the general TM in SMT, we explore the use of TextRank algorithm to identify and eliminate unimportant words for corpus preprocessing, and construct TM by important words. Compared with the traditional approaches which utilize the first pass translation hypotheses, cross-lingual data selection avoids the problem of noisy proliferation. Furthermore, phrase TM based cross-lingual data selection is more effective than the traditional approaches based on bag-of-words models and word-based TM, because it captures contextual information in modeling the selection of phrase as a whole. Large-scale experiments are conducted on LM perplexity and SMT performance, and the results demonstrate that our approach solves the two aforementioned disadvantages and significantly outperforms the state-of-the-art methods for LM adaptation.

There are some ways in which this research could be continued in the future. First, we will utilize our approach to mine large-scale corpora by distributed infrastructure system, and investigate the use of our approach for other domains, such as speech translation system. Second, the significant improvement of LM adaptation based on cross-lingual data selection is exciting, so it will be instructive to explore other knowledge based cross-lingual data selection for LM adaptation, such as latent semantic model.

## Abstract

Open Information Extraction (IE) systems extract relational tuples from text, without requiring a pre-specified vocabulary, by identifying relation phrases and associated arguments in arbitrary sentences. However, state-of-the-art Open IE systems such as REVERB and WOE share two important weaknesses – (1) they extract only relations that are mediated by verbs, and (2) they ignore *context*, thus extracting tuples that are not asserted as factual. This paper presents OLLIE, a substantially improved Open IE system that addresses both these limitations. First, OLLIE achieves high yield by extracting relations mediated by nouns, adjectives, and more. Second, a context-analysis step increases precision by including contextual information from the sentence in the extractions. OLLIE obtains 2.7 times the area under precision-yield curve (AUC) compared to REVERB and 1.9 times the AUC of WOE<sup>parse</sup>.

## 1 Introduction

While traditional Information Extraction (IE) (ARPA, 1991; ARPA, 1998) focused on identifying and extracting specific relations of interest, there has been great interest in scaling IE to a broader set of relations and to far larger corpora (Banko et al., 2007; Hoffmann et al., 2010; Mintz et al., 2009; Carlson et al., 2010; Fader et al., 2011). However, the requirement of having pre-specified relations of interest is a significant obstacle. Imagine an intelligence analyst who recently acquired a terrorist’s laptop or a news reader who wishes to keep abreast of important events. The substantial endeavor in

1. “After winning the Superbowl, the Saints are now the top dogs of the NFL.” O: (the Saints; win; the Superbowl)
2. “There are plenty of taxis available at Bali airport.” O: (taxis; be available at; Bali airport)
3. “Microsoft co-founder Bill Gates spoke at ...” O: (Bill Gates; be co-founder of; Microsoft)
4. “Early astronomers believed that the earth is the center of the universe.” R: (the earth; be the center of; the universe) W: (the earth; be; the center of the universe) O: ((the earth; be the center of; the universe) <i>AttributedTo</i> believe; Early astronomers)
5. “If he wins five key states, Romney will be elected President.” R,W: (Romney; will be elected; President) O: ((Romney; will be elected; President) <i>ClausalModifier</i> if; he wins five key states)

Figure 1: OLLIE (O) has a wider syntactic range and finds extractions for the first three sentences where REVERB (R) and WOE<sup>parse</sup> (W) find none. For sentences #4,5, REVERB and WOE<sup>parse</sup> have an incorrect extraction by ignoring the context that OLLIE explicitly represents.

analyzing their corpus is the *discovery* of important relations, which are likely not pre-specified. Open IE (Banko et al., 2007) is the state-of-the-art approach for such scenarios.

However, the state-of-the-art Open IE systems, REVERB (Fader et al., 2011; Etzioni et al., 2011) and WOE<sup>parse</sup> (Wu and Weld, 2010) suffer from two key drawbacks. Firstly, they handle a limited subset of sentence constructions for expressing relationships. Both extract only relations that are mediated by verbs, and REVERB further restricts this to a subset of verbal patterns. This misses important information mediated via other syntactic entities such as nouns and adjectives, as well as a wider range of verbal structures (examples #1-3 in Figure 1).

Secondly, REVERB and  $WOE^{parse}$  perform only a local analysis of a sentence, so they often extract relations that are not asserted as factual in the sentence (examples #4,5). This often occurs when the relation is within a belief, attribution, hypothetical or other conditional context.

In this paper we present OLLIE (Open Language Learning for Information Extraction),<sup>1</sup> our novel Open IE system that overcomes the limitations of previous Open IE by (1) expanding the syntactic scope of relation phrases to cover a much larger number of relation expressions, and (2) expanding the Open IE representation to allow additional context information such as attribution and clausal modifiers. OLLIE extractions obtain a dramatically higher yield at higher or comparable precision relative to existing systems.

The outline of the paper is as follows. First, we provide background on Open IE and how it relates to Semantic Role Labeling (SRL). Section 3 describes the syntactic scope expansion component, which is based on a novel approach that learns *open pattern templates*. These are relation-independent dependency parse-tree patterns that are automatically learned using a novel bootstrapped training set. Section 4 discusses the *context analysis* component, which is based on supervised training with linguistic and lexical features.

Section 5 compares OLLIE with REVERB and  $WOE^{parse}$  on a dataset from three domains: News, Wikipedia, and a Biology textbook. We find that OLLIE obtains 2.7 times the area in precision-yield curves (AUC) as REVERB and 1.9 times the AUC as  $WOE^{parse}$ . Moreover, for specific relations commonly mediated by nouns (*e.g.*, ‘is the president of’) OLLIE obtains two order of magnitude higher yield. We also compare OLLIE to a state-of-the-art SRL system (Johansson and Nugues, 2008) on an IE-related end task and find that they both have comparable performance at argument identification and have complimentary strengths in sentence analysis. In Section 6 we discuss related work on pattern-based relation extraction.

## 2 Background

*Open IE* systems extract tuples consisting of argument phrases from the input sentence and a phrase

from the sentence that expresses a relation between the arguments, in the format (arg1; rel; arg2). This is done without a pre-specified set of relations and with no domain-specific knowledge engineering. We compare OLLIE to two state-of-the-art Open IE systems: (1) REVERB (Fader et al., 2011), which uses shallow syntactic processing to identify relation phrases that begin with a verb and occur between the argument phrases;<sup>2</sup> (2)  $WOE^{parse}$  (Wu and Weld, 2010), which uses bootstrapping from entries in Wikipedia info-boxes to learn extraction patterns in dependency parses. Like REVERB, the relation phrases begin with verbs, but can handle long-range dependencies and relation phrases that do not come between the arguments. Unlike REVERB,  $WOE$  does not include nouns within the relation phrases (*e.g.*, cannot represent ‘is the president of’ relation phrase). Both systems ignore context around the extracted relations that may indicate whether it is a supposition or conditionally true rather than asserted as factual (see #4-5 in Figure 1).

The task of *Semantic role labeling* is to identify arguments of verbs in a sentence, and then to classify the arguments by mapping the verb to a semantic frame and mapping the argument phrases to roles in that frame, such as agent, patient, instrument, or benefactive. SRL systems can also identify and classify arguments of relations that are mediated by nouns when trained on NomBank annotations. Where SRL begins with a verb or noun and then looks for arguments that play roles with respect to that verb or noun, Open IE looks for a phrase that expresses a relation between a pair of arguments. That phrase is often more than simply a single verb, such as the phrase ‘plays a role in’, or ‘is the CEO of’.

## 3 Relational Extraction in OLLIE

Figure 2 illustrates OLLIE’s architecture for learning and applying binary extraction patterns. First, it uses a set of high precision seed tuples from REVERB to bootstrap a large training set. Second, it learns *open pattern templates* over this training set. Next, OLLIE applies these pattern templates at extraction time. This section describes these three steps in detail. Finally, OLLIE analyzes the context around the tuple (Section 4) to add information (attribution, clausal modifiers) and a confidence function.

<sup>1</sup>Available for download at <http://openie.cs.washington.edu>

<sup>2</sup>Available for download at <http://reverb.cs.washington.edu/>

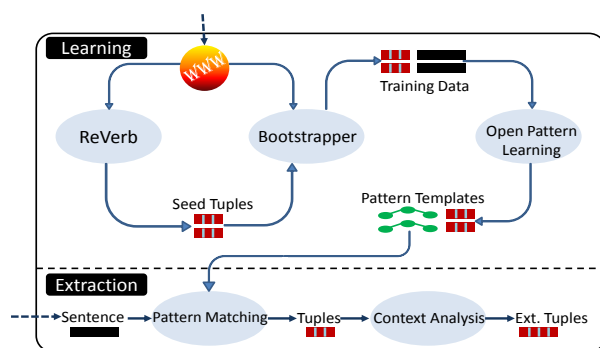

Figure 2: System architecture: OLLIE begins with seed tuples from REVERB, uses them to build a bootstrap training set, and learns open pattern templates. These are applied to individual sentences at extraction time.

### 3.1 Constructing a Bootstrapping Set

Our goal is to automatically create a large training set, which encapsulates the multitudes of ways in which information is expressed in text. The key observation is that almost every relation can also be expressed via a REVERB-style verb-based expression. So, bootstrapping sentences based on REVERB’s tuples will likely capture all relation expressions.

We start with over 110,000 seed tuples – these are high confidence REVERB extractions from a large Web corpus (ClueWeb)<sup>3</sup> that are asserted at least twice and contain only proper nouns in the arguments. These restrictions reduce ambiguity while still covering a broad range of relations. For example, a seed tuple may be (Paul Annacone; is the coach of; Federer) that REVERB extracts from the sentence “Paul Annacone is the coach of Federer.”

For each seed tuple, we retrieve all sentences in a Web corpus that contains all content words in the tuple. We obtain a total of 18 million sentences. For our example, we will retrieve all sentences that contain ‘Federer’, ‘Paul’, ‘Annacone’ and some syntactic variation of ‘coach’. We may find sentences like “Now coached by Annacone, Federer is winning more titles than ever.”

Our bootstrapping hypothesis assumes that all these sentences express the information of the original seed tuple. This hypothesis is not always true. As an example, for a seed tuple (Boyle; is born in; Ireland) we may retrieve a sentence “Felix G. Wharton was born in Donegal, in the northwest of Ireland, a county where the Boyles did their schooling.”

<sup>3</sup><http://lemurproject.org/clueweb09.php/>

To reduce bootstrapping errors we enforce additional dependency restrictions on the sentences. We only allow sentences where the content words from arguments and relation can be linked to each other via a linear path of size four in the dependency parse. To implement this restriction, we only use the subset of content words that are headwords in the parse tree. In the above sentence ‘Ireland’, ‘Boyle’ and ‘born’ connect via a dependency path of length six, and hence this sentence is rejected from the training set. This reduces our set to 4 million (seed tuple, sentence) pairs.

In our implementation, we use Malt Dependency Parser (Nivre and Nilsson, 2004) for dependency parsing, since it is fast and hence, easily applicable to a large corpus of sentences. We post-process the parses using Stanford’s CCprocessed algorithm, which compacts the parse structure for easier extraction (de Marneffe et al., 2006).

We randomly sampled 100 sentences from our bootstrapping set and found that 90 of them satisfy our bootstrapping hypothesis (64 without dependency constraints). We find this quality to be satisfactory for our needs of learning general patterns.

Bootstrapped data has been previously used to generate positive training data for IE (Hoffmann et al., 2010; Mintz et al., 2009). However, previous systems retrieved sentences that only matched the two arguments, which is error-prone, since multiple relations can hold between a pair of entities (*e.g.*, Bill Gates is the CEO of, a co-founder of, and has a high stake in Microsoft).

Alternatively, researchers have developed sophisticated probabilistic models to alleviate the effect of noisy data (Riedel et al., 2010; Hoffmann et al., 2011). In our case, by enforcing that a sentence additionally contains some syntactic form of the relation content words, our bootstrapping set is naturally much cleaner.

Moreover, this form of bootstrapping is better suited for Open IE’s needs, as we will use this data to generalize to other unseen relations. Since the relation words in the sentence and seed match, we can learn general pattern templates that may apply to other relations too. We discuss this process next.

### 3.2 Open Pattern Learning

OLLIE’s next step is to learn general patterns that encode various ways of expressing relations. OL-

Extraction Template	Open Pattern
1. (arg1; be {rel} {prep}; arg2)	{arg1} ↑nsubjpass↑ {rel:postag=VBN} ↓{prep_*}↓ {arg2}
2. (arg1; {rel}; arg2)	{arg1} ↑nsubj↑ {rel:postag=VBD} ↓dobj↓ {arg2}
3. (arg1; be {rel} by; arg2)	{arg1} ↑nsubjpass↑ {rel:postag=VBN} ↓agent↓ {arg2}
4. (arg1; be {rel} of; arg2)	{rel:postag=NN; <b>type=Person</b> } ↑nn↑ {arg1} ↓nn↓ {arg2}
5. (arg1; be {rel} {prep}; arg2)	{arg1} ↑nsubjpass↑ {slot:postag=VBN; <b>lex ∈ announce name choose...</b> } ↓dobj↓ {rel:postag=NN} ↓{prep_*}↓ {arg2}

Figure 3: Sample open pattern templates. Notice that some patterns (1-3) are purely syntactic, and others are semantic/lexically constrained (in bold font). A dependency parse that matches pattern #1 is shown in Figure 4.

LIE learns *open pattern templates* – a mapping from a dependency path to an open extraction, *i.e.*, one that identifies both the arguments and the exact (REVERB-style) relation phrase. Figure 3 gives examples of high-frequency pattern templates learned by OLLIE. Note that some of the dependency paths are completely unlexicalized (#1-3), whereas in other cases some nodes have lexical or semantic restrictions (#4, 5).

Open pattern templates encode the ways in which a relation (in the first column) may be expressed in a sentence (second column). For example, a relation (Godse; kill; Gandhi) may be expressed with a dependency path (#2) {Godse}↑nsubj↑{kill:postag=VBD}↓dobj↓{Gandhi}.

To learn the pattern templates, we first extract the dependency path connecting the arguments and relation words for each seed tuple and the associated sentence. We annotate the relation node in the path with the exact relation word (as a lexical constraint) and the POS (postag constraint). We create a relation template from the seed tuple by normalizing ‘is’/‘was’/‘will be’ to ‘be’, and replacing the relation content word with {rel}.<sup>4</sup>

If the dependency path has a node that is not part of the seed tuple, we call it a *slot* node. Intuitively, if slot words do not negate the tuple they can be skipped over. As an example, ‘hired’ is a slot word for the tuple (Annacone; is the coach of; Federer) in the sentence “Federer hired Annacone as a coach”. We associate postag and lexical constraints with the slot node as well. (see #5 in Figure 3).

Next, we perform several syntactic checks on each candidate pattern. These checks are the constraints that we found to hold in very general patterns, which we can safely generalize to other unseen relations. The checks are: (1) There are no slot

nodes in the path. (2) The relation node is in the middle of arg1 and arg2. (3) The preposition edge (if any) in the pattern matches the preposition in the relation. (4) The path has no *nn* or *amod* edges.

If the checks hold true we accept it as a purely *syntactic pattern* with no lexical constraints. Others are *semantic/lexical patterns* and require further constraints to be reliable as extraction patterns.

### 3.2.1 Purely Syntactic Patterns

For syntactic patterns, we aggressively generalize to unseen relations and prepositions. We remove all lexical restrictions from the relation nodes. We convert all preposition edges to an abstract {prep\_\*} edge. We also replace the specific prepositions in extraction templates with {prep}.

As an example, consider the sentences, “Michael Webb appeared on Oprah...” and “...when Alexander the Great advanced to Babylon.” and associated seed tuples (Michael Webb; appear on; Oprah) and (Alexander; advance to; Babylon). Both these data points return the same open pattern after generalization: “{arg1} ↑nsubj↑ {rel:postag=VBD} ↓{prep\_\*}↓ {arg2}” with the extraction template (arg1, {rel} {prep}, arg2). Other examples of syntactic pattern templates are #1-3 in Figure 3.

### 3.2.2 Semantic/Lexical Patterns

Patterns that do not satisfy the checks are not as general as those that do, but are still important. Constructions like “Microsoft co-founder Bill Gates...” work for some relation words (*e.g.*, founder, CEO, director, president, *etc.*) but would not work for other nouns; for instance, from “Chicago Symphony Orchestra” we should not conclude that (Orchestra; is the Symphony of; Chicago).

Similarly, we may conclude (Annacone; is the coach of; Federer) from the sentence “Federer hired Annacone as a coach.”, but this depends on the semantics of the slot word, ‘hired’. If we replaced

<sup>4</sup>Our current implementation only allows a single relation content word; extending to multiple words is straightforward – the templates will require rel1, rel2,...

‘hired’ by ‘fired’ or ‘considered’ then the extraction would be false.

To enable such patterns we retain the lexical constraints on the relation words and slot words.<sup>5</sup> We collect all patterns together based only on the syntactic restrictions and convert the lexical constraint into a list of words with which the pattern was seen. Example #5 in Figure 3 shows one such lexical list.

Can we generalize these lexically-annotated patterns further? Our insight is that we can generalize a list of lexical items to other similar words. For example, if we see a list like {CEO, director, president, founder}, then we should be able to generalize to ‘chairman’ or ‘minister’.

Several ways to compute semantically similar words have been suggested in the literature like Wordnet-based, distributional similarity, *etc.* (e.g., (Resnik, 1996; Dagan et al., 1999; Ritter et al., 2010)). For our proof of concept, we use a simple overlap metric with two important Wordnet classes – Person and Location. We generalize to these types when our list has a high overlap (> 75%) with hyponyms of these classes. If not, we simply retain the original lexical list without generalization. Example #4 in Figure 3 is a type-generalized pattern.

We combine all syntactic and semantic patterns and sort in descending order based on frequency of occurrence in the training set. This imposes a natural ranking on the patterns – more frequent patterns are likely to give higher precision extractions.

### 3.3 Pattern Matching for Extraction

We now describe how these open patterns are used to extract binary relations from a new sentence. We first match the open patterns with the dependency parse of the sentence and identify the base nodes for arguments and relations. We then expand these to convey all the information relevant to the extraction.

As an example, consider the sentence: “I learned that the 2012 Sasquatch music festival is scheduled for May 25th until May 28th.” Figure 4 illustrates the dependency parse. To apply pattern #1 from Figure 3 we first match arg1 to ‘festival’, rel to ‘scheduled’ and arg2 to ‘25th’ with prep ‘for’. However, (festival, be scheduled for, 25th) is not a very meaningful extraction. We need to expand this further.

<sup>5</sup>For highest precision extractions, we may also need semantic constraints on the arguments. In this work, we increase our yield by ignoring the argument-type constraints.

Figure 4: A sample dependency parse. The colored/greyed nodes represent all words that are extracted from the pattern {arg1} ↑subjpas↑ {rel:postag=VBN} ↓{prep\_\*}↓ {arg2}. The extraction is (the 2012 Sasquatch Music Festival; is scheduled for; May 25th).

For the arguments we expand on *amod*, *nn*, *det*, *neg*, *prep\_of*, *num*, *quantmod* edges to build the noun-phrase. When the base noun is not a proper noun, we also expand on *rcmod*, *infmod*, *partmod*, *ref*, *prepc\_of* edges, since these are relative clauses that convey important information. For relation phrases, we expand on *advmod*, *mod*, *aux*, *auxpass*, *cop*, *prt* edges. We also include *dobj* and *iobj* in the case that they are not in an argument. After identifying the words in arg/relation we choose their order as in the original sentence. For example, these rules will result in the extraction (the Sasquatch music festival; be scheduled for; May 25th).

### 3.4 Comparison with WOE<sup>parse</sup>

OLLIE’s algorithm is similar to that of WOE<sup>parse</sup> – both systems follow the basic structure of bootstrap learning of patterns based on dependency parse paths. However, there are three significant differences. WOE uses Wikipedia-based bootstrapping, finding a sentence in a Wikipedia article that contains the infobox values. Since WOE does not have access to a seed relation phrase, it heuristically assigns all intervening words between the arguments in the parse as the relation phrase. This often results in under-specified or nonsensical relation phrases. For example, from the sentence “David Miscavige learned that after Tom Cruise divorced Mimi Rogers, he was pursuing Nicole Kidman.” WOE’s heuristics will extract the relation *divorced was pursuing* between ‘Tom Cruise’ and ‘Nicole Kidman’. OLLIE, in contrast, produces well-formed relation phrases by basing its templates on REVERB relation phrases.

Secondly, WOE does not assign semantic/lexical restrictions to its patterns, and thus, has lower precision due to aggressive syntactic generalization. Finally, WOE is designed to have verb-mediated rela-

tion phrases that do not include nouns, thus missing important relations such as ‘is the president of’. In our experiments (see Figure 5) we find  $WOE^{parse}$  to have lower precision and yield than OLLIE.

#### 4 Context Analysis in OLLIE

We now turn to the context analysis component, which handles the problem of extractions that are not asserted as factual in the text. In some cases, OLLIE can handle this by extending the tuple representation with an extra field that turns an otherwise incorrect tuple into a correct one. In other cases, there is no reliable way to salvage the extraction, and OLLIE can avoid an error by giving the tuple a low confidence.

Cases where OLLIE extends the tuple representation include conditional truth and attribution. Consider sentence #4 in Figure 1. It is not asserting that the earth is the center of the universe. OLLIE adds an *AttributedTo* field, which makes the final extraction valid (see OLLIE extraction in Figure 1). This field indicates who said, suggested, believes, hopes, or doubts the information in the main extraction.

Another case is when the extraction is only conditionally true. Sentence #5 in Figure 1 does not assert as factual that (Romney; will be elected; President), so it is an incorrect extraction. However, adding a condition (“if he wins five states”) can turn this into a correct extraction. We extend OLLIE to have a *ClausalModifier* field when there is a dependent clause that modifies the main extraction.

Our approach for extracting these additional fields makes use of the dependency parse structure. We find that attributions are marked by a *ccomp* (clausal complement) edge. For example, in the parse of sentence #4 there is a *ccomp* edge between ‘believe’ and ‘center’. Our algorithm first checks for the presence of a *ccomp* edge to the relation node. However, not all *ccomp* edges are attributions. We match the context verb (e.g., ‘believe’) with a list of communication and cognition verbs from VerbNet (Schuler, 2006) to detect attributions. The context verb and its subject then populate the *AttributedTo* field.

Similarly, the clausal modifiers are marked by *advcl* (adverbial clause) edge. We filter these lexically, and add a *ClausalModifier* field when the first word of the clause matches a list of 16 terms created using a training set: {if, when, although, because, ...}.

OLLIE has high precision for *AttributedTo* and

*ClausalModifier* fields, nearly 98% on a development set, however, these two fields do not cover all the cases where an extraction is not asserted as factual. To handle others, we train OLLIE’s confidence function to reduce the confidence of an extraction if its context indicates it is likely to be non-factual.

We use a supervised logistic regression classifier for the confidence function. Features include the frequency of the extraction pattern, the presence of *AttributedTo* or *ClausalModifier* fields, and the position of certain words in the extraction’s context, such as function words or the communication and cognition verbs used for the *AttributedTo* field. For example, one highly predictive feature tests whether or not the word ‘if’ comes before the extraction when no *ClausalModifier* fields are attached. Our training set was 1000 extractions drawn evenly from Wikipedia, News, and Biology sentences.

#### 5 Experiments

Our experiments evaluate three main questions. (1) How does OLLIE’s performance compare with existing state-of-the-art open extractors? (2) What are the contributions of the different sub-components within OLLIE? (3) How do OLLIE’s extractions compare with semantic role labeling argument identification?

##### 5.1 Comparison of Open IE Systems

Since Open IE is designed to handle a variety of domains, we create a dataset of 300 random sentences from three sources: News, Wikipedia and Biology textbook. The News and Wikipedia test sets are a random subset of Wu and Weld’s test set for  $WOE^{parse}$ . We ran three systems, OLLIE, REVERB and  $WOE^{parse}$  on this dataset resulting in a total of 1,945 extractions from all three systems. Two annotators tagged the extractions as correct if the sentence asserted or implied that the relation was true. Inter-annotator agreement was 0.96, and we retained the subset of extractions on which the two annotators agree for further analysis.

All systems associate a confidence value with an extraction – ranking with these confidence values generates a precision-yield curve for this dataset. Figure 5 reports the curves for the three systems.

We find that OLLIE has a higher performance, owing primarily to its higher yield at comparable preci-

Figure 5: Comparison of different Open IE systems. OLLIE achieves substantially larger area under the curve than other Open IE systems.

sion. OLLIE finds 4.4 times more correct extractions than REVERB and 4.8 times more than  $WOE^{parse}$  at a precision of about 0.75. Overall, OLLIE has 2.7 times larger area under the curve than REVERB and 1.9 times larger than  $WOE^{parse}$ .<sup>6</sup> We use the Bootstrap test (Cohen, 1995) to find that OLLIE’s better performance compared to the two systems is highly statistically significant.

We perform further analysis to understand the reasons behind the high yield from OLLIE. We find that 40% of the OLLIE extractions that REVERB misses are due to OLLIE’s use of parsers – REVERB misses those because its shallow syntactic analysis cannot skip over the intervening clauses or prepositional phrases between the relation phrase and the arguments. About 30% of the additional yield is those extractions where the relation is not between its arguments (see instance #1 in Figure 1). The rest are due to other causes such as OLLIE’s ability to handle relationships mediated by nouns and adjectives, or REVERB’s shallow syntactic analysis, *etc.* In contrast, OLLIE misses very few extractions returned by REVERB, mostly due to parser errors.

We find that  $WOE^{parse}$  misses extractions found by OLLIE for a variety of reasons. The primary cause is that  $WOE^{parse}$  does not include nouns in relation phrases. It also misses some verb-based patterns, probably due to training noise. In other cases,  $WOE^{parse}$  misses extractions due to ill-formed relation phrases (as in the example of Section 3.4: ‘divorced was pursuing’ instead of the correct relation ‘was pursuing’).

While the bulk of OLLIE’s extractions in our test

<sup>6</sup>Evaluating recall is difficult at this scale – however, since yield is proportional to recall, the area differences also hold for the equivalent precision-recall curves.

Relation	OLLIE	REVERB	incr.
<i>is capital of</i>	8,566	146	59x
<i>is president of</i>	21,306	1,970	11x
<i>is professor at</i>	8,334	400	21x
<i>is scientist of</i>	730	5	146x

Figure 6: OLLIE finds many more correct extractions for relations that are typically expressed by noun phrases – up to 146 times that of REVERB.  $WOE^{parse}$  outputs no instances of these, because it does not allow nouns in the relation. These results are at point of maximum yield (with comparable precisions around 0.66).

set were verb-mediated, our intuition suggests that there exist many relationships that are most naturally expressed via noun phrases. To demonstrate this effect, we chose four such relations – *is capital of*, *is president of*, *is professor at*, and *is scientist of*. We ran our systems on 100 million random sentences from the ClueWeb corpus. Figure 6 reports the yields of these four relations.<sup>7</sup>

OLLIE found up to 146 times as many extractions for these relations than REVERB. Because  $WOE^{parse}$  does not include nouns in relation phrases, it is unable to extract any instance of these relations. We examine a sample of the extractions to verify that noun-mediated extractions are the main reason for this large yield boost over REVERB (73% of OLLIE extractions were noun-mediated). High-frequency noun patterns like “Obama, the president of the US”, “Obama, the US president”, “US President Obama” far outnumber sentences of the form “Obama is the president of the US”. These relations are seldom the primary information in a sentence, and are typically mentioned in passing in noun phrases that express the relation.

For some applications, noun-mediated relations are important, as they associate people with work places and job titles. Overall, we think of the results in Figure 6 as a “best case analysis” that illustrates the dramatic increase in yield for certain relations, due to syntactic scope expansion in Open IE.

## 5.2 Analysis of OLLIE

We perform two control experiments to understand the value of semantic/lexical restrictions in pattern learning and precision boost due to context analysis component.

<sup>7</sup>We multiply the total number of extractions with precision on a sample for that relation to estimate the yield.

Figure 7: Results on the subset of extractions from patterns with semantic/lexical restrictions. Ablation study on patterns with semantic/lexical restrictions. These patterns without restrictions (OLLIE[syn]) result in low precision. Type generalization improves yield compared to patterns with only lexical constraints (OLLIE[lex]).

Are semantic restrictions important for open pattern learning? How much does type generalization help? To answer these questions we compare three systems – OLLIE without semantic or lexical restrictions (OLLIE[syn]), OLLIE with lexical restrictions but no type generalization (OLLIE[lex]) and the full system (OLLIE). We restrict this experiment to the patterns where OLLIE adds semantic/lexical restrictions, rather than dilute the result with patterns that would be unchanged by these variants.

Figure 7 shows the results of this experiment on our dataset from three domains. As the curves show, OLLIE was correct to add lexical/semantic constraints to these patterns – precision is quite low without the restrictions. This matches our intuition, since these are not completely general patterns and generalizing to all unseen relations results in a large number of errors. OLLIE[lex] performs well though at lower yield. The type generalization helps the yield somewhat, without hurting the precision. We believe that a more data-driven type generalization that uses distributional similarity (*e.g.*, (Ritter et al., 2010)) may help much more. Also, notice that overall precision numbers are lower, since these are the more difficult relations to extract reliably. We conclude that lexical/semantic restrictions are valuable for good performance of OLLIE.

We also compare our full system to a version that does not use the context analysis of Section 4. Figure 8 compares OLLIE to a version (OLLIE[pat]) that does not add the `AttributedTo` and `ClausalModifier` fields, and, instead of context-sensitive confidence function, uses the pattern frequency in the training

Figure 8: Context analysis increases precision, raising the area under the curve by 19%.

set as a ranking function. 10% of the sentences have an OLLIE extraction with `ClausalModifier` and 6% have `AttributedTo` fields. Adding `ClausalModifier` corrects errors for 21% of extractions that have a `ClausalModifier` and does not introduce any new errors. Adding `AttributedTo` corrects errors for 55% of the extractions with `AttributedTo` and introduces an error for 3% of the extractions. Overall, we find that OLLIE gives a significant boost to precision over OLLIE[pat] and obtains 19% additional AUC.

Finally, we analyze the errors made by OLLIE. Unsurprisingly, because of OLLIE’s heavy reliance on the parsers, parser errors account for a large part of OLLIE’s errors (32%). 18% of the errors are due to aggressive generalization of a pattern to all unseen relations and 12% due to incorrect application of lexically annotated patterns. About 14% of the errors are due to important context missed by OLLIE. Another 12% of the errors are because of the limitations of binary representation, which misses important information that can only be expressed in n-ary tuples.

We believe that as parsers become more robust OLLIE’s performance will improve even further. The presence of context-related errors suggests that there is more to investigate in context analysis. Finally, in the future we wish to extend the representation to include n-ary extractions.

### 5.3 Comparison with SRL

Our final evaluation suggests answers to two important questions. First, how does a state-of-the-art Open IE system do in terms of absolute recall? Second, how do Open IE systems compare against state-of-the-art SRL systems?

SRL, as discussed in Section 2, has a very different goal – analyzing verbs and nouns to identify

their arguments, then mapping the verb or noun to a semantic frame and determining the role that each argument plays in that frame. These verbs and nouns need not make the full relation phrase, although, recent work has shown that they may be converted to Open IE style extractions with additional post-processing (Christensen et al., 2011).

While a direct comparison between OLLIE and a full SRL system is problematic, we can compare performance of OLLIE and the argument identification step of an SRL system. We set each system the following task – “based on a sentence, find all noun-pairs that have an asserted relationship.” This task is permissive for both systems, as it does not require finding an exact relation phrase or argument boundary, or determining the argument roles in a relation.

We create a gold standard by tagging a random 50 sentences of our test set to identify all pairs of NPs that have an asserted relation. We only counted relation expressed by a verb or noun in the text, and did not include relations expressed simply with “of” or apostrophe-s. Where a verb mediates between an argument and multiple NPs, we represent this as a binary relation for all pairs of NPs.

For example the sentence, “Macromolecules translocated through the phloem include proteins and various types of RNA that enter the sieve tubes through plasmodesmata.” has five binary relations.

arg1:	arg2:	relation term
Macromolecules	phloem	translocated
Macromolecules	proteins	include
Macromolecules	types of RNA	include
types of RNA	sieve tubes	enter
types of RNA	plasmodesmata	enter

We find an average of 4.0 verb-mediated relations and 0.3 noun-mediated relations per sentence. Evaluating OLLIE against this gold standard helps to answer the question of absolute recall: what percentage of binary relations expressed in a sentence can our systems identify.

For comparison, we use a state-of-the-art SRL system from Lund University (Johansson and Nugues, 2008), which is trained on PropBank (Martha and Palmer, 2002) for its verb-frames and NomBank (Meyers et al., 2004) for noun-frames. The PropBank version of the system won the very competitive 2008 CONLL SRL evaluation.

We conduct this experiment by manually compar-

	LUND	OLLIE	union
Verb relations	0.58 (0.69)	0.49 (0.55)	0.71 (0.83)
Noun relations	0.07 (0.33)	0.13 (0.13)	0.20 (0.33)
All relations	0.54 (0.67)	0.47 (0.52)	0.67 (0.80)

Figure 9: Recall of LUND and OLLIE on binary relations. In parentheses is recall with oracle co-reference. Both systems identify approximately half of all argument pairs, but have lower recall on noun-mediated relations.

ing the outputs of LUND and OLLIE against the gold standard. For each pair of NPs in the gold standard we determine whether the systems find a relation with that pair of NPs as arguments. Recall is based on the percentage of NP pairs where the head nouns matches head nouns of two different arguments in an extraction or semantic frame. If the argument value is conjunctive, we count a match against the head noun of each item in the list. We also count cases where system output would match the gold standard, given perfect co-reference.

Figure 9 shows the recall for OLLIE and LUND, with recall based on oracle co-referential matches in parentheses. Our analysis shows strong recall for both systems for verb-mediated relations: LUND finding about two thirds of the argument pairs and OLLIE finding over half. Both systems have low recall for noun-mediated relations, with most of LUND’s recall requiring co-reference. We observe that a union of the two systems raises recall to 0.71 for verb-mediated relations and 0.83 with co-reference, demonstrating that each system is identifying argument pairs that the other missed.

It is not surprising that OLLIE has recall of approximately 0.5, since it is tuned for high precision extraction, and avoids less reliable extractions from constructions such as reduced relative clauses and gerunds, or from noun-mediated relations with long-range dependencies. In contrast, SRL is tuned to identify the argument structure for nearly all verbs and nouns in a sentence. The missing recall from SRL is primarily where it does not identify both arguments of a binary relation, or where the correct argument is buried in a long argument phrase, but is not its head noun.

It is surprising that LUND, trained on NomBank, identifies so few noun-mediated argument pairs without co-reference. An example will make this clear. For the sentence, “Clarcor, a maker of packaging and filtration products, said ...”, the tar-

get relation is between Clarcor and the products it makes. LUND identifies a frame *maker.01* in which argument A0 has head noun ‘maker’ and A1 is a PP headed by ‘products’, missing the actual name of the maker without co-reference post-processing. OLLIE finds the extraction (Clarcor; be a maker of; packaging and filtration products) where the heads of both arguments matched those of the target. In another example, LUND identifies “his” and “brother” as the arguments of the frame *brother.01*, rather than the actual names of the two brothers.

We can draw several conclusions from this experiment. First, nouns, although less frequently mediating relations, are much harder and both systems are failing significantly on those – OLLIE is somewhat better. Two, neither system dominates the other; in fact, recall is increased significantly by a union of the two. Three, and probably most importantly, significant information is still being missed by both systems, and more research is warranted.

## 6 Related Work

There is a long history of bootstrapping and pattern learning approaches in traditional information extraction, *e.g.*, DIPRE (Brin, 1998), SnowBall (Agichtein and Gravano, 2000), Espresso (Pantel and Pennacchiotti, 2006), PORE (Wang et al., 2007), SOFIE (Suchanek et al., 2009), NELL (Carlson et al., 2010), and PROSPERA (Nakashole et al., 2011). All these approaches first bootstrap data based on seed instances of a relation (or seed data from existing resources such as Wikipedia) and then learn lexical or lexico-POS patterns to create an extractor. Other approaches have extended these to learning patterns based on full syntactic analysis of a sentence (Bunescu and Mooney, 2005; Suchanek et al., 2006; Zhao and Grishman, 2005).

OLLIE has significant differences from the previous work in pattern learning. First, and most importantly, these previous systems learn an extractor for each relation of interest, whereas OLLIE is an open extractor. OLLIE’s strength is its ability to generalize from one relation to many other relations that are expressed in similar forms. This happens both via syntactic generalization and type generalization of relation words (sections 3.2.1 and 3.2.2). This capability is essential as many relations in the test set are not even seen in the training set – in early exper-

iments we found that non-generalized pattern learning (equivalent to traditional IE) had significantly less yield at a slightly higher precision.

Secondly, previous systems begin with seeds that consist of a pair of entities, whereas we also include the content words from REVERB relations in our training seeds. This results in a much higher precision bootstrapping set and high rule precision while still allowing morphological variants that cover noun-mediated relations. A third difference is in the scale of the training – REVERB yields millions of training seeds, where previous systems had orders of magnitude less. This enables OLLIE to learn patterns with greater coverage.

The closest to our work is the pattern learning based open extractor *WOE<sup>parse</sup>*. Section 3.4 details the differences between the two extractors. Another extractor, StatSnowBall (Zhu et al., 2009), has an Open IE version, which learns general but shallow patterns. Preemptive IE (Shinyama and Sekine, 2006) is a paradigm related to Open IE that first groups documents based on pairwise vector clustering, then applies additional clustering to group entities based on document clusters. The clustering steps make it difficult for it to scale to large corpora.

## 7 Conclusions

Our work describes OLLIE, a novel Open IE extractor that makes two significant advances over the existing Open IE systems. First, it expands the syntactic scope of Open IE systems by identifying relationships mediated by nouns and adjectives. Our experiments found that for some relations this increases the number of correct extractions by two orders of magnitude. Second, by analyzing the context around an extraction, OLLIE is able to identify cases where the relation is not asserted as factual, but is hypothetical or conditionally true. OLLIE increases precision by reducing confidence in those extractions or by associating additional context in the extractions, in the form of attribution and clausal modifiers. Overall, OLLIE obtains 1.9 to 2.7 times more area under precision-yield curves compared to existing state-of-the-art open extractors. OLLIE is available for download at <http://openie.cs.washington.edu>.

## Abstract

Topic models are increasingly being used for text analysis tasks, often times replacing earlier semantic techniques such as latent semantic analysis. In this paper, we develop a novel adaptive topic model with the ability to adapt topics from both the previous segment and the parent document. For this proposed model, a Gibbs sampler is developed for doing posterior inference. Experimental results show that with topic adaptation, our model significantly improves over existing approaches in terms of perplexity, and is able to uncover clear sequential structure on, for example, Herman Melville's book "Moby Dick".

## 1 Introduction

Natural language text usually consists of topically structured and coherent components, such as groups of sentences that form paragraphs and groups of paragraphs that form sections. Topical coherence in documents facilitates readers' comprehension, and reflects the author's intended structure. Capturing this structural topical dependency should lead to improved topic modelling. It also seems reasonable to propose that text analysis tasks that involve the structure of a document, for instance, summarisation and segmentation, should also be improved by topic models that better model that structure.

Recently, topic models are increasingly being used for text analysis tasks such as summarisa-

tion (Arora and Ravindran, 2008) and segmentation (Misra et al., 2011; Eisenstein and Barzilay, 2008), often times replacing earlier semantic techniques such as latent semantic analysis (Deerwester et al., 1990). Topic models can be improved by better modelling the semantic aspects of text, for instance integrating collocations into the model (Johnson, 2010; Hardisty et al., 2010) or encouraging topics to be more semantically coherent (Newman et al., 2011) based on lexical coherence models (Newman et al., 2010), modelling the structural aspects of documents, for instance modelling a document as a set of segments (Du et al., 2010; Wang et al., 2011; Chen et al., 2009), or improving the underlying statistical methods (Teh et al., 2006; Wallach et al., 2009). Topic models, like statistical parsing methods, are using more sophisticated latent variable methods in order to model different aspects of these problems.

In this paper, we are interested in developing a new topic model which can take into account the structural topic dependency by following the higher level document subject structure, but we hope to retain the general flavour of topic models, where components (*e.g.*, sentences) can be a mixture of topics. Thus we need to depart from the earlier HMM style models, see, *e.g.*, (Blei and Moreno, 2001; Gruber et al., 2007). Inspired by the idea that documents usually exhibits internal structure (*e.g.*, (Wang et al., 2011)), in which semantically related units are clustered together to form semantically structural segments, we treat documents as sequences of segments (*e.g.*, sentences, paragraphs, sections, or chapters). In this way, we can model the topic correlation be-

\*This work was partially done when Du was at College of Engineering & Computer Science, the Australian National University when working together with Buntine and Jin there.

Figure 1: Different structural relationships for topics of sections in a 4-part document, hierarchical (H), sequential (S), both (B) or mixed (M).

tween the segments in a “bag of segments” fashion, *i.e.*, beyond the “bag of words” assumption, and reveal how topics evolve among segments.

Indeed, we were impressed by the improvement in perplexity obtained by the *segmented topic model* (STM) (Du et al., 2010), so we considered the problem of whether one can add sequence information into a structured topic model as well. Figure 1 illustrates the type of structural information being considered, where the vectors are some representation of the content. STM is represented by the hierarchical model. A strictly sequential model would seem unrealistic for some documents, for instance books. A topic model using the strictly sequential model was developed (Du et al., 2012) but it reportedly performs halfway between STM and LDA. In this paper, we develop an adaptive topic model to go beyond a strictly sequential model while allow some hierarchical influence. There are two possible hybrids, one called “mixed” has distinct breaks in the sequence, while the other called “both” overlays both sequence and hierarchy and there could be relative strengths associated with the arrows. We employ the “both” hybrid but use the relative strengths to adaptively allow it to approximate the “mixed” hybrid.

Research in Machine Learning and Natural Language Processing has attempted to model various topical dependencies. Some work considers structure within the sentence level by mixing hidden Markov models (HMMs) and topics on a word by word basis: the aspect HMM (Blei and Moreno, 2001) and the HMM-LDA model (Griffiths et al., 2005) that models both short-range syntactic dependencies and longer semantic dependencies. These

models operate at a finer level than we are considering at a segment (like paragraph or section) level. To make a tool like the HMM work at higher levels, one needs to make stronger assumptions, for instance assigning each sentence a single topic and then topic specific word models can be used: the hidden topic Markov model (Gruber et al., 2007) that models the transitional topic structure; a global model based on the generalised Mallows model (Chen et al., 2009), and a HMM based content model (Barzilay and Lee, 2004). Researchers have also considered time-series of topics: various kinds of dynamic topic models, following early work of (Blei and Lafferty, 2006), represent a collection as a sequence of sub-collections in epochs. Here, one is modelling the collections over broad epochs, not the structure of a single document that our model considers.

This paper is organised as follows. We first present background theory in Section 2. Then the new model is presented in Section 3, followed by Gibbs sampling theory and algorithm in Sections 4 and 5 respectively. Experiments are reported in Section 6 with a conclusion in Section 7.

## 2 Background

The basic topic model is first presented in Section 2.1, as a point of departure. In seeking to develop a general sequential topic model, we hope to go beyond a strictly sequential model and allow some hierarchical influence. This, however, presents two challenges: modelling and statistical inference. Hierarchical inference (and thus sequential inference) over probability vectors can be handled using the theory of hierarchical Poisson-Dirichlet processes (PDPs). This is presented in Section 2.2.

### 2.1 The LDA model

The benchmark model for topic modelling is latent Dirichlet allocation (LDA) (Blei et al., 2003), a latent variable model of documents. Documents are indexed by  $i$ , and words  $\vec{w}$  are observed data. The latent variables are  $\vec{\mu}_i$  (*the topic distribution* for a document) and  $\vec{z}$  (*the topic assignments* for observed words), and the model parameter of  $\vec{\phi}_k$ ’s (*word distributions*). These notation are later extended in Ta-

ble 1. The generative model is as follows:

$$\begin{aligned}\vec{\phi}_k &\sim \text{Dirichlet}_W(\vec{\gamma}) && \forall k \\ \vec{\mu}_i &\sim \text{Dirichlet}_K(\vec{\alpha}) && \forall i \\ z_{i,l} &\sim \text{Discrete}_K(\vec{\mu}_i) && \forall i, l \\ w_{i,l} &\sim \text{Discrete}_K(\vec{\phi}_{z_{i,l}}) && \forall i, l.\end{aligned}$$

$\text{Dirichlet}_K(\cdot)$  is a  $K$ -dimensional Dirichlet distribution. The hyper-parameter  $\vec{\gamma}$  is a Dirichlet prior on *word distributions* (i.e., a Dirichlet smoothing on the multinomial parameter  $\vec{\phi}_k$  (Blei et al., 2003)) and the Dirichlet prior  $\vec{\alpha}$  on topic distributions.

## 2.2 Hierarchical PDPs

A discrete probability vector  $\vec{\mu}$  of finite dimension  $K$  is sampled from some distribution  $F_\tau(\vec{\mu}_0)$  with a parameter set, say  $\tau$ , and is also dependent on a parent probability vector  $\vec{\mu}_0$  also of finite dimension  $K$ . Then a sample of size  $N$  is taken according to the probability vector  $\vec{\mu}$ , represented as  $\vec{z} \in \{1, \dots, K\}^N$ . This data is collected into counts  $\vec{n} = (n_1, \dots, n_K)$  where  $n_k$  is the number of data in  $\vec{z}$  with value  $k$  and  $\sum_k n_k = N$ . This situation is represented as follows:

$$\vec{\mu} \sim F_\tau(\vec{\mu}_0); \quad z_i \sim \text{Discrete}_K(\vec{\mu}) \text{ for } i = 1, \dots, N.$$

Commonly in topic modelling, the Dirichlet distribution is used for discrete probability vectors. In this case  $F_\tau(\vec{\mu}_0) \equiv \text{Dirichlet}_K(b\vec{\mu}_0)$ ,  $\tau \equiv (K, b)$  where  $b$  is the concentration parameter. Bayesian analysis yields a marginalised likelihood, after integrating out  $\vec{\mu}$ , of

$$p(\vec{z}|\tau, \vec{\mu}_0, \text{Dirichlet}) = \frac{\text{Beta}(\vec{n} + b\vec{\mu}_0)}{\text{Beta}(b\vec{\mu}_0)}, \quad (1)$$

where  $\text{Beta}(\cdot)$  is the vector valued function normalising the Dirichlet distribution. A problem here is that  $p(\vec{z}|b, \vec{\mu}_0)$  is an intractable function of  $\vec{\mu}_0$ .

Dirichlet processes and Poisson-Dirichlet processes alleviate this problem by using an auxiliary variable trick (Robert and Casella, 2004). That is, we introduce an *auxiliary variable* over which we also sample but do not need to record. The auxiliary variable is the *table count*<sup>1</sup> which is a  $t_k$  for each  $n_k$

<sup>1</sup>Based on the Chinese Restaurant analogy (Teh et al., 2006), each table has a dish, a data value, while data, the customer, is assigned to tables, and multiple tables can serve the same dish.

and it represents the number of “tables” over which the  $n_k$  “customers” are spread out. Thus the following constraints hold:

$$0 \leq t_k \leq n_k \quad \text{and} \quad t_k = 0 \text{ iff } n_k = 0. \quad (2)$$

When the distribution over probability vectors follows a Poisson-Dirichlet process which has two parameters  $\tau \equiv (a, b)$  and the parent distribution  $\vec{\mu}_0$ , then  $F_\tau(\vec{\mu}_0) \equiv \text{PDP}(a, b, \vec{\mu}_0)$ . Here  $a$  is the *discount parameter*,  $b$  the *concentration parameter* and  $\vec{\mu}_0$  the base measure. In this case Bayesian analysis yields an augmented marginalised likelihood (Buntine and Hutter, 2012), after integrating out  $\vec{\mu}$ , of

$$p(\vec{z}, \vec{t}|\tau, \vec{\mu}_0, \text{PDP}) = \frac{(b|a)_T}{(b)_N} \prod_k S_{t_k, a}^{n_k} (\mu_{0,k})^{t_k} \quad (3)$$

where  $T = \sum_k t_k$ ,  $(x|y)_N = \prod_{n=0}^{N-1} (x + ny)$  denotes the Pochhammer symbol,  $(x)_N = (x|1)_N$ , and  $S_{M,a}^N$  is a generalized Stirling number that is readily tabulated (Buntine and Hutter, 2012).

There are two fundamental things to notice about Equation (3). Positively, the term in  $\vec{\mu}_0$  takes the form of a multinomial likelihood, so we can propagate it up and perform inference on  $\vec{\mu}_0$  unencumbered by the functional mess of Equation (1). Thus Poisson-Dirichlet processes allow one to do Bayesian reasoning on hierarchies of probability vectors (Teh, 2006; Teh et al., 2006). Negatively, however, one needs to sample the auxiliary variables  $\vec{t}$  leading to some problems: The range of  $t_k$ ,  $\{0, \dots, n_k\}$ , is broad. Also, contributions from individual data  $z_i$  have been lost so the mixing of the MCMC can sometimes be slow. We confirmed these problems on our first implementation of the Adaptive Topic Model presented next in Section 3.

A further improvement on PDP sampling is achieved in (Chen et al., 2011), where another auxiliary variable is introduced, a so-called *table indicator*, that for each datum  $z_i$  indicates whether it is the “head of its table” (recall the  $n_k$  data are spread over  $t_k$  tables, each table has one and only one “head”). Let  $r_i = 1$  if  $z_i$  is the “head of its table,” and zero otherwise. According to this “table” logic, the number of tables for  $n_k$  must be the number of data  $z_i$  that are also head of table, so  $t_k = \sum_{i=1}^N 1_{z_i=k} 1_{r_i=1}$ . Moreover, given this definition, the first constraint of Equation (2) on  $t_k$  is

automatically satisfied. Finally, with  $t_k$  tables then there must be exactly  $t_k$  heads of table, and we are indifferent about which data are heads of table, thus

$$p(\vec{z}, \vec{r} | \tau, \vec{\mu}_0, \text{PDP}) = p(\vec{z}, \vec{t} | \tau, \vec{\mu}_0, \text{PDP}) \prod_k \binom{n_k}{t_k}^{-1}. \quad (4)$$

When using this marginalised likelihood in a Gibbs sampler, the  $z_i$  themselves are usually latent so also sampled, and we develop a blocked Gibbs sampler for  $(z_i, r_i)$ . Since  $\vec{r}$  only appears indirectly through the table counts  $\vec{t}$ , one does not need to store the  $\vec{r}$ , instead just resamples an  $r_i$  when needed according to the proportion  $t_w/n_w$  where  $z_i = w$ .

### 3 The proposed Adaptive Topic Model

In this section an adaptive topic model (AdaTM) is developed, a fully structured topic model, by using a PDP to simultaneously model the hierarchical and the sequential topic structures. Documents are assumed to be broken into a sequence of segments. Topic distributions are used to mimic the subjects of documents and subtopics of their segments. The notations and terminologies used in the following sections are given in Table 1.

In AdaTM, the two topic structures are captured by drawing topic distributions from the PDPs with two base distributions as follows. The document topic distribution  $\vec{\mu}_i$  and the  $j^{\text{th}}$  segment topic dis-

Table 1: List of notation for AdaTM

$K$	number of topics
$I$	number of documents
$J_i$	number of segments in document $i$
$L_{i,j}$	number of words in document $i$ , segment $j$
$W$	number of words in dictionary
$\vec{\mu}_i$	document topic probabilities for document $i$
$\vec{\alpha}$	$K$ -dimensional prior for each $\vec{\mu}_i$
$\vec{v}_{i,j}$	segment topic probabilities for document $i$ and segment $j$
$\rho_{i,j}$	mixture weight associating with the link between $\vec{v}_{i,j}$ and $\vec{v}_{i,j-1}$
$\vec{\Phi}$	word probability vectors as a $K \times W$ matrix
$\vec{\phi}_k$	word probability vector for topic $k$ , entries in $\vec{\Phi}$
$\vec{\gamma}$	$W$ -dimensional prior for each $\vec{\phi}_k$
$w_{i,j,l}$	word in document $i$ , segment $j$ , position $l$
$z_{i,j,l}$	topic for word $w_{i,j,l}$

Figure 2: The adaptive topic model:  $\vec{\mu}$  is the document topic distribution,  $\vec{v}_1, \vec{v}_2, \dots, \vec{v}_J$  are the segment topic distributions, and  $\vec{\rho}$  is a set of the mixture weights.

tribution  $\vec{v}_{i,j}$  are linearly combined to give a base distribution for the  $(j+1)^{\text{th}}$  segment's topic distribution  $\vec{v}_{i,j+1}$ . The topic distribution of the first segment, *i.e.*,  $\vec{v}_{i,1}$ , is drawn directly with the base distribution  $\vec{\mu}_i$ . Call this generative process *topic adaptation*. The graphical representation of AdaTM is shown in Figure 2, and clearly shows the combination of sequence and hierarchy for the topic probabilities. Note the linear combination at each node  $\vec{v}_{i,j}$  is weighted with latent proportions  $\rho_{i,j}$ .

The resultant model for AdaTM is:

$$\begin{aligned} \vec{\phi}_k &\sim \text{Dirichlet}_W(\vec{\gamma}) && \forall k \\ \vec{\mu}_i &\sim \text{Dirichlet}_K(\vec{\alpha}) && \forall i \\ \rho_{i,j} &\sim \text{Beta}(\lambda_S, \lambda_T) && \forall i, j \\ \vec{v}_{i,j} &\sim \text{PDP}(\rho_{i,j}\vec{v}_{i,j-1} + (1 - \rho_{i,j})\vec{\mu}_i, a, b) \\ z_{i,j,l} &\sim \text{Discrete}_K(\vec{v}_{i,j}) && \forall i, j, l \\ w_{i,j,l} &\sim \text{Discrete}_K(\vec{\phi}_{z_{i,j,l}}) && \forall i, j, l. \end{aligned}$$

For notational convenience, let  $\vec{v}_{i,0} = \vec{\mu}_i$ . Assume the dimensionality of the Dirichlet distribution (*i.e.*, the number of topics) is known and fixed, and word probabilities are parameterised with a  $K \times W$  matrix  $\vec{\Phi} = (\vec{\phi}_1, \dots, \vec{\phi}_K)$ .

### 4 Gibbs Sampling Formulation

Given observations and model parameters, computing the posterior distribution of latent variables is infeasible for AdaTM due to the intractable computa-

Table 2: List of statistics for AdaTM

$M_{i,k,w}$	the total number of words in document $i$ with dictionary index $w$ and being assigned to topic $k$
$M_{k,w}$	total $M_{i,k,w}$ for document $i$ , <i>i.e.</i> , $\sum_i M_{i,k,w}$
$\vec{M}_k$	vector of $W$ values $M_{k,w}$
$n_{i,j,k}$	topic count in document $i$ segment $j$ for topic $k$
$N_{i,j}$	topic total in document $i$ segment $j$ , <i>i.e.</i> , $\sum_{k=1}^K n_{i,j,k}$
$t_{i,j,k}$	table count in the CPR for document $i$ and paragraph $j$ , for topic $k$ that is inherited back to paragraph $j-1$ and $\vec{\mu}_{i,j-1}$ .
$s_{i,j,k}$	table count in the CPR for document $i$ and paragraph $j$ , for topic $k$ that is inherited back to the document and $\vec{\mu}_i$ .
$T_{i,j}$	total table count in the CRP for document $i$ and segment $j$ , equal to $\sum_{k=1}^K t_{i,j,k}$ .
$S_{i,j}$	total table count in the CRP for document $i$ and segment $j$ , equal to $\sum_{k=1}^K s_{i,j,k}$ .
$\vec{t}_{i,j}$	table count vector of $t_{i,j,k}$ 's for segment $j$ .
$\vec{s}_{i,j}$	table count vector of $s_{i,j,k}$ 's for segment $j$ .

tion of marginal probabilities. Therefore, we have to use approximate inference techniques. This section proposes a blocked Gibbs sampling algorithm based on methods from Chen et al. (2011). Table 2 lists all statistics needed in the algorithm. Note for easier understanding, terminologies of the Chinese Restaurant Process (Teh et al., 2006) will be used, *i.e.*, customers, dishes and restaurants, correspond to words, topics and segments respectively.

The first major complication, over the use of the hierarchical PDP and Equation (3) and the table indicator trick of Equation (4), is handling the linear combination of  $\rho_{i,j}\vec{\nu}_{i,j-1} + (1 - \rho_{i,j})\vec{\mu}_i$  used in the PDPs. We manage this as follows: First, Equation (3) shows that a contribution of the form  $(\mu_{0,k})^{t_k}$  results. In our case, this becomes

$$\prod_k (\rho_{i,j}\nu_{i,j-1,k} + (1 - \rho_{i,j})\mu_{i,k})^{t'_{i,j,k}}$$

where  $t'_{i,j,k}$  is the corresponding introduced auxiliary variable the table count which is involved with constraints on  $n_{i,j,k} + t_{i,j+1,k}$ , from Equation (2). To deal with this power of a sum, we break the counts  $t'_{i,j,k}$  into two parts, those that contribute to  $\vec{\nu}_{i,j-1}$  and those that contribute to  $\vec{\mu}_i$ . We call these parts  $t_{i,j,k}$  and  $s_{i,j,k}$  respectively. The product can then be

expanded and  $\rho_{i,j}$  integrated out. This yields:

$$\text{Beta}(S_{i,j} + \lambda_S, T_{i,j} + \lambda_T) \prod_k \nu_{i,j-1,k}^{t_{i,j,k}} \mu_{i,k}^{s_{i,j,k}}.$$

The powers  $\nu_{i,j-1,k}^{t_{i,j,k}}$  and  $\mu_{i,k}^{s_{i,j,k}}$  can then be pushed up to the next nodes in the PDP/Dirichlet hierarchy. Note the standard constraints and table indicators are also needed here.

The precise form of the table indicators needs to be considered as well since there is a hierarchy for them, and this is the second major complication in the model. As discussed in Chen et al. (2011), table indicators are not required to be recorded, instead, randomly sampled in Gibbs cycles. The table indicators when known can be used to reconstruct the table counts  $t_{i,j,k}$  and  $s_{i,j,k}$ , and are reconstructed by sampling from them. For now, denote the table indicators as  $u_{i,j,l}$  for word  $w_{i,j,l}$ .

To complete a formulation suitable for Gibbs sampling, we first compute the marginal distribution of the observations  $\vec{w}_{1:I,1:J}$  (words), the topic assignments  $\vec{z}_{1:I,1:J}$  and the table indicators  $\vec{u}_{1:I,1:J}$ . The Dirichlet integral is used to integrate out the document topic distributions  $\vec{\mu}_{1:I}$  and the topic-by-words matrix  $\vec{\Phi}$ , and the joint posterior distribution computed for a PDP is used to recursively marginalise out the segment topic distributions  $\vec{\nu}_{1:I,1:J}$ . With these variables marginalised out, we derive the following marginal distribution

$$p(\vec{z}_{1:I,1:J}, \vec{w}_{1:I,1:J}, \vec{u}_{1:I,1:J} \mid \vec{\alpha}, \vec{\gamma}, a, b) = \quad (5)$$

$$\prod_{i=1}^I \frac{\text{Beta}_K(\vec{\alpha} + \sum_{j=1}^{J_i} \vec{s}_{i,j})}{\text{Beta}_K(\vec{\alpha})} \prod_{k=1}^K \frac{\text{Beta}_W(\vec{\gamma} + \vec{M}_k)}{\text{Beta}_W(\vec{\gamma})} \prod_{i=1}^I \prod_{j=1}^{J_i} \text{Beta}(S_{i,j} + \lambda_S, T_{i,j} + \lambda_T) \frac{(b|a)^{T_{i,j} + S_{i,j}}}{(b)^{N_{i,j} + T_{i,j+1}}} \prod_{i=1}^I \prod_{j=1}^{J_i} \prod_{k=1}^K \left( \frac{(n_{i,j,k} + t_{i,j+1,k})}{(t_{i,j,k} + s_{i,j,k})} \right)^{-1} S_{t_{i,j,k} + s_{i,j,k}, a}^{n_{i,j,k} + t_{i,j+1,k}}.$$

And the following constraints apply:

$$t_{i,j,k} + s_{i,j,k} \leq n_{i,j,k} + t_{i,j+1,k}, \quad (6)$$

$$t_{i,j,k} + s_{i,j,k} = 0 \text{ iff } n_{i,j,k} + t_{i,j+1,k} = 0. \quad (7)$$

The first constraint falls out naturally when table indicators are used. For convenience of the formulas,

set  $t_{i,J_i+1,k} = 0$  (there is no  $J_i + 1$  segment) and  $t_{i,1,k} = 0$  (the first segment only uses  $\vec{\mu}_i$ ).

Now let us consider again the table indicators  $u_{i,j,l}$  for word  $w_{i,j,l}$ . If this word is in topic  $k$  at document  $i$  and segment  $j$ , then it contributes a count to  $n_{i,j,k}$ . It also indicates if it contributes a new table, or a count to  $t'_{i,j,k}$  for the PDP at this node. However, as we discussed above, this then contributes to either  $t_{i,j,k}$  or  $s_{i,j,k}$ . If it contributes to  $t_{i,j,k}$ , then it recurses up to contribute a data count to the PDP for document  $i$  segment  $j - 1$ . Thus it also needs a table indicator at that node. Consequently, the table indicator  $u_{i,j,l}$  for word  $w_{i,j,l}$  must specify whether it contributes a table to all PDP nodes reachable by it in the graph.

We define  $u_{i,j,l}$  specifically as  $u_{i,j,l} = (u_1, u_2)$  such that  $u_1 \in [-1, 0, 1]$  and  $u_2 \in [1, \dots, j]$ , where  $u_2$  indicates segment denoted by node  $v_j$  up to which  $w_{i,j,l}$  contributes a table. Given  $u_2$ ,  $u_1 = -1$  denotes  $w_{i,j,l}$  contributes a table count to  $s_{i,u_2,k}$  and  $t_{i,j',k}$  for  $u_2 < j' \leq j$ ;  $u_1 = 0$  denotes  $w_{i,j,l}$  does not contribute a table to node  $u_2$ , but contributes a table count to  $t_{i,j',k}$  for  $u_2 < j' \leq j$ ; and  $u_1 = 1$  denotes  $w_{i,j,l}$  contributes a table count to each  $t_{i,j',k}$  for  $u_2 \leq j' \leq j$ .

Now, we are ready to compute the conditional probabilities for jointly sampling topics and table indicators from the model posterior of Equation (5).

## 5 Gibbs Sampling Algorithm

The Gibbs sampler iterates over words, doing a blocked sample of  $(z_{i,j,l}, u_{i,j,l})$ . The first task is to reconstruct  $u_{i,j,l}$  since it is not stored. Since the posterior of Equation (5) does not explicitly mention the  $u_{i,j,l}$ 's, they occur indirectly through the table counts, and we can randomly reconstruct them by sampling them uniformly from the space of possibilities. Following this, we then remove the values  $(z_{i,j,l}, u_{i,j,l})$  from the full set of statistics. Finally, we block sample new values for  $(z_{i,j,l}, u_{i,j,l})$  and add them to the statistics. The new  $u_{i,j,l}$  is subsequently forgotten and the  $z_{i,j,l}$  recorded.

**Reconstructing table indicator  $u_{i,j,l}$ :** We start at the node indexed  $i, j$ . If  $s_{i,j,k} + t_{i,j,k} = 1$  and  $n_{i,j,k} + t_{i,j+1,k} > 1$  then no tables can be removed since there is only one table but several customers at the table. Thus  $u_{i,j,l} = (u_1, u_2) = (0, j)$  and there is no

sampling. Otherwise, by symmetry arguments, we sample  $u_1$  via

$$p(u_1 = -1, 0, 1 | u_2 = j, z_{i,j,l} = k) \propto (s_{i,j,k}, t_{i,j,k}, n_{i,j,k} + t_{i,j+1,k} - s_{i,j,k} - t_{i,j,k}),$$

since there are  $n_{i,j,k} + t_{i,j+1,k}$  data distributed across the three possibilities. If after sampling  $u_1 = -1$ , the data contributes a table count up to  $\vec{\mu}_i$  and so  $u_{i,j,l} = (u_1, u_2) = (-1, j)$ . If  $u_1 = 0$ , the  $u_{i,j,l} = (u_1, u_2) = (0, j)$ . Otherwise, the data contributes a table count up to the parent PDP for  $\vec{v}_{i,j-1}$  and we recurse, repeating the sampling process at the parent node. Note, however, that the table indicator  $(0, j')$  for  $j' < j$  is equivalent to the table indicator  $(1, j' + 1)$  as far as statistics is concerned.

**Block sampling  $(z_{i,j,l}, u_{i,j,l})$ :** The full set of possibilities are, for each possible topic  $z_{i,j,l} = k$ :

- no tables are created, so  $u_{i,j,l} = (0, j)$ ,
- tables are created contributing a table count all the way up to node  $j' (\leq j)$  but stop at  $j'$  and do not subsequently contribute a count to  $\vec{\mu}_i$ , so  $u_{i,j,l} = (1, j')$ ,
- tables are created contributing a table count all the way up to node  $j' \leq j$  but stop at  $j'$  and also subsequently contribute a count to  $\vec{\mu}_i$ , so  $u_{i,j,l} = (-1, j')$ .

These three possibilities lead to detailed but fairly straight forward changes to the posterior of Equation (5). Thus a full blocked sampler for  $(z_{i,j,l}, u_{i,j,l})$  can be constructed.

**Estimates:** learnt values of  $\vec{\mu}_i, \vec{v}_{i,j}, \vec{\phi}_k$  are needed for evaluation, perplexity calculations, *etc.* These are estimated by taking averages after the Gibbs sampler has burnt in, using the standard posterior means for Dirichlets and Poisson-Dirichlets.

## 6 Experiments

In the experimental work, we have three objectives: (1) to explore the setting of hyper-parameters, (2) to compare the model with the earlier sequential LDA (SeqLDA) of (Du et al., 2012), STM of (Du et al., 2010) and standard LDA, and (3) to view the results in detail on a number of characteristic problems.

Table 3: Datasets

	#docs	#segs	#words	vocab
Pat-A	500	51,748	2,146,464	16,573
Pat-B	397	9,123	417,631	7,663
Pat-G06	500	11,938	655,694	6,844
Pat-H	500	11,662	562,439	10,114
Pat-F	140	3,181	166,091	4,674
Prince-C	1	26	10,588	3,292
Prince-P	1	192	10,588	3,292
Moby Dick	1	135	88,802	16,223

## 6.1 Datasets

For general testing, five patent datasets are randomly selected from U.S. patents granted in 2009 and 2010. Patents in Pat-A are selected from international patent class (IPC) “A”, which is about “HUMAN NECESSITIES”; those in Pat-B are selected from class “B60” about “VEHICLES IN GENERAL”; those in Pat-H are selected from class “H” about “ELECTRICITY”; those in Pat-F are selected from class “F” about “MECHANICAL ENGINEERING; LIGHTING; HEATING; WEAPONS; BLASTING”; and those in Pat-G are selected from class “G06” about “COMPUTING; CALCULATING; COUNTING”. All the patents in these five datasets are split into paragraphs that are taken as segments, and the sequence of paragraphs in each patent is reserved in order to maintain the original layout. All the stop words, the top 10 common words, the uncommon words (i.e., words in less than five patents) and numbers have been removed.

Two books used for more detailed investigation are “The Prince” by Niccolò Machiavelli and “Moby Dick” by Herman Melville. They are split into chapters and/or paragraphs which are treated as segments, and only stop-words are removed. Table 3 shows in detail the statistics of these datasets after preprocessing.

## 6.2 Design

Perplexity, a standard measure of dictionary-based compressibility, is used for comparison. When reporting test perplexities, the held-out perplexity measure (Rosen-Zvi et al., 2004) is used to evaluate the generalisation capability to the unseen data. This is known to be unbiased. To compute the held-out perplexity, 20% of patents in each data set was ran-

Figure 3: Analysis of parameters of Poisson-Dirichlet process. (a) shows how perplexity changes with  $b$ ; (b) shows how it changes with  $a$ .

Figure 4: Analysis of the two parameters for Beta distribution. (a) how perplexity changes with  $\lambda_S$ ; (b) how it changes with  $\lambda_T$ .

domly held out from training to be used for testing. For this, 1000 Gibbs cycles were done for burn-in followed by 500 cycles with a lag for 100 for parameter estimation.

We implemented all the four models, *e.g.*, LDA, STM, SeqTM and AdaTM in C, and ran them on a desktop with Intel Core i5 CPU (2.8GHz $\times$ 4), even though our code is not multi-threaded. Perplexity calculations, data input and handling, *etc.*, were the same for all algorithms. We note that the current AdaTM implementation is an order of magnitude slower than regular LDA per major Gibbs cycle.

## 6.3 Hyper-parameters in AdaTM

Experiments on the impact of the hyper-parameters on the patent data sets were as follows: First, fixing  $K = 50$ , the Beta parameters  $\lambda_T = 1$  and  $\lambda_S = 1$ , optimise symmetric  $\alpha$ , and do two variations *fix-a*:  $a = 0.0$ , trying  $b = 1, 5, 10, 25, \dots, 300$ , and *fix-b*:  $b = 10$ , trying  $a = 0.1, 0.2, \dots, 0.9$ . Second, *fix- $\lambda_T$*  (*fix- $\lambda_S$* ): fix  $a = 0.2$  and  $\lambda_T(\lambda_S) = 1$ , optimise  $b$  and  $\alpha$ , change  $\lambda_S(\lambda_T) = 0.1, 1, 10, 50, 100, 200$ . Figures 3 and 4 show the corresponding plots. Figure 3(b) and Figure 4(a) show that varying the values of  $a$  and  $\lambda_S$  does not significantly change the

Figure 5: Perplexity comparisons.

perplexity. In contrast, Figure 3(a) shows different  $b$  values significantly change perplexity. Therefore, we sought to optimise  $b$ . The experiment of fixing  $\lambda_S = 1$  and changing  $\lambda_T$  shows a small  $\lambda_T$  is preferred.

#### 6.4 Perplexity Comparison

Perplexity comparisons were done with the default settings  $a = 0.2$ ,  $\alpha = 0.1$ ,  $\gamma = 0.01$ ,  $\lambda_S = 1$ ,  $\lambda_T = 1$  and  $b$  optimised automatically using the scheme from (Du et al., 2012). Figure 5 shows the results on these five patent datasets for different numbers of topics. LDA\_D is LDA run on whole patents, and LDA\_P is LDA run on the paragraphs within patents. Table 4 gives the p-values of a one-tail paired t-test for AdaTM versus the others, where lower p-value indicates AdaTM has statistically significant lower perplexity. From this we can see that AdaTM is statistically significantly better than SeqLDA and LDA, and somewhat better than STM.

In addition, we ran another set of experiments by randomly shuffling the order of paragraphs in each patent several times before running AdaTM. Then, we calculate the difference between perplexities with and without random shuffle. Figure 5(f) shows the plot of differences in each data sets. The positive difference means randomly shuffling the order of paragraphs indeed increases the perplexity.

It can further prove that there does exist sequential topic structure in patents, which confirms the finding in (Du et al., 2012).

#### 6.5 Topic Evolution Comparisons

All the comparison experiments reported in this section are run with 20 topics, the upper limit for easy visualisation, and without optimising any parameters. The Dirichlet Priors are fixed as  $\alpha_k = 0.1$  and  $\gamma_w = 0.01$ . For AdaTM, SeqLDA, and STM,  $a = 0.0$  and  $b = 100$  for “The Prince” and  $b = 200$  for “Moby Dick”. These settings have proven robust in experiments. To align the topics so visualisations match, the sequential models are initialised using an LDA model built at the chapter level. Moreover, all the models are run at both the chapter and the paragraph level. With the common initialisation, both paragraph level and chapter level models can

Table 4: P-values for one-tail paired t-test on the five patent datasets.

(a) Evolution of paragraph topics for LDA

(b) Topic alignment of LDA versus AdaTM topics for chapters

Figure 6: Analysis on “The Prince”.

be aligned.

To visualise topic evolution, we use a plot with one colour per topic displayed over the sequence. Figure 6(a) shows this for LDA run on paragraphs of “The Prince”. The proportion of 20 topics is the Y-axis, spread across the unit interval. The paragraphs run along the X-axis, so the topic evolution is clearly displayed. One can see there is no sequential structure in this derived by the LDA model, and similar plots result from “Moby Dick” for LDA. Figure 6(b) shows the alignment of topics between the initialising model (LDA+chapters) and AdaTM run on chapters. Each point in the matrix gives the Hellinger distance between the corresponding topics, color coded. The plots for the other models, chapters or paragraphs, are similar so plots like Figure 6(a) for the other models can be meaningfully compared.

Figure 7 then shows the corresponding evolution plots for AdaTM and SeqLDA on chapters and paragraphs. The contrast of these with LDA is stark. The large improvement in perplexity for AdaTM (see Section 6.4) along with no change in lexical coherence (see Section 6.2) means that the se-

quential information is actually beneficial statistically. Note that SeqLDA, while exhibiting slightly stronger sequential structure than AdaTM in these

(a) LDA on chapters

(b) STM on Chapters

(c) AdaTM on Chapters

Figure 8: Topic Evolution on “Moby Dick”.

figures has significantly worse test perplexity, so its sequential affect is too strong and harming results. Also, note that some topics have different time sequence profiles between AdaTM and SeqLDA. Indeed, inspection of the top words for each show these topics differ somewhat. So while the LDA to AdaTM/SeqLDA topic correspondences are quite good due to the use of LDA initialisation, the correspondences between AdaTM and SeqLDA have degraded. We see that AdaTM has nearly as good sequential characteristics as SeqLDA. Furthermore, segment topic distribution  $\nu_{i,j}$  of SeqLDA are gradually deviating from the document topic distribution

$\mu_i$ , which is not the case for AdaTM.

Results for “Moby Dick” on chapters are comparable. Figure 8 shows similar topic evolution plots for LDA, STM and AdaTM. In contrast, the AdaTM topic evolutions are much clearer for the less frequent topics, as shown in Figure 8(c). Various parts of this are readily interpreted from the storyline. Here we briefly discuss topics by their colour: *black*: Captain Peleg and the business of signing on; *yellow*: inns, housing, bed; *mauve*: Queequeg; *azure*: (around chapters 60-80) details of whales *aqua*: (peaks at 8, 82, 88) pulpit, schools and mythology of whaling.

We see that AdaTM can be used to understand the topics with regards to the sequential structure of a book. In contrast, the sequential nature for LDA and STM is lost in the noise. It can be very interesting to apply the proposed topic models to some text analysis tasks, such as topic segmentation, summarisation, and semantic title evaluation, which are subject to our future work.

## 7 Conclusion

A model for adaptive sequential topic modelling has been developed to improve over a simple exchangeable segments model STM (Du et al., 2010) and a naive sequential model SeqLDA (Du et al., 2012) in terms of perplexity and its confirmed ability to uncover sequential structure in the topics. One could extract meaningful topics from a book like Herman Melville’s “Moby Dick” and concurrently gain their sequential profile. The current Gibbs sampler is slower than regular LDA, so future work is to speed up the algorithm.

## Abstract

In this paper we address the problem of modeling compositional meaning for phrases and sentences using distributional methods. We experiment with several possible combinations of representation and composition, exhibiting varying degrees of sophistication. Some are shallow while others operate over syntactic structure, rely on parameter learning, or require access to very large corpora. We find that shallow approaches are as good as more computationally intensive alternatives with regards to two particular tests: (1) phrase similarity and (2) paraphrase detection. The sizes of the involved training corpora and the generated vectors are not as important as the fit between the meaning representation and compositional method.

## 1 Introduction

Distributional models of semantics have seen considerable success at simulating a wide range of behavioral data in tasks involving semantic cognition and also in practical applications. For example, they have been used to model judgments of semantic similarity (McDonald, 2000) and association (Denhire and Lemaire, 2004; Griffiths et al., 2007) and have been shown to achieve human level performance on synonymy tests (Landauer and Dumais, 1997; Griffiths et al., 2007) such as those included in the Test of English as a Foreign Language (TOEFL). This ability has been put to practical use in numerous natural language processing tasks such as automatic thesaurus extraction (Grefenstette, 1994),

word sense discrimination (Schütze, 1998), language modeling (Bellegarda, 2000), and the identification of analogical relations (Turney, 2006).

While much research has been directed at the most effective ways of constructing representations for individual words, there has been far less consensus regarding the representation of larger constructions such as phrases and sentences. The problem has received some attention in the connectionist literature, particularly in response to criticisms of the ability of connectionist representations to handle complex structures (Smolensky, 1990; Plate, 1995). More recently, several proposals have been put forward for computing the meaning of word combinations in vector spaces. This renewed interest is partly due to the popularity of distributional methods and their application potential to tasks that require an understanding of larger phrases or complete sentences.

For example, Mitchell and Lapata (2010) introduce a general framework for studying vector *composition*, which they formulate as a function  $f$  of two vectors  $\mathbf{u}$  and  $\mathbf{v}$ . Different composition models arise, depending on how  $f$  is chosen. Assuming that composition is a linear function of the Cartesian product of  $\mathbf{u}$  and  $\mathbf{v}$  allows to specify *additive* models which are by far the most common method of vector combination in the literature (Landauer and Dumais, 1997; Foltz et al., 1998; Kintsch, 2001). Alternatively, assuming that composition is a linear function of the tensor product of  $\mathbf{u}$  and  $\mathbf{v}$ , gives rise to models based on *multiplication*.

One of the most sophisticated proposals for semantic composition is that of Clark et al. (2008) and the more recent implementation of Grefenstette and

Sadrzadeh (2011a). Using techniques from logic, category theory, and quantum information they develop a compositional distributional semantics that brings type-logical and distributional vector space models together. In their framework, words belong to different type-based categories and different categories exist in different dimensional spaces. The category of a word is decided by the number and type of adjoints (arguments) it can take and the composition of a sentence results in a vector which exists in sentential space. Verbs, adjectives and adverbs act as relational functions, are represented by matrices, and modify the properties of nouns, that are represented by vectors (see also Baroni and Zamparelli (2010) for a proposal similar in spirit). Clarke (2012) introduces context-theoretic semantics, a general framework for combining vector representations, based on a mathematical theory of meaning as context, and shows that it can be used to describe a variety of models including that of Clark et al. (2008).

Socher et al. (2011a) and Socher et al. (2011b) present a framework based on recursive neural networks that learns vector space representations for multi-word phrases and sentences. The network is given a list of word vectors as input and a binary tree representing their syntactic structure. Then, it computes an  $n$ -dimensional representation  $p$  of two  $n$ -dimensional children and the process is repeated at every parent node until a representation for a full tree is constructed. Parent representations are computed essentially by concatenating the representations of their children. During training, the model tries to minimize the reconstruction errors between the  $n$ -dimensional parent vectors and those representing their children. This model can also compute compositional representations when the tree structure is not given, e.g., by greedily inferring a binary tree.

Although the type of function used for vector composition has attracted much attention, relatively less emphasis has been placed on the basic distributional representations on which the composition functions operate. In this paper, we examine three types of distributional representation of increasing sophistication and their effect on semantic composition. These include a simple semantic space, where a word's vector represents its co-occurrence with neighboring words (Mitchell and Lapata, 2010),

a syntax-aware space based on weighted distributional tuples that encode typed co-occurrence relations among words (Baroni and Lenci, 2010), and word embeddings computed with a neural language model (Bengio, 2001; Collobert and Weston, 2008). Word embeddings are distributed representations, low-dimensional and real-valued. Each dimension of the embedding represents a latent feature of the word, hopefully capturing useful syntactic and semantic properties.

Using these representations, we construct several compositional models, based on addition, multiplication, and recursive neural networks. We assess the effectiveness of these models using two evaluation protocols. The first one involves modeling similarity judgments for short phrases gathered in human experiments (Mitchell and Lapata, 2010). The second one is paraphrase detection, i.e., the task of examining two sentences and determining whether they have the same meaning (Socher et al., 2011a). We find that shallow approaches are as good as more computationally intensive alternatives. They achieve considerable semantic expressivity without any learning, sophisticated linguistic processing, or access to very large corpora.

Our contributions in this work are three-fold: an empirical comparison of a broad range of compositional models, some of which are introduced here for the first time; the use of an evaluation methodology that takes into account the full spectrum of compositionality from phrases to sentences; and the empirical finding that relatively simple compositional models can be used to perform competitively on the paraphrase detection and phrase similarity tasks.

## 2 Modeling

The elementary objects that we operate on are vectors associated with words. We instantiate these word representations following three distinct semantic space models which we describe in Section 2.1 below. Analogously, in Section 2.2 we consider three methods of vector composition, i.e., how a phrase or a sentence can be represented as a vector using the vectors of its constituent words. Combining different vector representations and composition methods gives rise to several compositional models whose performance we evaluate in Sections 3 and 4.

## 2.1 Word Representations

For all of our experiments we employ column vectors from a Cartesian, finitely-dimensional space. The dimensionality will depend on the source of the vectors involved. Similarly, the component values inside each source’s vectors are not to be interpreted in the same manner. Nonetheless, they have in common that they originate from distributive corpus statistics.

**Co-occurrence-based Semantic Space** Word meaning is commonly represented in a high-dimensional space, where each component corresponds to some contextual element in which the word is found. The contextual elements can be words themselves, or larger linguistic units such as sentences or documents, or even more complex linguistic representations such as the argument slots of predicates. A semantic space that is often employed in studying compositionality across a variety of tasks (Mitchell and Lapata, 2010; Grefenstette and Sadrzadeh, 2011a) uses a context window of five words on either side of the target word, and 2,000 vector dimensions. These are the common context words in the British National Corpus (BNC), a corpus of about 100 million tokens. Their values are set to the ratio of the probability of the context word given the target word to the probability of the context word overall.

More formally, let us consider the BNC as a set of sentences:

$$BNC = \{Sen_1^{(BNC)}, \dots, Sen_{n_{BNC}}^{(BNC)}\} \quad (1)$$

where the  $i$ -th sentence is a sequence of words  $Sen_i = (w_1^{(i)}, \dots, w_{n_i}^{(i)})$  from the BNC’s vocabulary  $Voc_{BNC}$ . Then  $freq_w$  is the amount of times that each word  $w \in Voc_{BNC}$  appears in the BNC. Mitchell and Lapata (2010) collect the  $M$  most frequent non-stoplist words in the set  $ctx_{top} = \{w_1^{(top)}, \dots, w_M^{(top)}\}$  and let them constitute the word vectors’ dimensions. Each dimension’s value is obtained from a co-occurrence count:

$$coCount_w[j] = \sum_{i=1}^{n_{BNC}} \sum_{t=1}^{n_i} \quad (2)$$

$$|\{k \in [t-5; t+5] \mid w_t^{(i)} = w, w_k^{(i)} = w_j^{(top)}\}|$$

for  $w \in Voc_{BNC}$  and  $j = 1, \dots, M$ . Using these counts, they define word vectors component-wise.

$$wVec_w^{(rp)}[j] = \frac{p(w_j^{(top)} \mid w)}{p(w_j^{(top)})} = \quad (3)$$

$$\frac{coCount_w[j]}{freq_w} \times \frac{totalCount}{freq_{w_j^{(top)}}}$$

for  $j = 1, \dots, M$ , where  $totalCount$  is the total number of words in the BNC.

This space is relatively simple, it has few parameters, requires no preprocessing other than tokenization and involves no syntactic information or parameter learning. Despite its simplicity, it is a good starting point for studying representations for compositional models as a baseline against which to evaluate more elaborate models.

**Neural Language Model** Another perhaps less well-known approach to meaning representation is to represent words as continuous vectors of parameters. Such word vectors can be obtained with an unsupervised *neural language model* (NLM, Bengio (2001); Collobert and Weston (2008)) which jointly learns an embedding of words into a vector space and uses these vectors to predict how likely a word is, given its context.

We induced word embeddings with Collobert and Weston (2008)’s neural language model. The model is discriminative and non-probabilistic. Each word  $i \in \mathcal{D}$  (the vocabulary) is embedded into a  $d$ -dimensional space using a lookup table  $LT_W(\cdot)$ :

$$LT_W(i) = W_i \quad (4)$$

where  $W \in \mathbb{R}^{d \times |\mathcal{D}|}$  is a matrix of parameters to be learned.  $W_i \in \mathbb{R}^d$  is the  $i$ -th column of  $W$  and  $d$  is the word vector size to be chosen by the user. The parameters  $W$  are automatically trained during the learning process using backpropagation.

Specifically, at each training update, the model reads an  $n$ -gram  $x = (w_1, \dots, w_n)$  from the corpus. The  $n$ -gram is paired with a *corrupted*  $n$ -gram  $\tilde{x} = (w_1, \dots, \tilde{w}_n)$  where  $\tilde{w}_n \neq w_n$  is chosen uniformly from the vocabulary. The model concatenates the learned embeddings of the  $n$  words and predicts a score for the  $n$ -gram sequence using the learned embeddings as features. The training criterion is that

$n$ -grams that are present in the training corpus must have a score at least some margin higher than the corrupted  $n$ -grams. The model learns via gradient descent over the neural network parameters and the embedding lookup table. Word vectors are stored in a word embedding matrix which captures syntactic and semantic information from co-occurrence statistics. As these representations are learned, albeit in an unsupervised manner, one would hope that they capture word meanings more succinctly, compared to the simpler distributional representations that are merely based on co-occurrence.

We trained the neural language model on the BNC. We optimized the model’s parameters on a word similarity task using 4% of the BNC as development data. Specifically, we used WordSim353, a benchmark dataset (Finkelstein et al., 2001), consisting of relatedness judgments (on a scale of 0 to 10) for 353 word pairs. We experimented with vectors of varying dimensionality (ranging from 50 to 200, with a step size of 50). The size of the target word’s context window was 2, 3 and 4 in turn. The rate at which embeddings were learned ranged from  $3.4 \times 10^{-10}$  to  $6.7 \times 10^{-10}$  to  $10^{-9}$ . We ran each training process for  $1.1 \times 10^8$  to  $2.7 \times 10^8$  iterations (ca. 2 days). We obtained the best results with 50 dimensions, a context window of size 4, and a embedding learning rate of  $10^{-9}$ . The NLM with these parameters was then trained for  $1.51 \times 10^9$  iterations (ca. 2 weeks).

Figure 1 illustrates a two-dimensional projection of the embeddings for the 500 most common words in the BNC. We only show two out of the actual 50 dimensions involved, but one can already begin to see clusterings of a syntactic and semantic nature. In one corner, for example, we encounter a grouping of possessive pronouns together with the possessive clitic ‘s. The singular ones *my*, *her* and *his* are closely positioned, as are the plural ones *our*, *your* and *their*. Also, there is a clustering of socio-political terms, such as *international*, *country*, *national*, *government*, and *council*.

**Distributional Memory Tensor** Baroni and Lenci (2010) present Distributional Memory, a generalized framework for distributional semantics from which several special-purpose models can be derived. In their framework distributional information

Figure 1: A two-dimensional projection of the word embeddings we trained on the BNC using Turian et al.’s (2010) implementation of the NLM. Two small sections have been blown up to a legible scale. They show examples of syntactic and semantic clustering, respectively.

Table 1: Example entries in Baroni and Lenci (2010)’s tensor

is extracted from the corpus once, in the form of a set of weighted word-link-word tuples arranged into a third-order tensor. Different matrices are then generated from the tensor, and their rows and columns give rise to different semantic spaces appropriate for capturing different semantic problems. In this way, the same distributional information can be shared across tasks such as word similarity or analogical learning.

More formally, Baroni and Lenci (2010) construct a 3-dimensional tensor  $T$  assigning a value  $c$  to instances of word pairs  $w, v$  and a connecting link-word  $l$ . This representation operates over a dependency-parsed corpus and the scores  $c$  are obtained via counting the occurrences of tuples, and weighting the raw counts by mutual information. Table 1 presents examples of tensor entries. These were taken from a distributional memory tensor<sup>1</sup>

Table 2: The 11 most frequent contexts in Baroni and Lenci (2010)’s tensor ( $v$  and  $j$  represent verbs and adjectives, respectively).

that Baroni and Lenci obtained via preprocessing several corpora: the web-derived ukWac corpus of about 1.915 billion words, a mid-2009 dump of the English Wikipedia containing about 820 million words, and the BNC.

Extracting a 3-dimensional tensor from the BNC alone would create very sparse representations. We therefore extract so-called word-fibres, essentially projections onto a lower-dimensional subspace, from the same tensor Baroni and Lenci (2010) collectively derived from the 3 billion word corpus just described (henceforth 3-BWC). We view the 3-dimensional tensor

$$T = \{(w_1^{(T)}, l_1^{(T)}, v_1^{(T)}, c_1^{(T)}), \dots\} \quad (5)$$

as a mapping which assigns each target word  $w$  a non-zero value  $c$ , given the context  $(l, v)$ . All word-context combinations not listed in  $T$  are implicitly assigned a zero value.

Now we consider two possible approaches for obtaining vectors, depending on their application. First, we let the  $D$  most frequent contexts

$$ctx_D = \{(l_1, v_1), \dots, (l_D, v_D)\} \quad (6)$$

constitute the  $D$  dimensions that each word vector will have. Table 2 shows the 11 contexts  $(l, v)$  that appear most frequently in  $T$ . Thus, each target word’s vector is defined component-wise as:

$$wdVec_w[j] = \begin{cases} c, & \text{if } (w, l_j, v_j, c) \in T \\ 0, & \text{otherwise} \end{cases} \quad (7)$$

for  $j = 1, \dots, D$ . This approach is used when a fixed vector dimensionality is necessary.

A more dynamic approach is possible when very few words  $w_1, \dots, w_n$  are involved in a test. Their representations can then have a denser format, that is, with no zero-valued components. For this we identify the set of contexts common to the words involved,

$$\begin{aligned} ctx_{dyn} &= \{(l_1^{(dyn)}, v_1^{(dyn)}), (l_2^{(dyn)}, v_2^{(dyn)}), \dots\} \quad (8) \\ &= \{(l, v) \mid (w_i, l, v, c) \in T, c \in \mathbb{R}, i = 1, \dots, n\} \end{aligned}$$

Each context  $(l, v)$  again constitutes a vector dimension. The dimensionality varies strongly depending on the selection of words, but if  $n$  does not exceed 4, the dimensionality  $|ctx_{dyn}|$  will typically be substantial enough. In this approach, each word’s vector consists of the values  $c$  found along with that word and its context in the tensor.

$$wdVec_{w_i}[j] = c, \quad (9)$$

where  $(w_i, l_j^{(dyn)}, v_j^{(dyn)}, c) \in T$ , for  $j = 1, \dots, |ctx_{dyn}|$ .

## 2.2 Composition Methods

In our experiments we compose word vectors to create representations for phrase vectors and sentence vectors. The phrases we are interested in consist of two words each: an adjective and a noun like *black hair*, a compound noun made up of two nouns such as *oil industry*, or a verbal phrase with a transitive verb and an object noun, e.g., *pour tea*.

Conceiving of a phrase  $phr = (w_1, w_2)$  as a binary tuple of words, we obtain its vector from its words’ vectors either by addition:

$$phrVec_{(w_1, w_2)} = wdVec_{w_1} + wdVec_{w_2} \quad (10)$$

or by point-wise multiplication:

$$phrVec_{(w_1, w_2)} = wdVec_{w_1} \odot wdVec_{w_2} \quad (11)$$

In the same way we acquire a vector  $senVec_i$  representing a sentence  $Sen_i = (w_1^{(i)}, \dots, w_{n_i}^{(i)})$  from the vectors for  $w_1, \dots, w_{n_i}$ . We simply sum the existing word vectors, that is, vectors obtained via the respective corpus for words that are not on our stoplist:

$$senVec_i^{(+)}[j] = \sum_{\substack{k=1, \dots, n_i \\ wdVec_{w_k} \text{ exists}}} wdVec_{w_k}[j] \quad (12)$$

And do the same with point-wise multiplication:

$$senVec_i^{(\odot)}[j] = \prod_{\substack{k=1, \dots, n_i \\ wdVec_{w_k} \text{ exists}}} wdVec_{w_k}[j] \quad (13)$$

The multiplication model in (13) can be seen as an instantiation of the categorical compositional framework put forward by Clark et al. (2008). In fact, a variety of multiplication-based models can be derived from this framework; and comparisons against component-wise multiplication on phrase similarity tasks yield comparable results (Grefenstette and Sadrzadeh, 2011a; Grefenstette and Sadrzadeh, 2011b). We thus opt for the model (13) as an example of compositional models based on multiplication due to its good performance across a variety of tasks, including language modeling and prediction of reading difficulty (Mitchell, 2011).

Our third method, for creating phrase and sentence vectors alike, is the application of Socher et al. (2011a)’s model. They use the Stanford parser (Klein and Manning, 2003) to create a binary parse tree for each input phrase or sentence. This tree is then used as the basis for a deep recursive autoencoder (RAE). The aim is to construct a vector representation for the tree’s root bottom-up where the leaves contain word vectors. The latter can in theory be provided by any type of semantic space, however Socher et al. use word embeddings provided by the neural language model (Collobert and Weston, 2008).

Given the binary tree input structure, the model computes parent representations  $p$  from their children  $(c_1, c_2)$  using a standard neural network layer:

$$p = f(W^{(1)}[c_1; c_2] + b^{(1)}), \quad (14)$$

where  $[c_1; c_2]$  is the concatenation of the two children,  $f$  is an element-wise activation function such as  $\tanh$ ,  $b$  is a bias term, and  $W \in \mathbb{R}^{n \times 2n}$  is an encoding matrix that we want to learn during training. One way of assessing how well  $p$  represents its direct children is to decode their vectors in a reconstruction layer:

$$[c'_1; c'_2] = f(W^{(2)}p + b^{(2)}) \quad (15)$$

During training, the goal is to minimize the reconstruction errors of all input pairs at nonterminal nodes  $p$  in a given parse tree by computing the

square of the Euclidean distance between the original input and its reconstruction:

$$E_{rec}([c_1; c_2]) = \frac{1}{2} |[c_1; c_2] - [c'_1; c'_2]|^2 \quad (16)$$

Socher et al. (2011a) extend the standard recursive autoencoder sketched above in two ways. Firstly, they present an unfolding autoencoder that tries to reconstruct all leaf nodes underneath each node rather than only its direct children. And secondly, instead of transforming the two children directly into a parent  $p$ , they introduce another hidden layer inbetween.

We obtained three compositional models per representation resulting in nine compositional models overall. Plugging different representations into the additive and multiplicative models is relatively straightforward. The RAE can also be used with arbitrary word vectors. Socher et al. (2011a) obtain best results with 100-dimensional vectors which we also used in our experiments. NLM vectors were trained with this dimensionality on the BNC for  $7.9 \times 10^8$  iterations (with window size 4 and an embedding learning rate of  $10^{-9}$ ). We constructed a simple distributional space with  $M = 100$  dimensions, i.e., those connected to the 100 most frequent co-occurrence words. In the case of vectors obtained from Baroni and Lenci (2010)’s DM tensor, we differentiated between phrases and sentences, due to the disparate amount of words contained in them (see Section 2.1). To represent phrases, we used vectors of dynamic dimensionality, since these form a richer and denser representation. The sentences considered in Section 4 are too large for this approach and all word vectors must be members of the same vector space. Hence, these sentence vectors have fixed dimensionality  $D = 100$ , consisting of the “most significant” 100 dimensions, i.e., those reflecting the 100 most frequent contexts.

### 3 Experiment 1: Phrase Similarity

Our first experiment focused on modeling similarity judgments for short phrases gathered in human experiments. Distributional representations of individual words are commonly evaluated on tasks based on their ability to model semantic similarity relations, e.g., synonymy or priming. Thus, it seems appropriate to evaluate phrase representations in a

	dim.	c.m.	Adj-N	N-N	V-Obj
SDS (BNC)	2000	+	0.37	0.38	0.28
	2000	⊙	<b>0.48</b>	<b>0.50</b>	<b>0.35</b>
	100	RAE	0.31	0.30	0.28
DM (3-BWC)	vary	+	0.37	0.30	0.29
	vary	⊙	0.21	0.37	0.33
	100	RAE	0.25	0.26	0.09
NLM (BNC)	50	+	0.28	0.26	0.24
	50	⊙	0.26	0.22	0.18
	100	RAE	0.19	0.24	0.28

Table 3: Correlation coefficients of model predictions with subject similarity ratings (Spearman’s  $\rho$ ); columns show dimensionality: fixed or varying (see Section 2.1), composition method: + is additive vector composition,  $\odot$  is component-wise multiplicative vector composition, RAE is Socher et al. (2011a)’s recursive auto-encoder.

similar manner. Specifically, we used the dataset from Mitchell and Lapata (2010) which contains similarity judgments for adjective-noun, noun-noun and verb-object phrases, respectively.<sup>2</sup> Each item is a phrase pair  $phr_1, phr_2$  which has a human rating from 1 (very low similarity) to 7 (very high similarity).

Using the composition models described above, we compute the cosine similarity of  $phr_1$  and  $phr_2$ :

$$phrSim_{phr_1, phr_2} = \frac{phrVec_{phr_1} \cdot phrVec_{phr_2}}{|phrVec_{phr_1}| \times |phrVec_{phr_2}|} \quad (17)$$

Model similarities were evaluated against the human similarity ratings using Spearman’s  $\rho$  correlation coefficient.

Table 3 summarizes the performance of the various models on the phrase similarity dataset. Rows in the table correspond to different vector representations: the simple distributional semantic space (SDS) from Mitchell and Lapata (2010), Baroni and Lenci’s (2010) distributional memory tensor (DM) and the neural language model (NLM), for each phrase combination: adjective noun (Adj-N), noun-noun (N-N) and verb object (V-Obj). For each phrase type we report results for each compositional model, namely additive (+), multiplicative ( $\odot$ ) and recursive autoencoder (RAE). The table also shows

<sup>2</sup>The dataset is publicly available from <http://homepages.inf.ed.ac.uk/s0453356/share>

the dimensionality of the input vectors next to the vector representation.

As can be seen, for SDS the best performing model is multiplication, as it is mostly for DM. With regard to NLM, vector addition yields overall better results. In general, neither DM or NLM in any compositional configuration are able to outperform SDS with multiplication. All models in Table 3 are significantly correlated with the human similarity judgments ( $p < 0.01$ ). Spearman’s  $\rho$  differences of 0.3 or more are significant at the 0.01 level, using a  $t$ -test (Cohen and Cohen, 1983).

## 4 Experiment 2: Paraphrase Detection

Although the phrase similarity task gives a fairly direct insight into semantic similarity and compositional representations, it is somewhat limited in scope as it only considers two-word constructions rather than naturally occurring sentences. Ideally, we would like to augment our evaluation with a task which is based on large quantities of natural data and for which vector composition has practical consequences. For these reasons, we used the Microsoft Research Paraphrase Corpus (MSRPC) introduced by Dolan et al. (2004). The corpus consists of sentence pairs  $Sen_{i_1}, Sen_{i_2}$  and labels indicating whether they are in a paraphrase relationship or not. The vector representations obtained from our various compositional models were used as features for the paraphrase classification task.

The MSRPC dataset contains 5,801 sentence pairs, we used the standard split of 4,076 training pairs (67.5% of which are paraphrases) and 1,725 test pairs (66.5% of which are paraphrases). In order to judge whether two sentences have the same meaning we employ Fan et al. (2008)’s liblinear classifier. For each of our three vector sources and three different compositional methods, we create the following features: (a) a vector representing the pair of input sentences either via concatenation (“con”) or subtraction (“sub”); (b) a vector encoding which words appear therein (“enc”); and (c) a vector made up of the following four other pieces of information: the cosine similarity of the sentence vectors, the length of  $Sen_{i_1}$ , the length of  $Sen_{i_2}$ , and the unigram overlap among the two sentences.

In order to encode which words appear in

	NLM (BNC)	DM (3-BWC)	SDS (BNC)
+	69.04 (con, other)	<b>73.51</b> (other)	72.93 (other)
⊙	67.83 (sub, other)	67.54 (other)	<b>73.04</b> (other)
RAE	<b>70.26</b> (con, other)	68.29 (sub, other)	69.10 (con, other)

Table 4: Paraphrase classification accuracy in %. Included features are in parentheses: “con” is sentence vector concatenation, “sub” is sentence vector subtraction, “other” stands for 4 other features (see Section 4)

each sentence and how often, we define a vector  $wdCount_i$  for sentence  $Sen_i$  and enumerate all words occurring in the MSRPC:

$$Voc_{MSRPC} = \{w_1^{(MSRPC)}, \dots, w_{n_{MSRPC}}^{(MSRPC)}\} \quad (18)$$

giving the word count vectors  $n_{MSRPC}$  dimensions. Thus the  $k$ -th component of  $wdCount_i$  is the frequency with which the word  $w_k^{(MSRPC)}$  appears in  $Sen_i = (w_1^{(i)}, \dots, w_{n_i}^{(i)})$ :

$$wdCount_i[k] = |\{j \in [1; n_i] \mid w_k^{(MSRPC)} = w_j^{(i)}\}| \quad (19)$$

for  $k = 1, \dots, n_{MSRPC}$ . Even though  $n_{MSRPC}$  may be large, the computer files storing our feature vectors do not explode in size because  $wdCount$  contains many zeros and the classifier allows a sparse notation of (non-zero) feature values.

Regarding the last four features, we measured the similarity between sentences the same way as we did with phrases in section 3.

$$senSim_{i_1, i_2} = \frac{senVec_{i_1} \cdot senVec_{i_2}}{|senVec_{i_1}| \times |senVec_{i_2}|} \quad (20)$$

Note that this is the cosine of the angle between  $senVec_{i_1}$  and  $senVec_{i_2}$ . This enables us to observe the similarity or dissimilarity of two sentences independent of their sentence length. Even though each contained word increases or decreases the norm of the resulting sentence vector, this does not distort the overall similarity value, due to normalization.

The lengths of  $Sen_{i_1}$  and  $Sen_{i_2}$  are simply the number of words they contain. The unigram overlap feature value may be viewed as the cardinal-

	NLM (BNC)	DM (3-BWC)	SDS (BNC)
+	81.00 (con, other)	<b>82.16</b> (other)	80.76 (other)
⊙	80.41 (sub, other)	80.18 (other)	<b>82.33</b> (other)
RAE	<b>81.28</b> (con, other)	80.43 (sub, other)	80.68 (con, other)

Table 5: Paraphrase classification F1-score in %. The involved features are exactly the same as in Table 4.

ity of the intersection of each sentence’s multiset-bag-of-words. The latter is encoded in the already-introduced  $wdCount$  vectors. Therefore,

$$uniOverlap_{i_1, i_2} = \sum_{k=1}^{n_{MSRPC}} \min_{s=1,2} \{wdCount_{i_s}[k]\} \quad (21)$$

In order to establish which features work best for each representation and composition method, we exhaustively explored all combinations on a development set (20% of the original MSRPC training set). Tables 4 (accuracy) and 5 (F1) show our results on the test set with the best feature combinations for each model (shown in parentheses). Each row corresponds to a different type of composition and each column to a different word representation model.

As can be seen, the distributional memory (DM) is the best performing representation for the additive composition model. The neural language model (NLM) gives best results for the recursive autoencoder (RAE), although the other two representations come close. And finally the simple distributional semantic space (SDS) works best with multiplication. Also note that the best performing models, namely DM with addition and SDS with multiplication, use a basic feature space consisting only of the cosine similarity of the composed sentence vectors, the length of the two sentences involved, and their unigram word overlap.

Although our intention was to use the paraphrase detection task as a test-bed for evaluating compositional models rather than achieving state-of-the-art results, Table 6 compares our approach against previous work on the same task and dataset. Initial research concentrated on individual words rather than sentential representations. Several approaches used

Model	Acc.	F1
Baseline	66.5	79.9
Mihalcea et al. (2006)	70.3	81.3
Rus et al. (2008)	70.6	80.5

WordNet in conjunction with distributional similarity in an attempt to detect meaning conveyed by synonymous words (Islam and Inkpen, 2007; Mihalcea et al., 2006; Fernando and Stevenson, 2008). More recently, the addition of syntactic features based on dependency parse trees (Wan et al., 2006; Das and Smith, 2009) has been shown to substantially boost performance. The model of Das and Smith (2009), for example, uses quasi-synchronous dependency grammar to model the structure of the sentences involved in the comparison and their correspondences. Socher et al. (2011a) obtain an accuracy that is higher than previously published results. This model is more sophisticated than the one we used in our experiments (see Table 4 and 5). Rather than using the output of the RAE as features for the classifier, it applies dynamic pooling, a procedure that takes a similarity matrix as input (e.g., created by sentences with differing lengths) and maps it to a matrix of fixed size that represents more faithfully the global similarity structure.<sup>3</sup>

Overall, we observe that our own models do as well as some of the models that employ WordNet and more sophisticated syntactic features. With regard to F1, we are comparable with Das and Smith (2009) and Socher et al. (2011a) without using elaborate features, or any additional manipulations over and above the output of the composition functions

<sup>3</sup>Without dynamic pooling, their model yields an accuracy of 74.2.

which if added could increase performance.

## 5 Discussion

In this paper we systematically compared three types of distributional representation and their effect on semantic composition. Our comparisons involved a simple distributional semantic space (Mitchell and Lapata, 2010), word embeddings computed with a neural language model (Collobert and Weston, 2008) and a representation based on weighted word-link-word tuples arranged into a third-order tensor (Baroni and Lenci, 2010). These representations vary in many respects: the amount of pre-processing and linguistic information involved (the third-order tensor computes semantic representations over parsed corpora), whether the semantic space is the by-product of a learning process (in the neural language model the parameters of the lookup table must be learned), and data requirements (the third-order tensor involves processing billions of words). These representations served as input to three composition methods involving addition, multiplication and a deep recursive autoencoder. Again these methods differ in terms of how they implement compositionality: addition and multiplication are commutative and associative operations and thus ignore word order and, more generally, syntactic structure. In contrast, the recursive autoencoder is syntax-aware as it operates over a parse tree. However, the composed representations must be learned with a neural network.

We evaluated nine models on the complementary tasks of phrase similarity and paraphrase detection. The former task simplifies the challenge of finding an adequate method of composition and places more emphasis on the representation, whereas the latter poses, in a sense, the ultimate challenge for composition models. It involves entire sentences exhibiting varied syntactic constructions and in the limit involves genuine natural language understanding. Across both tasks our results deliver a consistent message: simple is best. Despite being in theory more expressive, the representations obtained by the neural language model and the third-order tensor cannot match the simple semantic space on the phrase similarity task. In this task syntax-oblivious composition models are superior to the more sophis-

ticated recursive autoencoder. The latter performs better on the paraphrase detection task when its output is fed to a classifier. The simple semantic space may not take word order or sentence structure into account, but nevertheless achieves considerable semantic expressivity: it is on par with the third-order tensor without having access to as much data (3 billion words) or a syntactically parsed corpus.

What do these findings tell us about the future of compositional models for distributional semantics? The problem of finding the right methods of vector composition cannot be pursued independent of the choice of lexical representation. Having tested many model combinations, we argue that in a good model of distributive semantics representation and composition must go hand in hand, i.e., they must be mutually learned.

**Acknowledgments** We are grateful to Jeff Mitchell for his help with the re-implementation of his models. Thanks to Frank Keller and Micha Elsner for their input on earlier versions of this work and to Richard Socher for technical assistance. We acknowledge the support of EPSRC through project grant EP/I032916/1.

## Abstract

Most existing systems solved the phrase chunking task with the sequence labeling approaches, in which the chunk candidates cannot be treated as a whole during parsing process so that the chunk-level features cannot be exploited in a natural way. In this paper, we formulate phrase chunking as a joint segmentation and labeling task. We propose an efficient dynamic programming algorithm with pruning for decoding, which allows the direct use of the features describing the internal characteristics of chunk and the features capturing the correlations between adjacent chunks. A relaxed, online maximum margin training algorithm is used for learning. Within this framework, we explored a variety of effective feature representations for Chinese phrase chunking. The experimental results show that the use of chunk-level features can lead to significant performance improvement, and that our approach achieves state-of-the-art performance. In particular, our approach is much better at recognizing long and complicated phrases.

## 1 Introduction

Phrase chunking is a Natural Language Processing task that consists in dividing a text into syntactically correlated parts of words. These phrases are non-overlapping, i.e., a word can only be a member of one chunk (Abney, 1991). Generally speaking, there are two phrase chunking tasks, including text chunking (shallow parsing),

and noun phrase (NP) chunking. Phrase chunking provides a key feature that helps on more elaborated NLP tasks such as parsing, semantic role tagging and information extraction.

There is a wide range of research work on phrase chunking based on machine learning approaches. However, most of the previous work reduced phrase chunking to sequence labeling problems either by using the classification models, such as SVM (Kudo and Matsumoto, 2001), Winnow and voted-perceptrons (Zhang et al., 2002; Collins, 2002), or by using the sequence labeling models, such as Hidden Markov Models (HMMs) (Molina and Pla, 2002) and Conditional Random Fields (CRFs) (Sha and Pereira, 2003). When applying the sequence labeling approaches to phrase chunking, there exist two major problems. Firstly, these models cannot treat globally a sequence of continuous words as a chunk candidate, and thus cannot inspect the internal structure of the candidate, which is an important aspect of information in modeling phrase chunking. In particular, it makes impossible the use of local indicator function features of the type "the chunk consists of POS tag sequence  $p_1 \dots p_k$ ". For example, the Chinese NP "农业/NN(agriculture) 生产/NN(production) 和/CC(and) 农村/NN(rural) 经济/NN(economic) 发展/NN(development)" seems relatively difficult to be correctly recognized by a sequence labeling approach due to its length. But if we can treat the sequence of words as a whole and describe the formation pattern of POS tags of this chunk with a regular expression-like form "[NN]+[CC][NN]+", then it is more likely to be correctly recognized, since this pattern might better express the characteristics of its constituents. As another example, consider the recognition of special terms. In Chinese corpus, there exists a kind of NPs called special terms, such as "『生命

(Life) 禁区 (Forbidden Zone) 』", which are bracketed with the particular punctuations like "『, 』, 「, 」, 《, 》". When recognizing the special terms, it is difficult for the sequence labeling approaches to guarantee the matching of particular punctuations appearing at the starting and ending positions of a chunk. For instance, the chunk candidate "『生命(Life) 禁区(Forbidden Zone)』" is considered to be an invalid chunk. But it is easy to check this kind of punctuation matching in a single chunk by introducing a chunk-level feature.

Secondly, the sequence labeling models cannot capture the correlations between adjacent chunks, which should be informative for the identification of chunk boundaries and types. In particular, we find that some headwords in the sentence are expected to have a stronger dependency relation with their preceding headwords in preceding chunks than with their immediately preceding words within the same chunk. For example, in the following sentence:

" [双方/PN(Bilateral)]\_NP [经贸/NN(economic and trade) 关系/NN(relations)]\_NP [正/AD(just) 稳步/AD(steadily) 发展/VV(develop)]\_VP "

if we can find the three headwords "双方", "关系" and "发展" located in the three adjacent chunks with some head-finding rules, then the headword dependency expressed by headword bigrams or trigrams should be helpful to recognize these chunks in this sentence.

In summary, the inherent deficiency in applying the sequence labeling approaches to phrase chunking is that the chunk-level features one would expect to be very informative cannot be exploited in a natural way.

In this paper, we formulate phrase chunking as a joint segmentation and labeling problem, which offers advantages over previous learning methods by providing a natural formulation to exploit the features describing the internal structure of a chunk and the features capturing the correlations between the adjacent chunks.

Within this framework, we explored a variety of effective feature representations for Chinese phrase chunking. The experimental results on Chinese chunking corpus as well as English chunking corpus show that the use of chunk-level features can lead to significant performance improvement,

and that our approach performs better than other approaches based on the sequence labeling models.

## 2 Related Work

In recent years, many chunking systems based on machine learning approaches have been presented. Some approaches rely on  $k$ -order generative probabilistic models, such as HMMs (Molina and Pla, 2002). However, HMMs learn a generative model over input sequence and labeled sequence pairs. It has difficulties in modeling multiple non-independent features of the observation sequence. To accommodate multiple overlapping features on observations, some other approaches view the phrase chunking as a sequence of classification problems, including support vector machines (SVMs) (Kudo and Matsumoto 2001) and a variety of other classifiers (Zhang et al., 2002). Since these classifiers cannot trade off decisions at different positions against each other, the best classifier based shallow parsers are forced to resort to heuristic combinations of multiple classifiers. Recently, CRFs were widely employed for phrase chunking, and presented comparable or better performance than other state-of-the-art models (Sha and Pereira 2003; McDonald et al. 2005). Further, Sun et al. (2008) used the latent-dynamic conditional random fields (LDCRF) to explicitly learn the hidden substructure of shallow phrases, achieving state-of-the-art performance over the NP-chunking task on the CoNLL data.

Some similar approaches based on classifiers or sequence labeling models were also used for Chinese chunking (Li et al., 2003; Tan et al., 2004; Tan et al., 2005). Chen et al. (2006) conducted an empirical study of Chinese chunking on a corpus, which was extracted from UPENN Chinese Treebank-4 (CTB4). They compared the performances of the state-of-the-art machine learning models for Chinese chunking, and proposed some Tag-Extension and novel voting methods to improve performance.

In this paper, we model phrase chunking with a joint segmentation and labeling approach, which offer advantages over previous learning methods by explicitly incorporating the internal structural feature and the correlations between the adjacent chunks. To some extent, our model is similar to Semi-Markov Conditional Random Fields (called a Semi-CRF), in which the segmentation and

labeling can also be done directly (Sarawagi and Cohen, 2004). However, Semi-CRF just models label dependency, and it cannot capture more correlations between adjacent chunks, as is done in our approach. The limitation of Semi-CRF leads to its relatively low performance.

### 3 Problem Formulation

#### 3.1 Chunk Types

Unlike English chunking, there is not a benchmarking corpus for Chinese chunking. We follow the studies in (Chen et al. 2006) so that a more direct comparison with state-of-the-art systems for Chinese chunking would be possible. There are 12 types of chunks: ADJP, ADVP, CLP, DNP, DP, DVP, LCP, LST, NP, PP, QP and VP in the chunking corpus (Xue et al., 2000). The training and test corpus can be extracted from CTB4 with a public tool, as depicted in (Chen et al. 2006).

#### 3.2 Sequence Labeling Approaches to Phrase Chunking

The standard approach to phrase chunking is to use tagging techniques with a BIO tag set. Words in the input text are tagged with one of B for the beginning of a contiguous segment, I for the inside of a contiguous segment, or O for outside a segment. For instance, the sentence (word segmented and POS tagged) "他/NR(He) 到达/VV(reached) 北京/NR(Beijing) 机场/NN(airport) 。/PU" will be tagged as follows:

Example 1:

S1: [NP 他][VP 到达][NP 北京/机场][O 。]

S2: 他/B-NP 到达/B-VP 北京/B-NP 机场/I-NP 。/O

Here S1 denotes that the sentence is tagged with chunk types, and S2 denotes that the sentence is tagged with chunk tags based on the BIO-based model. With the data representation like the S2, the problem of phrase chunking can be reduced to a sequence labeling task.

#### 3.3 Phrase Chunking via a Joint Segmentation and Labeling Approach

To tackle the problems with the sequence labeling approaches to phrase chunking, we formulate it as a joint problem, which maps a Chinese sentence  $x$

with segmented words and POS tags to an output  $y$  with tagged chunk types, like the S1 in Example 1. The joint model considers all possible chunk boundaries and corresponding chunk types in the sentence, and chooses the overall best output. This kind of parser reads the input sentences from left to right, predicts whether current segment of continuous words is some type of chunk. After one chunk is found, parser move on and search for next possible chunk.

Given a sentence  $x$ , let  $y$  denote an output tagged with chunk types, and GEN a function that enumerates a set of segmentation and labeling candidates  $GEN(x)$  for  $x$ . A parser is to solve the following "argmax" problem:

$$\begin{aligned} \hat{y} &= \arg \max_{y \in GEN(x)} w^T \cdot \Phi(y) \\ &= \arg \max_{y \in GEN(x)} w^T \cdot \sum_{i=1}^{|y|} \phi(y_{[1..i]}) \end{aligned} \quad (1)$$

where  $\Phi$  and  $\phi$  are global and local feature maps and  $w$  is the parameter vector to learn. The inner product  $w^T \cdot \phi(y_{[1..i]})$  can be seen as the confidence score of whether  $y_i$  is a chunk. The parser takes into account confidence score of each chunk, by using the sum of local scores as its criteria. Markov assumption is necessary for computation, so  $\phi$  is usually defined on a limited history.

The main advantage of the joint segmentation and labeling approach to phrase chunking is to allow for integrating both the internal structural features and the correlations between the adjacent chunks for prediction. The two basic components of our model are decoding and learning algorithms, which are described in the following sections.

### 4 Decoding

The inference technique is one of the most important components for a joint segmentation and labeling model. In this section, we propose a dynamic programming algorithm with pruning to efficiently produce the optimal output.

#### 4.1 Algorithm Description

Given an input sentence  $x$ , the decoding algorithm searches for the highest-scored output with recognized chunks. The search space of combined candidates in the joint segmentation and labeling task is very large, which is an exponential growth

in the number of possible candidates with increasing sentence size. The rate of growth is  $O(2^n T^n)$  for the joint system, where  $n$  is the length of the sentence and  $T$  is the number of chunk types. It is natural to use some greedy heuristic search algorithms for inference in some similar joint problems (Zhang and Clark, 2008; Zhang and Clark, 2010). However, the greedy heuristic search algorithms only explore a fraction of the whole space (even with beam search) as opposed to dynamic programming. Additionally, a specific advantage of the dynamic programming algorithm is that constraints required in a valid prediction sequence can be handled in a principled way. We show that dynamic programming is in fact possible for this joint problem, by introducing some effective pruning schemes.

To make the inference tractable, we first make a first-order Markov assumption on the features used in our model. In other words, we assume that the chunk  $c_i$  and the corresponding label  $t_i$  are only associated with the preceding chunk  $c_{i-1}$  and the label  $t_{i-1}$ . Suppose that the input sentence has  $n$  words and the constant  $M$  is the maximum chunk length in the training corpus. Let  $V(b, e, t)$  denote the highest-scored segmentation and labeling with the last chunk starting at word index  $b$ , ending at word index  $e$  and the last chunk type being  $t$ . One way to find the highest-scored segmentation and labeling for the input sentence is to first calculate the  $V(b, n-1, t)$  for all possible start position  $b \in (n-M)..n-1$ , and all possible chunk type  $t$ , respectively, and then pick the highest-scored one from these candidates. In order to compute  $V(b, n-1, t)$ , the last chunk needs to be combined with all possible different segmentations of words  $(b-M)..b-1$  and all possible different chunk types so that the highest-scored can be selected. According to the principle of optimality, the highest-scored among the segmentations of words  $(b-M)..b-1$  and all possible chunk types with the last chunk being word  $b'..b-1$  and the last chunk type being  $t'$  will also give the highest score when combined with the word  $b..n-1$  and tag  $t$ . In this way, the search task is reduced recursively into smaller subproblems, where in the base case the subproblems  $V(0, e, t)$  for  $e \in 0..M-1$ , and each possible chunk type  $t$ , are solved in straightforward manner. And the final highest-scored segmentation and labeling can be

found by solving all subproblems in a bottom-up fashion.

The pseudo code for this algorithm is shown in Figure 1. It works by filling an  $n$  by  $n$  by  $T$  table  $chart$ , where  $n$  is the number of words in the input sentence  $sent$ , and  $T$  is the number of chunk types.  $chart[b, e, t]$  records the value of subproblem  $V(b, e, t)$ .  $chart[0, e, t]$  can be computed directly for  $e = 0..M-1$  and for chunk type  $t=1..T$ . The final output is the best among  $chart[b, n-1, t]$ , with  $b=n-M..n-1$ , and  $t=1..T$ .

**Inputs:** sentence  $sent$  (word segmented and POS tagged)

**Variables:**

word index  $b$  for the start of chunk;

word index  $e$  for the end of chunk;

word index  $p$  for the start of the previous chunk.

chunk type index  $t$  for the current chunk;

chunk type index  $t'$  for the previous chunk;

**Initialization:**

for  $e = 0..M-1$ :

  for  $t = 1..T$ :

$chart[0, e, t] \leftarrow$  single chunk  $sent[0, e]$  and type  $t$

**Algorithm:**

for  $e = 0..n-1$ :

  for  $b = (e-M)..e$ :

    for  $t = 1..T$ :

$chart[b, e, t] \leftarrow$  the highest scored segmentation and labeling among those derived by combining  $chart[p, b-1, t']$  with  $sent[b, e]$  and chunk type  $t$ , for  $p = (b-M)..b-1$ ,  $t' = 1..T$ .

**Outputs:** the highest scored segmentation and labeling among  $chart[b, n-1, t]$ , for  $b=n-M..n-1$ ,  $t=1..T$ .

**Figure 1:** A dynamic-programming algorithm for phrase chunking.

## 4.2 Pruning

The time complexity of the above algorithm is  $O(M^2 T^2 n)$ , where  $M$  is the maximum chunk size. It is linear in the length of sentence. However, the constant in the  $O$  is relatively large. In practice, the search space contains a large number of invalid partial candidates, which make the algorithm slow. In this section we describe three partial output pruning schemes which are helpful in speeding up the algorithm.

Firstly, we collect chunk type transition information between chunk types by observing every pair of adjacent chunks in the training corpus, and record a chunk type transition matrix. For example, from the Chinese Treebank that we used for our experiments, a transition from chunk type ADJP to ADVP does not occur in the training corpus, the corresponding matrix element is set to *false*, *true* otherwise. During decoding, the chunk type transition information is used to prune unlikely combinations between current chunk and the preceding chunk by their chunk types.

Secondly, a POS tag dictionary is used to record POS tags associated with each chunk type. Specifically, for each chunk type, we record all POS tags appearing in this type of chunk in the training corpus. During decoding, a segment of continuous words that contains only allowed POS tags according to the POS tag dictionary will be considered to be a valid chunk candidate.

Finally, the system records the maximum number of words for each type of chunk in the training corpus. For example, in the Chinese Treebank, most types of chunks have one to three words. The few chunk types that are seen with length bigger than ten are NP, QP and ADJP. During decoding, the chunk candidate whose length is greater than the maximum chunk length associated with its chunk type will be discarded.

For the above pruning schemes, development tests show that it improves the speed significantly, while having a very small negative influence on the accuracy.

## 5 Learning

### 5.1 Discriminative Online Training

By defining features, a candidate output  $y$  is mapped into a global feature vector, in which each dimension represents the count of a particular feature in the sentence. The learning task is to set the parameter values  $w$  using the training examples as evidence.

Online learning is an attractive method for the joint model since it quickly converges within a few iterations (McDonald, 2006). We focus on an online learning algorithm called MIRA, which is a relaxed, online maximum margin training algorithm with the desired accuracy and scalability properties (Crammer, 2004). Furthermore, MIRA

is very flexible with respect to the loss function. Any loss function on the output is compatible with MIRA since it does not require the loss to factor according to the output, which enables our model to be optimized with respect to evaluation metrics directly. Figure 2 outlines the generic online learning algorithm (McDonald, 2006) used in our framework.

MIRA updates the parameter vector  $w$  with two constraints: (1) the positive example must have a higher score by a given margin, and (2) the change to  $w$  should be minimal. This second constraint is to reduce fluctuations in  $w$ . In particular, we use a generalized version of MIRA (Crammer et al., 2005; McDonald, 2006) that can incorporate *k-best* decoding in the update procedure.

**Input:** Training set  $S = \{(x_t, y_t)\}_{t=1}^T$

- 1:  $w^{(0)} = 0; v = 0; i = 0$
- 2: for  $iter = 1$  to  $N$  do
- 3: for  $t = 1$  to  $T$  do
- 4:  $w^{(i+1)} = \text{update } w^{(i)}$  according to  $(x_t, y_t)$
- 5:  $v = v + w^{(i+1)}$
- 6:  $i = i + 1$
- 7: end for
- 8: end for
- 9:  $w = v/(N \times T)$

**Output:** weight vector  $w$

**Figure 2:** Generic Online Learning Algorithm

In each iteration, MIRA updates the weight vector  $w$  by keeping the norm of the change in the weight vector as small as possible. Within this framework, we can formulate the optimization problem as follows (McDonald, 2006):

$$w^{(i+1)} = \arg \min_w \|w - w^{(i)}\|$$

$$s.t. \forall y' \in \text{best}_k(x_t; w^{(i)}): \quad (2)$$

$$w^T \cdot \Phi(y_t) - w^T \cdot \Phi(y') \geq L(y_t, y')$$

where  $\text{best}_k(x_t; w^{(i)})$  represents a set of top *k-best* outputs for  $x_t$  given the weight vector  $w^{(i)}$ . In our implementation, the top *k-best* outputs are obtained with a straightforward *k-best* extension to the decoding algorithm in section 4.1. The above quadratic programming (QP) problem can be solved using Hildreth's algorithm (Yair Censor, 1997). Replacing Eq. (2) into line 4 of the algorithm in Figure 2, we obtain *k-best* MIRA.

As shown in (McDonald, 2006), parameter averaging can effectively avoid overfitting. The

final weight vector  $w$  is the average of the weight vectors after each iteration.

## 5.2 Loss Function

For the joint segmentation and labeling task, there are two alternative loss functions: 0-1 loss and F1 loss. 0-1 loss gives credit only when the entire output sequence is correct: there is no notion of partially correct solutions. The most common loss function for joint segmentation and labeling problems is F1 measure over chunks. This is the geometric mean of precision and recall over the (properly-labeled) chunk identification task, defined as follows.

$$L^f(y, \hat{y}) \triangleq 1 - \frac{2|y \cap \hat{y}'|}{|y| + |\hat{y}'|} \quad (3)$$

where the cardinality of  $y$  is simply the number of chunks identified. The cardinality of the intersection is the number of chunks in common. As can be seen in the definition, one is penalized both for identifying too many chunks (penalty in the denominator) and for identifying too few (penalty in the numerator).

In our experiments, we will compare the performance of the systems with different loss functions.

## 5.3 Features

Table 1 shows the feature templates for the joint segmentation and labeling model. In the row for feature templates,  $c$ ,  $t$ ,  $w$  and  $p$  are used to represent a chunk, a chunk type, a word and a POS tag, respectively. And  $c_0$  and  $c_{-1}$  represent the current chunk and the previous chunk respectively. Similarly,  $w_{-1}$ ,  $w_0$  and  $w_1$  represent the previous word, the current word and the next word, respectively.

Although it is slightly less natural to do so, part of the features used in the sequence labeling models can also be represented in our approach. Therefore the features employed in our model can be divided into three types: the features similar to those used in the sequence labeling models (called SL-type features), the features describing internal structure of a chunk (called Internal-type features), and the features capturing the correlations between the adjacent chunks (called Correlation-type features).

Firstly, some features associated with a single label (here refers to label "B" and "I") used in the

sequence labeling models are also represented in our model. In Table 1, templates 1-4 are SL-type features, where  $label(w)$  denotes the label indicating the position of the word  $w$  in the current chunk;  $len(c)$  denotes the length of chunk  $c$ . For example, given an NP chunk "北京(Beijing) 机场(Airport)", which includes two words, the value of  $label("北京")$  is "B" and the value of  $label("机场")$  is "I".  $Bigram(w)$  denotes the word bigrams formed by combining the word to the left of  $w$  and the one to the right of  $w$ . And the same meaning is for  $biPOS(w)$ . Template  $specitermMatch(c)$  is used to check the punctuation matching within chunk  $c$  for the special terms, as illustrated in *section 1*.

Secondly, in our model, we have a chance to treat the chunk candidate as a whole during decoding, which means that we can employ more expressive features in our model than in the sequence labeling models. In Table 1, templates 5-13 concern the Internal-type features, where  $start\_word(c)$  and  $end\_word(c)$  represent the first word and the last word of chunk  $c$ , respectively. Similarly,  $start\_POS(c)$  and  $end\_POS(c)$  represent the POS tags associated with the first word and the last word of chunk  $c$ , respectively. These features aim at expressing the formation patterns of the current chunk with respect to words and POS tags. Template  $internalWords(c)$  denotes the concatenation of words in chunk  $c$ , while  $internalPOSS(c)$  denotes the sequence of POS tags in chunk  $c$  using regular expression-like form, as illustrated in *section 1*.

Finally, in Table 1, templates 14-28 concern the Correlation-type features, where  $head(c)$  denotes the headword extracted from chunk  $c$ , and  $headPOS(c)$  denotes the POS tag associated with the headword in chunk  $c$ . These features take into account various aspects of correlations between adjacent chunks. For example, we extracted the headwords located in adjacent chunks to form headword bigrams to express semantic dependency between adjacent chunks. To find the headword within every chunk, we referred to the head-finding rules from (Bikel, 2004), and made a simple modification to them. For instance, the head-finding rule for NP in (Bikel, 2004) is as follows:

(NP (r NP NN NT NR QP) (r))

Since the phrases are non-overlapping in our task, we simply remove the overlapping phrase tags NP

and QP from the rule, and then the rule is modified as follows:

(NP (r NN NT NR) (r))

Additionally, the different bigrams formed by combining the first word (or POS) and last word (or POS) located in two adjacent chunks can also capture some correlations between adjacent chunks, and templates 17-22 are designed to express this kind of bigram information.

ID	Feature template
1	$wlabel(w) t_0$ for all $w$ in $c_0$
2	$bigram(w) label(w)t_0$ for all $w$ in $c_0$
3	$biPOS(w) label(w)t_0$ for all $w$ in $c_0$
4	$w_{-1}w_1label(w_0) t_0$ , where $len(c_0)=1$
5	$start\_word(c_0)t_0$
6	$start\_POS(c_0)t_0$
7	$end\_word(c_0)t_0$
8	$end\_POS(c_0)t_0$
9	$wend\_word(c_0) t_0$ where $w \in c_0$ and $w \neq end\_word(c_0)$
10	$pend\_POS(c_0) t_0$ where $p \in c_0$ and $p \neq end\_POS(c_0)$
11	$internalPOSS(c_0) t_0$
12	$internalWords(c_0) t_0$
13	$specitermMatch(c_0)$
14	$t_{-1}t_0$
15	$head(c_{-1})t_{-1}head(c_0)t_0$
16	$headPOS(c_{-1})t_{-1}headPOS(c_0)t_0$
17	$end\_word(c_{-1})t_{-1}start\_word(c_0)t_0$
18	$end\_POS(c_{-1})t_{-1}start\_POS(c_0)t_0$
19	$end\_word(c_{-1})t_{-1}end\_word(c_0)t_0$
20	$end\_POS(c_{-1})t_{-1}end\_POS(c_0)t_0$
21	$start\_word(c_{-1})t_{-1}start\_word(c_0)t_0$
22	$start\_POS(c_{-1})t_{-1}start\_POS(c_0)t_0$
23	$end\_word(c_{-1})t_0$
24	$end\_POS(c_{-1})t_0$
25	$t_{-1}t_0start\_word(c_0)$
26	$t_{-1}t_0start\_POS(c_0)$
27	$internalWords(c_{-1}) t_{-1} internalWords(c_0) t_0$
28	$internalPOSS(c_{-1}) t_{-1} internalPOSS(c_0) t_0$

## 6 Experiments

### 6.1 Data Sets and Evaluation

Following previous studies on Chinese chunking in (Chen et al., 2006), our experiments were performed on the CTB4 dataset. The dataset consists of 838 files. In the experiments, we used the first 728 files (FID from chtb 001.fid to chtb 899.fid) as training data, and the other 110 files (FID from chtb 900.fid to chtb 1078.fid) as testing data. The training set consists of 9878 sentences, and the test set consists of 5920 sentences. The standard evaluation metrics for this task are precision  $p$  (the fraction of output chunks matching the reference chunks), recall  $r$  (the fraction of reference chunks returned), and the F-measure given by  $F = 2pr/(p + r)$ .

Our model has two tunable parameters: the number of training iterations  $N$ ; the number of top  $k$ -best outputs. Since we were interested in finding an effective feature representation at chunk-level for phrase chunking, we fixed  $N = 10$  and  $k = 5$  for all experiments. In the following experiments, our model has roughly comparable training time to the sequence labeling approach based on CRFs.

### 6.2 Chinese NP chunking

NP is the most important phrase in Chinese chunking and about 47% phrases in the CTB4 Corpus are NPs. In this section, we present the results of our approach to NP recognition.

Table 2 shows the results of the two systems using the same feature representations as defined in Table 1, but using different loss functions for learning. As shown, learning with F1 loss can improve the F-score by 0.34% over learning with 0-1 loss. It is reasonable that the model optimized with respect to evaluation metrics directly can achieve higher performance.

Loss Function	Precision	Recall	F1
0-1 loss	91.39	90.93	91.16
F1 loss	<b>92.03</b>	<b>90.98</b>	<b>91.50</b>

Table 2: Experimental results on Chinese NP chunking.

### 6.3 Chinese Text Chunking

There are 12 different types of phrases in the chunking corpus. Table 3 shows the results from

two different systems with different loss functions for learning. Observing the results in Table 3, we can see that learning with F1 loss can improve the F-score by 0.36% over learning with 0-1 loss, similar to the case in NP recognition. More

specifically, learning with F1 loss provides much better results for ADJP, ADVP, DVP, NP and VP, respectively. And it yields equivalent or comparable results to 0-1 loss in other categories.

	F1 loss			0-1 loss		
	precision	recall	<i>F1</i>	precision	recall	<i>F1</i>
ADJP	87.86	87.09	87.47	86.74	86.55	86.64
ADVP	90.66	78.73	84.27	91.91	76.68	83.61
CLP	0.00	0.00	0.00	1.32	5.88	2.15
DNP	99.42	99.93	99.68	99.42	99.95	99.69
DP	99.46	99.76	99.61	99.46	99.76	99.61
DVP	99.61	99.61	99.61	99.22	99.61	99.42
LCP	99.74	99.96	99.85	99.74	99.93	99.84
LST	87.50	52.50	65.63	87.50	52.50	65.63
NP	91.87	91.01	91.44	91.34	90.52	90.93
PP	99.57	99.77	99.67	99.57	99.77	99.67
QP	96.45	96.64	96.55	96.45	97.07	96.76
VP	90.14	90.39	90.26	89.92	89.79	89.85
ALL	<b>92.54</b>	<b>91.68</b>	<b>92.11</b>	92.30	91.20	91.75

Table 3: Experimental results on Chinese text chunking.

#### 6.4 Comparison with Other Models

Chen et al. (2006) compared the performance of the state-of-the-art machine learning models for Chinese chunking, and found that the SVMs approach yields higher accuracy than respective CRFs, Transformation-based Learning (TBL) (Megyesi, 2002), and Memory-based Learning (MBL) (Sang, 2002) approaches.

In this section, we give a comparison and analysis between our model and other state-of-the-art machine learning models for Chinese NP chunking and text chunking tasks. Performance of our model and some of the best results from the state-of-the-art systems are summarized in Table 4. Row "Voting" refers to the phrase-based voting methods based on four basic systems, which are respectively SVMs, CRFs, TBL and MBL, as depicted in (Chen et al., 2006). Observing the results in Table 4, we can see that for both NP chunking and text chunking tasks, our model achieves significant performance improvement over those state-of-the-art systems in terms of the F1-score, even for the voting methods. For text

chunking task, our approach improves performance by 0.65% over SVMs, and 0.43% over the voting method, respectively.

	Method	<i>F1</i>
NP chunking	CRFs	89.72
	SVMs	90.62
	Voting	91.13
	Ours	<b>91.50</b>
Text chunking	CRFs	90.74
	SVMs	91.46
	Voting	91.68
	Ours	<b>92.11</b>

Table 4: Comparisons of chunking performance for Chinese NP chunking and text chunking.

In particular, for NP chunking task, the F1-score of our approach is improved by 0.88% in comparison with SVMs, the best single system. Further, we investigated the likely cause for performance improvement by comparing the recognized results from our system and SVMs

respectively. We first sorted NPs by their length, and then calculated the F1-scores associated with different lengths for the two systems respectively. Figure 3 shows the comparison of F1-scores of the two systems by the chunk length. In the Chinese chunking corpus, the max NP length is 27, and the mean NP length is 1.5. Among all NPs, the NPs with the length 1 account for 81.22%. For the NPs with the length 1, our system gives slight improvement by 0.28% over SVMs. From the figure, we can see that the performance gap grows rapidly with the increase of the chunk length. In particular, the gap between the two systems is 27.73% when the length hits 4. But the gap begins to become smaller with further growth of the chunk length. The reasons may include the following two aspects. First, the number of NPs with the greater length is relatively small in the corpus. Second, the NPs with greater length in Chinese corpus often exhibit some typical rules. For example, an NP with length 8 is given as follows.

"棉花/NN(cotton)、/PU 油料/NN(oil)、/PU 药材/NN(drug)、/PU 蔬菜/NN(vegetable) 等/ETC (et al)".

The NP consists of a sequence of nouns simply separated by a punctuation "、". So it is also easy to be recognized by the sequence labeling approach based on SVMs. In summary, the above investigation indicates that our system is better at recognizing the long and complicated phrases compared with the sequence labeling approaches.

Figure 3: Comparison of F1-scores of NP recognition on Chinese corpus by the chunk length.

### 6.5 Impact of Different Types of Features

Our phrase chunking model is highly dependent upon chunk-level information. To establish the impact of each type of feature (SL-type, Internal-type, Correlation-type), we look at the

improvement in F1-score brought about by adding each type of features. Table 5 shows the accuracy with various features added to the model.

First consider the effect of the SL-type features. If we use only the SL-type features, the system achieves slightly lower performance than CRFs or SVMs, as shown in Table 4. Since the SL-type features consist of the features associated with single label, not including the features associated with label bigrams. Then, adding the Internal-type features to the system results in significant performance improvement on NP chunking and on text chunking, achieving 2.53% and 1.37%, respectively. Further, if Correlation-type features are used, the F1-scores on NP chunking and on text chunking are improved by 1.01% and 0.66%, respectively. The results show a significant impact due to the use of Internal-type features and Correlation-type features for both NP chunking and text chunking.

Task Type	Feature Type	F1
NP chunking	SL-type	87.96
	+Internal-type	90.49
	+Correlation-type	91.50
Text chunking	SL-type	90.08
	+Internal-type	91.45
	+Correlation-type	92.11

Table 5: Test F1-scores for different types of features on Chinese corpus.

### 6.6 Performance on Other Languages

We mainly focused on Chinese chunking in this paper. However, our approach is generally applicable to other languages including English, except that the definition of feature templates may be language-specific. To validate this point, we evaluated our system on the CoNLL 2000 data set, a public benchmarking corpus for English chunking (Sang and Buchholz 2000). The training set consists of 8936 sentences, and the test set consists of 2012 sentences.

We conducted both the NP-chunking and text chunking experiments on this data set with our approach, using the same feature templates as in Chinese chunking task excluding template 13. To find the headword within every chunk, we referred to the head-finding rules from (Collins, 1999), and made a simple modification to them in a similar way as in Chinese. As we can see from Table 6,

our model is able to achieve better performance compared with state-of-the-art systems. Table 6 also shows state-of-the-art performance for both NP-chunking and text chunking tasks. LDCRF's results presented in (Sun et al., 2008) are the state-of-the-art for the NP chunking task, and SVM's results presented in (Wu et al., 2006) are the state-of-the-art for the text chunking task.

Moreover, the performance should be further improved if some additional features tailored for English chunking are employed in our model. For example, we can introduce an orthographic feature type called Token feature and the affix feature into the model, as used in (Wu et al., 2006).

	Method	Precision	Recall	F1
NP chunking	Ours	94.79	94.65	<b>94.72</b>
	LDCRF	94.65	94.03	94.34
Text chunking	Ours	94.31	94.12	<b>94.22</b>
	SVMs	94.12	94.13	94.12

Table 6: Performance on English corpus.

## 7 Conclusions and Future Work

In this paper we have presented a novel approach to phrase chunking by formulating it as a joint segmentation and labeling problem. One important advantage of our approach is that it provides a natural formulation to exploit chunk-level features. The experimental results on both Chinese chunking and English chunking tasks show that the use of chunk-level features can lead to significant performance improvement and that our approach outperforms the best in the literature.

Future work mainly includes the following two aspects. Firstly, we will explore applying external information, such as semantic knowledge, to represent the chunk-level features, and then incorporate them into our model to improve the performance. Secondly, we plan to apply our approach to other joint segmentation and labeling tasks, such as clause identification and named entity recognition.

{danielhe, nght}@comp.nus.edu.sg

## Abstract

We present a novel beam-search decoder for grammatical error correction. The decoder iteratively generates new hypothesis corrections from current hypotheses and scores them based on features of grammatical correctness and fluency. These features include scores from discriminative classifiers for specific error categories, such as articles and prepositions. Unlike all previous approaches, our method is able to perform correction of whole sentences with multiple and interacting errors while still taking advantage of powerful existing classifier approaches. Our decoder achieves an  $F_1$  correction score significantly higher than all previous published scores on the Helping Our Own (HOO) shared task data set.

## 1 Introduction

Grammatical error correction is an important problem in natural language processing (NLP) that has attracted an increasing amount of interest over the last few years. Grammatical error correction promises to provide instantaneous accurate feedback to language learners, e.g., learners of English as a Second Language (ESL).

The dominant paradigm that underlies most error correction systems to date is multi-class classification. A classifier is trained to predict a word from a *confusion set* of possible correction choices, given some feature representation of the surrounding sentence context. During testing, the classifier predicts the most likely correction for each test instance. If the prediction differs from the observed

word used by the writer and the classifier is sufficiently confident in its prediction, the observed word is replaced by the prediction. Although considerable progress has been made, the classification approach suffers from some serious shortcomings. Each classifier corrects a single word for a specific error category individually. This ignores dependencies between the words in a sentence. Also, by conditioning on the surrounding context, the classifier implicitly assumes that the surrounding context is free of grammatical errors, which is often not the case. Finally, the classifier typically has to commit to a single one-best prediction and is not able to change its decision later or explore multiple corrections. Instead of correcting each word individually, we would like to perform global inference over corrections of whole sentences which can contain multiple and interacting errors.

An alternative paradigm is to view error correction as a statistical machine translation (SMT) problem from “bad” to “good” English. While this approach can naturally correct whole sentences, a standard SMT system cannot easily incorporate models for specific grammatical errors. It also suffers from the paucity of error-annotated training data for grammar correction. As a result, applying a standard SMT system to error correction does not produce good results, as we show in this work.

In this work, we present a novel beam-search decoder for grammatical error correction that combines the advantages of the classification approach and the SMT approach. Starting from the original input sentence, the decoder performs an iterative search over possible sentence-level hypotheses

to find the best sentence-level correction. In each iteration, a set of *proposers* generates new hypotheses by making incremental changes to the hypotheses found so far. A set of *experts* scores the new hypotheses on criteria of grammatical correctness. These experts include discriminative classifiers for specific error categories, such as articles and prepositions. The decoder model calculates the overall hypothesis score for each hypothesis as a linear combination of the expert scores. The weights of the decoder model are discriminatively trained on a development set of error-annotated sentences. The highest scoring hypotheses are kept in the search beam for the next iteration. This search procedure continues until the beam is empty or the maximum number of iterations has been reached. The highest scoring hypothesis is returned as the sentence-level correction. We evaluate our proposed decoder in the context of the Helping Our Own (HOO) shared task on grammatical error correction (Dale and Kilgarriff, 2011). Our decoder achieves an  $F_1$  score of 25.48% which improves upon the current state of the art.

The remainder of this paper is organized as follows. The next section gives an overview of related work. Section 3 describes the proposed beam-search decoder. Sections 4 and 5 describe the experimental setup and results, respectively. Section 6 provides further discussion. Section 7 concludes the paper.

## 2 Related Work

In this section, we summarize related work in grammatical error correction. For a more detailed review, the readers can refer to (Leacock et al., 2010).

The classification approach to error correction has mainly focused on correcting article and preposition errors (Knight and Chander, 1994; Han et al., 2006; Chodorow et al., 2007; Tetreault and Chodorow, 2008; Gamon, 2010; Dahlmeier and Ng, 2011b; Rozovskaya and Roth, 2011). The advantage of the classification approach is that it can make use of powerful machine learning algorithms in connection with arbitrary features from the sentence context. Typical features include surrounding N-grams, part-of-speech (POS) tags, chunks, etc. In fact, a considerable amount of research effort has been invested in finding better features.

The SMT approach to error corrections has re-

ceived comparatively less attention. Brockett *et al.* (2006) use an SMT system to correct errors involving mass noun errors. Because no large annotated learner corpus was available, the training data was created artificially from non-learner text. Lee and Seneff (2006) describe a lattice-based correction system with a domain-specific grammar for spoken utterances from the flight domain. The work in (Désilets and Hermet, 2009) uses simple round-trip translation with a standard SMT system to correct grammatical errors. Dahlmeier and Ng (2011a) correct collocation errors using phrase-based SMT and paraphrases induced from the writer’s native language. Park and Levy (2011) propose a noisy channel model for error correction. While their motivation to correct whole sentences is similar to ours, their proposed generative method differs substantially from our discriminative decoder. Park and Levy’s model does not allow the use of discriminative expert classifiers as our decoder does, but instead relies on a bigram language model to find grammatical corrections. Indeed, they point out that the language model often fails to distinguish grammatical and ungrammatical sentences.

To the best of our knowledge, our work is the first discriminatively trained decoder for whole-sentence grammatical error correction.

## 3 Decoder

In this section, we describe the proposed beam-search decoder and its components.

The task of the decoder is to find the best hypothesis (i.e., the best corrected sentence) for a given input sentence. To accomplish this, the decoder needs to be able to perform two tasks: generating new hypotheses from current ones, and discriminating good hypotheses from bad ones. This is achieved by two groups of modules which we call *proposers* and *experts*, respectively. Proposers take a hypothesis and generate a set of new hypotheses, where each new hypothesis is the result of making an incremental change to the current hypothesis. Experts score hypotheses on particular aspects of grammaticality. This can be a general language model score, or the output of classifiers for particular error categories, for example for article and preposition usage. The overall score for a hypothesis is a linear combina-

tion of the expert scores. Note that in our decoder, each hypothesis corresponds to a complete sentence. This makes it easy to apply syntactic processing, like POS tagging, chunking, and dependency parsing, which provides necessary features for the expert models. The highest scoring hypotheses are kept in the search beam for the next iteration. The search ends when the beam is empty or the maximum number of iterations has been reached. The highest scoring hypothesis found during the search is returned as the sentence-level correction. The modular design of the decoder makes it easy to extend the model to new error categories by adding specific proposers and experts without having to change the decoding algorithm.

### 3.1 Proposers

The proposers generate new hypotheses, given a hypothesis. Because the number of possible hypotheses grows exponentially with the sentence length, enumerating all possible hypotheses is infeasible. Instead, each proposer only makes a small incremental change to the hypothesis in each iteration. A change corresponds to a correction of a single word or phrase. We experiment with the following proposers in this work. Additional proposers for other error categories can easily be added to the decoder.

- **Spelling** Generate a set of new hypotheses, by replacing a misspelled word with each correction proposed by a spellchecker.
- **Articles** For each noun phrase (NP), generate two new hypotheses by changing the observed article. Possible article choices are *a/an*, *the*, and the empty article  $\epsilon$ .
- **Prepositions** For each prepositional phrase (PP), generate a set of new hypotheses by changing the observed preposition. For each preposition, we define a confusion set of possible corrections.
- **Punctuation insertion** Insert commas, periods, and hyphens based on a set of simple rules.
- **Noun number** For each noun, change its number from singular to plural or vice versa.

### 3.2 Experts

The experts score hypotheses on particular aspects of grammaticality to help the decoder to discriminate grammatical hypotheses from ungrammatical ones. We employ two types of expert models. The first type of expert model is a standard N-gram language model. The language model expert is not specialized for any particular type of error. The second type of experts is based on linear classifiers and is specialized for particular error categories. We use the following classifier experts in our work. The features for the classifier expert models include features from N-grams, part-of-speech (POS) tags, chunks, web-scale N-gram counts, and dependency parse trees. Additional experts can easily be added to the decoder.

- **Article expert** Predict the correct article for a noun phrase.
- **Preposition expert** Predict the correct preposition for a prepositional phrase.
- **Noun number expert** Predict whether a noun should be in the singular or plural form.

The outputs of the experts are used as hypothesis features in the decoder, as described in the next section.

### 3.3 Hypothesis Features

Each hypothesis is associated with a vector of real-valued features which are indicators of grammaticality and are computed from the output of the expert models. We call these features *hypothesis features* to distinguish them from the features of the expert classifiers. The simplest hypothesis feature is the log probability of the hypothesis under the N-gram language model expert. To avoid a bias towards shorter hypotheses, we normalize the probability by the length of the hypothesis:

$$score_{lm} = \frac{1}{|\mathbf{h}|} \log Pr(\mathbf{h}), \quad (1)$$

where  $\mathbf{h}$  is a hypothesis sentence and  $|\mathbf{h}|$  is the hypothesis length in tokens.

For the classifier-based experts, we define two types of features. The first is the *average score* of

the hypothesis under the expert model:

$$score_{avg} = \frac{1}{n} \sum_{i=1}^n \left( \mathbf{u}^T f(\mathbf{x}_i^h, y_i^h) \right), \quad (2)$$

where  $\mathbf{u}$  is the expert classifier weight vector,  $\mathbf{x}_i^h$  and  $y_i^h$  are the feature vector and the observed class, respectively, for the  $i$ -th instance extracted from the hypothesis  $\mathbf{h}$  (e.g., the  $i$ -th NP in the hypothesis for the article expert), and  $f$  is a feature map that computes the expert classifier features. The average score reflects how much the expert model “likes” the hypothesis. The second expert score, which we call *delta score*, is the maximum difference between the highest scoring class and the observed class in any instance from the hypothesis:

$$score_{delta} = \max_{i,y} \left( \mathbf{u}^T f(\mathbf{x}_i^h, y) - \mathbf{u}^T f(\mathbf{x}_i^h, y_i^h) \right). \quad (3)$$

Generally speaking, the delta score measures how much the model “disagrees” with the hypothesis.

Finally, each hypothesis has a number of *correction count features* that keep track of how many corrections have been made to the hypothesis so far. For example, there is a feature that counts how often the article correction  $\epsilon \rightarrow the$  has been applied. We also add aggregated correction count features for each error category, e.g., how many article corrections have been applied in total. The correction count features allow the decoder to learn a bias against over-correcting sentences and to learn which types of corrections are more likely and which are less likely.

### 3.4 Decoder Model

The hypothesis features described in the previous subsection are combined to compute the score of a hypothesis according to the following linear model:

$$s = \mathbf{w}^T f_E(\mathbf{h}), \quad (4)$$

where  $\mathbf{w}$  is the decoder model weight vector and  $f_E$  is a feature map that computes the hypothesis features described above, given a set of experts  $E$ . The weight vector  $\mathbf{w}$  is tuned on a development set of error-annotated sentences using the PRO ranking optimization algorithm (Hopkins and May, 2011).<sup>1</sup>

<sup>1</sup>We also experimented with the MERT algorithm (Och, 2003) but found that PRO achieved better results.

PRO performs decoder parameter tuning through a pair-wise ranking approach. The algorithm starts by sampling hypothesis pairs from the N-best list of the decoder. The metric score for each hypothesis induces a ranking of the two hypotheses in each pair. The task of finding a weight vector that correctly ranks hypotheses can then be reduced to a simple binary classification task. In this work, we use PRO to optimize the  $F_1$  correction score, which is defined in Section 4.2. PRO requires a sentence-level score for each hypothesis. As  $F_1$  score is not decomposable, we optimize sentence-level  $F_1$  score which serves as an approximation of the corpus-level  $F_1$  score. Similarly, Hopkins and May optimize a sentence-level BLEU approximation (Lin and Och, 2004) instead of the corpus-level BLEU score (Papineni et al., 2002). We observed that optimizing sentence-level  $F_1$  score worked well in practice in our experiments.

### 3.5 Decoder Search

Given a set of proposers, experts, and a tuned decoder model, the decoder can be used to correct new unseen sentences. This is done by performing a search over possible hypothesis candidates. The decoder starts with the input sentence as the initial hypothesis, i.e., assuming that all words are correct. It then performs a beam search over the space of possible hypotheses to find the best hypothesis correction  $\hat{\mathbf{h}}$  for an input sentence  $e$ . The search proceeds in iterations until the beam is empty or the maximum number of iterations has been reached. In each iteration, the decoder takes each hypothesis in the beam and generates new hypothesis candidates using all the available proposers. The hypotheses are evaluated by the expert models that compute the hypothesis features and finally scored using the decoder model. As the search space grows exponentially, it is infeasible to perform exhaustive search. Therefore, we prune the search space by only accepting the most promising hypotheses to the pool of hypotheses for future consideration. If a hypothesis has a higher score than the best hypothesis found in previous iterations, it is definitely added to the pool. Otherwise, we use a simulated annealing strategy where hypotheses with a lower score can still be accepted with a certain probability which depends on the difference between the hypothesis score and

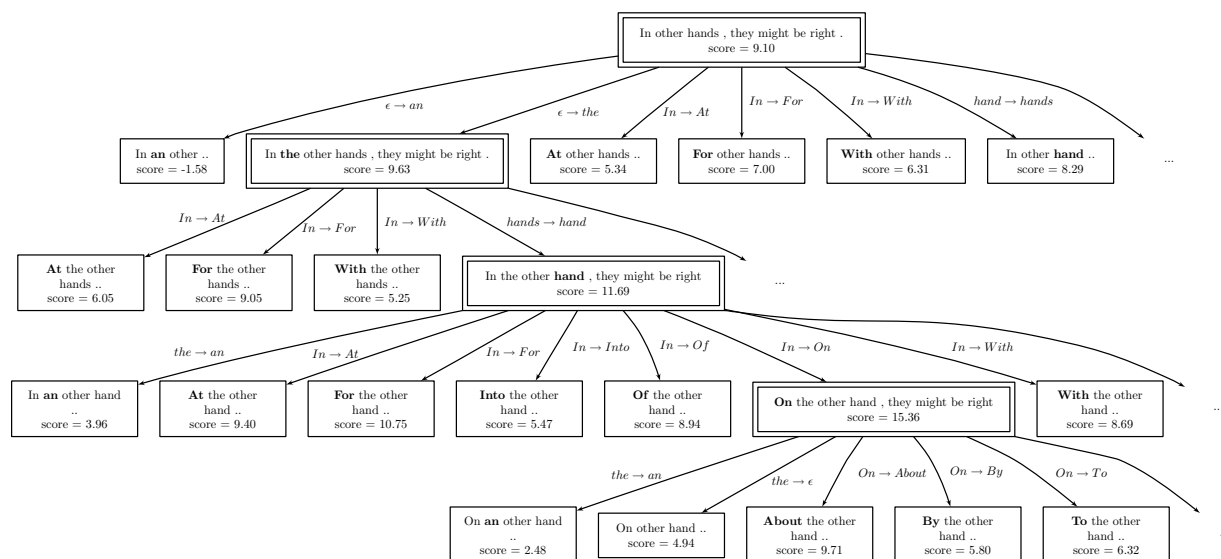

Figure 1: Example of a search tree produced by the beam-search decoder for the input *In other hands, they might be right*. The highest scoring hypothesis found is *On the other hand, they might be right*. Some hypotheses are omitted due to space constraints.

the score of the best hypothesis and the “temperature” of the system. We lower the temperature after each iteration according to an exponential cooling schedule. Hypotheses that have been explored before are not considered again to avoid cycles in the search. From all hypotheses in the pool, we select the top  $k$  hypotheses and add them to the beam for the next search iteration. The decoding algorithm is shown in Algorithm 1. The decoder can be considered an *anytime algorithm* (Russell and Norvig, 2010), as it has a current best hypothesis correction available at any point of the search, while gradually improving the result by searching for better hypotheses. An example of a search tree produced by our decoder is shown in Figure 1.

The decoding algorithm shares some similarities with the beam-search algorithm frequently used in SMT. There is however a difference between SMT decoding and grammar correction decoding that is worth pointing out. In SMT decoding, every input word needs to be translated exactly once. In contrast, in grammar correction decoding, the majority of the words typically do *not* need any correction (in the HOO data, for example, there are on average 6 errors per 100 words). On the other hand, some words might require *multiple* corrections, for example spelling correction followed by noun num-

ber correction. Errors can also be inter-dependent, where correcting one word makes it necessary to change another word, for example to preserve agreement. Our decoding algorithm has the option to correct some words multiple times, while leaving other words unchanged.

## 4 Experiments

We evaluate our decoder in the context of the HOO shared task on grammatical error correction. The goal of the task is to automatically correct errors in academic papers from NLP. The readers can refer to the overview paper (Dale and Kilgarriff, 2011) for details. We compare our proposed method with two baselines: a phrase-based SMT system (described in Section 4.3) and a pipeline of classifiers (described in Section 4.4).

### 4.1 Data

We split the HOO development data into an equal sized training (HOO-TRAIN) and tuning (HOO-TUNE) set. The official HOO test data (HOO-TEST) is used for evaluation. In the HOO shared task, participants were allowed to raise objections regarding the gold-standard annotations (corrections) of the test data after the test data was released. As a result, the gold-standard annotations could be biased in fa-

**Algorithm 1** The beam-search decoding algorithm.  $\mathbf{e}$ : original sentence,  $\mathbf{w}$ : decoder weight vector,  $P$ : set of proposers,  $E$ : set of experts,  $k$ : beam width,  $M$ : maximum number of iterations,  $T, c$ : initial temperature and cooling schedule for simulated annealing ( $0 < c < 1$ ).

**procedure** decode( $\mathbf{e}, \mathbf{w}, P, E, k, M$ )

```

1:  $beam \leftarrow \{\mathbf{e}\}$ 
2:  $previous \leftarrow \{\mathbf{e}\}$ 
3:  $\mathbf{h}_{best} \leftarrow \mathbf{e}$ 
4:  $s_{best} \leftarrow \mathbf{w}^T f_E(\mathbf{h}_{best})$ 
5:  $i \leftarrow 0$ 
6: while  $beam \neq \emptyset \wedge i < M$  do
7:    $pool \leftarrow \{\}$ 
8:   for all  $\mathbf{h} \in beam$  do
9:     for all  $p \in P$  do
10:      for all  $\mathbf{h}' \in p.propose(\mathbf{h})$  do
11:        if  $\mathbf{h}' \in previous$  then
12:          continue
13:         $previous \leftarrow previous \cup \{\mathbf{h}'\}$ 
14:         $s_{\mathbf{h}'} \leftarrow \mathbf{w}^T f_E(\mathbf{h}')$ 
15:        if  $accept(s_{\mathbf{h}'}, s_{best}, T)$  then
16:           $pool \leftarrow pool \cup \{(\mathbf{h}', s_{\mathbf{h}'})\}$ 
17:    $beam \leftarrow \emptyset$ 
18:   for all  $(\mathbf{h}, s_{\mathbf{h}}) \in nbest(pool, k)$  do
19:      $beam \leftarrow beam \cup \{\mathbf{h}\}$ 
20:     if  $s_{\mathbf{h}} > s_{best}$  then
21:        $\mathbf{h}_{best} \leftarrow \mathbf{h}$ 
22:        $s_{best} \leftarrow s_{\mathbf{h}}$ 
23:    $T \leftarrow T \times c$ 
24:    $i \leftarrow i + 1$ 
25: return  $\mathbf{h}_{best}$ 

```

**procedure** accept( $s_{\mathbf{h}}, s_{best}, T$ )

```

1:  $\delta \leftarrow s_{\mathbf{h}} - s_{best}$ 
2: if  $\delta > 0$  then
3:   return true
4: if  $exp(\frac{\delta}{T}) > random()$  then
5:   return true else return false

```

vor of specific systems participating in the shared task. We obtain both the original and the final official gold-standard annotations and report evaluation results on both annotations.

We use the ACL Anthology<sup>2</sup> as training data for the expert models. We crawl all non-OCR documents from the anthology, except those documents that overlap with the HOO data. Section headers, references, etc. are automatically removed. The Web 1T 5-gram corpus (Brants and Franz, 2006) is used for language modeling and collecting web N-gram counts. Table 1 gives an overview of the data sets.

<sup>2</sup><http://www.aclweb.org/anthology-new/>

Data Set	Sentences	Tokens
HOO-TRAIN	467	11,373
HOO-TUNE	472	11,435
HOO-TEST	722	18,790
ACL-ANTHOLOGY	943,965	22,465,690

Table 1: Overview of the data sets.

## 4.2 Evaluation

We evaluate performance by computing precision, recall, and  $F_1$  correction score without bonus as defined in the official HOO report (Dale and Kilgarriff, 2011)<sup>3</sup>.  $F_1$  correction score is simply the  $F_1$  measure (van Rijsbergen, 1979) between the corrections (called *edits* in HOO) proposed by a system and the gold-standard corrections. Let  $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$  be a set of test sentences and let  $\{\mathbf{g}_1, \dots, \mathbf{g}_n\}$  be the set of gold-standard edits for the sentences. Let  $\{\mathbf{h}_1, \dots, \mathbf{h}_n\}$  be the set of corrected sentences output by a system. One difficulty in the evaluation is that the set of system edits  $\{\mathbf{d}_1, \dots, \mathbf{d}_n\}$  between the test sentences and the system outputs is ambiguous. For example, assume that the original test sentence is *The data is similar with test set.*, the system output is *The data is similar to the test set.*, and the gold-standard edits are two corrections *with*  $\rightarrow$  *to*,  $\epsilon$   $\rightarrow$  *the* that change *with* to *to* and insert *the* before *test set*. The official HOO scorer however extracts a single system edit *with*  $\rightarrow$  *to the* for this instance. As the extracted system edit is different from the gold-standard edits, the system would be considered wrong, although it proposes the *exact same* corrected sentence as the gold standard edits. This problem has also been recognized by the HOO shared task organizers (see (Dale and Kilgarriff, 2011), Section 5).

Our *MaxMatch* ( $M^2$ ) scorer (Dahlmeier and Ng, 2012) overcomes this problem through an efficient algorithm that computes the set of system edits which has the maximum overlap with the gold-standard edits. We use the  $M^2$  scorer as the main evaluation metric in our experiments. Additionally, we also report results with the official HOO scorer. Once the set of system edits is extracted, precision, recall, and  $F_1$  measure are computed as follows.

<sup>3</sup>“Without bonus” means that a system does not receive extra credit for not making corrections that are considered optional in the gold standard.

$$P = \frac{\sum_{i=1}^n |\mathbf{d}_i \cap \mathbf{g}_i|}{\sum_{i=1}^n |\mathbf{d}_i|} \quad (5)$$

$$R = \frac{\sum_{i=1}^n |\mathbf{d}_i \cap \mathbf{g}_i|}{\sum_{i=1}^n |\mathbf{g}_i|} \quad (6)$$

$$F_1 = 2 \times \frac{P \times R}{P + R} \quad (7)$$

We note that the  $M^2$  scorer and the HOO scorer adhere to the same score definition and only differ in the way the system edits are computed. For statistical significance testing, we use sign-test with bootstrap re-sampling (Koehn, 2004) with 1,000 samples.

### 4.3 SMT Baseline

We build a baseline error correction system, using the MOSES SMT system (Koehn et al., 2007). Word alignments are created automatically on “good-bad” parallel text from HOO-TRAIN using GIZA++ (Och and Ney, 2003), followed by phrase extraction using the standard heuristic (Koehn et al., 2003). The maximum phrase length is 5. Parameter tuning is done on the HOO-TUNE data with the PRO algorithm (Hopkins and May, 2011) implemented in MOSES. The optimization objective is sentence-level BLEU (Lin and Och, 2004). We note that the objective function is not the same as the final evaluation  $F_1$  score. Also, the training and tuning data are small by SMT standards. The aim for the SMT baseline is not to achieve a state-of-the-art system, but to serve as the simplest possible baseline that uses only off-the-shelf software.

### 4.4 Pipeline Baseline

The second baseline system is a pipeline of classifier-based and rule-based correction steps. Each step takes sentence segmented plain text as input, corrects one particular error category, and feeds the corrected text into the next step. No search or global inference is applied. The correction steps are:

1. Spelling errors
2. Article errors
3. Preposition errors
4. Punctuation errors
5. Noun number errors

We use the following tools for syntactic processing: OpenNLP<sup>4</sup> for POS tagging, YamCha (Kudo and Matsumoto, 2003) for constituent chunking, and the MALT parser (Nivre et al., 2007) for dependency parsing. For language modeling, we use RandLM (Talbot and Osborne, 2007).

For spelling correction, we use GNU Aspell<sup>5</sup>. Words that contain upper-case characters inside the word or are shorter than four characters are excluded from spell checking. The spelling dictionary is augmented with all words that appear at least 10 times in the ACL-ANTHOLOGY data set.

Article correction is cast as a multi-class classification problem. As the learning algorithm, we choose multi-class confidence-weighted (CW) learning (Crammer et al., 2009) which has been shown to perform well for NLP problems with high dimensional and sparse feature spaces. The possible classes are the articles *a*, *the*, and the empty article  $\epsilon$ . The article *an* is normalized as *a* and restored later using a rule-based heuristic. We consider all NPs that are not pronouns and do not have a non-article determiner, e.g., *this*, *that*. The classifier is trained on over 5 million instances from ACL-ANTHOLOGY. We use a combination of features proposed by (Rozovskaya et al., 2011) (which include lexical and POS N-grams, lexical head words, etc.), web-scale N-gram count features from the Web 1T 5-gram corpus following (Bergsma et al., 2009), and dependency head and child features. During testing, a correction is proposed if the predicted article is different from the observed article used by the writer, and the difference between the confidence score for the predicted article and the confidence score for the observed article is larger than a threshold. Threshold parameters are tuned via a grid-search on the HOO-TUNE data. We tune a separate threshold value for each class.

Preposition correction and noun number correction are analogous to article correction. They differ only in terms of the classes and the features. For preposition correction, the classes are 36 frequent English prepositions<sup>6</sup>. The features are surrounding

<sup>4</sup><http://opennlp.sourceforge.net>

<sup>5</sup><http://aspell.net>

<sup>6</sup>*about, along, among, around, as, at, beside, besides, between, by, down, during, except, for, from, in, inside, into, of, off, on, onto, outside, over, through, to, toward, towards, under,*

lexical N-grams, web-scale N-gram counts, and dependency features following (Tetreault et al., 2010). The preposition classifier is trained on 1 million training examples from the ACL-ANTHOLOGY. For noun number correction, the classes are *singular* and *plural*. The features are lexical N-grams, web-scale N-gram counts, dependency features, the noun lemma, and a binary countability feature. The noun number classifier is trained on over 5 million examples from ACL-ANTHOLOGY. During testing, the singular or plural word surface form is generated using WordNet (Fellbaum, 1998) and simple heuristics. Punctuation correction is done using a set of simple rules developed on the HOO development data.

At the end of every correction step, all proposed corrections are filtered using a 5-gram language model from the Web 1T 5-gram corpus and only corrections that strictly increase the normalized language model score of the sentence are applied.

#### 4.5 Decoder

We experiment with different decoder configurations with different proposers and expert models. In the simplest configuration, the decoder only has the spelling proposer and the language model expert. We then add the article proposer and expert, the preposition proposer and expert, the punctuation proposer, and finally the noun number proposer and expert. We refer to the final configuration with all proposers and experts as the *full decoder model*. Note that error categories are corrected jointly and not in sequential steps as in the pipeline.

To make the results directly comparable to the pipeline, the decoder uses the same resources as the pipeline. As the expert models, we use a 5-gram language model from the Web 1T 5-gram corpus with the Berkeley LM (Pauls and Klein, 2011)<sup>7</sup> in the decoder and the CW-classifiers described in the last section. The spelling proposer uses the same spellchecker as the pipeline, and the punctuation proposer uses the same rules as the pipeline. The beam width and the maximum number of iterations are set to 10. In earlier experiments, we found that larger values had no effect on the result. The simu-

*underneath, until, up, upon, with, within, without*

<sup>7</sup>Berkeley LM is written in Java and was easier to integrate into our Java-based decoder than RandLM.

lated annealing temperature  $T$  is initialized to 10 and the exponential cooling schedule  $c$  is set to 0.9. The decoder weight vector is initialized as follows. The weight for the language model score and the weights for the classifier expert average scores are initialized to 1.0, and the weights for the classifier expert delta scores are initialized to  $-1.0$ . The weights for the correction count features are initialized to zero. For PRO optimization, we use the HOO-TUNE data and the default PRO parameters from (Hopkins and May, 2011): we sample 5,000 hypothesis pairs from the N-best list ( $N = 100$ ) for every input sentence and keep the top 50 sample pairs with the highest difference in  $F_1$  measure. The weights are optimized using MegaM (Daumé III, 2004) and interpolated with the previous weight vector with an interpolation parameter of 0.1. We normalize feature values to avoid having features on a larger scale dominate features on a smaller scale. We linearly scale all hypothesis features to a unit interval  $[0, 1]$ . The minimum and maximum values for each feature are estimated from the development data. We use an early stopping criterion that terminates PRO if the objective function on the tuning data drops. To balance the skewed data where samples without errors greatly outnumber samples with errors, we give a higher weight to sample pairs where the decoder proposed a valid correction. We found a weight of 20 to work well, based on initial experiments on the HOO-TUNE data. We keep all these parameters fixed for all experiments.

## 5 Results

The complete results of our experiments are shown in Table 2. Each row contains the results for one error correction system. Each system is scored on the original and official gold-standard annotations, both with the  $M^2$  scorer and the official HOO scorer. This results in four sets of precision, recall, and  $F_1$  scores for each system. The best published result to date on this data set is the UI Run1 system from the HOO shared task. We include their system as a reference point.

We make the following observations. First, the scores on the official gold-standard annotations are higher compared to the original gold-standard annotations. We note that the gap between the two

System	Original gold-standard						Official gold-standard

Table 2: Experimental results on HOO-TEST. Precision, recall, and F<sub>1</sub> score are shown in percent. The best F<sub>1</sub> score for each system is highlighted in bold. Statistically significant improvements ( $p < 0.01$ ) over the pipeline baseline are marked with an asterisk (\*). Statistically significant improvements over the UI Run1 system are marked with a dagger (†). All improvements of the pipeline and the decoder over the SMT baseline are statistically significant.

annotations is the largest for the UI Run1 system which confirms the suspected bias of the official gold-standard annotations in favor of participating systems. Second, the scores computed with the M<sup>2</sup> scorer are higher than the scores computed with the official HOO scorer. With more error categories and more ambiguity in the edits segmentation, the gap between the scorers widens. In the case of the full pipeline and decoder model, the HOO scorer even shows a *decrease* in F<sub>1</sub> score when the score actually goes up as shown by the M<sup>2</sup> scorer. We therefore focus on the scores of the M<sup>2</sup> scorer from now on. The SMT baseline achieves 8.68% and 11.21% F<sub>1</sub> on the original and official gold standard, respectively. Although the worst system in our experiments, it would still have claimed the third place in the HOO shared task. One problem is certainly the small amount of training data. Another reason is that the phrase-based model is unaware of syntactic structure and cannot express correction rules of the form  $NP \rightarrow the\ NP$ . Instead, it has to have seen the exact correction rule, e.g.,  $house \rightarrow the\ house$ , in the training data. As a result, the model does not generalize well. The pipeline achieves state-of-the-art results. Each additional correction step improves the score. Our proposed decoder achieves the best

result. When only a few error categories are corrected, the pipeline and the decoder are close to each other. When more error categories are added, the gap between the pipeline and the decoder becomes larger. The full decoder model achieves an F<sub>1</sub> score of 23.48% and 25.48% on the original and official gold standard, respectively, which is statistically significantly better than both the pipeline system and the UI Run1 system.

## 6 Discussion

As pointed out in Section 3.5, the majority of sentences require zero or few corrections. Therefore, the depth of the search tree is typically small. In our experiments, the average depth of the search tree is only 1.9 (i.e., 0.9 corrections per sentence) on the test set. Usually, the search depth will be one larger than the number of corrections made, since the decoder will explore the next level of the search tree before deciding that none of the new hypotheses are better than the current best one. On the other hand, there are many possible hypotheses that can be proposed for any sentence. The breadth of the search tree is therefore quite large. In our experiments, the decoder explored on average 99 hypotheses per sentence on the test set.

PRO iteration	P	R	F <sub>1</sub>
1	14.13	20.17	16.62
2	19.71	20.85	20.27
3	23.12	21.03	22.02
4	24.35	20.85	22.47
5	25.53	20.51	22.75
6	26.27	20.34	22.93
7	27.25	20.68	<b>23.52</b>
8	26.73	19.83	22.77

Table 3: PRO tuning of the full decoder model on HOO-TUNE

Feature	Weight
$a \rightarrow the$	-1.3660
$a \rightarrow \epsilon$	0.5253
$the \rightarrow a$	-0.9997
$the \rightarrow \epsilon$	0.0532
$\epsilon \rightarrow a$	0.0694
$\epsilon \rightarrow the$	-0.0529

Table 4: Example of PRO-tuned weights for article correction count features for the full decoder model.

We found that PRO tuning is very important to achieve good performance for our decoder. Most importantly, PRO tunes the correction count features that bias the decoder against over-correcting sentences thus improving precision. But PRO is also able to improve recall during tuning. Table 3 shows the trajectory of the performance for the full decoder model during PRO tuning on HOO-TUNE. After PRO tuning has converged, we inspect the learned weight vector and observe some interpretable patterns learned by PRO. First, the language model score and all classifier expert average scores receive positive weights, while all classifier expert delta scores receive negative weights, in line with our initial intuition described in Section 3.3. Second, most correction count features receive negative weights, thus acting as a bias against correction if it is not necessary. Finally, the correction count features reveal which corrections are more likely and which are less likely. For example, article replacement errors are less common in the HOO-TUNE data than article insertions or deletions. The weights learned for the article correction count features shown in Table 4 reflect this.

Although our decoder achieves state-of-the-art results, there remain many error categories which the decoder currently cannot correct. This includes, for

example, verb form errors (*Much research (have → has) been put into . . .*) and lexical choice errors (*The (concerned → relevant) relation . . .*). We believe that our decoder provides a promising framework to build grammatical error correction systems that include these types of errors in the future.

## 7 Conclusion

We have presented a novel beam-search decoder for grammatical error correction. The model performs end-to-end correction of whole sentences with multiple, interacting errors, is discriminatively trained, and incorporates existing classifier-based models for error correction. Our decoder achieves an F<sub>1</sub> correction score of 25.48% on the HOO shared task which outperforms the current state of the art on this data set.

## Abstract

*Evidence-based medicine* is an approach whereby clinical decisions are supported by the best available findings gained from scientific research. This requires efficient access to such evidence. To this end, abstracts in evidence-based medicine can be labeled using a set of predefined medical categories, the so-called *PICO* criteria. This paper presents an approach to automatically annotate sentences in medical abstracts with these labels. Since both structural and sequential information are important for this classification task, we use *kLog*, a new language for statistical relational learning with kernels. Our results show a clear improvement with respect to state-of-the-art systems.

## 1 Introduction

*Evidence-based medicine (EBM)* or *evidence-based practice (EBP)* combines clinical expertise, the preferences and values of the patient and the best available evidence to make good patient care decisions. Clinical research findings are systematically reviewed, appraised and used to improve the patient care, for which efficient access to such evidence is required. In order to facilitate the search process, medical documents are labeled using a set of predefined medical categories, the *PICO criteria*. PICO is an acronym for the mnemonic concepts that are used to construct queries when searching for scientific evidence in the EBM process. The need to automatize the annotation process has initiated research into automatic approaches to annotate sentences in medical documents with the PICO labels.

As indicated by Kim et al. (2011), both the structural information of the words in the sentence, and that of the sentences in the document are important features for this task. Furthermore, sequential information can leverage the dependencies between different sentences in the text. Therefore we propose an approach using *kLog* (Frasconi et al., 2012) to tackle this problem. *kLog* is a new language for statistical relational learning with kernels, that is embedded in Prolog, and builds upon and links together concepts from database theory, logic programming and learning from interpretations. Learning from interpretations is a logical and relational learning setting (De Raedt et al., 2008) in which the examples are interpretations, that is, sets of tuples that are true in the examples. In a sense, each example can be viewed as a small relational database. *kLog* is able to transform relational into graph-based representations and apply kernel methods to extract an extended high-dimensional feature space.

The choice for *kLog* was motivated by previous results (Verbeke et al., 2012), where we showed that a statistical relational learning approach using *kLog* is able to process the contextual aspects of language improving on state-of-the-art results for hedge cue detection. However, the current task adds two levels of complexity. First, next to the relations between the words in the sentence, now also the relations between the sentences in the document become important. In the proposed approach, we first generate a feature space with *kLog* that captures the intrasentential properties and relations. Hereafter, these features serve as input for a structured output support vector machine that can handle sequence tagging

(Tsochantaridis et al., 2004), in order to take the intersentential features into account. Second, since there are more than two categories, and each sentence can have multiple labels, the problem is now a multiclass multilabel classification task.

The main contribution of this paper is that we show that kLog’s relational nature and its ability to declaratively specify and use background knowledge is beneficial for natural language learning problems. This is shown on the NICTA-PIBOSO corpus, for which we present results that indicate a clear improvement on the state-of-the-art.

The remainder of this paper is organized as follows. In Section 2, we outline earlier work that is related to the research presented here. Section 3 describes the methodology of our method. We present a thorough evaluation of our method in Section 4. The last section draws conclusions and presents some ideas for future work.

## 2 Related Work

EBM is an approach to clinical problem-solving based on “systematically finding, appraising, and using contemporaneous research findings as the basis for clinical decisions” (Rosenberg and Donald, 1995). The evidence-based process consists of four steps: (1) Formulating a question from a patient’s problem; (2) Searching the literature for relevant clinical articles; (3) Evaluating the evidence; And (4) implementing useful findings in clinical practice. Given the amounts of medical publications available in databases such as PubMed, automating step 2 is crucial to help doctors in their practice. Efforts in this direction from the NLP community have so far focused on corpus annotation (Demner-Fushman and Lin, 2007; Kim et al., 2011), text categorization (Davis-Desmond and Mollá, 2012), summarization (Mollá and Santiago-Martínez, 2011), and question-answering (Niuet et al., 2003; Demner-Fushman and Lin, 2007).

The existing corpora are usually annotated with the PICO mnemonic (Armstrong, 1999) concepts, that are used to build queries when searching for literature for EBM purposes. The PICO concepts are: primary Problem (P) or population, main Intervention (I), main intervention Comparison (C), and

Outcome of intervention (O). PICO helps determining what terms are important in a query and therefore it helps building the query, which is sent to the search repositories. Once the documents are found, they need to be read by a person who eliminates irrelevant documents.

The first attempt to classify PICO concepts is presented in Demner-Fushman and Lin (2007), who apply a rule-based approach to identify sentences where PICO concepts occur and a supervised approach to classify sentences that contain an *Outcome*. The features used by this classifier are n-grams, position, and semantic information from the parser used to process the data. The system is trained on 275 abstracts manually annotated. The accuracies reported range from 80% for *Population*, 86% for *Problem*, 80% for *Intervention*, and, from 64% to 95% for *Outcome* depending on the test set of abstracts.

Kim et al. (2011) perform a similar classification task in two steps. First a classifier identifies the sentences that contain PICO concepts, and then another classifier assigns PICO tags to the sentences found to be relevant by the previous classifier. The system is based on a CRF algorithm and is trained on the NICTA-PIBOSO corpus. This dataset contains 1,000 medical abstracts manually annotated with an extension of the PICO tagset, for which the definitions are listed in Table 1. The annotation is performed at sentence level and one sentence may have more than one tag. An example of an annotated abstract from the corpus can be found in the supplementary material. The features used by the algorithm include features derived from the context, semantic relations, structure and sequencing of the text. The system is evaluated for 5-way and 6-way classification and results are provided apart from structured and unstructured abstracts. The F-scores for structured abstracts is 89.32% for 5-way classification and 80.88% for 6-way classification, whereas for unstructured abstracts it is 71.54% for 5-way classification and 64.66% for 6-way classification.

Chung (2009) uses CRF to classify PICO concepts by combining them with general categories associated with rhetorical roles: *Aim*, *Method*, *Results* and *Conclusion*. Her system is tested on corpora of abstracts of randomized control trials. First structured abstracts with headings labeled with PICO

Background	Material that informs and may place the current study in perspective, e.g. work that preceded the current; information about disease prevalence; etc.
Population	The group of individual persons, objects or items comprising the study’s sample, or from which the sample was taken for statistical measurement
Intervention	The act of interfering with a condition to modify it or with a process to change its course (includes prevention)
Outcome	The sentence(s) that best summarizes the consequences of an intervention
Study Design	The type of study that is described in the abstract
Other	Any sentence not falling into one of the other categories and presumed to provide little help with clinical decision making, i.e. non-key or irrelevant sentences

Table 1: Definitions of the semantic tags used as annotation categories (taken from Kim et al. (2011)).

concepts are used. A sentence level classification task is performed, assigning only one rhetorical role per sentence. The F-scores obtained range from 0.93 to 0.98. Then another sentence level classification task is performed to automatically assign the labels *Intervention*, *Participant* and *Outcome Measures* to sentences in unstructured and structured abstracts without headings. F-scores of up to 0.83 and 0.84 are obtained for *Intervention* and *Outcome Measure* sentences.

Other work aimed at identifying rhetorical zones in biomedical articles. In this case areas of text are classified in terms of the rhetorical categories *Introduction*, *Methods*, *Results* and *Discussion* (IMRAD) (Agarwal and Yu, 2009) or richer categories, such as problem-setting or insight (Mizuta et al., 2006).

There exists a wide range of statistical relational learning systems (Getoor and Taskar, 2007; De Raedt et al., 2008), and many of these systems are in principle useful for natural language processing. The most popular formalism today is Markov Logic, which has already been used for natural language processing tasks such as semantic role labeling (Riedel and Meza-Ruiz, 2008) and coreference resolution (Poon and Domingos, 2008). With respect to Markov Logic, two distinguishing features of kLog are that 1) it employs kernel based methods grounded in statistical learning theory, and 2) it employs a Prolog like language for defining and using background knowledge. As Prolog is a programming language, this is more flexible than the formalism used by Markov Logic.

### 3 Methodology

In learning from examples, or *interpretations* (De Raedt et al., 2008), the instances are sampled identically and independently from some unknown but fixed distribution. They can be represented as pairs  $z = (x, y)$ , in which  $x$  represents the inputs and  $y$  the outputs. An example interpretation can be found in Figure 3, where the `hasCategory` relation represents  $y$  in this case, since it is the target relation we want to predict. The inputs  $x$  are formed by all other facts. The task is now to learn a function  $h : X \rightarrow Y$  that maps the inputs to the outputs. Sentences may have multiple labels. Hence this is a structured output task where the output is a sequence of sets of labels attached to the sentences in a given document.

kLog is the new statistical relational language for learning with kernels that we use to tackle the PICO categories classification task. The novelty of kLog is that, based on the regular, linguistic features, it allows to define an extended high-dimensional feature space that is also able to take relational features into account in a principled manner. Furthermore, its declarative approach offers a flexible and interpretable way to construct features.

The choice of kLog is motivated by our previous results (Verbeke et al., 2012), where we showed that the relational representation of the domain as used by kLog is able to take the contextual aspects of language into account. Whereas there we only used the relations at the sentence level, the current task adds a new level of complexity, since the identification of PICO categories in abstracts also requires to take into account various relations between the sentences of an abstract. The general workflow of our approach is depicted in Figure 1, which will be de-

Figure 1: General kLog workflow.

scribed step by step in the following paragraphs.

**Preprocessing** The sentences have been preprocessed with a named entity tagger and a dependency parser.

Named entity tagging has been performed with the BiographTA named entity module, which matches token sequences with entries in the UMLS database<sup>1</sup>. UMLS integrates over 2 million names for some 900,000 concepts from more than 60 families of biomedical vocabularies (Bodenreider, 2004). The tagger matches sequences with a length of maximum 4 tokens. This covers 66.2% of the UMLS entries. By using UMLS, different token sequences referring to the same concept can be mapped to the same concept identifier (CID). The BiographTA named entity tagger has been evaluated on the BioInfer corpus (Pyysalo et al., 2007) obtaining a 72.02 F1 score.

Dependency parsing has been performed with the GENIA dependency parser GDep (Sagae and Tsujii, 2007), which uses a best-first probabilistic shift-reduce algorithm based on the LR algorithm (Knuth, 1965) and extended by the pseudo-projective parsing technique. This parser is a version of the KSDep dependency parser trained on the GENIA Treebank for parsing biomedical text. KSDep was evaluated in the CoNLL Shared Task 2007 obtaining a Labeled Attachment Score of 89.01% for the English dataset. GDEP outputs the lemmas, chunks, Genia named entities and dependency relations of the tokens in a sentence.

This information can be represented as an Entity/Relationship (E/R) diagram, a modeling paradigm that is frequently used in database theory (Garcia-Molina et al., 2008). The E/R-model for the

problem under consideration is shown in Figure 2, which provides an abstract representation of the examples, i.e. medical abstracts in this case. We will show later how this abstract representation can be unrolled for each example, resulting in a graph; cf. also Figure 4 for our example sentence. This relational database representation will serve as the input for kLog.

Figure 2: E/R-diagram modeling the sentence identification task.

The *entities* are the words and sentences in the abstract. They are represented by the rectangles in the E/R-model. Each entity can have a number of properties attached to it, depicted by the ovals and has a unique identifier (underlined properties). As in database theory, each entity corresponds with a tuple, or *fact*, in the database.

Figure 3 shows a part of an example interpretation  $\mathcal{z}$ . For example,  $w(w4\_1, \text{'Surgical'}, \text{'Surgical'}, b\_np, jj, \text{'O'}, \text{'O'})$  specifies a word entity, with  $w4\_1$  as identifier and the other arguments as properties. As indicated before, as lexical information we take the token string itself, its lemma, the part-of-speech tag and the chunk tag into account. We also include some semantic information, namely two binary values indicating if the word is a (biological) named entity.  $sentence(s4,4)$  represents a sentence entity, with its index in the abstract as a property.

Furthermore, the E/R-diagram also contains a number of *relationships*, which are represented by

<sup>1</sup>From UMLS only the MRCONSO.RRF and MRSTY.RRF files are used.

```

sentence(s4,4)
hasCategory(s4,'background')
w(w4_1,'Surgical','Surgical',b-np,
jj,'O','O') hasWord(s4,w4_1)
dh(w4_1,w4_2,nmod)
nextW(w4_2,w4_1)
w(w4_2,'excision','excision',i-np,
nn,'O','O') hasWord(s4,w4_2)
dh(w4_2,w4_5,sub)
nextW(w4_3,w4_2)
w(w4_3,'of','of',b-pp,in,'O','O')
hasWord(s4,w4_3)
dh(w4_3,w4_2,nmod)
nextW(w4_4,w4_3)
w(w4_4,'CNV','CNV',b-np,nn,
'B-protein','O') hasWord(s4,w4_4)
dh(w4_4,w4_3,pmod)
nextW(w4_5,w4_4)
...

```

Figure 3: Part of an example interpretation  $z$ , representing the example sentence in Figure 4.

the diamonds. They are linked to the entities that participate in the relationship, or stand alone if they characterize general properties of the interpretation. An example relation is `nextW(w4_2,w4_1)`, which indicates the sequence of the words in the sentence. `dh(w4_1,w4_2,nmod)` specifies that word `w4_1` is a noun modifier of word `w4_2`, and thus serves to incorporate the dependency relationships between the words. `hasCategory(s4,'background')` signifies that sentence `s4` is a sentence describing background information. This relation is the target relation that we want to predict for this task and will not be taken into account as a feature, but is listed in the database and only used during the training of the model.

Since the previously described entities and relationships are listed explicitly in the database, these are called *extensional relations*, in contrast to the *intensional relations*, as we will describe next.

**Declarative feature construction** A strength of kLog is that it is also capable of constructing features *declaratively*, by using intensional relations. This enables one to encode additional background knowledge based on a small set of preprocessed fea-

tures, which renders experimentation very flexible and makes the results more interpretable. It furthermore allows one to limit the required features to the core discriminative ones. These intensional features are defined through definite clauses, and is done using an extension of the declarative programming language Prolog. The following features were used. We make a distinction between the features used for structured and unstructured abstracts.

For structured abstracts, four intensional relations were defined. The relation `lemmaRoot(S,L)` is specified as:

```

lemmaRoot(S,L) ←
  hasWord(S, I),
  w(I,_,L,_,_,_,_),
  dh(I,_,root).

```

For each sentence, it only selects the lemmas of the root word in the dependency tree, which markedly limits the number of word features used. The following relations are related to, and try to capture the document structure imposed by the section headers present in the structured abstracts. `hasHeaderWord(S,X)` identifies whether a sentence is a header of a section. In order to realize this, it selects the words of a sentence that count more than four characters (to discard short names of biological entities), which all need to be uppercase.

```

hasHeaderWord(S,X) ←
  w(W,X,_,_,_,_,_),
  hasWord(S,W),
  (atom(X) -> name(X,C) ; C = X),
  length(C,Len),
  Len > 4,
  all_upper(C).

```

Also the sentences below a certain section header need to be marked as belonging to this section, which is done by the relation `hasSectionHeader(S,X)`.

```

hasSectionHeader(S,X) ←
  nextS(S1,S),
  hasHeaderWord(S1,X).
hasSectionHeader(S,X) ←
  nextS(S1,S),
  not isHeaderSentence(S),
  once(hasSectionHeader(S1,X)).

```

For the unstructured abstracts, also the lemma-Root relation is used, but next to the lemma, now also the part-of-speech tag of the root word is taken into account. Since the unstructured abstracts lack section headers, other features were needed to distinguish between the different sections, for which the relation `prevLemmaRoot` proved to be very informative. It adds the lemma of the root word in the previous sentence as a property to the current sentence under consideration.

```
prevLemmaRoot(S, L) ←
  nextS(S1, S),
  lemmaRoot(S1, L, _).
```

The intensional predicates are grounded. This is a process similar to materialization in databases, that is, the atoms implied by the background knowledge and the facts in the example are all computed using Prolog’s deduction mechanism. This leads to the *extensionalized database*, in which both the extensional as well as the grounded intensional predicates are listed.

**Graphicalization and feature generation** In the third step, the interpretations are *graphicalized*, i.e. transformed into graphs. Since the facts that form the interpretation still conform to the E/R-diagram, this can be interpreted as unfolding the E/R-diagram over the data. An example illustrating this process is given in Figure 4. Each interpretation is converted into a bipartite graph, for which there is a vertex for every ground atom of every E-relation, one for every ground atom of every R-relation, and an undirected edge  $\{e, r\}$  if an entity  $e$  participates in relationship  $r$ .

The obtained graphs can then be used in the next step for *feature generation*. This is done by means of a graph kernel  $\kappa$ , which calculates the similarity between two graphicalized interpretations. Any graph kernel that allows fast computations on large graphs and has a flexible bias to enable heterogeneous features can in theory be applied. In the current implementation, an extension of the Neighborhood Subgraph Pairwise Distance Kernel (NSPDK) (Costa and De Grave, 2010) is used.

NSPDK is a decomposition kernel (Haussler, 1999), in which pairs of subgraphs are compared

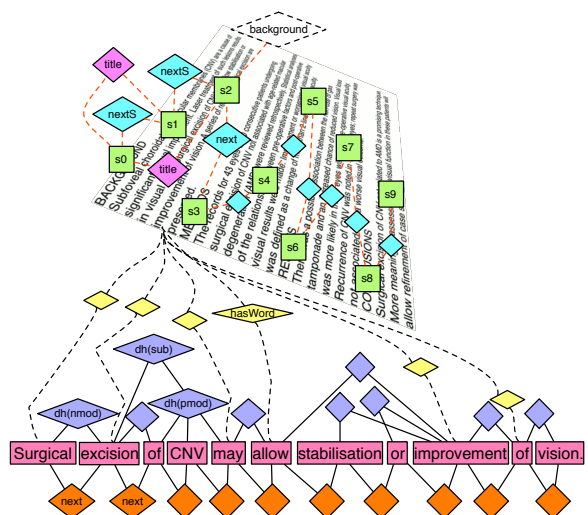

Figure 4: Graphicalization  $G_z$  of interpretation  $z$ .

to each other in order to calculate the similarity between two graphs. These subgraphs can be seen as circles in the graph, and are defined by three hyperparameters. First of all, there is the center of the subgraph, the *kernel point*, which can be any entity or relation in the graph. The entities and relations to be taken into account as kernel points are marked beforehand as a subset of the intensional and extensional domain relations. The *radius*  $r$  determines the size of the subgraphs and defines which entities or relations around the kernel point are taken into account. Each entity or relation that is within a number of  $r$  edges away from the kernel point is considered to be part of the subgraph. The third hyperparameter, the *distance*  $d$ , determines how far apart from each other the kernel points can be. Each subgraph around a kernel point that is within a distance  $d$  or less from the current kernel point will be considered. This is captured by the relation  $R_{r,d}(A_v, B_u, G)$  between two rooted subgraphs  $A_v, B_u$  and a graph  $G$ , which selects all pairs of neighborhood graphs of radius  $r$  whose roots are at distance  $d$  in a given graph  $G$ .

The kernel  $\kappa_{r,d}(G, G')$  between graphs  $G$  and  $G'$  on the relation  $R_{r,d}$  is then defined as:

$$\kappa_{r,d}(G, G') = \sum_{\substack{A_v, B_u \in R_{r,d}^{-1}(G) \\ A_{v'}, B_{u'} \in R_{r,d}^{-1}(G')}} \delta(A_v, A_{v'}) \delta(B_u, B_{u'}) \quad (1)$$

For efficiency reasons, an upper bound is imposed on the radius and distance parameters, which leads to the following kernel definition:

$$K_{r^*,d^*}(G, G') = \sum_{r=0}^{r^*} \sum_{d=0}^{d^*} \kappa_{r,d}(G, G') \quad (2)$$

We hereby limit the sum of the  $\kappa_{r,d}$  kernels for all increasing values of the radius and distance parameter up to a maximum given value of  $r^*$ , respectively  $d^*$ .

The result of this graphicalization and feature generation process is an extended, high-dimensional feature space, which serves as input for the statistical learner in the next step.

**Learning** The constructed feature space contains one feature vector per sentence. This implies that the sequence information of the sentences at the document level is not taken into account yet. Since the order of the sentences in the abstract is a valuable feature for this prediction problem, a learner that reflects this in the learning process is needed, although in principle any statistical learner can be used on the feature space constructed by kLog. Therefore we opted for SVM-HMM<sup>2</sup> (Tsochantaridis et al., 2004), which is an implementation of structural support vector machines for sequence tagging. In contrast to a conventional Hidden Markov Model, SVM-HMM is able to take these entire feature vectors as observations, and not just atomic tokens.

In our case, the instances to be tagged are formed by the sentences for which feature vectors were created in the previous step. The *qid* is a special feature that is used in the structured SVM to restrict the generation of constraints. Since every document needs to be represented as a sequence of sentences, in SVM-HMM, the *qid*'s are used to obtain the document structure. The order of the HMM was set to 2, which means that the two previous sentences were considered for collective classification. The cost value was set to 500, and was determined via cross-validation. For epsilon, the default value, 0.5, was kept, since this mainly only influences the running time and memory consumption during training.

Table 2: Number of abstracts and sentences for Structured (S) and Unstructured (U) abstract sets, including number of sentences per class (taken from (Kim et al., 2011)).

## 4 Evaluation

We evaluate the performance of kLog against a baseline system and a memory-based tagger (Daelemans and van den Bosch, 2005). The results are also compared against those from Kim et al. (2011), which is the state-of-the-art system for this task.

### 4.1 Datasets

We perform our experiments on the NICTA-PIBOSO dataset from Kim et al. (2011) (kindly provided by the authors). It contains 1,000 abstracts of which 500 were retrieved from MEDLINE by querying for diverse aspects in the traumatic brain injury and spinal cord injury domain. The dataset consists of two types of abstracts. If the abstract contains section headings (e.g. *Background*, *Methodology*, *Results*, etc.), it is considered to be *structured*. This information can be used as a feature in the model. The other abstracts are regarded *unstructured*.

The definitions of the semantic tags used as annotations categories are a variation on the PICO tag set, with the addition of two additional categories (see Table 1 in Section 2). Each sentence can be annotated with multiple classes. This renders the task a multiclass multilabel classification problem. The statistics on this dataset can be found in Table 2.

In order to apply the same evaluation setting as Kim et al. (2011), we used the dataset from Demner-Fushman et al. (2005) as external dataset. It consists of 100 sentences of which 51 are structured. Because the semantic tag set used for annotation slightly differs from the one presented in Table 1, and to make our results comparable, we will use the same mapping as used in Kim et al. (2011).

## 4.2 Baseline and benchmarks

We compare the kLog system to three other systems: a baseline system, a memory-based system, and the scores reported by Kim et al. (2011).

The memory-based system that we use is based on the memory-based tagger MBT<sup>3</sup> (Daelemans and van den Bosch, 2005). This machine learner is originally designed for part-of-speech tagging. It processes data on a sentence basis by carrying out sequential tagging, *viz.* the class label or other features from previously tagged tokens can be used when classifying a new token. In our setup, the sentences of an abstract are taken as the processing unit and the collection of all sentences in an abstract is taken as one sequence.

The features that are used to label a sentence are the class labels of four previous sentences, the ambitags of the following two sentences, the lemma of the dependency root of the sentence, the position of the sentence in the abstract, the lemma of the root of the previous sentence, and section information. For each root lemma, all possible class labels, as observed in the training data, are concatenated into one ambitag. These tags are stored in a list. An ambitag for a sentence is retrieved by looking up the root lemma in this list. The position of the sentence is expressed by a number. Section information is obtained by looking for a previous sentence that consists of only one token in uppercase. Finally, basic lemmatization is carried out by removing a final *S*. All other settings of MBT are the default settings and no feature optimization nor feature selection has been carried out to prevent overfitting.

When a class label contains multiple labels, like *e.g. population* and *study design*, these labels are concatenated in an alphabetically sorted manner. This method of working reduces the multilabel problem to a problem with many different labels, *i.e.* the label powerset method of Tsoumakas et al. (2010).

The baseline system is exactly the same as the memory-based system except that no machine learner is included. The most frequent class label in the training data, *i.e. Outcome*, is assigned to each instance. The memory-based system enables us to compare kLog against a basic machine learning approach, using few features. The majority baseline

<sup>3</sup><http://ilk.uvt.nl/mbt> [16 March 2012]

system enables us to compare the memory-based system and kLog against a baseline in which no information about the observations is used.

## 4.3 Parametrization

From the kernel definition it might be clear that the kLog hyperparameters, namely the distance  $d$  and radius  $r$ , can have a strong influence on the results. This requires a deliberate choice during parametrization. From a linguistic perspective, the use of unigrams and bigrams is justifiable, since most phrases that reveal clues on the structure of the abstract (*e.g. evaluation measures, methodology, future work*) can be expressed with single or pairs of words. This is reflected by a distance and radius both set to 1, which enables to take all possible combinations of consecutive words into account and captures the relational information attached to the word in focus, *i.e.* the current kernel point. This is confirmed by cross-validation on other settings for the hyperparameters.

Since kLog generates a feature vector, only the sequence information at word level is taken into account by kLog. Since we use a sequence labeling approach as statistical learner, *i.e.* SVM-HMM, at the level of the abstract this information is however implicitly taken into account during learning. For SVM-HMM, only the cost parameter  $C$ , which regulates the trade-off between the slack and the magnitude of the weight-vector, and  $\epsilon$ , that specifies the precision to which constraints are required to be satisfied by the solution, were optimized by means of cross-validation. For the other parameters, the default values were used.

## 4.4 Results

Experiments are run on structured and unstructured abstracts separately. On the NICTA-PIBOSO corpus, we performed 10-fold cross-validation. Over all folds, all labels, *i.e.* the parts of the multilabels, are compared in a binary way between gold standard and prediction. Summing all true positives, false positives, and false negatives over all folds leads to micro-averaged F-scores. This was done for two different settings. In one setting, *CV/6-way*, we combined the labeling of the sentences with the identification of irrelevant information, by adding the *Other*

label as an extra class in the classification. The results are listed in Table 3.

CV/6-way Label	MBT		Kim et al.		kLog	
	S	U	S	U	S	U
Background	71.0	61.3	81.84	68.46	86.19	76.90
Intervention	24.3	6.4	20.25	12.68	26.05	16.14
Outcome	87.9	70.4	92.32	72.94	92.99	77.69
Population	50.6	15.9	56.25	39.80	35.62	21.58
Study Design	45.9	13.10	43.95	4.40	45.5	6.67
Other	86.1	20.9	69.98	24.28	87.98	24.42

Table 3: F-scores per class for structured (S) and unstructured (U) abstracts.

For this setting, kLog is able to outperform both MBT and the system of Kim et al. (2011), for both structured and unstructured abstracts on all classes except *Population*. From Table 4, where the micro-average F-scores over all classes and for all settings are listed, it can be observed that kLog performs up to 3.73% better than MBT over structured abstracts, and 9.67% better over unstructured ones.

Although to a lesser extent for the structured abstracts, the same pattern can be observed for the *CV/5-way* setting, where we tried to classify the sentences only, without considering the irrelevant ones. The per-class results for this setting are shown in Table 5. Now the scores for *Population* are comparable to the other systems, due to which we assume these sentences are similar in structure to the ones labeled with *Other*.

For the external corpus, the results are listed in Table 6. Although kLog performs comparably for the individual classes *Background* and *Intervention*, its overall performance is worse on the structured abstracts. In case of the unstructured abstracts, kLog performs better on the majority of the individual classes and in overall performance for the 5-way setting, and comparable for the 4-way setting.

Method	Baseline		MBT		kLog	
	S	U	S	U	S	U
CV/6-way	43.90	41.87	80.56	57.47	84.29	67.14
CV/5-way	61.79	46.66	86.96	64.37	87.67	72.95
Ext/5-way	66.18	6.76	36.34	11.56	20.50	14.00
Ext/4-way	30.11	27.23	67.29	55.96	50.40	50.50

Table 6: F-scores per class for 5-way and 4-way classification over structured (S) and unstructured (U) abstracts on the external corpus.

As a general observation, it is important to note that there is a high variability between the different labels. Due to kLog’s ability to take the structured input into account, we assume a correlation between the sentence structure of the label and the prediction quality. We intend to perform an extensive error analysis, in order to detect patterns which may allow us to incorporate additional declarative background knowledge into our model.

## 5 Conclusions

We presented a statistical relational learning approach for the automatic identification of PICO categories in medical abstracts. To this extent, we used kLog, a new framework for logical and relational learning with kernels. Due to its graphical approach, it is able to exploit the full relational representation, that is often inherent in language structure. Since contextual features are often essential and relations are prevalent, the aim of this paper was to show that statistical relational learning in general, and the graph kernel-based approach of kLog in particular, is specifically suited for problems in natural lan-

guage learning.

In future work, we intend to explore additional ways to incorporate background knowledge in a declarative way, since it renders the language learning problem more intuitive and gives a better understanding of feature contribution. Furthermore, we also want to investigate the use of SRL approaches for high-relational domains, and make a clear comparison with related techniques.

strappa@fbk.eu

## Abstract

In this paper, we explore the classification of emotions in songs, using the music and the lyrics representation of the songs. We introduce a novel corpus of music and lyrics, consisting of 100 songs annotated for emotions. We show that textual and musical features can both be successfully used for emotion recognition in songs. Moreover, through comparative experiments, we show that the joint use of lyrics and music brings significant improvements over each of the individual textual and musical classifiers, with error rate reductions of up to 31%.

## 1 Introduction

Language and music are peculiar characteristics of human beings. The capability of producing and enjoying language and music appears in every human society, regardless of the richness of its culture (Nettl, 2000).

Importantly, language and music complement each other in many different ways. For instance, looking at music and language in terms of features, we can observe that music organizes pitch and rhythm in ways that language does not, and it lacks the specificity of language in terms of semantic meaning. On the other hand, language is built from categories that are absent in music (e.g., nouns and verbs), whereas music seems to have a deeper power over our emotions than does ordinary speech.

Composers, musicians, and researchers in poetry and literature alike have been long fascinated by the combination of language and music, even since the

time of the earliest written records of music encountered in musical settings for poetry. Despite this interest, and despite the long history of the interaction between music and lyrics, there is only little work that explicitly focuses on the connection between music and lyrics.

In this paper, we focus on the connection between the musical and linguistic representations in popular songs, and their role in the expression of *affect*. We introduce a novel corpus of lyrics and music, annotated for emotions at line level, and explore the automatic recognition of emotions using both textual and musical features. Through comparative experiments, we show that emotion recognition can be performed using either textual or musical features, and that the joint use of lyrics and music can improve significantly over classifiers that use only one dimension at a time. We believe our results demonstrate the promise of using joint music-lyric models for song processing.

## 2 Related Work

The literature on music analysis is noticeably large, and there are several studies concerning the music's power over emotions (Juslin and Sloboda, 2001), thinking (Rauscher et al., 1993), or physical effort (Karageorghis and Priest, 2008).

In particular, there has been significant research in music and psychology focusing on the idea of a parallel between affective cues in music and speech (Sundberg, 1982; Scherer, 1995). For instance, (Scherer, 2004) investigated the types of emotions that can be induced by music, their mechanisms, and how they can be empirically measured. (Juslin and

Laukka, 2003) conducted a comprehensive review of vocal expressions and music performance, finding substantial overlap in the cues used to convey basic emotions in speech and music.

The work most closely related to ours is the combination of audio and lyrics for emotion classification in songs, as thoroughly surveyed in (Kim et al., 2010). Although several methods have been proposed, including a combination of textual features and beats per minute and MPEG descriptors (Yang and Lee, 2004); individual audio and text classifiers for arousal and valence, followed by a combination through meta-learning (Yang et al., 2008); and the use of crowdsourcing labeling from Last.fm to collect large datasets of songs annotated for emotions (Laurier et al., 2008; Hu et al., 2009), all this previous work was done at song level, and most of it focused on valence-arousal classifications. None of the previous methods considered the fine-grained classification of emotions at line level, as we do, and none of them considered the six Ekman emotions used in our work.

Other related work consists of the development of tools for music accessing, filtering, classification, and retrieval, focusing primarily on music in digital format such as MIDI. For instance, the task of music retrieval and music recommendation has received a lot of attention from both the arts and the computer science communities (see for instance (Orio, 2006) for an introduction to this task). There are also several works on MIDI analysis. Among them, particularly relevant to our research is the work by (Das et al., 2000), who described an analysis of predominant up-down motion types within music, through extraction of the kinematic variables of music velocity and acceleration from MIDI data streams. (Cataltepe et al., 2007) addressed music genre classification (e.g., classic, jazz, pop) using MIDI and audio features, while (Wang et al., 2004) automatically aligned acoustic musical signals with their corresponding textual lyrics. MIDI files are typically organized into one or more parallel “tracks” for independent recording and editing. A reliable system to identify the MIDI track containing the *melody*<sup>1</sup> is very relevant for music information retrieval, and

---

<sup>1</sup>A melody can be defined as a “cantabile” sequence of notes, usually the sequence that a listener can remember after hearing a song.

there are several approaches that have been proposed to address this issue (Rizo et al., 2006; Velusamy et al., 2007).

Another related study concerned with the interaction of lyrics and music using an annotated corpus is found in (O’Hara, 2011), who presented preliminary research that checks whether the expressive meaning of a particular harmony or harmonic sequence could be deduced from the lyrics it accompanies, by using harmonically annotated chords from the Usenet group alt.guitar.tab.

Finally, in natural language processing, there are a few studies that mainly exploited the lyrics component of the songs, while generally ignoring the musical component. For instance, (Mahedero et al., 2005) dealt with language identification, structure extraction, and thematic categorization for lyrics. (Xia et al., 2008) addressed the task of sentiment classification in lyrics, recognizing positive and negative moods in a large dataset of Chinese pop songs, while (Yang and Lee, 2009) approached the problem of emotion identification in lyrics, classifying songs from allmusic.com using a set of 23 emotions.

### 3 A Corpus of Music and Lyrics Annotated for Emotions

To enable our exploration of emotions in songs, we compiled a corpus of 100 popular songs (e.g., *Dancing Queen* by ABBA, *Hotel California* by Eagles, *Let it Be* by The Beatles). Popular songs exert a lot of power on people, both at an individual level as well as on groups, mainly because of the message and emotions they convey. Songs can lift our moods, make us dance, or move us to tears. Songs are able to embody deep feelings, usually through a combined effect of both music and lyrics.

The corpus is built starting with the MIDI tracks of each song, by extracting the parallel alignment of melody and lyrics. Given the non-homogeneous quality of the MIDI files available on the Web, we asked a professional MIDI provider for high quality MIDI files produced for singers and musicians. The MIDI files, which were purchased from the provider, contain also lyrics that are synchronized with the notes. In these MIDI files, the melody channel is unequivocally decided by the provider, making it easier to extract the music and the corresponding lyrics.

**MIDI format.** MIDI is an industry-standard protocol that enables electronic musical instruments, computers, and other electronic equipment to communicate and synchronize with each other. Unlike analog devices, MIDI does not transmit an audio signal: it sends event messages about musical notation, pitch, and intensity, control signals for parameters such as volume, vibrato, and panning, and cues and clock signals to set the tempo. As an electronic protocol, it is notable for its widespread adoption throughout the music industry.

MIDI files are typically created using computer-based sequencing software that organizes MIDI messages into one or more parallel “tracks” for independent recording, editing, and playback. In most sequencers, each track is assigned to a specific MIDI channel, which can be then associated to specific instrument patches. MIDI files can also contain lyrics, which can be displayed in synchrony with the music.

Starting with the MIDI tracks of a song, we extract and explicitly encode the following features. At the song level, the key of the song (e.g., G major, C minor). At the line level, we represent the raising, which is the musical interval (in half-steps) between the first note in the line and the most important note (i.e., the note in the line with the longest duration). Finally, at the note level, we encode the time code of the note with respect to the beginning of the song; the note aligned with the corresponding syllable; the degree of the note with relation to the key of the song; and the duration of the note.

Table 1 shows statistics on the corpus. An example from the corpus, consisting of the first two lines from the Beatles’ song *A hard day’s night*, is illustrated in Figure 3.

SONGS	100
SONGS IN “MAJOR” KEY	59
SONGS IN “MINOR” KEY	41
LINES	4,976
ALIGNED SYLLABLES / NOTES	34,045

Table 1: Some statistics of the corpus

**Emotion Annotations with Mechanical Turk.** In order to explore the classification of emotions in songs, we needed a gold standard consisting of manual emotion annotations of the songs. Following

previous work on emotion annotation of text (Alm et al., 2005; Strapparava and Mihalcea, 2007), to annotate the emotions in songs we use the six basic emotions proposed by (Ekman, 1993): ANGER, DISGUST, FEAR, JOY, SADNESS, SURPRISE. To collect the annotations, we use the Amazon Mechanical Turk service, which was previously found to produce reliable annotations with a quality comparable to those generated by experts (Snow et al., 2008).

The annotations are collected at line level, with a separate annotation for each of the six emotions. We collect numerical annotations using a scale between 0 and 10, with 0 corresponding to the absence of an emotion, and 10 corresponding to the highest intensity. Each HIT (i.e., annotation session) contains an entire song, with a number of lines ranging from 14 to 110, for an average of 50 lines per song.

The annotators were instructed to: (1) Score the emotions from the writer perspective, not their own perspective; (2) Read and interpret each line in context; i.e., they were asked to read and understand the entire song before producing any annotations; (3) Produce the six emotion annotations independent from each other, accounting for the fact that a line could contain none, one, or multiple emotions. In addition to the lyrics, the song was also available online, so they could listen to it in case they were not familiar with it. The annotators were also given three different examples to illustrate the annotation.

While the use of crowdsourcing for data annotation can result in a large number of annotations in a very short amount of time, it also has the drawback of potential spamming that can interfere with the quality of the annotations. To address this aspect, we used two different techniques to prevent spam. First, in each song we inserted a “checkpoint” at a random position in the song – a fake line that reads “Please enter 7 for each of the six emotions.” Those annotators who did not follow this concrete instruction were deemed as spammers who produce annotations without reading the content of the song, and thus removed. Second, for each remaining annotator, we calculated the Pearson correlation between her emotion scores and the average emotion scores of all the other annotators. Those annotators with a correlation with the average of the other annotators below 0.4 were also removed, thus leaving only the reliable annotators in the pool.

Figure 1: Two lines of a song in the corpus: *It-'s been a hard day-'s night, And I-'ve been wor-king li-ke a d-o-g*

For each song, we start by asking for ten annotations. After spam removal, we were left with about two-five annotations per song. The final annotations are produced by averaging the emotions scores produced by the reliable annotators. Figure 3 shows an example of the emotion scores produced for two lines. The overall correlation between the remaining reliable annotators was calculated as 0.73, which represents a strong correlation.

For each of the six emotions, Table 2 shows the number of lines that had that emotion present (i.e., the score of the emotion was different from 0), as well as the average score for that emotion over all 4,976 lines in the corpus. Perhaps not surprisingly, the emotions that are dominant in the corpus are JOY and SADNESS – which are the emotions that are often invoked by people as the reason behind a song.

Note that the emotions do not exclude each other: i.e., a line that is labeled as containing JOY may also contain a certain amount of SADNESS, which is the reason for the high percentage of songs containing both JOY and SADNESS. The emotional load for the overlapping emotions is however very different. For instance, the lines that have a JOY score of 5 or higher have an average SADNESS score of 0.34. Conversely, the lines with a SADNESS score of 5 or

Emotion	Number	
	lines	Average
ANGER	2,516	0.95
DISGUST	2,461	0.71
FEAR	2,719	0.77
JOY	3,890	3.24
SADNESS	3,840	2.27
SURPRISE	2,982	0.83

Table 2: Emotions in the corpus of 100 songs: number of lines including a certain emotion, and average emotion score computed over all the 4,976 lines.

higher have a JOY score of 0.22.

## 4 Experiments and Evaluations

Through our experiments, we seek to determine the extent to which we can automatically determine the emotional load of each line in a song, for each of the six emotion dimensions.

We use two main classes of features: textual features, which build upon the textual representation of the lyrics; and musical features, which rely on the musical notation associated with the songs. We run three sets of experiments. The first one is intended to determine the usefulness of the textual features for

emotion classification. The second set specifically focuses on the musical features. Finally, the last set of experiments makes joint use of textual and musical features.

The experiments are run using linear regression,<sup>2</sup> and the results are evaluated by measuring the Pearson correlation between the classifier predictions and the gold standard. For each experiment, a ten-fold cross validation is run on the entire dataset.<sup>3</sup>

#### 4.1 Textual Features

First, we attempt to identify the emotions in a line by relying exclusively on the features that can be derived from the lyrics of the song. We decided to focus on those features that were successfully used in the past for emotion classification (Strapparava and Mihalcea, 2008). Specifically, we use: (1) unigram features obtained from a bag-of-words representation, which are the features typically used by corpus-based methods; and (2) lexicon features, indicating the appartenance of a word to a semantic class defined in manually crafted lexicons, which are often used by knowledge-based methods.

**Unigrams.** We use a bag-of-words representation of the lyrics to derive unigram counts, which are then used as input features. First, we build a vocabulary consisting of all the words, including stop-words, occurring in the lyrics of the training set. We then remove those words that have a frequency below 10 (value determined empirically on a small development set). The remaining words represent the unigram features, which are then associated with a value corresponding to the frequency of the unigram inside each line. Note that we also attempted to use higher order n-grams (bigrams and trigrams), but evaluations on a small development dataset did not show any improvements over the unigram model, and thus all the experiments are run using unigrams.

**Semantic Classes.** We also derive and use coarse textual features, by using mappings between words and semantic classes. Specifically, we use the Lin-

guistic Inquiry and Word Count (LIWC) and WordNet Affect (WA) to derive coarse textual features. LIWC was developed as a resource for psycholinguistic analysis (Pennebaker and Francis, 1999; Pennebaker and King, 1999). The 2001 version of LIWC includes about 2,200 words and word stems grouped into about 70 broad categories relevant to psychological processes (e.g., emotion, cognition). WA (Strapparava and Valitutti, 2004) is a resource that was created starting with WordNet, by annotating synsets with several emotions. It uses several resources for affective information, including the emotion classification of Ortony (Ortony et al., 1987). From WA, we extract the words corresponding to the six basic emotions used in our experiments. For each semantic class, we infer a feature indicating the number of words in a line belonging to that class.

Table 3 shows the Pearson correlations obtained for each of the six emotions, when using only unigrams, only semantic classes, or both.

Emotion	Semantic		All
	Unigrams	Classes	Textual
ANGER	0.5525	0.3044	0.5658
DISGUST	0.4246	0.2394	0.4322
FEAR	0.3744	0.2443	0.4041
JOY	0.5636	0.3659	0.5769
SADNESS	0.5291	0.3006	0.5418
SURPRISE	0.3214	0.2153	0.3392
AVERAGE	0.4609	0.2783	0.4766

Table 3: Evaluations using textual features: unigrams, semantic classes, and all the textual features.

#### 4.2 Musical Features.

In a second set of experiments, we explore the role played by the musical features. While the musical notation of a song offers several characteristics that could be potentially useful for our classification experiments (e.g., notes, measures, dynamics, tempo), in these initial experiments we decided to focus on two main features, namely the notes and the key.

**Notes.** A note is a sign used in the musical notation associated with a song, to represent the relative duration and pitch of a sound. In traditional music theory, the notes are represented using the first seven letters of the alphabet (C-D-E-F-G-A-B), al-

<sup>2</sup>We use the Weka machine learning toolkit.

<sup>3</sup>There is no clear way to determine a baseline for these experiments. A simple baseline that we calculated, which assumed by default an emotional score equal to the average of the scores on the training data, and measured the correlation between these default scores and the gold standard, consistently led to correlations close to 0 (0.0081-0.0221).

though other notations can also be used. Notes can be modified by “accidentals” – a sharp or a flat symbol that can change the note by half a tone. A written note can also have associated a value, which refers to its duration (e.g., whole note; eighth note). Similar to the unigram features, for each note, we record a feature indicating the frequency of that note inside a line.

**Key.** The key of a song refers to the harmony or “pitch class” used for a song, e.g., *C major*, or *F#*. Sometime the term *minor* or *major* can be appended to a key, to indicate a minor or a major scale. For instance, a song in “the key of C minor” means that the song is harmonically centered on the note C, and it makes use of the minor scale whose first note is C. The key system is the structural foundation of most of the Western music. We use a simple feature that reflects the key of the song. Note that with a few exceptions, when more than one key is used in a song, all the lines in a song will have the same key.

Table 4 shows the results obtained in these classification experiments, when using only the notes as features, only the key, or both.

Emotion	All		
	Notes	Key	Musical
ANGER	0.2453	0.4083	0.4405
DISGUST	0.1485	0.2922	0.3199
FEAR	0.1361	0.2203	0.2450
JOY	0.1533	0.3835	0.4001
SADNESS	0.1738	0.3502	0.3762
SURPRISE	0.0983	0.2241	0.2412
AVERAGE	0.1592	0.3131	0.3371

Table 4: Evaluations using musical features: notes, key, and all the musical features.

### 4.3 Joint Textual and Musical Features.

To explore the usefulness of the joint lyrics and music representation, we also run a set of experiments that use all the textual and musical features. Table 5 shows the Pearson correlations obtained when using all the features. To facilitate the comparison, the table also includes the results obtained with the textual-only and musical-only features (reported in Tables 3 and 4).

Emotion	All	All	Textual &
	Textual	Musical	Musical
ANGER	0.5658	0.4405	0.6679
DISGUST	0.4322	0.3199	0.5068
FEAR	0.4041	0.2450	0.4384
JOY	0.5769	0.4001	0.6456
SADNESS	0.5418	0.3762	0.6193
SURPRISE	0.3392	0.2412	0.3855
AVERAGE	0.4766	0.3371	0.5439

Table 5: Evaluations using both textual and musical features.

## 5 Discussion

One clear conclusion can be drawn from these experiments: the textual and musical features are both useful for the classification of emotions in songs, and, more importantly, their joint use leads to the highest classification results. Specifically, the joint model gives an error rate reduction of 12.9% with respect to the classifier that uses only textual features, and 31.2% with respect to the classifier that uses only musical features. This supports the idea that lyrics and music represent orthogonal dimensions for the classification of emotions in songs.

Among the six emotions considered, the largest improvements are observed for JOY, SADNESS, and ANGER. This was somehow expected for the first two emotions, since they appear to be dominant in the corpus (see Table 2), but comes as a surprise for ANGER, which is less dominant. Further explorations are needed to determine the reason for this effect.

Looking at the features considered, textual features appear to be the most useful. Nonetheless, the addition of the musical features brings clear improvements, as shown in the last column from the same table.

Additionally, we made several further analyses of the results, as described below.

**Feature ablation.** To determine the role played by each of the feature groups we consider, we run an ablation study where we remove one feature group at a time from the complete set of features and measure the accuracy of the resulting classifier. Table 6 shows the feature ablation results. Note that feature ablation can also be done in the reverse direction, by

Emotion	All Features	All features, excluding				
		Unigrams	Semantic Classes	Notes	Key	Semantic Classes and Notes
ANGER	0.6679	0.4996	0.5525	0.6573	0.6068	0.6542
DISGUST	0.5068	0.3831	0.4246	0.5013	0.4439	0.4814
FEAR	0.4384	0.3130	0.3744	0.4313	0.4150	0.4114
JOY	0.6456	0.5141	0.5636	0.6432	0.5829	0.6274
SADNESS	0.6193	0.4586	0.5291	0.6176	0.5540	0.6029
SURPRISE	0.3855	0.3083	0.3214	0.3824	0.3421	0.3721
AVERAGE	0.5439	0.4127	0.4609	0.5388	0.4908	0.5249

Table 6: Ablation studies excluding one feature group at a time.

Emotion	Baseline	Textual and Musical		
		Textual	Musical	Musical
ANGER	89.27%	91.14%	89.63%	92.40%
DISGUST	93.85%	94.67%	93.85%	94.77%
FEAR	93.58%	93.87%	93.58%	93.87%
JOY	50.26%	70.92%	61.95%	75.64%
SADNESS	67.40%	75.84%	70.65%	79.42%
SURPRISE	94.83%	94.83%	94.83%	94.83%
AVERAGE	81.53%	86.87%	84.08%	88.49%

Table 7: Evaluations using a coarse-grained binary classification.

keeping only one group of features at a time; the results obtained with the individual feature groups are already reported in Tables 3 and 4.

The ablation studies confirm the findings from our earlier experiments: while the unigrams and the keys are the most predictive features, the semantic classes and the notes are also contributing to the final classification even if to a lesser extent. To measure the effect of these groups of somehow weaker features (semantic classes and notes), we also perform an ablation experiment where we remove both these feature groups from the feature set. The results are reported in the last column of Table 6.

**Coarse-grained classification.** As an additional evaluation, we transform the task into a binary classification by using a threshold empirically set at 3. Thus, to generate the coarse binary annotations, if the score of an emotion is below 3, we record it as “negative” (i.e., the emotion is absent), whereas if the score is equal to or above 3, we record it as “positive” (i.e., the emotion is present).

For the classification, we use Support Vector Ma-

chines (SVM), which are binary classifiers that seek to find the hyperplane that best separates a set of positive examples from a set of negative examples, with maximum margin (Vapnik, 1995). Applications of SVM classifiers to text categorization led to some of the best results reported in the literature (Joachims, 1998).

Table 7 shows the results obtained for each of the six emotions, and for the three major settings that we considered: textual features only, musical features only, and a classifier that jointly uses the textual and the musical features. As before, the classification accuracy for each experiment is reported as the average of the accuracies obtained during a ten-fold cross-validation on the corpus. The table also shows a baseline, computed as the average of the accuracies obtained when using the most frequent class observed on the training data for each fold.

As seen from the table, on average, the joint use of textual and musical features is also beneficial for this binary coarser-grained classification. Perhaps not surprisingly, the effect of the classifier is stronger for

Emotion	1,000 news headlines		4,976 song lines
	Best result SEMEVAL '07	(Strapparava and Mihalcea, 08)	Joint Text and Music
ANGER	0.3233	0.1978	0.6679
DISGUST	0.1855	0.1354	0.5068
FEAR	0.4492	0.2956	0.4384
JOY	0.2611	0.1381	0.6456
SADNESS	0.4098	0.1601	0.6193
SURPRISE	0.1671	0.1235	0.3855
AVERAGE	0.2993	0.1750	0.5439

Table 8: Results obtained in previous work on emotion classification.

those emotions that are dominant in the corpus, i.e., JOY and SADNESS (see Table 2). The improvement obtained with the classifiers is much smaller for the other emotions (or even absent, e.g., for SURPRISE), which is also explained by their high baseline of over 90%.

**Comparison to previous work.** There is no previous research that has considered the joint use of lyrics and songs representations for emotion classification at line level, and thus we cannot draw a direct comparison with other work on emotion classification in songs.

Nonetheless, as a point of reference, we consider the previous work done on emotion classification of texts. Table 8 shows the results obtained in previous work for the recognition of emotions in a corpus consisting of 1,000 news headlines (Strapparava and Mihalcea, 2007) annotated for the same six emotions. Specifically, the table shows the best overall correlation results obtained by the three emotion recognition systems in the SEMEVAL task on Affective Text (Strapparava and Mihalcea, 2007): (Chaumartin, 2007; Kozareva et al., 2007; Katz et al., 2007). The table also shows the best results obtained in follow up work carried out on the same dataset (Strapparava and Mihalcea, 2008).

Except for one emotion (FEAR), the correlation figures we obtain are significantly higher than those reported in previous work. As mentioned before, however, a direct comparison cannot be made, since the earlier work used a different, smaller dataset. Moreover, our corpus of songs is likely to be more emotionally loaded than the news titles used in previous work.

## 6 Conclusions

Popular songs express universally understood meanings and embody experiences and feelings shared by many, usually through a combined effect of both music and lyrics. In this paper, we introduced a novel corpus of music and lyrics, annotated for emotions at line level, and we used this corpus to explore the automatic recognition of emotions in songs. Through experiments carried out on the dataset of 100 songs, we showed that emotion recognition can be performed using either textual or musical features, and that the joint use of lyrics and music can improve significantly over classifiers that use only one dimension at a time.

The dataset introduced in this paper is available by request from the authors of the paper.

## Acknowledgments

The authors are grateful to Rajitha Schellenberg for her help with collecting the emotion annotations. Carlo Strapparava was partially supported by a Google Research Award. ## Abstract

This study presents a novel method that measures English language learners' syntactic competence towards improving automated speech scoring systems. In contrast to most previous studies which focus on the length of production units such as the mean length of clauses, we focused on capturing the differences in the distribution of morpho-syntactic features or grammatical expressions across proficiency. We estimated the syntactic competence through the use of corpus-based NLP techniques. Assuming that the range and sophistication of grammatical expressions can be captured by the distribution of Part-of-Speech (POS) tags, vector space models of POS tags were constructed. We use a large corpus of English learners' responses that are classified into four proficiency levels by human raters. Our proposed feature measures the similarity of a given response with the most proficient group and is then estimates the learner's syntactic competence level.

Widely *outperforming* the state-of-the-art measures of syntactic complexity, our method attained a significant correlation with human-rated scores. The correlation between human-rated scores and features based on manual transcription was 0.43 and the same based on ASR-hypothesis was slightly lower, 0.42. An important advantage of our method is its robustness against speech recognition errors not to mention the simplicity of feature generation that captures a reasonable set of learner-specific syntactic errors.

## 1 Introduction

This study provides a novel method that measures ESL (English as a second language) learners' competence in grammar usage (syntactic competence). Being interdisciplinary in nature, it shows how to combine the core findings in the ESL literature with various empirical NLP techniques for the purpose of automated scoring.

Grammar usage is one of the dimensions of language ability that is assessed during non-native proficiency level testing in a foreign language. Overall proficiency in the target language can be assessed by testing the abilities in various areas including fluency, pronunciation, and intonation; grammar and vocabulary; and discourse structure. Testing rubrics for human raters contain descriptors used for the subjective assessment of several of these features. With the recent move towards the objective assessment of language ability (spoken and written), it is imperative that we develop methods for quantifying these abilities and measuring them automatically.

Ortega (2003) indicated that “the *range* of forms that surface in language production and the degree of *sophistication* of such forms” were two important areas in grammar usage and called the combination of these two areas “syntactic complexity.” Features that measure syntactic complexity have been frequently studied in ESL literature and have been found to be highly correlated with students' proficiency levels in writing.

Studies in automated speech scoring have focused on fluency (Cucchiari et al., 2000; Cucchiari et al., 2002), pronunciation (Witt and Young, 1997;

Witt, 1999; Franco et al., 1997; Neumeyer et al., 2000), and intonation (Zechner et al., 2009), and relatively fewer studies have been conducted on grammar usage. More recently, Lu (2010), Chen and Yoon (2011) and Chen and Zechner (2011) have measured syntactic competence in speech scoring. Chen and Yoon (2011) estimated the complexity of sentences based on the average length of the clauses or sentences. In addition to these length measures, Lu (2010) and Chen and Zechner (2011) measured the parse-tree based features such as the mean depth of parsing tree levels. However, these studies found that these measures did not show satisfactory empirical performance in automatic speech scoring (Chen and Yoon, 2011; Chen and Zechner, 2011) when the features were calculated from the output of a speech recognition engine.

This study considers new features that measure syntactic complexity and is novel in two important ways. First, in contrast to most features that infer syntactic complexity based upon the length of the unit, we directly measure students' sophistication and range in grammar usage. Second, instead of rating a student's response using a scale based on native speech production, our experiments compare it with a similar body of learners' speech. Eliciting native speakers' data and rating it for grammar usage (supervised approach) can be arbitrary, since there can be a very wide range of possible grammatical structures that native speakers utilize. Instead, we proceed in a semi-supervised fashion. A large amount of learners' spoken responses were collected and classified into four groups according to their proficiency level. We then sought to find how distinct the proficiency classes were based on the distribution of POS tags. Given a student's response, we calculated the similarity with a sample of responses for each score level based on the proportion and distribution of Part-of-Speech using NLP techniques.

POS tag distribution has been used in various tasks such as text genre classification (Feldman et al., 2009); in a language testing context, it has been used in grammatical error detection (Chodorow and Leacock, 2000; Tetreault and Chodorow, 2008) and essay scoring. Recently, Roark et al. (2011) explored POS tag distribution to capture the differences in syntactic complexity between healthy subjects and subjects with mild cognitive impairment,

but no other research has used POS tag distribution in measuring syntactic complexity, to the best of authors' knowledge.

An assessment of ESL learners' syntactic competence should consider the structure of sentences as a whole - a task which may not be captured by the simplistic POS tag distribution. However, studies of Lu (2010) and Chen and Zechner (2011) showed that more complex syntactic features are unreliable in ASR-based scoring system. Furthermore, we show that POS unigrams or bigrams indeed capture a reasonable portion of learners' range and sophistication of grammar usage in our discussion in Section 7.

This paper will proceed as follows: we will review related work in Section 2 and present the method to calculate syntactic complexity in Section 3. Data and experiment setup will be explained in Section 4 and Section 5. The results will be presented in Section 6. Finally, in Section 7, we discuss the levels of syntactic competence that are captured using our proposed measure.

## 2 Related Work

Second Language Acquisition (SLA) researchers have developed many quantitative measures to estimate the level of acquisition of syntactic competence. Bardovi-Harlig and Bofman (1989) classified these measures into two groups. The first group is related to the acquisition of specific morphosyntactic features or grammatical expressions. Tests of negations or relative clauses - whether these expressions occurred in the test responses without errors - fell into this group (hereafter, the expression-based group). The second group is related to the length of the clause or the relationship between clauses and hence not tied to particular structures (hereafter, the length-based group). Examples of the second group measures include the average length of clause unit and dependent clauses per sentence unit.

These syntactic measures have been extensively studied in ESL writing. Ortega (2003) synthesized 25 research studies which employed syntactic measures on ESL writing and reported a significant relationship between the proposed features and writing proficiency. He reported that a subset of features such as the mean length of the clause unit increased with students' proficiency. More recently, Lu (2010)

has conducted a more systematic study using an automated system. He applied 14 syntactic measures to a large database of Chinese learners' writing samples and found that syntactic measures were strong predictors of students' writing proficiency.

Studies in the area of automated speech scoring have only recently begun to actively investigate the usefulness of syntactic measures for scoring spontaneous speech (Chen et al., 2010; Bernstein et al., 2010). These have identified clause boundaries (identified from manual annotations and automatically) and obtained length-based features. In addition to these conventional syntactic complexity features, Lu (2009) implemented an automated system that calculates the revised Developmental Level (D-Level) Scale (Covington et al., 2006) using natural language processing (NLP) techniques. The original D-Level Scale was proposed by Rosenberg and Abbeduto (1987) based primarily on observations of child language acquisition. They classified children's grammatical acquisition into 7 different groups according to the presence of certain types of complex sentences. The revised D-Level Scale classified sentences into the eight levels according to the presence of particular grammatical expressions. For instance, level 0 is comprised of simple sentences, while level 5 is comprised of sentences joined by subordinating conjunction or nonfinite clauses in an adjunct position. The D-Level Scale has been less studied in the speech scoring. To our knowledge, Chen and Zechner (2011) is the only study that applied the D-Level analyzer to ESL learners' spoken responses.

In contrast to ESL writing, applying syntactic complexity features, both conventional length-based features and D-Level features, presents serious obstacles for speaking. First, the length of the spoken responses are typically shorter than written responses. Most measures are based on sentence or sentence-like units, and in speaking tests that elicit only a few sentences the measures are less reliable. Chen and Yoon (2011) observed a marked decrease in correlation between syntactic measures and proficiency as response length decreased. In addition, speech recognition errors only worsen the situation. Chen and Zechner (2011) showed that the significant correlation between syntactic measures and speech proficiency (correlation coefficient

= 0.49) became insignificant when they were applied to the speech recognition word hypotheses. Errors in speech recognition seriously influenced the measures and decreased the performance. Due to these problems, the existing syntactic measures do not seem reliable enough for being used in automated speech proficiency scoring.

In this study, we propose novel syntactic measures which are relatively robust against speech recognition errors and are reliable in short responses. In contrast to recent studies focusing on length-based features, we focus on capturing differences in the distribution of morphosyntactic features or grammatical expressions across proficiency levels. We investigate the distribution of a broader class of grammatical forms through the use of corpus-based NLP techniques.

### 3 Method

Many previous studies, that assess syntactic complexity based on the distribution of morphosyntactic features and grammatical expressions, limited their experiments to a few grammatical expressions. Covington et al. (2006) and Lu (2009) covered all sentence types, but their approaches were based on expert observation (supervised rubrics), and descriptions of each level were brief and abstract. It is important to develop a more detailed and refined scale, but developing scales in a supervised way is difficult due to the subjectivity and the complexity of structures involved.

In order to overcome this problem, we employed NLP technology and a corpus-based approach. We hypothesize that the level of acquired grammatical forms is signaled by the distribution of the POS tags, and the differences in grammatical proficiency result in differences in POS tag distribution. Based on this assumption, we collected large amount of ESL learners' spoken responses and classified them into four groups according to their proficiency levels. The syntactic competence was estimated based on the similarity between the test responses and learners' corpus.

A POS-based vector space model (VSM), in which the response belonging to separate proficiency levels were converted to vectors and the similarity between vectors were calculated using cosine

similarity measure and tf-idf weighting, was employed. Such a score-category-based VSM has been used in automated essay scoring. Attali and Burstein (2006) to assess the lexical content of an essay by comparing the words in the test essay with the words in a sample essays from each score category. We extend this to assessment of grammar usage using vectors of POS tags.

Proficient speakers use complicated grammatical expressions, while beginners use simple expressions and sentences with frequent grammatical errors. POS tags (or sequences) capturing these expressions may be seen in corresponding proportions in each score group. These distributional differences are captured by inverse-document frequency.

In addition, we identify frequent POS tag sequences as those having high mutual information and include them in our experiments. Temple (2000) pointed out that the proficient learners are characterized by increased automaticity in speech production. These speakers tend to memorize frequently used multi-word sequences as a chunk and retrieve the whole chunk as a single unit. The degree of automaticity can be captured by the frequent occurrence of POS sequences with high mutual information.

We quantify the usefulness of the generated features for the purpose of automatic scoring by first considering its correlation with the human scores. We then compare the performance of our features with those in Lu (2011), where the features are a collection of measures of syntactic complexity that have shown promising directions in previous studies.

## 4 Data

Two different sets of data were used in this study: the AEST 48K dataset and AEST balanced dataset. Both were collections of responses from the AEST, a high-stakes test of English proficiency and had no overlaps. The AEST assessment consists of 6 items in which speakers are prompted to provide responses lasting between 45 and 60 seconds per item. In summary, approximately 3 minutes of speech is collected per speaker.

Among the 6 items, two items are tasks that ask examinees to provide information or opinions on familiar topics based on their personal experience or

background knowledge. The four remaining items are integrated tasks that include other language skills such as listening and reading. All items extract spontaneous, unconstrained natural speech. The size, purpose, and speakers' native language information for each dataset is summarized in Table 1.

Each response was rated by trained human raters using a 4-point scoring scale, where 1 indicates a low speaking proficiency and 4 indicates a high speaking proficiency. In order to evaluate the reliability of the human ratings, the data should be scored by two raters. Since none of the AEST balanced data was double scored the inter-rater agreement ratio was estimated using a large (41K) double-scored dataset using the same scoring guidelines and scoring process. The Pearson correlation coefficient was 0.63 suggesting a reasonable inter-rater agreement. The distribution of the scores for this data can be found in Table 2.

We used the AEST 48K dataset as the training data and the AEST balanced dataset as the evaluation data.

## 5 Experiments

### 5.1 Overview

Our experimental procedure is as follows. All transcriptions were tagged using the POS tagger described in Section 5.3 and POS tag sequences were extracted. Next, the POS-based VSMs (one for each score class) were created using the AEST 48K dataset. Finally, for a given test response in the AEST balanced dataset, similarity features were generated.

A score-class-specific POS-based VSM was created using POS tags generated from the manual transcriptions. For evaluation, two different types of transcriptions (manual transcription and word hypotheses from the speech recognizer described in Section 5.2) were used in order to investigate the influence of speech recognition errors in the feature performance.

### 5.2 Speech recognition

An HMM recognizer was trained on AEST 48K dataset - approximately 733 hours of non-native speech collected from 7872 speakers. A gender-independent triphone acoustic model and combination

Corpus name	Purpose	Number of speakers	Number of responses	Native languages	Size (Hrs)
AEST 48K data	ASR training and POS model training	7872	47227	China (20%), Korea (19%), Japanese (7%), India (7%), others (46%)	733
AEST balanced data	Feature development and evaluation	480	2880	Korean (15%), Chinese (14%), Japanese (7%), Spanish (9%), Others (55%)	44

Table 1: Data size and speakers native languages

Corpus name	Size	Score1	Score2	Score3	Score4
AEST 48K data	Number of files	1953	16834	23106	5334
	(%)	4	36	49	11
AEST balanced data	Number of files	141	1133	1266	340
	(%)	5	40	45	12

Table 2: Proficiency scores and data sizes

of bigram, trigram, and four-gram language models were used. The word error rate (WER) on the held-out test dataset was 27%.

### 5.3 POS tagger

POS tags were generated using the POS tagger implemented in the OpenNLP toolkit. It was trained on the Switchboard (SWBD) corpus. This POS tagger was trained on about 528K word/tag pairs and achieved a tagging accuracy of 96.3% on a test set of 379K words. The Penn POS tag set was used in the tagger.

### 5.4 Unit generation using mutual information

POS bigrams with high mutual information were selected and used as a single unit. First, all POS bigrams which occurred less than 50 times were filtered out. Next, the remaining POS tag bigrams were sorted by their mutual information scores, and two different sets (top50 and top110) were selected. The selected POS pairs were transformed into compound tags. As a result, we generated three sets of POS units by this process: the original POS set without the compound unit (Base), the original set and an additional 50 compound units (Base+mi50), and the original set and an additional 110 units (Base+mi110).

Finally, unigram, bigram and trigram were generated for each set separately. The size of total terms in each condition was presented in table 3.

	Base	Base+mi50	Base+mi110
Unigram	42	93	151
Bigram	1366	4284	9691
Trigram	21918	54856	135430

Table 3: Number of terms used in VSMs

### 5.5 Building VSMs

For each ngram, three sets of VSMs were built using three sets of tags as terms, yielding a total of nine VSMs. The results were based on the individual model and we did not combine any models.

### 5.6 Cosine similarity-based features

The cosine similarity has been frequently used in the information retrieval field to identify the relevant documents for the given query. This measures the similarity between a given query and a document by measuring the cosine of the angle between vectors in a high-dimensional space, whereby each term in the query and documents corresponding to a unique dimension. If a document is relevant to the query, then it shares many terms resulting in a small angle. In this study, the term was a single or compound POS tag (unigram, bigram or trigram) weighted by its tf-idf, and the document was the response.

First, the inverse document frequency was calculated from the training data, and each response was treated as a document. Next, responses in the same

	Unigram			Bigram			Trigram		
	Base	Base +mi50	Base +mi110	Base	Base +mi50	Base +mi110	Base	Base +mi50	Base +mi110
Transcription	0.301**	0.297**	0.329**	0.427**	0.361**	0.366**	0.402**	0.322**	0.295**
ASR	0.246**	0.272**	0.304**	0.415**	0.348**	0.347**	0.373**	0.311**	0.282**

Table 4: Pearson correlation coefficients between ngram-based features and expert proficiency scores  
 \*\* Correlation is significant at the 0.01 level

score group were concatenated, and a single vector was generated for each score group. A total of 4 vectors were generated using training data. For each test response, a similarity score was calculated as follows:

$$\cos(\vec{q}, \vec{d}_j) = \frac{\sum_{i=1}^n q_i d_{ji}}{\sqrt{\sum_{i=1}^n q_i^2 \sum_{i=1}^n d_i^2}}$$

$$q_i \equiv tf(t_i, \vec{q}) \times \log\left(\frac{N}{df(t_i)}\right)$$

$$d_{ji} \equiv tf(t_i, \vec{d}_j) \times \log\left(\frac{N}{df(t_i)}\right)$$

where  $\vec{q}$  is a vector of the test response,  
 $\vec{d}_j$  is a vector of the *scoreGroup<sub>j</sub>*,  
 $n$  is the total number of POS tags,  
 $tf(t_i, \vec{q})$  is the term frequency of POS tag  $t_i$  in the test response,  
 $tf(t_i, \vec{d}_j)$  is the term frequency of POS tag  $t_i$  in the *scoreGroup<sub>j</sub>*,  
 $N$  is the total number of training responses,  
 $df(t_i)$  is the document frequency of POS tag  $t_i$  in the total training responses

Finally, a total of 4 *cos* scores (one per score group) were generated. Among these four values, the *cos4*, the similarity score to the responses in the score group 4, was selected as a feature with the following intuition. *cos4* measures the similarity of a given test response to the representative vector of score class 4; the larger the value, the closer it would be to score class 4.

## 6 Results

### 6.1 Correlation

Table 4 shows correlations between cosine similarity features and proficiency scores rated by experts.

The bigram-based features outperformed both unigram-based and trigram-based features. In particular, the similarities using the *base* tag set with bigrams achieved the best performance. By adding the mutual information-based compound units to the original POS tag sets, the performance of features improved in the unigram models. However, there was no performance gain in either bigram or trigram models; on the contrary, there was a large drop in performance. Unigrams have good coverage but limited power in distinguishing different score levels. On the other hand, trigrams have opposite characteristics. Bigrams seem to strike a balance in both coverage and complexity (from among the three considered here) and may thus have resulted in the best performance.

The performance of ASR-based features were comparable to that of transcription-based features. The best performing feature among ASR-based-features were from the bigram and *base* set, with correlations nearly the same as the best performing one among the transcription-based-features. Seeing how close the correlations were in the case of transcription-based and ASR-hypothesis based feature extraction, we conclude that the proposed measure is robust to ASR errors.

### 6.2 Comparison with other Measures of Syntactic Complexity

We compared the performance of our features with the features of syntactic complexity proposed in (Lu, 2011). Towards this, the clause boundaries of the ASR hypotheses, were automatically detected using the automated clause boundary detection method<sup>1</sup>.

<sup>1</sup>The automated clause boundary detection method in this study was a Maximum Entropy Model based on word bigrams, POS tag bigrams, and pause features. The method achieved an

The utterances were then parsed using the Stanford Parser, and a total of 22 features including both length-related features and parse-tree based features were generated using (Lu, 2011). Finally, we calculated Pearson correlation coefficients between these features and human proficiency scores.

Study	Feature	Correlation
Current study	bigram based cos4	0.41**
(Lu, 2011)	DCC	0.14**

Table 5: Comparison between (Lu, 2011) and this study  
\*\* Correlation is significant at the 0.01 level

As indicated in Table 5, the best performing feature was mean number of dependent clauses per clause (DCC) and the correlation  $r$  was 0.14. No features other than DCC achieved statistically significant correlation. Our best performing feature (bigram based cos4) *widely outperformed* the best of Lu (2011)’s features (correlations approximately 0.3 apart).

A logical explanation for the poor performance of Lu (2011)’s features is that the features are generated using multi-stage automated process, and the errors in each process contributes the low feature performance. For instance, the errors in the automated clause boundary detection may result in a serious drop in the performance. With the spoken responses being particularly short (a typical response in the data set had 10 clauses on average), even one error in clause boundary detection can seriously affect the reliability of features.

## 7 Discussion

While the measure of syntactic competence that we study here is an abstraction of the overall syntactic competence, without consideration of specific constructions, we analyzed the results further with the intention of casting light on the level of details of syntactic competence that can be explained using our measure. Furthermore, this section will show that bigram POS sequences can yield significant information on the range and sophistication of grammar usage in the specific assessment context (spon-

F-score of 0.60 on the non-native speakers’ ASR hypotheses. A detailed description of the method is presented in (Chen and Zechner, 2011)

aneous speech comprised of only declarative sentences).

ESL speakers with high proficiency scores are expected to use more complicated grammatical expressions that result in a high proportion of POS tags related to these expressions in that score group. The distribution of POS tags was analyzed in detail in order to investigate whether there were systematic distributional changes according to proficiency levels. Owing to space constraints, we restrict our discussion to the analysis using unigrams (base and compound). For each score group, the POS tags were sorted based on the frequencies in training data, and the rank orders were calculated. The more frequent the POS tag, the higher its rank.

A total of 150 POS tags, including the original POS tag set and top 110 compound tags, were classified into 5 classes:

- Absence-of-low-proficiency (ABS): Group of POS tags that appear in all score groups except the lowest proficiency group;
- Increase (INC): Group of POS tags whose ranks increase consistently as proficiency increases;
- Decrease (DEC): Group of POS tags whose ranks decrease consistently as proficiency increases;
- Constant (CON): Group of POS tags whose ranks remain same despite change in proficiency;
- Mix: Group of POS tags of with no consistent pattern in the ranks.

Table 6 presents the number of POS tags in each class.

ABS	INC	DEC	CON	Mix
14	37	33	18	48

Table 6: Tag distribution and proficiency scores

The ‘ABS’ class mostly consists of ‘WP’ and ‘WDT’; more than 50% of tags in this class are related to these two tags. ‘WP’ is a Wh-pronoun while ‘WDT’ is a Wh-determiner. Since most sentences in

our data are declarative sentences, ‘Wh’ phrase signals the use of relative clause. Therefore, the lack of these tags strongly support the hypothesis that the speakers in score group 1 showed incompetence in the use of relative clauses or their use in limited situations.

The ‘INC’ class can be sub-classified into three groups: verb, comparative, and relative clause. Verb group includes the infinitive (TO\_VB), passive (VB\_VBN, VBD\_VBN, VBN, VBN\_IN, VBN\_RP), and gerund forms (VBG, VBG\_RP, VBG\_TO). Next, the comparative group encompasses comparative constructions. Finally, the relative clause group signals the presence of relative clauses. The increased proportion of these tags reflects the use of more complicated tense forms and modal forms as well as more frequent use of relative clauses. It supports the hypothesis that speakers with higher proficiency scores tend to use more complicated grammatical expressions.

The ‘DEC’ class can be sub-classified into five groups: noun, simple tense verb, GW and UH, non-compound, and comparative. The noun group is comprised of many noun or proper noun-related expressions, and their high proportions are consistent with the tendency that less proficient speakers use nouns more frequently. Secondly, the simple tense verb group is comprised of the base form (VB) and simple present and past forms (PRP\_VBD, VB, VBD\_TO, VBP\_TO, VBZ). The expressions in these groups are simpler than those in ‘Increase’ group.

The ‘UH’ tag is for interjection and filler words such as ‘uh’ and ‘um’, while the ‘GW’ tag is for word-fragments. These two spontaneous speech phenomena are strongly related to fluency, and it signals problems in speech production. Frequent occurrences of these two tags are evidence of frequent planning problems and their inclusion in the ‘DEC’ class suggests that instances of speech planning problems decrease with increased proficiency.

Tags in the non-compound group, such as ‘DT’, ‘MD’, ‘RBS’, and ‘TO’, have related compound tags. The non-compound tags are associated with the expressions that do not co-occur with strongly related words, and they tend to be related to errors. For instance, the non-compound ‘MD’ tag signals that there is an expression that a modal verb is not followed by ‘VB’ (base form) and as seen in the ex-

amples, ‘the project may can change’ and ‘the others must can not be good’, they are related to grammatical errors.

Finally, the comparative group includes ‘RBR\_JJR’. The decrease of ‘RBR\_JJR’ is related to the correct acquisition of the comparative form. ‘RBR’ is for comparative adverbs and ‘JJR’ is for comparative adjectives, and the combination of two tags is strongly related to double-marked errors such as ‘more easier’. In the intermediate stage in the acquisition of comparative form, learners tend to use the double-marked form. The compound tags correctly capture this erroneous stage.

The ‘Decrease’ class also includes three Wh-related tags (WDT\_NN, WDT\_VBP, WRB), but the proportion is much smaller than the ‘Increase’ class.

The above analysis shows that the combination of original and compound POS tags correctly capture systematic changes in the grammatical expressions according to changes in proficiency levels.

The robust performance of our proposed measure to speech recognition errors may be better appreciated in the context of similar studies. Compared with the state-of-the-art measures of syntactic complexity proposed in Lu (2011) our features achieve significantly better performance especially when generated from ASR hypotheses. It is to be noted that the performance drop between the transcription-based feature and the ASR hypothesis-based feature was marginal.

## 8 Conclusions

In this paper, we presented features that measure syntactic competence for the automated speech scoring. The features measured the range and sophistication of grammatical expressions based on POS tag distributions. A corpus with a large number of learners’ responses was collected and classified into four groups according to proficiency levels. The syntactic competence of the test response was estimated by identifying the most similar group from the learners’ corpus. Furthermore, speech recognition errors only resulted in a minor performance drop. The robustness against speech recognition errors is an important advantage of our method.

## Acknowledgments

The authors would like to thank Shasha Xie, Klaus Zechner, and Keelan Evanini for their valuable comments, help with data preparation and experiments.

# A Unified Approach to Transliteration-based Text Input with Online Spelling Correction

Hisami Suzuki      Jianfeng Gao

Microsoft Research

One Microsoft Way, Redmond WA 98052 USA

{hisamis, jfgao}@microsoft.com

## Abstract

This paper presents an integrated, end-to-end approach to online spelling correction for text input. Online spelling correction refers to the spelling correction as you type, as opposed to post-editing. The online scenario is particularly important for languages that routinely use transliteration-based text input methods, such as Chinese and Japanese, because the desired target characters cannot be input at all unless they are in the list of candidates provided by an input method, and spelling errors prevent them from appearing in the list. For example, a user might type *suesheng* by mistake to mean *xuesheng* 学生 'student' in Chinese; existing input methods fail to convert this misspelled input to the desired target Chinese characters. In this paper, we propose a unified approach to the problem of spelling correction and transliteration-based character conversion using an approach inspired by the phrase-based statistical machine translation framework. At the phrase (substring) level, *k* most probable pinyin (Romanized Chinese) corrections are generated using a monotone decoder; at the sentence level, input pinyin strings are directly transliterated into target Chinese characters by a decoder using a log-linear model that refer to the features of both levels. A new method of automatically deriving parallel training data from user keystroke logs is also presented. Experiments on Chinese pinyin conversion show that our integrated method reduces the character error rate by 20% (from 8.9% to 7.12%) over the previous state-of-the-art based on a noisy channel model.

## 1 Introduction

This paper addresses the problem of online spelling correction, which tries to correct users' misspellings as they type, rather than post-editing them after they have already been input. This online scenario is particularly important for languages that routinely use transliteration-based text input methods, including Chinese and Japanese: in these languages, characters (called *hanzi* in Chinese and *kanji/kana* in Japanese) are typically input by typing how they are pronounced in Roman alphabet (called *pinyin* in Chinese, *romaji* in Japanese), and selecting a conversion candidate among those that are offered by an input method system, often referred to as IMEs or input method editors. One big challenge posed by spelling mistakes is that they prevent the desired candidates from appearing as conversion candidates, as in Figure 1: *suesheng* is likely to be a spelling error of *xuesheng* 学生 'student', but it is not included as one of the candidates.

suesheng  
1. 苏鄂生 2. 苏俄 3. 素娥 4. 苏 5. 素

**Figure 1:** Spelling mistake prevents the desired output (学生) from appearing in the list of candidates

This severely limits the utility of an IME, as spelling errors are extremely common. Speakers of a non-standard dialect and non-native speakers have a particularly hard time, because they may not know the standard pronunciation of the word to begin with, preventing them from inputting the word altogether. Error-tolerant word completion and next word prediction are also highly desirable features for text input on software (onscreen) keyboards for any language, making the current work relevant beyond Chinese and Japanese.

In this paper, we propose a novel, unified system of text input with spelling correction, using

Chinese pinyin-to-hanzi conversion as an example. We first formulate the task of pinyin spelling correction as a substring-based monotone translation problem, inspired by phrase-based statistical machine translation (SMT) systems (Koehn et al., 2003; Och and Ney, 2004): we consider the pinyin input (potentially with errors) as the source language and the error-corrected pinyin as the target, and build a log-linear model for spelling correction. In doing so, we also propose a novel, unsupervised method of collecting parallel training data from user input logs. We then build an integrated end-to-end text input system that directly converts a potentially erroneous input pinyin sequence into a desired hanzi sequence, also formulated as a monotone phrase-based SMT problem, in which the feature functions of the substring-based error correction component are integrated and jointly optimized with the sentence-level feature functions for character conversion

Our method generalizes and improves over the previous state-of-the-art methods for the task of error correction and text input in several crucial respects. First, our error correction model is designed and implemented as a substring-based, fully trainable system based on a log-linear model, which has been shown effective for related tasks such as transliteration and letter-to-phone conversion, but has not been attempted for the task of spelling correction. Second, we build an end-to-end pinyin-to-hanzi conversion system by combining all the feature functions used in the error correction and character conversion components in an SMT-style log-linear model, where the feature weights are trained discriminatively for the end-to-end task. This integration method generalizes the previous approach based on a noisy channel model (Chen and Lee, 2000; Zheng et al. 2011b), in which only the error model and the conversion model probabilities are used and combined with equal weights. Finally, like other statistical systems, the amount and quality of training data control the quality of the outcome; we thus propose a new, language-independent method of deriving parallel data for spelling correction from user keystroke logs.

We performed experiments on various methods of integrating the error correction and character conversion sub-components. Our best system, a

fully integrated SMT-based approach, reduces the character error rate by 35% on test data that is completely independent of the creation of error correction and character conversion models.

In what follows, we first give the background of this research in Section 2. We then describe our approach to the spelling correction task (Section 3) and the end-to-end conversion task (Section 4). We summarize our contribution and conclude with remarks for future directions in Section 5.

## 2 Related Work

The current work builds on many previous works on the task of monotone substring-based transduction, including spelling correction, letter-to-phone conversion and transliteration between different scripts. In particular, our substring-based approach to spelling correction is motivated by the success on transliteration (e.g., Sherif and Kondrak, 2007; Cherry and Suzuki, 2009) and letter-to-phoneme conversion (e.g., Jiampojarn et al., 2007; Rama et al., 2009). One big challenge of the spelling correction research is the general lack of naturally occurring paired data of contextual spelling errors and their correction. Previous work has therefore either focused on the task of correcting out-of-vocabulary words out of context (e.g., Brill and Moore, 2000; Toutanova and Moore, 2002), or has resorted to innovative methods of data collection. For example, Banko and Brill (2001) generate data artificially by substituting words from a confusion word set in text for building a contextual speller; Whitelaw et al. (2009) use word frequency and edit distance information to harvest error pairs from a web corpus in an unsupervised manner; Bertoldi et al. (2010) intentionally corrupt clean text by adding noise to the data. Another approach to spelling error data collection uses web search query logs, available in large quantity (albeit to limited institutions), and limit its focus on the task of correcting misspelled queries (e.g., Cucerzan and Brill, 2004; Gao et al., 2010; Sun et al., 2010; Duan and Hsu, 2011). The problem of data collection is particularly difficult for pinyin error correction, as pinyin is not a final form of text in Chinese, so it is not recorded in final text. Zheng et al. (2011a) study a log of pinyin input method and use the backspace key to learn the user mistyping behavior, but they do so only for the purpose of

data analysis, and do not build a statistical model from this data.

Text input methods have been commercially available for decades for inputting Chinese and Japanese, but have also recently become available for other non-Roman script languages including Arabic and the languages of India.<sup>1</sup> Early research work on text input methods includes e.g., Mori et al. (1998), Chen and Lee (2000) and Gao et al. (2002), all of which approach the problem using a noisy channel model. Discriminative approaches have also been proposed, e.g., Suzuki and Gao (2005); Tokunaga et al. (2011). There is only a very limited amount of work that deals with spelling correction in the context of text input: Zheng et al. (2011b) represents a recent work based on a noisy channel model, which defines our baseline. Their work is strictly word-based and only handles the correction of out-of-vocabulary pinyin words into in-vocabulary pinyin words, while our substring-based model is not limited by these constraints.

The current work also has an affinity to the task of speech translation in that the parallel data between the input (speech signal) and the output (text in foreign language) is not directly available, but is mediated by a corrected (transcribed) form of input. Zhang et al. (2011) is thus relevant to our study, though their approach differs from ours in that we build an integrated system that include the feature functions of both error correction and character conversion sub-systems.

### 3 Substring-based Spelling Correction using a Log-linear Model

In this section, we describe our approach to pinyin error correction within a log-linear framework. Though our current target is pinyin error correction, the method described in this section is applicable to any language of interest.

The spelling correction problem has been standardly formulated within the framework of noisy channel model (e.g., Kernighan et al., 1990). Let  $A$  be the input phonetic string in pinyin. The task of spelling correction is to search for the best

correction candidate in pinyin  $C^*$  among all possible corrections for each potentially misspelled pinyin  $A$ :

$$C^* = \operatorname{argmax}_{C \in \text{GEN}(A)} P(C|A) \quad \dots (1)$$

Applying Bayes' Rule and dropping the constant denominator, we have

$$C^* = \operatorname{argmax}_{C \in \text{GEN}(A)} P(A|C)P(C) \quad \dots (2)$$

where the error model  $P(A|C)$  models the translation probability from  $C$  to  $A$ , and the language model  $P(C)$  models how likely the output  $C$  is a correctly spelled pinyin sequence. Many variations on the error model have been proposed, including substring-based (Brill and Moore, 2000) and pronunciation-based (Toutanova and Moore, 2002) models.

Our model is inspired by the SMT framework, in which the error correction probability  $P(C|A)$  of Equation (1) is directly modeled using a log-linear model of the following form:

$$P(C|A) = \frac{1}{Z(A)} \exp \sum_i \lambda_i h_i(A, C) \quad \dots (3)$$

where  $Z(A)$  is the normalization factor,  $h_i$  is a feature function and  $\lambda_i$  is the feature weight. Similarly to phrase-based SMT, many feature functions are derived from the translation and language models, where the translation model-derived features are trained using a parallel corpus of original pinyin and correction pairs. The argmax of Equation (1) defines the search operation: we use a left-to-right beam search decoder to seek for each input pinyin the best correction according to Equation (3).

We first describe how the paired data for deriving the error model probabilities is generated from user logs in Section 3.1, and then how the models are trained and the model weights are learned in Section 3.2. We discuss the results of pinyin error correction as an independent task in Section 3.3.

#### 3.1 Generating error correction pairs from keystroke logs

Unlike English text, which includes instances of misspelled words explicitly, pinyin spelling errors are not found in a corpus, because pinyin is used as a means of inputting text, and is not part of the

<sup>1</sup> A few examples include Google Transliterate (<http://www.google.com/transliterate/>) and Microsoft Maren (<http://www.microsoft.com/middleeast/egypt/cm/mic/maren/>) / ILIT (<http://specials.msn.co.in/ilit/Hindi.aspx>). Quillpad (<http://quillpad.in/>) is also popularly used in India.

final written form of the language. Therefore, pinyin error correction pairs must be created intentionally. We chose the method of implementing a version of an input method which records the keystrokes of users while they are asked to type a particular Chinese text in hanzi; in doing so, we captured each keystroke issued by the user behind the scene. Such keystroke logs include the use of the backspace key, from which we compute the pinyin strings after the usage of the backspace keys as well as the putative pinyin string had the user not corrected it using the backspace key.<sup>2</sup> Table 1 shows a few examples of the entries in the keystroke log, along with the computed pinyin strings before and after correction. Each entry (or phrase) in the log represents the unit that corresponds to the sequence the user input at once, at the end of which the user committed to a conversion candidate, which typically consists of one or more words. While the post-correction string can be straightforwardly derived by deleting the same number of characters preceding the backspaces, the computation of the pre-correction string is trickier and ambiguous, because the backspace key is used for the purpose of both deletion and substitution (delete and replace) operations. In Table 1, a backspace usage is indicated by `_` in the original keystroke sequence that is logged. In the second example, a deletion interpretation will generate `zhonguo` as a pre-correction string, while substitution interpretation will generate `zhonguoo`. In order to recover the desired pre-correcting string, we compared the prefix of the backspace usage (`zhonguo`) with the substrings after error correction (`zhong`, `zhongg`, `zhonggu...`). We considered that the prefix was spell-corrected into the substring which is the longest and with the smallest edit distance: in this case, `zhonguo` is considered an error for `zhongguoo`, therefore recovering the pre-correction string of the whole sequence as `zhonguo`. Note that this method of error data extraction is general

<sup>2</sup> Zheng et al. (2011a) also uses the backspace key in the IME log to generate error-correction pairs, but they focus on the usage of a backspace after the desired hanzi characters have been input, i.e., the backspace key is used to delete one or more hanzi characters. In contrast, our method focuses on the use of backspace to delete one or more pinyin characters before conversion. This simulates the scenario of online error correction more truthfully, and can collect paired data in large quantity faster.

keystroke	pre-correction	post-correction
n a n s _ r e n	nansen	nanren
z h o n g u o _ _ g u o	zhonguo	zhongguo
	(*zhonguoo)	

**Table 1:** Computation of pre- and post-correction strings from keystroke log

and is language-independent. Since paired error correction data do not exist naturally and is expensive to collect for any language, we believe that the proposed method is useful beyond the case of Chinese text input and applicable to the data collection of the spelling correction task in general. In a related work (Baba and Suzuki, 2012), we collected such keystroke data using Amazon's Mechanical Turk for English and Japanese, and released the error-correction pairs for research purposes.<sup>3</sup>

The extracted pairs are still quite noisy, because one error correction behavior might not completely eliminate the errors in typing a word. For example, in trying to type *women* 我们 'we', a user might first type *wmen*, hit the backspaces key four times, retype *womeen*, and commit to a conversion candidate by mistake. We extract the pair (*wmen*, *womeen*) from this log incorrectly, which is one of the causes of the noise in the data. Despite these remaining errors, we use the data without further cleaning, as we expect our approach to be robust against a certain amount of noise.

Keystroke data was collected for three text domains (chat, blog and online forum) from 60 users, resulting in 86,783 pairs after removing duplicates. The data includes the pairs with the same source and target, with about 41% representing the case of correction. We used 5,000 pairs for testing, 1,000 pairs for tuning the log-linear model weights (see the next subsection), and the remaining portion for training the error correction component.

### 3.2 Training the log-linear model

The translation model captures substring-based spelling error patterns and their transformation probabilities. The model is learned from large amounts of pinyin-correction pairs mined from user keystroke logs discussed above. Take the

<sup>3</sup> Available at <http://research.microsoft.com/en-us/downloads/4eb8d4a0-9c4e-4891-8846-7437d9dbd869/default.aspx>.

following pinyin-correction pair as an example, where the input pinyin and its correction are aligned at the character level: given a pair  $(A,C)$ , we align the letters in  $A$  with those in  $C$  so as to minimize the edit distance between  $A$  and  $C$  based on single character insertions, deletions and substitutions.

```
wanmiandshijie
| | | | | | | | | |
waimiandeshijie
```

From this pair, we learn a set of error patterns that are consistent with the character alignment,<sup>4</sup> each of which is a pair of substrings indicating how the spelling is transformed from one to another. Some examples of extracted phrases are (wanmian, waimian) and (andshi, andeshi). In our implementation, we extract all patterns with a substring length of up to 9 characters. We then learn the translation probabilities for each pair using maximum likelihood estimation (MLE). Let  $(a,c)$  denote a pair. For each pair, we learn the translation probabilities  $P(c|a)$  and  $P(a|c)$ , estimated using MLE, as well as lexical weights in two directions following Koehn et al. (2003). Our error correction model is completely substring-based and does not use a word-based lexicon, which gives us the flexibility of generating unseen correction targets as well as supporting pinyin input consisting of multiple words at a time. For the language model, we use a character 9-gram model to capture the knowledge of correctly spelled pinyin words and phrases. We trained the language model using the target portion of the parallel data described in Section 3.1, though it is possible to train it with an arbitrary text in pinyin when such data is available.

In addition to the feature functions derived from the error and language models, we also use word and phrase penalties as feature functions, which are commonly used in SMT. These features also make sense in the current context, as using fewer phrase means encouraging longer ones with more context, and the target character length can capture tendencies to delete or insert words in errors.

<sup>4</sup> Consistency here implies two things. First, there must be at least one aligned character pair in the aligned phrase. Second, there must not be any alignments from characters inside the aligned phrase to characters outside the phrase. That is, we do not extract a phrase pair if there is an alignment from within the phrase pair to outside the phrase pair.

Overall, the log-linear model uses 7 feature functions: 4 derived from the translation models, word and phrase penalties, and the language model. The model weights were trained using the minimum error rate training algorithm (MERT, Och, 2003). We tried MERT with two objective functions: one that uses the 4-gram BLEU score as straightforwardly adapted from SMT, and the other that minimizes the character error rate (CER). CER is based on the edit distance between the reference and system output, which is used for evaluating the IME accuracy (Section 4.3). It is more directly related with the word/phrase-level accuracy, which we used to evaluate the error correction module in isolation, than the BLEU metric. As we will show below, however, using different objective functions turned out to have only a minimal impact on the spelling correction accuracy.

### 3.3 Experiments and results

The performance of pinyin error correction was evaluated on two data sets: (1) *log-test*: the test set of the data in Section 3.1, which is derived in the same way as the training data but is noisy, consisting of 5,000 phrases of which 2,020 are misspelled; (2) *CHIME*: the gold standard from the CHIME data set made available by Zheng et al. (2011b),<sup>5</sup> which is also used in the end-to-end evaluation in Section 4. This data set consists of 2,000 sentence pairs of pinyin input with errors and the target hanzi characters, constructed by collecting actual user typing logs of the Lancaster corpus (McEnery and Xiao, 2004), which includes text from newspaper, fiction, and essays.<sup>6</sup> The CHIME data set does not include the corrected pinyin string; we therefore generated this by running a text-to-pinyin utility,<sup>7</sup> and created the pairs before and after error correction for evaluating our pinyin spelling correction module. The set contains 11,968 words of which 908 are misspelled.

The results of the evaluation are given in Table 2. They are for phrase/word-level accuracy, as the log-derived data set is for each phrase (a user-

<sup>5</sup> Available from <http://chime.ics.uci.edu/>

<sup>6</sup> Details on the Lancaster corpus are found at <http://www.lancs.ac.uk/fass/projects/corpus/LCMC/>.

<sup>7</sup> We used an in-house tool, but many tools are available online. Unlike pinyin-to-hanzi, hanzi-to-pinyin is relatively straightforward as most characters have a unique pronunciation.

	1-best	3-best	20-best
log-test: No correction	59.6		
log-test: Noisy Channel	49.5	67.86	84.8
log-test: Proposed (BLEU)	62.46	74.58	86.66
log-test: Proposed (CER)	62.82	75.06	86.8
CHIME: No correction	92.41		
CHIME: Noisy Channel	91.29	95.75	98.82
CHIME: Proposed (BLEU)	93.51	97.38	99.06
CHIME: Proposed (CER)	93.49	97.29	99.08

**Table 2:** Pinyin error correction accuracy (in %)

defined unit of conversion, consisting of one to a few words), while the CHIME data set is word-segmented. The baseline accuracy is the accuracy of not correcting any error, which is very strong in this task: 59.6% and 92.41% for the two data sets, respectively. The accuracy on the log-test data is generally much lower than the CHIME data, presumably because the latter is cleaner, contains less errors to begin with, and the unit of evaluation is smaller (word) than the log-test (phrase). Though CHIME is an out-of-domain data set, the proposed model works very well on this set, achieving more than 93% accuracy with the best output, significantly (at  $p < 0.001$  using McNemar’s test) improving on the strong baseline of not correcting any error. The proposed log-linear approach is also compared against the noisy channel model baseline, which is simulated by only using one error model-derived feature function  $P(A|C)$  and the language model, weighted equally, using the same beam search decoder. Somewhat surprisingly, the noisy channel model results fall below the baseline in both data sets, while the log-linear model improves over the baseline, especially on the 1-best accuracy: all differences between the noisy channel model and the log-linear model outputs are significant. Finally, regarding the effect of using the CER as the objective function of MERT, we only observe minimal impact: none of the differences in accuracy between the BLEU and CER objectives is statistically significant on either data set. For a monotone decoding task such as spelling correction, using either objective function therefore seems to suffice, even though BLEU is more indirect and redundant in capturing the phrase-level accuracy.

## 4 A Unified Model of Character Conversion with Spelling Correction

In this section we describe our unified model of spelling correction and transliteration-based character conversion. Analogous to the spelling correction task, the character conversion problem can also be considered as a substring-based translation problem. The novelty of our approach lies in the fact that we take advantage of the parallelism between these tasks, and build an integrated model that performs spelling correction and character conversion at the same time, within the log-linear framework. This allows us to optimize the feature weights directly for the end goal, from which from we can expect a better overall conversion accuracy.

### 4.1 Noisy channel model approach to incorporating error correction in character conversion

The task of pinyin-to-hanzi conversion consists of converting the input phonetic strings provided by the user into the appropriate word string using ideographic characters. This has been formulated within the noisy channel model (Chen and Lee, 2000), in exactly the same manner as the spelling correction, as describe in Equations (1) and (2) in Section 3. Given the pinyin input  $A$ , the task is to find the best output hanzi sequence  $W^*$ :

$$\begin{aligned}
 W^* &= \operatorname{argmax}_{W \in \text{GEN}(A)} P(W|A) \quad \dots (4) \\
 &= \operatorname{argmax}_{W \in \text{GEN}(A)} P(W)P(A|W)
 \end{aligned}$$

In traditional conversion systems which do not consider spelling errors,  $P(A|W)$  is usually set to 1 if the word is found in a dictionary of word-pronunciation pairs, which also defines  $\text{GEN}(A)$ . Therefore, the ranking of the candidates relies exclusively on the language model probability  $P(W)$ .

An extension of this formulation to handle spelling errors can be achieved by incorporating an actual error model  $P(A|W)$ . Assuming a conditional independence of  $A$  and  $W$  given the error-corrected pinyin sequence  $C$ , Equation (4) can be re-written as:

Figure 2: Generation of integrated translation table for the pinyin input  $a = xueshseng$

$$\begin{aligned}
 W^* &= \operatorname{argmax}_W P(W|A) \\
 &= \operatorname{argmax}_W \sum_C P(W|C)P(C|A) \\
 &= \operatorname{argmax}_W \sum_C P(C|W)P(W)P(C|A)
 \end{aligned}$$

Here,  $P(C|W)$  corresponds to the channel model of traditional input methods,  $P(W)$  the language model, and  $P(C|A)$  the pinyin error correction model. There have been attempts to use this formulation in text input: for example, Chen and Lee (2000) trained a syllable-based model for  $P(C|A)$  with user keystroke data,<sup>8</sup> and Zheng et al. (2011b) used a model based on a weighted character edit distance whose weights are manually assigned. This noisy channel integration of error correction and character conversion is the state-of-the-art in the task of error-correcting text input, and will serve as our baseline.

#### 4.2 Log-linear model for error-correcting character conversion

Similar to the formulation of our error correction model in Section 3, we adopt the log-linear model for modeling the character conversion probability in (4):

$$P(W|A) = \frac{1}{Z(A)} \exp \sum_i \lambda_i h_i(A, W)$$

where  $A = a_1, \dots, a_n$  is a sequence of phrases in pinyin, and  $W = w_1, \dots, w_n$  is the corresponding sequence in hanzi. A unique challenge of the current task is that the parallel data for  $A$  and  $W$  do not exist directly. Therefore, we generated the translation phrase table offline by merging the

substring-based phrase table generated for the pinyin error correction task in Section 3 with the results of character conversion. This process is described in detail in Figure 2:  $k$ -best candidates for each input pinyin phrase  $a$  are generated by the error model in Section 3, which are then submitted offline to an IME system to obtain  $n$ -best conversion candidates with probabilities. For the IME system, we used an in-house conversion system, which only uses a word trigram language model for ranking. In the resulting translation table, defined for each  $(a, w)$  pair, the feature functions and their values are inherited from the pinyin error correction translation table mediated by the correction candidates  $c_{1...k}$  for  $a$ , plus the function that defines the IME conversion probability for  $(c_j, w)$ . Note that in this final phrase table, the correction candidates for  $a$  are latent, only affecting the values of the feature functions.<sup>9</sup> The final end-to-end system uses the following 11 features:

- 7 error correction model features at the phrase level
- IME conversion probability at the phrase level
- language model probability at the sentence level
- word/phrase penalty features at the sentence level

The language model at the sentence level is trained on a large monolingual corpus of Chinese in hanzi, consisting of about 13 million sentences (176 million words). The IME conversion probability

<sup>9</sup> The final phrase table needs to be unique for each phrase pair  $(a, w)$ , though the process described here results in multiple entries with the same pair having different feature values, because the generation of  $(a, w)$  is mediated by multiple correction candidates  $c_{1...k}$ . These entries need to be added up to remove duplicates; we used a heuristic approximation of taking the pair where  $a$  equals  $c_j$  (i.e., no spelling correction) when multiple entries are found.

<sup>8</sup> No detail of this data is available in Chen and Lee (2000).

also uses a word trigram model, but it is trained on a different data set which we did not have access to; we therefore used both of these models. The values for  $k$  and  $n$  can be determined empirically; we used 20 for both of them.<sup>10</sup> This generates maximally 400 conversion candidates for each input pinyin.

The feature weights of the log-linear model are tuned using MERT. As running MERT on a CER-based target criterion on the similar, monotone translation task of spelling correction did not lead to a significant improvement (Section 3.3), we simply report the results of using the 4-gram BLEU as the training criterion in this task.

### 4.3 Experiments and results

For the evaluation of the end-to-end conversion task, we used the CHIME corpus mentioned above. In order to use the word trigram language model that is built in-house, we re-segmented the CHIME corpus using our word-breaker, resulting in 12,102 words in 2,000 sentences. We then divided the sentences in the corpus randomly into two halves, and performed a two-fold cross validation evaluation. The development portion of the data is used to tune the weights of the feature functions in MERT-style training. We measured our results using character error rate (CER), which is based on the longest common subsequence match in characters between the reference and the best system output. This is a standard metric used in evaluating IME systems (e.g., Mori et al., 1998; Gao et al., 2002). Let  $N_{REF}$  be the number of characters in a reference sentence,  $N_{SYS}$  be the character length of a system output, and  $N_{LCS}$  be the length of the longest common subsequence between them. Then the character-level recall is defined as  $N_{LCS}/N_{REF}$ , and the precision as  $N_{LCS}/N_{SYS}$ . The CER based on recall and on precision are then defined as  $1 - \text{recall}$  and  $1 - \text{precision}$ , respectively. We report the harmonic mean of these values, similarly to the widely used F1-measure.

As our goal is to show the effectiveness of the unified approach, we used simpler methods of integrating pinyin error correction with character conversion to create baselines. The simplest

<sup>10</sup> From Table 2, we observe that the accuracy of the 20-best output of the spelling correction component is over 99%. An offline run with the IME system on an independent data set also showed that the accuracy of the 20-best IME output is over 99%.

	CER on 1-best	CER on 5-best
Baseline: No correction	10.91	7.76
Baseline: Pre-processing	9.93	6.75
Baseline: Zheng et al. (2011b)	8.90	
Baseline: Noisy channel	7.92	3.93
Proposed: SMT model	7.12	3.63
Oracle	4.08	1.51

**Table 3:** CER results for the conversion task (%)

baseline is a pre-processing approach: we use the pinyin error correction model to convert  $A$  into a single best candidate  $C$ , and run an IME system on  $C$ . Another more realistic baseline is the noisy channel integration discussed in Section 4.1. We approximated this integration method by re-ranking all the candidates generated by the proposed log-linear model with only the channel and language model probabilities, equally weighted.

The results are shown Table 3. 5-best results as well as the 1-best results are shown, because in an IME application, providing the correct candidate in the candidate list is particularly important even if it is not the best candidate. Let us first discuss the 1-best results. The CER of this test corpus using the in-house IME system without correcting any errors is 10.91. The oracle CER, which is the result of applying the IME on the gold standard pinyin input derived from the reference text using a hanzi-to-pinyin converter (as mentioned in Section 3.3), is 4.08, which is the upper-bound imposed by the IME conversion accuracy. The simple pipeline approach of concatenating the pinyin correction component with the character conversion component improves the CER by 1% to 9.93. Assuming that there are on average 20 words in a sentence, and each word consists of 2 characters, 1% CER reduction means one improvement every 2.5 sentences. Noisy channel integration improves over this quite substantially, achieving a CER of 7.92, demonstrating the power of the word language model in character conversion. Incidentally, the CER of the output by Zheng et al. (2011b)'s model is 8.90.<sup>11</sup> Their results are not as good as our noisy channel integration, as their system uses a manually defined error model and a word bigram language model. With the use of additional feature functions weighted discriminatively for the final conversion task, the

<sup>11</sup> Available at <http://chime.ics.uci.edu/>.

Overall errors (words)	1,074 / 12,102
Conversion	646 (60.14%)
Over-corrections	155 (14.43%)
Under-correction	161 (14.99%)
Wrong correction	112 (10.42%)

**Table 4:** Classification of errors

proposed method outperforms all these baselines to reduce the CER to 7.12, a 35% relative error rate reduction compared with the no correction baseline, a 20% reduction against Zheng et al (2011b) and a 10% reduction from our noisy channel baseline. The 5-best results follow the same trend of steady improvement as we use a more integrated system.

In order to understand the characteristics of the errors and remaining issues, we ran an error analysis on the 1-best results of the proposed system. For each word in the test data (all 2,000 sentences) for which the system output had an error, we classified the reasons of failure into one of the four categories: (1) **character conversion error**: correct pinyin was input to the IME but the conversion failed; (2) **over-correction of pinyin input**: the system corrected the pinyin input when it should not have; (3) **under-correction of pinyin input**: the system did not correct an error in the input pinyin when it should have; (4) **wrong correction**: input pinyin string had a spelling error but it was corrected incorrectly.

Table 4 shows the results of the error analysis. We find that somewhat contrary to our expectation, over-correction of the spelling mistakes was not a conspicuous problem, even though the pinyin correction rate of the training data is much higher than that of the test data. We therefore conclude that the error correction model adapts very well to the characteristics of the test data in our integrated SMT-based approach, which trains the unified feature weights to optimize the end goal.

## 5 Conclusion and Future Work

In this paper we have presented a unified approach to error-tolerant text input, inspired by the phrase-based SMT framework, and demonstrated its effectiveness over the traditional method based on the noisy channel model. We have also presented a new method of automatically collecting parallel data for spelling correction from user keystroke logs, and showed that the log-linear model works well on the task of spelling correction in isolation as well.

In this study, we isolated the problem of spelling errors and studied the effectiveness of error correction over a basic IME system that does not include advanced features such as abbreviated input (e.g., typing only "py" for 朋友 *péngyǒu* 'friend' or 拼音 *pīnyīn* in Chinese) and auto-completion (e.g., typing only "ari" for ありがとう *arigatou* 'thank you' in Japanese). Integrating data-driven error correction feature with these advanced features for the benefit of users is the challenge we face in the next step.

## Acknowledgements

We are indebted to many colleagues at Microsoft and MSR for their help in conducting this research, particularly to Xi Chen, Pallavi Choudhury, Chris Quirk, Mei-Yuh Hwang and Kristina Toutanova. We are also grateful for the comments we received from the reviewers of this paper.

## Abstract

We propose a new semantic orientation, Excitation, and its automatic acquisition method. Excitation is a semantic property of predicates that classifies them into excitatory, inhibitory and neutral. We show that Excitation is useful for extracting contradiction pairs (e.g., *destroy cancer*  $\perp$  *develop cancer*) and causality pairs (e.g., *increase in crime*  $\Rightarrow$  *heighten anxiety*). Our experiments show that with automatically acquired Excitation knowledge we can extract one million contradiction pairs and 500,000 causality pairs with about 70% precision from a 600 million page Web corpus. Furthermore, by combining these extracted causality and contradiction pairs, we can generate one million plausible causality hypotheses that are not written in any single sentence in our corpus with reasonable precision.

## 1 Introduction

Recognizing semantic relations between events in texts is crucial for such NLP tasks as question answering (QA). For example, to answer the question “*What ruined the crops in Japan?*” a QA system must recognize that the sentence “*the Fukushima nuclear power plant caused radioactive pollution and contaminated the crops in Japan*” contains a causal relation and that *contaminate crops* entails *ruin crops* but contradicts *preserve crops*.

To facilitate the acquisition of causality, contradiction, paraphrase and entailment relations between events we propose a new semantic orientation, Excitation, that classifies unary predicates (templates, hereafter) into excitatory, inhibitory and neutral. An excitatory template entails that the main function or

effect of the referent of its argument is activated or enhanced (e.g., *cause X*, *preserve X*), while an inhibitory template entails that it is deactivated or suppressed (e.g., *ruin X*, *contaminate X*, *prevent X*).

Excitation is useful for extracting contradiction; if two templates with similar distributional profiles have opposite Excitation polarities, they tend to be contradictions (e.g., *contaminate crops* and *preserve crops*). With extracted contradictions we can distinguish paraphrases from contradictions among distributionally similar phrases. Furthermore, contradiction in itself is important knowledge for Recognizing Textual Entailment (RTE) (Voorhees, 2008).

Excitation is also a powerful indicator of causality. In the physical world, the activation or deactivation of one thing often causes the activation or deactivation of another. Two excitatory or inhibitory templates that co-occur in some temporal or logical order in the same narrative often describe a causal chain of events, like “*the Fukushima nuclear power plant caused radioactive pollution and contaminated crops in Japan*”.

In this paper we propose both the concept of Excitation and an automatic method for its acquisition. Our method acquires Excitation templates based on certain natural, language independent constraints on narrative structures found in text. We also propose acquisition methods for contradiction and causality relations based on Excitation. Our methods extract one million contradiction pairs with over 70% precision, and 500,000 causality pairs with about 70% precision from a 600 million page Web corpus. Moreover, by combining these extracted causality pairs and contradiction pairs, we generated one million plausible causality hypotheses that were not

written in any single sentence in our corpus with reasonable precision. For example, a causality hypothesis *prevent radioactive pollution*  $\Rightarrow$  *preserve crops* can be generated from an extracted causality *cause radioactive pollution*  $\Rightarrow$  *contaminate crops*.

We target the Japanese language in this paper.

## 2 What is Excitation?

Excitation classifies templates into excitatory, inhibitory, and neutral, as explained below.

**excitatory templates** entail that the function, effect, purpose or role of their argument's referent is activated or enhanced. (e.g., *cause X*, *buy X*, *produce X*, *import X*, *increase X*, *enable X*)

**inhibitory templates** entail that the function, effect, purpose or role of their argument's referent is deactivated or suppressed. (e.g., *prevent X*, *discard X*, *remedy X*, *decrease X*, *disable X*)

**neutral templates** are neither excitatory nor inhibitory. (e.g., *consider X*, *proportional to X*, *related to X*, *evaluate X*, *close to X*)

For example, when *fire* fills the *X* slot of *cause X*, it suggests that the effect of *fire* is activated. If *prevent X*'s slot is filled with *flu*, the effect of *flu* is suppressed. In this study, we aim to acquire excitatory and inhibitory templates that are useful for extracting contradiction and causality, though neutral templates are the most frequent in our data (See Section 5.1). Collectively we call excitatory and inhibitory templates *Excitation templates*, and excitatory and inhibitory two opposite *polarities*.

Excitation is independent of the good/bad semantic orientation. (Hatzivassiloglou and McKeown, 1997; Turney, 2002; Rao and Ravichandran, 2009). For example, *sophisticate X* and *complicate X* are both excitatory, but only the former has a positive connotation. Similarly, *remedy X* and *degrade X* are both inhibitory but only the latter is negative.

General Inquirer (Stone et al., 1966) deals with semantic factors some of which were proposed by Osgood et al. (1957). Their 'activity' factor involves binary opposition between 'active' and 'passive.' Notice that activity and Excitation are independent. In General Inquirer, both *accelerate X* and *abolish X* are active, but only the former is excitatory. Both *accept X* and *abate X* are passive, but only the latter is inhibitory. Pustejovsky (1995) proposed telic

and agentive roles, which inspired our excitatory notion, but they have no corresponding notion of inhibitory. Andreevskaia and Bergler (2006) acquired the increase/decrease semantic orientation, which is a subclass of Excitation.

Excitation is inverted if a template's predicate is negated. For example, *preserve X* is excitatory, while *don't preserve X* is inhibitory. We acknowledge that this may seem somewhat counter-intuitive and will address this issue in future work.

## 3 Excitation Template Acquisition

This section presents our acquisition method of Excitation templates. We introduce constraints in the co-occurrence of templates in text that seem both robust and language independent in Section 3.1. Our method exploits these constraints for the acquisition of Excitation templates. First we construct a template network where nodes are templates and links represent that two connected templates have either SAME or OPPOSITE polarities. Given 46 manually prepared seed templates we calculate the *Excitation value* of each template, a value in range  $[-1, 1]$  that is positive if the template is excitatory and negative if it is inhibitory. Technically, our method treats all templates as excitatory or inhibitory, and, upon completion, regards templates with small absolute Excitation values as neutral.

The whole method is a bootstrapping process. Each iteration expands the network and the Excitation value of each template is (re-)calculated.

### 3.1 Characteristics of Excitation Templates

Our method exploits natural discourse constraints on the possible combinations of (a) the polarity of co-occurring templates, (b) the nouns that fill their argument slots and (c) the connectives that link the templates in a given sentence. Table 1 shows the constraints and Figure 1 shows examples that will be explained shortly. Though our target is Japanese we believe these constraints are universal discourse principles, and as such not language dependent. Examples are given in English for ease of explanation.

We first identify two categories of connectives in our target sentences: AND/THUS-type (e.g., *and*, *thus* and *since*) and BUT-type (e.g., *but* and *though*). Both types suggest a sort of *consistency* or *inconsistency* between predicates. We manually classified 169 frequently used connectives into AND/THUS-

- (1) He smoked cigarettes, AND/THUS he suffered lung cancer. (Both *smoke X* and *suffer X* are excitatory.)
- (2) He quit cigarettes, AND/THUS was immune from lung cancer. (*quit X* and *immune from X* are inhibitory.)
- (3) He smoked cigarettes, BUT didn't suffer lung cancer. (*smoke X* is excitatory, *not suffer X* is inhibitory.)
- (4) He quit cigarettes, BUT he suffered lung cancer. (*quit X* is inhibitory, but *suffer X* is excitatory.)
- (5) He underwent cancer treatment, AND/THUS he could cure the cancer. (*undergo X* is excitatory, *cure X* is inhibitory.)
- (6) He underwent cancer treatment, BUT still had cancer. (Both *undergo X* and *have X* are excitatory.)
- (7) **Unnatural:** He smoked cigarettes, BUT he suffered lung cancer. (*smoke X* and *suffer X* are excitatory.)

Figure 1: Examples of constraints: (*cigarettes, lung cancer*) is PNP and (*cancer treatment, cancer*) is NNP.

	PNPs	NNPs	others
AND/THUS	SAME	OPPOSITE	N/A
BUT	OPPOSITE	SAME	N/A

Table 1: Constraint matrix.

and BUT-type (See supplementary materials).

Next we extract sentences from the Web in which two templates co-occur and are joined by one of these connectives, and then classify the noun pairs filling the templates' argument slots into "positively-associated" and "negatively-associated" noun pairs (PNPs and NNPs). Mirroring our definition of Excitation, PNPs are noun pairs in which the referent of the first noun facilitates the emergence of the referent of the second noun. PNPs can range from causally related noun pairs like (*cigarettes, lung cancer*) to "material-product" relation pairs like (*semiconductor, electronic circuit*). We found that PNPs only fill the argument slots of (a) same Excitation polarity templates connected by AND/THUS-type connectives (examples 1 and 2 in Figure 1), or (b) opposite Excitation polarity templates connected by a BUT-type connectives (examples 3 and 4). Violating such constraints (example 7) seems unnatural. Similarly, NNPs are noun pairs in which the referent of one noun suppresses the emergence of the referent of the other noun. Examples include such "inverse causality" pairs as (*cancer treatment, cancer*). NNPs only fill the argument slots of (a) opposite Excitation polarity templates connected by AND/THUS-type connectives (example 5), or (b) same polarity templates connected by a BUT-type connective (example 6).

All these constraints are summarized in Table 1,

which we will call the constraint matrix. According to the constraint matrix, we can know whether two templates' polarities are the same or opposite if we know whether a noun pair filling the two templates' slots is PNP or NNP. Conversely, we can know whether a noun pair is PNP or NNP if we know whether two templates whose slots are filled with the noun pair have the same or opposite polarities. We believe these constraints capture certain universal principles of discourse, since it is difficult in any language to produce natural sounding sentences that violate these constraints. We empirically confirm their validity for Japanese in Section 5.1.

### 3.2 Bootstrapping Approach to Excitation Template Acquisition

To calculate the Excitation values for the templates, we construct a template network where templates are connected by links indicating polarity agreement between two connected templates (either SAME or OPPOSITE polarity), as determined by the constraint matrix. Excitation values are determined by spreading activation applied to the network, given a small number of manually prepared seed templates.

However, we cannot construct the network unless we know whether each noun pair is PNP or NNP, due to the configuration of the constraint matrix, and currently we have no feasible method to classify all of them into PNPs and NNPs in advance. We therefore adopt a bootstrapping method (Figure 2) that starts from manually prepared excitatory and inhibitory seed templates (Step 1 in Figure 2). Our method begins by extracting noun pairs from the Web that co-occur with two seed templates connected by a AND/THUS- or BUT-type connective, and classifies these noun pairs into PNPs and NNPs based on the constraint matrix (Steps 2 and 3). Next, we automatically extract additional (non-seed) template pairs from the Web that co-occur with these PNPs and NNPs. Links (either SAME or OPPOSITE) between all template pairs are determined by the constraint matrix (Step 4), and we construct a template network from both seed and non-seed template pairs (Step 5).

Our method calculates the Excitation values for all the templates in the network by first assigning Excitation values +1 and -1 to the excitatory and inhibitory seed templates, and applies a spreading activation method proposed by Takamura et al. (2005) (Step 6) to the network. This method calcu-

1. Prepare initial seed templates with fixed excitation values (either +1 or -1).
2. Make seed template pairs that are combinations of two seed templates and a connective (either AND/THUS-type or BUT-type).
3. Extract noun pairs that co-occur with one of the seed template pairs from the Web. Classify the noun pairs into PNPs and NNPs based on the constraints matrix. Filter out those noun pairs that appear as both PNP and NNP on the Web or those whose occurrence frequency is less than or equal to F, which is set to 5.
4. Extract additional (non-seed) template pairs that are filled by one of the PNPs or NNPs from the Web. Determine the link type (SAME or OPPOSITE) for each template pair based on the constraint matrix. If a template pair appears on the Web as having both link types, we determine its link type by majority vote.
5. Construct the template network from all the template pairs. Remove from the network those templates whose number of linked templates is less than D, which is set to 5.
6. Apply Takamura et al.'s method to the network and fix the Excitation value of each template.
7. Extract the top- and bottom-ranked  $N \times i$  templates from the result of Takamura et al.'s method.  $N$  is a constant, which is set to 30.  $i$  is the iteration number. They are used as additional seed templates for the next iteration. The top-ranked templates are given Excitation value +1 and the bottom-ranked templates are assigned -1. Go to Step 2.

Figure 2: Bootstrapping for template acquisition.

lates all templates' excitation values by solving the network constraints imposed by the SAME and OPPOSITE links, and the Excitation values of the seed templates (This method is detailed in Section 3.3). In each iteration  $i$ , our method selects the  $N \times i$  top-ranked and bottom-ranked templates as additional seed templates for the next iteration ( $N$  is set to 30) (Step 7). Our method then constructs a new template network using the augmented seed templates and restarts the calculation process. Figure 2 summarizes our bootstrapping process.

Bootstrapping stops after  $M$  iterations, with  $M$  set to 7 based on our preliminary experiments.

To prepare the initial seed templates we constructed a *maximal* template network that could in theory be created by our bootstrapping method. This maximal network consists of any two templates that co-occur in a sentence with any connective, regardless of their arguments. We manually selected 36 excitatory and 10 inhibitory seed templates from among 114 templates with the most links in the network (See supplementary materials).

### 3.3 Determining Excitation in the Network

This section details Step 6 of our bootstrapping method, i.e., how Takamura et al.'s method calculates the Excitation value of each template. Their method is based on the spin model in physics, where each electron has a spin of either *up* or *down*. We

chose this method due to the straightforward parallel between the spin model and our Excitation template model. Both models capture the spreading of activation (either spin direction or excitation polarity) between neighboring objects in a network. Determining the optimal algorithm for this task is beyond our current scope, but for the purpose of our experiments we found that Takamura et al.'s method gave satisfactory results.

The spin model defines an energy function on a spin network, and each electron's spin can be estimated by minimizing this function:

$$E(\mathbf{x}, W) = -1/2 \times \sum_{ij} w_{ij} x_i x_j$$

Here,  $x_i, x_j \in \mathbf{x}$  are spins of electrons  $i$  and  $j$ , and matrix  $W = \{w_{ij}\}$  assigns weights to links between electrons. We regard templates as electrons and Excitation polarities as their spins (*up* and *down* correspond to excitatory and inhibitory). We define the weight  $w_{ij}$  of the link between templates  $i$  and  $j$  as:

$$w_{ij} = \begin{cases} 1/\sqrt{d(i)d(j)} & \text{if SAME}(i, j) \\ -1/\sqrt{d(i)d(j)} & \text{if OPPOSITE}(i, j) \end{cases}$$

Here,  $d(i)$  denotes the number of templates linked to  $i$ . SAME( $i, j$ ) (OPPOSITE( $i, j$ )) indicates a SAME (OPPOSITE) link exists between  $i$  and  $j$ . We obtain excitation values by minimizing the above energy function. Note that after minimizing  $E$ ,  $x_i$  and  $x_j$  tend to get the same polarity when  $w_{ij}$  is positive. When  $w_{ij}$  is negative,  $x_i$  and  $x_j$  tend to have opposite polarities. Initially seed templates are given values +1 or -1 depending on whether they are excitatory or inhibitory, and others are given 0.

We used SUPPIN (<http://www.lr.pi.titech.ac.jp/~takamura/pubs/SUPPIN-0.01.tar.gz>), an implementation of Takamura et al.'s method. Its parameter  $\beta$  is set to the default value (0.75).

## 4 Knowledge Acquisition by Excitation

This section shows how the concept of Excitation can be used for automatic knowledge acquisition.

### 4.1 Contradiction Extraction

Our first knowledge acquisition method extracts contradiction pairs like *destroy cancer*  $\perp$  *develop cancer*, based on our assumption that they often consist of distributionally similar templates that have a sharp contrast in Excitation value. Concretely, we

extract two phrases as a contradiction pair if (a) their templates have opposite Excitation polarities, (b) they share the same argument noun, and (c) the part-of-speech of their predicates is the same. Then the contradiction pairs are ranked by  $Ct$ :

$$Ct(p_1, p_2) = |s_1| \times |s_2| \times sim(t_1, t_2)$$

Here  $p_1$  and  $p_2$  are two phrases that satisfy conditions (a), (b) and (c) above,  $t_1$  and  $t_2$  are their respective templates, and  $|s_1|$  and  $|s_2|$  are the absolute values of  $t_1$  and  $t_2$ 's excitation values.  $sim(t_1, t_2)$  is the distributional similarity proposed by Lin (1998).

Note that “contradiction” here includes what we call “quasi-contradiction.” This consists of two phrases such that, if the tendencies of the events they describe get stronger, they eventually become contradictions. For example, the pair *emit smells*  $\perp$  *reduce smells* is not logically contradictory since the two events can happen at the same time. However, they become almost contradictory when their tendencies get stronger (i.e., *emit smells more strongly*  $\perp$  *thoroughly reduce smells*). We believe quasi-contradictions are useful for NLP tasks.

## 4.2 Causality Extraction

Our second knowledge acquisition method extracts causality pairs like *increase in crime*  $\Rightarrow$  *heighten anxiety* that co-occur with AND/THUS-type connectives in a sentence. The assumption is that if two templates ( $t_1$  and  $t_2$ ) with a strong Excitation tendency are connected by an AND/THUS-type connective in a sentence, the event described by  $t_1$  and its argument  $n_1$  tends to be a cause of the event described by  $t_2$  and its argument  $n_2$ . Here, Excitation strength is expressed by absolute Excitation values. The intuition is that, if the referent of  $n_1$  is strongly activated or suppressed, it tends to have some causal effect on the referent of  $n_2$  in the same sentence.

We focus on extracting causality pairs that co-occur with only “non-causal connectives” like *and*, which are AND/THUS-type connectives that do NOT explicitly signal causality, since causal connectives like *thus* can mask the effectiveness of Excitation. We prepared 139 non-causal connectives (See supplementary materials). We extract two templates such as *increase in X* and *heighten Y* co-occurring with only non-causal connectives, as well as the noun pair that fills the two templates' slots (e.g., (*crime*, *anxiety*)) to obtain causal phrase pairs. In

Japanese, the temporal order between events is usually determined by precedence in the sentence.  $Cs$  ranks the obtained causality pairs:

$$Cs(p_1, p_2) = |s_1| \times |s_2|$$

Here  $p_1$  and  $p_2$  are the phrases of causality pair, and  $|s_1|$  and  $|s_2|$  are absolute Excitation values of  $p_1$ 's and  $p_2$ 's templates. As is common in the literature, this notion of causality should be interpreted probabilistically rather than logically, i.e., we interpret causality  $A \Rightarrow B$  as “if  $A$  happens, the probability of  $B$  increases”. This interpretation is often more useful for NLP tasks than a strict logical interpretation.

## 4.3 Causality Hypothesis Generation

Our third knowledge acquisition method generates plausible causality hypotheses that are not written in any single sentence using the previously extracted contradiction and causality pairs. We assume that if a causal relation (e.g., *increase in crime*  $\Rightarrow$  *heighten anxiety*) is valid, its inverse (e.g., *decrease in crime*  $\Rightarrow$  *diminish anxiety*) is often valid as well. From a logical definition of causation, taking the inverse of an implication obviously does not preserve validity. However, at least under our probabilistic interpretation, taking the inverse of a given causality pair using the extracted contradiction pairs proves to be a viable strategy for generating non-trivial causality hypotheses, as our experiments in Section 5.4 show.

For an extracted causality pair, we generate its inverse as a causality hypothesis by replacing both phrases in the original pair with their contradiction counterparts. For instance, a causality hypothesis *decrease in crime*  $\Rightarrow$  *diminish anxiety* is generated from a causality *increase in crime*  $\Rightarrow$  *heighten anxiety* by two contradictions, *decrease in crime*  $\perp$  *increase in crime* and *diminish anxiety*  $\perp$  *heighten anxiety*. Since we are interested in finding new causal hypotheses, we filter out hypotheses whose phrase pair co-occurs in a sentence in our corpus. Remaining causality hypotheses are ranked by  $Hp$ .

$$Hp(q_1, q_2) = Ct(p_1, q_1) \times Ct(p_2, q_2) \times Cs'(p_1, p_2)$$

Here,  $q_1$  and  $q_2$  are two phrases of a causality hypothesis.  $p_1$  and  $p_2$  are two phrases of a hypothesis's original causality. That is,  $p_1 \perp q_1$  and  $p_2 \perp q_2$  are contradiction pairs, and  $Ct(p_1, q_1)$  and  $Ct(p_2, q_2)$  are their contradiction scores.  $Cs'(p_1, p_2)$  is the original causality's causality score.  $Cs'$  can be  $Cs$

from Section 4.2, but based on preliminary experiments we found the following score works better:

$$Cs'(p_1, p_2) = |s_1| \times |s_2| \times npfreq(n_1, n_2)$$

$|s_1|$  and  $|s_2|$  are absolute Excitation values of  $p_1$ 's and  $p_2$ 's templates, whose slots are filled with  $n_1$  and  $n_2$ .  $npfreq(n_1, n_2)$  is the co-occurrence frequency of  $(n_1, n_2)$  with polarity-identical template pairs (if  $(n_1, n_2)$  is PNP) or with polarity-opposite template pairs (if  $(n_1, n_2)$  is NNP). Thus,  $npfreq$  indicates a sort of association strength between two nouns.

## 5 Experiments

This section shows that our template acquisition method acquired many Excitation templates. Moreover, using only the acquired templates we extracted one million contradiction pairs with more than 70% precision, and 500,000 causality pairs with about 70% precision. Further, using only these extracted contradiction and causality pairs we generated one million causality hypotheses with 57% precision.

In our experiments we removed evaluation samples containing the initial seed templates and examples used for annotation instruction from the evaluation data. Three annotators (not the authors) marked all evaluation samples, which were randomly shuffled so that they could not identify which sample was produced by which method. Information about the predicted labels or ranks was also removed from the evaluation data. Final judgments were made by majority vote between the annotators. They were non-experts without formal training in linguistics or semantics. See supplementary materials for our annotation manuals (translated into English).

We used 600 million Japanese Web pages (Akamine et al., 2010) parsed by KNP (Kawahara and Kurohashi, 2006) as a corpus. We restricted the argument positions of templates to *ha* (topic), *ga* (nominative), *wo* (accusative), *ni* (dative), and *de* (instrumental). We discarded templates appearing fewer than 20 times in compound sentences (regardless of connectives) in our corpus.

### 5.1 Excitation Template Acquisition

We show that our proposed method for template extraction ( $PROP_{tmp}$ ) successfully acquired many Excitation templates from which we obtained a huge number of contradiction and causality pairs, and that Excitation is a reasonably comprehensible notion

even for non-experts. We also show that  $PROP_{tmp}$  outperformed two baselines by a large margin.

The template network constructed by  $PROP_{tmp}$  contained 10,825 templates. Among these, the bootstrapping process classified 8,685 templates as excitatory and 2,140 as inhibitory. Note that these candidates in fact also contain neutral templates, as explained at the beginning of Section 3.

**Baselines** The baseline methods are ALLEXC and SIM. ALLEXC regards all templates that are randomly extracted from the Web as excitatory, since in our data excitatory templates outnumber inhibitory ones. Actually, in our data neutral templates represent the most frequent class, but since our objective is to acquire excitatory and inhibitory templates, a baseline marking all templates as neutral would make little sense. SIM is a distributional similarity baseline that takes as input the same 10,825 templates of  $PROP_{tmp}$  above, constructs a network by connecting two templates whose distributional similarity is greater than zero, and regards two connected templates as having the same polarity. The weight of the links between templates is set to their distributional similarity based on Lin (1998). Then SIM is given the same initial seed templates as  $PROP_{tmp}$ , by which it calculates the Excitation values of templates using Takamura et al.'s method. As a result, SIM assigned positive Excitation values to all templates, and except for the 10 inhibitory initial seed templates no templates were regarded inhibitory.

**Evaluation scheme** We randomly sampled 100 templates each from  $PROP_{tmp}$ 's 8,685 excitatory candidates,  $PROP_{tmp}$ 's 2,140 inhibitory candidates, all the ALLEXC's templates, and all the SIM's templates, i.e., 400 templates in total. To make the annotators' judgements easier, we randomly filled the argument slot of each template with a noun filling its argument slot in our Web corpus. Three annotators labeled each sample (a combination of a template and a noun) as 'excitatory,' 'inhibitory,' 'neutral,' or 'undecided' if they were not sure about its label.

**Results for excitatory** In the top graph in Figure 3, 'Proposed' shows  $PROP_{tmp}$ 's precision curve. The curve is drawn from its 100 samples whose X-axis positions represent their ranks. We plot a dot for every 5 samples. Among the 100 samples, 37 were judged as excitatory, 6 as inhibitory, 45 as neutral, and 6 as 'undecided'. For the remaining 6 samples,

Figure 3: Precision of template acquisition: excitatory (top) and inhibitory (bottom).

the three annotators gave three different labels and the label was not fixed (‘split-votes’ hereafter). For calculating precision, only the 37 samples labeled excitatory were regarded as correct.  $PROP_{tmp}$  outperformed all baselines by a large margin, with an estimated 70% precision for the top 2,000 templates. ‘Allexc’ and ‘Sim’ in Figure 3 denote ALLEXC and SIM. Among ALLEXC’s 100 samples, 19 were judged as excitatory, 5 as inhibitory, 74 as neutral, and 2 as ‘undecided’. SIM’s low performance reflects the fact that templates with opposite polarities are sometimes distributionally similar, and as a result get connected by SAME links.

**Results for inhibitory** ‘Proposed’ in the bottom graph in Figure 3 shows the precision curve drawn from the 100 samples of  $PROP_{tmp}$ ’s inhibitory candidates. Among the 100 samples, 41 were judged as inhibitory, 15 as excitatory, 32 as neutral, 4 as ‘undecided’, and 8 as ‘split-votes’. Only the 41 inhibitory samples were regarded as correct. From the curve we estimate that  $PROP_{tmp}$  achieved about 70% precision for the top 500. Note that SIM could not acquire any inhibitory templates, yet we can think of no other reasonable baseline for this task.

**Inter-annotator agreement** The Fleiss’ kappa (Fleiss, 1971) of annotator judgements was 0.48 (moderate agreement (Landis and Koch, 1977)). For training, the annotators were given a one-page annotation manual (see supplementary materials), which basically described the same contents in Section 2,

in addition to 14 examples of excitatory, 14 examples of inhibitory, and 6 examples of neutral templates that were manually prepared by the authors. Using the manual and the examples, we instructed all the annotators face-to-face for a few hours. We also made sure the evaluation data did not contain any examples used during instruction.

**Observations about argument positions** Among the 200 evaluation samples of  $PROP_{tmp}$  (for both excitatory and inhibitory evaluations), 52 were judged as excitatory, 47 as inhibitory, and 77 as neutral. For the excitatory templates, the numbers of nominative, topic, accusative, dative, and instrumental argument positions are 15, 11, 10, 8, and 8, respectively. For the inhibitory templates, the numbers are 17, 11, 16, 3, and 0. For the neutral templates, the numbers are 8, 23, 17, 21, and 8. Accordingly, we found no noticeable bias with regard to their numbers. Likewise, we found no noticeable bias regarding their usefulness for contradiction and causality acquisition reported shortly, too.

**Summary**  $PROP_{tmp}$  works well, as it outperforms the baselines. Its performance demonstrates the validity of our constraint matrix in Table 1. Besides, since our annotators were non-experts but showed moderate agreement, we conclude that Excitation is a reasonably comprehensible notion.

## 5.2 Contradiction Extraction

This section shows that our proposed method for contradiction extraction ( $PROP_{cont}$ ) extracted one million contradiction pairs with more than 70% precision, and that Excitation values are useful for contradiction ranking. As input for  $PROP_{cont}$  we took the top 2,000 excitatory and the top 500 inhibitory templates from the previous experiment (i.e., the other templates were regarded as neutral).

**Baselines** Our baseline methods are  $RAND_{cont}$  and  $PROP_{cont-NE}$ .  $RAND_{cont}$  randomly combines two phrases, each consisting of a template and a noun that they share. It does not rank its output.  $PROP_{cont-NE}$  is the same as  $PROP_{cont}$  except that it does not use Excitation values; ranking is based only on  $sim(t_1, t_2)$ .  $PROP_{cont-NE}$  does combine phrases with opposite template polarities, just like  $PROP_{cont}$ .

**Evaluation scheme** We randomly sampled 200 phrase pairs from the top one million results of each

Figure 4: Precision of contradiction extraction.

$PROP_{cont}$  and  $PROP_{cont-NE}$ , and 100 samples from the output of  $RAND_{cont}$ 's output, giving 500 samples. Three annotators labeled whether the samples are contradictions. Fleiss' kappa was 0.78 (substantial agreement).

**Results** 'Proposed' in Figure 4 shows the precision curve of  $PROP_{cont}$ .  $PROP_{cont}$  achieved an estimated 70% precision for its top one million results. Readers might wonder whether  $PROP_{cont}$ 's output consists of a small number of template pairs that are filled with many different nouns. If this were the case,  $PROP_{cont}$ 's performance would be somewhat misleading. However, we found that  $PROP_{cont}$ 's 200 samples contained 194 different template pairs, suggesting that our method can acquire a large variety of contradiction phrases. 'Proposed-ne' is the precision curve for  $PROP_{cont-NE}$ . Its precision is more than 10% lower than  $PROP_{cont}$  at the top one million results. 'Random' shows that  $RAND_{cont}$ 's precision is only 4%. Table 2 shows examples of  $PROP_{cont}$ 's outputs and their English translation. The labels 'Cont,' 'Quasi' and '✖' denote whether a pair is contradictory, quasi-contradictory, or not contradictory. Among  $PROP_{cont}$ 's 145 samples judged by the annotators as contradiction, 46 were judged as quasi-contradictory by one of the authors. The first ✖ case in Table 2 was caused by the template, Xを改善する (*improve X*). It is tricky since it is excitatory when taking arguments like *function*, while it is inhibitory when taking arguments like *disorder*. However,  $PROP_{tmp}$  currently cannot distinguish these usages and judged it as inhibitory in our experiments in Section 5.1, though it must be interpreted as excitatory for the ✖ case. The second ✖ case was due to  $PROP_{tmp}$ 's error; it incorrectly judged the neutral template, Xが関係する (*related to X*), as inhibitory.

Rank	Contradiction Pairs	Label
8,767	アンバランスを是正する ⊥ アンバランスを生じさせる <i>repair imbalance ⊥ become imbalanced</i>	Cont
103,581	運転を助ける ⊥ 運転を妨げる <i>assist the driver ⊥ disturb the driver</i>	Cont
151,338	緊張感が緩和される ⊥ 緊張を伴う <i>calm tension ⊥ feel tension</i>	Quasi
184,014	機能を改善する ⊥ 機能を高める <i>improve function ⊥ boost function</i>	✖
316,881	円安が止まる ⊥ 円安が進行する <i>yen depreciation stops ⊥ yen depreciation develops</i>	Cont
317,028	騒音がひどくなる ⊥ 騒音は減少する <i>noise gets worse ⊥ noise abates</i>	Cont
334,642	酸味がますます ⊥ 酸味が消える <i>a sour taste is augmented ⊥ a sour taste is lost</i>	Cont
487,496	痛みが発症する ⊥ 痛みを減らす <i>feel pain ⊥ reduce pain</i>	Quasi
529,173	アクセスが生ずる ⊥ アクセスを抑制する <i>access occurs ⊥ curb access</i>	Cont
555,049	原発をなくす ⊥ 原発を増やす <i>lose nuclear plants ⊥ augment nuclear plants</i>	Cont
608,895	放射能が放出される ⊥ 放射能が減る <i>radioactivity is released ⊥ radioactivity is reduced</i>	Quasi
638,092	ユーロが下落する ⊥ ユーロが強くなる <i>Euro falls ⊥ Euro gets strong</i>	Cont
757,423	シェアを有する ⊥ シェアが低下する <i>have share (in market) ⊥ share decreases</i>	Quasi
833,941	活性酸素が放出される ⊥ 活性酸素が関係する <i>generate active oxygen ⊥ related to active oxygen</i>	✖
848,331	ガンを破壊する ⊥ ガンを進行させる <i>destroy cancer ⊥ develop cancer</i>	Cont
982,980	ウイルスが死滅する ⊥ ウイルスが活性化する <i>virus becomes extinct ⊥ virus is activated</i>	Cont

Table 2: Examples of  $PROP_{cont}$ 's outputs.

**Summary**  $PROP_{cont}$  is a low cost but high performance method, since it acquired one million contradiction pairs with over 70% precision from only the 46 initial seed templates. Besides, Excitation contributes to contradiction ranking since  $PROP_{cont}$  outperformed  $PROP_{cont-NE}$  by a 10% margin for the top one million results. Thus we conclude that our assumption on contradiction extraction is valid.

### 5.3 Causality Extraction

We show that our method for causality extraction ( $PROP_{caus}$ ) extracted 500,000 causality pairs with about 70% precision, and that Excitation values contribute to the ranking of causal pairs.  $PROP_{caus}$  took as input all 10,825 templates classified by  $PROP_{tmp}$ .

**Baselines**  $RAND_{caus}$  randomly extracts two phrases that co-occur in a sentence with one of the AND/THUS-type connectives, i.e., it uses not only non-causal connectives but also causal ones like *thus*.  $FREQ$  is the same as  $PROP_{caus}$  except that it ranks its output by the phrase pair co-occurrence frequency rather than Excitation values.

Figure 5: Precision of causality extraction.

**Evaluation scheme** We randomly sampled 100 pairs each from the top one million results of  $\text{PROP}_{\text{caus}}$  and  $\text{FREQ}$ , and all  $\text{RAND}_{\text{caus}}$ 's output. The annotators were shown the original sentences from which the samples were extracted. Fleiss' kappa was 0.68 (substantial agreement).

**Results** 'Proposed' in Figure 5 is the precision curve for  $\text{PROP}_{\text{caus}}$ . From this curve the estimated precision of  $\text{PROP}_{\text{caus}}$  is about 70% around the top 500,000. Note that  $\text{PROP}_{\text{caus}}$  outperformed  $\text{FREQ}$  by a large margin, and extracted a large variety of causal pairs since its 100 samples contained 91 different template pairs. Table 3 shows examples of  $\text{PROP}_{\text{caus}}$ 's output along with English translations. The labels '✓' and '✗' denote whether a pair is causality or not. The ✗ cases in Table 3 were exceptions to our assumption described in Section 4.2; even if two Excitation templates co-occur in a sentence with an AND/THUS-type connective, they sometimes do not constitute causality. Actually, the first ✗ case consists of two phrases that co-occurred in a sentence with a (non-causal) AND/THUS-type connective but described two events that happen as the effects of introducing the RAID storage system; both are caused by the third event. In the second ✗ case, the two phrases co-occurred in a sentence with a (non-causal) AND/THUS-type connective but just described two opposing events.

**Summary**  $\text{PROP}_{\text{caus}}$  performs well since it extracted 500,000 causality pairs with about 70% precision. Moreover, Excitation values contribute to causality ranking since  $\text{PROP}_{\text{caus}}$  outperformed  $\text{FREQ}$  by a large margin. Then we conclude that our assumption on causality extraction is confirmed.

Table 3: Examples of  $\text{PROP}_{\text{caus}}$ 's outputs.

## 5.4 Causality Hypothesis Generation

Here we show that our causality hypothesis generation method in Section 4.3 ( $\text{PROP}_{\text{hyp}}$ ) extracted one million hypotheses with about 57% precision.

This experiment took the top 100,000 results of  $\text{PROP}_{\text{caus}}$  as input, generated hypotheses from them, and randomly selected 100 samples from the top one million hypotheses. We evaluated only  $\text{PROP}_{\text{caus}}$ , since we could not think of any reasonable baseline for this task. Randomly coupling two phrases might be a baseline, but it would perform so poorly that it could not be a reasonable baseline.

The annotators judged each sample in the same way as Section 5.3, except that we presented them with source causality pairs from which hypotheses were generated, as well as the original sentences of these source pairs. Fleiss' kappa was 0.51 (moderate agreement).

As a result,  $\text{PROP}_{\text{hyp}}$  generated one million hypotheses with 57% precision. It generated various kinds of hypotheses, since these 100 samples contained 99 different template pairs. Table 4 shows some causal hypotheses generated by  $\text{PROP}_{\text{hyp}}$ . The source causal pair is shown in parentheses. The la-

bels ‘✓’ and ‘✗’ denote whether a pair is causality or not. The first ✗ case was due to an error made by

Rank	Causality Hypotheses (and their Origin)	Label

837,850	景気をコントロールする ⇒ 問題を伴う (景気が良くなる ⇒ 問題が解消される) <i>control economic conditions ⇒ accompany problems</i> ( <i>economic conditions improve ⇒ problems are solved</i> )	✗ ✓

Table 4: Examples of causality hypotheses.

our causality extraction method  $\text{PROP}_{\text{caus}}$ ; the case was erroneous since its original causality was erroneous. The second ✗ case was due to the fact that one of the contradiction phrase pairs used to generate the hypothesis was in fact not contradictory (景気をコントロールする  $\not\perp$  景気が良くなる ‘*control economic conditions*  $\not\perp$  *economic conditions improve*’).

From these results, we conclude that our assumption on causality hypothesis generation is valid.

## 6 Related Work

While the semantic orientation involving good/bad (or desirable/undesirable) has been extensively stud-

ied (Hatzivassiloglou and McKeown, 1997; Turney, 2002; Rao and Ravichandran, 2009; Velikovich et al., 2010), we believe Excitation represents a genuinely new semantic orientation.

Most previous methods of contradiction extraction require either thesauri like Roget’s or WordNet (Harabagiu et al., 2006; Mohammad et al., 2008; de Marneffe et al., 2008) or large training data for supervision (Turney, 2008). In contrast, our method requires only a few seed templates. Lin et al. (2003) used a few “incompatibility” patterns to acquire antonyms, but they did not report their method’s performance on the incompatibility identification task.

Many methods for extracting causality or script-like knowledge between events exist (Girju, 2003; Torisawa, 2005; Torisawa, 2006; Abe et al., 2008; Chambers and Jurafsky, 2009; Do et al., 2011; Shibata and Kurohashi, 2011), but none uses a notion similar to Excitation. As we have shown, we expect that Excitation will improve their performance.

Regarding the acquisition of semantic knowledge that is not explicitly written in corpora, Tsuchida et al. (2011) proposed a novel method to generate semantic relation instances as hypotheses using automatically discovered inference rules. We think that automatically generating plausible semantic knowledge that is not written (explicitly) in corpora as hypotheses and augmenting semantic knowledge base is important for the discovery of so-called “unknown unknowns” (Torisawa et al., 2010), among others.

## 7 Conclusion

We proposed a new semantic orientation, Excitation, and its acquisition method. Our experiments showed that Excitation allows to acquire one million contradiction pairs with over 70% precision, as well as causality pairs and causality hypotheses of the same volume with reasonable precision from the Web. We plan to make all our acquired knowledge resources available to the research community soon (Visit <http://www.alagin.jp/index-e.html>).

We will investigate additional applications of Excitation in future work. For instance, we expect that Excitation and its related semantic knowledge acquired in this study will improve the performance of Why-QA system like the one proposed by Oh et al. (2012).

## Abstract

This paper presents a paraphrase acquisition method that uncovers and exploits generalities underlying paraphrases: paraphrase patterns are first induced and then used to collect novel instances. Unlike existing methods, ours uses both bilingual parallel and monolingual corpora. While the former are regarded as a source of high-quality seed paraphrases, the latter are searched for paraphrases that match patterns learned from the seed paraphrases. We show how one can use monolingual corpora, which are far more numerous and larger than bilingual corpora, to obtain paraphrases that rival in quality those derived directly from bilingual corpora. In our experiments, the number of paraphrase pairs obtained in this way from monolingual corpora was a large multiple of the number of seed paraphrases. Human evaluation through a paraphrase substitution test demonstrated that the newly acquired paraphrase pairs are of reasonable quality. Remaining noise can be further reduced by filtering seed paraphrases.

## 1 Introduction

Paraphrases are semantically equivalent expressions in the same language. Because “equivalence” is the most fundamental semantic relationship, techniques for generating and recognizing paraphrases play an important role in a wide range of natural language processing tasks (Madnani and Dorr, 2010).

In the last decade, automatic acquisition of knowledge about paraphrases from corpora has been drawing the attention of many researchers. Typically, the acquired knowledge is simply represented as pairs of semantically equivalent sub-sentential expressions as in (1).

- (1) a. look like  $\Leftrightarrow$  resemble
- b. control system  $\Leftrightarrow$  controller

The challenge in acquiring paraphrases is to ensure good coverage of the targeted classes of paraphrases along with a low proportion of incorrect pairs. However, no matter what type of resource has been used, it has proven difficult to acquire paraphrase pairs with both high recall and high precision.

Among various types of corpora, monolingual corpora can be considered the best source for high-coverage paraphrase acquisition, because there is far more monolingual than bilingual text available. Most methods that exploit monolingual corpora rely on the Distributional Hypothesis (Harris, 1968): expressions that appear in similar contexts are expected to have similar meaning. However, if one uses purely distributional criteria, it is difficult to distinguish real paraphrases from pairs of expressions that are related in other ways, such as antonyms and cousin words.

In contrast, since the work in (Bannard and Callison-Burch, 2005), bilingual parallel corpora have been acknowledged as a good source of high-quality paraphrases: paraphrases are obtained by putting together expressions that receive the same translation in the other language (pivot language). Because translation expresses a specific meaning more directly than context in the aforementioned approach, pairs of expressions acquired in this manner tend to be correct paraphrases. However, the coverage problem remains: there is much less bilingual parallel than monolingual text available.

Our objective in this paper is to obtain paraphrases that have high **quality** (like those extracted from bilingual parallel corpora via pivoting) but can be generated in large **quantity** (like those extracted

from monolingual corpora via contextual similarity). To achieve this, we propose a method that exploits general patterns underlying paraphrases and uses both bilingual parallel and monolingual sources of information. Given a relatively high-quality set of paraphrases obtained from a bilingual parallel corpus, a set of paraphrase patterns is first induced. Then, appropriate instances of such patterns, i.e., potential paraphrases, are harvested from a monolingual corpus.

After reviewing existing methods in Section 2, our method is presented in Section 3. Section 4 describes our experiments in acquiring paraphrases and presents statistics summarizing the coverage of our method. Section 5 describes a human evaluation of the quality of the acquired paraphrases. Finally, Section 6 concludes this paper.

## 2 Literature on Paraphrase Acquisition

This section summarizes existing corpus-based methods for paraphrase acquisition, following the classification in (Hashimoto et al., 2011): similarity-based and alignment-based methods.

### 2.1 Similarity-based Methods

Techniques that use monolingual (non-parallel) corpora mostly rely on the Distributional Hypothesis (Harris, 1968). Because a large quantity of monolingual data is available for many languages, a large number of paraphrase candidates can be acquired (Lin and Pantel, 2001; Paşca and Dienes, 2005; Bhagat and Ravichandran, 2008, etc.). The recipes proposed so far are based on three main ingredients, i.e., features used for representing context of target expression (contextual features), criteria for weighting and filtering features, and aggregation functions.

A drawback of relying only on contextual similarity is that it tends to give high scores to semantically related but non-equivalent expressions, such as antonyms and cousin words. To enhance the precision of the results, filtering mechanisms need to be introduced (Marton et al., 2011).

### 2.2 Alignment-based Methods

Pairs of expressions that get translated to the same expression in a different language can be regarded as paraphrases. On the basis of this hypothesis, Barzilay and McKeown (2001) and Pang et al. (2003)

created monolingual parallel corpora from multiple human translations of the same source. Then, they extracted corresponding parts of such parallel sentences as sub-sentential paraphrases.

Leveraging recent advances in statistical machine translation (SMT), Bannard and Callison-Burch (2005) proposed a method for acquiring sub-sentential paraphrases from bilingual parallel corpora. As in SMT, a translation table is first built on the basis of alignments between expressions, such as words, phrases, and subtrees, across a parallel sentence pair. Then, pairs of expressions ( $e_1, e_2$ ) in the same language that are aligned with the same expressions in the other language (pivot language) are extracted as paraphrases. The likelihood of  $e_2$  being a paraphrase of  $e_1$  is given by

$$p(e_2|e_1) = \sum_{f \in Tr(e_1, e_2)} p(e_2|f)p(f|e_1), \quad (1)$$

where  $Tr(e_1, e_2)$  stands for the set of shared translations of  $e_1$  and  $e_2$ . Each factor  $p(e|f)$  and  $p(f|e)$  is estimated from the number of times  $e$  and  $f$  are aligned and the number of occurrences of each expression in each language. Kok and Brockett (2010) showed how one can discover paraphrases that do not share any translation in one language by traversing a graph created from multiple translation tables, each corresponding to a bilingual parallel corpus.

This approach, however, suffers from a coverage problem, because both monolingual parallel and bilingual parallel corpora tend to be significantly smaller than monolingual non-parallel corpora. The acquired pairs of expressions include some non-paraphrases as well. Many of these come from erroneous alignments, which are particularly frequent when the given corpus is small.

Monolingual comparable corpora have also been exploited as sources of paraphrases using alignment-based methods. For instance, multiple news articles covering the same event (Shinyama et al., 2002; Barzilay and Lee, 2003; Dolan et al., 2004; Wubben et al., 2009) have been used. Such corpora have also been created manually through crowdsourcing (Chen and Dolan, 2011). However, the availability of monolingual comparable corpora is very limited for most languages; thus, approaches relying on these corpora have typically produced only very

small collections of paraphrases. Hashimoto et al. (2011) found a way around this limitation by collecting sentences that constitute explicit definitions of particular words or phrases from monolingual non-parallel Web documents, pairing sentences that define the same noun phrase, and then finding corresponding phrases in each sentence pair. One limitation of this approach is that it requires a considerable amount of labeled data for both the corpus construction and the paraphrase extraction steps.

## 2.3 Summary

Existing methods have investigated one of the following four types of corpora as their principal resource<sup>1</sup>: monolingual non-parallel corpora, monolingual parallel corpora, monolingual comparable corpora, and bilingual parallel corpora. No matter what type of resource has been used, however, it has proven difficult to acquire paraphrases with both high recall and precision, with the possible exception of the method in (Hashimoto et al., 2011) which requires large amounts of labeled data.

## 3 Proposed Method

While most existing methods deal with expressions only at the surface level, ours exploits generalities underlying paraphrases to achieve better coverage while retaining high precision. Furthermore, unlike existing methods, ours uses both bilingual parallel and monolingual non-parallel corpora as sources for acquiring paraphrases.

The process is illustrated in Figure 1. First, a set of high-quality seed paraphrases,  $P_{Seed}$ , is acquired from bilingual parallel corpora by using an alignment-based method. Then, our method collects further paraphrases through the following two steps.

**Generalization (Step 2):** Paraphrase patterns are learned from the seed paraphrases,  $P_{Seed}$ .

**Instantiation (Step 3):** A novel set of paraphrase pairs,  $P_{Hvst}$ , is finally harvested from monolingual non-parallel corpora using the learned patterns; each newly acquired paraphrase pair is assessed by contextual similarity.

<sup>1</sup>Chan et al. (2011) used monolingual corpora only for re-ranking paraphrases obtained from bilingual parallel corpora. To the best of our knowledge, bilingual comparable corpora have never been used as sources for acquiring paraphrases.

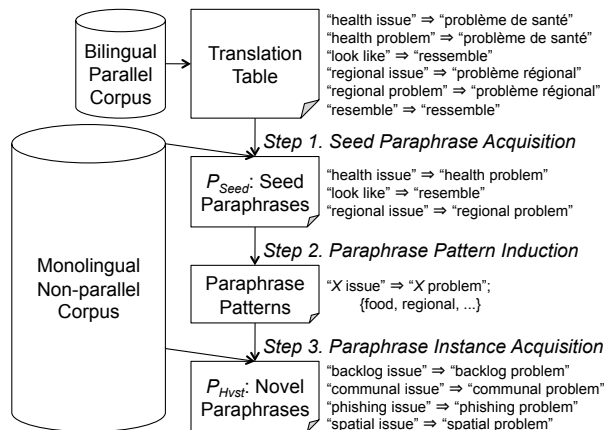

Figure 1: Process of paraphrase acquisition.

The set  $P_{Seed}$  acquired early in the process can be pooled with the set  $P_{Hvst}$  harvested in the last stage of the process.

### 3.1 Step 1. Seed Paraphrase Acquisition

The goal of the first step is to obtain a set of high-quality paraphrase pairs,  $P_{Seed}$ .

For this purpose, alignment-based methods with bilingual or monolingual parallel corpora are preferable to similarity-based methods applied to non-parallel corpora. Among various options, in this paper, we start from the standard technique proposed by Bannard and Callison-Burch (2005) with bilingual parallel corpora (see also Section 2.2). In particular, we assume the phrase-based SMT framework (Koehn et al., 2003). Then, we purify the results with several filtering methods.

The phrase pair extraction process of phrase-based SMT systems aims at high recall for increased robustness of the translation process. As a result, a naive application of the paraphrase acquisition method produces pairs of expressions that are not exact paraphrases. For instance, the algorithm explained in Koehn (2009, p.134) extracts both “dass” and “, dass” as counterparts of “that” from the sentence pair. To reduce that kind of noise, we apply some filtering techniques to the candidate translation pairs. First, statistically unreliable translation pairs (Johnson et al., 2007) are filtered out. Then, we also filter out phrases made up entirely of stop words (including punctuation marks), both in the language of interest and in the pivot language.

Let  $P_{Raw}$  be the initial set of paraphrase pairs extracted from the sanitized translation table. We first

Figure 2: RHS-filtering for “control apparatus”.

discard pairs whose difference comprises only stop words, such as “the schools”  $\Rightarrow$  “schools and”. We also remove pairs containing only singular-plural differences, such as “family unit”  $\Rightarrow$  “family units”. Depending on the language of interest, other types of morphological variants, such as those shown in (2), may also be ignored.

- (2) a. “européenne”  $\Rightarrow$  “européen”  
(Gender in French)  
b. “guten Lösungen”  $\Rightarrow$  “gute Lösungen”  
(Case in German)

We further filter out less reliable pairs, such as those shown with dotted lines in Figures 2 and 3. This is carried out by comparing the right-hand side (RHS) phrases of each left-hand side (LHS) phrase, and vice versa<sup>2</sup>. Given a set of paraphrase pairs, RHS phrases corresponding to the same LHS phrase  $lp$  are compared. A RHS phrase  $rp$  is not licensed iff  $lp$  has another RHS phrase  $rp' (\neq rp)$  which satisfies the following two conditions (see also Figure 2).

- $rp'$  is a word sub-sequence of  $rp$
- $rp'$  is a more likely paraphrase than  $rp$ ,  
i.e.,  $p(rp'|lp) > p(rp|lp)$

LHS phrases for each RHS phrase  $rp$  are also compared in a similar manner, i.e., a LHS phrase  $lp$  is not qualified as a legitimate source of  $rp$  iff  $rp$  has another LHS phrase  $lp' (\neq lp)$  which satisfies the following conditions (see also Figure 3).

- $lp'$  is a word sub-sequence of  $lp$
- $lp'$  is a more likely source than  $lp$ ,  
i.e.,  $p(lp'|rp) > p(lp|rp)$

The two directions of filtering are separately applied and the intersection of their results is retained.

<sup>2</sup>cf. Denkowski and Lavie (2011); they only compared each RHS phrase to its corresponding LHS phrase.

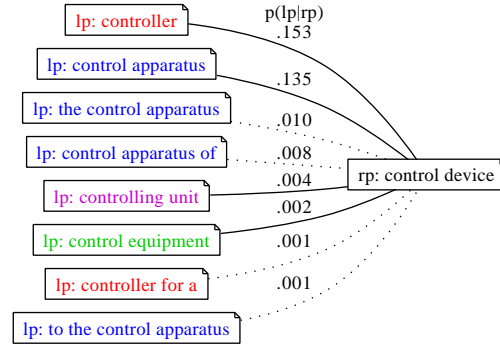

Figure 3: LHS-filtering for “control device”.

Candidate pairs are finally filtered on the basis of their reliability score. Traditionally, a threshold ( $th_p$ ) on the conditional probability given by Eq. (1) is used (Du et al., 2010; Max, 2010; Denkowski and Lavie, 2011, etc.). Furthermore, we also require that LHS and RHS phrases exceed a threshold ( $th_s$ ) on their contextual similarity in a monolingual corpus. This paper neither proposes a specific recipe nor makes a comprehensive comparison of existing recipes for computing contextual similarity, although one particular recipe is used in our experiments (see Section 4.1).

### 3.2 Step 2. Paraphrase Pattern Induction

From a set of seed paraphrases,  $P_{Seed}$ , paraphrase patterns are induced. For instance, from paraphrases in (3), we induce paraphrase patterns in (4).

- (3) a. “restraint system”  $\Rightarrow$  “restraint apparatus”  
b. “movement against racism”  
 $\Rightarrow$  “anti-racism movement”  
c. “middle eastern countries”  
 $\Rightarrow$  “countries in the middle east”
- (4) a. “X system”  $\Rightarrow$  “X apparatus”  
b. “X against Y”  $\Rightarrow$  “anti-Y X”  
c. “X eastern Y”  $\Rightarrow$  “Y in the X east”

Word pairs of LHS and RHS phrases will be replaced with variable slots iff they are fully identical or singular-plural variants. Note that stop words are retained. While a deeper level of lexical correspondences, such as “eastern” and “east” in (3c) and “system” and “apparatus” in (3a), could be captured, this would require the use of rich language resources, thereby making the method less portable to resource-poor languages.

Note that our aim is to automatically capture general paraphrase patterns of the kind that have sometimes been manually described (Jacquemin, 1999; Fujita et al., 2007). This is different from approaches that attach variable slots to paraphrases for calculating their similarity (Lin and Pantel, 2001; Szpektor and Dagan, 2008) or for constraining the context in which they are regarded legitimate (Callison-Burch, 2008; Zhao et al., 2009).

### 3.3 Step 3. Paraphrase Instance Acquisition

Given a set of paraphrase patterns, such as those shown in (4), a set of novel instances, i.e., novel paraphrases,  $P_{Hvst}$ , will now be harvested from monolingual non-parallel corpora. In other words, a set of appropriate slot-fillers will be extracted.

First, expressions that match both elements of the pattern, except stop words, are collected from a given monolingual corpus. Pattern matching alone may generate inappropriate pairs, so we then assess the legitimacy of each collected slot-filler.

Let  $LHS(\mathbf{w})$  and  $RHS(\mathbf{w})$  be the expressions generated by instantiating the  $k$  variable slots in LHS and RHS phrases of the pattern with a  $k$ -tuple of slot-fillers  $\mathbf{w} (= w_1, \dots, w_k)$ , respectively. We estimate how likely  $RHS(\mathbf{w})$  is to be a paraphrase of  $LHS(\mathbf{w})$  based on the contextual similarity between them using a monolingual corpus; a pair of phrases is discarded if they are used in substantially dissimilar contexts. We use the same recipe and threshold value for  $th_s$  with Step 1 in our experiments.

Contextual similarity of antonyms and cousin words can also be high, as they are often used in similar contexts. However, this is not a problem in our framework, because semantic equivalence between  $LHS(\mathbf{w})$  and  $RHS(\mathbf{w})$  is almost entirely guaranteed as a result of the way the corresponding patterns were learned from a bilingual parallel corpus.

### 3.4 Characteristics

In terms of coverage,  $P_{Hvst}$  is expected to be greatly larger than  $P_{Seed}$ , although it will not cover totally different pairs of paraphrases, such as those shown in (1). On the other hand, the quality of  $P_{Hvst}$  depends on that of  $P_{Seed}$ . Unlike in the pure similarity-based method,  $P_{Hvst}$  is constrained by the paraphrase patterns derived from the set of high-quality paraphrases,  $P_{Seed}$ , and will therefore gen-

erally exclude the kind of semantically similar but non-equivalent pairs that contextual similarity alone tends to extract alongside real paraphrases.

As mentioned in Section 3.1, other types of methods can be used for obtaining high-quality seed paraphrases,  $P_{Seed}$ . For instance, the supervised method proposed by Hashimoto et al. (2011) uses the existence of shared words as a feature to determine whether the given pair of expressions are paraphrases, and thereby extracts many pairs sharing the same words. Thus, their output has a high potential to be used as an alternative seed for our method.

Another advantage of our method is that it does not require any labeled data, unlike the supervised methods proposed by Zhao et al. (2009) and Hashimoto et al. (2011).

## 4 Quantitative Impact

### 4.1 Experimental Settings

Two different sets of corpora were used as data sources; in both settings, we acquired English paraphrases.

**Europarl:** The English-French version of the Europarl Parallel Corpus<sup>3</sup> consisting of 1.8M sentence pairs (51M words in English and 56M words in French) was used as a bilingual parallel corpus, while its English side and the English side of the 10<sup>9</sup> French-English corpus<sup>4</sup> consisting of 23.8M sentences (649M words) were used as monolingual data.

**Patent:** The Japanese-English Patent Translation data (Fujii et al., 2010) consisting of 3.2M sentence pairs (122M morphemes in Japanese and 106M words in English) was used as a bilingual parallel corpus, while its English side and the 30.0M sentences (626M words) from the 2007 chapter of NTCIR unaligned patent documents were used as monolingual data.

To study the behavior of our method for different amounts of bilingual parallel data, we carried out learning curve experiments.

We used our in-house tokenizer for segmentation of English and French sentences and MeCab<sup>5</sup> for Japanese sentences.

<sup>3</sup><http://statmt.org/europarl/>, release 6

<sup>4</sup><http://statmt.org/wmt10/training-giga-fren.tar>

<sup>5</sup><http://mecab.sourceforge.net/>, version 0.98

Figure 4: # of paraphrase pairs in  $P_{Seed}$  (left: Europarl, right: Patent).

Stop word lists for sanitizing translation pairs and paraphrase pairs were manually compiled: we enumerated 442 English words, 193 French words, and 149 Japanese morphemes, respectively.

From a bilingual parallel corpus, a translation table was created by our in-house phrase-based SMT system, PORTAGE (Sadat et al., 2005). Phrase alignments of each sentence pair were identified by the heuristic “grow-diag-final”<sup>6</sup> with a maximum phrase length 8. The resulting translation pairs were then filtered with the significance pruning technique of (Johnson et al., 2007), using  $\alpha + \epsilon$  as threshold.

As contextual features for computing similarity of each paraphrase pair, all of the 1- to 4-grams of words adjacent to each occurrence of a phrase were counted. This is a compromise between less expensive but noisier approaches, such as bag-of-words, and more accurate but more expensive approaches that incorporate syntactic features (Lin and Pantel, 2001; Shinyama et al., 2002; Pang et al., 2003; Szpektor and Dagan, 2008). Contextual similarity is finally measured by taking cosine between two feature vectors.

## 4.2 Statistics on Acquired Paraphrases

### Seed Paraphrases ( $P_{Seed}$ )

Figure 4 shows the number of paraphrase pairs  $P_{Seed}$  obtained from the bilingual parallel corpora. The general trend is simply that the larger the corpus is, the more paraphrases are acquired.

Given the initial set of paraphrases,  $P_{Raw}$  (“x”), our filtering techniques (“□”) discarded a large portion (63-75% in Europarl and 43-64% in Patent) of them. Pairs with zero similarity were also filtered out, i.e.,  $th_s = \epsilon$ . This suggests that many incorrect

<sup>6</sup><http://statmt.org/moses/?n=FactoredTraining.AlignWords>

and/or relatively useless pairs, such as those shown in Figures 2 and 3, had originally been acquired.

Lines with “○” show the results based on a widely-used threshold value on the conditional probability in Eq. (1), i.e.,  $th_p = 0.01$  (Du et al., 2010; Max, 2010; Denkowski and Lavie, 2011, etc.). The percentage of paraphrase pairs thereby discarded varied greatly depending on the corpus size (17-78% in Europarl and 31-82% in Patent), suggesting that the threshold value should be determined depending on the given corpus. In the following experiment, however, we conform to the convention  $th_p = 0.01$  (“△”) to ensure the quality of  $P_{Seed}$  that we will be using for inducing paraphrase patterns, even though this results in discarding some less frequent but correct paraphrase pairs, such as “control apparatus”  $\Rightarrow$  “controlling device” in Figure 2.

### Paraphrase Patterns

Figures 5 and 6 show the number of paraphrase patterns that our method induced and their coverage against  $P_{Seed}$ , respectively. Due to their rather rigid form, the patterns covered no more than 15% of  $P_{Seed}$  in Europarl. In contrast, a higher proportion of  $P_{Seed}$  in Patent was generalized into patterns. We speculate it is because the patent domain contains many expressions, including technical terms, that have similar variations of constructions.

The acquired patterns were mostly one-variable patterns: 88-93% and 80-91% of total patterns for different variants of the Europarl and Patent settings, respectively. Given that there are far more one-variable patterns than other types, and that one-variable patterns are the simplest type, we henceforth focus on them. More complex patterns, including two-variable patterns (7-11% and 8-17% in each setting), will be investigated in our future work.

Figure 5: # of paraphrase patterns.

Figure 6: Coverage of the paraphrase patterns.

Figure 7: # of paraphrase pairs and unique LHS phrases in  $P_{Seed}$  and  $P_{Hvst}$  (left: Europarl, right: Patent).

### Novel Paraphrases ( $P_{Hvst}$ )

Using the paraphrase patterns, novel paraphrase pairs,  $P_{Hvst}$ , were harvested from the monolingual non-parallel corpora. In this experiment, we only retained one-variable patterns and regarded only single words as slot-fillers for them. Nevertheless, we managed to acquire a large number of paraphrase pairs as depicted in Figure 7, where pairs having zero similarity were excluded. For instance, when the full size of bilingual parallel corpus in Patent was used, we acquired 1.41M pairs of seed paraphrases,  $P_{Seed}$ , and 28.7M pairs of novel paraphrases,  $P_{Hvst}$ . In other words, our method expanded  $P_{Seed}$  by about 21 times. The number of unique LHS phrases that  $P_{Hvst}$  covers was also significantly larger than that of  $P_{Seed}$ .

Figure 8 highlights the remarkably large ratio of  $P_{Hvst}$  to  $P_{Seed}$  in terms of the number of paraphrase pairs and the number of unique LHS phrases. The smaller the bilingual corpus is, the higher the ratio is, except when there is only a very small amount of Europarl data. This demonstrates that our method is quite powerful, given a minimum amount of data.

Another striking difference between  $P_{Seed}$  and  $P_{Hvst}$  is the average number of RHS phrases per

unique LHS phrase, i.e., their relative yield. As displayed in Figure 9, the yield for  $P_{Hvst}$  increased rapidly with the scaling up of the bilingual corpus, while that of  $P_{Seed}$  only grew slowly. The alignment-based method with bilingual corpora cannot produce very many RHS phrases per unique LHS phrase due to its reliance on conditional probability and the surface level processing. In contrast, our method does not limit the number of RHS phrases: each RHS phrase is separately assessed by its similarity to the corresponding LHS phrase. One limitation of our method is that it cannot achieve high yield for  $P_{Hvst}$  whenever only a small number of paraphrase patterns can be extracted from the bilingual corpus (see also Figure 5).

Both the ratio of  $P_{Hvst}$  to  $P_{Seed}$  and the relative yield could probably be increased by scaling up the monolingual corpus. For instance, in the patent domain, monolingual documents 10 times larger than the one used in the above experiments are available at the NTCIR project<sup>7</sup>. It would be interesting to compare the relative gains brought by in-domain versus general-purpose corpora.

<sup>7</sup><http://ntcir.nii.ac.jp/PatentMT-2/>

Figure 8: Ratio of  $P_{Hvst}$  to  $P_{Seed}$ .

Figure 9: Average # of RHS phrases per LHS phrase.

Figure 10: # of acquired paraphrase pairs against threshold values.

(left: probability-based ( $0.01 \leq th_p \leq 0.9$ ,  $th_s = \epsilon$ ), right: similarity-based ( $\epsilon \leq th_s \leq 0.9$ ,  $th_p = 0.01$ ))

Finally, we investigated how the number of paraphrase pairs varies depending on the values for the two thresholds, i.e.,  $th_p$  on the conditional probability and  $th_s$  on the contextual similarity, respectively. Figure 10 shows the results when the full sizes of bilingual corpora are used. When the pairs were filtered only with  $th_p$ , the number of paraphrase pairs in  $P_{Hvst}$  decreased more slowly than that of  $P_{Seed}$  according to the increase of the threshold value. This is a benefit from our generalization and instantiation method. The same paraphrase pattern is often induced from more than one paraphrase pair in  $P_{Seed}$ . Thus, as long as at least one of them has a probability higher than the given threshold value, corresponding novel paraphrases can be harvested.

On the other hand, as a results of assessing each individual paraphrase pair by the contextual similarity, many pairs in  $P_{Hvst}$ , which are supposed to be incorrect instances of their corresponding pattern, are filtered out by a larger threshold value for  $th_s$ . In contrast, many pairs in  $P_{Seed}$  have a relatively high similarity, e.g., 40% of all pairs have similarity higher than 0.4. This indicates the quality of  $P_{Seed}$  is highly guaranteed by the shared translations.

## 5 Human Evaluation of Quality

To confirm that the quality of  $P_{Hvst}$  is sufficiently high, we carried out a substitution test.

First, by substituting sub-sentential paraphrases to existing sentences in a given test corpus, pairs of slightly different sentences were automatically generated. For instance, by applying “looks like”  $\Rightarrow$  “resembles” to (5), (6) was generated.

(5) The roof *looks like* a prehistoric lizard’s spine.

(6) The roof *resembles* a prehistoric lizard’s spine.

Human evaluators were then asked to score each pair of an original sentence and a paraphrased sentence with the following two 5-point scale grades proposed by Callison-Burch (2008):

**Grammaticality:** whether the paraphrased sentence is grammatical (1: horrible, 5: perfect)

**Meaning:** whether the meaning of the original sentence is properly retained by the paraphrased sentence (1: totally different, 5: equivalent)

To make results more consistent and reduce the human labor, evaluators were asked to rate at the same time several paraphrases for the same source phrase. For instance, given a source sentence (5), the

evaluators might be given the following sentences in addition to a paraphrased sentence (6).

(7) The roof *seems like* a prehistoric lizard’s spine.

(8) The roof *would look like* a prehistoric lizard’s spine.

In this experiment, we showed five paraphrases per source phrase, assuming that evaluators would get confused if too large a number of paraphrase candidates were presented at the same time.

### 5.1 Data for Evaluation

As in previous work (Callison-Burch, 2008; Chan et al., 2011), we evaluated paraphrases acquired from the Europarl corpus on news sentences. Paraphrase examples were automatically generated from the English part of WMT 2008-2011 “newstest” data (10,050 unique sentences) by applying the union of  $P_{Seed}$  and  $P_{Hvst}$  of the Europarl setting (19.3M paraphrases for 5.95M phrases).

On the other hand, paraphrases acquired from patent documents are much more difficult to evaluate due to the following reasons. First, they may be too domain-specific to be of any use in general areas such as news sentences. However, conducting an in-domain evaluation would be difficult without enrolling domain experts. We expect that paraphrases from a domain can be used safely in that domain. Nevertheless, deciding under what circumstances they can be used safely in another domain is an interesting research question.

To reduce the human labor for the evaluation, sentences were restricted to those with moderate length: 10-30 words, which are expected to provide sufficient but succinct context. To propose multiple paraphrase candidates at the same time, we also restricted phrases to be paraphrased (LHS phrases) to those having at least five paraphrases including ones from  $P_{Hvst}$ . This resulted in 60,421 paraphrases for 988 phrase tokens (353 unique phrases).

Finally, we randomly sampled 80 unique phrase tokens and five unique paraphrases for each phrase token (400 examples in total), and asked six people having a high level of English proficiency to evaluate them. Inter-evaluator agreement was calculated from five different pairs of evaluators, each judging the same 10 examples. The remaining 350 examples were divided into six chunks of slightly unequal length, with each chunk being judged by one of the six evaluators.

	$n$	5-point		Binary		
		G	M	G	M	Both
$P_{Seed}$	55	4.60	4.35	0.85	0.93	0.78
$P_{Hvst}$	295	4.22	3.35	0.74	0.67	0.55
Total	350	4.28	3.50	0.76	0.71	0.58

Table 1: Avg. score and precision of binary classification.

### 5.2 Results

Table 1 shows the average of the original 5-point scale scores and the percentage of examples that are judged correct based on a binary judgment (Callison-Burch, 2008): an example is considered to be correct iff the grammaticality score is 4 or above and/or the meaning score is 3 or above. Paraphrases based on  $P_{Seed}$  achieved a quite high performance in both grammaticality (“G”) and meaning (“M”) in part because of the effectiveness of our filtering techniques. The performance of paraphrases drawn from  $P_{Hvst}$  was reasonably high and similar to the scores 0.68 for grammaticality, 0.61 for meaning, and 0.55 for both, of the best model reported in (Callison-Burch, 2008), although it was inferior to  $P_{Seed}$ .

Despite the fact that all of our evaluators had a high-level command of English, the agreement was not very high. This was true even when the collected scores were mapped into binary classes. In this case, the  $\kappa$  values (Cohen, 1960) for each criterion were 0.45 and 0.45, respectively, which indicate the agreement was “fair”. To obtain a better  $\kappa$  value, the criteria for grading will need to be improved. However, we think that was not too low either<sup>8</sup>.

The most promising way for improving the quality of  $P_{Hvst}$  is to ensure that paraphrase patterns cover only legitimate paraphrases. We investigated this by filtering the manually scored paraphrase examples with two thresholds for cleaning seed paraphrases  $P_{Seed}$ :  $th_p$  on the conditional probability estimated using the bilingual parallel corpus and  $th_s$  on the contextual similarity in the monolingual non-parallel corpus. Figure 11 shows the average score of the examples whose corresponding paraphrase is obtainable with the given threshold values. Note that the points in the figure with higher threshold values are less reliable than the others, because filtering reduces the number of the manually scored examples

<sup>8</sup>Note that Callison-Burch (2008) might possibly underestimate the chance agreement and overestimate the  $\kappa$  values, because the distribution of human scores would not be uniform.

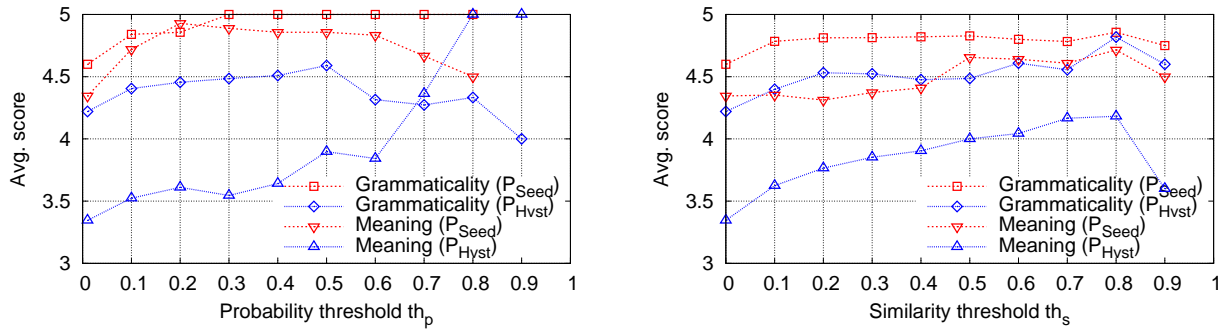

Figure 11: Average score of paraphrase examples against threshold values. (left: probability-based ( $0.01 \leq th_p \leq 0.9$ ,  $th_s = \epsilon$ ), right: similarity-based ( $\epsilon \leq th_s \leq 0.9$ ,  $th_p = 0.01$ ))

The points with higher threshold values are less reliable than the others, because filtering reduces the number of the manually scored examples used to calculate scores.

used to calculate scores. Nevertheless, it indicates that better filtering of  $P_{Seed}$  with higher threshold values is likely to produce a better-quality set of paraphrases  $P_{Hvst}$ . For instance, an inappropriate paraphrase pattern (9a) was excluded with  $th_p = 0.1$  or  $th_s = 0.1$ , while correct ones (9b) and (9c) remained even when a large threshold value is used.

- (9) a. “ $X$  years”  $\Rightarrow$  “turn  $X$ ”  
 b. “ $X$  supplied”  $\Rightarrow$  “ $X$  provided”  
 c. “main  $X$ ”  $\Rightarrow$  “most significant  $X$ ”

Kendall’s correlation coefficient  $\tau_B$  (Kendall, 1938) between the contextual similarity and each of the human scores were 0.24 for grammaticality and 0.21 for meaning, respectively. Although they are rivaling the best results reported in (Chan et al., 2011), i.e., 0.24 and 0.21, similarity metrics should be further investigated to realize a more accurate filtering.

## 6 Conclusion

In this paper, we exploited general patterns underlying paraphrases to acquire automatically a large number of high-quality paraphrase pairs using both bilingual parallel and monolingual non-parallel corpora. Experiments using two sets of corpora demonstrated that our method is able to leverage information in a relatively small bilingual parallel corpus to exploit large amounts of information in a relatively large monolingual non-parallel corpus. Human evaluation through a paraphrase substitution test revealed that the acquired paraphrases are generally of reasonable quality. Our original objective was to extract from monolingual corpora a large **quantity** of paraphrases whose **quality** is as high as

that of paraphrases from bilingual parallel corpora. We have met the quantity part of the objective, and have come close to meeting the quality part.

There are three main directions for our future work. First, we intend to carry out in-depth analyses of the proposed method. For instance, while we showed that the performance of phrase substitution could be improved by removing noisy seed paraphrases, this also strongly affected the quantity. We will therefore investigate similarity metrics in our future work. Other interesting questions related to the work presented here are, as mentioned in Section 4.2, exploitation of patterns with more than one variable, learning curve experiments with different amounts of monolingual data, and comparison of in-domain and general-purpose monolingual corpora. Second, we have an interest in exploiting sophisticated paraphrase patterns; for instance, by inducing patterns hierarchically (recursively) and incorporating lexical resources such as those exemplified in (4). Finally, the developed paraphrase collection will be attested through applications, such as sentence compression (Cohn and Lapata, 2008; Ganitkevitch et al., 2011) and machine translation (Callison-Burch et al., 2006; Marton et al., 2009).

## Abstract

Learning the meaning of words from ambiguous and noisy context is a challenging task for language learners. It has been suggested that children draw on syntactic cues such as lexical categories of words to constrain potential referents of words in a complex scene. Although the acquisition of lexical categories should be interleaved with learning word meanings, it has not previously been modeled in that fashion. In this paper, we investigate the interplay of word learning and category induction by integrating an LDA-based word class learning module with a probabilistic word learning model. Our results show that the incrementally induced word classes significantly improve word learning, and their contribution is comparable to that of manually assigned part of speech categories.

## 1 Learning the Meaning of Words

For young learners of a natural language, mapping each word to its correct meaning is a challenging task. Words are often used as part of an utterance rather than in isolation. The meaning of an utterance must be inferred from among numerous possible interpretations that the (usually complex) surrounding scene offers. In addition, the linguistic and visual context in which words are heard and used is often noisy and highly ambiguous. Particularly, many words in a language are polysemous and have different meanings.

Various learning mechanisms have been proposed for word learning. One well-studied mechanism is *cross-situational learning*, a bottom-up strategy based on statistical co-occurrence of words and referents across situations (Quine 1960, Pinker 1989).

Several experimental studies have shown that adults and children are sensitive to cross-situational evidence and use this information for mapping words to objects, actions and properties (Smith and Yu 2007, Monaghan and Mattock 2009). A number of computational models have been developed based on this principle, demonstrating that cross-situational learning is a powerful and efficient mechanism for learning the correct mappings between words and meanings from noisy input (e.g. Siskind 1996, Yu 2005, Fazly et al. 2010).

Another potential source of information that can help the learner to constrain the relevant aspects of a scene is the sentential context of a word. It has been suggested that children draw on syntactic cues provided by the linguistic context in order to guide word learning, a hypothesis known as *syntactic bootstrapping* (Gleitman 1990). There is substantial evidence that children are sensitive to the structural regularities of language from a very young age, and that they use these structural cues to find the referent of a novel word (e.g. Naigles and Hoff-Ginsberg 1995, Gertner et al. 2006). In particular, young children have robust knowledge of some of the abstract lexical categories such as nouns and verbs (e.g. Gelman and Taylor 1984, Kemp et al. 2005).

Recent studies have examined the interplay of cross-situational learning and sentence-level learning mechanisms, showing that adult learners of an artificial language can successfully and simultaneously apply cues and constraints from both sources of information when mapping words to their referents (Gillette et al. 1999, Lidz et al. 2010, Koehne and Crocker 2010; 2011). Several computational models have also investigated this interaction by adding manually annotated part-of-speech tags as

input to word learning algorithms, and suggesting that integration of lexical categories can boost the performance of a cross-situational model (Yu 2006, Alishahi and Fazly 2010).

However, none of the existing experimental or computational studies have examined the acquisition of word meanings and lexical categories in parallel. They all make the simplifying assumption that *prior* to the onset of word learning, the categorization module has already formed a relatively robust set of lexical categories. This assumption can be justified in the case of adult learners of a second or artificial language. But children’s acquisition of categories is most probably interleaved with the acquisition of word meaning, and these two processes must ultimately be studied simultaneously.

In this paper, we investigate concurrent acquisition of word meanings and lexical categories. We use an online version of the LDA algorithm to induce a set of word classes from child-directed speech, and integrate them into an existing probabilistic model of word learning which combines cross-situational evidence with cues from lexical categories. Through a number of simulations of a word learning scenario, we show that our automatically and incrementally induced categories significantly improve the performance of the word learning model, and are closely comparable to a set of gold-standard, manually-annotated part of speech tags.

## 2 A Word Learning Model

We want to investigate whether lexical categories (i.e. word classes) that are incrementally induced from child-directed speech can improve the performance of a cross-situational word learning model. For this purpose, we use the model of Alishahi and Fazly (2010). This model uses a probabilistic learning algorithm for combining evidence from word-referent co-occurrence statistics and the meanings associated with a set of pre-defined categories. They use child-directed utterances, manually annotated with a small set of part of speech tags, from the Manchester corpus (Theakston et al. 2001) in the CHILDES database (MacWhinney 1995). Their experimental results show that integrating these gold-standard categories into the algorithm boosts its performance over a pure cross-situational version.

The model of Alishahi and Fazly (2010) has the suitable architecture for our goal: it provides an integrated learning mechanism which combines evidence from word-referent co-occurrence with cues from the meaning representation associated with word categories. However, the model has two major shortcomings. First, it assumes that lexical categories are formed and finalized prior to the onset of word learning and that a correct and unique category for a target word can be identified at each point in time, assumptions that are highly unlikely. Second, it does not handle any ambiguity in the meaning of a word. Instead, each word is assumed to have only one correct meaning. Considering the high level of lexical ambiguity in most natural languages, this assumption unreasonably simplifies the word learning problem.

To investigate the plausibility of integrating word and category learning, we use an online algorithm for automatically and incrementally inducing a set of lexical categories. Moreover, we use each word in its original form instead of lemmatizing them, which implies that categories contain different morphological forms of the same word. By applying these changes, we are able to study the contribution of lexical categories to word learning in a more realistic scenario.

**Representation of input.** The input to the model consists of a sequence of utterances, each paired with a representation of an observed scene. We represent an utterance as a set of words,  $U = \{w\}$  (e.g.  $\{she, went, home, \dots\}$ ), and the corresponding scene as a set of semantic features,  $S = \{f\}$  (e.g.  $\{ANIMATE, HUMAN, FEMALE, \dots\}$ ).

**Word and category meaning.** We represent the meaning of a word as a time-dependent probability distribution  $p^{(t)}(\cdot|w)$  over all the semantic features, where  $p^{(t)}(f|w)$  is the probability of feature  $f$  being associated with word  $w$  at time  $t$ . In the absence of any prior knowledge, the model assumes a uniform distribution over all features as the meaning of a novel word. Also, a function  $cat^{(t)}(w)$  gives us the category to which a word  $w$  in utterance  $U^{(t)}$  belongs.

At each point in time, a category  $c$  contains a set of word tokens. We assign a meaning to each cat-

egory as a weighted sum of the meaning learned so far for each of its members, or  $p^{(t)}(f|c) = (1/|c|) \sum_{w \in c} p^{(t)}(f|w)$ , where  $|c|$  is the number of word tokens in  $c$  at the current moment.

**Learning algorithm.** Given an utterance-scene pair  $(U^{(t)}, S^{(t)})$  received at time  $t$ , the model first calculates an alignment score  $a$  for each word  $w \in U^{(t)}$  and each semantic feature  $f \in S^{(t)}$ . A semantic feature can be aligned to a word according to the meaning acquired for that word from previous observations (word-based alignment, or  $a_w$ ). Alternatively, distributional clues of the word can be used to determine its category, and the semantic features can be aligned to the word according to the meaning associated to its category (category-based alignment, or  $a_c$ ). We combine these two sources of evidence when estimating an alignment score:

$$a(w|f, U^{(t)}, S^{(t)}) = \lambda(w) \times a_w(w|f, U^{(t)}, S^{(t)}) + (1 - \lambda(w)) \times a_c(w|f, U^{(t)}, S^{(t)}) \quad (1)$$

where the word-based and category-based alignment scores are estimated based on the acquired meanings of the word and its category, respectively:

$$a_w(w|f, U^{(t)}, S^{(t)}) = \frac{p^{(t-1)}(f|w)}{\sum_{w_k \in U^{(t)}} p^{(t-1)}(f|w_k)}$$

$$a_c(w|f, U^{(t)}, S^{(t)}) = \frac{p^{(t-1)}(f|\text{cat}(w))}{\sum_{w_k \in U^{(t)}} p^{(t-1)}(f|\text{cat}(w_k))}$$

The relative contribution of the word-based versus the category-based alignment is determined by the weight function  $\lambda(w)$ . Cross-situational evidence is a reliable cue for frequent words; on the other hand, the category-based score is most informative when the model encounters a low-frequency word (See Alishahi and Fazly (2010) for a full analysis of the frequency effect). Therefore, we define  $\lambda(w)$  as a function of the frequency of the word  $n(w)$ :

$$\lambda(w) = n(w)/(n(w) + 1)$$

Once an alignment score is calculated for each word  $w \in U^{(t)}$  and each feature  $f \in S^{(t)}$ , the model revises the meanings of all the words in  $U^{(t)}$  and

their corresponding categories as follows:

$$\text{assoc}^{(t)}(w, f) = \text{assoc}^{(t-1)}(w, f) + a(w|f, U^{(t)}, S^{(t)})$$

where  $\text{assoc}^{(t-1)}(w, f)$  is zero if  $w$  and  $f$  have not co-occurred before. These association scores are then used to update the meaning of the words in the current input:

$$p^{(t)}(f|w) = \frac{\text{assoc}^{(t)}(f, w)}{\sum_{f_j \in \mathcal{F}} \text{assoc}^{(t)}(f_j, w)} \quad (2)$$

where  $\mathcal{F}$  is the set of all features seen so far. We use a smoothed version of this formula to accommodate noisy or rare input. This process is repeated for all the input pairs, one at a time.

**Uniform categories.** Adding the category-based alignment as a new factor to Eqn. (1) might imply that the role of categories in this model is nothing more than smoothing the cross-situational-based alignment of words and referents. In order to investigate this issue, we use the following alignment formula as an informed baseline in our experiments, where we replace  $a_c(\cdot|f, U^{(t)}, S^{(t)})$  with a uniform distribution:<sup>1</sup>

$$a(w|f, U^{(t)}, S^{(t)}) = \lambda(w) \times a_w(w|f, U^{(t)}, S^{(t)}) + (1 - \lambda(w)) \times \frac{1}{|U^{(t)}|} \quad (3)$$

where  $a_w(w|f, U^{(t)}, S^{(t)})$  and  $\lambda(w)$  are estimated as before. In our experiments in Section 4, we refer to this baseline as the ‘uniform’ condition.

### 3 Online induction of word classes with LDA

Empirical findings suggest that young children form their knowledge of abstract categories, such as verbs, nouns, and adjectives, gradually (e.g. Gelman and Taylor 1984, Kemp et al. 2005). In addition, several unsupervised computational models have been proposed for inducing categories of words which resemble part-of-speech categories, by

<sup>1</sup>We thank an anonymous reviewers for suggesting this condition as an informed baseline.

drawing on distributional properties of their context (see for example Redington et al. 1998, Clark 2000, Mintz 2003, Parisien et al. 2008, Chrupała and Alishahi 2010). However, explicit accounts of how such categories can be integrated in a cross-situational model of word learning have been rare. Here we adopt an online version of the model proposed in Chrupała (2011), a method of soft word class learning using Latent Dirichlet Allocation. The approach is much more efficient than the commonly used alternative (Brown clustering, (Brown et al. 1992)) while at the same time matching or outperforming it when the word classes are used as automatically learned features for supervised learning of various language understanding tasks. Here we adopt this model as our approach to learning lexical categories.

In Section 3.1 we describe the LDA model for word classes; in Section 3.2 we discuss the online Gibbs sampler we use for inference.

### 3.1 Word class learning with LDA

Latent Dirichlet Allocation (LDA) was introduced by Blei et al. (2003) and is most commonly used for modeling the topic structure in document collections. It is a generative, probabilistic hierarchical Bayesian model that induces a set of latent variables, which correspond to the topics. The topics themselves are multinomial distributions over words.

The generative structure of the LDA model is the following:

$$\begin{aligned}
 \phi_k &\sim \text{Dirichlet}(\beta), & k &\in [1, K] \\
 \theta_d &\sim \text{Dirichlet}(\alpha), & d &\in [1, D] \\
 z_{n_d} &\sim \text{Categorical}(\theta_d), & n_d &\in [1, N_d] \\
 w_{n_d} &\sim \text{Categorical}(\phi_{z_{n_d}}), & n_d &\in [1, N_d]
 \end{aligned} \tag{4}$$

Chrupała (2011) reinterprets the LDA model in terms of word classes as follows:  $K$  is the number of classes,  $D$  is the number of unique word types,  $N_d$  is the number of context features (such as right or left neighbor) associated with word type  $d$ ,  $z_{n_d}$  is the class of word type  $d$  in the  $n_d^{\text{th}}$  context, and  $w_{n_d}$  is the  $n_d^{\text{th}}$  context feature of word type  $d$ . Hyperparameters  $\alpha$  and  $\beta$  control the sparseness of the vectors  $\theta_d$  and  $\phi_k$ .

Wordtype	Features		
How	do <sub>R</sub>		
do	How <sub>L</sub>	you <sub>R</sub>	you <sub>L</sub>
you	do <sub>L</sub>	do <sub>R</sub>	

Table 1: Matrix of context features

1.8M words (CHILDES)		100M words (BNC)	
train	car	can	will
give	bring	June	March
shoes	clothes	man	woman
book	hole	black	white
monkey	rabbit	business	language

Table 2: Most similar word pairs

As an example consider the small corpus consisting of the single sentence *How do you do*. The rows in Table 1 show the features  $w_1 \dots w_{N_d}$  for each word type  $d$  if we use each word’s left and right neighbors as features, and subscript words with  $L$  and  $R$  to indicate left and right.

After inference, the  $\theta_d$  parameters correspond to word class probability distributions given a word type while the  $\phi_k$  correspond to feature distributions given a word class: the model provides a probabilistic representation for word types independently of their context, and also for contexts independently of the word type.

Probabilistic, *soft* word classes are more expressive than hard categories. First, they make it easy and efficient to express shared ambiguities: Chrupała (2011) gives an example of words used as either first names or surnames, and this shared ambiguity is reflected in the similarity of their word class distributions. Second, with soft word classes it becomes easy to express graded similarity between words: as an example, Table 2 shows a random selection out of the 100 most similar word pairs according to the Jensen-Shannon divergence between their word class distributions, according to a word class model with 25 classes induced from (i) 1.8 million words of the CHILDES corpus or (ii) 100 million word of the BNC corpus. The similarities were measured between each of the 1000 most frequent CHILDES or BNC words.

### 3.2 Online Gibbs sampling for LDA

There have been a number of attempts to develop online inference algorithms for topic modeling with LDA. A simple modification of the standard Gibbs sampler (**o-LDA**) was proposed by Song et al. (2005) and Banerjee and Basu (2007).

Canini et al. (2009) experiment with three sampling algorithms for online topic inference: (i) **o-LDA**, (ii) incremental Gibbs sampler, and (iii) a particle filter. Only **o-LDA** is truly online in the sense that it does not revisit previously seen documents. The other two, the incremental Gibbs sampler and the particle filter, keep seen documents and periodically resample them. In Canini et al.’s experiments all of the online algorithms perform worse than the standard batch Gibbs sampler on a document clustering task.

Hoffman et al. (2010) develop an online version of the variational Bayes (VB) optimization method for inference for topic modeling with LDA. Their method achieves good empirical results compared to batch VB as measured by perplexity on held-out data, especially when used with large minibatch sizes.

Online VB for LDA is appropriate when streaming documents: with online VB documents are represented as word count tables. In our scenario where we apply LDA to modeling word classes we need to process context features from sentences arriving in a stream: i.e. we need to sample entries from a table like Table 1 in order of arrival rather than row by row. This means that online VB is not directly applicable to online word-class induction.

However it also means that one issue with **o-LDA** identified by Canini et al. (2009) is ameliorated. When sampling in a topic modeling setting, documents are unique and are never seen again. Thus, the topics associated with old documents get *stale* and need to be periodically *rejuvenated* (i.e. resampled). This is the reason why the incremental Gibbs sampler and the particle filter algorithms in Canini et al. (2009) need to keep old documents around and cannot run in a true online fashion. Since for word class modeling we stream context features as they arrive, we will continue to see features associated with the seen word types, and will automatically resample their class assignments. In exploratory ex-

periments we have seen that this narrows the performance gap between the **o-LDA** sampler and the batch collapsed Gibbs sampler.

We present our version of the **o-LDA** sampler in Algorithm 1. For each incoming sentence  $t$  we run  $J$  passes of sampling, updating the counts tables after each sampling step. We sample the class assignment  $z_{t_i}$  for feature  $w_{t_i}$  according to:

$$P(z_t | \mathbf{z}_{t-1}, \mathbf{w}_t, \mathbf{d}_t) \propto \frac{(n_{t-1}^{z_t, d_t} + \alpha) \times (n_{t-1}^{z_t, w_t} + \beta)}{\sum_{j=1}^{V_{t-1}} n_{t-1}^{z_t, w_j} + \beta}, \quad (5)$$

where  $n_t^{z,d}$  stands for the number of times class  $z$  co-occurred with word type  $d$  up to step  $t$ , and similarly  $n_t^{z,w}$  is the number of times feature  $w$  was assigned to class  $z$ .  $V_t$  is the number of unique features seen up to step  $t$ , while  $\alpha$  and  $\beta$  are the LDA hyperparameters. There are two differences between the original **o-LDA** and our version: we do not initialize the algorithm with a batch run over a prefix of the data, and we allow more than one sampling pass per sentence.<sup>2</sup> Exploratory experiments have shown that batch initialization is unnecessary, and that multiple passes typically improve the quality of the induced word classes.

---

**Algorithm 1** Online Gibbs sampler for word class induction with LDA

---

```

for  $t = 1 \rightarrow \infty$  do
  for  $j = 1 \rightarrow J$  do
    for  $i = 1 \rightarrow I_t$  do
      sample  $z_{t_i} \sim P(z_{t_i} | \mathbf{z}_{t_i-1}, \mathbf{w}_{t_i}, \mathbf{d}_{t_i})$ 
      increment  $n_t^{z_{t_i}, w_{t_i}}$  and  $n_t^{z_{t_i}, d_{t_i}}$ 

```

---

Figure 1 shows the top 10 words for each of the 10 word classes induced with our online Gibbs sampler from 1.8 million words of CHILDES. Similarly, Figure 2 shows the top 10 words for 5 randomly chosen topics out of 50, learned online from 100 million words of the BNC.

The topics are relatively coherent and at these levels of granularity express mostly part of speech and subcategorization frame information.

Note that for each word class we show the words most frequently assigned to it while Gibbs sampling.

---

<sup>2</sup>Note that we do not allow multiple passes over the stream of sentences. Rather, while processing the current sentence, we allow the words in this sentence to be sampled more than once.

do are have can not go put did get play

the his her their this an that its your my

Figure 2: Top 10 words of 5 randomly chosen classes learned from BNC

Since we are dealing with soft classes, most word-types have non-zero assignment probabilities for many classes. Thus frequently occurring words such as *not* will typically be listed for several classes.

## 4 Evaluation

### 4.1 Experimental setup

As training data, we extract utterances from the Manchester corpus (Theakston et al. 2001) in the CHILDES database (MacWhinney 1995), a corpus that contains transcripts of conversations with children between the ages of 1 year, 8 months and 3 years. We use the mother’s speech from transcripts of 12 children (henceforth referred to by children’s names).

We run word class induction while simultaneously outputting the highest scoring word-class label for each word: for a new sentence, we sample class assignments for each feature (doing  $J$  passes), update the counts, and then for each word  $d_{t_i}$  output the highest scoring class label according to  $\text{argmax}_z n_t^{z, d_{t_i}}$  (where  $n_t^{z, d_{t_i}}$  stands for the num-

ber of times class  $z$  co-occurred with word type  $d_{t_i}$  up to step  $t$ ).

During development we ran the online word class induction module on data for Aran, Becky, Carl and Anne and then started the word learning module for the Anne portion while continuing inducing categories. We then evaluated word learning on Anne. We chose the parameters of the word class induction module based on those development results:  $\sum_{i=1}^K \alpha = 10$ ,  $\beta = 0.1$ ,  $K = 10$  and  $J = 20$ .

We used cross-validation for the final evaluation. For each of six data files (Anne, Aran, Becky, Carl, Dominic and Gail), we ran word-class induction on the whole corpus with the chosen file last, and then started applying the word-learning algorithm on this last chosen file (while continuing with category induction). We evaluated how well word meanings were learned in those six cases.

We follow Alishahi and Fazly (2010) in the construction of the input. We need a semantic representation paired with each utterance. Such a representation is not available from the corpus and has to be constructed. We automatically construct a gold lexicon for all nouns and verbs in this corpus as follows. For each word, we extract all hypernyms for its first sense in the appropriate (verb or noun) hierarchy in WordNet (Fellbaum 1998), and add the first word in the synset of each hypernym to the set of semantic features for the target word. For verbs, we also extract features from VerbNet (Kipper et al. 2006). A small subset of words (pronouns and frequent quantifiers) are also manually added. This lexicon represents the *true* meaning of each word, and is used in generating the scene representations in the input and in evaluation.

For each utterance in the input corpus, we form the union of the feature representations of all its words. Words not found in the lexicon (i.e. for which we could not extract a semantic representation from WordNet and VerbNet) are removed from the utterance (only for the word learning module).

In order to simulate the high level of noise that children receive from their environment, we follow Alishahi and Fazly (2010) and pair each utterance with a combination of its own scene representation and the scene representation for the following utterance. This decision was based on the intuition that consequent utterances are more likely to be about re-

<b>Utterance:</b>	{ <i>mommy, ate, broccoli</i> }
<b>Scene:</b>	{ ANIMATE, HUMAN, ..., CONSUMPTION, ACTION, ... BROCCOLI, VEGETABLE, ... PLATE, OBJECT, ... }

Figure 3: A sample input item to the word learning model

lated topics and scenes. This results in a (roughly) 200% ambiguity. In addition, we remove the meaning of one random word from the scene representation of every second utterance in an attempt to simulate cases where the referent of an uttered word is not within the perception field (such as ‘daddy is not home yet’). A sample utterance and its corresponding scene are shown in Figure 3.

As mentioned before, many words in our input corpus are polysemous. For such words, we extract different sets of features depending on their manually tagged part of speech and keep them in the lexicon (e.g. the lexicon contains two different entries for *set:N* and *set:V*). When constructing a scene representation for an utterance which contains an ambiguous word, we choose the correct sense from our lexicon according to the word’s part of speech tag in Manchester corpus.

In the experiments reported in the next section, we assess the performance of our model on learning words at each point in time: for each target word, we compare its set of features in the lexicon with its probability distribution over the semantic features that the model has learned. We use mean average precision (MAP) to measure how well  $p^{(t)}(\cdot|w)$  ranks the features of  $w$ .

## 4.2 Learning curves

To understand whether our categories contribute to learning of word–meaning mappings, we compare the pattern of word learning over time in four conditions. The first condition represents our baseline, in which we do not use category-based alignment in the word learning model by setting  $\lambda(w) = 1$  in Eqn. (1). In the second condition we use a set of uniformly distributed categories for alignment, as estimated by Eqn. (3) on page 3 (this condition is introduced to examine whether categories act as more than a simple smoothing factor in the align-

Category	Avg. MAP	Std. Dev.
None	0.626	0.032
Uniform	0.633	0.032
LDA	0.659	0.029
POS	0.672	0.030

Table 3: Final Mean Average Precision scores

ment process.) In the third condition we use the categories induced by online LDA in the word learning model. The fourth condition represents the performance ceiling, in which we use the pre-defined and manually annotated part of speech categories from the Manchester corpus.

Table 3 shows the average and the standard deviation of the *final* MAP scores across the six datasets, for the four conditions (no categories, uniform categories, LDA categories and gold part-of-speech tags). The differences between LDA and None, and between LDA and Uniform are statistically significant according to the paired  $t$  test ( $p < 0.01$ ), while the difference between LDA and POS is not ( $p = 0.16$ ).

Figure 4 shows the learning curves in each condition, averaged over the six splits explained in the previous section. The top panel shows the average learning curve over the minimum number of sentences across the six sub-corpora (8800 sentences). The curves show that our LDA categories significantly improve the performance of the model over both baselines. That means that using these categories can improve word learning compared to not using them and relying on cross-situational evidence alone. Moreover, LDA-induced categories are not merely acting as a smoothing function the way the ‘uniform’ categories are. Our results show that they are bringing relevant information to the task at hand, that is, improving word learning by using the sentential context. In fact, this improvement is comparable to the improvement achieved by integrating the ‘gold-standard’ POS categories.

The middle and bottom panels of Figure 4 zoom in on shorter time spans (5000 and 1000 sentences, respectively). These diagrams suggest that the pattern of improvement over baseline is relatively constant, even at very early stages of learning. In fact, once the model receives enough input data, cross-situational evidence becomes stronger (since fewer

words in the input are encountered for the first time) and the contribution of the categories becomes less significant.

### 4.3 Class granularity

In Figure 5 we show the influence of the number of word classes used on the performance in word learning. It is evident that in the range between 5 to 20 classes the performance of the word learning module is quite stable and insensitive to the exact class granularity. Even with only 5 classes the model can still roughly distinguish noun-like words from verb-like words from pronoun-like words, and this will help learn the meaning elements derived from the higher levels of WordNet hierarchy. Notwithstanding that, ideally we would like to avoid having to pre-specify the number of classes for the word class induction module: we thus plan to investigate non-parametric models such as Hierarchical Dirichlet Process for this purpose.

## 5 Related Work

This paper investigates the interplay between two language learning tasks which have so far been studied in isolation: the acquisition of lexical categories from distributional clues, and learning the mapping between words and meanings. Previous models have shown that lexical categories can be learned from unannotated text, mainly drawing on distributional properties of words (e.g. Redington et al. 1998, Clark 2000, Mintz 2003, Parisien et al. 2008, Chrupała and Alishahi 2010).

Independently, several computational models have exploited cross-situational evidence in learning the correct mappings between words and meanings, using rule-based inference (Siskind 1996), neural networks (Li et al. 2004, Regier 2005), hierarchical Bayesian models (Frank et al. 2007) and probabilistic alignment inspired by machine translation models (Yu 2005, Fazly et al. 2010).

There are only a few existing computational models that explore the role of syntax in word learning. Maurits et al. (2009) investigates the joint acquisition of word meaning and word order using a batch model. This model is tested on an artificial language with a simple first order predicate representation of meaning, and limited built-in possibilities for word

Figure 4: Mean average precision for all observed words at each point in time for four conditions: with gold POS categories, with LDA categories, with uniform categories, and without using categories. Each panel displays a different time span.

Figure 5: Mean average precision for all observed words at each point in time in four conditions: using online LDA categories of varying numbers of 20, 10 and 5, and without using categories.

order. The model of Niyogi (2002) simulates the mutual bootstrapping effects of syntactic and semantic knowledge in verb learning, that is the use of syntax to aid in inducing the semantics of a verb, and the use of semantics to narrow down possible syntactic frames in which a verb can participate. However, this model relies on manually assigned priors for associations between syntactic and semantic features, and is tested on a toy language with very limited vocabulary and a constrained syntax.

Yu (2006) integrates automatically induced syntactic word categories into his model of cross-situational word learning, showing that they can improve the model’s performance. Yu’s model also processes input utterances in a batch mode, and its evaluation is limited to situations in which only a coarse distinction between referring words (words that could potentially refer to objects in a scene, e.g. concrete nouns) and non-referring words (words that cannot possibly refer to objects, e.g. function words) is sufficient. It is thus not clear whether information about finer-grained categories (e.g. verbs and nouns) can indeed help word learning in a more naturalistic incremental setting.

On the other hand, the model of Alishahi and Fazly (2010) integrates manually annotated part-of-speech tags into an incremental word learning algorithm, and shows that these tags boost the over-

all word learning performance, especially for infrequent words.

In a different line of research, a number of models have been proposed which study the acquisition of the link between syntax and semantics within the Combinatory Categorical Grammar (CCG) framework (Briscoe 1997, Villavicencio 2002, Buttery 2006, Kwiatkowski et al. 2012). These approaches set the parameters of a semantic parser on a corpus of utterances paired with a logical form as their meaning.

These models bring in extensive and detailed prior assumptions about the nature of the syntactic representation (i.e. atomic categories such as S and NP, and built-in rules which govern their combination), as well as about the representation of meaning via the formalism of lambda calculus.

This is fundamentally different than the approach taken in this paper, which in comparison only assumes very simple syntactic and semantic representations of syntax. We view word and category learning as stand-alone cognitive tasks with independent representations (word meanings as probabilistic collections of properties or features as opposed to single symbols; categories as sets of word tokens with similar context distribution) and we do not bring in any prior knowledge of specific atomic categories.

## 6 Conclusion

In this paper, we show the plausibility of using automatically and incrementally induced categories while learning word meanings. Our results suggest that the sentential context that a word appears in across its different uses can be used as a complementary source of guidance for mapping it to its featural meaning representation.

In Section 4 we show that the improvement achieved by our categories is comparable to that gained by integrating gold POS categories. This result is very encouraging, since manually assigned POS tags are typically believed to set the upper bound on the usefulness of category information.

We believe that it automatically induced categories have the potential to do even better: Chrupala and Alishahi (2010) have shown that categories induced from usage data in an unsupervised fashion can be used more effectively than POS categories in

a number of tasks. In our experiments here on the development data we observed some improvements over POS categories. This advantage can result from the fact that our categories are more fine-grained (if also more noisy) than POS categories, which sometimes yields more accurate predictions.

One important characteristic of the category induction algorithm we have used in this paper is that it provides a *soft* categorization scheme, where each word is associated with a probability distribution over all categories. In future, we plan to exploit this feature: when estimating the category-based alignment, we can interpolate predictions of multiple categories to which a word belongs, weighted by its probabilities associated with membership in each category.

## Abstract

This paper presents a comparative study of graph-based approaches for cross-domain sentiment classification. In particular, the paper analyses two existing methods: an optimisation problem and a ranking algorithm. We compare these graph-based methods with each other and with the other state-of-the-art approaches and conclude that graph domain representations offer a competitive solution to the domain adaptation problem. Analysis of the best parameters for graph-based algorithms reveals that there are no optimal values valid for all domain pairs and that these values are dependent on the characteristics of corresponding domains.

## 1 Introduction

The sentiment classification (SC) is an active area of research concerned automatic identification of sentiment strength or valence of texts. SC of product reviews is commercially important and widely researched but it typically needs to be optimised separately for each type of product (i.e. domain). When domain-specific data are absent or insufficient the researchers usually seek solution in semi-supervised, unsupervised or cross-domain approaches. In this paper, we focus on cross-domain methods in order to take advantage of the huge amount of annotated sentiment data available on the Internet. Our aim is to find out to what extent it is possible to learn sentiment phenomena from these data and transfer them to new domains rather than induce them from scratch for each new domain.

Previous research has shown that models trained on one data usually give much worse results on another, especially when both data sets belong to completely different domains. This is largely because the sentiment words and their valences depend a lot on the domain where they are expressed. The first problem concerns the words that can convey opposite sentiments with respect to the context or domain. For example, a word “ridiculous” in book reviews may express a negative meaning when talking about a book content, however for reviews on electronics this word can bear a positive meaning when talking about prices. Another and more common problem is related to sentiment words that are specific for each domain. For instance, words like “boring”, “inspiring”, “engaging” are very common in book reviews but it is almost impossible to find them in reviews on electronics. At the same time, the electronics domain can contain words like “defective”, “refund”, “return”, “customer service”, which are very unusual for book reviews.

Several cross-domain approaches have been suggested recently to solve the problem of accuracy loss in cross-domain sentiment classification, namely Structural Correspondence Learning (SCL) (Blitzer et al., 2007), the graph-based approach (Wu et al., 2009) and Spectral Feature Alignment (SFA) (Pan et al., 2010). In this paper, we explore graph-based algorithms which refer to a group of techniques that model data as a graph of documents. This data representation takes into account not only document contents but also document connectivity which is modeled as document sentiment similarity rather than content similarity. Our interest in graph

algorithms is two-fold. First, graph-based domain representations can benefit from two independent sources of information: scores given by a machine learning technique which indicate the probability of a document to belong to a sentiment class and similarity relations between documents. Second, unlike other suggested methods, this approach can be easily adapted to multiple classes, which makes it possible to classify documents using finer-grained sentiment scales.

Different graph-based algorithms have been applied to several SA tasks (Pang and Lee, 2005; Goldberg and Zhu, 2006; Wu et al., 2009), but no comparison has been made to find the most appropriate one for SC. Moreover, in the framework of the domain adaption task, we come across the problem of choosing the best set of parameters, which, as we further demonstrate, depends on the characteristics of a corresponding domain pair. Unfortunately, no study has investigated this problem. (Pang and Lee, 2005; Goldberg and Zhu, 2006) exploited the graph-based approach for a semi-supervised task and experimented with data belonging to one domain and, therefore did not come across this issue. The work of (Wu et al., 2009) lacks any discussion about the choice of the parameter values; the authors set some values equal for all domains without mentioning how they obtained these numbers.

The present research brings several contributions. First, we compare two graph-based algorithms in cross-domain SC settings: the algorithm exploited in (Goldberg and Zhu, 2006), which seeks document sentiments as an output of an optimisation problem (OPTIM) and the algorithm adopted by (Wu et al., 2009), that uses ranking to assign sentiment scores (RANK). Second, as document similarity is a crucial factor for satisfactory performance of graph-based algorithms, we suggest and evaluate various sentiment similarity measures. Sentiment similarity is different from topic similarity as it compares documents with respect to the sentiment they convey rather than their topic. Finally, we discover the dependency of algorithm parameter values on domain properties and, subsequently, the impossibility to find universal parameter values suitable for all domain pairs. We discuss a possible strategy for choosing the

best set of parameters based on our previous study (Ponomareva and Thelwall, 2012), where we introduced two domain characteristics: domain similarity and domain complexity and demonstrated their strong correlation with cross-domain accuracy loss.

The rest of the paper is structured as follows. In Section 2 we give a short overview of related works on cross-domain SC. Section 3 describes and compares the OPTIM and RANK algorithms. In Section 4 we discuss an issue of document similarity and select document representation that correlates best with document sentiments. Experimental results are described in Section 5 followed by a discussion on the strategy for choosing the best parameter values of the algorithms (Section 6). Finally, in Section 7 we summarise our contributions and discuss further research.

## 2 Related work

Cross-domain sentiment analysis has received considerable attention during the last five years and, since then, several approaches to tackle this problem have emerged. The most straightforward approach is to use an ensemble of classifiers as tested in several works (Aue and Gamon, 2005; Li and Zong, 2008). It is a well-explored technique in machine learning concerned with training classifiers on domains where annotated data are available and then, combining them in ensembles for the classification of target data. Aue and Gamon (2005) studied several possibilities to combine data from domains with known annotations and came up with the conclusion that an ensemble of classifiers in a meta-classifier gives higher performance than a simple merge of all features.

Structural Correspondence Learning (SCL) (Blitzer et al., 2007) is another domain transfer approach, which was also tested on parts of speech (PoS) tagging (Blitzer et al., 2006). Its underlying idea is to find correspondences between features from source and target domains through modeling their correlations with pivot features. Pivot features are features occurring frequently in both domains, which, at the same time, serve as good predictors of document classes, like the general sentiment words “excellent” and “awful”. The extraction

of pivot features was made on the basis of their frequency in source and target corpora and their mutual information with positive and negative source labels. The correlations between the pivot features and all other features were modeled using a supervised learning of linear pivot predictors to predict occurrences of each pivot in both domains. The proposed approach was tested on review data from 4 domains (books, DVDs, kitchen appliances and electronics) and demonstrated a significant gain of accuracy for most domain pairs compared to the baseline. However, for a few domains the performance degraded due to feature misalignment: the narrowness of the source domain and diversity of the target domain created false projections of features in the target domain. The authors proposed to correct this misalignment with a small amount of annotated in-domain data.

Spectral Feature Alignment (SFA), introduced by Pan et al. (2010), holds the same idea as SCL, i.e., an alignment of source and target features through their co-occurrences with general sentiment words. But instead of learning representations of pivots in source and target domains the authors used spectral clustering to align domain-specific and domain-independent words into a set of feature-clusters. The constructed clusters were then used for the representation of all data examples and training the sentiment classifier. This new solution yields a significant improvement on cross-domain accuracy compared with SCL for almost all domain pairs.

The method suggested by Bollegala et al. (2011) also relies on word co-occurrences. In particular, the authors presented a method for automatic construction of a sentiment-sensitive thesaurus where each lexical element (either unigram or bigram) is connected to a list of related lexical elements which most frequently appear in the context expressing the same sentiment. This thesaurus is then used on the training step to expand feature vectors with related elements to overcome the feature mismatch problem. The method was tested on the same data set as SCL and SFA but unlike previous works the authors used a combination of domains to create sentiment-sensitive thesauri and to train the cross-domain classifier. They compare the accuracy of their approach with an average accuracy over the results

with the same target domain given by SCL and SFA, and concluded that their method surpasses all existing approaches. However, we think that such a comparison is not optimal. Indeed, using the approach described in (Ponomareva and Thelwall, 2012) we can choose the most appropriate data for training our classifier rather than averaging the results given by all data sets. Therefore, instead of average accuracies, the best accuracies with respect to the same target domain should be compared. This comparison leads to opposite conclusions, namely that SCL and SFA significantly outperform the sentiment-sensitive thesaurus-based method.

Unlike the approaches mentioned above, graph-based algorithms exploit relations between documents for finding the correct document scores. We describe them in more details in the next section.

### 3 Graph-based algorithms

In this section we present and compare 2 graph-based algorithms which use similar graph structures but completely different methods to infer node scores. The RANK algorithm (Wu et al., 2009) is based on node ranking, while OPTIM (Goldberg and Zhu, 2006) determines solution of graph optimisation problem. Initially OPTIM was applied for the rating-inference problem in a semi-supervised setting. This study, for the first time, analyses its behaviour for cross-domain SC and compares its performance with a similar approach.

#### 3.1 OPTIM algorithm

The OPTIM algorithm represents graph-based learning as described in (Zhu et al., 2003). Let us introduce the following notation:

- $G = (V, E)$  is an undirected graph with  $2n$  nodes  $V$  and weighted edges  $E$ .
- $L$  stands for labeled data (source domain data) and  $U$  for unlabeled data (target domain data).
- $x_i$  is a graph node which refers to a document,  $f(x_i)$  is a true label of a document which is supposed to be unknown even for annotated documents, allowing for noisy labels. Each  $x_i \in L$  is connected to  $y_i$  which represents a given rating of a document. The edge weight between  $x - i$  and  $y_i$  is a large number

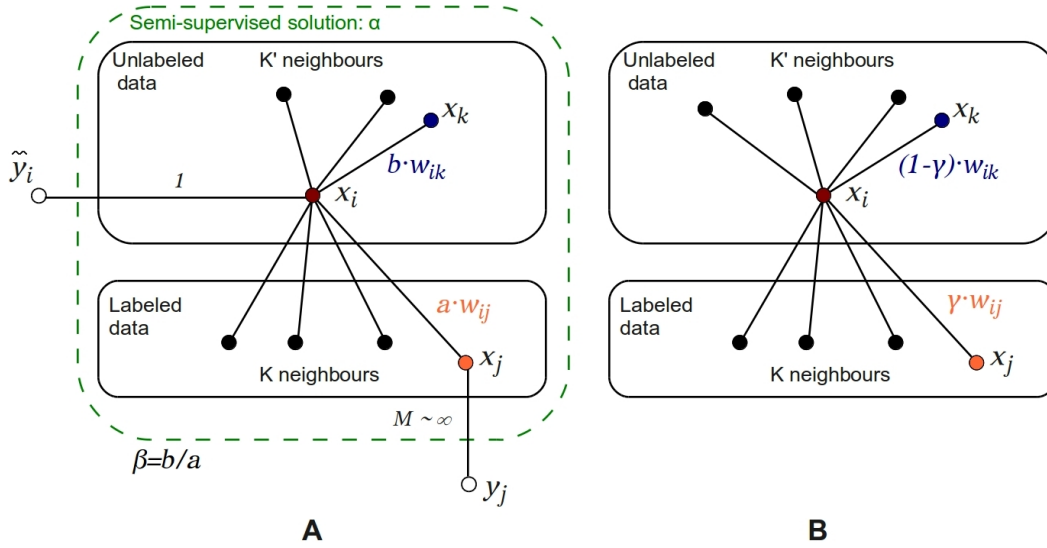

Figure 1: Graph models for the OPTIM (A) and RANK (B) algorithms

$M$  introducing the hard constraints between labeled documents and their ratings. Each  $x_i \in U$  is connected to  $\hat{y}_i$  that stands for predicted rating of a document. The edge weight between  $x_i$  and  $\hat{y}_i$  is equal to 1.

- Each unlabeled document  $x_i$  is connected to its  $k$  nearest labeled documents  $kNN_L(i)$  (source domain neighbours). The weight between  $x_i$  and  $x_j \in kNN_L(i)$  is measured by a given similarity  $w$  and denoted  $a \cdot w_{ij}$ .
- Each unlabeled document  $x_i$  is connected to its  $k'$  nearest unlabeled documents  $k'NN_U(i)$  (target domain neighbours). The weight between  $x_i$  and  $x_j \in k'NN_U(i)$  is denoted by  $b \cdot w_{ij}$ .

Figure 1A illustrates the graph structure described. The algorithm is based on the assumption that the rating function  $f(x)$  is smooth with respect to the graph, so there are no harsh jumps of sentiment between nearest neighbours. To satisfy the smoothness condition sentiment variability between the closest nodes should be minimised. Another requirement is to minimise the difference between each initial node rating and its final value, although in the case of unlabeled nodes this is optional. Taking into consideration the conditions mentioned the sentiment-inference problem can be formulated as an optimisation problem:

$$\begin{aligned} \mathcal{L}(f) = & \sum_{i \in L} M(f(x_i) - y_i)^2 + \sum_{i \in U} (f(x_i) - \hat{y}_i)^2 + \\ & \sum_{i \in U} \sum_{j \in kNN_L(i)} a w_{ij} (f(x_i) - f(x_j))^2 + \\ & \sum_{i \in U} \sum_{j \in k'NN_U(i)} b w_{ij} (f(x_i) - f(x_j))^2 \rightarrow \min \quad (1) \end{aligned}$$

After the substitutions  $\alpha = ak + bk'$  and  $\beta = \frac{b}{a}$  the final optimisation problem can be written as:

$$\begin{aligned} \mathcal{L}(f) = & \sum_{i \in L} M(f(x_i) - y_i)^2 + \sum_{i \in U} [(f(x_i) - \hat{y}_i)^2 + \\ & \frac{\alpha}{k + \beta k'} \left( \sum_{j \in kNN_L(i)} w_{ij} (f(x_i) - f(x_j))^2 + \right. \\ & \left. \sum_{j \in k'NN_U(i)} \beta w_{ij} (f(x_i) - f(x_j))^2 \right)] \rightarrow \min \quad (2) \end{aligned}$$

where  $\beta$  defines the relative weight between labeled and unlabeled neighbours, while  $\alpha$  controls the weight of the graph-based solution with respect to the primarily obtained supervised sentiment scores.

The minimum-loss function which gives the solution of the optimisation problem can be found by setting the gradient to zero. For more details on the problem solution see (Goldberg and Zhu, 2006).

### 3.2 RANK algorithm

The RANK algorithm has a similar graph structure (Figure 1B): nodes represent labeled and unlabeled documents and there is a parameter (in this case  $\gamma$ ) that controls the relative importance of labeled data over unlabeled data and is an analogue of  $\beta$  in OPTIM. The weight of edges between different nodes is also measured by document similarity. However, there are no edges between nodes and their initial sentiments because RANK is an iterative algorithm and each iteration gives new scores to unlabeled nodes while labeled nodes remain constant. More precisely, on each iteration sentiment scores of unlabeled documents are updated on the basis of the weighted sum of sentiment scores of the nearest labeled neighbours and the nearest unlabeled neighbours. The process stops when convergence is achieved, i.e. the difference in sentiment scores is less than a predefined tolerance.

Using the same notation as for OPTIM we can formulate the iterative procedure in the following way:

$$f_k(x_i) = \sum_{j \in kNN_L(i)} \gamma w_{ij} f(x_j) + \sum_{j \in k'NN_U(i)} (1 - \gamma) w_{ij} f_{k-1}(x_j) \quad (3)$$

where  $f_k(x_i)$  is the node sentiment score on the  $k$ -th iteration. Document scores are normalised after each iteration to ensure convergence (Wu et al., 2009). It is worth noting that initially the authors did not consider having a different number of neighbours for the source and target domains.

Analysing differences in the graph structures and assumptions of both models we can say that they are almost identical. Even the smoothness condition holds for the RANK algorithm as the score of a node is an averaged sum of the neighbours. The only principal difference concerns the requirement of closeness of initial and final sentiment scores for

OPTIM. This condition gives more control on the stability of the algorithm performance.

## 4 Measure of document similarity

A good measure of document similarity is a key factor for the successful performance of graph-based algorithms. In this section we propose and evaluate several measures of document similarity based on different vector representations and the cosine of document vectors.

Following (Goldberg and Zhu, 2006) and (Pang and Lee, 2005) we consider 2 types of document representations:

- **feature-based:** this involves weighted document features. The question here concerns the features to be selected. When machine learning is employed the answer is straightforward: the most discriminative features are the best ones for our task. However, we assume that we do not know anything about the domain when measuring sentiment similarity and, thus, we should establish the appropriate set of features only relying on our prior knowledge about sentiment words. According to previous studies, adjectives, verbs and adverbs are good indicators of sentiment (Pang and Lee, 2008), therefore, we keep only unigrams and bigrams that contain these PoS. We test two feature weights - tfidf and idf ( $F_{tfidf}$  and  $F_{idf}$  in Table 1 respectively). The evident drawback of such a vector representation concerns the discarding of nouns, which in many cases also bear sentiments. To overcome this issue we introduce a new measure that uses sentiment dictionaries to add nouns expressing sentiments ( $F_{idf+SOCAL}$ ).

- **lexicon-based:** uses sentiment dictionaries to assign scores to lexical elements of two types: words or sentences. The dimension of the corresponding document vector representation conforms with the granularity of the sentiment scale. For example, in case of binary sentiment scales, a document vector consists of two dimensions, where first component corresponds to the percentage of positive words (sentences) and the second component - to the percentage of negative words (sentences). To assign sentiment scores to lexical elements we exploit different sentiment resources, namely

domain	$F_{tfidf}$	$F_{idf}$	$F_{idf+SOCAL}$	$W_2$	$W_{10}$	$S_2$
BO	0.61	0.62	0.64	0.49	0.50	0.44
DV	0.61	0.61	0.64	0.56	0.56	0.51
EL	0.62	0.66	0.68	0.47	0.49	0.46
KI	0.65	0.67	0.68	0.51	0.54	0.53

Table 1: Correlation for various similarity measures with sentiment scores of documents across different domains.

SentiWordNet (Esuli and Sebastiani, 2006), SO-CAL (Taboada et al., 2010) and SentiStrength (Thelwall et al., 2012). The scores of sentences are averaged by the number of their positive and negative words. Preliminary experiments show a big advantage of SO-CAL-dictionaries comparing with other resources. SentiWordNet demonstrates quite an unsatisfactory performance, while SentiStrength, being very precise, has an insufficient scope and, therefore, finds no sentiment in a substantial number of documents.

The best document representation is selected on the basis of its correlation with the sentiment scores of documents. To compute correlations for feature-based measures, we take 1000 features with highest average tfidf weights. Table 1 gives the results of a comparison for two document representations and their different settings. Here  $W_2$  and  $S_2$  stand for word-based and sentence-based representations of dimension 2 and  $W_{10}$  - for word-based representation of dimension 10. All use SO-CAL-dictionaries to assign scores to words or sentences. Feature-based representations demonstrate significantly better correlations with document sentiments although for some domains, like DV, the lexical element-based representation produces a similar result. Integration of SO-CAL-dictionaries gives insignificant contribution into the overall correlation, which maybe due to the limited number of features participated in the analysis. In our further experiments we use both  $F_{idf}$  and  $F_{idf+SOCAL}$  document representations.

## 5 Experimental results

Our data comprises Amazon product reviews on 4 topics: books (BO), electronics (EL), kitchen (KI) and DVDs (DV), initially collected and described by Blitzer et al. (2007). Reviews are rated using a binary scale, 1-2 star reviews are considered as

negative and 4-5 star reviews as positive. The data within each domain are balanced: they contain 1000 positive and 1000 negative reviews.

First, we compute a baseline for each domain pair by training a Support Vector Machines (SVMs) classifier using one domain as training data and another as test data. We choose SVMs as our main learning technique because they have proved to be the best supervised algorithm for SC (Pang and Lee, 2008). In particular, we use the LIBSVM library (Chang and Lin, 2011) and a linear kernel function to train the classifier. For the feature set we experiment with different features and feature weights and conclude that unigrams and bigrams weighted with binary values yield the best performance.

Figure 2: Baseline accuracy for cross-domain SC. (x-axis - source domains, y-axis - target domains).

Figure 2 presents an isoline image of cross-domain accuracies for all domain pairs.<sup>1</sup> Products on the x-axis represent source domains and products

<sup>1</sup>We should point out that in the images the shading between points is not intended to suggest interpolation but is used to highlight the overall pattern. Of course the pattern depends on a domain order on the axes, therefore, similar domains are placed together to make the regions with high and low accuracies evident.

on the y-axis represent target domains. The isolines image of the baseline accuracy delivers a good representation of domain relations. In particular, we can observe two regions with the highest accuracy (EL-KI, KI-EL) and (BO-DV, DV-BO) and two regions with a big performance drop (EL-BO, EL-DV, KI-BO, KI-DV) and (BO-EL, BO-KI, DV-EL, DV-KI). As shown in our previous study (Ponomareva and Thelwall, 2012) the first two regions conform with the most similar domain pairs BO, DV and EL, KI.

OPTIM and RANK require the setting of several parameters:  $(k, k', \alpha, \beta)$  for OPTIM and  $(k, k', \gamma)$  for RANK. As it is computationally expensive to iterate over all possible values of parameters we first run the algorithms on a small matrix of parameters and then apply the gradient descent method which takes the values with highest accuracy as its starting points. We execute both algorithms with different similarity measures,  $F_{idf}$  and  $F_{idf+SOCAL}$ . In Table 2 OPTIM and RANK run with  $F_{idf}$ , while OPTIM+SOCAL and RANK+SOCAL run with  $F_{idf+SOCAL}$ . We give the best accuracies achieved by these algorithms for each domain pair. Unlike the correlations, the accuracies increase significantly with the integration of SO-CAL-dictionaries, the average improvement is about 3% for RANK and 1.5% for OPTIM. In general, RANK consistently outperforms OPTIM for all domain pairs, OPTIM shows competitive performance only for the pairs of similar domains BO-DV, KI-EL and EL-KI. We should also point out that OPTIM is more time-consuming as it requires expensive matrix operations. Due to these advantages of the RANK algorithm, we mostly focus on its analysis in the rest of the paper.

It is interesting to examine the performance of RANK on the basis of the 3D isolines image (Figure 3B). The isolines stretch from left to right indicating that accuracy is almost independent of the source domain. Such behaviour for RANK suggests a positive answer to our question stated in the title: even if domains are quite different, neighbours from the same domain will fix these discrepancies. This property is definitely a big advantage of the RANK algorithm in the context of the cross-domain task as it minimises the importance of the source domain. Obviously more experiments with different data

must be accomplished to prove this conclusion with a higher level of confidence.

We also compare graph-based algorithms with other state-of-the-art approaches, such as SCL and SFA (Table 2, Figure 3). The best results in Table 2 are highlighted and if the difference is statistically significant with  $\alpha = 0.05$  the corresponding accuracy is underlined. Note that we compare graph-based approaches against the others but not each other, therefore, if the result given by RANK is underlined it means that it is statistically significant only in comparison with SCL and SFA and not with OPTIM. According to Table 2, RANK surpasses SCL for almost all domain pairs with an average difference equal to 2%. Interestingly, without using SO-CAL-dictionaries RANK loses to both SCL and SFA for almost all domain pairs. The advantage of RANK over SFA is disputable as there is not much consistency about when one algorithm outperforms another, except that SFA is better overall for close domains. However Figure 3 suggests an interesting finding: that for domains with different complexities swapping source and target also changes the method that produces the best performance. A comparison of RANK and SCL on the Chinese texts given by (Wu et al., 2009) shows the same phenomenon. It seems that RANK works better when the target domain is simpler, maybe because it can benefit more from in-domain neighbours of the less rich and ambiguous domain. In the future, we plan to increase the impact of lexically different but reliably labeled source data by implementing the SFA algorithm and measuring document similarity between feature clusters rather than separate features.

## 6 Strategy for choosing optimal parameters

The results of the RANK and OPTIM algorithms presented in the previous section represent the highest accuracies obtained after running gradient descent method. Table 3 lists the best parameter values of the RANK algorithm over several domain pairs. Our attempt to establish some universal values valid for all domain pairs was not successful as the choice of the parameters depends upon the domain properties. Of course, in real life situations we do

source-target	baseline	OPTIM	RANK	OPTIM+SOCAL	RANK+SOCAL	SCL	SFA
BO-EL	70.0	74.0	77.2	74.4	<b>79.8</b>	77.5	72.5
BO-DV	76.5	78.6	77.4	79.9	79.8	75.8	<b>81.4</b>
BO-KI	69.5	74.6	78.6	77.3	<b>82.8</b>	78.9	78.8
DV-BO	74.4	78.8	78.9	80.5	<b>82.1</b>	79.7	77.5
DV-EL	67.2	73.6	78.8	74.4	<b>80.9</b>	74.1	76.7
DV-KI	70.2	75.6	80.4	77.3	<b>83.2</b>	81.4	80.8
EL-BO	65.5	67.8	69.9	69.5	73.6	75.4	<b>75.7</b>
EL-DV	71.3	74.2	72.6	75.6	77.0	76.2	<b>77.2</b>
EL-KI	81.6	83.6	83.2	85.7	85.3	85.9	<b>86.8</b>
KI-BO	64.7	68.4	70.9	69.7	<b>74.8</b>	68.6	<b>74.8</b>
KI-DV	70.1	72.3	72.4	73.4	<b>78.4</b>	76.9	77.0
KI-EL	79.7	82.6	81.9	83.7	83.7	<b>86.8</b>	85.1
average	71.7	75.3	76.9	76.8	<b>80.1</b>	78.1	78.7

Table 2: Comparison of different cross-domain algorithms

KI-BO	1.17	1.26	0.64
KI-DV	1.18	1.32	0.54
KI-EL	1.87	-0.67	0.76

Table 4: Similarity, complexity variance and  $\gamma$  averaged over the best results (confidence level of 95%) of the RANK algorithm. The values are given on various domain pairs

not have a knowledge of the parameter values which produce the best performance and, therefore, it would be useful to elaborate a strategy for choosing the optimal values with respect to a corresponding domain pair. In our previous work (Ponomareva and Thelwall, 2012) we introduced two domain characteristics: domain similarity and domain complexity variance and proved their impact into the cross-domain accuracy loss. Domain similarity and complexity are independent properties of a domain pair as the former measures similarity of data distributions for frequent words, while the latter compares the tails of distributions. In Ponomareva and Thelwall (2012), we tested various metrics to estimate these domain characteristics. As a result, inversed  $\chi^2$  was proved to be the best measure of domain similarity as it gave the highest correlation with the cross-domain accuracy drop. The percentage of rare words (words that occur less than 3 times) was found to be the closest approximation to domain complexity as it showed

the highest correlation with the in-domain accuracy drop.

It is naturally to assume that if domain similarity and complexity are responsible for the cross-domain accuracy loss, they might influence on the parameter values of domain adaptation algorithms. This is proved to be true for the  $\gamma$  parameter, whose values averaged over the top results of the RANK algorithm are listed in Table 4. We use the confidence interval of 95% to select the top values of  $\gamma$ . Table 4 shows that  $\gamma$  is the lowest for dissimilar domains with a simpler target (negative values of domain complexity variance), which means that the RANK algorithm benefits the most from unlabeled but simpler data.  $\gamma$  grows to values close to 0.6 for dissimilar domains with more complex target (positive values of domain complexity variance), which shows that the impact of simpler source data, though different from target, increases. Finally  $\gamma$  reaches its maximum for similar domains with the same level of complexity. Unfortunately, due to comparable amount of data for each domain, no cases of similar domains with different complexity are observed. We plan to study these particular cases in the future.

High dependency of  $\gamma$  on both domain characteristics is proved numerically. The correlation between  $\gamma$  and domain similarity and complexity reaches 0.91, and decreases drastically when one of these characteristics is ignored.

Concerning the optimal number of labeled and unlabeled neighbours, no regularity is evident (Table 3). In our opinion, that is an effect of choosing the neighbours on the basis of the quantitative threshold. Nevertheless, different domains have distinct pairwise document similarity distributions. Figure 4 demonstrates similarity distributions for BO, EL and DV inside and across domains. Therefore, taking into account only the quantitative threshold we ignore discrepancies

Figure 4: Pairwise document similarity distributions inside domains (A) and across domains (B)

in graph connectivities inside and across domains and may bring “bad” neighbours to participate in decision-making. In our further research we plan to explore the idea of a qualitative threshold, which chooses neighbours according to their similarity and uses the same similarity levels for in-domain and cross-domain graphs.

## 7 Conclusions and future work

This paper has studied the performance of two graph-based algorithms, OPTIM and RANK when applied to cross-domain sentiment classification. Comparison on their performance on the same data has revealed that, in spite of the similar graph structures, RANK consistently produces better results than OPTIM. We also have compared the graph-based algorithms with other cross-domain methods, including SCL and SFA, and concluded that RANK considerably outperforms SCL and obtains better results than SFA for half of the cases. Given that we consider only the best accuracies obtained with RANK, such comparison is not completely fair but it shows the potential of the RANK algorithm once the strategy for choosing its optimal parameters is established. In this paper, we also discuss some ideas about how to infer optimal parameter values for the algorithms on the basis of domain characteristics. In particular, the strong correlation for  $\gamma$  with domain similarity and complexity has been observed. Unfortunately we are not able to find any regularity in the number of source and target domain neighbours, which we think is the result of the qualitative approach to

selecting the closest neighbours.

As a result of this research we have identified the following future directions. First, we plan to improve the RANK performance by choosing the number of neighbours on the basis of the document similarity threshold which we set equal for both in-domain and cross-domain neighbours. We expect that this modification will diminish the number of “bad” neighbours and allow us to reveal a dependency of similarity threshold on some domain properties. Another research direction will focus on the integration of SFA into the similarity measure to overcome the problem of lexical discrepancy in the source and target domains. Finally, as all our conclusions have been drawn on a data set of 12 domain pairs, we plan to increase a number of domains to verify our findings on larger data sets.

## Abstract

This paper explores log-based query expansion (QE) models for Web search. Three lexicon models are proposed to bridge the lexical gap between Web documents and user queries. These models are trained on pairs of user queries and titles of clicked documents. Evaluations on a real world data set show that the lexicon models, integrated into a ranker-based QE system, not only significantly improve the document retrieval performance but also outperform two state-of-the-art log-based QE methods.

## 1 Introduction

Term mismatch is a fundamental problem in Web search, where queries and documents are composed using different vocabularies and language styles. Query expansion (QE) is an effective strategy to address the problem. It expands a query issued by a user with additional related terms, called *expansion terms*, so that more relevant documents can be retrieved.

In this paper we explore the use of clickthrough data and translation models for QE. We select expansion terms for a query according to how likely it is that the expansion terms occur in the title of a document that is relevant to the query. Assuming that a query is parallel to the titles of documents clicked for that query (Gao et al. 2010a), three lexicon models are trained on query-title pairs extracted from clickthrough data. The first is a word model that learns the translation probability between single words. The second model uses lexi-

calized triplets to incorporate word dependencies for translation. The third is a bilingual topic model, which represents a query as a distribution of hidden topics and learns the translation between a query and a title term at the semantic level. We will show that the word model provides a rich set of expansion candidates while the triplet and topic models can effectively select good expansion terms, and that a ranker-based QE system which incorporates all three of these models not only significantly improves Web search result but outperforms other log-based QE methods that are state-of-the-art.

There is growing interest in applying user logs to improve QE. A recent survey is due to Baeza-Yates and Ribeiro-Neto (2011). Below, we briefly discuss two log-based QE methods that are closest to ours and are re-implemented in this study for comparison. Both systems use the same type of log data that we used to train the lexicon models. The term correlation model of Cui et al. (2002; 2003) is to our knowledge the first to explore query-document relations for direct extraction of expansion terms for Web search. The method outperforms traditional QE methods that do not use log data e.g. the local analysis model of Xu and Croft (1996). In addition, as pointed out by Cui et al. (2003) there are three important advantages that make log-based QE a promising technology to improve the performance of commercial search engines. First, unlike traditional QE methods that are based on relevance feedback, log-based QE derives expansion terms from search logs, allowing term correlations to be pre-computed offline. Compared to methods that are based on thesauri either compiled manually (Prager et al. 2001) or derived au-

tomatically from document collections (Jing and Croft 1994), the log-based method is superior in that it explicitly captures the correlation between query terms and document terms, and thus can bridge the lexical gap between them more effectively. Second, since search logs retrain query-document pairs clicked by millions of users, the term correlations reflect the preference of the majority of users. Third, the term correlations evolve along with the accumulation of user logs, thus can reflect updated user interests at a specific time.

However, as pointed out by Riezler et al. (2008), Cui et al.’s correlation-based method suffers low precision of QE partly because the correlation model does not explicitly capture context information and is susceptible to noise. Riezler et al. developed a QE system by retraining a standard phrase-based statistical machine translation (SMT) system using query-snippet pairs extracted from clickthrough data (Riezler et al. 2008; Riezler and Liu 2010). The SMT-based system can produce cleaner, more relevant expansion terms because rich context information useful for filtering noisy expansions is captured by combining language model and phrase translation model in its decoder. Furthermore, in the SMT system all component models are properly smoothed using sophisticated techniques to avoid sparse data problems while the correlation model relies on pure counts of term frequencies. However, the SMT system is used as a black box in their experiments. So the relative contribution of different SMT components is not verified empirically. In this study we break this black box in order to build a better, simpler QE system. We will show that the proposed lexicon models outperform significantly the term correlation model, and that a simpler QE system that incorporates the lexicon models can beat the sophisticated, black-box SMT system.

## 2 Lexicon Models

We view search queries and Web documents as two different languages, and cast QE as a means to bridge the language gap by translating queries to documents, represented by their titles. In this section, we will describe three translation models that are based on terms, triplets, and topics, respectively, and the way these models are learned from query-title pairs extracted from clickthrough data.

### 2.1 Word Model

The word model takes the form of IBM Model 1 (Brown et al. 1993; Berger and Lafferty 1999). Let  $Q = (q_1, \dots, q_J)$  be a query,  $e$  be an expansion term candidate, the translation probability from  $Q$  to  $e$  is defined as

$$P(e|Q)_{wm} = \sum_{j=1}^J P(e|q_j)P(q_j|Q) \quad (1)$$

where  $P(q|Q)$  is the unsmoothed unigram probability of word  $q$  in query  $Q$ . The word translation probabilities  $P(e|q)$  are estimated on the query-title pairs derived from the clickthrough data by assuming that the title terms are likely to be the desired expansions of the paired query. Our training method follows the standard procedure of training statistical word alignment models proposed by Brown et al. (1993). Formally, we optimize the model parameters  $\theta$  by maximizing the probability of generating document titles from queries over the entire training corpus:

$$\theta^* = \operatorname{argmax}_{\theta} \prod_{i=1}^H P(D_i|Q_i, \theta) \quad (2)$$

where both the titles  $D$  and the paired queries  $Q$  are viewed as bag of words. The translation probability  $P(D_i|Q_i, \theta)$  takes the form of IBM Model 1 as

$$P(D|Q, \theta) = \frac{\varepsilon}{(J+1)^I} \prod_{i=1}^I \sum_{j=1}^J P(w_i|q_j, \theta) \quad (3)$$

where  $\varepsilon$  is a constant,  $I$  is the length of  $D$ , and  $J$  is the length of  $Q$ . To find the optimal word translation probabilities of IBM Model 1, we used the EM algorithm, where the number of iterations is determined empirically on held-out data.

### 2.2 Triplet Model

The word model is context independent. The triplet model, which is originally proposed for SMT (Hasan et al. 2008), is intended to capture inter-term dependencies for selecting expansion terms. The model is based on lexicalized triplets  $(e, q, q')$  which can be understood as two query terms triggering one expansion term. The translation probability of  $e$  given  $Q$  for the triplet model is parameterized as

$$P(e|Q)_{tm} = \frac{1}{Z} \sum_{j=1}^{J-1} \sum_{k=j+1}^J P(e|q_j, q_k) \quad (4)$$

where  $Z$  is a normalization factor based on the corresponding query length, i.e.,  $Z = \frac{J(J-1)}{2}$ , and  $P(e_i|q_j, q_k)$  is the probability of translating  $q_j$  into  $e_i$  given another query word  $q_k$ . Since  $q_k$  can be any word in  $Q$  that is not necessary to be adjacent to  $q_j$ , the triple model is able to combine local (i.e. word and phrase level) and global (i.e. query level) contextual information useful for word translation.

Similar to the case of word model, we used the EM algorithm to estimate the translation probabilities  $P(e|q, q')$  on the query-title pairs. Since the number of all possible triplets  $(e, q, q')$  is large and as a consequence the model training could suffer the data sparseness problem, in our experiments count-based cutoff is applied to prune the model to a manageable size.

### 2.3 Bilingual Topic Model (BLTM)

The BLTM was originally proposed for Web document ranking by Gao et al. (2011). The idea underlying the model is that a search query and its relevant Web documents share a common distribution of (hidden) topics, but use different (probably overlapping) vocabularies to express these topics. Intuitively, BLTM-based QE works as follows. First, a query is represented as a vector of topics. Then, all the candidate expansion terms, which are selected from document, are ranked by how likely it is that these document terms are selected to best describe those topics. In a sense, BLTM is similar to the word model and the triplet model since they all map a query to a document word. BLTM differs in that the mapping is performed at the topic level (via a language independent semantic representation) rather than at the word level. In our experiments BLTM is found to often select a different set of expansion terms and is complementary to the word model and the triplet model.

Formally, BLTM-based QE assumes the following story of generating  $e$  from  $Q$ :

1. First, for each topic  $z$ , a pair of different word distributions  $(\phi_z^Q, \phi_z^D)$  are selected from a Dirichlet prior with concentration parameter  $\beta$ , where  $\phi_z^Q$  is a topic-specific query

<b>Original query</b>	jaguar locator
<b>Ranked expansion candidates</b> (altered words are in italic)	jaguar <i>finder</i> <i>car</i> locator jaguar <i>location</i> jaguar <i>directory</i> ... jaguar <i>list</i>
<b>Expanded query</b> (selected expansion terms are in italic)	OR (jaguar, <i>car</i> ) OR (locator, <i>finder</i> , <i>location</i> , <i>directory</i> )

**Figure 1.** An example of an original query, its expansion candidates and the expanded query generated by the ranker-based QE system.

term distribution, and  $\phi_z^D$  a topic-specific document term distribution. Assuming there are  $T$  topics, we have two sets of distributions  $\phi^Q = (\phi_1^Q, \dots, \phi_T^Q)$  and  $\phi^D = (\phi_1^D, \dots, \phi_T^D)$ .

2. Given  $Q$ , a topic distribution  $\theta^Q$  is drawn from a Dirichlet prior with concentration parameter  $\alpha$ .
3. Then a document term (i.e., expansion term candidate)  $e$  is generated by first selecting a topic  $z$  according to the topic distribution  $\theta^Q$ , and then drawing a word from  $\phi_z^D$ .

By summing over all possible topics, we end up with the following model form

$$P_{bltm}(e|Q) = \sum_z P(e|\phi_z^D)P(z|\theta^Q) \quad (5)$$

The BLTM training follows the method described in Gao et al. (2011). We used the EM algorithm to estimate the parameters  $(\theta, \phi^Q, \phi^D)$  of BLTM by maximizing the joint log-likelihood of the query-title pairs and the parameters. In training, we also constrain that the paired query and title have similar fractions of tokens assigned to each topic. The constraint is enforced on expectation using posterior regularization (Ganchev et al. 2010).

### 3 A Ranker-Based QE System

This section describes a ranker-based QE system in which the three lexicon models described above are incorporated. The system expands an input query in two distinct stages, candidate generation and ranking, as illustrated by an example in Figure 1.

In candidate generation, an input query  $Q$  is first tokenized into a sequence of terms. For each term  $q$  that is not a stop word, we consult a word model described in Section 2.1 to identify the best  $M$  altered words according to their word translation probabilities from  $q$ . Then, we form a list of expansion candidates, each of which contains all the original words in  $Q$  except for the word that is substituted by one of its altered words. So, for a query with  $J$  terms, there are at most  $M \times J$  candidates.

In the second stage, all the expansion candidates are ranked using a ranker that is based on the Markov Random Field (MRF) model in which the three lexicon models are incorporated as features. Expansion terms of a query are taken from those terms in the  $N$ -best ( $N = 10$  in our experiments) expansion candidates of the query that have not been seen in the original query string.

In the remainder of this section we will describe in turn the MRF-based ranker, the ranking features, and the way the ranker parameters are estimated.

### 3.1 MRF-Based Ranker

The ranker is based on the MRF model that models the joint distribution of  $P_\Lambda(E, Q)$  over a set of expansion term random variables  $E = \{e_1, \dots, e_I\}$  and a query random variable  $Q$ . It is constructed from a graph  $G$  consisting of a query node and nodes for each expansion term. Nodes in the graph represent random variables and edges define the independence semantics between the variables. An MRF satisfies the Markov property (Bishop 2006), which states that a node is independent of all of its non-neighboring nodes given observed values of its neighbors, defined by the clique configurations of  $G$ . The joint distribution over the random variables in  $G$  is defined as

$$P_\Lambda(E, Q) = \frac{1}{Z_\Lambda} \prod_{c \in \mathcal{C}(G)} \varphi(c; \Lambda) \quad (6)$$

where  $\mathcal{C}(G)$  is the set of cliques in  $G$ , and each  $\varphi(c; \Lambda)$  is a non-negative potential function defined over a clique configuration  $c$  that measures the *compatibility* of the configuration,  $\Lambda$  is a set of parameters that are used within the potential function, and  $Z_\Lambda$  normalizes the distribution. For ranking expansion candidates, we can drop the expensive computation of  $Z_\Lambda$  since it is independent of  $E$ , and simply rank each expansion candidate  $E$  by

**Figure 2:** The structure of the Markov random field for representing the term dependency among the query  $Q$  and the expansion terms  $e_1, \dots, e_I$ .

its unnormalized joint probability with  $Q$  under the MRF. It is common to define MRF potential functions of the exponential form as  $\varphi(c; \Lambda) = \exp(\lambda_c f(c))$ , where  $f(c)$  is a real-valued feature function over clique values and  $\lambda_c$  is the weight of the feature function. Then, we can compute the posterior  $P_\Lambda(E|Q)$  as

$$P_\Lambda(E|Q) = \frac{P_\Lambda(E, Q)}{P_\Lambda(Q)} \quad (7)$$

$$\stackrel{rank}{\implies} \sum_{c \in \mathcal{C}(G)} \log \varphi(c; \Lambda) = \sum_{c \in \mathcal{C}(G)} \lambda_c f(c),$$

which is essentially a weighted linear combination of a set of features.

Therefore, to instantiate the MRF model, one needs to define a graph structure and a set of potential functions. In this paper, the graphical model representation we propose for QE is a fully connected graph shown in Figure 2, where all expansion terms and the original query are assumed dependent with each other. In what follows, we will define six types of cliques that we are interested in defining features (i.e., potential functions) over.

### 3.2 Features

The cliques and features are inspired by the component models used in SMT systems. The cliques defined in  $G$  for MRF can be grouped into two categories. The first includes three types of cliques involving both the query node and one or more expansion terms. The potential functions defined over these cliques attempt to abstract the idea behind the query to title translation models. The other three types, belonging to the second category, involve only expansion terms. Their potential func-

tions attempt to abstract the idea behind the target language models.

The first type of cliques involves a single expansion term and the query node. The potentials functions for these cliques are defined as

$$\begin{aligned} \varphi_T(e_i, Q; \Lambda) = & \exp[\lambda_{wm}f_{wm}(e_i, Q) + \quad (6) \\ & \lambda_{tm}f_{tm}(e_i, Q) + \\ & \lambda_{bltm}f_{bltm}(e_i, Q)] \end{aligned}$$

where the three feature functions of the form  $f(e, Q)$  are defined as the log probabilities of translating  $Q$  to  $e$  according to the word, triplet and topic models defined in Equations (1), (4) and (5), respectively.

$$\begin{aligned} f_{wm}(e_i, Q) &= \log P_{wm}(e_i|Q) \\ f_{tm}(e_i, Q) &= \log P_{tm}(e_i|Q) \\ f_{bltm}(e_i, Q) &= \log P_{bltm}(e_i|Q) \end{aligned}$$

The second type of cliques contains the query node and two expansion terms,  $e_i$  and  $e_{i+1}$ , which appear in consecutive order in the expansion. The potential functions over these cliques are defined as

$$\varphi_{ob}(e_i, e_{i+1}, Q; \Lambda) = \exp[\lambda_{ob}f_{ob}(e_i, e_{i+1}, Q)] \quad (7)$$

where the feature  $f_{ob}(\cdot)$  is defined as the log probability of generating an expansion bigram given  $Q$

$$f_{ob}(e_i, e_{i+1}|Q) = \log P(e_i, e_{i+1}|Q)$$

Unlike the language models used for document ranking (e.g., Zhai and Lafferty 2001), we cannot compute the bigram probability by simply counting the relative frequency of  $(e_i, e_{i+1})$  in  $Q$  because the query is usually very short and the bigram is unlikely to occur. Thus, we approximate the bigram probability by assuming that the words in  $Q$  are independent with each other. We thus have

$$\begin{aligned} P(e_i, e_{i+1}|Q) &= \frac{P(e_i, e_{i+1}, Q)}{P(Q)} \\ &= \frac{P(e_i)P(e_{i+1}|e_i) \prod_{j=1}^J P(q_j|e_i, e_{i+1})}{\prod_{j=1}^J P(q_j)}, \end{aligned}$$

where  $P(q_j|e_i, e_{i+1})$  is the translation probability computed using a variant of the triplet model described in Section 2.2. The model variation differs from the one of Equation (4) in two respects. First, it models the translation in a different direction i.e.,

from expansion to query. Second, we add a constraint to the triplets such that  $(e_i, e_{i+1})$  must be an ordered, contiguous bigram. The model variation is also trained using EM on query-title pairs.  $P(e_i)$  and  $P(e_{i+1}|e_i)$  are assigned respectively by the unigram and bigram language models, estimated from the collection of document titles of the clickthrough data, and  $P(q_j)$  is the unigram probability of the query term, estimated from the collection of queries of the clickthrough data.

The third type of cliques contains the query node and two expansion terms,  $e_i$  and  $e_k$ , which occur unordered within the expansion. The potential functions over these cliques are defined as

$$\varphi_{ub}(e_i, e_k, Q; \Lambda) = \exp[\lambda_{ub}f_{ub}(e_i, e_k, Q)] \quad (8)$$

where the feature  $f_{ub}(\cdot)$  is defined as the log probability of generating a pair of expansion terms  $(e_i, e_k)$  given  $Q$

$$f_{ub}(e_i, e_k|Q) = \log P(e_i, e_k|Q).$$

Unlike  $f_{ob}(e_i, e_{i+1}|Q)$  defined in Equation (7), this class of features captures long-span term dependency in the expansion candidate. Similar to the computation of  $P(e_i, e_{i+1}|Q)$  in Equation (7), we approximate  $P(e_i, e_k|Q)$  as

$$\begin{aligned} P(e_i, e_k|Q) &= \frac{P(e_i, e_k, Q)}{P(Q)} \\ &= \frac{P(e_i)P(e_k|e_i) \prod_{j=1}^J P(q_j|e_i, e_k)}{\prod_{j=1}^J P(q_j)}, \end{aligned}$$

where  $P(q_j|e_i, e_k)$  is the translation probability computed using the triplet model described in Section 2.2, but in the expansion-to-query direction.  $P(e_i)$  is assigned by a unigram language model estimated from the collection of document titles of the clickthrough data.  $P(e_k|e_i)$  is assigned by a co-occurrence model, estimated as

$$P(e_k|e_i) = \frac{N(e_i, e_k)}{\sum_e N(e_i, e)}$$

where  $N(e_i, e_k)$  is the number of times that the two terms occur in the same title in clickthrough data.

We now turn to the other three types of cliques that do not contain the query node. The fourth type of cliques contains only one expansion term. The potential functions are defined as

$$\begin{aligned}\varphi_{um}(e_i; \Lambda) &= \exp[\lambda_{um}f_{um}(e_i)] \\ f_{um}(e_i) &= \log P(e_i)\end{aligned}\quad (9)$$

where  $P(e_i)$  is the unigram probability computed using a unigram language model trained on the collection of document titles.

The fifth type of cliques contains a pair of terms appearing in consecutive order in the expansion. The potential functions are defined as

$$\begin{aligned}\varphi_{bm}(e_i, e_{i+1}; \Lambda) &= \exp[\lambda_{bm}f_{bm}(e_i, e_{i+1})] \\ f_{bm}(e_i, e_{i+1}) &= \log P(e_{i+1}|e_i)\end{aligned}\quad (10)$$

where  $P(e_{i+1}|e_i)$  is the bigram probability computed using a bigram language model trained on the collection of document titles.

The sixth type of cliques contains a pair of terms appearing unordered within the expansion. The potential functions are defined as

$$\begin{aligned}\varphi_{cm}(e_i, e_k; \Lambda) &= \exp[\lambda_{cm}f_{cm}(e_i, e_k)] \\ f_{cm}(e_i, e_k) &= \log P(e_k|e_i)\end{aligned}\quad (11)$$

where  $P(e_k|e_i)$  is the assigned by a co-occurrence model trained on the collection of document titles.

### 3.3 Parameter Estimation

The MRF model uses 8 classes of features defined on 6 types of cliques, as in Equations (6) to (11). Following previous work (e.g., Metzler and Croft 2005; Bendersky et al. 2010), we assume that all features within the same feature class are weighted by the same tied parameter  $\lambda$ . Thus, the number of free parameters of the MRF model is significantly reduced. This not only makes the model training easier but also improves the robustness of the model. After tying the parameters and using the exponential potential function form, the MRF-based ranker can be parameterized as

$$\begin{aligned}P_{\Lambda}(E|Q) &\stackrel{rank}{\implies} \lambda_{wm} \sum_{i=1}^I f_{wm}(e_i, Q) + \\ &\lambda_{tm} \sum_{i=1}^I f_{tm}(e_i, Q) + \\ &\lambda_{bltm} \sum_{i=1}^I f_{bltm}(e_i, Q) + \\ &\lambda_{ob} \sum_{i=1}^{I-1} f_{ob}(e_i, e_{i+1}, Q) +\end{aligned}\quad (12)$$

$$\begin{aligned}&\lambda_{ub} \sum_{i=1}^{I-1} \sum_{k=i+1}^I f_{ob}(e_i, e_k, Q) + \\ &\lambda_{um} \sum_{i=1}^I f_{um}(e_i) + \\ &\lambda_{bm} \sum_{i=1}^{I-1} f_{bm}(e_i, e_{i+1}) + \\ &\lambda_{cm} \sum_{i=1}^{I-1} \sum_{k=i+1}^I f_{cm}(e_i, e_k)\end{aligned}$$

where there are in total 8  $\lambda$ 's to be estimated.

Although the MRF is by nature a generative model, it is not always appropriate to train the parameters using conventional likelihood based approaches due to the metric divergence problem (Morgan et al. 2004): i.e., the maximum likelihood estimate is unlikely to be the one that optimizes the evaluation metric. In this study the effectiveness of a QE method is evaluated by first issuing a set of queries which are expanded using the method to a search engine and then measuring the Web search performance. Better QE methods are supposed to lead to better Web search results using the correspondingly expanded query set.

For this reason, the parameters of the MRF-based ranker are optimized directly for Web search. In our experiments, the objective in training is *Normalized Discounted Cumulative Gain* (NDCG, Jarvelin and Kekalainen 2000), which is widely used as quality measure for Web search. Formally, we view parameter training as a multi-dimensional optimization problem, with each feature class as one dimension. Since NDCG is not differentiable, we tried in our experiments numerical algorithms that do not require the computation of gradient. Among the best performers was the Powell Search algorithm (Press et al., 1992). It first constructs a set of  $N$  virtual directions that are conjugate (i.e., independent with each other), then it uses *line search*  $N$  times ( $N = 8$  in our case), each on one virtual direction, to find the optimum. Line search is a one-dimensional optimization algorithm. Our implementation follows the one described in Gao et al. (2005), which is used to optimize averaged precision.

## 4 Experiments

We evaluate the performance of a QE method by first issuing a set of queries which are expanded using the method to a search engine and then

measuring the Web search performance. Better QE methods are supposed to lead to better Web search results using the correspondingly expanded query set.

Due to the characteristics of our QE methods, we cannot conduct experiments on standard test collections such as the TREC data because they do not contain related user logs we need. Therefore, following previous studies of log-based QE (e.g., Cui et al. 2003; Riezler et al. 2008), we use the proprietary datasets that have been developed for building a commercial search engine, and demonstrate the effectiveness of our methods by comparing them against previous state-of-the-art log-based QE methods.

The relevance judgment set consists of 4,000 multi-term English queries. On average, each query is associated with 197 Web documents (URLs). Each query-URL pair has a relevance label. The label is human generated and is on a 5-level relevance scale, 0 to 4, with 4 meaning document  $D$  is the most relevant to query  $Q$  and 0 meaning  $D$  is not relevant to  $Q$ .

The relevance judgment set is constructed as follows. First, the queries are sampled from a year of search engine logs. Adult, spam, and bot queries are all removed. Queries are “de-duped” so that only unique queries remain. To reflect a natural query distribution, we do not try to control the quality of these queries. For example, in our query sets, there are roughly 20% misspelled queries, 20% navigational queries, and 10% transactional queries. Second, for each query, we collect Web documents to be judged by issuing the query to several popular search engines (e.g., Google, Bing) and fetching retrieval results from each. Finally, the query-document pairs are judged by a group of well-trained assessors. In this study all the queries are preprocessed as follows. The text is white-space tokenized and lowercased, numbers are retained, and no stemming/inflection treatment is performed. We split the judgment set into two non-overlapping datasets, namely training and test sets, respectively. Each dataset contains 2,000 queries.

The query-title pairs used for model training are extracted from one year of query log files using a procedure similar to Gao et al. (2009). In our experiments we used a randomly sampled subset of 20,692,219 pairs that do not overlap the queries and documents in the test set.

#	QE methods	NDCG@1	NDCG@3	NDCG@10
1	NoQE	34.70	36.50	41.54

**Table 1:** Ranking results using BM25 with different query expansion systems. The superscripts  $\alpha$ ,  $\beta$ , and  $\gamma$  indicate statistically significant improvements ( $p < 0.05$ ) over NoQE, TC, and SMT, respectively. Rows 5 to 11 are different versions of MRF in Row 5, They use the same candidate generator but use in the ranker different feature classes, as specified by the subscript. **tc** specifies the feature class defined as the scoring function in Equation (13). Refer to Equation (12) for the names of other feature classes.

Our Web document collection consists of approximately 2.5 billion Web pages. In the retrieval experiments we use the index based on the content fields (i.e., body and title text) of each Web page.

The Web search performance is evaluated by mean NDCG. We report NDCG scores at truncation levels of 1, 3, and 10. We also perform a significance test using the paired  $t$ -test. Differences are considered statistically significant when  $p$ -value is less than 0.05.

#### 4.1 Comparing Systems

Table 1 shows the main document ranking results using different QE systems, developed and evaluated using the datasets described above.

NoQE (Row 1) is the baseline retrieval system that uses the raw input queries and the BM25 document ranking model. Rows 2 to 4 are different QE systems. Their results are obtained by first expanding a query, then using BM25 to rank the documents with respect to the expanded query.

TC (Row 2) is our implementation of the correlation-based QE system (Cui et al. 2002; 2003). It takes the following steps to expand an input query  $Q$ :

1. Extract all query terms  $q$  (eliminating stopwords) from  $Q$ .
2. Find all documents that have clicks on a query that contains one or more of these query terms.
3. For each title term  $w$  in these documents, calculate its evidence of being selected as an expansion term according to the whole query via a scoring function  $Score(w|Q)$ .
4. Select  $n$  title terms with the highest score (where the value of  $n$  is optimized on training data) and formulate the expanded query by adding these terms into  $Q$ .
5. Use the expanded query to rank documents.

The scoring function is based on the term correlation model, and is defined as

$$Score(w|Q) = \ln \left( \prod_{q \in Q} P(w|q) + 1 \right) \quad (13)$$

$$P(w|q) = \sum_{D \in \mathbf{D}_q} P(w|D)P(D|q)$$

where  $\mathbf{D}_q$  is the set of documents clicked for the queries containing the term  $q$  and is collected from search logs,  $P(w|D)$  is a normalized *tf-idf* weight of the document term in  $D$ , and  $P(D|q)$  is the relative occurrence of  $D$  among all the documents clicked for the queries containing  $q$ . Table 1 shows that **TC** leads to significant improvement over **NoQE** in NDCG@10, but not in NDCG@1 and NDCG@3 (Row 2 vs. Row 1). The result is not entirely consistent with what reported in Cui et al. (2003). A possible reason is that Cui et al. performed the evaluation using documents and search logs collected from the Encarta website, which is much cleaner and more homogenous than the data sets we used. The result suggests that although QE improves the recall of relevant documents, it is also likely to introduce noise that hurts the precision of document retrieval.

**SMT** (Row 3) is a SMT-based QE system. Following Riezler et al. (2008), the system is an implementation of a phrase-based SMT system with a standard set of features for translation model and language model, combined under a log linear model framework (Koehn et al. 2003). Different from Riezler et al.’s system where the translation model is trained on query-snippet pairs and the language model on queries, in our implementation the trans-

lation model is trained on query-title pairs and the language model on titles. To apply the system to QE, expansion terms of a query are taken from those terms in the 10-best translations of the query that have not been seen in the original query string. We see that **SMT** significantly outperforms **TC** in NDCG at all levels. The result confirms the conclusion of Riezler et al., demonstrating that context information is crucial for improving retrieval precision by filtering noisy expansions.

Both **TC** and **SMT**, considered as state-of-the-art QE methods, have been frequently used for comparison in related studies. Thus, we also used them as baselines in our experiments.

**MRF** (Row 4) is the ranker-based QE system described in Section 3, which uses a MRF-based ranker to incorporate all 8 classes of features derived from a variety of lexicon translation models and language models as in Equation (12). Results show that the ranker-based QE system significantly outperforms both **NoQE** and the two state-of-the-art QE methods. The fact that **MRF** beats **SMT** with a statistically significant margin although the former is a much simpler system indicates that text translation and QE are different tasks and some SMT components, designed for the task of regular text translation, are not as effective in selecting expansion terms. We will explore this in more detail in the next section.

## 4.2 Comparing Models

The experiments presented in this section investigate in detail the effectiveness of different models, e.g., the lexicon models and the language models described in Sections 2 and 3, in ranking expansion candidates for QE. The results are summarized in Rows 5 to 11 in Table 1, where a number of different versions of the ranker-based QE system are compared. These versions, labeled as **MRF<sub>f</sub>**, use the same candidate generator, and differ in the feature classes (which are specified by the subscript  $f$ ) incorporated in the MRF-based ranker. In what follows, we focus our discussion on the results of the three lexicon models.

**MRF<sub>vm</sub>** (Row 7) uses the word translation model described in Section 2.1. Both the word model and term correlation model used in **MRF<sub>m</sub>** (Row 6) are context independent. They differ mainly in the training methods. For the sake of comparison, in our experiment the word model is

EM-trained with the correlation model as initial point. Rezler et al. (2008) hypothesize that statistical translation model is superior to correlation model because the EM training captures the hidden alignment information when mapping document terms to query terms, leading to a better smoothed probability distribution. Our result (Row 7 vs. Row 6) verifies the hypothesis. Notice that  $\mathbf{MRF}_{tc}$  outperforms  $\mathbf{TC}$  in NDCG@1 (Row 6 vs. Row 2) mainly because in the former the expansion candidates are generated by a word translation model and are less noisy.

It is encouraging to observe that the rankers using the triplet model features achieve the QE performance either in par with or better than that of  $\mathbf{SMT}$  (Rows 8, 10 and 11 vs. Row 3), although the latter is a much more sophisticated system. The result suggests that not all SMT components are useful for QE. For example, language models are indispensable for translation but are less effective than word models for QE (Row 5 vs. Rows 6 and 7). We also observe that the triplet model not only outperforms significantly the word model due to the use of contextual information (Row 8 vs. Row 7), but also seems to subsume the latter in that combining the features derived from both models in the ranker leads to little improvement over the ranker that uses only the triplet model features (Row 10 vs. Row 8).

The bilingual topic model underperforms the word model and the triplet model (Row 9 vs. Rows 7 and 8). However, we found that the bilingual topic model often selects a different set of expansion terms and is complementary to the other two lexicon models. As a result, unlike the case of combining the word model and triplet model features, incorporating the bilingual topic model features in the ranker leads to some visible improvement in NDCG at all positions (Row 11 vs. Row 10).

To better understand empirically how the MRF-based QE system achieves the improvement, we analyzed the expansions generated by our system in detail and obtained several interesting findings. First, as expected, in comparison with the word model, the triplet translation model is more effective in benefitting long queries, e.g., notably queries containing questions and queries containing song lyrics. Second, unlike the two lexicon models, the bilingual topic model tends to generate expansions that are more likely to relate to an entire query rather than individual query terms. Third, the

features involving the order of the expansion terms benefitted queries containing named entities.

## 5 Related Work

In comparison with log-based methods studied in this paper, the QE methods based on automatic relevance feedback have been studied much more extensively in the information retrieval (IR) community, and have been proved useful for improving IR performance on benchmark datasets such as TREC (e.g., Rocchio 1971; Xu and Croft 1996; Lavrenko 2001; Zhai and Lafferty 2001). However, these methods cannot be applied directly to a commercial Web search engine because the relevant documents are not always available and generating pseudo-relevant documents requires multi-phase retrieval, which is prohibitively expensive. Although automatic relevance feedback is not the focus of this study, our method shares a lot of similarities with some of them. For example, similar to the way the parameters of our QE ranker are estimated, Cao et al. (2008) propose a method of selecting expansion terms to directly optimize average precision. The MRF model has been previously used for QE, in the form of relevance feedback and pseudo-relevance feedback (Metzler et al. 2007; Lang et al. 2010). While their MRF models use the features derived from IR systems such as Indri, we use the SMT-inspired features.

Using statistical translation models for IR is not new (e.g., Berger and Lafferty 1999; Jin et al. 2002; Xue et al. 2008). The effectiveness of the statistical translation-based approach to Web search has been demonstrated empirically in recent studies where word-based and phrase-based translation models are trained on large amounts of clickthrough data (e.g., Gao et al. 2010a; 2011). Our work extends these studies and constructs QE-oriented translation models that capture more flexible dependencies.

In addition to QE, search logs have also been used for other Web search tasks, such as document ranking (Joachims 2002; Agichtein et al. 2006), search query processing and spelling correction (Huang et al. 2010; Gao et al. 2010b) image retrieval (Craswell and Szummer 2007), and user query clustering (Baeza-Yates and Tiberi 2007; Wen et al. 2002).

## 6 Conclusions

In this paper we extend the previous log-based QE methods in two directions. First, we formulate QE as the problem of translating a source language of queries into a target language of documents, represented as titles. This allows us to adapt the established techniques developed for SMT to QE. Specially, we propose three lexicon models based on terms, lexicalized triplets, and topics, respectively. These models are trained on pairs of user queries and the titles of clicked documents using EM. Second, we present a ranker-based QE system, the heart of which is a MRF-based ranker in which the lexicon models are incorporated as features. We perform experiments on the Web search task using a real world data set. Results show that the proposed system outperforms significantly other state-of-the-art QE systems.

This study is part of a bigger, ongoing project, aiming to develop a real-time QE system for Web search, where simplicity is the key to the success. Thus, what we learned from this study is particularly encouraging. We demonstrate that with large amounts of clickthrough data for model training, simple lexicon models can achieve state-of-the-art QE performance, and that the MRF-based ranker provides a simple and flexible framework to incorporate a variety of features capturing different types of term dependencies in such an effective way that the Web search performance can be directly optimized.

## Abstract

This paper addresses the task of constructing a timeline of events mentioned in a given text. To accomplish that, we present a novel representation of the temporal structure of a news article based on time intervals. We then present an algorithmic approach that jointly optimizes the temporal structure by coupling local classifiers that predict associations and temporal relations between pairs of temporal entities with global constraints. Moreover, we present ways to leverage knowledge provided by event coreference to further improve the system performance. Overall, our experiments show that the joint inference model significantly outperformed the local classifiers by 9.2% of relative improvement in  $F_1$ . The experiments also suggest that good event coreference could make remarkable contribution to a robust event timeline construction system.

## 1 Introduction

Inferring temporal relations amongst a collection of events in a text is a significant step towards various important tasks such as automatic information extraction and document comprehension. Over the past few years, with the development of the TimeBank corpus (Pustejovsky et al., 2003), there have been several works on building automatic systems for such a task (Mani et al., 2006; Chambers and Jurafsky, 2008; Yoshikawa et al., 2009; Denis and Muller, 2011).

Most previous works devoted much efforts to the task of identifying relative temporal relations (such as *before*, or *overlap*) amongst events (Chambers

Figure 1: A graphical illustration of our timeline representation. The  $e$ 's,  $t$ 's and  $I$ 's are events, time points and time intervals, respectively.

and Jurafsky, 2008; Denis and Muller, 2011), without addressing the task of identifying correct associations between events and their absolute time of occurrence. Even if this issue is addressed, certain restrictions are often imposed for efficiency reasons (Yoshikawa et al., 2009; Verhagen et al., 2010). In practice, however, being able to automatically infer the correct time of occurrence associated with each event is crucial. Such information not only leads to better text comprehension, but also enables fusion of event structures extracted from multiple articles or domains.

In this work, we are specifically interested in mapping events into an universal *timeline* representation. Besides inferring the relative temporal relations amongst the events, we would also like to automatically infer a specific absolute time of occurrence for each event mentioned in the text. Unlike previous work, we associate each event with a specific absolute time interval inferred from the text. An example timeline representation is illustrated in Fig.

1. Further details of our timeline representation are given in Sec. 2.3.

We perform global inference by combining a collection of local pairwise classifiers through the use of an Integer Linear Programming (ILP) formulation that promotes global coherence among local decisions. The formulation allows our model to predict both event-event relations and event-time interval associations simultaneously. We show that, with the use of time intervals instead of time points, our approach leads to a more concise ILP formulation with reduced number of variables and constraints.

Moreover, we observed that event coreference can reveal important information for such a task. We propose that different event mentions that refer to the same event can be grouped together before classification and performing global inference. This can reduce the amount of efforts in both classification and inference stages and can potentially eliminate mistakes that would be made otherwise without such coreference information. To the best of our knowledge, our proposal of leveraging event coreference to support event timeline construction is novel.

Our experiments on a collection of annotated news articles from the standard ACE dataset demonstrate that our approach produces robust timelines of events. We show that our algorithmic approach is able to combine various local evidences to produce a global coherent temporal structure, with improved overall performance. Furthermore, the experiments show that the overall performance can be further improved by exploiting knowledge from event coreference.

## 2 Background

We focus on the task of mapping event mentions in a news article to a timeline. We first briefly describe and define several basic concepts.

### 2.1 Events

Following the annotation guidelines of the ACE project, we define an event as an action or occurrence that happens with associated participants or arguments. We also distinguish between events and event mentions, where a unique event can be coreferred to by a set of explicit event mentions in an article. Formally, an event  $E^i$  is co-referred to by

a set of event mentions  $(e_1^i, e_2^i, \dots, e_k^i)$ . Each event mention  $e$  can be written as  $p(a_1, a_2, \dots, a_l)$ , where the predicate  $p$  is the word that triggers the presence of  $e$  in text, and  $a_1, a_2, \dots, a_l$  are the arguments associated with  $e$ . In this work we focus on four temporal relations between two event mentions including *before*, *after*, *overlap* and *no relation*.

### 2.2 Time Intervals

Similar to Denis and Muller (2011), we define time intervals as pairs of time endpoints. Each time interval  $I$  is denoted by  $[t^-, t^+]$ , where  $t^-$  and  $t^+$  are two time endpoints representing the lower and upper bound of the interval  $I$ , respectively, with  $t^- \leq t^+$ . The general form of a time endpoint is written as “YYYY-MM-DD hh:mm:ss”. An endpoint can be undefined, in which case it is set to an infinity value:  $-\infty$ , or  $+\infty$ . There are two types of time intervals:

**Explicit intervals** are time intervals that can be extracted directly from a given text. For example, consider the following snippet of an article in our data set: *The litigation covers buyers in auctions outside the United States between January 1, 1993 and February 7, 2000*. In this example, we can extract and normalize two time intervals which are explicitly written, including *January 1, 1993*  $\rightarrow$  [1993-01-01 00:00:00, 1993-01-01 23:59:59] and *February 7, 2000*  $\rightarrow$  [2000-02-07 00:00:00, 2000-02-07 23:59:59]. Moreover, an explicit interval can also be formed by one or more separate explicit temporal expressions. In the example above, the connective term *between* relates the two expressions to form a single time interval: *between January 1, 1993 and February 7, 2000*  $\rightarrow$  [1993-01-01 00:00:00, 2000-02-07 23:59:59]. To extract explicit time intervals from text, we use the time interval extractor described in Zhao et al. (2012).

**Implicit intervals** are time intervals that are not explicitly mentioned in the text. We observed that there are events that cannot be assigned to any precise time interval but are roughly known to occur in the past or in the future relative to the Document Creation Time (DCT) of the article. We introduce two implicit time intervals to represent the past and the future events as  $(-\infty, t_{DCT}^-]$  and  $[t_{DCT}^+, +\infty)$ , respectively. In addition, we also allow an event mention to be assigned into the entire timeline, which is denoted by  $(-\infty, +\infty)$  if we can-

not identify its time of occurrence. We also consider DCT as an implicit interval.

We say that the time interval  $I_i$  precedes the time interval  $I_j$  on a timeline if and only if  $t_i^+ \leq t_j^-$ , which also implies that  $I_i$  succeeds  $I_j$  if and only if  $t_i^- \geq t_j^+$ . The two intervals overlap, otherwise.

### 2.3 Timeline

We define a timeline as a partially ordered set of time intervals. Fig. 1 gives a graphical illustration of an example timeline, where events are annotated and associated with time intervals. Relations amongst events can be properly reflected in the timeline representation. For example, in the figure, the events  $e_1$  and  $e_2$  are both associated with the interval  $I_1$ . The relation between them is *no relation*, since it is unclear which occurs first. On the other hand,  $e_5$  and  $e_3$  both happen in the interval  $I_2$  but they form an *overlap* relation. The events  $e_6$  and  $e_7$  occur within the same interval  $I_3$ , but  $e_7$  precedes (i.e. *before*)  $e_6$  on the timeline. The event  $e_4$  is associated with the interval  $(-\infty, +\infty)$ , indicating there is no knowledge about its time of occurrence.

We believe that such a timeline representation for temporally ordering events has several advantages over the temporal graph representations used in previous works (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009; Denis and Muller, 2011). Unlike previous works, in our model the events are partially ordered in a single timeline, where each event is associated with a precise time interval. This improves human interpretability of the temporal relations amongst events and time. This property of our timeline representation, thus, facilitates merging multiple timelines induced from different articles. Furthermore, as we will show later, the use of time intervals within the timeline representation simplifies the global inference formulation and thus the inference process.

## 3 A Joint Timeline Model

Our task is to induce a globally coherent timeline for a given article. We thus adopt a global inference model for performing the task. The model consists of two components: (1) two local pairwise classifiers, one between event mentions and time intervals (the  $E-T$  classifier) and one between event

mentions themselves (the  $E-E$  classifier), and (2) a joint inference module that enforces global coherency constraints on the final outputs of the two local classifiers. Fig. 2 shows a simplified temporal structure of event mentions and time intervals of an article in our model.

Our  $E-T$  classifier is different from previous work (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009; Denis and Muller, 2011), where such classifiers were trained to identify temporal relations between event mentions and a temporal *expression*. In our work, in order to construct absolute timeline of event mentions, temporal expressions are captured and normalized as absolute time intervals. The  $E-T$  classifiers are then used to assign event mentions to their contextually corresponding time intervals.

We also lifted several restrictions imposed in previous work (Bethard et al., 2007; Yoshikawa et al., 2009; Verhagen et al., 2010). Specifically, we do not require that event mentions and time expressions have to appear in the same sentence, and we do not require two event mentions have to appear very close to each other (e.g., main event mentions in adjacent sentences) in order to be considered as candidate pairs for classification. Instead, we performed classifications over all pairs of event mentions and time intervals as well as over all pairs of event mentions. We show through experiments that lifting these restrictions is indeed important (see Sec. 5).

Another important improvement over previous work is our global inference model. We would like to highlight that our work is also distinct from most previous works in the global inference component. Specifically, our global inference model jointly optimizes the  $E-E$  relations amongst event mentions and their associations,  $E-T$ , with temporal information (intervals in our case). Previous work (Chambers and Jurafsky, 2008; Denis and Muller, 2011), on the other hand, assumed that the  $E-T$  information is given and only tried to improve  $E-E$ .

### 3.1 The Pairwise Classifiers

We first describe our local classifiers that associate event mention with time interval and classify temporal relations between event mentions, respectively.

$C_{E-T}$ : is the  $E-T$  classifier that associates an event mention with a time interval. Given an event mention and a time interval, the classifier predicts

Figure 2: A simplified temporal structure of an article. There are  $m$  time intervals  $I_1 \dots I_m$  and  $n$  event mentions  $e_1 \dots e_n$ . A solid edge indicates an association between an interval and an event mention, whereas a dash edge illustrates a temporal relation between two event mentions.

whether the former associates with the latter.

$$C_{E-T}(e_i, I_j) \rightarrow \{0, 1\}, \quad \forall i, j, 1 \leq i \leq n, 1 \leq j \leq m, \quad (1)$$

where  $n$  and  $m$  are the number of event mentions and time intervals in an article, respectively.

$C_{E-E}$ : is the  $E-E$  classifier that identifies the temporal relation between two event mentions. Given a pair of event mentions, the classifier predicts one of the four temporal relations between them: *before*, *after*, *overlap* and *no relation*. Specifically:

$$C_{E-E}(e_i, e_j) \rightarrow \{\bar{b}, \bar{a}, \bar{o}, \bar{n}\}, \quad \forall i, j, 1 \leq i, j \leq n, i \neq j, \quad (2)$$

For training of the classifiers, we define a set of features following some previous work (Bethard et al., 2007; Chambers and Jurafsky, 2008; Yoshikawa et al., 2009), together with some additional features that we believe to be helpful for the interval-based representation. We describe the base features below and use  $\dagger$  and  $\ddagger$  to denote the features used for  $C_{E-T}$  and  $C_{E-E}$ , respectively. We use the term *temporal entity* (or *entity*, for short) to refer to either an event mention or a time interval.

**Lexical Features:** A set of lexical features related to the temporal entities: (i) $\dagger\ddagger$  the word, lemma and part-of-speech of the input event mentions and the context surrounding them, where the context is defined as a window of 2 words before and after the mention; (ii) $\dagger$  the modal verbs to the left and to the right of the event mention; (iii) $\ddagger$  the temporal connectives between the event mentions<sup>1</sup>.

<sup>1</sup>We define a list of temporal connectives including *before*, *after*, *since*, *when*, *meanwhile*, *lately*, etc.

**Syntactic Features:** (i) $\dagger\ddagger$  which entity appears first in the text; (ii) $\dagger\ddagger$  whether the two entities appear in the same sentence; (iii) $\dagger\ddagger$  the quantized number of sentences between the two entities<sup>2</sup>; (iv) $\dagger\ddagger$  whether the input event mentions are covered by prepositional phrases and what are the heads of the phrases; (v) $\dagger\ddagger$  if the entities are in the same sentence, what is their least common constituent on the syntactic parse tree; (vi) $\dagger$  whether there is any other temporal entity that is closer to one of the two entities.

**Semantic Features $\ddagger$ :** A set of semantic features, mostly related to the input event mentions: (i) whether the input event mentions have a common synonym from their synsets in WordNet (Fellbaum, 1998); (ii) whether the input event mentions have a common derivational form derived from WordNet.

**Linguistic Features $\dagger\ddagger$ :** The tense and the aspect of the input event mentions. We use an in-house rule-based recognizer to extract these features.

**Time Interval Features $\dagger$ :** A set of features related to the input time interval: (i) whether the interval is implicit; (ii) if it is implicit, identify its interval type: “dct” =  $[t_{DCT}^-, t_{DCT}^+]$ , “past” =  $(-\infty, t_{DCT}^-]$ , “feature” =  $[t_{DCT}^+, +\infty)$ , and “entire” =  $(-\infty, +\infty)$ ; (iii) the interval is before, after or overlapping with the DCT.

We note that unlike many previous work (Mani et al., 2006; Chambers and Jurafsky, 2008; Denis and Muller, 2011), our classifiers do not use any gold annotations of event attributes (event class, tense, aspect, modal and polarity) provided in the TimeBank corpus as features.

In our work, we use a regularized averaged Perceptron (Freund and Schapire, 1999) as our classification algorithm<sup>3</sup>. We used the one-vs.-all scheme to transform a set of binary classifiers into a multi-class classifier (for  $C_{E-E}$ ). The raw prediction scores were converted into probability distribution using the Softmax function (Bishop 1996). If there are  $n$  classes and the raw score of class  $i$  is  $act_i$ , the posterior estimation for class  $i$  is:

$$\tilde{P}(i) = \frac{e^{act_i}}{\sum_{1 \leq j \leq n} e^{act_j}}$$

<sup>2</sup>We quantize the number of sentences between two entities to 0, 1, 2, less than 5 and greater than or equal to 5

<sup>3</sup>Other algorithm (e.g. SVM) gave comparable or worse results, so we only show the results from Averaged Perceptron.

### 3.2 Joint Inference for Event Timeline

To exploit the interaction among the temporal entities in an article, we optimize the predicted temporal structure, formed by predictions from  $C_{E-T}$  and  $C_{E-E}$ , w.r.t. a set of global constraints that enforce coherency on the final structure. We perform exact inference using Integer Linear Programming (ILP) as in (Roth and Yih, 2007; Clarke and Lapata, 2008). We use the Gurobi Optimizer<sup>4</sup> as a solver.

Let  $\mathcal{I} = \{I_1, I_2, \dots, I_m\}$  denote the set of time intervals extracted from an article, and let  $\mathcal{E} = \{e_1, e_2, \dots, e_n\}$  denote all event mentions in the same article. Let  $\mathcal{EI} = \{(e_i, I_j) \in \mathcal{E} \times \mathcal{I} | e_i \in \mathcal{E}, I_j \in \mathcal{I}\}$  denote the set of all pairs of event mentions and time intervals. We also denote the set of event mention pairs by  $\mathcal{EE} = \{(e_i, e_j) \in \mathcal{E} \times \mathcal{E} | e_i \in \mathcal{E}, e_j \in \mathcal{E}, i \neq j\}$ . The prediction probability of an association of a pair  $eI \in \mathcal{EI}$ , given by classifier  $C_{E-T}$ , is denoted by  $p_{\langle eI, 1 \rangle}$ <sup>5</sup>. Now, let  $\mathcal{R} = \{\bar{b}, \bar{a}, \bar{o}, \bar{n}\}$  be the set of temporal relations between two event mentions. The prediction probability of an event mention pair  $ee \in \mathcal{EE}$  that takes temporal relation  $r$ , given by  $C_{E-E}$ , is denoted by  $p_{\langle ee, r \rangle}$ . Furthermore, we define  $x_{\langle eI, 1 \rangle}$  to be a binary indicator variable that takes on the value 1 iff an association is predicted between  $e$  and  $I$ . Similarly, we define a binary indicator variable  $y_{\langle ee, r \rangle}$  of a pair of event mentions  $ee$  that takes on the value 1 iff  $ee$  is predicted to hold the relation  $r$ .

The objective function is then defined as a linear combination of the prediction probabilities from the two local classifiers as follows:

$$\arg \max_{x, y} \left[ \lambda \sum_{eI \in \mathcal{EI}} p_{\langle eI, 1 \rangle} \cdot x_{\langle eI, 1 \rangle} + (1 - \lambda) \sum_{ee \in \mathcal{EE}} \sum_{r \in \mathcal{R}} p_{\langle ee, r \rangle} \cdot y_{\langle ee, r \rangle} \right] \quad (3)$$

subject to the following constraints:

$$x_{\langle eI, 1 \rangle} \in \{0, 1\}, \quad \forall eI \in \mathcal{EI} \quad (4)$$

$$y_{\langle ee, r \rangle} \in \{0, 1\}, \quad \forall ee \in \mathcal{EE}, r \in \mathcal{R} \quad (5)$$

$$\sum_{r \in \mathcal{R}} y_{\langle ee, r \rangle} = 1, \quad \forall ee \in \mathcal{EE} \quad (6)$$

<sup>4</sup><http://gurobi.com/>

<sup>5</sup>This value is complementary to the non-association probability, denoted by  $p_{\langle eI, 0 \rangle} = 1 - p_{\langle eI, 1 \rangle}$

We use the single parameter  $\lambda$  to balance the overall contribution of two components  $E-T$  and  $E-E$ .  $\lambda$  is determined through cross validation tuning on a development set. We use (4) and (5) to make sure  $x_{\langle eI, 1 \rangle}$  and  $y_{\langle ee, r \rangle}$  are binary values. The equality constraint (6) ensures that exactly one particular relation can be assigned to each event mention pair.

In addition, we also require that each event is associated with only one time interval. These constraints are encoded as follows:

$$\sum_{I \in \mathcal{I}} x_{\langle eI, 1 \rangle} = 1, \quad \forall e \in \mathcal{E} \quad (7)$$

Our model also enforces reflexivity and transitivity constraints on the relations among event mentions as follows:

$$y_{\langle e_i e_j, r \rangle} - y_{\langle e_j e_i, \hat{r} \rangle} = 0, \quad \forall e_i e_j = (e_i, e_j) \in \mathcal{EE}, i \neq j \quad (8)$$

$$y_{\langle e_i e_j, r_1 \rangle} + y_{\langle e_j e_k, r_2 \rangle} - y_{\langle e_i e_k, r_3 \rangle} \leq 1, \quad \forall e_i e_j, e_j e_k, e_i e_k \in \mathcal{EE}, i \neq j \neq k \quad (9)$$

The equality constraints in (8) encode reflexive property of event-event relations, where the relation  $\hat{r}$  denotes the inversion of the relation  $r$ . The set of possible  $(r, \hat{r})$  pairs is defined as follows:  $\{(\bar{b}, \bar{a}), (\bar{a}, \bar{b}), (\bar{o}, \bar{o}), (\bar{n}, \bar{n})\}$ . Following the work of (Bramsen et al., 2006; Chambers and Jurafsky, 2008), we encode transitive closure of relations between event mentions with inequality constraints in (9), which states that if the pair  $(e_i, e_j)$  has a certain relation  $r_1$ , and the pair  $(e_j, e_k)$  has the relation  $r_2$ , then the relation  $r_3$  must be satisfied between  $e_i$  and  $e_k$ . Examples of such triple  $(r_1, r_2, r_3)$  include  $(\bar{b}, \bar{b}, \bar{b})$  and  $(\bar{a}, \bar{a}, \bar{a})$ .

Finally, to capture the interactions between our local pairwise classifiers we add the following constraints:

$$x_{\langle e_i I_k, 1 \rangle} + x_{\langle e_j I_l, 1 \rangle} - y_{\langle e_i e_j, \bar{b} \rangle} \leq 1, \quad \forall e_i I_k, e_j I_l \in \mathcal{EI}, \forall e_i e_j \in \mathcal{EE}, \quad I_k \text{ precedes } I_l, i \neq j, k \neq l \quad (10)$$

Intuitively, the inequality constraints in (10) specify that a temporal relation between two event mentions can be inferred from their respective associated

time intervals. Specifically, if two event mentions  $e_i$  and  $e_j$  are associated with two time intervals  $I_k$  and  $I_l$  respectively, and  $I_k$  precedes  $I_l$  in the timeline, then  $e_i$  must happen before  $e_j$ .

It is important to note that our interval-based formulation is more concise in terms of the number of variables and constraints needed in the ILP relative to time expression-based (or timepoint-based) formulations used in previous work (Chambers and Jurafsky, 2008). Specifically, in such timepoint-based formulations, the relation between each event mention and each time expression needs to be inferred, resulting in  $|\mathcal{E}||\mathcal{T}||\mathcal{R}_{\mathcal{T}}|$  variables, where  $|\mathcal{E}|$ ,  $|\mathcal{T}|$ , and  $|\mathcal{R}_{\mathcal{T}}|$  are the numbers of event mentions, time points, and temporal relations respectively. In contrast, only  $|\mathcal{E}||\mathcal{I}|$  variables are required in our formulation, where  $|\mathcal{I}|$  is the number of intervals (since we extract intervals explicitly,  $|\mathcal{I}|$  is roughly equal to  $|\mathcal{T}|$ ). Furthermore, performing inference with the timepoint-based formulation would require  $|\mathcal{E}||\mathcal{T}|$  equality constraints to enforce that each event mention can take only one relation in  $\mathcal{R}_{\mathcal{T}}$  for a particular time point, whereas our interval-based model only requires  $|\mathcal{E}|$  constraints, since each event is strictly associated with one interval (see Eqn. (7)). We justify the benefits of our formulation later in Sec. 5.4.

#### 4 Incorporating Knowledge from Event Coreference

One of the key contributions of our work is using event coreference information to enhance the timeline construction performance. This is motivated by the following two principles:

(P1) *All mentions of a unique event are associated with the same time interval, and overlap with each other.*

(P2) *All mentions of an event have the same temporal relation with all mentions of another event.*

The example below, extracted from an article published on 03/11/2003 in the Automatic Content Extraction (ACE), 2005, corpus<sup>6</sup> serves to illustrate the significance of event coreference to our task.

<sup>6</sup><http://www.itl.nist.gov/iad/mig/tests/ace/2005/>

*The world's most powerful fine art auction houses, Sotheby's and Christie's, have agreed to [e<sub>1</sub><sup>1</sup> = **pay**] 40 million dollars to settle an international price-fixing scam, Sotheby's said. The [e<sub>2</sub><sup>1</sup> = **payment**], if approved by the courts, would settle a slew of [e<sub>1</sub><sup>2</sup> = **suits**] by clients over auctions held between 1993 and 2000 outside the US. ... Sotheby's and Christie's will each [e<sub>3</sub><sup>1</sup> = **pay**] 20 million dollars," said Sotheby's, which operates in 34 countries.*

In this example, there are 4 event mentions, whose trigger words are highlighted in bold face. The underlined text gives an explicit time interval:  $I_1 = [1993-01-01\ 00:00:00, 2000-12-31\ 23:59:59]$  (we ignore 2 other intervals given by 1993 and 2000 to simplify the illustration). Now if we consider the event mention  $e_2^1$ , it actually belongs to the implicit future interval  $I_2 = [2003-03-11\ 23:59:59, +\infty)$ . Nevertheless, there is a reasonable chance that  $C_{E-T}$  associates it with  $I_1$ , given that they both appear in the same sentence, and there is no direct evident feature indicating the event will actually happen in the future. In such a situation, using a local classifier to identify the correct temporal association could be challenging.

Fortunately, precise knowledge from event coreference may help alleviate such a problem. The knowledge reveals that the 4 event mentions can be grouped into 2 distinct events:  $E^1 = \{e_1^1, e_2^1, e_3^1\}$ ,  $E^2 = \{e_4^1\}$ . If  $C_{E-T}$  can make a strong prediction in associating the event mention  $e_1^1$  (or  $e_3^1$ ) to  $I_2$ , instead of  $I_1$ , the system will have a high chance to re-assign  $e_2^1$  to  $I_2$  based on principle (P1). Similarly, if  $C_{E-E}$  is effective in figuring out that some mention of event  $E^1$  occurs *after* some mention of  $E^2$ , then all the mentions of  $E^1$  would be predicted to occur *after* all mentions in  $E^2$  according to (P2).

To incorporate knowledge from event coreference into our classifiers and the joint inference model, we use the following procedure: (1) performing classification with  $C_{E-T}$  and  $C_{E-E}$  on the data, (2) using the knowledge from event coreference to overwrite the prediction probabilities obtained by the two local classifiers in step (1), and (3) applying the joint inference model on the new prediction probabilities obtained from (2). We note that if we stop at step (2), we get the outputs of the local classifiers enhanced by event coreference knowledge.

To overwrite the classification probabilities using

event coreference knowledge, we propose two approaches as follows:

**MaxScore:** We define the probability between any mention  $e \in E^i$  and an interval  $I$  as follows:

$$p_{\langle eI,1 \rangle} = \max_{e' \in E^i} \tilde{P}(e', I) \quad (11)$$

where  $\tilde{P}(e', I)$  is the classifier ( $C_{E-T}$ ) probability for associating event mention  $e'$  to the time interval.

On the other hand, the probabilities for associating the set of temporal relations,  $\mathcal{R}$ , to each pair of mentions in  $E^i \times E^j$ , is given by the following pair:

$$\begin{aligned} (e^i, e^j)^* &= \arg \max_{(e^{i'}, e^{j'}) \in E^i \times E^j, r \in \mathcal{R}} \tilde{P}((e^{i'}, e^{j'}), r) \\ p_{\langle ee, r \rangle} &= \tilde{P}((e^i, e^j)^*, r), \forall r \in \mathcal{R} \end{aligned} \quad (12)$$

In other words, over all possible event mention pairs and relations, we first pick the pair who globally obtains the highest probability for some relation. Next, we simply take the probability distribution of that event mention pair as the distribution over the relations, for the event pair.

**SumScore:** The probability between any mention  $e \in E^i$  and an interval  $I$  is obtained by:

$$p_{\langle eI,1 \rangle} = \frac{1}{|E^i|} \sum_{e' \in E^i} \tilde{P}(e', I) \quad (13)$$

To obtain the probability distribution over the set of temporal relations,  $\mathcal{R}$ , for any pair of mentions in  $E^i \times E^j$ , we used the following procedure:

$$\begin{aligned} r^* &= \arg \max_{r \in \mathcal{R}} \sum_{e^i \in E^i} \sum_{e^j \in E^j} \tilde{P}((e^i, e^j), r) \\ (e^i, e^j)^* &= \arg \max_{(e^{i'}, e^{j'}) \in E^i \times E^j} \tilde{P}((e^{i'}, e^{j'}), r^*) \\ p_{\langle ee, r \rangle} &= \tilde{P}((e^i, e^j)^*, r), \forall r \in \mathcal{R} \end{aligned} \quad (14)$$

In other words, given two groups of event mentions, we first compute the total score of each relation, and select the relation which has the highest score. Next from the list of pairs of event mentions from the two groups, we select the pair which has the relation  $r^*$  with highest score compared to all other pairs. The probability distribution of this pair will be used as the probability distribution of all event mention pairs between the two events.

In both approaches, we assign the *overlap* relations to all pairs of event mentions in the same event with probability 1.0.

## 5 Experimental Study

We first describe the experimental data and then present and discuss the experimental results.

### 5.1 Data and Setup

Most previous works in temporal reasoning used the TimeBank corpus as a benchmark. The corpus contains a fairly diverse collection of annotated event mentions, without any specific focus on certain event types. According to the annotation guideline of the corpus, most of verbs, nominalizations, adjectives, predicative clauses and prepositional phrases can be tagged as events. However, in practice, when performing temporal reasoning about events in a given text, one is typically interested in significant and typed events, such as *Killing*, *Legislation*, *Election*. Furthermore, event mentions in TimeBank are annotated with neither event arguments nor event coreference information.

We noticed that the ACE 2005 corpus contains the annotation that we are interested in. The corpus consists of articles annotated with event mentions (with event triggers and arguments) and event coreference information. To create an experimental data set for our work, we selected from the corpus 20 newswire articles published in March 2003. To extract time intervals from the articles, we used the time interval extractor described in (Zhao et al., 2012) with minimal post-processing. Implicit intervals are also added according to Sec. 2.2. We then hired an annotator with expertise in the field to annotate the data with the following information: (i) event mention and time interval association, and (ii) the temporal relations between event mentions, including  $\{\bar{b}, \bar{a}, \bar{o}\}$ . The annotator was not required to annotate all pairs of event mentions, but as many as possible. Next, we saturated the relations based on the initial annotations as follows: (i) event mentions that had not been associated with any time intervals were assigned to the entire timeline interval  $(-\infty, +\infty)$ , and (ii) added inferred temporal relations between event mentions with reflectivity and transitivity. Table 1 shows the data statistics before and after saturation. There are totally 8312 event pairs from 20 documents, including *no relation* pairs. We note that in a separate experiment, we still evaluated  $C_{E-E}$  on the TimeBank corpus and got better performance

Data	#Intervals	#E-mentions	#E-T	#E-E
Initial	232	324	305	376
Saturated	232	324	324	5940

Table 1: The statistics of our experimental data set.

than a corresponding classifier in an existing work (see Sec. 5.4).

We conducted all experiments with 5-fold cross validation at the instance level on our data set after saturation. The global inference model was applied on a whole document. The results of the systems are reported in averaged precision, recall and  $F_1$  score on the association performance, for  $C_{E-T}$ , and the temporal relations (we excluded the  $\bar{n}$  relation, for  $C_{E-E}$ ). We also measured the overall performance of the systems by computing the average of the performance of the classifiers.

## 5.2 A Baseline

We developed a baseline system that works as follows. It associates an event mention with the closest time interval found in the same sentence. If such an interval is not found, the baseline associates the mention with the closest time interval to the left. If the interval is again not found, the mention will be associated with the DCT interval. The baseline is based on the intuition of natural reading order: events that are mentioned earlier are likely to precede those mentioned later. For the temporal relation between a pair of event mentions, the baseline treats the event mention that appears earlier in the text as temporally happening before the other mention. The baseline performance is shown in the first group of results in Table 2.

## 5.3 Our Systems

For our systems, we first evaluated the performance of our local pairwise classifiers and the global inference model. The second group of results in Table 2 shows the systems’ performance. Overall, the results show that our global inference model relatively outperformed the baseline and the local classifiers by 57.8% and 9.2% in  $F_1$ , respectively. We perform a bootstrap resampling significance test (Koehn, 2004) on the output predictions of the local classifiers with and without the inference model.

The test shows that the overall improvement with the inference model is statistically significant ( $p < 0.01$ ). This indicates the effectiveness of our joint inference model with global coherence constraints.

Next, we integrated event coreference knowledge into our systems (as described in Sec. 4) and evaluated their performance. Our experiments showed that the *SumScore* approach works better for  $C_{E-T}$ , while *MaxScore* is more suitable for  $C_{E-E}$ . Our observations showed that event mentions of an event may appear in close proximity with multiple time intervals in the text, making  $C_{E-T}$  produce high prediction scores for many event mention-interval pairs. This, consequently, confuses *MaxScore* on the best association of the event and the time intervals, whereas *SumScore* overcomes the problem by averaging out the association scores. On the other hand,  $C_{E-E}$  gets more benefit from *MaxScore* because  $C_{E-E}$  works better on pairs of event mentions that appear closely in the text, which activate more valuable learning features. We will report the results using the best approach of each classifier.

To evaluate our systems with event coreference knowledge, we first experimented our systems with gold event coreference as given by the ACE 2005 corpus. Table 2 shows the contribution of event coreference to our systems in the third group of the results. The results show that injecting knowledge from event coreference remarkably improved both the local classifiers and the joint inference model. Overall, the system that combined event coreference and the global inference model achieved the best performance, which significantly overtook all other compared systems. Specifically, it outperformed the baseline system, the local classifiers, and the joint inference model without event coreference with 80%, 25%, and 14% of relative improvement in  $F_1$ , respectively. It also consistently outperformed the local classifiers enhanced with event coreference. We note that the precision and recall of  $C_{E-T}$  in the joint inference model are the same because the inference model enforced each event mention to be associated with exactly one time interval. This is also true for the systems integrated with event coreference because our integration approaches assign only one time interval to an event mention.

We next move to experimenting with automatically learned event coreference systems. In this ex-

	Model	$C_{E-T}$			$C_{E-E}$			Overall

Table 2: Performance under various evaluation settings. All figures are averaged scores from 5-fold cross-validation experiments.

periment, we re-trained the event coreference system described in Chen et al. (2009) on all articles in the ACE 2005 corpus, excluding the 20 articles used in our data set. The performance of these systems are shown in the fourth group of the results in Table 2. The results show that by using a learned event coreference system, we achieved the same improvement trends as with gold event coreference. However, we did not obtain significant improvement when comparing with global inference without event coreference information. This result shows that the performance of an event coreference system can have a significant impact on the overall performance. While this suggests that a better event coreference system could potentially help the task more, it also opens the question whether event coreference can be benefited from our local classifiers through the use of a joint inference framework. We would like to leave this for future investigations.

#### 5.4 Previous Work-Related Experiments

We also performed experiments using the same setting as in (Yoshikawa et al., 2009), which followed the guidelines of the TempEval challenges (Verhagen et al., 2007; Verhagen et al., 2010), on our saturated data. Several assumptions were made to simplify the task. For example, only main events in adjacent sentences are considered when identifying event-event relations. See (Yoshikawa et al., 2009) for more details. We performed 5-fold cross validation without event coreference. Overall, the system achieved 29.99  $F_1$  for the local classifiers and 34.69 when the global inference is used. These results are better than the baseline but underperform our full models where those simplification assumptions are

not imposed, as shown in Table 2, indicating the importance of relaxing their assumptions in practice.

We also evaluated our  $C_{E-E}$  on the TimeBank corpus. We followed the settings of Chambers and Jurafsky (2008) to extract all event mention pairs that were annotated with *before* (or *ibefore*, “immediately before”) and *after* (or *iafter*) relations in 183 news articles in the corpus. We trained and evaluated our  $C_{E-E}$  on these examples with the same feature set that we evaluated in our experiments above, with gold tense and aspect features but without event type. Following their work, we performed 10-fold cross validation. Our classifier achieved a micro-averaged accuracy of 73.45%, whereas Chambers and Jurafsky (2008) reported 66.8%. We next injected the knowledge of an event coreference system trained on the ACE2005 corpus into our  $C_{E-E}$ , and obtained a micro-averaged accuracy of 73.39%. It was not surprising that event coreference did not help in this dataset because: (i) different domains – the event coreference was trained on ACE 05 but applied on TimeBank, and (ii) different annotation guidelines on events in ACE 2005 and TimeBank.

Finally, we conducted an experiment that justifies the advantages of our interval-based inference model over a time point-based inference. To do this, we first converted our data in Table 1 from intervals to time points and infer the temporal relations between the annotated event mentions and the time points: *before*, *after*, *overlap*, and *unknown*. We modified the first component in the objective function in (3) to accommodate these temporal relations. We also made several changes to the constraints, including removing those in (7) since they are no longer required, and adding constraints that ensure

the relation between a time point and an event mention takes exactly one value. Proper changes were also made to other constraints in (10) to reflect the fact that time points are considered rather than intervals. We observed that experiment with such a formulation was unable to finish within 5 hours (we terminated the ILP inference after waiting for 5 hours), whereas our interval-based model finished the experiment with an average of 21 seconds per article.

## 6 Related Work

Research in temporal reasoning recently received much attention. Allen (1983) introduced an interval based temporal logic which has been used widely in the field. Recent efforts in building an annotated temporal corpus (Pustejovsky et al., 2003) has popularized the use of machine learning techniques for the task (Mani et al., 2006; Bethard et al., 2007). This corpus was later used (with simplifications) in two TempEval challenges (Verhagen et al., 2007; Verhagen et al., 2010). In these challenges, several temporal-related tasks were defined including the tasks of identifying the temporal relation between an event mention and a temporal expression in the same sentence, and recognizing temporal relations of pairs of event mentions in adjacent sentences. However, with several restrictions imposed to these tasks, the developed systems were not practical.

Recently, there has been much work attempting to leverage Allen’s interval algebra of temporal relations to enforce global constraints on local predictions. The work of Tatu and Srikanth (2008) used global relational constraints to not only expand the training data but also identifies temporal inconsistencies to improve local classifiers. They used greedy search to select the most appropriate configuration of temporal relations among events and temporal expressions. For exact inferences, Bramsen et al. (2006), Chambers and Jurafsky (2008), Denis and Muller (2011), and Talukdar et al. (2012) formulated the temporal reasoning problem in an ILP. However, the inference models in their work were not a joint model involving multiple local classifiers but only one local classifier was involved in their objective functions.

The work of Yoshikawa et al. (2009) did formulate a joint inference model with Markov Logic Net-

work (MLN). They, however, used the same setting as the TempEval challenges, thus only pairs of temporal entities in the same or adjacent sentences are considered. Our work, on the other hand, focuses on constructing an event timeline with time intervals, taking multiple local pairwise predictions into a joint inference model and removing the restrictions on the positions of the temporal entities. Furthermore, we propose for the first time to use event coreference and evaluate the importance of its role in the task of event timeline construction.

## 7 Conclusions and Future Work

We proposed an interval-based representation of the timeline of event mentions in an article. Our representation allowed us to formalize the joint inference model that can be solved efficiently, compared to a time point-based inference model, thus opening up the possibility of building more practical event temporal inference systems. Our inference model achieved significant improvement over the local classifiers. We also showed that event coreference can naturally support timeline construction, and good event coreference led to significant improvement in the system performance. Specifically, when such gold event coreference knowledge was injected into the model, a significant improvement in the overall performance could be obtained. While our experiments suggest that the temporal classifiers can potentially help enhance the performance of event coreference, in future work we would like to investigate into coupling event coreference with other components in a global inference framework.

## Abstract

We present a new family of models for unsupervised parsing, *Dependency and Boundary* models, that use cues at constituent boundaries to inform head-outward dependency tree generation. We build on three intuitions that are explicit in phrase-structure grammars but only implicit in standard dependency formulations: (i) Distributions of words that occur at sentence boundaries — such as English determiners — resemble constituent edges. (ii) Punctuation at sentence boundaries further helps distinguish full sentences from fragments like headlines and titles, allowing us to model grammatical differences between complete and incomplete sentences. (iii) Sentence-internal punctuation boundaries help with longer-distance dependencies, since punctuation correlates with constituent edges. Our models induce state-of-the-art dependency grammars for many languages without special knowledge of optimal input sentence lengths or biased, manually-tuned initializers.

## 1 Introduction

Natural language is ripe with all manner of boundaries at the surface level that align with hierarchical syntactic structure. From the significance of function words (Berant et al., 2006) and punctuation marks (Seginer, 2007; Ponvert et al., 2010) as separators between constituents in longer sentences — to the importance of isolated words in children’s early vocabulary acquisition (Brent and Siskind, 2001) — word boundaries play a crucial role in language learning. We will show that boundary information can also be useful in dependency grammar induction models, which traditionally focus on head rather than fringe words (Carroll and Charniak, 1992).

Figure 1: A partial analysis of our running example.

Consider the example in Figure 1. Because the determiner (DT) appears at the left edge of the sentence, it should be possible to learn that determiners may generally be present at left edges of phrases. This information could then be used to correctly parse the sentence-internal determiner in *the mail*. Similarly, the fact that the noun head (NN) of the object *the mail* appears at the right edge of the sentence could help identify the noun *check* as the right edge of the subject NP. As with jigsaw puzzles, working inwards from boundaries helps determine sentence-internal structures of both noun phrases, neither of which would be quite so clear if viewed separately.

Furthermore, properties of noun-phrase edges are partially shared with prepositional- and verb-phrase units that contain these nouns. Because typical head-driven grammars model valence separately for each class of head, however, they cannot see that the left fringe boundary, *The check*, of the verb-phrase is shared with its daughter’s, *check*. Neither of these insights is available to traditional dependency formulations, which could learn from the boundaries of this sentence only that determiners might have no left- and that nouns might have no right-dependents.

We propose a family of dependency parsing models that are capable of inducing longer-range implications from sentence edges than just fertilities of their fringe words. Our ideas conveniently lend themselves to implementations that can reuse much of the standard grammar induction machinery, including efficient dynamic programming routines for the relevant expectation-maximization algorithms.

## 2 The Dependency and Boundary Models

Our models follow a standard generative story for head-outward automata (Alshawi, 1996a), restricted to the split-head case (see below),<sup>1</sup> over lexical word classes  $\{c_w\}$ : first, a sentence root  $c_r$  is chosen, with probability  $\mathbb{P}_{\text{ATTACH}}(c_r \mid \diamond; \text{L})$ ;  $\diamond$  is a special start symbol that, by convention (Klein and Manning, 2004; Eisner, 1996), produces exactly one child, to its left. Next, the process recurses. Each (head) word  $c_h$  generates a left-dependent with probability  $1 - \mathbb{P}_{\text{STOP}}(\cdot \mid \text{L}; \dots)$ , where dots represent additional parameterization on which it may be conditioned. If the child is indeed generated, its identity  $c_d$  is chosen with probability  $\mathbb{P}_{\text{ATTACH}}(c_d \mid c_h; \dots)$ , influenced by the identity of the parent  $c_h$  and possibly other parameters (again represented by dots). The child then generates its own subtree recursively and the whole process continues, moving away from the head, until  $c_h$  fails to generate a left-dependent. At that point, an analogous procedure is repeated to  $c_h$ 's right, this time using stopping factors  $\mathbb{P}_{\text{STOP}}(\cdot \mid \text{R}; \dots)$ . All parse trees derived in this way are guaranteed to be projective and can be described by split-head grammars.

Instances of these split-head automata have been heavily used in grammar induction (Paskin, 2001b; Klein and Manning, 2004; Headden et al., 2009, *inter alia*), in part because they allow for efficient implementations (Eisner and Satta, 1999, §8) of the inside-outside re-estimation algorithm (Baker, 1979). The basic tenet of split-head grammars is that every head word generates its left-dependents independently of its right-dependents. This assumption implies, for instance, that words' left- and right-valences — their numbers of children to each side — are also independent. But it does *not* imply that descendants that are closer to the head cannot influence the generation of farther dependents on the same side. Nevertheless, many popular grammars for unsupervised parsing behave as if a word had to generate all of its children (to one side) — or at least their count — *before* allowing any of these children themselves to recurse.

For example, Klein and Manning's (2004) dependency model with valence (DMV) could be imple-

mented as both head-outward and head-inward automata. (In fact, arbitrary permutations of siblings to a given side of their parent would not affect the likelihood of the modified tree, with the DMV.) We propose to make fuller use of split-head automata's head-outward nature by drawing on information in partially-generated parses, which contain useful predictors that, until now, had not been exploited even in featurized systems for grammar induction (Cohen and Smith, 2009; Berg-Kirkpatrick et al., 2010).

Some of these predictors, including the identity — or even number (McClosky, 2008) — of already-generated siblings, can be prohibitively expensive in sentences above a short length  $k$ . For example, they break certain modularity constraints imposed by the charts used in  $O(k^3)$ -optimized algorithms (Paskin, 2001a; Eisner, 2000). However, in bottom-up parsing and training from text, everything about the yield — i.e., the ordered sequence of all already-generated descendants, on the side of the head that is in the process of spawning off an additional child — is not only known but also readily accessible. Taking advantage of this availability, we designed three new models for dependency grammar induction.

### 2.1 Dependency and Boundary Model One

DBM-1 conditions all stopping decisions on adjacency and the identity of the fringe word  $c_e$  — the currently-farthest descendant (edge) derived by head  $c_h$  in the given head-outward direction ( $dir \in \{\text{L}, \text{R}\}$ ):

$$\mathbb{P}_{\text{STOP}}(\cdot \mid dir; adj, c_e).$$

In the adjacent case ( $adj = \text{T}$ ),  $c_h$  is deciding whether to have any children on a given side: a first child's subtree would be right next to the head, so the head and the fringe words coincide ( $c_h = c_e$ ). In the non-adjacent case ( $adj = \text{F}$ ), these will be different words and their classes will, in general, not be the same.<sup>2</sup> Thus, non-adjacent stopping decisions will be made independently of a head word's identity. Therefore, all word classes will be equally likely to continue to grow or not, for a specific proposed fringe boundary.

For example, production of *The check is* involves two non-adjacent stopping decisions on the left: one by the noun *check* and one by the verb *is*, both of which stop after generating a first child. In DBM-1,

<sup>1</sup>Unrestricted head-outward automata are strictly more powerful (e.g., they recognize the language  $a^n b^n$  in finite state) than the split-head variants, which process one side before the other.

<sup>2</sup>Fringe words differ also from other standard dependency features (Eisner, 1996, §2.3): parse siblings and adjacent words.

Figure 2: Our running example — a simple sentence and its unlabeled dependency parse structure’s probability, as factored by DBM-1; highlighted comments specify heads associated to non-adjacent stopping probability factors.

this outcome is captured by squaring a shared parameter belonging to the left-fringe determiner *The*:  $\mathbb{P}_{\text{STOP}}(\cdot | L; F, \text{DT})^2$  — instead of by a product of two factors, such as  $\mathbb{P}_{\text{STOP}}(\cdot | L; F, \text{NN}) \cdot \mathbb{P}_{\text{STOP}}(\cdot | L; F, \text{VBZ})$ .

In these grammars, dependents’ attachment probabilities, given heads, are additionally conditioned only on their relative positions — as in traditional models (Klein and Manning, 2004; Paskin, 2001b):

$$\mathbb{P}_{\text{ATTACH}}(c_d | c_h; \text{dir}).$$

Figure 2 shows a completely factored example.

## 2.2 Dependency and Boundary Model Two

DBM-2 allows different but related grammars to co-exist in a single model. Specifically, we presuppose that all sentences are assigned to one of two classes: complete and incomplete ( $\text{comp} \in \{\text{T}, \text{F}\}$ , for now taken as exogenous). This model assumes that word-word (i.e., head-dependent) interactions in the two domains are the same. However, sentence lengths — for which stopping probabilities are responsible — and distributions of root words may be different.

Consequently, an additional  $\text{comp}$  parameter is added to the context of two relevant types of factors:

$$\mathbb{P}_{\text{STOP}}(\cdot | \text{dir}; \text{adj}, c_e, \text{comp});$$

and  $\mathbb{P}_{\text{ATTACH}}(c_r | \Delta; L, \text{comp}).$

For example, the new stopping factors could capture the fact that incomplete fragments — such as the noun-phrases *George Morton*, headlines *Energy* and *Odds and Ends*, a line item *c - Domestic car*, dollar

quantity *Revenue: \$3.57 billion*, the time *1:11am*, and the like — tend to be much shorter than complete sentences. The new root-attachment factors could further track that incomplete sentences generally lack verbs, in contrast to other short sentences, e.g., *Excerpts follow:*, *Are you kidding?*, *Yes, he did.*, *It’s huge.*, *Indeed it is.*, *I said, ‘NOW?’*, *‘Absolutely,’ he said.*, *I am waiting.*, *Mrs. Yeargin declined.*, *McGraw-Hill was outraged.*, *‘It happens.’*, *I’m OK, Jack.*, *Who cares?*, *Never mind.* and so on.

All other attachment probabilities  $\mathbb{P}_{\text{ATTACH}}(c_d | c_h; \text{dir})$  remain unchanged, as in DBM-1. In practice,  $\text{comp}$  can indicate presence of sentence-final punctuation.

## 2.3 Dependency and Boundary Model Three

DBM-3 adds further conditioning on punctuation context. We introduce another boolean parameter,  $\text{cross}$ , which indicates the presence of intervening punctuation between a proposed head word  $c_h$  and its dependent  $c_d$ . Using this information, longer-distance punctuation-crossing arcs can be modeled separately from other, lower-level dependencies, via

$$\mathbb{P}_{\text{ATTACH}}(c_d | c_h; \text{dir}, \text{cross}).$$

For instance, in *Continental believe that the strongest growth area will be southern Europe.*, four words appear between *that* and *will*. Conditioning on (the absence of) intervening punctuation could help tell true long-distance relations from impostors.

All other probabilities,  $\mathbb{P}_{\text{STOP}}(\cdot | \text{dir}; \text{adj}, c_e, \text{comp})$  and  $\mathbb{P}_{\text{ATTACH}}(c_r | \Delta; L, \text{comp})$ , remain the same as in DBM-2.

## 2.4 Summary of DBMs and Related Models

Head-outward automata (Alshawi, 1996a; Alshawi, 1996b; Alshawi et al., 2000) played a central part as generative models for probabilistic grammars, starting with their early adoption in supervised split-head constituent parsers (Collins, 1997; Collins, 2003). Table 1 lists some parameterizations that have since been used by unsupervised dependency grammar inducers sharing their backbone split-head process.

## 3 Experimental Set-Up and Methodology

We first motivate each model by analyzing the Wall Street Journal (WSJ) portion of the Penn English Treebank (Marcus et al., 1993),<sup>3</sup> before delving into

<sup>3</sup>We converted labeled constituents into unlabeled dependencies using deterministic “head-percolation” rules (Collins,

Split-Head Dependency Grammar		$\mathbb{P}_{\text{ATTACH}}$ (head-root)	$\mathbb{P}_{\text{ATTACH}}$ (dependent-head)	$\mathbb{P}_{\text{STOP}}$ (adjacent and not)
GB	(Paskin, 2001b)	$1 /  \{w\} $	$d \mid h; \text{dir}$	$1 / 2$
DMV	(Klein and Manning, 2004)	$c_r \mid \diamond; L$	$c_d \mid c_h; \text{dir}$	$\cdot \mid \text{dir}; \text{adj}, c_h$
EVG	(Headden et al., 2009)	$c_r \mid \diamond; L$	$c_d \mid c_h; \text{dir}, \text{adj}$	$\cdot \mid \text{dir}; \text{adj}, c_h$
DBM-1	(§2.1)	$c_r \mid \diamond; L$	$c_d \mid c_h; \text{dir}$	$\cdot \mid \text{dir}; \text{adj}, c_e$
DBM-2	(§2.2)	$c_r \mid \diamond; L, \text{comp}$	$c_d \mid c_h; \text{dir}$	$\cdot \mid \text{dir}; \text{adj}, c_e, \text{comp}$
DBM-3	(§2.3)	$c_r \mid \diamond; L, \text{comp}$	$c_d \mid c_h; \text{dir}, \text{cross}$	$\cdot \mid \text{dir}; \text{adj}, c_e, \text{comp}$

Table 1: Parameterizations of the split-head-outward generative process used by DBMs and in previous models.

grammar induction experiments. Although motivating solely from this treebank biases our discussion towards a very specific genre of just one language, it has the advantage of allowing us to make concrete claims that are backed up by significant statistics.

In the grammar induction experiments that follow, we will test each model’s incremental contribution to accuracies empirically, across many disparate languages. We worked with all 23 (disjoint) train/test splits from the 2006/7 CoNLL shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007), spanning 19 languages.<sup>4</sup> For each data set, we induced a baseline grammar using the DMV. We excluded all training sentences with more than 15 tokens to create a conservative bias, because in this set-up the baseline is known to excel (Spitkovsky et al., 2009). Grammar inducers were initialized using (the same) uniformly-at-random chosen parse trees of training sentences (Cohen and Smith, 2010); thereafter, we applied “add one” smoothing at every training step.

To fairly compare the models under consideration — which could have quite different starting perplexities and ensuing consecutive relative likelihoods — we experimented with two termination strategies. In one case, we blindly ran each learner through 40 steps of inside-outside re-estimation, ignoring any convergence criteria; in the other case, we ran until numerical convergence of soft EM’s objective function or until the likelihood of resulting Viterbi parse trees suffered — an “early-stopping lateen EM” strategy (Spitkovsky et al., 2011a, §2.3). We evaluated against all sentences of the blind test sets (except one 145-token item in Arabic ’07 data).

Table 2 shows experimental results, averaged over

1999), discarding any empty nodes, etc., as is standard practice.

<sup>4</sup>We did not test on WSJ data because such evaluation would not be blind, as parse trees from the PTB are our motivating examples; instead, performance on WSJ serves as a strong baseline in a separate study (Spitkovsky et al., 2012a): bootstrapping of DBMs from mostly incomplete inter-punctuation fragments.

all 19 languages, for the DMV baselines and DBM-1 and 2. We did not test DBM-3 in this set-up because most sentence-internal punctuation occurs in longer sentences; instead, DBM-3 will be tested later (see §7), using most sentences,<sup>5</sup> in the final training step of a curriculum strategy (Bengio et al., 2009) that we will propose for DBMs. For the three models tested on shorter inputs (up to 15 tokens) both terminating criteria exhibited the same trend; lateen EM consistently scored slightly higher than 40 EM iterations.

Termination Criterion	DMV	DBM-1	DBM-2
40 steps of EM	33.5	38.8	40.7
early-stopping lateen EM	34.0	39.0	<b>40.9</b>

Table 2: Directed dependency accuracies, averaged over all 2006/7 CoNLL evaluation sets (all sentences), for the DMV and two new dependency-and-boundary grammar inducers (DBM-1,2) — using two termination strategies.<sup>6</sup>

## 4 Dependency and Boundary Model One

The primary difference between DBM-1 and traditional models, such as the DMV, is that DBM-1 conditions non-adjacent stopping decisions on the identities of fringe words in partial yields (see §2.1).

### 4.1 Analytical Motivation

Treebank data suggests that the class of the fringe word — its part-of-speech,  $c_e$  — is a better predictor of (non-adjacent) stopping decisions, in a given direction  $\text{dir}$ , than the head’s own class  $c_h$ . A statistical analysis of logistic regressions fitted to the data shows that the  $(c_h, \text{dir})$  predictor explains only about 7% of the total variation (see Table 3). This seems low, although it is much better compared to direction alone (which explains less than 2%) and slightly better than using the (current) number of the head’s de-

<sup>5</sup>Results for DBM-3 — given only standard input sentences, up to length fifteen — would be nearly identical to DBM-2’s.

<sup>6</sup>We down-weighted the four languages appearing in both CoNLL years (see Table 8) by 50% in all reported averages.

<i>Non-Adjacent Stop Predictor</i>	$R_{adj}^2$	$AIC_c$
<i>(dir)</i>	0.0149	1,120,200
<i>(n, dir)</i>	0.0726	1,049,175
<i>(c<sub>h</sub>, dir)</i>	0.0728	1,047,157
<i>(c<sub>e</sub>, dir)</i>	0.2361	904,102.4
<i>(c<sub>h</sub>, c<sub>e</sub>, dir)</i>	0.3320	789,594.3

Table 3: Coefficients of determination ( $R^2$ ) and Akaike information criteria (AIC), both adjusted for the number of parameters, for several single-predictor logistic models of non-adjacent stops, given direction  $dir$ ;  $c_h$  is the class of the head,  $n$  is its number of descendants (so far) to that side, and  $c_e$  represents the farthest descendant (the edge).

scendants on that side,  $n$ , instead of the head’s class. In contrast, using  $c_e$  in place of  $c_h$  boosts explanatory power to 24%, keeping the number of parameters the same. If one were willing to roughly square the size of the model, explanatory power could be improved further, to 33% (see Table 3), using both  $c_e$  and  $c_h$ .

Fringe boundaries thus appear to be informative even in the supervised case, which is not surprising, since using just one probability factor (and its complement) to generate very short (geometric coin-flip) sequences is a recipe for high entropy. But as suggested earlier, fringes should be extra attractive in unsupervised settings because yields are observable, whereas heads almost always remain hidden. Moreover, every sentence exposes two true edges (Hänig, 2010): integrated over many sample sentence beginnings and ends, cumulative knowledge about such markers can guide a grammar inducer inside long inputs, where structure is murky. Table 4 shows distributions of all part-of-speech (POS) tags in the treebank versus in sentence-initial, sentence-final and sentence-root positions. WSJ often leads with determiners, proper nouns, prepositions and pronouns — all good candidates for starting English phrases; and its sentences usually end with various noun types, again consistent with our running example.

## 4.2 Experimental Results

Table 2 shows DBM-1 to be substantially more accurate than the DMV, on average: 38.8 versus 33.5% after 40 steps of EM.<sup>7</sup> Lateen termination improved both models’ accuracies slightly, to 39.0 and 34.0%, respectively, with DBM-1 scoring five points higher.

<sup>7</sup>DBM-1’s 39% average accuracy with uniform-at-random initialization is two points above DMV’s scores with the “ad-hoc harmonic” strategy, 37% (Spitkovsky et al., 2011a, Table 5).

Figure 3: Histograms of lengths (in tokens) for 2,261 non-clausal fragments (red) and other sentences (blue) in WSJ.

## 5 Dependency and Boundary Model Two

DBM-2 adapts DBM-1 grammars to two classes of inputs (complete sentences and incomplete fragments) by forking off new, separate multinomials for stopping decisions and root-distributions (see §2.2).

### 5.1 Analytical Motivation

Unrepresentative short sentences — such as headlines and titles — are common in news-style data and pose a known nuisance to grammar inducers. Previous research sometimes took radical measures to combat the problem: for example, Gillenwater et al. (2009) excluded all sentences with three or fewer tokens from their experiments; and Mareček and Zabokrtský (2011) enforced an “anti-noun-root” policy to steer their Gibbs sampler away from the undercurrents caused by the many short noun-phrase fragments (among sentences up to length 15, in Czech data). We refer to such snippets of text as “incomplete sentences” and focus our study of WSJ on non-clausal data (as signaled by top-level constituent annotations whose first character is not S).<sup>8</sup>

Table 4 shows that roots of incomplete sentences, which are dominated by nouns, barely resemble the other roots, drawn from more traditional verb and modal types. In fact, these two empirical root distributions are more distant from one another than either is from the uniform distribution, in the space of discrete probability distributions over POS-tags (see Table 5). Of the distributions we considered, only sentence boundaries are as or more different from

<sup>8</sup>I.e., separating top-level types {S, SINV, SBARQ, SQ, SBAR} from the rest (ordered by frequency): {NP, FRAG, X, PP, ...}.

(complete) roots, suggesting that heads of fragments too may warrant their own multinomial in the model.

Further, incomplete sentences are uncharacteristically short (see Figure 3). It is this property that makes them particularly treacherous to grammar inducers, since by offering few options of root positions they increase the chances that a learner will incorrectly induce nouns to be heads. Given that expected lengths are directly related to stopping decisions, it could make sense to also model the stopping probabilities of incomplete sentences separately.

### 5.2 Experimental Results

Since it is not possible to consult parse trees during grammar induction (to check whether an input sentence is clausal), we opted for a proxy: presence of sentence-final punctuation. Using punctuation to divide input sentences into two groups, DBM-2 scored higher: 40.9, up from 39.0% accuracy (see Table 2).

After evaluating these multi-lingual experiments, we checked how well our proxy corresponds to actual clausal sentences in WSJ. Table 6 shows the binary confusion matrix having a fairly low (but positive) Pearson correlation coefficient. False positives

$r_\phi \approx 0.31$	Clausal	non-Clausal	Total
Punctuation	46,829	1,936	48,765
no Punctuation	118	325	443
Total	46,947	2,261	49,208

Table 6: A contingency table for clausal sentences and trailing punctuation in WSJ; the mean square contingency coefficient  $r_\phi$  signifies a low degree of correlation. (For two binary variables,  $r_\phi$  is equivalent to Karl Pearson’s better-known product-moment correlation coefficient,  $\rho$ .)

include parenthesized expressions that are marked as noun-phrases, such as (*See related story: “Fed Ready to Inject Big Funds”: WSJ Oct. 16, 1989*); false negatives can be headlines having a main verb, e.g., *Population Drain Ends For Midwestern States*. Thus, our proxy is not perfect but seems to be tolerable in practice. We suspect that identities of punctuation marks (Collins, 2003, Footnote 13) — both sentence-final and sentence-initial — could be of extra assistance in grammar induction, specifically for grouping imperatives, questions, and so forth.

## 6 Dependency and Boundary Model Three

DBM-3 exploits sentence-internal punctuation contexts by modeling punctuation-crossing dependency arcs separately from other attachments (see §2.3).

### 6.1 Analytical Motivation

Many common syntactic relations, such as between a determiner and a noun, are unlikely to hold over long distances. (In fact, 45% of all head-percolated dependencies in WSJ are between adjacent words.) However, some common constructions are more remote: e.g., subordinating conjunctions are, on average, 4.8 tokens away from their dependent modal verbs. Sometimes longer-distance dependencies can be vetted using sentence-internal punctuation marks.

It happens that the presence of punctuation between such conjunction (IN) and verb (MD) types serves as a clue that they are not connected (see Table 7a); by contrast, a simpler cue — whether these words are adjacent — is, in this case, hardly of any use (see Table 7b). Conditioning on crossing punctuation could be of help then, playing a role similar to that of comma-counting (Collins, 1997, §2.1) — and “verb intervening” (Bikel, 2004, §5.1) — in early head-outward models for supervised parsing.

a) $r_\phi \approx -0.40$	Attached	not Attached	Total
Punctuation	337	7,645	7,982
no Punctuation	2,144	4,040	6,184
Total	2,481	11,685	14,166
non-Adjacent	2,478	11,673	14,151
Adjacent	3	12	15
b) $r_\phi \approx +0.00$	Attached	not Attached	Total

Table 7: Contingency tables for IN right-attaching MD, among closest ordered pairs of these tokens in WSJ sentences with punctuation, versus: (a) presence of intervening punctuation; and (b) presence of intermediate words.

## 6.2 Experimental Results Postponed

As we mentioned earlier (see §3), there is little point in testing DBM-3 with shorter sentences, since most sentence-internal punctuation occurs in longer inputs. Instead, we will test this model in a final step of a staged training strategy, with more data (see §7.3).

## 7 A Curriculum Strategy for DBMs

We propose to train up to DBM-3 iteratively — by beginning with DBM-1 and gradually increasing model complexity through DBM-2, drawing on the intuitions of IBM translation models 1–4 (Brown et al., 1993). Instead of using sentences of up to 15 tokens, as in all previous experiments (§4–5), we will now make use of nearly all available training data: up to length 45 (out of concern for efficiency), during later stages. In the first stage, however, we will use only a subset of the data with DBM-1, in a process sometimes called *curriculum learning* (Bengio et al., 2009; Krueger and Dayan, 2009, *inter alia*). Our grammar inducers will thus be “starting small” in both senses suggested by Elman (1993): simultaneously scaffolding on model- and data-complexity.

### 7.1 Scaffolding Stage #1: DBM-1

We begin by training DBM-1 on sentences without sentence-internal punctuation but with at least one trailing punctuation mark. Our goal is to avoid, when possible, overly specific arbitrary parameters like the “15 tokens or less” threshold used to select training sentences. Unlike DBM-2 and 3, DBM-1 does not model punctuation or sentence fragments, so we instead explicitly restrict its attention to this cleaner subset of the training data, which takes advantage of the fact that punctuation may generally correlate with sentence complexity (Frank, 2000).<sup>9</sup>

Aside from input sentence selection, our experimental set-up here remained identical to previous training of DBMs (§4–5). Using this new input data, DBM-1 averaged 40.7% accuracy (see Table 8). This is slightly higher than the 39.0% when using sentences up to length 15, suggesting that our heuristic for clean, simple sentences may be a useful one.

<sup>9</sup>More incremental training strategies are the subject of an unpublished companion manuscript (Spitkovsky et al., 2012a).

Table 8: Average accuracies over CoNLL evaluation sets (all sentences), for the DMV baseline and DBM1–3 trained with a curriculum strategy, and state-of-the-art results for systems that: (i) are also POS-agnostic and monolingual, including SCAJ (Spitkovsky et al., 2011a, Tables 5–6) and SAJ (Spitkovsky et al., 2011b); (ii) rely on gold POS-tag identities to discourage noun roots (Mareček and Zabokrtský, 2011, MZ) or to encourage verbs (Rasooli and Faili, 2012, RF); and (iii) transfer delexicalized parsers (Søgaard, 2011a, S) from resource-rich languages with translations (McDonald et al., 2011, MPH). DMV and DBM-1 trained on simple sentences, from uniform; DBM-2 and 3 trained on most sentences, from DBM-1 and 2, respectively; +inference is DBM-3 with punctuation constraints.

## 7.2 Scaffolding Stage #2: DBM-2 ← DBM-1

Next, we trained on all sentences up to length 45. Since these inputs are punctuation-rich, in both remaining stages we used the constrained Viterbi EM set-up suggested by Spitkovsky et al. (2011b) instead of plain soft EM; we employ an early termination strategy, quitting hard EM as soon as soft EM’s objective suffers (Spitkovsky et al., 2011a). Punctuation was converted into Viterbi-decoding constraints during training using the so-called *loose* method, which stipulates that all words in an inter-punctuation fragment must be dominated by a single (head) word, also from that fragment — with only these head words allowed to attach the head words of other fragments, across punctuation boundaries.

To adapt to full data, we initialized DBM-2 using Viterbi parses from the previous stage (§7.1), plus

uniformly-at-random chosen dependency trees for the new complex and incomplete sentences, subject to punctuation-induced constraints. This approach improved parsing accuracies to 41.7% (see Table 8).

## 7.3 Scaffolding Stage #3: DBM-3 ← DBM-2

Next, we repeated the training process of the previous stage (§7.2) using DBM-3. To initialize this model, we combined the final instance of DBM-2 with uniform multinomials for punctuation-crossing attachment probabilities (see §2.3). As a result, average performance improved to 42.2% (see Table 8).

Lastly, we applied punctuation constraints also in inference. Here we used the *sprawl* method — a more relaxed approach than in training, allowing arbitrary words to attach inter-punctuation fragments (provided that each entire fragment still be derived

by one of its words) — as suggested by Spitkovsky et al. (2011b). This technique increased DBM-3’s average accuracy to 42.9% (see Table 8). Our final result substantially improves over the baseline’s 33.6% and compares favorably to previous work.<sup>10</sup>

## 8 Discussion and the State-of-the-Art

DBMs come from a long line of head-outward models for dependency grammar induction yet their generative processes feature important novelties. One is conditioning on more observable state — specifically, the left and right end words of a phrase being constructed — than in previous work. Another is allowing multiple grammars — e.g., of complete and incomplete sentences — to coexist in a single model. These improvements could make DBMs quick-and-easy to bootstrap directly from any available partial bracketings (Pereira and Schabes, 1992), for example capitalized phrases (Spitkovsky et al., 2012b).

The second part of our work — the use of a curriculum strategy to train DBM-1 through 3 — eliminates having to know tuned cut-offs, such as sentences with up to a predetermined number of tokens. Although this approach adds some complexity, we chose conservatively, to avoid overfitting settings of sentence length, convergence criteria, etc.: stage one’s data is dictated by DBM-1 (which ignores punctuation); subsequent stages initialize additional pieces uniformly: uniform-at-random parses for new data and uniform multinomials for new parameters.

Even without curriculum learning — trained with vanilla EM — DBM-2 and 1 are already strong. Further boosts to accuracy could come from employing more sophisticated optimization algorithms, e.g., better EM (Samdani et al., 2012), constrained Gibbs sampling (Mareček and Zabokrtský, 2011) or locally-normalized features (Berg-Kirkpatrick et al., 2010). Other orthogonal dependency grammar induction techniques — including ones based on universal rules (Naseem et al., 2010) — may also benefit in combination with DBMs. Direct comparisons to previous work require some care, however, as there are several classes of systems that make different assumptions about training data (see Table 8).

<sup>10</sup>Note that DBM-1’s 39% average accuracy with standard training (see Table 2) was already nearly a full point higher than that of any single previous best system (SCAJ<sub>6</sub> — see Table 8).

### 8.1 Monolingual POS-Agnostic Inducers

The first type of grammar inducers, including our own approach, uses standard training and test data sets for each language, with gold part-of-speech tags as anonymized word classes. For the purposes of this discussion, we also include in this group transductive learners that may train on data from the test sets. Our DBM-3 (decoded with punctuation constraints) does well among such systems — for which accuracies on *all* sentence lengths of the evaluation sets are reported — attaining highest scores for 8 of 19 languages; the DMV baseline is still state-of-the-art for one language; and the remaining 10 bests are split among five other recent systems (see Table 8).<sup>11</sup> Half of the five came from various lateen EM strategies (Spitkovsky et al., 2011a) for escaping and/or avoiding local optima. These heuristics are compatible with how we trained our DBMs and could potentially provide further improvement to accuracies.

Overall, the final scores of DBM-3 were better, on average, than those of any other single system: 42.9 versus 38.2% (Spitkovsky et al., 2011a, Table 6). The progression of scores for DBM-1 through 3 without using punctuation constraints in inference — 40.7, 41.7 and 42.2% — fell entirely above this previous state-of-the-art result as well; the DMV baseline — also trained on sentences without internal but with final punctuation — averaged 33.6%.

### 8.2 Monolingual POS-Identified Inducers

The second class of techniques assumes knowledge about identities of part-of-speech tags (Naseem et al., 2010), i.e., which word tokens are verbs, which ones are nouns, etc. Such grammar inducers generally do better than the first kind — e.g., by encouraging verbocentricity (Gimpel and Smith, 2011) — though even here our results appear to be competitive. In fact, to our surprise, only in 5 of 19 languages a “POS-identified” system performed better than all of the “POS-agnostic” ones (see Table 8).

### 8.3 Multi-Lingual Semi-Supervised Parsers

The final broad class of related algorithms we considered extends beyond monolingual data and uses

<sup>11</sup>For Turkish ’06, the “right-attach” baseline outperforms even the DMV, at 65.4% (Rasooli and Faili, 2012, Table 1); an important difference between 2006 and 2007 CoNLL data sets has to do with segmentation of morphologically-rich languages.

both identities of POS-tags and/or parallel bitexts to transfer (supervised) delexicalized parsers across languages. Parser projection is by far the most successful approach to date and we hope that it too may stand to gain from our modeling improvements. Of the 10 languages for which we found results in the literature, transferred parsers underperformed the grammar inducers in only one case: on English (see Table 8). The unsupervised system that performed better used a special “weighted” initializer (Spitkovsky et al., 2011b, §3.1) that worked well for English (but less so for many other languages).

DBMs may be able to improve initialization. For example, modeling of incomplete sentences could help in incremental initialization strategies like *baby steps* (Spitkovsky et al., 2009), which are likely sensitive to the proverbial “bum steer” from unrepresentative short fragments, *pace* Tu and Honavar (2011).

#### 8.4 Miscellaneous Systems on Short Sentences

Several recent systems (Cohen et al., 2011; Sjøgaard, 2011b; Naseem et al., 2010; Gillenwater et al., 2010; Berg-Kirkpatrick and Klein, 2010, *inter alia*) are absent from Table 8 because they do not report performance for all sentence lengths. To facilitate comparison with this body of important previous work, we also tabulated final accuracies for the “up-to-ten words” task under heading @10: 51.9%, on average.

## 9 Conclusion

Although a dependency parse for a sentence can be mapped to a constituency parse (Xia and Palmer, 2001), the probabilistic models generating them use different conditioning: dependency grammars focus on the relationship between arguments and heads, constituency grammars on the coherence of chunks covered by non-terminals. Since redundant views of data can make learning easier (Blum and Mitchell, 1998), integrating aspects of both constituency and dependency ought to be able to help grammar induction. We have shown that this insight is correct: dependency grammar inducers can gain from modeling boundary information that is fundamental to constituency (i.e., phrase-structure) formalisms.

DBMs are a step in the direction towards modeling constituent boundaries jointly with head dependencies. Further steps must involve more tightly

coupling the two frameworks, as well as showing ways to incorporate both kinds of information in other state-of-the-art grammar induction paradigms.

## Abstract

The task of inferring the native language of an author based on texts written in a second language has generally been tackled as a classification problem, typically using as features a mix of  $n$ -grams over characters and part of speech tags (for small and fixed  $n$ ) and unigram function words. To capture arbitrarily long  $n$ -grams that syntax-based approaches have suggested are useful, adaptor grammars have some promise. In this work we investigate their extension to identifying  $n$ -gram collocations of arbitrary length over a mix of PoS tags and words, using both maxent and induced syntactic language model approaches to classification. After presenting a new, simple baseline, we show that learned collocations used as features in a maxent model perform better still, but that the story is more mixed for the syntactic language model.

## 1 Introduction

The task of inferring the native language of an author based on texts written in a second language — *native language identification* (NLI) — has, since the seminal work of Koppel et al. (2005), been primarily tackled as a text classification task using supervised machine learning techniques. Lexical features, such as function words, character  $n$ -grams, and part-of-speech (PoS)  $n$ -grams, have been proven to be useful in NLI (Koppel et al., 2005; Tsur and Rappoport, 2007; Estival et al., 2007). The recent work of Wong and Dras (2011), motivated by ideas from Second Language Acquisition (SLA), has shown that syntactic features — potentially capturing syntactic er-

rors characteristic of a particular native language — improve performance over purely lexical ones.

PoS  $n$ -grams can be leveraged to characterise surface syntactic structures: in Koppel et al. (2005), for example, ungrammatical structures were approximated by rare PoS bigrams. For the purpose of NLI, small  $n$ -gram sizes like bigram or trigram might not suffice to capture sequences that are characteristic of a particular native language. On the other hand, an attempt to represent these with larger  $n$ -grams would not just lead to feature sparsity problems, but also computational efficiency issues. Some form of feature selection should then come into play.

*Adaptor grammars* (Johnson, 2010), a hierarchical non-parametric extension of PCFGs (and also interpretable as an extension of LDA-based topic models), hold out some promise here. In that initial work, Johnson’s model learnt collocations of arbitrary length such as *gradient descent* and *cost function*, under a topic associated with machine learning. Hardisty et al. (2010) applied this idea to perspective classification, learning collocations such as *palestinian violence* and *palestinian freedom*, the use of which as features was demonstrated to help the classification of texts from the Bitter Lemons corpus as either Palestinian or Israeli perspective.

Typically in NLI and other authorship attribution tasks, the feature sets exclude content words, to avoid unfair cues due to potentially different domains of discourse. In our context, then, what we are interested in are ‘quasi-syntactic collocations’ of either pure PoS (e.g. NN IN NN) or a mixture of PoS with function words (e.g. NN of NN). The particular question of interest for this paper, then, is to

investigate whether the power of adaptor grammars to discover collocations — specifically, ones of arbitrary length that are useful for classification — extends to features beyond the purely lexical.

We examine two different approaches in this paper. We first utilise adaptor grammars for discovery of high performing ‘quasi-syntactic collocations’ of arbitrary length as mentioned above and use them as classification features in a conventional maximum entropy (maxent) model for identifying the author’s native language. In the second approach, we adopt a grammar induction technique to learn a grammar-based language model in a Bayesian setting. The grammar learned can then be used to infer the most probable native language that a given text written in a second language is associated with. The latter approach is actually closer to the work of Hardisty et al. (2010) using adaptor grammars for perspective modeling, which inspired our general approach. This alternative approach is also similar in nature to the work of Börschinger et al. (2011) in which grounded learning of semantic parsers was reduced to a grammatical inference task.

The structure of the paper is as follows. In Section 2, we review the existing work of NLI as well as the mechanics of adaptor grammars along with their applications to classification. Section 3 details the supervised maxent classification of NLI with collocation (n-gram) features discovered by adaptor grammars. The language model-based classifier is described in Section 4. Finally, we present a discussion in Section 5 and follow with concluding remarks.

## 2 Related Work

### 2.1 Native Language Identification

Most of the existing research treats the task of native language identification as a form of text classification deploying supervised machine learning approaches.

The earliest notable work in this classification paradigm is that of Koppel et al. (2005) using as features function words, character n-grams, and PoS bigrams, together with some spelling errors. Their experiments were conducted on English essays written by authors whose native language one of Bulgarian, Czech, French, Russian, or Spanish. The corpus used is the first version of *International Corpus*

*of Learner English* (ICLE). Apart from investigating lexical features, syntactic features (errors in particular) were highlighted by Koppel et al. (2005) as potentially useful features, but they only explored this by characterising ungrammatical structures with rare PoS bigrams: they chose 250 rare bigrams from the Brown corpus.

Features for this task can include content words or not: Koppel et al. (2009), in reviewing work in the general area of authorship attribution (including NLI), discuss the (perhaps unreasonable) advantage that content word features can provide, and comment that consequently they “are careful . . . to distinguish results that exploit content-based features from those that do not”. We will not be using content words as features; we therefore note only approaches to NLI that similarly do not use them.

Following Koppel et al. (2005), Tsur and Rapoport (2007) replicated their work and hypothesised that word choices in second language writing is highly influenced by the frequency of native language syllables. They investigated this through measuring classification performance with only character bigrams as features.

Estival et al. (2007) tackled the broader task of developing profiles of authors, including native language and various other demographic and psychometric author traits, across a smaller set of languages (English, Spanish and Arabic). To this end, they deployed various lexical and document structure features.

Wong and Dras (2011), starting from the Koppel et al. (2005) approach, explored the usefulness of syntactic features in a broader sense in which they characterised syntactic errors with cross sections of parse trees obtained from statistical parsers, both horizontal slices of the parse trees in the form of CFG production rules, and the feature schemata used in discriminative parse reranking (Charniak and Johnson, 2005); they also found that using the top 200 PoS bigrams helped. Their results on the second version of the ICLE corpus, across seven languages (those of Koppel et al., plus two Oriental languages, Chinese and Japanese) demonstrated that syntactic features of these kinds lead to significantly better performance than the Koppel et al. features alone, with a top accuracy (on 5-fold cross-validation) of 77.75%.

Subsequently, Wong et al. (2011) explored Bayesian *topic modeling* (Blei et al., 2003; Griffiths and Steyvers, 2004) as a form of feature dimensionality reduction technique to discover coherent latent factors (‘topics’) that might capture predictive features for individual native languages. Their topics, rather than the typical word n-grams, consisted of bigrams over (only) PoS. However, while there was some evidence of topic cluster coherence, this did not improve classification performance.

The work of the present paper differs in that it uses Bayesian techniques to discover collocations of arbitrary length for use in classification, over a mix of both PoS and function words, rather than for use as feature dimensionality reduction.

## 2.2 Adaptor Grammars

Adaptor Grammars are a non-parametric extension to PCFGs that are associated with a Bayesian inference procedure. Here we provide an informal introduction to Adaptor Grammars; Johnson et al. (2007) provide a definition of Adaptor Grammars as a hierarchy of mixtures of Dirichlet (or 2-parameter Poisson-Dirichlet) Processes to which the reader should turn for further details.

Adaptor Grammars can be viewed as extending PCFGs by permitting the grammar to contain an unbounded number of productions; they are non-parametric in the sense that the particular productions used to analyse a corpus depends on the corpus itself. Because the set of possible productions is unbounded, they cannot be specified by simply enumerating them, as is standard with PCFGs. Instead, the productions used in an adaptor grammar are specified indirectly using a *base grammar*: the subtrees of the base grammar’s “adapted non-terminals” serve as the possible productions of the adaptor grammar (Johnson et al., 2007), much in the way that subtrees function as productions in Tree Substitution Grammars.<sup>1</sup>

Another way to view Adaptor Grammars is that they relax the independence assumptions associated with PCFGs. In a PCFG productions are generated independently conditioned on the parent non-terminal, while in an Adaptor Grammar the probability of generating a subtree rooted in an adapted

<sup>1</sup>For computational efficiency reasons Adaptor Grammars require the subtrees to completely expand to terminals. The *Fragment Grammars* of O’Donnell (2011) lift this restriction.

non-terminal is roughly proportional to the number of times it has been previously generated (a certain amount of mass is reserved to generate “new” subtrees). This means that the distribution generated by an Adaptor Grammar “adapts” based on the corpus being generated.

### 2.2.1 Mechanics of adaptor grammars

Adaptor Grammars are specified by a PCFG  $G$ , plus a subset of  $G$ ’s non-terminals that are called the *adapted non-terminals*, as well as a *discount parameter*  $a_A$ , where  $0 \leq a_A < 1$  and a *concentration parameter*  $b_A$ , where  $b > -a$ , for each adapted non-terminal  $A$ . An adaptor grammar defines a two-parameter Poisson-Dirichlet Process for each adapted non-terminal  $A$  governed by the parameters  $a_A$  and  $b_A$ . For computational purposes it is convenient to integrate out the Poisson-Dirichlet Process, resulting in a predictive distribution specified by a Pitman-Yor Process (PYP). A PYP can be understood in terms of a “Chinese Restaurant” metaphor in which “customers” (observations) are seated at “tables”, each of which is labelled with a sample from a “base distribution” (Pitman and Yor, 1997).

In an Adaptor Grammar, unadapted non-terminals expand just as they do in a PCFG; a production  $r$  expanding the non-terminal is selected according to the multinomial distribution  $\theta_r$  over productions specified in the grammar. Each adapted non-terminal  $A$  is associated with its own Chinese Restaurant, where the tables are labelled with subtrees generated by the grammar rooted in  $A$ . In the Chinese Restaurant metaphor, the customers are expansions of  $A$ , each table corresponds to a particular subtree expanding  $A$ , and the PCFG specifies the base distribution for each of the adapted non-terminals. An adapted non-terminal  $A$  expands as follows.  $A$  expands to a subtree  $t$  with probability proportional to  $n_t$ , where  $n_t$  is the number of times  $t$  has been previously generated. In addition,  $A$  expands using a PCFG rule  $r$  expanding  $A$  with probability proportional to  $(m_A a_A + b_A) \theta_r$ , where  $m_A$  is the number of subtrees expanding  $A$  (i.e., the number of tables in  $A$ ’s restaurant). Because the underlying Pitman-Yor Processes have a “rich get richer” property, they generate power-law distributions over the subtrees for adapted non-terminals.

## 2.2.2 Adaptor grammars as LDA extension

With the ability to rewrite non-terminals to entire subtrees, adaptor grammars have been used to extend unigram-based LDA topic models (Johnson, 2010). This allows topic models to capture sequences of words with arbitrary length rather than just unigrams of word. It has also been shown that it is crucial to go beyond the bag-of-words assumption as topical collocations capture more meaning information and represent more interpretable topics (Wang et al., 2007).

Taking the PCFG formulation for the LDA topic models, it can be modified such that each topic  $Topic_i$  generates sequences of words by adapting each of the  $Topic_i$  non-terminals (usually indicated with an *underline* in an adaptor grammar). The overall schema for capturing topical collocations with an adaptor grammar is as follows:

$$\begin{aligned} Sentence &\rightarrow Doc_j && j \in 1, \dots, m \\ Doc_j &\rightarrow \_j && j \in 1, \dots, m \\ Doc_j &\rightarrow Doc_j Topic_i && i \in 1, \dots, t; \\ &&& j \in 1, \dots, m \\ \underline{Topic_i} &\rightarrow Words && i \in 1, \dots, t \\ \underline{Words} &\rightarrow Word \\ Words &\rightarrow Words Word \\ Word &\rightarrow w && w \in V \end{aligned}$$

There is a non-grammar-based approach to finding topical collocations as demonstrated by Wang et al. (2007). Both of these approaches learned useful collocations: for instance, as mentioned in Section 1, Johnson (2010) found collocations such *gradient descent* and *cost function* associated with the topic of machine learning; Wang et al. (2007) found the topic of human receptive system comprises of collocations such as *visual cortex* and *motion detector*.

Adaptor grammars have also been deployed as a form of feature selection in discovering useful collocations for perspective classification. Hardisty et al. (2010) argued that indicators of perspectives are often beyond the length of bigrams and demonstrated that the use of the adaptor grammar inferred n-grams of arbitrary length as features establishes the start-of-the-art performance for perspective classification on the Bitter Lemons corpus, depicting two different perspectives of Israeli and Palestinian. We are adopting a similar approach in this paper for classi-

fying texts with respect to the author’s native language; but the key difference with Hardisty et al. (2010)’s approach is that our focus is on collocations that mix PoS and lexical elements, rather than being purely lexical.

## 3 Maxent Classification

In this section, we first explain the procedures taken to set up the conventional supervised classification task for NLI through the deployment of adaptor grammars for discovery of ‘quasi-syntactic collocations’ of arbitrary length. We then present the classification results attained based on these selected sets of n-gram features. In all of our experiments, we investigate two sets of collocations: pure PoS and a mixture of PoS and function words. The idea of examining the latter set is motivated by the results of Wong and Dras (2011) where inclusion of parse production rules lexicalised with function words as features had shown to improve the classification performance relative to unlexicalised ones.

### 3.1 Experimental Setup

#### 3.1.1 Data and evaluation

The classification experiments are conducted on the second version of ICLE (Granger et al., 2009).<sup>2</sup> Following our earlier NLI work in Wong and Dras (2011), our data set consists of 490 texts written in English by authors of seven different native language groups: Bulgarian, Czech, French, Russian, Spanish, Chinese, and Japanese. Each native language contributes 70 out of the 490 texts. As we are using a relative small data set, we perform  $k$ -fold cross-validation, choosing  $k = 5$ .

#### 3.1.2 Adaptor grammars for supervised classification

We derive two adaptor grammars for the maxent classification setting, where each is associated with a different set of vocabulary (i.e. either pure PoS or the mixture of PoS and function words). We use

<sup>2</sup>Joel Tetreault and Daniel Blanchard from ETS have pointed out (personal communication) that there is a subtle issue with ICLE that could have an impact on the classification performance of NLI tasks; in particular, when character n-grams are used as features, some special characters used in some ICLE texts might affect performance. For our case, this should not be of much issue since they will not appear in our collocations.

the grammar of Johnson (2010) as presented in Section 2.2.2, except that the vocabulary differs: either  $w \in V_{pos}$  or  $w \in V_{pos+fw}$ . For  $V_{pos}$ , there are 119 distinct PoS tags based on the Brown tagset.  $V_{pos+fw}$  is extended with 398 function words as per Wong and Dras (2011).  $m = 490$  is the number of documents, and  $t = 25$  the number of topics (chosen as the best performing one from Wong et al. (2011)).

Rules of the form  $\text{Doc}_j \rightarrow \text{Doc}_j \text{Topic}_i$  that encode the possible topics that are associated with a document  $j$  are given similar  $\alpha$  priors as used in LDA ( $\alpha = 5/t$  where  $t = 25$  in our experiments). Likewise, similar  $\beta$  priors from LDA are placed on the adapted rules expanding from  $\text{Topic}_i \rightarrow \text{Words}$ , representing the possible sequences of words that each topic comprises ( $\beta = 0.01$ ).<sup>3</sup> The inference algorithm for the adaptor grammars are based on the Markov Chain Monte Carlo technique made available online by Johnson (2010).<sup>4</sup>

### 3.1.3 Classification models with n-gram features

Based on the two adaptor grammars inferred, the resulting collocations (n-grams) are extracted as features for the classification task of identifying authors' native language. These n-grams found by the adaptor grammars are only a (not necessarily proper) subset of those n-grams that are strongly characteristic of a particular native language. In principle, one could find all strongly characteristic n-grams by enumerating all the possible instances of n-grams up to a given length if the vocabulary is of a small enough closed set, such as for PoS tags, but this is infeasible when the set is extended to PoS plus function words. The use of adaptor grammars here can be viewed as a form of feature selection, as in Hardisty et al. (2010).

**Baseline models** To serve as a baseline, we take the commonly used PoS bigrams as per the previous work of NLI (Koppel et al., 2005). A set of 200 PoS bigrams is selected in two ways: the 200 most frequent in the training data (as in Wong and Dras (2011)) and the 200 with the highest information gain (IG) values in the training data (not evalu-

<sup>3</sup>The values of  $\alpha$  and  $\beta$  are also based on the established values presented in Wong et al. (2011).

<sup>4</sup>Adaptor grammar software is available on <http://web.science.mq.edu.au/~mjohnson/Software.htm>.

ated in other work).

**Enumerated n-gram models** Here, we enumerate all the possible n-grams up to a fixed length and select the best of these according to IG, as a generalisation of the baseline. The first motivation for this feature set is that, in a sense, this should give a rough upper bound for the adaptor grammar's PoS-alone n-grams, as these latter should most often be a subset of the former. The second motivation is that it gives a robust comparison for the mixed PoS and function word n-grams, where it is infeasible to enumerate all of them.

**ENUM-POS** We enumerate all possible n-grams up to the length of 5, and select those that actually occur (i.e. of the  $\sum_{i=1}^5 119^i$  possible n-grams, this is 218,042 based on the average of 5 folds). We look at the top n-grams up to length 5 selected by IG: the top 2,800 and the top 6,500 (for comparability with adaptor grammar feature sets, below), as well as the top 10,000 and the top 20,000 (to study the effect of larger feature space).

**Adaptor grammar n-gram models** The classification features are the two sets of selected collocations inferred by the adaptor grammars which are the main interest of this paper.

**AG-POS** This first set of the adaptor grammar-inferred features comprise of pure PoS n-grams (i.e.  $V_{pos}$ ). The largest length of n-gram found is 17, but about 97% of the collocations are of length between 2 to 5. We investigate three variants of this feature set: top 200 n-grams of all lengths (based on IG), all n-grams of all lengths ( $n = 2, 795$  on average), and all n-grams up to the length of 5 ( $n = 2, 710$  on average).

**AG-POS+FW** This second set of the adaptor grammar-inferred features are mixtures of PoS and function words (i.e.  $V_{pos+fw}$ ). The largest length of n-gram found for this set is 19 and the total number of different collocations found is much higher. For the purpose of comparability with the first set of adaptor grammar features, we investigate the following five variants for this feature set: top 200 n-grams of all lengths, all n-grams of all lengths ( $n = 6, 490$  on average), all n-grams up to the length of 5 ( $n = 6, 417$  on average), top 2,800 n-grams of all different lengths,

Features (n-grams)	Accuracy
BASELINE-POS [top200 MOST-FREQ]	53.87
BASELINE-POS [top200 IG]	56.12
AG-POS [top200 IG]	61.02
AG-POS [all $\leq 17$ -gram] ( $n \approx 2800$ )	68.37
AG-POS [all $\leq 5$ -gram] ( $n \approx 2700$ )	68.57
AG-POS+FW [top200 IG]	58.16
AG-POS+FW [all $\leq 19$ -gram] ( $n \approx 6500$ )	<b>74.49</b>
AG-POS+FW [all $\leq 5$ -gram] ( $n \approx 6400$ )	<b>74.49</b>
AG-POS+FW [top2800 IG $\leq 19$ -gram]	71.84
AG-POS+FW [top2800 IG $\leq 5$ -gram]	71.84

and top 2,800 n-grams up to the length of 5. (All the selections are based on IG).

In our models, all feature values are of binary type. For the classifier, we employ a maximum entropy (MaxEnt) machine learner — MegaM (fifth release) by Hal Daumé III.<sup>5</sup>

### 3.2 Classification results

Table 1 presents all the classification results for the individual feature sets, along with the baselines. On the whole, both sets of the collocations inferred by the adaptor grammars perform better than the two baselines. We make the following observations:

- Regarding ENUM-POS as a (rough) upper bound, the adaptor grammar AG-POS with a comparable number of features performs almost as well. However, because it is possible to enumerate many more n-grams than are found during the sampling process, ENUM-POS opens up a gap over AG-POS of around 4%.
- Collocations with a mix of PoS and function words do in fact lead to higher accuracy as compared to those of pure PoS (except for the top 200 n-grams); for instance, compare the 2,800 n-grams up to length 5 from the two corresponding sets (71.84 vs. 68.57).
- Furthermore, the adaptor grammar-inferred collocations with mixtures of PoS and function

<sup>5</sup>MegaM software is available on <http://www.cs.utah.edu/~hal/megam/>.

Features (n-grams)	Accuracy
AG-POS [all $\leq 5$ -gram] & FW	72.04
ENUM-POS [top2800 $\leq 5$ -gram] & FW	73.67
AG-POS+FW & AG-POS <sup>a</sup>	<b>75.71</b>
AG-POS+FW & AG-POS <sup>b</sup>	74.90
AG-POS+FW & ENUM-POS [top2800] <sup>a</sup>	73.88
AG-POS+FW & ENUM-POS [top2800] <sup>b</sup>	74.69
AG-POS+FW & ENUM-POS [top10K] <sup>b</sup>	74.90
AG-POS+FW & ENUM-POS [top20K] <sup>b</sup>	75.10

Table 2: Maxent classification results for combined feature sets (with 5-fold cross validation). <sup>a</sup>Features from the two sets are selected based on the overall top 3700 with highest IG; <sup>b</sup>features from the two sets are just linearly concatenated.

words (AG-POS+FW) in general perform better than our rough upper bound of PoS collocations, i.e. the enumerated PoS n-grams (ENUM-POS): the overall best results of the two feature sets are 74.49 and 72.44 respectively.

Given that the AG-POS+FW n-grams are capturing different sorts of document characteristics, they could potentially usefully be combined with the PoS-alone features. We thus combined them with both AG-POS and ENUM-POS feature sets, and the classification results are presented in Table 2. We tried two ways of integrating the feature sets: one way is to take the overall top 2,800 of the two sets based on IG; the other way is to just combine the two sets of features by concatenation of feature vectors (as indicated by *a* and *b* respectively in the result table). For comparability purposes, we considered only n-grams up to the length of 5. A baseline approach to this is just to add in function words as unigram features by feature vector concatenation, giving two further models, AG-POS [all  $\leq 5$ -gram] & FW and ENUM-POS [top2800  $\leq 5$ -gram] & FW.

Overall, the classification accuracies attained by the combined feature sets are higher than the individual feature sets. The best performing of all the models is achieved by combining the mixed PoS and function word collocations with the adaptor grammar-inferred PoS, producing the best accuracy thus far of 75.71. This demonstrates that features inferred by adaptor grammars do capture some useful information and function words are playing a role. The way of integrating the two feature sets has different effects on the types of combination. As seen in Table 2, method *a* works better for the com-

bination of the two adaptor grammar feature sets; whereas method *b* works better for combining adaptor grammar features with enumerated n-gram features.

Using adaptor grammar collocations also outperforms the alternative baseline of adding in function words as unigrams. For instance, the best performing combined feature set of both AG-POS and AG-POS+FW does result in higher accuracy as compared to the two alternative baseline models, comparing 75.71 with 72.04 (and 75.71 with 73.67). This demonstrates that our more general PoS plus function word collocations derived from adaptor grammars are indeed useful, and supports the argument of Wang et al. (2007) that they are a useful technique for looking into features beyond just the bag of words.

#### 4 Language Model-based Classification

In this section, we take a language modeling approach to native language identification; the idea here is to adopt grammatical inference to learn a grammar-based language model to represent the texts written by non-English native users. The grammar learned is then used to predict the most probable native language that a document (a sentence) is associated with.

In a sense, we are using a parser-based language model to rank the documents with respect to native language. We draw on the work of Börschinger et al. (2011) for this section. In that work, the task was grounded learning of a semantic parser. Training examples there consisted of natural language strings (descriptions of a robot soccer game) and a set of candidate meanings (actions in the robot soccer game world) for the string; each was tagged with a context identifier reflecting the actual action of the game. A grammar was then induced that would parse the examples, and was used on test data (where the context identifier was absent) to predict the context. We take a similar approach to developing an grammatical induction technique, although where they used a standard LDA topic model-based PCFG, we use an adaptor grammar. We expect that the results will likely to be lower than for the discriminative approach of Section 3. However, the approach is of interest for a few reasons: because, whereas the adaptor grammar plays an ancillary, fea-

ture selection role in Section 3, here the feature selection is an organic part of the approach as per the actual implementation of Hardisty et al. (2010); because adaptor grammars can potentially be extended in a natural way with unlabelled data; and because, for the purposes of this paper, it constitutes a second, quite different way to evaluate the use of n-gram collocations.

#### 4.1 Language Models

We derive two adaptor grammar-based language models. One consists of only unigrams and bigrams, and the other finds n-gram collocations, in both cases over either PoS or the mix of PoS and function words. The assumption that we make is that each document (each sentence) is a mixture of two sets of topics: one is the native language-specific topic (i.e. characteristic of the native language) and the other is the generic topic (i.e. characteristic of the second language — English in our case). The generic topic is thus shared across all languages, and will behave quite differently from a language-specific topic, which is not shared. In other words, there are eight topics, representing seven native language groups that are of interest (Bulgarian, Czech, French, Russian, Spanish, Chinese, and Japanese) and the second language English itself.<sup>6</sup>

**Bigram models** The following rule schema is applicable to both vocabulary types of PoS and the mixture of PoS and function words.

$$\begin{aligned}
 \text{Root} &\rightarrow \_lang \text{langTopics} \\
 \text{langTopics} &\rightarrow \text{langTopics} \text{langTopic} \\
 \text{langTopics} &\rightarrow \text{langTopics} \text{nullTopic} \\
 \text{langTopics} &\rightarrow \text{langTopic} \\
 \text{langTopics} &\rightarrow \text{nullTopic} \\
 \underline{\text{langTopic}} &\rightarrow \text{Words} \\
 \underline{\text{nullTopic}} &\rightarrow \text{Words} \\
 \text{Words} &\rightarrow \text{Word Word} \\
 \text{Words} &\rightarrow \text{Word} \\
 \text{Word} &\rightarrow w \qquad w \in V_{pos}; w \in V_{pos+fw}
 \end{aligned}$$

**N-gram models** The grammar is the same as the above with the exception that the non-terminal *Words* is now rewritten as follows in order to

<sup>6</sup>We could just induce a regular PCFG here, rather than an adaptor grammar, by taking as terminals all pairs of PoS tags. We use the adaptor grammar formulation for comparability.

capture n-gram collocations of arbitrary length.

*Words*  $\rightarrow$  *Words Word*

*Words*  $\rightarrow$  *Word*

It should be noted that the two grammars above can in theory be applied to an entire document or on individual sentences. For this present work, we work on the sentence level as the run-time of the current implementation of the adaptor grammars grows proportional to the cube of the sentence length. For each grammar we try both sparse and uniform Dirichlet priors ( $\alpha = \{0.01, 0.1, 1.0\}$ ). The sparse priors encourage only a minority of the rules to be associated with high probabilities.

## 4.2 Training and Evaluation

As we are using the same data set as per the previous approach, we perform 5-fold cross validation as well. However, the training for each fold is conducted with a different grammar consisting of only the vocabulary that occur in each training fold. The reason is that we are now having a form of *supervised* topic models where the learning process is guided by the native languages. Hence, each of the training sentences are prefixed with the (native) language identifiers *lang*, as seen in the *Root* rules of the grammar presented above.

To evaluate the grammars learned, as in Börschinger et al. (2011) we need to slightly modify the grammars above by removing the language identifiers (*lang*) from the *Root* rules and then parse the *unlabeled* sentences using a publicly available CKY parser.<sup>7</sup> The predicted native language is inferred from the parse output by reading off the *langTopics* that the *Root* is rewritten to. We take that as the most probable native language for a particular test sentence. At the document level, we select as the class the language predicted for the largest number of sentences in that document.

## 4.3 Parsing Results

Tables 3 and 4 present the parsing results at the sentence level and the document level, respectively. On the whole, the results at the sentence level are much poorer as compared to those at the document level. In light of the results of Section 3.2, it is surprising

<sup>7</sup>CKY parser by Mark Johnson is available on <http://web.science.mq.edu.au/~mjohnson/Software.htm>.

Features (n-grams)	Accuracy		
	( $\alpha = 0.01$ )	( $\alpha = 0.1$ )	( $\alpha = 1.0$ )
AG-POS [bigrams]	26.84	27.03	26.77
AG-POS [n-grams]	25.85	25.78	25.62
AG-POS+FW [bigrams]	28.58	28.40	27.43
AG-POS+FW [n-grams]	26.64	27.64	28.75

Table 3: Language modeling-based classification results based on parsing (at the sentence level).

Features (n-grams)	Accuracy		
	( $\alpha = 0.01$ )	( $\alpha = 0.1$ )	( $\alpha = 1.0$ )
AG-POS [bigrams]	41.22	38.88	39.69
AG-POS [n-grams]	36.12	34.90	35.20
AG-POS+FW [bigrams]	47.45	46.94	44.64
AG-POS+FW [n-grams]	43.97	49.39	<b>50.15</b>

Table 4: Language modeling-based classification results based on parsing (at the document level).

that bigram models appear to perform better than n-gram models for both types of vocabulary, with the exception of AG-POS+FW at the document level. In fact, one would expect n-gram models to perform better in general as it is a generalisation that would contain all the potential bigrams. Nonetheless, the language models over the mixture of PoS and function words appear to be a more suitable representative of our learner corpus as compared to those over purely PoS, confirming the usefulness of integrated function words for the NLI classification task.

It should also be noted that sparse priors generally appear to be more appropriate; except that for AG-POS+FW n-grams, uniform priors are indeed better and resulted in the highest parsing result of 50.15. (Although all the parsing results are much weaker as compared to the results presented in Section 3.2, they are all higher than the majority baseline of 14.29% i.e. 70/490).

## 5 Discussion

Here we take a closer look at how well each approach does in identifying the individual native languages. The confusion matrix for the best model of two approaches are presented in Table 5 and Table 6. Both approaches perform reasonably well for the two Oriental languages (Chinese in particular); this is not a major surprise, as the two languages are not part of the language family that the rest of the languages come from (i.e. Indo-European). Under the supervised maxent classification, misclassifications largely are observed in the Romance ones (French and Spanish) as well as Russian; for the language model-based approach, Bulgarian is identi-

fied poorly, and Spanish moreso. However, the latter approach appears to be better in identifying Czech. On the whole, the maxent approach results in much fewer misclassifications compared to its counterpart.

In fact, there is a subtle difference in the experimental setting of the models derived from the two approaches with respect to the adaptor grammar: the number of topics. Under the maxent setting, the number of topics  $t$  was set to 25, while we restricted the models with the language modeling approach to only eight topics (seven for the individual native languages and one for the common second language, English). Looking more deeply into the topics themselves reveals that there appears to be at least two out of the 25 topics (from the supervised models) associated with n-grams that are indicative of the native languages, taking Chinese and Japanese as examples (see the associated topics in Table 7).<sup>8</sup> Perhaps associating each native language with only one generalised topic is not sufficient.

Furthermore, the distribution of n-grams among the topics (i.e. subtrees of collocations derived from the adaptor grammars) are quite different between the two approaches although the total num-

<sup>8</sup>Taking the examples from Wong et al. (2011) as reference, we found similar n-grams that are indicative of Japanese and Chinese.

Table 7: Top mixture n-grams (collocations) for 4 out of the 25 topics representative of Japanese and Chinese (under maxent setting). N-grams of pronoun with verb are found at the upper end of  $Topic_2$  and  $Topic_{23}$  reflecting the frequent usage of Japanese; n-grams of noun are top n-grams under  $Topic_9$  and  $Topic_{17}$  indicating Chinese’s common error of determiner-noun disagreement.

ber of n-grams inferred by each approach is about the same. For the language modeling ones, a high number of n-grams were associated with the generic topic  $nullTopic^9$  and each language-specific topic  $langTopic$  has a lower number of n-grams relative to bi-grams (Table 8) associated with it. For the maxent models, in contrast, the majority of the topics were associated with a higher number of n-grams (Table 9). The smaller number of n-grams to be used as features — and the fact that their extra length means that they will occur more sparsely in the documents — seems to be the core of the problem.

Nonetheless, the language models inferred discover relevant n-grams that are representative of individual native languages. For instance, the bigram NN NN, which Wong and Dras (2011) claim may reflect the error of determiner-noun disagreement commonly found amongst Chinese learners, was found under the Chinese topic at the top-2 position with a probability of 0.052 as compared to the other languages at the probability range of 0.0005-0.003. Similarly, one example for Japanese, the mixture bigram PPSS think, indicating frequent usage of pronouns within Japanese was seen under the Japanese topic at the top-9 position with a probability of 0.025 in relation to other languages within the range of 0.0002-0.006: this phenomenon as char-

<sup>9</sup>This is quite plausible as there should be quite a number of structures that are representative of native English speakers that are shared by non-native speakers.

acteristic of Japanese speakers has also been noted for different corpora by Ishikawa (2011). (Note that this collocation as well as its pure PoS counterpart PPSS VB are amongst the top n-grams discovered under the maxent setting as seen in Table 7.) Table 10 presents some excerpts extracted from the corpus that illustrate these two common phenomena.

To investigate further the issue associated with the number of topics under the language modeling setting, we attempted to extend the adaptor grammar with three additional topics that represent the language family of the seven native languages of interest: Slavic, Romance, and Oriental. (The resulting grammar is presented as below.) However, the parsing result does not improve over the initial setting with eight topics in total.

*Root* → *lang langTopics*  
*langTopics* → *langTopics langTopic*

## 6 Conclusion and Future Work

This paper has shown that the extension of adaptor grammars to discovering collocations beyond the lexical, in particular a mix of PoS tags and function words, can produce features useful in the NLI classification problem. More specifically, when added to a new baseline presented in this paper, the combined feature set of both types of adaptor grammar inferred collocations produces the best result in the context of using n-grams for NLI. The usefulness of the collocations does vary, however, with the technique used for classification.

Future work will involve a broader exploration of the parameter space of the adaptor grammars, in particular the number of topics and the value of  $\alpha$ ; a look at other non-parametric extensions of PCFGs, such as infinite PCFGs (Liang et al., 2007) for finding a set of non-terminals permitting more fine-grained topics; and an investigation of how the approach can be extended to semi-supervised learning to take advantage of the vast quantity of texts with errors available on the Web.

## Acknowledgments

We would like to acknowledge the support of ARC Linkage Grant LP0776267. We also thank the anonymous reviewers for useful feedback. Much gratitude is due to Benjamin Börschinger for his help with the language modeling implementation.

## Abstract

We propose a novel probabilistic technique for modeling and extracting salient structure from large document collections. As in clustering and topic modeling, our goal is to provide an organizing perspective into otherwise overwhelming amounts of information. We are particularly interested in revealing and exploiting *relationships* between documents. To this end, we focus on extracting diverse sets of *threads*—singly-linked, coherent chains of important documents. To illustrate, we extract research threads from citation graphs and construct timelines from news articles. Our method is highly scalable, running on a corpus of over 30 million words in about four minutes, more than 75 times faster than a dynamic topic model. Finally, the results from our model more closely resemble human news summaries according to several metrics and are also preferred by human judges.

## 1 Introduction

The increasing availability of large document collections has the potential to revolutionize our ability to understand the world. However, the scale and complexity of such collections frequently make it difficult to quickly grasp the important details and the relationships between them. As a result, automatic interfaces for data navigation, exploration, aggregation, and analysis are becoming increasingly valuable.

In this work we propose a novel approach: *threading* structured document collections. Con-

sider a large graph, with documents as nodes and edges indicating relationships, as in Figure 1. Our goal is to find a diverse set of paths (or threads) through the collection that are individually coherent and together cover the most salient parts. For example, given a collection of academic papers, we might want to identify the most significant lines of research, threading the citation graph to produce chains of important papers. Or, given news articles connected chronologically, we might want to extract threads of articles to form timelines describing the major events from the most significant news stories. Top-tier news organizations like The New York Times and The Guardian regularly publish such timelines, but have so far been limited to creating them by hand. Other possible applications might include discovering trends on social media sites, or perhaps mining blog entries for important conversations through *trackback* links. We show how these kinds of threading tasks can be done efficiently, providing a simple, practical tool for representing graph-based data that offers new possibilities compared with existing models.

The Topic Detection and Tracking (TDT) program (Wayne, 2000) has recently led to some research in this direction. Several of TDT’s core tasks, like link detection, topic detection, and topic tracking, can be seen as subroutines for the threading problem. Our work, however, addresses these tasks *jointly*, using a global probabilistic model with a tractable inference algorithm. To achieve this, we employ structured determinantal point processes (SDPPs) (Kulesza

Figure 1: An illustration of document collection threading. We first build a graph from the collection, using measures of importance and relatedness to weight nodes (documents) and build edges (relationships). Then, from this graph, we extract a diverse, salient set of threads to represent the collection. The supplement contains a version of this figure for our real-world news dataset.

and Taskar, 2010), which offer a natural probabilistic model over sets of structures (such as threads) where diversity is desired, and we incorporate  $k$ -DPP extensions to control the number of threads (Kulesza and Taskar, 2011).

We apply our model to two real-world datasets, extracting threads of research papers and timelines of news articles. An example of news threads extracted using our model is shown in Figure 2. Quantitative evaluation shows that our model significantly outperforms multiple baselines, including dynamic topic models, in comparisons with human-produced news summaries. It also outperforms baseline methods in a user evaluation of thread coherence, and runs 75 times faster than a dynamic topic model.

**The primary contributions of this paper are:** (1) proposing a novel framework for finding diverse and salient *sets* of document threads; (2) combining SDPPs and  $k$ -DPPs to implement the proposed model; (3) introducing random projections to improve efficiency with only bounded deviation; and (4) demonstrating the model on large-scale, real-world datasets.

## 2 Related Work

A variety of papers from the topic tracking literature are broadly related to our work (Mei and Zhai, 2005; Blei and Lafferty, 2006; Leskovec et al., 2009; Ahmed and Xing, 2010). Blei and Lafferty (2006) recently introduced dynamic topic models (DTMs). Assuming a division of documents into time slices, a DTM draws in each slice a set of topics from a Gaussian distribution whose mean is determined by the topics from the previous slice. In this way, a DTM generates

*topic* threads. In this work we are interested in the related but not identical task of generating *document* threads. We engineer a baseline for constructing document threads from DTM topic threads (see Section 6.2.2), but the topic-centric nature of DTMs means they are not ideal for this task. Figure 2 illustrates some of the issues.

The work of Ahmed and Xing (2010) generalizes DTMs to iDTMs (infinite DTMs) by allowing topics to span only a subset of time slices, and allowing an arbitrary number of topics. However, iDTMs still require placing documents into discrete epochs, and the issue of generating *topic* rather than *document* threads remains. In Section 6 we compare to DTMs but not iDTMs because an implementation of iDTMs was not readily available.

In the information retrieval community there has also been work on extracting temporal information from document collections. Swan and Jensen (2000) proposed a system for finding temporally clustered named entities in news text and presenting them on a timeline. Allan, Gupta, and Khandelwal (2001) introduced the task of *temporal summarization*, which takes a stream of news articles on a particular topic and tries to extract sentences describing important events as they occur. Yan et al (2011) evaluated methods for choosing sentences from temporally clustered documents that are relevant to a query. Here, we are interested not in extracting topically grouped entities or sentences, but instead in organizing a subset of the articles themselves into timelines, with topic identification as a side effect.

There has also been some prior work focusing more directly on threading. Shahaf and

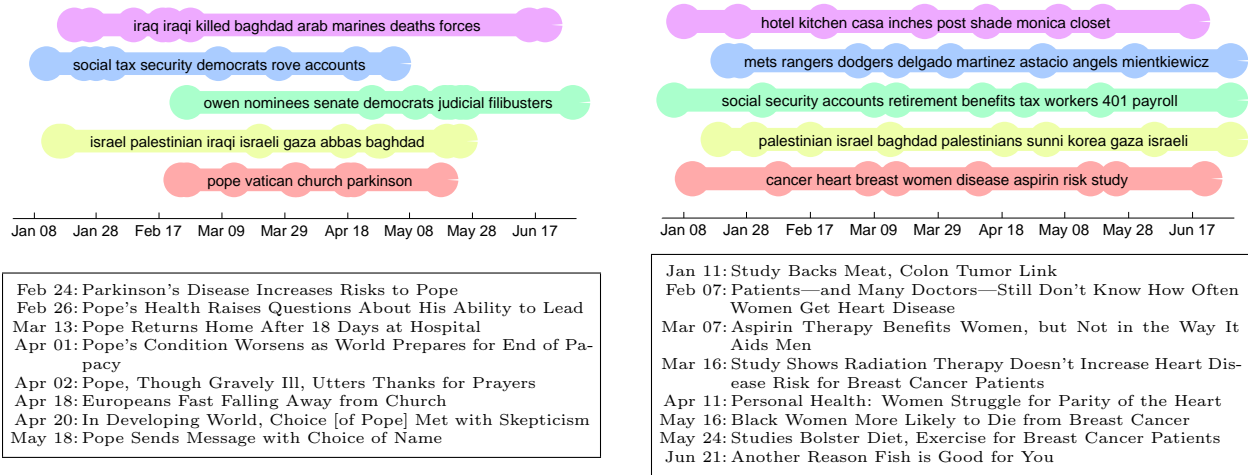

Figure 2: A set of five news threads generated by our method (left) and a dynamic topic model (right) for the first half of 2005. Above, the threads are shown on a timeline with the most salient words superimposed; below, the dates and headlines from the threads appearing at the bottom are listed. Topic models are not designed for threading and often link together topically similar documents that do not constitute a coherent news story, as on the right.

Guestrin (2010) and Chieu and Lee (2004) proposed selecting a *single* thread, whereas we seek a *set* of threads, which is a more general task. Shahaf, Guestrin, and Horvitz (2012) recently proposed *metro maps* as alternative structured representations of related news stories. Metro maps are effectively sets of non-chronological threads that are encouraged to intersect and thus create a “map” of events and topics. However, these approaches assume some prior knowledge about content. Shahaf and Guestrin (2010), for example, assume the thread endpoints are specified, and Chieu and Lee (2004) require a set of query words. These inputs make it possible to quickly pare down the document graph. In contrast, we work with very large graphs and consider all possible threads. Furthermore, while some prior work has relied on heuristics and approximate optimization, we can efficiently sample a joint probabilistic model with approximation guarantees.

In previous work on SDPPs (structured DPPs), which we use here to model threads, Kulesza and Taskar (2010) derived exact polynomial-time algorithms for sampling and other inference. However, their experiments involved feature vectors of only 32 dimensions. For text, natural features

like word occurrences typically yield dimensionality in the tens of thousands, making SDPP inference prohibitively expensive. We solve this problem by reducing the feature space using random projections (see Section 5). We prove that even a logarithmic number of projections is sufficient to yield a close approximation to the original SDPP distribution.

### 3 Framework

Before presenting our probabilistic model, we describe a natural framework for representing document collections. We assume that the collection has been transformed into a directed graph  $G = (V, E)$  on  $n$  vertices, where each node corresponds to a document and each edge represents a relationship between documents whose semantics depend on the task. We also assume the existence of a weight function  $w$  on nodes and edges, which measures the importance or salience of documents and the relative strength of the relationships between them. Formally, we define the weight of a path (or thread)  $y = (y^{(1)}, y^{(2)}, \dots, y^{(T)}), (y^{(t)}, y^{(t+1)}) \in E$  by:

$$w(y) = \sum_{t=1}^T w(y^{(t)}) + \sum_{t=1}^{T-1} w(y^{(t)}, y^{(t+1)}) . \quad (1)$$

Lastly, we also assume the existence of node features. Specifically, let  $\phi$  represent a feature mapping from nodes to  $\mathbb{R}^D$  (for example, tf-idf word vectors). The feature map on a thread is then just a sum over the nodes in the thread:

$$\phi(y) = \sum_{t=1}^T \phi(y^{(t)}) . \quad (2)$$

(If it is convenient to have features on edges as well as on nodes, it is possible to accommodate them without affecting asymptotic performance.) Given this framework, our goal is to develop a probabilistic model over sets of  $k$  threads of length  $T$ , favoring sets whose threads have large weight but are also distinct from one another with respect to  $\phi$ . In other words, a high-probability set under the model should include threads that are both salient and diverse.

This is a daunting problem, given that the number of possible sets of threads is  $O(n^{kT})$ . For the datasets we use later, the actual number is around  $2^{1000}$ . However, we will show how to construct the desired model in a way that allows efficient inference, even for large datasets, using determinantal point processes (DPPs). We begin with some background.

## 4 Determinantal point processes

A DPP is a type of distribution over subsets. Formally, a DPP  $\mathcal{P}$  on a set of items  $\mathcal{Y} = \{y_1, \dots, y_N\}$  is a probability measure on  $2^{\mathcal{Y}}$ , the set of all subsets of  $\mathcal{Y}$ . (In our setting,  $\mathcal{Y}$  will be the set of all possible threads.) For every  $Y \subseteq \mathcal{Y}$  we have:

$$\mathcal{P}(Y) = \frac{\det(L_Y)}{\sum_{Y \subseteq \mathcal{Y}} \det(L_Y)} = \frac{\det(L_Y)}{\det(L + I)} , \quad (3)$$

where  $L$  is a positive semidefinite matrix and  $I$  is the  $N \times N$  identity matrix.  $L_Y \equiv [L_{ij}]_{y_i, y_j \in Y}$  denotes the restriction of  $L$  to the entries indexed by elements of  $Y$ , and  $\det(L_\emptyset) = 1$ . We can define the entries of  $L$  as follows:

$$L_{ij} = q(y_i)\phi(y_i)^\top \phi(y_j)q(y_j) , \quad (4)$$

where we can think of  $q(y_i) \in \mathbb{R}^+$  as the ‘‘quality’’ of an item  $y_i$ , and  $\phi(y_i) \in \mathbb{R}^D$ ,  $\|\phi(y_i)\|_2 = 1$

Figure 3: (a) The DPP probability of a set  $Y$  depends on the volume spanned by vectors  $q(y_i)\phi(y_i)$  for  $i \in Y$ . (b) As quality (length) increases, so does volume. (c) As similarity increases, volume decreases.

as a normalized  $D$ -dimensional feature vector such that  $\phi(y_i)^\top \phi(y_j) \in [-1, 1]$  is a measure of similarity between items  $y_i$  and  $y_j$ . This simple definition gives rise to a distribution that places most of its weight on sets that are both high quality and diverse. To understand why this is the case, note that determinants are closely related to volumes; in particular,  $\det(L_Y)$  is proportional to the volume spanned by the vectors  $q(y_i)\phi(y_i)$  for  $y_i \in Y$ . Thus, sets with high-quality, diverse items have the highest probability; see Figure 3 for an illustration.

### 4.1 Structured DPPs

Kulesza and Taskar (2010) introduced *structured* DPPs (SDPPs) to efficiently handle  $\mathcal{Y}$  containing exponentially many structures. In our setting,  $\mathcal{Y}$  contains all threads of length  $T$ , so each  $y_i \in \mathcal{Y}$  is a sequence  $(y_i^{(1)}, \dots, y_i^{(T)})$ , where  $y_i^{(t)}$  is the document included in the thread at position  $t$ . When  $G$  is a complete graph, there are  $n^T$  possible sequences, so  $|\mathcal{Y}| = N = n^T$ .

In order to allow for efficient normalization and sampling, SDPPs assume a factorization of the quality score  $q(y_i)$  and similarity score  $\phi(y_i)^\top \phi(y_j)$  into parts, decomposing quality multiplicatively and similarity additively:

$$q(y_i) = \prod_{t=1}^T q(y_i^{(t)}) \quad \phi(y_i) = \sum_{t=1}^T \phi(y_i^{(t)}) \quad (5)$$

For threading, the definition of  $\phi$  is just as given in Equation (2). However, in order to convert the weight function defined in Equation (1) to the

appropriate multiplicative form, we use a simple log-linear model, setting  $q(y_i) = \exp(\lambda w(y_i))$ , where  $\lambda$  is a hyperparameter that effectively governs the balance between quality and diversity by adjusting the dynamic range of the quality function.

An efficient algorithm for sampling structures (in this case, sets of threads) from an SDPP is derived in Kulesza and Taskar (2010). While the details are beyond the scope of this paper, we note that the sampling algorithm requires  $O(Tn^2D^2)$  time. If the node degrees are bounded by  $r$  then the time is reduced to  $O(TrnD^2)$ . This is not quite efficient enough when the number of features,  $D$ , is large, as it often is for textual tasks, but we will show in Section 5 how to overcome this last hurdle.

Note that, in our later experiments, we fix  $T$  to moderate values ( $T = 5, 8$ ) for ease of analysis and display. However, it is possible (and efficient, due to the linear scaling) to allow longer threads, as well as threads of variable length. The latter effect can be achieved by adding a single “dummy” node to the document graph, with incoming edges from all other documents and a single outgoing self-loop edge. Shorter threads will simply transition to this dummy node when they are complete.

## 4.2 $k$ -DPPs

SDPPs allow us to efficiently model all sets of threads; however, for practical reasons we would prefer to focus only on sets of exactly  $k$  threads. To do so we exploit recently developed methods for working with DPPs of fixed size (Kulesza and Taskar, 2011). A  $k$ -DPP  $\mathcal{P}^k$  is a DPP conditioned on the event that the subset  $Y \in \mathcal{Y}$  has cardinality  $k$ ; formally, whenever  $|Y| = k$ :

$$\mathcal{P}^k(Y) = \frac{\det(L_Y)}{\sum_{|Y'|=k} \det(L_{Y'})}. \quad (6)$$

In this work we combine  $k$ -DPPs with SDPPs, referring to the result as a  $k$ -SDPP. We note that using  $k$ -SDPPs instead of SDPPs does not affect efficiency of sampling; it merely affords a mechanism for controlling the number of threads.

## 5 Random projections

As described above, the time complexity for sampling sets from SDPPs is  $O(TrnD^2)$ . Although this is polynomial, for practical problems  $nD^2$  is prohibitively large. While previous work has dealt only with small datasets, in our experiments we typically have  $n, D > 30,000$ ; storing a single message for the message-passing routine involved in SDPP sampling would require over 200 terabytes of memory. To make the model practical, therefore, we turn to techniques for dimensionality reduction.

Standard PCA requires  $O(D^3)$  time and would be much too slow. But a classic result of Johnson and Lindenstrauss (1984) shows that high-dimensional points can be *randomly* projected onto a logarithmic number of dimensions while approximately preserving the distances between them. More recently, Magen and Zouzias (2008) extended this idea to the preservation of volumes spanned by sets of points. Here, we use a relationship between determinants and volumes to adapt the latter result. We will prove the following bound on the variational distance between the original  $k$ -SDPP and a randomly projected version.

**Theorem 1.** Fix  $\epsilon, \delta < 1/2$ , and set  $d =$

$$\max \left\{ \frac{2k}{\epsilon}, \frac{24}{\epsilon^2} \left( \frac{\log(3/\delta)}{\log N} + 1 \right) \log 2N + k - 1 \right\}. \quad (7)$$

Let  $\mathcal{P}^k$  be the  $k$ -SDPP distribution in Equation (6), let  $G$  be a  $d \times D$  random matrix whose entries are independently sampled from  $\mathcal{N}(0, 1/d)$ , and let  $\tilde{\mathcal{P}}^k(Y)$  be the  $k$ -SDPP distribution after projecting  $\phi$  by  $G$ —that is, replacing  $\phi$  with  $G\phi$ . Then with probability at least  $1 - \delta$ ,

$$\|\mathcal{P}^k - \tilde{\mathcal{P}}^k\|_1 = \sum_{|Y|=k} |\mathcal{P}^k(Y) - \tilde{\mathcal{P}}^k(Y)| \leq e^{6k\epsilon} - 1. \quad (8)$$

Note that  $e^{6k\epsilon} - 1 \approx 6k\epsilon$  when  $k\epsilon$  is small, and  $d = O(\max\{k/\epsilon, (\log(1/\delta) + T \log n)/\epsilon^2\})$ .

Practically, Theorem 1 says that if we project  $\phi$  down to dimension  $d$  logarithmic in the number of documents and linear in thread length, the  $L_1$  variational distance between the true model and the projected model is bounded.

To prove Theorem 1, we will first state a variant of Magen and Zouzias' result, which bounds the ratio of volumes before and after projection from  $D$  down to  $d$  dimensions.

**Lemma 1.** *Let  $X$  be a  $D \times N$  matrix. Fix  $k < N$  and  $\epsilon, \delta < 1/2$ , and set  $d$  and  $G$  as in Theorem 1. Then with probability at least  $1 - \delta$  we have, for all  $D \times k$  matrices  $Y$  formed by a subset of  $k$  columns from  $X$ :*

$$(1 - \epsilon)^k \leq \frac{\text{Vol}(GY)}{\text{Vol}(Y)} \leq (1 + \epsilon)^k ,$$

where  $\text{Vol}(Y)$  is the  $k$ -dimensional volume spanned by the columns of  $Y$  and the origin.

We can make use of the following fact to convert this bound on volumes to a bound on determinants:

$$\text{Vol}(Y) = \frac{1}{k!} \sqrt{\det(Y^\top Y)} . \quad (9)$$

In order to handle the  $k$ -SDPP normalization constant

$$\sum_{|Y|=k} \left( \prod_{y_i \in Y} q^2(y_i) \right) \det(\phi(Y)^\top \phi(Y)) , \quad (10)$$

we also must adapt Lemma 1 to sums of determinants. The following lemma gives the details.

**Lemma 2.** *Under the same conditions as Lemma 1, with probability at least  $1 - \delta$ ,*

$$(1+2\epsilon)^{-2k} \leq \frac{\sum_{|Y|=k} \det((GY)^\top (GY))}{\sum_{|Y|=k} \det(Y^\top Y)} \leq (1+\epsilon)^{2k} .$$

*Proof.*

$$\begin{aligned} & \sum_{|Y|=k} \det((GY)^\top (GY)) \\ &= \sum_{|Y|=k} (k! \text{Vol}(GY))^2 \\ &\geq \sum_{|Y|=k} \left( k! \text{Vol}(Y) (1 - \epsilon)^k \right)^2 \\ &\geq (1 + 2\epsilon)^{-2k} \sum_{|Y|=k} \det(Y^\top Y) , \end{aligned}$$

Figure 4: The effect of random projections. In black, on the left, we estimate the  $L_1$  variational distance between the true and projected models. In blue, on the right, we plot the memory required for sampling. Running time is proportional to memory use.

where the first inequality holds with probability at least  $1 - \delta$  by Lemma 1, and the second follows from the fact that  $(1 - \epsilon)(1 + 2\epsilon) \geq 1$  (since  $\epsilon < 1/2$ ), thus  $(1 - \epsilon)^{2k} \geq (1 + 2\epsilon)^{-2k}$ . A symmetric argument gives the upper bound.  $\square$

*Proof (of Theorem 1).* Let  $B$  be the matrix whose columns are given by  $B_i = q(y_i)\phi(y_i)$ . We have

$$\begin{aligned} \|\mathcal{P}^k - \tilde{\mathcal{P}}^k\|_1 &= \sum_{|Y|=k} |\mathcal{P}^k(Y) - \tilde{\mathcal{P}}^k(Y)| \\ &= \sum_{|Y|=k} \mathcal{P}^k(Y) \left| 1 - \frac{\tilde{\mathcal{P}}^k(Y)}{\mathcal{P}^k(Y)} \right| \\ &= \sum_{|Y|=k} \mathcal{P}^k(Y) \left| 1 - \frac{\det([GB_Y^\top][GB_Y])}{\det(B_Y^\top B_Y)} \right| \\ &\quad \cdot \frac{\sum_{|Y'|=k} \det(B_{Y'}^\top B_{Y'})}{\sum_{|Y'|=k} \det([GB_{Y'}^\top][GB_{Y'}])} \\ &\leq \left| 1 - (1 + \epsilon)^{2k} (1 + 2\epsilon)^{2k} \right| \sum_{|Y|=k} \mathcal{P}^k(Y) \\ &\leq e^{6k\epsilon} - 1 , \end{aligned}$$

where the first inequality follows from Lemma 1 and Lemma 2, which hold simultaneously with probability at least  $1 - \delta$ , and the second follows from  $(1 + a)^b \leq e^{ab}$  for  $a, b \geq 0$ .  $\square$

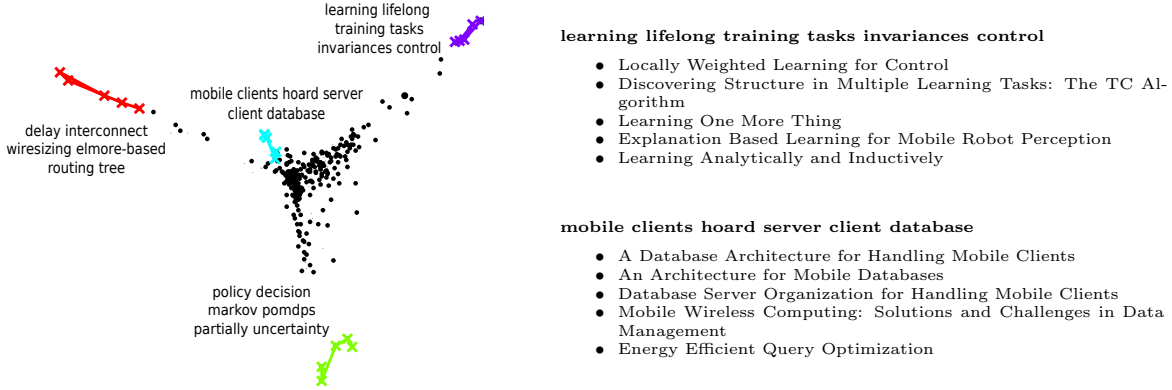

Figure 5: Example threads sampled from a 4-SDPP with thread length  $T = 5$  on the Cora dataset. We project from word-space to two dimensions by running PCA on the centroids of the threads. The nodes not on the thread paths form a representative subset of the other documents from Cora. Displayed beside each thread are a few of its maximum-tfidf words. Paper titles from two of the threads are shown to the right.

## 6 Experiments

We begin by showing the performance of random projections on a small, synthetic threading task where the exact model is tractable, with  $n = 600$  and  $D = 150$ . Figure 4 shows the  $L_1$  variational distance (estimated by sampling) as well as the actual memory required for a variety of projection dimensions  $d$ . Note that, as predicted by Theorem 1, fidelity to the true model increases rapidly with  $d$ .

### 6.1 Cora citation graph

To qualitatively illustrate our model, we apply it to Cora (McCallum et al., 2000). Cora is a large collection of academic papers on computer science topics, plus citations between them. We construct a directed graph with papers as nodes and citations as edges; after removing papers with missing metadata or zero outgoing citations, our graph contains  $n = 28,155$  papers.

To obtain useful threads, we set edge weights to reflect the degree of textual similarity between the citing and cited papers, and set node weights to reflect paper “importance”. Edge weights are given by normalized cosine similarity (NCS), which for two documents  $i$  and  $j$  is the dot product of their normalized tfidf vectors:

$$\frac{\sum_{w \in W} \text{tfidf}_i(w) \text{tfidf}_j(w)}{\sqrt{\sum_{w \in W} \text{tfidf}_i(w)^2} \sqrt{\sum_{w \in W} \text{tfidf}_j(w)^2}},$$

where  $W$  is a subset of the words found in the documents. We select  $W$  by filtering according to document frequency; that is, we remove words that are too common or too rare. After filtering, there are 50,912 unique words. The node weights are given by LexRank scores (Erkan and Radev, 2004), which are similar to node degrees.

Finally, we build a similarity feature map  $\phi$  to encourage diversity. We represent each document by the 1000 documents to which it is most similar according to NCS; this results in binary  $\phi$  of dimension  $m = n$  with exactly 1000 non-zeros. The dot product between the similarity features of two documents is thus proportional to the fraction of top-1000 similar documents they have in common. As described in Section 5, we then randomly project this large feature set from  $D \approx 28,000$  to  $d = 50$  dimensions.

We illustrate the behavior of the resulting model in Figure 5. The discovered threads occupy distinct regions of word-space, standing apart visually, and contain diverse salient terms.

### 6.2 News articles

For quantitative evaluation, we use newswire data. Our dataset comprises over 200,000 articles from the New York Times, collected from 2005-2007 as part of the English Gigaword corpus (Graff and Cieri, 2009). We split the articles into six-month time periods, with an average of

$n = 34,504$  articles per period. After filtering, there are a total of 36,356 unique words.

For each time period, we generate a graph with articles as nodes. We use NCS for edge weights, and throw away edges with weight  $< 0.1$ . We also require that edges go forward in time; this enforces the chronological ordering of our threads. The supplement contains illustrations of one of the resulting graphs. We use LexRank for node weights and the top-1000 similar documents as similarity features  $\phi$ , projecting to  $d = 50$ , as before (Section 6.1). We also add a constant feature  $\rho$  to  $\phi$ , which controls the overall degree of repulsion; large values of  $\rho$  make all documents more similar. This makes the  $k$ -SDPP distribution more peaked around diverse sets. For all of the following results, we use  $T = 8$  and  $k = 10$  so that the resulting timelines are of a manageable size for analysis. However, we tried several values of  $k$  and  $T$  in our experiments, and did not see significant differences in relative performance. We report all metrics averaged over 100 random samples from the model for each six-month period.

### 6.2.1 Graph visualizations

The (very large) news graph for the first half of 2005 can be viewed interactively at <http://zoom.it/jOKV>. In this graph each node (dark circle) represents a news article, and is annotated with its headline. Node size corresponds to weight (LexRank score). Nodes are laid out chronologically, left-to-right, from January to June of 2005. The five colored paths indicate a set of threads sampled from the  $k$ -SDPP. Headlines of the articles in each thread are colored to match the thread. Edges are included as described in the paper, but due to the scale of this dataset, only 1% of the edges are shown. Edge thickness corresponds to weight (NCS).

We provide a view of a small subgraph for illustration purposes in Figure 6, which shows the incoming and outgoing edges for a single node. A zoomable version of this subgraph is available at <http://zoom.it/GUCR>.

Figure 6: Snapshot of a single article node and all of its neighboring article nodes. See <http://zoom.it/GUCR> for the zoomable image.

### 6.2.2 Baselines

**$k$ -means baseline:** A simple baseline is to split each six-month period of articles into  $T$  equal time slices, then apply  $k$ -means clustering to each slice, using NCS to measure distance. We then select the most central article from each cluster, and finally match the  $k$  articles from time slice  $i$  one-to-one with those from slice  $i + 1$  by computing the pairing that maximizes the average NCS of the pairs, i.e., the coherence of the threads. The result is a set of  $k$  threads of length  $T$ , where no two threads contain the same article. In its use of clustering, this baseline is somewhat similar to the “event threading” baseline of Shahaf and Guestrin (2010).

**DTM baseline:** A more sophisticated baseline is the dynamic topic model (Blei and Lafferty, 2006), which explicitly attempts to find topics that are smooth through time. We use code provided by the authors to fit DTMs with the number of topics set to  $k$  and with the data split into  $T$  equal slices, as before. We then choose, for each topic at each time step, the document with the highest per-word probability of being generated by that topic. Documents from the same topic form a single thread.

	CosSim	ROUGE-1		ROUGE-2		ROUGE-SU4	
		F	Prec/Rec	F	Prec / Rec	F	Prec/Rec

<i>k</i> -SDPP	<b>33.2</b>	<b>17.2</b>	<b>17.7/16.7</b>	<b>0.892</b>	<b>0.917/0.870</b>	<b>3.98</b>	<b>4.11/3.87</b>

Table 1: Similarity of automatically generated timelines to human summaries. Bold entries are significantly higher than others in the column at 99% confidence, computed using bootstrapping (Hesterberg et al., 2003).

### 6.2.3 Comparison to human summaries

We compare the threads generated by our baselines and sampled from the *k*-SDPP to a set of human-generated news summaries. The human summaries are not threaded; they are flat, roughly daily news summaries published by Agence France-Presse and found in the Gigaword corpus, distinguished by their “multi” type tag. A sample summary is included in the supplement. These summaries tend to focus on world news, which is only a subset of the contents of our dataset. However, they allow us to provide an extrinsic evaluation of our method without gold standard timelines. We compute four statistics:

- **Cosine similarity:** NCS (in percent) between the concatenated threads and concatenated human summaries. The hyperparameters for all methods—such as the constant feature magnitude  $\rho$  for *k*-SDPPs and the parameter governing topic proportions for DTMs—were tuned to optimize cosine similarity on a development set from January-June 2005.
- **ROUGE-1, 2, and SU4:** Standard ROUGE scores for summarization evaluation (Lin, 2004).

Table 1 shows the results of these comparisons, averaged across all six half-year intervals. Under each measure, the *k*-SDPP threads more closely resemble human summaries.

### 6.2.4 Mechanical Turk evaluation

An important distinction between the baselines and the *k*-SDPP is that the former are *topic*-oriented, choosing articles that relate to broad subject areas, while our approach is *story*-oriented, chaining together articles with direct

	Rating	Interlopers
<i>k</i> -means	2.73	0.71
DTM	3.19	1.10
<i>k</i> -SDPP	<b>3.31</b>	1.15

Table 2: Rating: average coherence score from 1 (worst) to 5 (best). Interlopers: average number of interloper articles identified (out of 2). Bold entries are significantly higher with 95% confidence.

individual relationships. An example of this distinction can be seen in Figure 2.

To obtain a large-scale evaluation of thread coherence, we turn to Mechanical Turk. We asked Turkers to read the headlines and first few sentences of each article in a timeline and then rate the overall narrative coherence of the timeline on a scale of 1 (“the articles are totally unrelated”) to 5 (“the articles tell a single clear story”). Five separate Turkers rated each timeline; the average ratings are shown in Table 2. Note that *k*-means does particularly poorly in terms of coherence since it has no way to ensure that clusters are similar between time slices.

We also had Turkers evaluate threads implicitly by performing a simple task. We showed them timelines into which two additional “interloper” articles selected at random had been inserted, and asked them to remove the two articles that they thought should be removed to “improve the flow of the timeline”. A screenshot of the task is provided in the supplement. Intuitively, the interlopers should be selected more often when the original timeline is coherent. The average number of interloper articles correctly identified is shown in Table 2.

	Runtime
$k$ -means	625.63
DTM	19,433.80
$k$ -SDPP	<b>252.38</b>

Table 3: Time (in seconds) required to produce a complete set of threads. The test machine has eight Intel Xeon E5450 cores and 32GB of memory.

### 6.2.5 Runtimes

Finally, we report in Table 3 the time required to produce a complete set of threads for each method. This time includes clustering for  $k$ -means, model fitting for DTM and random projections, computation of the covariance matrix, and sampling for  $k$ -SDPP. We view the graph as an input (much like tfidf vectors for the baselines), and so do not include its computation in the runtime for the  $k$ -SDPP. Constructing the graph only requires an additional 160 seconds though.

### 6.3 Analysis

Below we briefly summarize the main differences between the  $k$ -SDPP and the baselines, and discuss their significance.

- Neither baseline *directly* models the document threads themselves. In contrast, the  $k$ -SDPP defines a probability distribution over all possible sets of document threads. This makes the  $k$ -SDPP a better choice for applications where, for instance, the coherence of individual threads is important.
- While the baselines seek threads that cover or explain as much of the dataset as possible,  $k$ -SDPPs are better suited for tasks where a balance between quality and diversity is key, since its hyperparameters correspond to weights on these quantities. With news timelines, for example, we want not just topical diversity but also a focus on the most important stories.
- Both baselines require input to be split into time slices, whereas the  $k$ -SDPP does not; this flexibility allows the  $k$ -SDPP to put multiple articles from a single time slice in

a thread, or to build threads that span only part of the input period.

- While clustering and topic models rely on EM to approximately optimize their objectives, the  $k$ -SDPP comes with an exact, polynomial-time sampling algorithm.

Revisiting Figure 2, we can see all of these advantages in action. The  $k$ -SDPP produces more consistent threads due to its use of graph information, while the DTM threads, though topic-focused, are less coherent as a story. Furthermore, DTM threads span the entire time period, while our method selects threads covering only relevant spans. The quantitative results in this section underscore the empirical value of these characteristics.

## 7 Conclusion

We introduced the novel problem of finding diverse and salient threads in graphs of large document collections. We developed a probabilistic approach, combining SDPPs and  $k$ -SDPPs, and showed how random projections make inference efficient and yield an approximate model with bounded variational distance to the original. We then demonstrated that the method produces qualitatively reasonable results, and, relative to several baselines, reproduces human news summaries more faithfully, builds more coherent story threads, and is significantly faster. It would be interesting to extend our model to structures beyond linear chains to trees and other structures.

# Generalizing Sub-sentential Paraphrase Acquisition across Original Signal Type of Text Pairs

Aurélien Max

Houda Bouamor

Anne Vilnat

LIMSI-CNRS & Univ. Paris Sud  
Orsay, France

firstname.lastname@limsi.fr

## Abstract

This paper describes a study on the impact of the original signal (text, speech, visual scene, event) of a text pair on the task of both manual and automatic sub-sentential paraphrase acquisition. A corpus of 2,500 annotated sentences in English and French is described, and performance on this corpus is reported for an efficient system combination exploiting a large set of features for paraphrase recognition. A detailed quantified typology of sub-sentential paraphrases found in our corpus types is given.

## 1 Introduction

Sub-sentential paraphrases can be acquired from text pairs expressing the same meaning (Madnani and Dorr, 2010). If the semantic similarity of a text pair has a direct impact on the quality of the acquired paraphrases, it has, to our knowledge, never been shown what impact the type of original signal has on paraphrase acquisition. In this work, we consider four types of corpora, which we think are representative of the main types of original semantic signals: text pairs (roughly, sentences) originating *a*) from independent translations of a text (TEXT), *b*) from independent translations of a speech (SPEECH), *c*) from independent descriptions of a visual scene (SCENE), and *d*) from independent descriptions of some event (EVENT). We will report the results of experiments on sub-sentential paraphrase acquisition on all these corpus types in two languages, English and French, and provide some answers to the following questions: What types of

paraphrases can be found by human annotators, with what confidence and in which quantities? How well can representative paraphrase acquisition systems perform on each corpus type, and how performance can be improved through combination? On what corpus types can performance be improved by using training material from other corpus types? Our experimental results will provide several indications of the differences and complementarities of the corpus types under study, and will notably show that performance on the most readily available corpus type can be improved by using training data from the set of all other corpus types.

We will first describe the building procedures and characteristics of our corpora (section 2), and then describe our experimental settings for evaluating paraphrase acquisition (section 3.1). Our experiments will first consist of the description (section 3.2) and evaluation (section 3.3) of a system combination on each corpus type and then of our system provided with additional training data from the other corpus types (section 3.4). We will finally briefly review related work (section 4) and discuss our main findings and future work (section 5).

## 2 Collection of sentence pair corpora

In this study, we will focus on paraphrase acquisition from related sentence pairs characteristic of 4 corpus types, which correspond to different original signal types of text pairs illustrated by the word alignment matrices on Figure 1. A corpus for each type has been collected for 2 languages, English and French, and comprises 625 sentence pairs per language. We now briefly describe how each corpus was built.

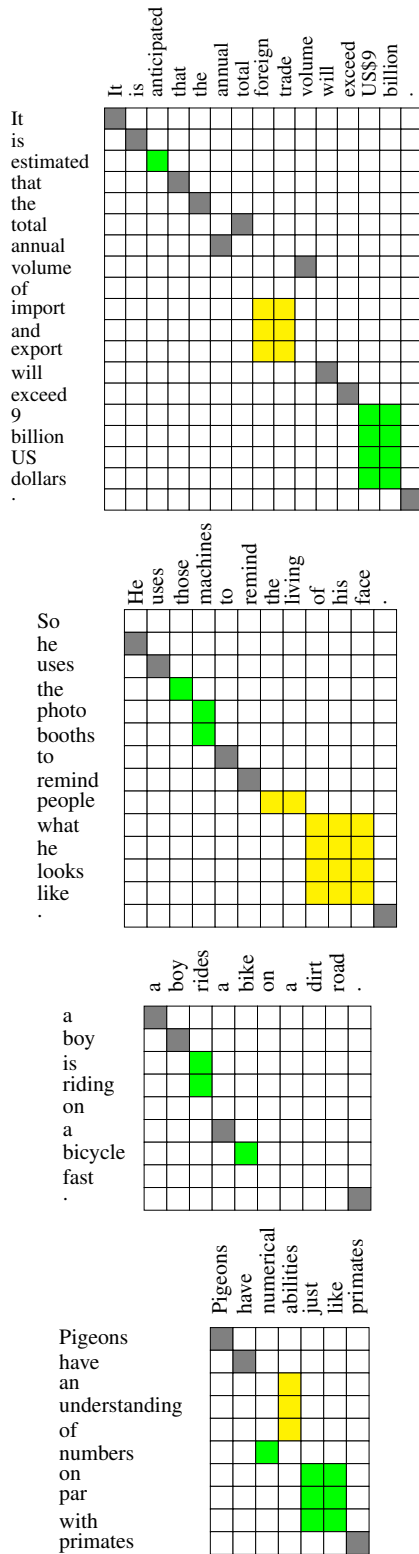

Figure 1: Example reference alignment matrices for (from top to bottom) TEXT, SPEECH, SCENE and EVENT. *Sure* alignments appear in green or gray (identities) and *possible* alignments in yellow.

**TEXT** For English, we used the MTC corpus<sup>1</sup> (described in (Cohn et al., 2008)) consisting of sets of news article translations from Chinese, and for French the CESTA corpus<sup>2</sup> consisting of sets of news article translations from English. For each sentence cluster, we selected sentence pairs with minimal edit distance above an empirically-selected threshold, covering all clusters first and then selecting from already used clusters to reach the target number of sentence pairs.

e.g. *It is estimated that the total annual volume of import and export will exceed 9 billion US dollars.* ↔ *It is anticipated that the annual total foreign trade volume will exceed US\$9 billion.*

**SPEECH** For English, we used two freely available subtitle files<sup>3</sup> of the French movies *Le Fabuleux Destin d'Amélie Poulain* and *Les Choristes*, and for French we used two subtitle files from the *Desperate Housewives* TV series. We first aligned each parallel corpus using the algorithm described in (Tiedemann, 2007), based on time frames and developed for bilingual subtitles, we then filtered out sentence pairs below a minimal edit distance threshold, and manually removed obvious errors made by the algorithm.

e.g. *So he uses the photo booths to remind people what he looks like.* ↔ *He uses those machines to remind the living of his face.*

**SCENE** We used the Multiple Video Description Corpus (Chen and Dolan, 2011) obtained from multiple descriptions of short videos. Similarly to what we did for TEXT, we selected sentence pairs from clusters by minimal edit distance above a threshold. An important fact is that for English we were able to use what is described as “verified” descriptions. There were, however, far fewer descriptions available for French, and none had the “verified” status. We decided to use this corpus nonetheless, but with the knowledge that this source for French is of a substantially lower quality (this corpus type will therefore appear as “(SCENE)” in all tables to reflect this). e.g. *a boy is riding on a bicycle fast.* ↔ *a boy rides a bike on a dirt road.*

EVENT	9,121	9.1	67.8	3.8	19.6	1793	9.6	876

Table 1: Description of all corpora and paraphrase reference sets for English (top) and French (bottom). Note that SCENE for French appears within parentheses as we do not consider it of the same quality as the other corpora.

**EVENT** We used titles of news article clusters from the Google News<sup>4</sup> news aggregation service. We further refined the clustering algorithm by filtering out article pairs whose publication dates differed from more than one day. We repeated the same selection procedure as for TEXT and SCENE to have a maximal cluster coverage and select more similar pairs first.

e.g. *Pigeons Have an Understanding of Numbers on Par With Primates* ↔ *Pigeons Have Numerical Abilities Just Like Primates*

Table 1 provides various statistics for these corpora. The first observation is that TEXT contains significantly larger sentences than the other types, more than twice as long as those of SPEECH. Annotation was performed following the guidelines proposed by Cohn *et al.* (2008)<sup>5</sup> using the YAWAT tool (Germann, 2008), except that alignments were not initially obtained automatically so as not to bias our annotators’ work (there were two annotators per language). The main guidelines that they had to follow were that *sure* and *possible* paraphrases must be distinguished, smaller alignments were to be preferred but any-to-any alignments may be used, and sentences should be aligned as much as possible. Henceforth, we will only consider for all reported statistics and experiments those paraphrases that are not identity pairs (e.g. *(a nice day ↔ a nice day)*), as they are

considered trivial as far as acquisition is concerned.

Table 1 also reports inter-annotator agreement<sup>6</sup> values computed on sets of 50 sentence pairs. We find that acceptable values are obtained for sure paraphrases, but that low values are obtained for possible paraphrases. This was somehow expected, given the many possible interpretations of possible paraphrases, but was not a problem for our experiments: as we will describe in section 3.1, the evaluation metrics we use will not count them as expected solutions, but will simply not count them as false when proposed as candidates.

Table 1 finally shows proportions and absolute numbers of paraphrases of each type for all corpora. We find that there are approximately the same total number of paraphrases for English (16,799) and French (17,001), but that English corpora collectively have an equivalent number of sure and possible paraphrases (8,303 vs. 8,496) and French have more sure paraphrases (11,953 vs. 5,048). This may be explained by the fact that our annotators worked independently and that the corpora used have differences by nature, as our experiments will show. Other salient results include the fact that TEXT contains more sure paraphrases in number than the other corpora, that SPEECH contains relatively more possible paraphrases than the other corpora, and that SCENE has significantly fewer paraphrases, both in proportion and number. In Figure 2 various mea-

EVENT	36.9	15.0	8.2	19.1	1.3	6.8	6.8	5.4
<b>FRENCH</b>								
TEXT	46.9	9.0	8.7	2.1	3.6	6.6	3.0	19.8
SPEECH	45.5	14.2	8.0	8.0	2.6	11.6	3.5	6.2
(SCENE)	46.4	5.3	3.5	8.9	0.0	5.3	0.0	30.3
EVENT	28.3	19.7	6.1	16.0	7.4	8.6	7.4	6.1

Table 2: Percentages of paraphrase classes in 50 randomly selected sentence pairs for reference paraphrases for English (top) and French (bottom). Classes are illustrated by the following examples: (*mutual understanding*  $\leftrightarrow$  *consensus*) (**synonymy**), (*California*  $\leftrightarrow$  *CA*) (**typography**), (*letting*  $\leftrightarrow$  *having let*) (**tense**), (*Asian Development Bank*  $\leftrightarrow$  *Asian Bank*) (**inclusion**), (*police dispatcher*  $\leftrightarrow$  *woman*) (**pragmatics**), (*grief-stricken*  $\leftrightarrow$  *struck with grief*) (**syntactic**), (*Viet-name*  $\leftrightarrow$  *Vietnam*) (**morphology**), (*mortgage*  $\leftrightarrow$  *mortgages*) (**number**).

asures of sentence pair similarities are given. TEXT contains the most similar sentence pairs according to all metrics, with EVENT at a similar level on French. SCENE has sentence pairs that are more similar than those in SPEECH for English, but this is not the case for French. While the metrics used can only provide a crude account of semantic equivalence at the sentence level, these results clearly indicate that translating from text yields more similar sentences than translating from speech.

Table 2 provides a typology of paraphrases found in all our corpora and two languages, where each class has been quantified with respect to the reference alignments.<sup>7</sup> The main observation here is that phrasal **synonymy** (e.g. *mutual understanding*  $\leftrightarrow$  *consensus*) is the most present phenomenon. It is also interesting to note that the EVENT corpus type, which is easy to collect on a daily basis, contains reference paraphrases spread over all classes. Lastly, it is expected that paraphrases in the **pragmatics** class (e.g. *police dispatcher*  $\leftrightarrow$  *woman*) would be difficult to acquire, as this would often rely on document context and costly world knowledge.<sup>8</sup>

<sup>7</sup>Note that typologies of paraphrases have already been proposed in the literature (e.g. (Culicover, 1968; Vila et al., 2011)), but that the choice of our classes has been primarily motivated by potential subsequent uses of the acquired paraphrases (paraphrases could be annotated as belonging to more than one class). Note also that our experiments will also include results focused on the **synonymy** class only (cf. Table 5).

<sup>8</sup>Reusing such types of paraphrases into applications would however often be too strongly context-dependent.

Figure 2: Sentence pair average similarities for all corpora for English (left) and French (right) using the cosine of token vectors, BLEU (Papineni et al., 2002), TER (Snover et al., 2006) and METEOR (Lavie and Agarwal, 2007).

### 3 Bilingual experiments across corpus types

#### 3.1 Evaluation of paraphrase acquisition

We followed the PARAMETRIC methodology described in (Callison-Burch et al., 2008) for assessing the performance of systems on the task of sub-sentential paraphrase acquisition. In this methodology, a set of paraphrase candidates extracted from a sentence pair is compared with a set of reference paraphrases, obtained through human annotation, by computing usual measures of *precision* ( $P$ ) and *recall* ( $R$ ). The first value corresponds to the proportion of paraphrase candidates, denoted  $\mathcal{H}$ , produced by a system and that are correct relative to the reference set containing *sure* and *possible* paraphrases, denoted  $\mathcal{R}_{\text{all}}$ . Recall is obtained by measuring the proportion of the reference set of *sure* paraphrases,

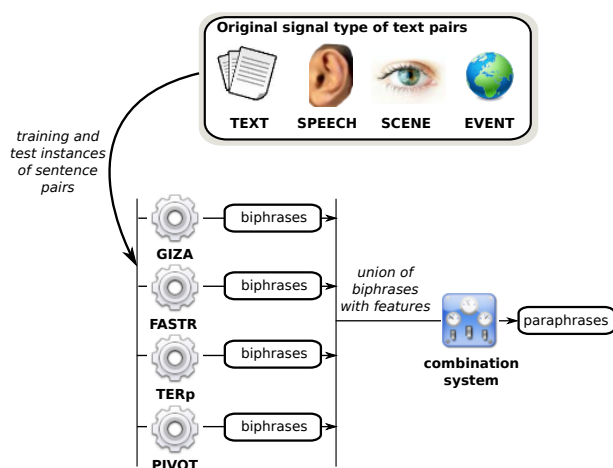

Figure 3: Architecture of our combination system for paraphrase identification.

denoted  $\mathcal{R}_{\text{sure}}$ , that are found by a system. We also computed an F-measure value ( $F_1$ ), which considers recall and precision as equally important. These values are thus given by the following formulae:

$$P = \frac{|\mathcal{H} \cap \mathcal{R}_{\text{all}}|}{|\mathcal{H}|} \quad R = \frac{|\mathcal{H} \cap \mathcal{R}_{\text{sure}}|}{|\mathcal{R}_{\text{sure}}|} \quad F_1 = \frac{2PR}{P + R}$$

Note that the way the sets  $\mathcal{R}_{\text{all}}$  and  $\mathcal{R}_{\text{sure}}$  of reference paraphrase pairs are defined ensures that paraphrase pair candidates that include possible reference paraphrases will not penalize precision while not increasing recall.

All performance values reported in the following sections will be obtained using 10-fold cross-validation and averaging the results on each sub-test. All data sets of cross-validation contain 500 sentence pairs per corpus type, and 125 pairs are kept for development.

### 3.2 A framework for sub-sentential paraphrase identification

We now describe the systems that will be tested on the various corpora described in section 2 using the methodology described in section 3.1. Following (Bouamor et al., 2012), a combination system is used to automatically weight paraphrase pair candidates produced by individual systems using a set of features aiming at recognizing paraphrases, as illustrated on Figure 3. Four individual systems have been used and are described below: the reasons for considering those systems include their free avail-

ability, the possibility of using comparable resources when relevant for our two languages, and the specific characteristics of the techniques used.

#### Statistical learning of word alignments (GIZA)

The GIZA++ tool (Och and Ney, 2004) computes statistical word alignment models of increasing complexity from parallel corpora. It was run on each monolingual corpus of sentence pairs in both directions, symmetrized alignments were kept and classical phrase extraction heuristics were applied (Koehn et al., 2003), without growing phrases with unaligned tokens.

#### Linguistic knowledge on term variation (FASTR)

The FASTR tool (Jacquemin, 1999) spots term variants in large corpora, where variants are described through metarules expressing how the morphosyntactic structure of a term variant can be derived from a given term by means of regular expressions on morphosyntactic categories. Paradigmatic variation can also be expressed with constraints between words, imposing that they be of the same morphological or semantic family using existing resources available in our two languages. Variants for all phrases from one sentence of a pair are extracted from the other sentence, and the intersection of the sets for both directions is kept.

**Edit rate on word sequences (TER<sub>p</sub>)** The TER<sub>p</sub> tool (Snover et al., 2010) can be used to compute an optimal set of word and phrase edits that can transform one sentence into another one.<sup>9</sup> Edit types are parameterized by one or more weights which were optimized towards F-measure by hill climbing with 100 random restarts using the held-out data set consisting of 125 sentence pairs for each corpus type.

**Translational equivalence (PIVOT)** We exploited the paraphrase probability defined by Bannard and Callison-Burch (2005) on bilingual parallel corpora. We used the Europarl corpus<sup>10</sup> of parliamentary debates in English and French, consisting of approximately 1.7 million parallel sentences, using each language as source and pivot in turn. GIZA++

<sup>9</sup>Note that contrarily to what TER<sub>p</sub> allows, we did not use the possibility of using word or phrase equivalents as those are only made available for English. This type of knowledge is however captured in part by the FASTR and PIVOT systems.

<sup>10</sup><http://statmt.org/europarl>

---

<b>Phrase pair features</b>	– edit distance between paraphrases, stem identity, bag-of-tokens similarity, phrase length ratio
<b>Sentence pair features</b>	– sentence pair similarity (cosine, BLEU, TER, METEOR), relative position of paraphrases, presence of common tokens at paraphrase boundaries, presence of another paraphrase pair from each system at paraphrase boundaries, presence of a paraphrase at a different position in the other sentence
<b>Distributional features</b>	– similarity of token context vectors for each phrase of a paraphrase (derived from counts in the large English-French parallel corpus from WMT’11 ( <a href="http://www.statmt.org/wmt11/translation-task.html">http://www.statmt.org/wmt11/translation-task.html</a> ) (approx. 30 million parallel sentences)
<b>System features</b>	– combination of the individual systems that proposed the paraphrase pair

---

Table 3: Features used by our classifiers. Discretized intervals based on median values are used for real values, and binarized values are used for combinations.

was used for word alignment and phrase translation probabilities were estimated from them by the MOSES system (Koehn et al., 2007). For each phrase of a sentence pair, we built its set of paraphrases, and extracted its paraphrase from the other sentence with highest probability. We repeated this process in both directions, and finally kept for each phrase its paraphrase pair from any direction with highest probability.

### Automatic validation of candidate paraphrases

Taking the union of all paraphrase pair candidates from all the above systems for each sentence pair, we perform a Maximum Entropy two-class classification<sup>11</sup>, which allows us to include features that were not necessarily exploited or straightforward to exploit by individual systems to determine the probability that each candidate is a good paraphrase. More generally, this allows us to attempt to learn a more generic characterization of paraphrases, which could trivially accept any number of systems as inputs. Positive examples for the classifier are those from the union of candidates that are also in the reference set  $\mathcal{R}_{\text{sure}}$ , while negative examples are the remaining ones from the union. The features that we used are summarized in Table 3.

### 3.3 Experimental results

Results for individual systems, their union and our validation system trained on each corpus type are given on Table 4. First, we find that all individual systems fare better on TEXT, for which more training data were available and where semantic equiv-

alence of sentence pairs is most likely. EVENT appears to be the most difficult corpus type, whereas one could say that being the most readily data source this is a disappointing result: we will return to this in section 3.4. In terms of performance on F-measure per corpus type, GIZA performs best for TEXT and SPEECH, containing long sentences with possible repetitions, while  $\text{TER}_p$  performs on par with GIZA for SCENE and best for EVENT, where equivalences that are rare at the corpus level are more present. FASTR achieves a very low recall, showing that the encoded definitions of term variants do not cover all types of paraphrases, and also possibly that the lexical resource that it uses has incomplete coverage. It nonetheless obtains high precision values, most notably on TEXT. One last comment regarding individual systems is that PIVOT is by far the most precise of all the techniques used, but with a recall much lower than those of GIZA and  $\text{TER}_p$ : as is the case for FASTR, which makes use of manually-encoded lexical resources, PIVOT encodes in some sense some kind of semantic knowledge.<sup>12</sup>

In all cases, our combination system manages to increase F-measure substantially over the best individual system for a corpus type and the simple union. Improvements are strong on TEXT (resp. +12.5 and +11.6 on English and French) and on SPEECH (+11.7 and +11.1) and quite good on SCENE (+3.2 and +6.4) and on EVENT (+5.4

<sup>11</sup>Using the implementation at: [http://homepages.inf.ed.ac.uk/lzhang10/maxent\\_toolkit.html](http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit.html)

<sup>12</sup>Note that the fact that English and French were used as the pivot for one another may have had some positive effect here, but, incidentally, the two corpora obtained by translating from the other language (TEXT and SPEECH) are not those where PIVOT fares better. The difference observed may however lie in the higher complexity of the sentences in these corpus types.

Table 4: Evaluation results for individual systems (left) and combination systems (right) on all corpus types for English (top) and French (bottom). Values in bold are for highest values for a given metric for each corpus type and language.

and +6.1). Recall from Table 1 that TEXT and SPEECH were the two corpus types with the highest number of sure paraphrase examples for both languages: results show that our classifier was able to efficiently use them.

Recall values for the union are quite strong for all corpus types, ranging from 71.4 (SPEECH in English) to 83.4 (SCENE in English). There is, however, a substantial decrease between the unions and the results of our combination systems, although recall values for our systems are roughly between 56 and 67, which may be considered an acceptable range on such a task. Further study of false negatives should help with engineering new features to improve paraphrase recognition. Lastly, we note that precision is in general highest for a specific system (PIVOT), and reaches high values for our validation system on TEXT, where we have the most examples (resp. 68.4 and 74.7 for English and French).

As seen in Table 2, synonymy is the most present phenomenon in all our corpora; it is also probably one of the most useful type of knowledge for many applications. We now therefore focus on this class, for which all the sure paraphrases in our corpora falling in this class have been annotated. Table 5 shows F-measure values for the individual techniques and our combination systems on all corpus types. We first observe that our combination system also always improves here over the best individual system, albeit not by a large margin on EVENT.

	GIZA	FASTR	TER <sub>p</sub>	PIVOT	validation
<b>ENGLISH</b>					
TEXT	52.2	6.1	47.3	47.1	68.1
SPEECH	42.6	5.0	30.3	39.5	54.9
SCENE	51.8	6.0	48.0	26.0	56.3
EVENT	22.5	2.1	34.8	24.7	35.5
<b>FRENCH</b>					
TEXT	55.3	3.9	50.7	50.5	70.3
SPEECH	49.8	1.6	40.9	36.2	57.2
(SCENE)	19.6	4.2	23.1	0.0	24.7
EVENT	36.8	3.5	35.3	25.6	39.9

Table 5: F-measure values for test instances in the **synonymy** class (see Table 2) for all individual systems and our validation system for English (top) and French (bottom).

Also, we find that PIVOT performs relatively closer to GIZA and TER<sub>p</sub> on TEXT and SPEECH than for the full set of classes, confirming the intuition that translational equivalence may be appropriate to recognize synonymy.

### 3.4 Experiments across corpus types

To test how different the corpora under study are as regards paraphrase identification, we now consider using as additional training data for our classifiers corpora of the other types, both individually and collectively. Results are given on Table 6.<sup>13</sup>

<sup>13</sup>Note that our results are still given by performing cross-validation averaging over 10 test sets for each tested corpus type.

	+TEXT	+SPEECH	+SCENE	+EVENT	+All
<b>ENGLISH</b>					
#ex+	7,342	2,296	1,784	1,171	12,593
TEXT	65.5	66.2	65.1	66.2	65.1
SPEECH	56.0	53.5	52.8	54.8	56.6
SCENE	49.7	54.3	53.7	53.8	42.7
EVENT	51.1	45.3	42.5	46.0	56.2
<b>FRENCH</b>					
#ex+	12,961	3,340	966	2,160	19,427
TEXT	67.1	67.2	66.7	67.0	66.6
SPEECH	57.6	60.0	56.4	59.6	57.9
(SCENE)	23.7	22.0	29.8	23.9	21.1
EVENT	45.2	45.6	44.3	46.8	49.3

Table 6: Evaluation results ( $F_1$  scores) for all corpus types for English (top) and French (bottom) when adding training material from other corpus types (values with gray background on the diagonal are when no additional training data are used). “#ex+” rows indicate numbers of positive paraphrase examples for each additional corpus type.

The most notable observation is that EVENT is substantially improved by using all available additional training data for English (+10.2), and to a lesser extent for French (+2.5). It should be noted that no individual corpus type, save TEXT, individually improves results on EVENT, and that results are yet substantially improved over the use of training data from TEXT when using all available data, revealing a collective contribution of all corpus types. The second major observation is that all other corpus types seem to be quite specific in nature, as no addition of training data from other types yields any improvement (with the exception of SPEECH on English), but they often in fact decrease performance. For instance, SCENE in English is substantially negatively impacted by the use of the numerous examples of TEXT (-4 in F-measure) and even more when using all other training data (-9). This underlines the specific nature of this corpus type: independent descriptions of the same scene in a video may be worded with much variation that mostly differ from that present in other corpus types.

Our main conclusion here is therefore that all our corpora under study are quite specific in nature, but that EVENT can benefit from all training data from the other corpus types. We can further note that the

fact that TEXT is almost not impacted by additional data may also be explained by the fact that this corpus type contains more than half of the total number of examples for the two languages. Finally, there are substantially more positive paraphrase examples for French (19,427) than for English (12,593).

## 4 Related work

Over the years, paraphrase acquisition and generation have attracted a wealth of research works that are too many to adequately summarize here: (Madnani and Dorr, 2010) presents a complete and up-to-date review of the main approaches. Sentential paraphrase collection has been tackled from specific resources increasing the probability of sentences being paraphrases (Dolan et al., 2004; Bernhard and Gurevych, 2008; Wubben et al., 2009), from comparable monolingual corpora (Barzilay and Elhadad, 2003; Fung and Cheung, 2004; Nelken and Shieber, 2006), and even at web scale (Pasça and Dienes, 2005; Bhagat and Ravichandran, 2008).

Various techniques have been proposed for paraphrase acquisition from related sentence pairs (Barzilay and McKeown, 2001; Pang et al., 2003) and from bilingual parallel corpora (Bannard and Callison-Burch, 2005; Kok and Brockett, 2010). The issue of corpus construction for developing and evaluating paraphrase acquisition techniques are addressed in (Cohn et al., 2008; Callison-Burch et al., 2008). To the best of our knowledge, this is the first time that a study in paraphrase acquisition is conducted on several corpus types and for 2 languages. Faruqui and Padó (2011) study the acquisition of *entailment pairs* (premise and hypothesis), with experiments in 3 languages and various domains of newspaper corpora for one language. Although their work is not directly comparable to ours, they report that robustness across domains is difficult to achieve.

Lastly, the evaluation of automatically generated paraphrases has recently received some attention (Liu et al., 2010; Chen and Dolan, 2011; Metzler et al., 2011) although it remains a difficult issue. Application-driven paraphrase generation provides indirect means of evaluating paraphrase generation (Zhao et al., 2009). For instance, the field of Statistical Machine Translation has produced works showing both the usefulness of human-produced

(Schroeder et al., 2009; Resnik et al., 2010) and automatically produced paraphrases (Madnani et al., 2008; Marton et al., 2009; Max, 2010; He et al., 2011) for improving translation performance.

## 5 Discussion and future work

This work has addressed the issue of sub-sentential paraphrase acquisition from text pairs. Analogously to bilingual parallel corpora, which are still to date the most reliable resources for automatic acquisition of sub-sentential translations, monolingual parallel corpora are generally regarded as very appropriate for paraphrase acquisition. However, their low availability makes searching for *less parallel* corpora a necessity. In this study, we have attempted to identify corpora of various degrees of semantic textual similarity by considering text pairs originating from various signal types. These signal types allow various degrees of freedom as to how to formulate a text: a text is read and translated into a different language (TEXT); some speech is listened to in the context of a visual story and translated into a different language (SPEECH); some action is looked at and described (SCENE); and some event that took place is concisely reported (EVENT).

The results presented in this paper have shown how these corpora differed in various aspects. First, they contain varying quantities of paraphrases that are differently distributed into paraphrase classes. Individual acquisition techniques, based on statistical learning of word alignments (GIZA), linguistic knowledge on term variation (FASTR), edit rate on word sequence ( $TER_p$ ), and translational equivalence (PIVOT), for which different performances were observed among them on the same corpus type, were shown to achieve different performances across corpus types. An efficient combination of candidate paraphrases from these individual techniques exploiting additional features to characterize paraphrases has yielded substantial increases in performance on all corpus types; however, it is interesting to note that the highest amplitude in performance across corpus types was not so much on *recall* (amplitude of 10.5 on English and 4.7 on French) than on *precision* (amplitude of 33.4 on English and 34.7<sup>14</sup> on French). This, some other fac-

tors aside, emphasizes the fact that the correct identification of paraphrases is facilitated when equivalence of semantic content is more probable. Many works have accordingly attempted to identify text units that are *as parallel as possible* from large corpora, and the task of measuring semantic textual similarity, which can find many uses, has received some attention lately (Agirre et al., 2012). However, it itself relies on some knowledge on paraphrasing.

Our avenues for future work lie in three main areas. The first one is to continue our current line of work and study the impact of additional individual acquisition techniques and better characterizations of paraphrases in context, in tandem with working on identifying parallel text pairs in large corpora. Another avenue is to start from the output of high recall techniques and to attempt to characterize the contexts of possible substitution for candidate paraphrases from large corpora as a means to acquire precise paraphrases. As the examples from Table 7 show, some classes of paraphrases, and in particular in the continuum from our **synonymy** to **pragmatics** classes, require the joint acquisition of contextual information that license substitution. Lastly, we plan to apply such knowledge in text-to-text applications.

	<b>synonymy</b>
TEXT	<i>take part in</i> ↔ <i>participate in</i> <i>great assistance</i> ↔ <i>enormous help</i>
SPEECH	<i>make a deal</i> ↔ <i>come to an agreement</i> <i>I don't care</i> ↔ <i>I don't give a damn</i>
SCENE	<i>riding a bicycle</i> ↔ <i>cycling</i> <i>lady</i> ↔ <i>woman</i>
EVENT	<i>jail escapee</i> ↔ <i>prison fugitive</i> <i>apologizes</i> ↔ <i>expresses regret</i>
	<b>pragmatics</b>
TEXT	<i>flew in</i> ↔ <i>arrived in</i> <i>flood-control materials</i> ↔ <i>needed supplies</i>
SPEECH	<i>face</i> ↔ <i>picture</i> <i>want to sleep</i> ↔ <i>dream about sleeping</i>
SCENE	<i>a man</i> ↔ <i>someone</i> <i>bento</i> ↔ <i>food</i>
EVENT	<i>violence</i> ↔ <i>bloodshed</i> <i>anger</i> ↔ <i>emotion</i>

Table 7: Examples in English for the **synonymy** and **pragmatics** classes.

# Parse, Price and Cut—Delayed Column and Row Generation for Graph Based Parsers

Sebastian Riedel    David Smith    Andrew McCallum

Department of Computer Science

University of Massachusetts, Amherst

{riedel,dasmith,mccallum}@cs.umass.edu

## Abstract

Graph-based dependency parsers suffer from the sheer number of higher order edges they need to (a) score and (b) consider during optimization. Here we show that when working with LP relaxations, large fractions of these edges can be pruned before they are fully scored—without any loss of optimality guarantees and, hence, accuracy. This is achieved by iteratively parsing with a subset of higher-order edges, adding higher-order edges that may improve the score of the current solution, and adding higher-order edges that are implied by the current best first order edges. This amounts to delayed column and row generation in the LP relaxation and is guaranteed to provide the optimal LP solution. For second order grandparent models, our method considers, or scores, no more than 6–13% of the second order edges of the full model. This yields up to an eightfold parsing speedup, while providing the same empirical accuracy and certificates of optimality as working with the full LP relaxation. We also provide a tighter LP formulation for grandparent models that leads to a smaller integrality gap and higher speed.

## 1 Introduction

Many problems in NLP, and structured prediction in general, can be cast as finding high-scoring structures based on a large set of candidate parts. For example, in second order graph-based dependency parsing (Kübler et al., 2009) we have to choose a quadratic number of first order and a cubic number of second order edges such that the graph is both high-scoring and a tree. In coreference, we have to select high-scoring clusters of mentions from an

exponential number of candidate clusters, such that each mention is in exactly one cluster (Culotta et al., 2007). In segmentation of citation strings, we need to consider a quadratic number of possible segments such that every token is part of exactly one segment (Poon and Domingos, 2007).

What makes such problems challenging is the large number of possible parts to consider. This number not only affects the cost of search or optimization but also slows down the process of scoring parts before they enter the optimization problem. For example, the cubic grandparent edges in second-order dependency parsing slow down dynamic programs (McDonald and Pereira, 2006), belief propagation (Smith and Eisner, 2008) and LP solvers (Martins et al., 2009), since there are more value functions to evaluate, more messages to pass, or more variables to consider. But to even calculate the score for each part we need a cubic number of operations that usually involve expensive feature extraction. This step often becomes a major bottleneck in parsing, and structured prediction in general.

Candidate parts can often be heuristically pruned. In the case of dependency parsing, previous work has used coarse-to-fine strategies where simpler first order models are used to prune unlikely first order edges, and hence all corresponding higher order edges (Koo and Collins, 2010; Martins et al., 2009; Riedel and Clarke, 2006). While such methods can be effective, they are more convoluted, often require training of additional models as well as tuning of thresholding hyper-parameters, and usually provide no guarantees of optimality.

We present an approach that can solve problems with large sets of candidate parts without considering all of these parts in either optimization or scor-

ing. And in contrast to most pruning heuristics, our algorithm can give certificates of optimality before having optimized over, or even scored, all parts. It does so without the need of auxiliary models or tuning of threshold parameters. This is achieved by a delayed column and row generation algorithm that iteratively solves an LP relaxation over a small subset of current candidate parts, and then finds new candidates that score highly and can be inserted into the current optimal solution without removing high scoring existing structure. The latter step subtracts from the cost of a part the price of resources the part requires, and is often referred as *pricing*. Sometimes parts may score highly after pricing, but are necessary in order to make the current solution feasible. We add such parts in a step that roughly amounts to violated *cuts* to the LP.

We illustrate our approach in terms of a second-order grandparent model for dependency parsing. We solve these models by iteratively parsing, pricing, and cutting. To this end we use a variant of the LP relaxation formulated by Martins et al. (2009). Our variant of this LP is designed to be amenable to column generation. It also turns out to be a tighter outer bound that leads to fewer fractional solutions and faster runtimes. To find high scoring grandparent edges without explicitly enumerating all of them, we prune out a large fraction using factorized upper bounds on grandparent scores.

Our parse, price and cut algorithm is evaluated using a non-projective grandparent model on three languages. Compared to a brute force approach of solving the full LP, we only score about 10% of the grandparent edges, consider only 8% in optimization, and so observe an increase in parsing speed of up to 750%. This is possible without loss of optimality, and hence accuracy. We also find that our extended LP formulation leads to a 15% reduction of fractional solutions, up to 12 times higher speed, and generally higher accuracy when compared to the grandparent formulation of Martins et al. (2009).

## 2 Graph-Based Dependency Parsing

Dependency trees are representations of the syntactic structure of a sentence (Nivre et al., 2007). They determine, for each token of a sentence, the syntactic head the token is modifying. As a lightweight al-

ternative to phrase-based constituency trees, dependency representations have by now seen widespread use in the community in various domains such as question answering, machine translation, and information extraction.

To simplify further exposition, we now formalize the task, and mostly follow the notation of Martins et al. (2009). Consider a sentence  $\mathbf{x} = \langle t_0, t_1, \dots, t_n \rangle$  where  $t_1, \dots, t_n$  correspond to the  $n$  tokens of the sentence, and  $t_0$  is an artificial root token. Let  $V \triangleq \{0, \dots, n\}$  be a set of vertices corresponding to the tokens in  $\mathbf{x}$ , and  $\mathcal{C} \subseteq V \times V$  a set of candidate directed edges. Then a directed graph  $y \subseteq \mathcal{C}$  is a *legal dependency parse* if and only if it is a tree over  $V$  rooted at vertex 0. Given a sentence  $\mathbf{x}$ , we use  $\mathcal{Y}$  to denote the set of its legal parses. Note that all of the above definitions depend on  $\mathbf{x}$ , but for simplicity we omit this dependency in our notation.

### 2.1 Arc-Factored Models

Graph-based models define parametrized scoring functions that are trained to discriminate between correct and incorrect parse trees. So called *arc-factored* or *first order* models are the most basic variant of such functions: they assess the quality of a tree by scoring each edge in isolation (McDonald et al., 2005b; McDonald et al., 2005a). Formally, arc-factored models are scoring functions of the form

$$s(y; \mathbf{x}, \mathbf{w}) = \sum_{\langle h, m \rangle \in y} s_{\langle h, m \rangle}(\mathbf{x}, \mathbf{w}) \quad (1)$$

where  $\mathbf{w}$  is a weight vector and  $s_{\langle h, m \rangle}(\mathbf{x}, \mathbf{w})$  scores the edge  $\langle h, m \rangle$  with respect to sentence  $\mathbf{x}$  and weights  $\mathbf{w}$ . From here on we will omit both  $\mathbf{x}$  and  $\mathbf{w}$  from our notation if they are clear from the context.

Given such a scoring function, parsing amounts to solving:

$$\begin{aligned} & \underset{y}{\text{maximize}} && \sum_{\langle h, m \rangle \in y} s_{\langle h, m \rangle} \\ & \text{subject to} && y \in \mathcal{Y}. \end{aligned} \quad (2)$$

### 2.2 Higher Order Models

Arc-factored models cannot capture higher order dependencies between two or more edges. Higher order models remedy this by introducing scores for larger configurations of edges appearing in the

tree (McDonald and Pereira, 2006). For example, in *grandparent* models, the score of a tree also includes a score  $s_{\langle g,p,c \rangle}^{\text{gp}}$  for each grandparent-parent-child triple  $\langle g, p, c \rangle$ :

$$s(y) = \sum_{\langle h,m \rangle \in y} s_{\langle h,m \rangle} + \sum_{\langle g,p \rangle \in y, \langle p,c \rangle \in y} s_{\langle g,p,c \rangle}^{\text{gp}} \quad (3)$$

There are other variants of higher order models that include, in addition to grandparent triples, pairs of siblings (adjacent or not) or third order edges. However, to illustrate our approach we will focus on grandparent models and note that most of what we present can be generalized to other higher order models.

### 2.3 Feature Templates

For our later exposition the factored and parametrized nature of the scoring functions will be crucial. In the following we therefore illustrate this property in more detail.

The scoring functions for arcs or higher order edges usually decompose into a sum of feature *template* scores. For example, the grandparent edge score  $s_{\langle g,p,c \rangle}^{\text{gp}}$  is defined as

$$s_{\langle g,p,c \rangle}^{\text{gp}} \triangleq \sum_{t \in \mathcal{T}^{\text{gp}}} s_{\langle g,p,c \rangle}^{\text{gp},t} \quad (4)$$

where  $\mathcal{T}^{\text{gp}}$  is the set of grandparent templates, and each template  $t \in \mathcal{T}^{\text{gp}}$  defines a scoring function  $s_{\langle g,p,c \rangle}^{\text{gp},t}$  to assess a specific property of the grandparent-parent-child edge  $\langle g, p, c \rangle$ .

The template scores again decompose. Considering grandparent scores, we get

$$s_{\langle g,p,c \rangle}^t \triangleq \mathbf{w}_t^\top \mathbf{f}^t(h_g^t, h_p^t, h_c^t, d_{g,p,c}^t) \quad (5)$$

where  $h_i^t$  is an attribute of token  $t_i$ , say  $h_i^{101} = \text{Part-of-Speech}(t_i)$ . The term  $d_{g,p,c}^t$  corresponds to a representation of the relation between tokens corresponding to  $g, p$  and  $c$ . For example, for template 101 it could return their relative positions to each other:

$$d_{g,p,c}^{101} \triangleq \langle \mathbb{I}[g > p], \mathbb{I}[g > c], \mathbb{I}[p > c] \rangle. \quad (6)$$

The feature function  $\mathbf{f}^t$  maps the representations of  $g, p$  and  $c$  into a vector space. For the purposes of our work this mapping is not important, and hence we omit details.

### 2.4 Learning

The scoring functions we consider are parametrized by a family of per-template weight vectors  $\mathbf{w} = \langle \mathbf{w}_t \rangle_{t \in \mathcal{T}}$ . During learning we need to estimate  $\mathbf{w}$  such that our scoring functions learns to differentiate between correct and incorrect parse trees. This can be achieved in many ways: large margin training, maximizing conditional likelihood, or variants in between. In this work we follow Smith and Eisner (2008) and train the models with stochastic gradient descent on the conditional log-likelihood of the training data, using belief propagation in order to calculate approximate gradients.

### 3 LP and ILP Formulations

Riedel and Clarke (2006) showed that dependency parsing can be framed as Integer Linear Program (ILP), and efficiently solved using an off-the-shelf optimizer if a cutting plane approach is used.<sup>1</sup> Compared to tailor made dynamic programs, such generic solvers give the practitioner more modeling flexibility (Martins et al., 2009), albeit at the cost of efficiency. Likewise, compared to approximate solvers, ILP and Linear Program (LP) formulations can give strong guarantees of optimality. The study of Linear LP relaxations of dependency parsing has also lead to effective alternative methods for parsing, such as dual decomposition (Koo et al., 2010; Rush et al., 2010). As we see later, the capability of LP solvers to calculate dual solutions is also crucial for efficient and exact pruning. Note, however, that dynamic programs provide dual solutions as well (see section 4.5 for more details).

#### 3.1 Arc-Factored Models

To represent a parse  $y \in \mathcal{Y}$  we first introduce an vector of variables  $\mathbf{z} \triangleq \langle z_a \rangle_a$  where  $z_a$  is 1 if  $a \in y$  and 0 otherwise. With this representation parsing amounts to finding a vector  $\mathbf{z}$  that corresponds to a legal parse tree and that maximizes  $\sum_a z_a s_a$ . One way to achieve this is to search through the *convex hull* of all legal incidence vectors, knowing that any linear objectives would take on its maximum on one of the hull's vertices. We will use  $\mathcal{Z}$  to denote this convex hull of incidence vectors of legal parse trees,

<sup>1</sup>Such as the highly efficient and free-for-academic-use Gurobi solver.

and call  $\mathcal{Z}$  the *arborescence polytope* (Martins et al., 2009). The Minkowski-Weyl theorem tells us that  $\mathcal{Z}$  can be represented as an intersection of halfspaces, or constraints,  $\mathcal{Z} = \{\mathbf{z} | \mathbf{A}\mathbf{z} \leq \mathbf{b}\}$ . Hence optimal dependency parsing, in theory, can be addressed using LPs.

However, it is difficult to describe  $\mathcal{Z}$  with a *compact* number of constraints and variables that lend themselves to efficient optimization. In general we therefore work with *relaxations*, or outer bounds, on  $\mathcal{Z}$ . Such outer bounds are designed to cut off all illegal *integer* solutions of the problem, but still allow for *fractional* solutions. In case the optimum is achieved at an integer vertex of the outer bound, it is clear that we have found the optimal solution to the original problem. In case we find a fractional point, we need to map it onto  $\mathcal{Z}$  (e.g., by projection or rounding). Alternatively, we can use the outer bound together with 0/1 constraints on  $\mathbf{z}$ , and then employ an ILP solver (say, branch-and-bound) to find the true optimum. Given the NP-hardness of ILP, this will generally be slow.

In the following we will present the outer bound  $\bar{\mathcal{Z}} \supseteq \mathcal{Z}$  proposed by Martins et al. (2009). Compared to the representation Riedel and Clarke (2006), this bound has the benefit a small polynomial number of constraints. Note, however, that often exponentially many constraints can be efficiently handled if polynomial separation algorithms exist, and that such representations can lead to tighter outer bounds.

The constraints we employ are:

**No Head For Root** In a dependency tree the root node never has a head. While this could be captured through linear constraints, it is easier to simply restrict the candidate set  $\mathcal{C}$  to never contain edges of the form  $\langle \cdot, 0 \rangle$ .

**Exactly One Head for Non-Roots** Any non-root token has to have exactly one head token. We can enforce this property through the set of constraints:

$$m > 0 : \sum_h z_{\langle h, m \rangle} = 1. \quad (\text{OneHead})$$

**No Cycles** A parse tree cannot have cycles. This is equivalent, together with the head constraints above, to enforcing that the tree be fully connected. Martins et al. (2009) capture this connectivity constraint

using a *single commodity flow formulation*. This requires the introduction of flow variables  $\phi \triangleq \langle \phi_a \rangle_{a \in \mathcal{C}}$ . By enforcing that token 0 has  $n$  outgoing flow,

$$\sum_{m > 0} \phi_{\langle 0, m \rangle} = n, \quad (\text{Source})$$

that any other token *consumes one unit of flow*,

$$t > 0 : \sum_h \phi_{\langle h, t \rangle} - \sum_{m > 0} \phi_{\langle t, m \rangle} = 1 \quad (\text{Consume})$$

and that *flow is zero on disabled arcs*

$$\phi_{\langle h, m \rangle} \leq n z_{\langle h, m \rangle}, \quad (\text{NoFlow})$$

connectivity can be ensured.

Assuming we have such a representation, parsing with an LP relaxation amounts to solving

$$\begin{aligned} & \underset{\mathbf{z} \geq \mathbf{0}}{\text{maximize}} && \sum_{a \in A} z_a s_a \\ & \text{subject to} && \mathbf{A} \begin{bmatrix} \mathbf{z} \\ \phi \end{bmatrix} \leq \mathbf{b}. \end{aligned} \quad (7)$$

### 3.2 Higher Order Models

The 1st-Order LP can be easily extended to capture second (or higher) order models. For for the case of grandparent models, this amounts to introducing another class of variables,  $z_{g,p,c}^{\text{gp}}$ , that indicate if the parse contains both the edge  $\langle g, p \rangle$  and the edge  $\langle p, c \rangle$ . With the help of the indicators  $\mathbf{z}^{\text{gp}}$  we can represent the second order objective as a linear function. We now need an outer bound on the convex hull of vectors  $\langle \mathbf{z}, \mathbf{z}^{\text{gp}} \rangle$  where  $\mathbf{z}$  is a legal parse tree and  $\mathbf{z}^{\text{gp}}$  is a consistent set of grandparent indicators. We will refer to this convex hull as the *grandparent polytope*  $\mathcal{Z}^{\text{gp}}$ .

We can re-use the constraints  $\mathbf{A}$  of section 3.1 to ensure that  $\mathbf{z}$  is in  $\mathcal{Z}$ . To make sure  $\mathbf{z}^{\text{gp}}$  is consistent with  $\mathbf{z}$ , Martins et al. (2009) linearize the equivalence  $z_{g,p,c}^{\text{gp}} \Leftrightarrow z_{g,p} \wedge z_{p,c}$  we know to hold for legal incidence vectors, yielding

$$g, p, c : z_{\langle g, p \rangle} + z_{\langle p, c \rangle} - z_{\langle g, p, c \rangle}^{\text{gp}} \leq 1 \quad (\text{ArcGP})$$

and

$$g, p, c : z_{\langle g, p \rangle} \geq z_{\langle g, p, c \rangle}^{\text{gp}}, z_{\langle p, c \rangle} \geq z_{\langle g, p, c \rangle}^{\text{gp}} \quad (\text{GP Arc})$$

There are additional constraints we know to hold in  $\mathcal{Z}^{\text{gp}}$ . First, we know that for any active edge  $\langle p, c \rangle \in$

$y$  with  $p > 0$  there is exactly one grandparent edge  $\langle g, p, c \rangle$ . Likewise, for an inactive edge  $\langle p, c \rangle \notin y$  there must be no grandparent edge  $\langle g, p, c \rangle$ . This can be captured through the constraint:

$$p > 0, c : \sum_g z_{\langle g, p, c \rangle}^{\text{gp}} = z_{\langle p, c \rangle}. \quad (\text{OneGP})$$

We also know that if an edge  $\langle g, p \rangle$  is inactive, there must not be any grandparent edge  $\langle g, p, c \rangle$  that goes through  $\langle g, p \rangle$ :

$$g, p : \sum_c z_{\langle g, p, c \rangle}^{\text{gp}} \leq n z_{\langle g, p \rangle}. \quad (\text{NoGP})$$

It can be easily shown that for *integer* solutions the constraints ArcGP and GP Arc of Martins et al. (2009) are sufficient conditions for consistency between  $\mathbf{z}$  and  $\mathbf{z}^{\text{gp}}$ . It can equally be shown that the same holds for the constraints OneGP and NoGP. However, when working with LP relaxations, the two polytopes have different fractional vertices. Hence, by combining both constraint sets, we can get a tighter outer bound on the grandparent polytope  $\mathcal{Z}^{\text{gp}}$ . In section 6 we show empirically that this combined polytope in fact leads to fewer fractional solutions. Note that when using the union of all four types of constraints, the NoGP constraint is implied by the constraint GP Arc (left) by summing over  $c$  on both sides, and can hence be omitted.

## 4 Parse, Price and Cut

We now introduce our parsing algorithm. To this end, we first give a general description of column and row generation for LPs; then, we illustrate how these techniques can be applied to dependency parsing.

### 4.1 Column and Row Generation

LPs often have too many variables and constraints to be efficiently solved. In such cases delayed column and row generation can substantially reduce runtime by lazily adding variables only when needed (Gilmore and Gomory, 1961; Lübbecke and Desrosiers, 2004).

To illustrate column and row generation let us consider the following general primal LP and its cor-

responding dual problem:

<p><i>Primal</i></p> <p>maximize <math>\mathbf{s}^\top \mathbf{z}</math></p> <p style="text-align: center;"><math>\mathbf{z} \geq \mathbf{0}</math></p> <p>subject to <math>\mathbf{A} \mathbf{z} \leq \mathbf{b}</math></p>	<p><i>Dual</i></p> <p>minimize <math>\boldsymbol{\lambda}^\top \mathbf{b}</math></p> <p style="text-align: center;"><math>\boldsymbol{\lambda} \geq \mathbf{0}</math></p> <p>subject to <math>\mathbf{A}^\top \boldsymbol{\lambda} \geq \mathbf{s}</math>.</p>
--	--

Say you are given a primal feasible  $\mathbf{z}'$  and a dual feasible  $\boldsymbol{\lambda}'$  for which *complementary slackness* holds: for all variables  $i$  we have  $z'_i > 0 \Rightarrow s_i = \sum_j \lambda'_j a_{i,j}$  and for all constraints  $j$  we have  $\lambda'_j > 0 \Rightarrow b_j = \sum_i z'_i a_{i,j}$ . In this case it is easy to show that  $\mathbf{z}'$  is an optimal primal solution,  $\boldsymbol{\lambda}'$  and optimal dual solution, and that both objectives meet at these values (Bertsekas, 1999).

The idea behind delayed column and row generation is to only consider a small subset of variables (or *columns*)  $I$  and subset of constraints (or *rows*)  $J$ . Optimizing over this restricted problem, either with an off-the-shelf solver or a more specialized method, yields the pair  $(\mathbf{z}'_I, \boldsymbol{\lambda}'_J)$  of partial primal and dual solutions. This pair is feasible and complementary with respect to variables  $I$  and constraints  $J$ . We can extend it to a solution  $(\mathbf{z}', \mathbf{y}')$  over all variables and constraints by heuristically setting the remaining primal and dual variables. If it so happens that  $(\mathbf{z}', \mathbf{y}')$  is feasible and complementary for all variables and constraints, we have found the optimal solution. If not, we add the constraints and variables for which feasibility and slackness are violated, and resolve the new partial problem.

In practice, the uninstantiated primal and dual variables are often set to 0. In this case complementary slackness holds trivially, and we only need to find violated primal and dual constraints. For primal constraints,  $\sum_i z_i a_{i,j} \leq b_j$ , searching for violating constraints  $j$  is the well-known *separation* step in cutting plane algorithms. For the dual constraints,  $\sum_j \lambda_j a_{i,j} \geq s_i$ , the same problem is referred to as *pricing*. Pricing is often framed as searching for all, or some, variables  $i$  with positive *reduced cost*  $r_i \triangleq s_i - \sum_j \lambda_j a_{i,j}$ . Note that while these problems are, naturally, dual to each other, they can have very different flavors. When we assess dual constraints we need to calculate a cost  $s_i$  for variable  $i$ , and usually this cost would be different for different  $i$ . For primal constraints the corresponding right-hand-sides are usually much more homogenous.

---

**Algorithm 1** Parse, Price and Cut.

---

**Require:** Initial candidate edges and hyperedges  $P$ .**Ensure:** The optimal  $\mathbf{z}$ .

```
1: repeat
2:    $\mathbf{z}, \boldsymbol{\lambda} \leftarrow \text{parse}(P)$ 
3:    $N \leftarrow \text{price}(\boldsymbol{\lambda})$ 
4:    $M \leftarrow \text{cut}(\mathbf{z})$ 
5:    $P \leftarrow P \cup N \cup M$ 
6: until  $N = \emptyset \wedge M = \emptyset$ 
7: return  $\mathbf{z}$ 
```

---

The reduced cost  $r_i = s_i - \sum_j \lambda_j a_{i,j}$  has several interesting interpretations. First, intuitively it measures the score we could gain by setting  $z_i = 1$ , and subtracts an estimate of what we would lose because  $z_i = 1$  may compete with other variables for shared resources (constraints). Second, it corresponds to the coefficient of  $z_i$  in the Lagrangian  $L(\boldsymbol{\lambda}, \mathbf{z}) \triangleq \mathbf{s}^\top \mathbf{z} + \boldsymbol{\lambda} [\mathbf{b} - \mathbf{A}\mathbf{z}]$ . For any  $\boldsymbol{\lambda}$ ,  $U_{z_i=k} = \max_{\mathbf{z} \geq 0, z_i=k} L(\boldsymbol{\lambda}, \mathbf{z})$  is an upper bound on the best possible primal objective with  $z_i = k$ . This means that  $r_i = U_{z_i=1} - U_{z_i=0}$  is the difference between an upper bound that considers  $z_i = 1$ , and one that considers  $z_i = 0$ . The tighter the bound  $U_{z_i=0}$  is, the closer  $r_i$  is to an upper bound on the maximal increase we can get for setting  $z_i$  to 1. At convergence of column generation, complementary slackness guarantees that  $U_{z_i=0}$  is tight for all  $z'_i = 0$ , and hence  $r_i$  is a true upper bound.

## 4.2 Application to Dependency Parsing

The grandparent formulation in section 3.2 has a cubic number of variables  $z_{\langle g,p,c \rangle}$  as well as a cubic number of constraints. For longer sentences this number can slow us down in two ways. First, the optimizer works with a large search space, and will naturally become slower. Second, for every grandparent edge we need to calculate the score  $s_{\langle g,p,c \rangle}$ , and this calculation can often be a major bottleneck, in particular when using complex feature functions. To overcome this bottleneck, our parse, price and cut algorithm, as shown in algorithm 1, uses column and row generation. In particular, it lazily instantiates the grandparent edge variables  $z_{\langle g,p,c \rangle}^{\text{GP}}$ , and the corresponding cubic number of constraints. All un-instantiated variables are implicitly set to 0.

The algorithm requires some initial set of vari-

ables to start with. In our case this set  $P$  contains all first-order edges  $\langle h, m \rangle$  in the candidate set  $\mathcal{C}$ , and for each of these one grandparent edge  $\langle 0, h, m \rangle$ . The primary purpose of these grandparent edges is to ensure feasibility of the OneGP constraints.

In step 2, the algorithm parses with the current set of candidates  $P$  by solving the corresponding LP relaxation. The LP contains all columns and constraints that involve the edges and grandparent edges of  $P$ . The solver returns both the best primal solution  $\mathbf{z}$  (for both edges and grandparents), and a complementary dual solution  $\boldsymbol{\lambda}$ .

In step 3 the dual variables  $\boldsymbol{\lambda}$  are used to find un-instantiated grandparent edges  $\langle g, p, c \rangle$  with positive reduced cost. The price routine returns such edges in  $N$ . In step 4 the primal solution is inspected for violations of constraint ArcGP. The cut routine performs this operation, and returns  $M$ , the set of edges  $\langle g, p, c \rangle$  that violate ArcGP.

In step 5 the algorithm converges if no more constraint violations, or promising new columns, can be found. If there have been violations ( $M \neq \emptyset$ ) or promising columns ( $N \neq \emptyset$ ), steps 2 to 4 are repeated, with the newly found parts added to the problem. Note that LP solvers can be efficiently *warm-started* after columns and rows have been added, and hence the cost of calls to the solver in step 2 is substantially reduced after the first iteration.

## 4.3 Pricing

In the pricing step we need to efficiently find a set of grandparent edge variables  $z_{\langle g,p,c \rangle}^{\text{GP}}$  with positive reduced cost, or the empty set if no such variables exist. Let  $\lambda_{\langle p,c \rangle}^{\text{OneGP}}$  be the dual variables for the OneGP constraints and  $\lambda_{\langle g,p \rangle}^{\text{NoGP}}$  the duals for constraints NoGP. Then for the reduced cost of  $z_{\langle g,p,c \rangle}^{\text{GP}}$  we know that:

$$r_{\langle g,p,c \rangle} = s_{\langle g,p,c \rangle} - \lambda_{\langle p,c \rangle}^{\text{OneGP}} - \lambda_{\langle g,p \rangle}^{\text{NoGP}}. \quad (8)$$

Notice that the duals for the remaining two constraints ArcGP and GP Arc do not appear in this equation. This is valid because we can safely set their duals to zero without violating dual feasibility or complementary slackness of the solution returned by the solver.

### 4.3.1 Upper Bounds for Efficient Pricing

A naive pricing implementation would exhaustively iterate over all  $\langle g, p, c \rangle$  and evaluate  $r_{\langle g, p, c \rangle}$  for each. In this case we can still substantially reduce the number of grandparent variables that enter the LP, provided many of these variables have non-positive reduced cost. However, we still need to calculate the score  $s_{\langle g, p, c \rangle}$  for each  $\langle g, p, c \rangle$ , an expensive operation we hope to avoid. In the following we present an upper bound on the reduced cost,  $\bar{r}_{\langle g, p, c \rangle}^{\text{gp}} \geq r_{\langle g, p, c \rangle}^{\text{gp}}$ , which decomposes in a way that allows for more efficient search. Using this bound, we find all new grandparent edges  $\bar{N}$  for which this upper bound is positive:

$$\bar{N} \leftarrow \left\{ \langle g, p, c \rangle \mid \bar{r}_{\langle g, p, c \rangle}^{\text{gp}} > 0 \right\}. \quad (9)$$

Next we prune away all but the grandparent edges for which the exact reduced cost is positive:

$$N \leftarrow \bar{N} \setminus \{e : r_e^{\text{gp}} > 0\}. \quad (10)$$

Our bound  $\bar{r}_{\langle g, p, c \rangle}^{\text{gp}}$  on the reduced cost of  $\langle g, p, c \rangle$  is based on an upper bound  $\bar{s}_{\langle g, p, \cdot \rangle}^{\text{gp}} \geq \max_c s_{\langle g, p, c \rangle}^{\text{gp}}$  on the grandparent score involving  $\langle g, p \rangle$  as grandparent and parent, and the bound  $\bar{s}_{\langle \cdot, p, c \rangle}^{\text{gp}} \geq \max_g s_{\langle g, p, c \rangle}^{\text{gp}}$  on the grandparent score involving  $\langle p, c \rangle$  as parent and child. Concretely, we have

$$\bar{r}_{\langle g, p, c \rangle}^{\text{gp}} \triangleq \min \left( \bar{s}_{\langle g, p, \cdot \rangle}^{\text{gp}}, \bar{s}_{\langle \cdot, p, c \rangle}^{\text{gp}} \right) - \lambda_{\langle p, c \rangle}^{\text{OneGP}} - \lambda_{\langle g, p \rangle}^{\text{NoGP}}. \quad (11)$$

To find edges  $\langle g, p, c \rangle$  for which this bound is positive, we can filter out all edges  $\langle p, c \rangle$  such that  $s_{\langle \cdot, p, c \rangle}^{\text{gp}} - \lambda_{\langle p, c \rangle}^{\text{OneGP}}$  is non-positive. This is possible because NoGP is a  $\leq$  constraint and therefore  $\lambda_{\langle g, p \rangle}^{\text{NoGP}} \geq 0$ .<sup>2</sup> Hence  $\bar{r}_{\langle g, p, c \rangle}^{\text{gp}}$  is at most  $\bar{s}_{\langle \cdot, p, c \rangle}^{\text{gp}} - \lambda_{\langle p, c \rangle}^{\text{OneGP}}$ . This filtering step cuts off a substantial number of edges, and is the main reason why can avoid scoring all edges.

Next we filter, for each remaining  $\langle p, c \rangle$ , all possible grandparents  $g$  according to the definition of  $\bar{r}_{\langle g, p, c \rangle}^{\text{gp}}$ . This again allows us to avoid calling the

<sup>2</sup>Notice that in section 4.1 we discussed the LP dual in case were all constraints are inequalities. When equality constraints are used, the corresponding dual variables have no sign constraints. Hence we could not make the same argument for  $\lambda_{\langle p, c \rangle}^{\text{OneGP}}$ .

grandparent scoring function on  $\langle g, p, c \rangle$ , and yields the candidate set  $\bar{N}$ . Only if  $\bar{r}_{\langle g, p, c \rangle}^{\text{gp}}$  is positive do we have to evaluate the exact reduced cost and score.

### 4.3.2 Upper Bounds on Scores

What remains to be done is the calculation of upper bounds  $\bar{s}_{\langle g, p, \cdot \rangle}^{\text{gp}}$  and  $\bar{s}_{\langle \cdot, p, c \rangle}^{\text{gp}}$ . Our bounds factor into per-template bounds according to the definitions in section 2.3. In particular, we have

$$\bar{s}_{\langle \cdot, p, c \rangle}^{\text{gp}} \triangleq \sum_{t \in \mathcal{T}^{\text{gp}}} \bar{s}_{\langle \cdot, p, c \rangle}^{\text{gp}, t} \quad (12)$$

where  $\bar{s}_{\langle \cdot, p, c \rangle}^t$  is a per-template upper bound defined as

$$\bar{s}_{\langle \cdot, p, c \rangle}^{\text{gp}, t} \triangleq \max_{\substack{v \in \text{range}(h^t) \\ e \in \text{range}(d^t)}} \mathbf{w}_t^\top \mathbf{f}^t(v, h_p^t, h_c^t, e). \quad (13)$$

That is, we maximize over all possible attribute values  $v$  any token  $g$  could have, and any possible relation  $e$  a token  $g$  can have to  $p$  and  $c$ .

Notice that these bounds can be calculated offline, and hence amortize after deployment of the parser.

### 4.3.3 Tightening Duals

To price variables, we use the duals returned by the solver. This is a valid default strategy, but may lead to  $\lambda$  with overcautious reduced costs. Note, however, that we can arbitrary alter  $\lambda$  to minimize reduced costs of uninstantiated variables, as long as we ensure that feasibility and complementary slackness are maintained for the instantiated problem.

We use this flexibility for increasing  $\lambda_{\langle p, c \rangle}^{\text{OneGP}}$ , and hence lowering reduced costs  $z_{\langle g, p, c \rangle}^{\text{gp}}$  for all tokens  $c$ . Assume that  $z_{\langle p, c \rangle} = 0$  and let  $r_{\langle p, c \rangle} = \lambda_{\langle p, c \rangle}^{\text{OneGP}} + K$  be the current reduced cost for  $z_{\langle p, c \rangle}$  in the instantiated problem. Here  $K$  is a value depending on  $s_{\langle p, c \rangle}$  and the remaining constraints  $z_{\langle p, c \rangle}$  is involved in.

We know that  $r_{\langle p, c \rangle} \leq 0$  due to dual feasibility and hence  $r_{\langle p, c \rangle}$  may be 0, but note that  $r_{\langle p, c \rangle} < 0$  in many cases. In such cases we can increase  $\lambda_{\langle p, c \rangle}^{\text{OneGP}}$  to  $-K$  and get  $r_{\langle p, c \rangle} = 0$ . With respect to  $z_{\langle p, c \rangle}$  this maintains dual feasibility (because  $r_{\langle p, c \rangle} \leq 0$ ) and complementary slackness (because  $z_{\langle p, c \rangle} = 0$ ). Furthermore, with respect to the  $z_{\langle g, p, c \rangle}^{\text{gp}}$  for all tokens  $c$  this also maintains feasibility (because the increased  $\lambda_{\langle p, c \rangle}^{\text{OneGP}}$  appears with negative sign in 8) and complementary slackness (because  $z_{\langle g, p, c \rangle}^{\text{gp}} = 0$  due to  $z_{\langle p, c \rangle} = 0$ ).

## 4.4 Separation

What happens if both  $z_{\langle g,p \rangle}$  and  $z_{\langle p,c \rangle}$  are active while  $z_{\langle g,p,c \rangle}^{\text{SP}}$  is still implicitly set to 0? In this case we violate constraint ArcGP. We could remedy this by adding the cut  $z_{\langle g,p \rangle} + z_{\langle p,c \rangle} \leq 1$ , resolve the LP, and then use the dual variable corresponding to this constraint to get an updated reduced cost  $r_{\langle g,p,c \rangle}$ . However, in practice we found this does not happen as often, and when it does, it is cheaper for us to add the corresponding column  $r_{\langle g,p,c \rangle}$  right away instead of waiting to the next iteration to price it.

To find all pairs of variables for  $z_{\langle g,p \rangle} + z_{\langle p,c \rangle} \leq 1$  is violated, we first filter out all edges  $\langle h,m \rangle$  for which  $z_{\langle h,m \rangle} = 0$  as these automatically satisfy any ArcGP constraint they appear in. Now for each  $z_{\langle g,p \rangle} > 0$  all  $z_{\langle p,c \rangle} > 0$  are found, and if their sum is larger than 1, the corresponding grandparent edge  $\langle g,p,c \rangle$  is returned in the result set.

## 4.5 Column Generation in Dynamic Programs

Column and Row Generation can substantially reduce the runtime of an off-the-shelf LP solver, as we will find in section 6. Perhaps somewhat surprisingly, it can also be applied in the context of dynamic programs. It is well known that for each dynamic program there is an equivalent polynomial LP formulation (Martin et al., 1990). Roughly speaking, in this formulation primal variables correspond to state transitions, and dual variables to value functions (e.g., the forward scores in the Viterbi algorithm).

In pilot studies we have already used DCG to speed up (exact) Viterbi on linear chains (Belanger et al., 2012). We believe it could be equally applied to dynamic programs for higher order dependency parsing.

## 5 Related Work

Our work is most similar in spirit to the relaxation method presented by Riedel and Smith (2010) that incrementally adds second order edges to a graphical model based on a gain measure—the analog of our reduced cost. However, they always score every higher order edge, and also provide no certificates of optimality.

Several works in parsing, and in MAP inference in general, perform some variant of row genera-

tion (Riedel and Clarke, 2006; Tromble and Eisner, 2006; Sontag and Jaakkola, 2007; Sontag et al., 2008). However, none of the corresponding methods lazily add columns, too. The cutting plane method of Riedel (2008) can omit columns, but only if their coefficient is negative. By using the notion of reduced costs we can also omit columns with positive coefficient. Niepert (2010) applies column generation, but his method is limited to the case of k-Bounded MAP Inference.

Several ILP and LP formulations of dependency parsing have been proposed. Our formulation is inspired by Martins et al. (2009), and hence uses fewer constraints than Riedel and Clarke (2006). For the case of grandparent edges, our formulation also improves upon the outer bound of Martins et al. (2009) in terms of speed, tightness, and utility for column generation. Other recent LP relaxations are based on dual decomposition (Rush et al., 2010; Koo et al., 2010; Martins et al., 2011). These relaxations allow the practitioner to utilize tailor-made dynamic programs for tractable substructure, but still every edge needs to be scored. Given that column generation can also be applied in dynamic programs (see section 4.5), our algorithm could in fact accelerate dual decomposition parsing as well.

Pruning methods are a major part of many structured prediction algorithms in general, and of parsing algorithms in particular (Charniak and Johnson, 2005; Martins et al., 2009; Koo and Collins, 2010; Rush and Petrov, 2012). Generally these methods follow a coarse-to-fine scheme in which simpler models filter out large fractions of edges. Such methods are effective, but require tuning of threshold parameters, training of additional models, and generally lead to more complex pipelines that are harder to analyze and have fewer theoretical guarantees.

A\* search (Ahuja et al., 1993) has been used to search for optimal parse trees, for example by Klein and Manning (2003) or, for dependency parsing, by Dienes et al. (2003). There is a direct relation between both A\* and Column Generation based on an LP formulation of the shortest path problem. Roughly speaking, in this formulation any feasible dual assignments correspond to a consistent (and thus admissible) heuristic, and the corresponding reduced costs can be used as edge weights. Run-

ning Dijkstra’s algorithm with these weights then amounts to  $A^*$ . Column generation for the shortest path problem can then be understood as a method to lazily construct a consistent heuristic. In every step this method finds edges for which consistency is violated, and updates the heuristic such that all these edges are consistent.

## 6 Experiments

We claim that LP relaxations for higher order parsing can be solved without considering, and scoring, all candidate higher order edges. In practice, how many grandparent edges do we need to score, and how many do we need to add to the optimization problem? And what kind of reduction in runtime does this reduction in edges lead to?

We have also pointed out that our outer bound on the grandparent polytope of legal edge and grandparent vectors is tighter than the one presented by Martins et al. (2009). What effect does this bound have on the number of fractional solutions and the overall accuracy?

To answer these questions we will focus on a set of non-projective grandparent models, but point out that our method and formulation can be easily extended to projective parsing as well as other types of higher order edges. We use the Danish test data of Buchholz and Marsi (2006) and the Italian and Hungarian test datasets of Nivre et al. (2007).

### 6.1 Impact of Price and Cut

Table 1 compares brute force optimization (BF) with the full model, in spirit of Martins et al. (2009), to running parse, price and cut (PPC) on the same model. This model contains all constraints presented in 3.2. The table shows the average number of parsed sentences per second, the average objective, number of grandparent edges scored and added, all relative to the brute force approach. We also present the average unlabeled accuracy, and the percentage of sentences with integer solutions. This number shows us how often we not only found the optimal solution to the LP relaxation, but also the optimal solution to the full ILP.

We first note that both systems achieve the same objective, and therefore, also the same accuracy. This is expected, given that column and row gen-

eration are known to yield optimal solutions. Next we see that the number of grandparent edges scored and added to the problem is reduced to 5–13% of the full model. This leads to up to 760% improvement in speed. This improvement comes for free, without any sacrifice in optimality or guarantees. We also notice that in all cases at least 97% of the sentences have no fractional solutions, and are therefore optimal even with respect to the ILP. Table 1 also shows that our bounds on reduced costs are relatively tight. For example, in the case of Italian we score only one percent more grandparent edges than we actually need to add.

Our fastest PCC parser processes about one sentence per second. This speed falls below the reported numbers of Martins et al. (2009) of about 0.6 seconds per sentence. Crucially, however, in contrast to their work, our speed is achieved without any first-order pruning. In addition, we expect further improvements in runtime by optimizing the implementation of our pricing algorithm.

### 6.2 Tighter Grandparent Polytope

To investigate how the additional grandparent constraints in section 3.2 help, we compare three models, this time without PPC. The first model follows Martins et al. (2009) and uses constraints ArcGP and GP Arc only. The second model uses only constraints OneGP and NoGP. The final model incorporates all four constraints.

Table 2 shows speed relative to the baseline model with constraints ArcGP and GP Arc, as well as the percentage of integer solutions and the average unlabeled accuracy—all for the Italian and Hungarian datasets. We notice that the full model has less fractional solutions than the partial models, and either substantially (Italian) or slightly (Hungarian) faster runtimes than ArcGP+GP Arc. Interestingly, both sets of constraints in isolation perform worse, in particular the OneGP and NoGP model.

## 7 Conclusion

We have presented a novel method for parsing in second order grandparent models, and a general blueprint for more efficient and optimal structured prediction. Our method lazily instantiates candidate parts based on their reduced cost, and on constraint

	Italian		Hungarian		Danish

Table 2: Different outer bounds on the grandparent polytope, for nonprojective parsing of Italian and Danish.

violations. This allows us to discard a large fraction of parts during both scoring and optimization, leading to nearly 800% speed-ups without loss of accuracy and certificates. We also present a tighter bound on the grandparent polytope that is useful in its own right.

Delayed column and row generation is very useful when solving large LPs with off-the-shelf solvers. Given the multitude of work in NLP that uses LPs and ILPs in this way (Roth and Yih, 2004; Clarke and Lapata, 2007), we hope that our approach will prove itself useful for other applications. We stress that this approach can also be used when working with dynamic programs, as pointed out in section 4.5, and therefore also in the context of dual decomposition. This suggests even wider applicability, and usefulness in various structured prediction

problems.

The underlying paradigm could also be useful for more approximate methods. In this paradigm, algorithms maintain an estimate of the cost of certain resources (duals), and use these estimates to guide search and the propose new structures. For example, a local-search based dependency parser could estimate how contested certain tokens, or edges, are, and then use these estimates to choose better next proposals. The notion of reduced cost can give guidance on what such estimates should look like.

## Abstract

We propose an adaptive ensemble method to adapt coreference resolution across domains. This method has three features: (1) it can optimize for any user-specified objective measure; (2) it can make document-specific prediction rather than rely on a fixed base model or a fixed set of base models; (3) it can automatically adjust the active ensemble members during prediction. With simplification, this method can be used in the traditional within-domain case, while still retaining the above features. To the best of our knowledge, this work is the first to both (i) develop a domain adaptation algorithm for the coreference resolution problem and (ii) have the above features as an ensemble method. Empirically, we show the benefits of (i) on the six domains of the ACE 2005 data set in domain adaptation setting, and of (ii) on both the MUC-6 and the ACE 2005 data sets in within-domain setting.

## 1 Introduction

Coreference resolution is a fundamental component of natural language processing (NLP) and has been widely applied in other NLP tasks (Stoyanov et al., 2010). It gathers together noun phrases (mentions) that refer to the same real-world entity (Ng and Cardie, 2002). In the past decade, several coreference resolution systems have been proposed, e.g., (Ng and Cardie, 2002), (Denis and Baldridge, 2007) and (Stoyanov et al., 2010). All of these focus on the within-domain case — to use the labeled documents from a domain to predict on the unlabeled

documents in the same domain. However, in practice, there is usually limited labeled data in a specific domain of interest, while there may be plenty of labeled data in other related domains. Effective use of data from the other domains for predicting in the domain of interest is therefore an important strategy in NLP. This is called domain adaptation, and, in this context, the former domains is called the *source domains*, while the latter domain is called the *target domain* (Blitzer et al., 2006; Jiang and Zhai, 2007).

Based on the type of the knowledge to be transferred to the target domain, domain adaptation learning can be categorized as instance-based method, feature-based method, parameter-based method or relational-knowledge-based method (Pan and Yang, 2010). Previously, domain adaptation learning has been successfully used in other NLP tasks such as relation extraction (Jiang, 2009) and POS tagging (Jiang and Zhai, 2007), semantic detection (Tan et al., 2008), name entity recognition (Guo et al., 2009) and entity type classification (Jiang and Zhai, 2007). However, to the best of our knowledge, it has yet to be explored for coreference resolution.

In this paper, we propose an adaptive ensemble method to adapt coreference resolution across domains. This proposed method can be categorized as both feature-based and parameter-based domain adaptation learning methods. It has three main steps: *ensemble creation*, *cross-domain knowledge learning* and *decision inference*. The first step creates the ensemble by collecting a set of base models, which can be any individual methods with various features/instances/parameters settings. The second step analyzes the collected base models from vari-

\*The work is done during postdoc in NTU, Singapore.

ous domains and learns the cross-domain knowledge between each target domain and the source domain. The third step infers the final decision in the target domain based on all ensemble results.

In addition to domain adaptation, the proposed adaptive ensemble method has the following features that are absent in the other ensemble methods. First, it can optimize any *user-specified objective measure* without using a separate development set. Second, it can provide *document-specific prediction* instead of relying on a fixed base model or a fixed set of base models for all documents. Third, it can automatically *adjust the active ensemble members* in decision inference so that underperforming base models are filtered out. The proposed method can also be used in the traditional within-domain problem with some simplifications.

We conduct experiments for coreference resolution under both the within-domain setting and the domain-adaptation setting. In the within-domain setting, we compare the proposed adaptive ensemble method with the mention-pair methods and other ensemble methods on the MUC-6 and ACE 2005 corpora. The results show that the proposed adaptive ensemble method consistently outperforms these baselines. In the domain adaptation setting, we use the ACE 2005 corpora to create six domain adaptation tasks to evaluate the effectiveness of our domain adaptation learning. The results show that our method outperforms baselines that do not use domain adaptation.

The paper is organized as follows. Section 2 reviews some existing ensemble methods for coreference resolution. Section 3 presents the proposed adaptive ensemble method for domain adaptation problems. Section 4 presents a special case of the proposed method for the within-domain setting. Section 5 presents the experiments under both the within-domain and the domain adaptation settings. We conclude and discuss future work in Section 6.

## 2 Existing Ensemble Methods

Many ensemble methods have been proposed in the machine learning literature, e.g., bagging (Breiman, 1996), boosting (Freund and Schapire, 1996), random forest (Breiman, 2001) and mixture models (Bishop, 2007). Some of them have been success-

fully used in coreference resolution (Pang and Fan, 2009; Munson et al., 2005; Rahman and Ng, 2011a). However, these methods only focus on the within-domain setting.

All these methods comprise of two steps: ensemble creation and decision inference. Ng and Cardie (2003) and Vemulapalli et al. (2009) applied the bagging and boosting techniques on the documents to create the ensemble. Recently, Rahman and Ng (2011a) further enriched the ensemble by considering various feature sets and learning models. Specifically, three types of feature sets (conventional, lexical and combined) and three learning algorithms (mention-pair model, mention-ranking model and the clustering-ranking model) are employed. In decision inference, these methods used voting or averaging to get the final prediction. Rahman and Ng (2011a) proposed four voting strategies for prediction: applying best Per-NP-Type model, antecedent-based voting, cluster-based voting and weighted clustering-based voting. Although their approaches achieved promising results in their end-to-end systems, these do not consider the user-specific performance measure during the ensemble learning.

Another branch of ensemble methods uses model selection (Munson et al., 2005; Ng, 2005), similar to the conventional model selection method for generic parameter-tuning. The method of (Munson et al., 2005) first collects a large family of base models. Then, a separate tuning set with ground truth is used to evaluate each base model's performance. Finally, an iterative approach is used to select the best performed base models to form the ensemble. Like other methods, this method uses the average strategy in decision inference. Similarly, the method of (Ng, 2005) ranks base models according to their performance on separate tuning set, and then uses the highest-ranked base model for predicting on test documents. These methods require a separate set of labeled documents to assess the generalization performance.

## 3 Adaptive Ensemble Method

In this section, we give our adaptive ensemble method for domain adaptation for coreference resolution. We first introduce some notations.

For a corpus of  $N$  documents, document  $D_i$

is the  $i^{\text{th}}$  document, and it contains  $n_i$  mentions  $\mathbf{m}_i = (m_i^1, \dots, m_i^{n_i})$  with the ordering of each mention as they appear in the document. The index set of all mention pairs in  $\mathcal{D}_i$  is  $\mathcal{E}_i = \{(a, b) \mid 1 \leq a < b \leq n_i\}$ . The transpose of vector  $x$  is  $x'$ . The performance measure function for document  $\mathcal{D}$  is  $\Lambda(g(\mathcal{D}); f(\mathcal{D}))$ , where  $g(\mathcal{D})$  and  $f(\mathcal{D})$  represent the coreference ground-truth and prediction by model  $f$  on document  $\mathcal{D}$  respectively. In coreference resolution, typical performance measure functions include MUC (Vilain et al., 1995), Rand index (Rand, 1971), B-CUBED (Bagga and Baldwin, 1998) and CEAF (Luo, 2005). In this paper,  $\Lambda$  can either be used as part of an objective function in learning or as an evaluation measure for assessing the performance of a coreference system.

We consider the typical domain adaptation problem, which has one target domain  $t$  and  $p$  ( $p \geq 1$ ) source domains  $s_1, \dots, s_p$ . The target domain contains  $N^{(t)}$  labeled documents and  $M$  unlabeled documents, while source domains contain  $N^{(s_1)}, \dots, N^{(s_p)}$  labeled documents. Unlabeled data in the source domains are not used. We use  $\mathcal{D}_i^{(v)}$  for the  $i^{\text{th}}$  document in domain  $v$ .

### 3.1 Ensemble Creation

Mention-pair methods have been widely-used for coreference resolution due to their efficiency and effectiveness, and they have often been taken as base models in ensemble learning (Rahman and Ng, 2011a; Munson et al., 2005). We adopt a similar approach by using the standard mention-pair method (Soon et al., 2001; Ng and Cardie, 2002) with various parameters to form the ensemble, though our framework can incorporate other coreference methods in the ensemble. Mention-pair methods usually comprise of two steps. The first step classifies every mention pair into either coreference or non-coreference with a confidence between 0 and 1. The second step partitions the set of mentions into clusters based on the confidence values, where mentions in each cluster are presumed to be the same underlying entity.

**Classification** We use Soon’s approach (Soon et al., 2001) to select a portion of mention pairs to train a binary classifier because this has better generalization (Soon et al., 2001). The positive mention pairs

are the anaphoric mention  $m_i^b$  ( $b = 2, \dots, n_i$ ) paired with its closest antecedent mention  $m_i^a$  ( $a < b$ ), while the negative mention pairs are the mention  $m_i^b$  paired with each of the intervening mentions  $m_i^{a+1}, m_i^{a+2}, \dots, m_i^{b-1}$ . Following (Rahman and Ng, 2011a), our binary classifier is SVM with the regularization parameter  $C$ . The classifier is trained with the software Liblinear (Fan et al., 2008), which is also used to give probabilistic binary predictions.

**Clustering** We adopt closest-first clustering (Soon et al., 2001) and best-first clustering (Ng and Cardie, 2002) to determine whether a mention pair is coreferent. For each mention, the closest-first method (or best-first method) links it to the the closest (or the best) preceding mention if the confidence value (obtained from the first step) of this mention pair is above a specified threshold  $t$ .

**Features** For each mention pair, we use the  $d = 39$  features proposed by Rahman and Ng (2011b) to represent it. These features can be extracted using the Reconcile software (Stoyanov et al., 2010). We use  $\hat{\phi}_{a,b} \in R^d$  to represent the features of a mention pair  $(m^a, m^b)$ . With this feature set, we found that the linear kernel is insufficient to fit the training data. However, using an rbf kernel would be too computationally expensive. Hence, we augment  $\hat{\phi}_{a,b}$  with a  $\hat{d}$ -dimensional feature vector  $[\psi^1 \dots \psi^{\hat{d}}]$  to give a new feature vector

$$\phi_{a,b} = [\hat{\phi}_{a,b} \ \psi^1 \ \dots \ \psi^{\hat{d}}], \quad (1)$$

where the  $\hat{d}$  augmented features  $[\psi^1 \dots \psi^{\hat{d}}]$  are determined by

$$\psi^j = \exp\left(-\frac{\|\hat{\phi}_{a,b} - c^j\|^2}{d}\right), \forall j = 1, \dots, \hat{d}. \quad (2)$$

Herein,  $c^1, \dots, c^{\hat{d}}$  are the  $\hat{d}$  centroids of the randomly-selected subset  $\mathcal{C}$  from all labeled mention pairs  $\{\hat{\phi}_{a,b} \mid (a, b) \in \mathcal{E}_1, \dots, \mathcal{E}_N\}$ . In our experiments, we use the  $k$ -means algorithm to obtain the centroids of  $\mathcal{C}$ .

**Ensemble** For domain  $v$ , we create a domain-specified ensemble  $\mathcal{F}^{(v)} = \{f^1, \dots, f^\ell\}$  of  $\ell$  base models by including the closest-first and best-first mention-pair methods with the different  $C$  and  $t$  values. If multiple domains are provided, we gather all

the domain-specific ensembles into a grand ensemble  $\mathcal{F} = \mathcal{F}^{(s_1)} \cup \dots \cup \mathcal{F}^{(s_p)} \cup \mathcal{F}^{(t)}$ .

### 3.2 Cross-domain Knowledge Learning

Generally, the feature distributions are different in different domains. Therefore, effective domain adaptation requires using some knowledge of cross-domain similarity. We now propose an approach to learn the parametric-distances between the documents in source and target domains to characterize this cross-domain knowledge.

**Distances between documents** A document  $\mathcal{D}_i$  is represented by the sum of its new mention-pair features (Yu and Joachims, 2009; Finley and Joachims, 2005):

$$\Phi(\mathcal{D}_i) = \sum_{(a,b) \in \mathcal{E}_i} \phi_{a,b}. \quad (3)$$

The distance between a source labeled document  $\mathcal{D}_i^{(s_u)}$  in domain  $s_u$  and a target labeled document  $\mathcal{D}_j^{(t)}$  is parameterized as

$$\text{Dist}(\mathcal{D}_i^{(s_u)}, \mathcal{D}_j^{(t)}; \boldsymbol{\mu}) = \boldsymbol{\mu}' \Delta(\mathcal{D}_i^{(s_u)}, \mathcal{D}_j^{(t)}), \quad (4)$$

where vector  $\boldsymbol{\mu} \in \mathbb{R}^{d+\hat{d}}$  is to be learned, and vector function  $\Delta(\mathcal{D}_i^{(s_u)}, \mathcal{D}_j^{(t)}) \in \mathbb{R}^{d+\hat{d}}$  is the Euclidean distance vector between two documents given by

$$\Delta(\mathcal{D}_i^{(s_u)}, \mathcal{D}_j^{(t)}) = (\Phi(\mathcal{D}_i^{(s_u)}) - \Phi(\mathcal{D}_j^{(t)})) \odot (\Phi(\mathcal{D}_i^{(s_u)}) + \Phi(\mathcal{D}_j^{(t)})). \quad (5)$$

The operator  $\odot$  is the element-wise product. Distance (4) is actually the Mahalanobis distance (Yang and Jin, 2006) with the scaling of features:

$$(\Phi(\mathcal{D}_i^{(s_u)}) - \Phi(\mathcal{D}_j^{(t)}))' W (\Phi(\mathcal{D}_i^{(s_u)}) - \Phi(\mathcal{D}_j^{(t)})),$$

where  $W$  is a diagonal matrix with diagonal entries  $\boldsymbol{\mu}$ . Matrix  $W$  is diagonal to reduce computation cost and to increase statistical confidence in estimation when there is limited target labeled data (as is typically the case in domain adaptation).

That  $\boldsymbol{\mu}$  is the vector of diagonal entries in  $W$  requires that each entry in  $\boldsymbol{\mu}$  is non-negative. If the  $l^{\text{th}}$  entry of  $\boldsymbol{\mu}$  is non-zero, then the  $l^{\text{th}}$  feature in  $\phi_{a,b}$  contribute towards (4). To ensure that at least  $B$  features are used, we also constrain that each entry in  $\boldsymbol{\mu}$  is not more than unity and that  $\mathbf{1}'\boldsymbol{\mu} \geq B$ .

**Matching best base models** For each labeled document  $\mathcal{D}_j^{(v)}$  in domain  $v$ , we identify the best performing base model  $f_j^{(v)*}$  in  $\mathcal{F}^{(v)}$  with

$$f_j^{(v)*} = \arg \max_{f \in \mathcal{F}^{(v)}} \Lambda(g(\mathcal{D}_j^{(v)}); f(\mathcal{D}_j^{(v)})), \quad (6)$$

where  $\Lambda(\cdot; \cdot)$  is the the performance objective function to be instantiated in Section 3.3.

Then, for each source domain  $s_u$  and document  $\mathcal{D}_j^{(t)}$  in the target domain, we find the set  $\mathcal{I}(\mathcal{D}_j^{(t)}; s_u)$  of the documents in domain  $s_u$  that have the same best performing base model as that for  $\mathcal{D}_j^{(t)}$ :

$$\mathcal{I}(\mathcal{D}_j^{(t)}; s_u) = \{\mathcal{D}_i^{(s_u)} \mid f_i^{(s_u)*} = f_j^{(t)*}, i = 1, \dots, N^{(s_u)}\}. \quad (7)$$

The key idea in  $\mathcal{I}(\mathcal{D}_j^{(t)}; s_u)$  is to select documents in a source domain  $s_u$  that are similar to document  $\mathcal{D}_j^{(t)}$  in the sense that they have the same best performing base model under a specific  $\Lambda$ . This ensures that optimization step (to be described next) is targeted towards  $\Lambda$  and not confounded by document pairs that should be dissimilar anyway.

**Optimization** We determine the vector  $\boldsymbol{\mu}$  by minimizing the parametric distance (4) between all target labeled documents and their corresponding source labeled document identified in the previous step. That is,

$$\min_{\boldsymbol{\mu}} \boldsymbol{\mu}' \sum_{j=1}^{N^{(t)}} \sum_{\mathcal{D}_i^{(s_u)} \in \mathcal{I}(\mathcal{D}_j^{(t)}; s_u)} \Delta(\mathcal{D}_i^{(s_u)}, \mathcal{D}_j^{(t)}). \quad (8)$$

The solution  $\boldsymbol{\mu}$  to this linear programming problem can be regarded as the cross-domain knowledge between source domain  $s_u$  and the target domain  $t$ . Repeating for every source domain  $s_u$ ,  $u = 1, \dots, p$ , gives the cross-domain knowledge between every source domain and the target domain.

The above three-steps procedure selects the effective features for each pair of source and target domains. Generally, the results of feature selection vary for different pairs of source and target domains, due to the diversities of the feature distributions in different domains.

### 3.3 Decision Inference

After ensemble creation and cross-domain knowledge learning, we need to provide the coreference result on an unseen document in the target domain based on the results of all the members in  $\mathcal{F}$ . Unlike the previous methods using the voting/average or their variants (Pang and Fan, 2009; Munson et al., 2005; Rahman and Ng, 2011a), we propose the following nearest neighbor based approach.

Given the grand ensemble  $\mathcal{F}$  and all labeled documents, the task is to predict on the target unlabeled document  $\mathcal{D}_j^{(t)}$ ,  $j = 1, \dots, M$ . The idea of the proposed method is to first find the  $k$  most similar documents  $\mathcal{N}(\mathcal{D}_j^{(t)})$  from all labeled documents for document  $\mathcal{D}_j^{(t)}$ . Then, we choose the base model that performs best on the documents in  $\mathcal{N}(\mathcal{D}_j^{(t)})$  as the method  $f_j^{(t)*}$  for document  $\mathcal{D}_j^{(t)}$ .

Firstly, we employ the parametric-distance (4) to measure the similarity between any labeled document  $\mathcal{D}_i^{(v)}$ ,  $\forall v, i$ , from all source and target domains, and the target unlabeled document  $\mathcal{D}_j^{(t)}$ . Here, the cross-domain knowledge  $\mu$  in (4) has already been determined by the optimization (8) in Section 3.2.

Secondly, based on the computed distance values, we select  $k$  nearest neighbor documents for the target unlabeled document  $\mathcal{D}_j^{(t)}$  from all labeled documents  $\mathcal{D}_i^{(v)}$ ,  $\forall v, i$ . These  $k$  nearest neighbor documents for document  $\mathcal{D}_j^{(t)}$  make up the set  $\mathcal{N}(\mathcal{D}_j^{(t)})$ .

Thirdly, the optimal base model for the unlabeled document  $\mathcal{D}_j^{(t)}$  prediction is chosen by

$$f_j^{(t)*} = \arg \max_{\mathcal{D}_p \in \mathcal{N}(\mathcal{D}_j^{(t)}), f \in \mathcal{F}} \Lambda(g(\mathcal{D}_p); f(\mathcal{D}_p)). \quad (9)$$

We can instantiate the performance objective function  $\Lambda(g(\cdot); f(\cdot))$  in expressions (6) and (9) to be any coreference resolution measures, such as MUC, Rand index, B-CUBED and CEAF. We have not known of other (ensemble) coreference resolution methods that optimize for these measures. This absence is possibly due to their complex discrete and non-convex properties.

### 3.4 Discussion

The above proposed adaptive ensemble approach incorporates the domain adaptation knowledge during

(a) the identification of similar documents between different domains and (b) the determination of active ensemble members. Beside these, it has the following features over other (ensemble) coreference methods: (i) It can optimize any user-specified objective measure via (6) and (9). An intuitive recommendation is to directly optimize for an objective function that matches the evaluation measure. (ii) It can make document-specific decisions, as expressions (4) and (9) deal with each testing document separately. (iii) The prediction on the testing document  $\mathcal{D}_j^{(t)}$  is not based on all members in  $\mathcal{F}$  but only on the active ensemble members  $\mathcal{N}(\mathcal{D}_j^{(t)})$ . This can filter out some potentially unsuitable base models for document  $\mathcal{D}_j^{(t)}$ . Moreover, the active ensemble members  $\mathcal{N}(\mathcal{D}_j^{(t)})$  is dynamically adjusted for each test document.

For computational cost, the majority is by ensemble creation, since a large number of base models are usually used. This is common among all ensemble methods. In contrast, the costs in (4) and (9) are trivial as both are at the document level. The cost of generating centroids in (2) can also be high if the size of  $\mathcal{C}$  is more than ten thousand, but this is still negligible compared to the cost of ensemble creation.

## 4 Special Case: Within-domain Setting

The adaptive ensemble method presented in Section 3 is for the domain adaptation setting. However, it is possible to simplify it for the special case of within-domain setting. In the within-domain setting, the adaptive ensemble method only has ensemble creation and decision inference steps.

In the ensemble creation step, we still use the closest-first and best-first mention-pair methods with various parameters to create the ensemble. Unlike the domain adaptation setting, here we can only use the labeled documents in the target domain to create the ensemble  $\mathcal{F}^{(t)}$ . Therefore, the size of ensemble here is reduced by  $p$  times compared to the domain adaptation setting.

In the decision inference step, we directly use the Euclidean distance  $\Delta(\mathcal{D}_i^{(t)}, \mathcal{D}_j^{(t)})$  in (5) for the labeled document  $\mathcal{D}_i^{(t)}$ ,  $i = 1, \dots, N^{(t)}$  and unlabeled document  $\mathcal{D}_j^{(t)}$ ,  $j = 1, \dots, M$ . Based on these dis-

tance values, we similarly select  $k$  nearest neighbor documents  $\mathcal{N}(\mathcal{D}_j^{(t)})$  for document  $\mathcal{D}_j^{(t)}$ , and then determine the final method  $f_j^{(t)*}$  for document  $\mathcal{D}_j^{(t)}$  by (9) but with  $\mathcal{F}$  replaced by  $\mathcal{F}^{(t)}$ .

## 5 Experiments

We test the proposed adaptive method and several baselines under both the within-domain and the domain adaptation settings on the MUC-6 and ACE 2005 corpora. MUC-6 contains 60 documents. ACE 2005 contains 599 documents from six different domains: Newswire (NW), Broadcast News (BN), Broadcast Conversations (BC), Weblog (WL), Usenet (UN), and Conversational Telephone Speech (CTS). In all our experiments, we use two popular performance measures, B-CUBED F-measure (Bagga and Baldwin, 1998) and CEAF F-measure (Luo, 2005)<sup>1</sup>, to evaluate the coreference resolution result. Since the focus of the paper is to investigate the effectiveness of coreference resolution methods, we use the *gold standard mentions* in all experiments.

For the proposed method, the ensemble  $\mathcal{F}^{(v)}$  in every domain  $v$  has 208 members totally. They are created by the closest-first and the best-first mention-pair methods using SVM trained with parameter  $C$  taking values

$$C \in [0.001, 0.01, 0.1, 1, 10, 100, 1000, 1000] \quad (10)$$

and using clustering with the threshold parameters  $t$  taking values

$$t \in [0.2, 0.25, 0.3, 0.34, 0.38, 0.4, 0.42, 0.44, 0.46, 0.48, 0.5, 0.6, 0.7]. \quad (11)$$

The size of the selected subset  $\mathcal{C}$  is fixed to 2000, and the number of centroids is determined by the validation procedure from four possible values [10, 20, 30, 40]. We use  $k$ -means algorithm to compute the centroids. Due to the randomness of subset  $\mathcal{C}$  and  $k$ -means algorithm, we run the proposed method 5 times and report the average results. For the number of nearest neighbor  $k$ , we report three results, each for  $k \in \{1, 3, 5\}$ .

<sup>1</sup>More exactly, we use the widely used  $\phi_3$ -CEAF F-measure.

Table 1: The settings in the experiments under within-domain setting on MUC-6 and ACE 2005 corpora.  $N^{(t)}$  and  $M^{(t)}$  and Total are the numbers of training, testing and all documents respectively.

WL	95	24	119

### 5.1 Within-domain Setting

We conduct the experiment under the within-domain setting on seven tasks, with the per-domain setting shown in Table 1. The validation set is created by further splitting training data into validation training and validation testing sets with the ratio of  $\frac{N^{(t)}}{M^{(t)}}$ , where  $N^{(t)}$  and  $M^{(t)}$  are given in Table 1. In this experiment, we attempt to study the following three things. First, we investigate whether the proposed ensemble method is better than the tuned mention-pair methods and other ensemble methods. Second, we investigate the optimal number of active ensemble members. Third, we investigate the impact to the performance of the coreference system, when different objective measures are used with different evaluation measures.

For the proposed ensemble method, we experimented with nearest neighbor set of sizes  $k = 1, 3, 5$  paired with objective function  $\Lambda$  in (9) set to Rand Index, CEAF or B-CUBED. For baselines, the following four are used:

- Two mention-pair baselines. Two baselines are the closest-first and the best-first mention-pair methods with the tuned parameters  $C$  and  $t$ . In the tuning process, the ranges of  $C$  and  $t$  are specified in (10) and (11) respectively. These two mention-pair methods are named as  $S_c$  and  $S_b$  for short.
- Two existing ensemble baselines. The other two baselines are the ensemble methods using the voting procedure in decision inference.

BN	75.9	74.8	57.7	48.0	75.7	75.1	74.9	76.3	75.9	75.3	76.4	76.3	<b>76.7</b>
CTS	71.0	65.1	39.6	31.5	70.6	69.3	68.3	71.3	69.9	70.4	<b>71.7</b>	70.6	69.1
NW	74.6	74.4	45.6	34.1	74.3	74.8	72.9	73.2	71.4	70.1	<b>75.0</b>	74.6	73.7
UN	69.5	70.2	44.1	27.4	70.4	69.9	69.3	69.6	67.6	66.0	70.3	<b>71.4</b>	70.3
WL	73.8	75.4	69.8	58.5	75.5	74.6	73.9	75.5	73.0	73.4	<b>76.2</b>	75.5	75.6
Average	70.7	70.2	50.4	40.2	71.4	70.9	70.5	71.0	69.6	69.1	<b>72.1</b>	71.6	71.3

These two baselines use the same ensemble as the proposed method for fair comparison. In decision inference, these two baselines use the mention-based voting and cluster-based voting respectively, as proposed in (Rahman and Ng, 2011a). In these two baselines, all members in the ensemble participate the voting process. These two ensemble baselines are named as  $E_m$  and  $E_c$  for short.

Tables 2 and 3 show the experiment results using B-CUBED and CEAF as the evaluation measures respectively. The best result for each of the seven tasks is highlighted in bold. The last rows of the tables show the average performance value among all seven tasks.

From the results, we observe that the proposed ensemble method with objective function matching the evaluation measure and with  $k = 1$  generally performs best among all methods and all tasks. Surprisingly, the common ensemble method with mention-based voting  $E_m$  and cluster-based voting  $E_c$  strategies do not perform well. The plausible reason is the current ensemble may incorporate some bad base models due to inappropriate  $C$  and  $t$  values, which would undermine the voting result. Nevertheless, it is difficult to judge the quality of the ensemble members in advance. Therefore, this validates the importance of choosing an active set of ensemble members in decision inference. The better performance of the proposed method over the mention-pair baselines  $S_c$  and  $S_b$  is probably because of the document-specific decision. This is reasonable, as different base mod-

els in the ensemble would be good at predicting the different documents. For the proposed ensemble method with various configurations, we observe using an objective function that matches the evaluation measures is generally better. An exception is the MUC-6 and BN tasks in CEAF F-measure. We also observe that the ensemble method with  $k = 1$  is generally better than that with the larger  $k$ , except the BN and UN tasks in B-CUBED F-measure. This suggests that the fewer the active ensemble members the better the generalization performance. Following (Rahman and Ng, 2011a), we also conduct the Student’s t-test, and the results show that the proposed method with the objective function matching the evaluation measure and with  $k = 1$  is significantly better than the best baseline. In contrast, the two baseline ensemble methods that use voting are significantly worse than the best baseline. The significance level 0.05.

## 5.2 Domain-adaptation Setting

We employ ACE 2005 corpora to simulate the domain adaptation settings in experiments. Specifically, we create six domain adaptation tasks, BC, BN, CTS, NW, UN, WL in total. Each task has one target domain and five source domains. For example, in the task UN, the target domain is UN while the other five source domains are BC, BN, CTS, NW and WL. The number of labeled documents in each domain is as the same as in Table 1, except when that domain is the target domain, in which case we use only five labeled documents. The number of test

Table 3: CEAF F-measure results by all methods under within-domain setting on MUC-6 and ACE 2005 corpora.

	Baselines				$\Lambda = \text{Rand}$			$\Lambda = \text{B-CUBED}$			$\Lambda = \text{CEAF}$		
	$S_c$	$S_b$	$E_m$	$E_c$	$k=1$	3	5	$k=1$	3	5	$k=1$	3	5
MUC-6	62.6	62.5	62.7	57.5	62.0	60.6	61.0	<b>64.5</b>	62.7	63.8	63.1	58.7	59.2

BN	67.9	66.5	55.1	44.7	69.4	69.4	69.9	69.8	<b>70.2</b>	69.6	69.5	69.0	68.7
CTS	61.0	60.7	38.6	31.5	67.1	66.9	63.6	68.1	68.4	68.2	<b>68.5</b>	67.6	67.7
NW	66.9	66.4	41.1	31.2	68.4	68.0	64.6	69.2	68.4	66.4	<b>69.3</b>	66.1	66.7
UN	62.5	63.5	46.2	28.9	62.9	61.8	60.9	62.2	63.7	62.9	<b>63.9</b>	61.5	60.4
WL	69.7	70.3	63.5	54.3	70.7	70.2	72.5	71.5	71.4	72.3	<b>72.4</b>	69.4	70.0
Average	64.2	63.8	49.1	39.2	65.3	64.9	64.2	66.2	66.2	65.8	<b>66.6</b>	64.5	64.5

(or unlabeled) documents in the target document is also the same as in Table 1. The validation set is created similarly as in the experiment under within-domain setting.

For the proposed ensemble method, we heuristically determine the parameter  $B$  in  $\mu$  to be the number of non-zero elements in  $\Gamma$ , where

$$\Gamma = \sum_{j=1}^{N^{(t)}} \sum_{\mathcal{D}_i^{(s_u)} \in \mathcal{I}(\mathcal{D}_j^{(t)}; s_u)} \Delta(\mathcal{D}_i^{(s_u)}, \mathcal{D}_j^{(t)}).$$

Making use of the conclusion in the experiments for the within-domain setting, we fix the optimized measure to be the final performance measure in (9). We compare with the following five baselines.

- Two mention-pair baselines in within-domain setting. Two baselines are same as  $S_c$  and  $S_b$  in the experiments under within-domain settings, except that the labeled training documents are reduced to 5.
- Three proposed adaptive ensemble methods without cross-domain knowledge learning. These three baselines uses neighborhood sizes  $k = 1, 3, 5$  with the grand ensemble  $\mathcal{F}$  rather than the target domain ensemble  $\mathcal{F}^{(t)}$ . In other words, these three baselines are the same as the proposed method, but with  $\mu = 1$ .

Tables 4 and 5 show the experimental results in the domain adaptation settings using B-CUBED and

CEAF as the final performance measures respectively. From the results, we can see that the proposed method with cross-domain knowledge generally outperforms all the five baselines. Among them, the best proposed domain adaptation method on average outperforms the best of  $S_c, S_b$  by 7.2% for B-CUBED F-measure and 3% for CEAF F-measure. The grand-ensemble baselines are also significantly better than the within-domain baselines. These results clearly illustrate the usefulness of making use of the labeled documents in the source domains. For the comparison between the proposed method with and without cross-domain knowledge learning, all tasks, except UN task in CEAF F-measure, show the superiority of the proposed method with cross-domain knowledge learning. Among them, except tasks BN and CTS in B-CUBED F-measure, the performance gains are among 1%—3% for all tasks in both measures. These results verify the necessity of cross-domain knowledge learning. For the comparison of the proposed method with different  $k$ , unlike the results in the within-domain setting, the results here show that choosing optimal  $k$  is task-dependent. The reason of this observation is not clear yet. It is plausible due to the increased uncertainties from multiple domains.

## 6 Conclusions and Future Work

In this paper, we proposed an adaptive ensemble method for coreference resolution under both within-domain and domain adaptation settings. The key advantage of the proposed method is incor-

Table 4: B-CUBED F-measure results by all methods under domain adaptation setting on ACE 2005 corpora, with  $\Lambda$  set to B-CUBED. The *within-domain* and *grand ensemble* methods are the baselines.

porating the cross-domain knowledge to aid coreference resolution learning. This is useful when the labeled coreference labels are scarce. We also demonstrate that the proposed adaptive ensemble method can be readily applied to conventional coreference tasks without cross-domain knowledge learning. Compared with existing ensemble methods, the proposed method is simultaneously endowed with the following three distinctive features: optimizing any user-specified performance measure, making the document-specific prediction and automatically adjusting the active ensemble members. In the experiments under both within-domain settings and domain adaptation settings, the results evidence the effectiveness of the proposed cross-domain knowledge learning method, and also demonstrate the superiority of the proposed adaptive ensemble method over other baselines.

Currently, the proposed method relies on some

limited target annotations. It would be interesting to consider the pure unsupervised tasks that have no any target annotations. Besides, to develop some better ways for document-level representation, e.g., incorporating the domain knowledge, also deserves our attentions. Similarly, to extend the diagonal Mahalanobis matrix to the general covariance matrix is also desirable. Last but not least, to find a more systematical way to determine the optimal  $k$  in the proposed method is also our possible future work.

## Abstract

We present a method for training a semantic parser using only a knowledge base and an unlabeled text corpus, without any individually annotated sentences. Our key observation is that multiple forms of weak supervision can be combined to train an accurate semantic parser: *semantic supervision* from a knowledge base, and *syntactic supervision* from dependency-parsed sentences. We apply our approach to train a semantic parser that uses 77 relations from Freebase in its knowledge representation. This semantic parser extracts instances of binary relations with state-of-the-art accuracy, while simultaneously recovering much richer semantic structures, such as conjunctions of multiple relations with partially shared arguments. We demonstrate recovery of this richer structure by extracting logical forms from natural language queries against Freebase. On this task, the trained semantic parser achieves 80% precision and 56% recall, despite never having seen an annotated logical form.

## 1 Introduction

Semantic parsing converts natural language statements into logical forms in a meaning representation language. For example, the phrase “town in California” might be represented as  $\lambda x. \text{CITY}(x) \wedge \text{LOCATEDIN}(x, \text{CALIFORNIA})$ , where  $\text{CITY}$ ,  $\text{LOCATEDIN}$  and  $\text{CALIFORNIA}$  are predicates and entities from a knowledge base. The expressivity and utility of semantic parsing is derived from this meaning representation, which is essentially a program that is directly executable by a computer.

In this sense, broad coverage semantic parsing is the goal of natural language understanding.

Unfortunately, due to data annotation constraints, modern semantic parsers only operate in narrow domains. The best performing semantic parsers are trained using extensive manual annotation: typically, a number of sentences must be annotated with their desired logical form. Although other forms of supervision exist (Clarke et al., 2010; Liang et al., 2011), these methods similarly require annotations for individual sentences. More automated training methods are required to produce semantic parsers with richer meaning representations.

This paper presents an algorithm for training a semantic parser without per-sentence annotations. Instead, our approach exploits two easily-obtainable sources of supervision: a large knowledge base and (automatically) dependency-parsed sentences. The semantic parser is trained to identify relation instances from the knowledge base while simultaneously producing parses that syntactically agree with the dependency parses. Combining these two sources of supervision allows us to train an accurate semantic parser *for any knowledge base* without annotated training data.

We demonstrate our approach by training a Combinatory Categorical Grammar (CCG) (Steedman, 1996) that parses sentences into logical forms containing any of 77 relations from Freebase. Our training data consists of relation instances from Freebase and automatically dependency-parsed sentences from a web corpus. The trained semantic parser extracts binary relations with state-of-the-art performance, while recovering considerably richer semantic structure. We demonstrate recovery of this semantic structure using natural language queries

$$\frac{\frac{\text{town}}{N : \lambda x. \text{CITY}(x)} \text{Lex} \quad \frac{\text{California}}{N : \lambda x. x = \text{CALIFORNIA}} \text{Lex}}{\frac{\text{in}}{(N \setminus N) / N : \lambda f. \lambda g. \lambda x. \exists y. f(y) \wedge g(x) \wedge \text{LOCATEDIN}(x, y)} \text{Lex}}{N \setminus N : \lambda g. \lambda x. \exists y. y = \text{CALIFORNIA} \wedge g(x) \wedge \text{LOCATEDIN}(x, y)} \text{Lex}}{N : \lambda x. \exists y. y = \text{CALIFORNIA} \wedge \text{CITY}(x) \wedge \text{LOCATEDIN}(x, y)} \text{Lex} \begin{matrix} > \\ < \end{matrix}$$

Figure 1: An example parse of “town in California” using the example CCG lexicon. The first stage in parsing retrieves a category from each word from the lexicon, represented by the “Lex” entries. The second stage applies CCG combination rules, in this case both forms of function application, to combine these categories into a semantic parse.

against Freebase. Our weakly-supervised semantic parser predicts the correct logical form for 56% of queries, despite never seeing a labeled logical form.

This paper is structured as follows. We first provide some background information on CCG and the structure of a knowledge base in Section 2. Section 3 formulates the weakly supervised training problem for semantic parsers and presents our algorithm. Section 4 describes how we applied our algorithm to construct a semantic parser for Freebase, and Section 5 presents our results. We conclude with related work and discussion.

## 2 Background

### 2.1 Combinatory Categorical Grammar

Combinatory Categorical grammar (CCG) is a linguistic formalism that represents both the syntax and semantics of language (Steedman, 1996). CCG is a lexicalized formalism that encodes all grammatical information in a lexicon  $\Lambda$ . This lexicon contains syntactic and semantic categories for each word. A lexicon may include entries such as:

$$\begin{aligned} \text{town} &:= N : \lambda x. \text{CITY}(x) \\ \text{California} &:= N : \lambda x. x = \text{CALIFORNIA} \\ \text{in} &:= (N \setminus N) / N : \lambda f. \lambda g. \lambda x. \\ &\quad \exists y. f(y) \wedge g(x) \wedge \text{LOCATEDIN}(x, y) \end{aligned}$$

Each entry of the lexicon  $w := s : l$  maps a word or short phrase  $w$  to a syntactic category  $s$  and a logical form  $l$ . Syntactic categories  $s$  may be atomic ( $N$ ) or complex ( $N \setminus N$ ). Logical forms  $l$  are lambda calculus expressions constructed using predicates from a knowledge base. These logical forms combine during parsing to form a complete logical form for the parsed text.

Parses are constructed by combining adjacent categories using several combination rules, such as forward ( $>$ ) and backward ( $<$ ) application:

$$\begin{aligned} X/Y : f \quad Y : g &\implies X : f(g) \quad (>) \\ Y : g \quad X \setminus Y : f &\implies X : f(g) \quad (<) \end{aligned}$$

These rules mean that the complex category  $X/Y$  ( $X \setminus Y$ ) behaves like a function which accepts an argument of type  $Y$  on its right (left) and returns a value of type  $X$ . Parsing amounts to sequentially applying these two rules, as shown in Figure 1. The result of parsing is an ordered pair, containing both a syntactic parse tree and an associated logical form. We refer to such an ordered pair as a semantic parse, or by using the letter  $\ell$ .

Given a lexicon, there may be multiple semantic parses  $\ell$  for a given phrase  $\mathbf{w}$ . Like context-free grammars (CFGs), CCGs can be extended to represent a probability distribution over parses  $P(\ell | \mathbf{w}; \theta)$  where  $\theta$  is a parameter vector.

### 2.2 Knowledge Base

The main input to our system is a propositional knowledge base  $K = (E, R, C, \Delta)$ , containing entities  $E$ , categories  $C$ , relations  $R$  and relation instances  $\Delta$ . Categories and relations are predicates which operate on entities and return truth values; categories  $c \in C$  are one-place predicates ( $\text{CITY}(e)$ ) and relations  $r \in R$  are two-place predicates ( $\text{LOCATEDIN}(e_1, e_2)$ ). Entities  $e \in E$  represent real-world entities and have a set of known text names. For example,  $\text{CALIFORNIA}$  is an entity whose text names include “California” and “CA.” Relation instances  $r(e_1, e_2) \in \Delta$  are facts asserted by the knowledge base, such as  $\text{LOCATEDIN}(\text{SACRAMENTO}, \text{CALIFORNIA})$ . Examples of such knowledge bases include Freebase (Bollacker et al., 2008), NELL (Carlson et al., 2010), and YAGO (Suchanek et al., 2007).

The knowledge base influences the semantic parser in two ways. First, CCG logical forms are constructed by combining categories, relations and entities from the knowledge base with logical connectives; hence, the predicates in the knowledge base determine the expressivity of the parser’s semantic representation. Second, the known relation

instances  $r(e_1, e_2) \in \Delta$  are used as weak supervision to train the semantic parser.

### 3 Weakly Supervised Semantic Parsing

We define *weakly supervised semantic parsing* as the following learning problem.

#### Input:

1. A knowledge base  $K = (E, R, C, \Delta)$ , as defined above.
2. A corpus of dependency-parsed sentences  $S$ .
3. A CCG lexicon  $\Lambda$  that produces logical forms containing predicates from  $K$ . Section 4.1 describes an approach to generate this lexicon.
4. A procedure for identifying mentions of entities from  $K$  in sentences from  $S$ . (e.g., simple string matching).

#### Output:

1. Parameters  $\theta$  for the CCG that produce correct semantic parses  $\ell$  for sentences  $s \in S$ .

This problem is ill-posed without additional assumptions: since the correct logical form for a sentence is never observed, there is no *a priori* reason to prefer one semantic parse to another. Our training algorithm makes two assumptions about correct semantic parses, which are encoded as weak supervision constraints. These constraints make learning possible by adding an inductive bias:

1. Every relation instance  $r(e_1, e_2) \in \Delta$  is expressed by at least one sentence in  $S$  (Riedel et al., 2010; Hoffmann et al., 2011).
2. The correct semantic parse of a sentence  $s$  contains a subset of the syntactic dependencies contained in a dependency parse of  $s$ .

Our weakly supervised training uses these constraints as a proxy for labeled semantic parses. The training algorithm has two steps. First, the algorithm constructs a graphical model that contains both the semantic parser and constant factors encoding the above two constraints. This graphical model is then used to estimate parameters  $\theta$  for the semantic parser, essentially optimizing  $\theta$  to produce parses that satisfy the weak supervision constraints. If our assumptions are correct and sufficiently constrain the parameter space, then this procedure will identify parameters for an accurate semantic parser.

### 3.1 Encoding the Weak Supervision Constraints

The first step of training constructs a graphical model containing the semantic parser and two weak supervision constraints. However, the first weak supervision constraint couples the semantic parses for every sentence  $s \in S$ . Such coupling would result in an undesirably large graphical model. We therefore modify this constraint to enforce that every relation  $r(e_1, e_2)$  is expressed at least once in  $S_{(e_1, e_2)} \subseteq S$ , the subset of sentences which mention both  $e_1$  and  $e_2$ . These mentions are detected using the provided mention-identification procedure.

Figure 2 depicts the graphical model constructed for training. The semantic constraint couples the extractions for all sentences  $S_{(e_1, e_2)}$ , so the graphical model is instantiated once per  $(e_1, e_2)$  tuple. The model has 4 types of random variables and values:  $S_i = s_i$  represents a sentence,  $L_i = \ell_i$  represents a semantic parse,  $Z_i = z_i$  represents the satisfaction of the syntactic constraint and  $Y_r = y_r$  represents the truth value of relation  $r$ .  $S_i, L_i$  and  $Z_i$  are replicated once for each sentence  $s \in S_{(e_1, e_2)}$ , while  $Y_r$  is replicated once for each relation type  $r$  in the knowledge base (all  $r \in R$ ).

For each entity pair  $(e_1, e_2)$ , this graphical model defines a conditional distribution over  $\mathbf{L}, \mathbf{Y}, \mathbf{Z}$  given  $\mathbf{S}$ . This distribution factorizes as:

$$p(\mathbf{Y} = \mathbf{y}, \mathbf{Z} = \mathbf{z}, \mathbf{L} = \ell | \mathbf{S} = \mathbf{s}; \theta) = \frac{1}{Z_{\mathbf{s}}} \prod_r \Psi(y_r, \ell) \prod_i \Phi(z_i, \ell_i, s_i) \Gamma(s_i, \ell_i; \theta)$$

The factorization contains three replicated factors.  $\Gamma$  represents the semantic parser, which is parametrized by  $\theta$  and produces a semantic parse  $\ell_i$  for each sentence  $s_i$ .  $\Psi$  and  $\Phi$  are deterministic factors representing the two weak supervision constraints. We now describe each factor in more detail.

#### Semantic Parser

The factor  $\Gamma$  represents the semantic parser, which is a log-linear probabilistic CCG using the input lexicon  $\Lambda$ . Given a sentence  $s$  and parameters  $\theta$ , the parser defines an unnormalized probability distribution over semantic parses  $\ell$ , each of which includes both a syntactic CCG parse tree and logical form.

Figure 2: Factor graph containing the semantic parser  $\Gamma$  and weak supervision constraints  $\Psi$  and  $\Phi$ , instantiated for an  $(e_1, e_2)$  tuple occurring in 2 sentences  $S_1$  and  $S_2$ , with corresponding semantic parses  $L_1$  and  $L_2$ . The knowledge base contains 3 relations, represented by the  $Y$  variables.

Let  $f(\ell, s)$  represent a feature function mapping semantic parses to vectors of feature values<sup>1</sup>. The factor  $\Gamma$  is then defined as:

$$\Gamma(s, \ell; \theta) = \exp\{\theta^T f(\ell, s)\}$$

If the features  $f(\ell, s)$  factorize according to the structure of the CCG parse tree, it is possible to perform exact inference using a CKY-style dynamic programming algorithm. However, other aspects of the graphical model preclude exact inference, so we perform approximate inference using beam search. Inference is explained in more detail in Section 3.2.

### Semantic Constraint

The semantic constraint states that, given an entity tuple  $(e_1, e_2)$ , every relation instance  $r(e_1, e_2) \in \Delta$  must be expressed somewhere in  $S_{(e_1, e_2)}$ . Furthermore, no semantic parse can express a relation instance which is not in the knowledge base. This constraint is identical to the multiple deterministic-OR constraint used by Hoffmann et al. (2011) to train a sentential relation extractor.

The graphical model contains a semantic constraint factor  $\Psi$  and one binary variable  $Y_r$  for each relation  $r$  in the knowledge base.  $Y_r$  represents whether  $r(e_1, e_2)$  is expressed by any sentence in  $S_{(e_1, e_2)}$ . The  $\Psi$  factor determines whether each semantic parse in  $\ell$  extracts a relation between  $e_1$  and  $e_2$ . It then aggregates these sentence-level extractions using a deterministic OR: if any sentence extracts  $r(e_1, e_2)$  then  $Y_r = 1$ . Otherwise,  $Y_r = 0$ .

<sup>1</sup>Section 4.3 describes the features used by our semantic parser for Freebase.

$$\Psi(Y_r, \ell) = \begin{cases} 1 & \text{if } Y_r = 1 \wedge \exists i. \text{EXTRACTS}(\ell_i, r, e_1, e_2) \\ 1 & \text{if } Y_r = 0 \wedge \nexists i. \text{EXTRACTS}(\ell_i, r, e_1, e_2) \\ 0 & \text{otherwise} \end{cases}$$

The EXTRACTS function determines the relation instances that are asserted by a semantic parse  $\ell$ .  $\text{EXTRACTS}(\ell, r, e_1, e_2)$  is true if  $\ell$  asserts the relation  $r(e_1, e_2)$  and false otherwise. This function essentially converts the semantic parser into a sentential relation extractor, and its implementation may depend on the types of logical connectives included in the lexicon  $\Lambda$ . Logical forms in our Freebase semantic parser consist of conjunctions of predicates from the knowledge base; we therefore define  $\text{EXTRACTS}(\ell, r, e_1, e_2)$  as true if  $\ell$ 's logical form contains the clauses  $r(x, y)$ ,  $x = e_1$  and  $y = e_2$ .

### Syntactic Constraint

A problem with the semantic constraint is that it admits a large number of ungrammatical parses. The syntactic constraint penalizes ungrammatical parses by encouraging the semantic parser to produce parse trees that agree with a dependency parse of the same sentence. Specifically, the syntactic constraint requires the predicate-argument structure of the CCG parse to agree with the predicate-argument structure of the dependency parse.

Agreement is defined as a function of each CCG rule application in  $\ell$ . In the parse tree  $\ell$ , each rule application combines two subtrees,  $\ell_h$  and  $\ell_c$ , into a single tree spanning a larger portion of the sentence. A rule application is consistent with a dependency parse  $t$  if the head words of  $\ell_h$  and  $\ell_c$  have a dependency edge between them in  $t$ .  $\text{AGREE}(\ell, t)$  is true if and only if every rule application in  $\ell$  is consistent with  $t$ . This syntactic constraint is encoded in the graphical model by the  $\Phi$  factors and  $Z$  variables:

$$\Phi(z, \ell, s) = \begin{cases} 1 & \text{if } z = \text{AGREE}(\ell, \text{DEPPARSE}(s)) \\ 0 & \text{otherwise} \end{cases}$$

### 3.2 Parameter Estimation

To train the model, a single training example is constructed for every tuple of entities  $(e_1, e_2)$ . The input to the model is  $\mathbf{s} = S_{(e_1, e_2)}$ , the set of sentences

containing  $e_1$  and  $e_2$ . The weak supervision variables,  $\mathbf{y}, \mathbf{z}$ , are the output of the model.  $\mathbf{y}$  is constructed by setting  $y_r = 1$  if  $r(e_1, e_2) \in \Delta$ , and 0 otherwise. This setting trains the semantic parser to extract every true relation instance between  $(e_1, e_2)$  from some sentence in  $S_{(e_1, e_2)}$ , while simultaneously avoiding incorrect instances. Finally,  $\mathbf{z} = \mathbf{1}$ , to encourage agreement between the semantic and dependency parses. The training data for the model is therefore a collection,  $\{(\mathbf{s}^j, \mathbf{y}^j, \mathbf{z}^j)\}_{j=1}^n$ , where  $j$  indexes entity tuples  $(e_1, e_2)$ .

Training optimizes the semantic parser parameters  $\theta$  to predict  $\mathbf{Y} = \mathbf{y}^j, \mathbf{Z} = \mathbf{z}^j$  given  $\mathbf{S} = \mathbf{s}^j$ . The parameters  $\theta$  are estimated by running the structured perceptron algorithm (Collins, 2002) on the training data defined above. The structured perceptron algorithm iteratively applies a simple update rule for each example  $(\mathbf{s}^j, \mathbf{y}^j, \mathbf{z}^j)$  in the training data:

$$\begin{aligned} \ell^{predicted} &\leftarrow \arg \max_{\ell} \max_{\mathbf{y}, \mathbf{z}} p(\ell, \mathbf{y}, \mathbf{z} | \mathbf{s}^j; \theta^t) \\ \ell^{actual} &\leftarrow \arg \max_{\ell} p(\ell | \mathbf{y}^j, \mathbf{z}^j, \mathbf{s}^j; \theta^t) \\ \theta^{t+1} &\leftarrow \theta^t + \sum_i f(\ell_i^{actual}, s_i) \\ &\quad - \sum_i f(\ell_i^{predicted}, s_i) \end{aligned}$$

Each iteration of training requires solving two maximization problems. The first maximization,  $\max_{\ell, \mathbf{y}, \mathbf{z}} p(\ell, \mathbf{y}, \mathbf{z} | \mathbf{s}; \theta^t)$ , is straightforward because  $\mathbf{y}$  and  $\mathbf{z}$  are deterministic functions of  $\ell$ . Therefore, it is solved by finding the maximum probability assignment  $\ell$ , then choosing values for  $\mathbf{y}$  and  $\mathbf{z}$  that satisfy the weak supervision constraints.

The second maximization,  $\max_{\ell} p(\ell | \mathbf{y}, \mathbf{z}, \mathbf{s}; \theta^t)$ , is more challenging. When  $\mathbf{y}$  and  $\mathbf{z}$  are given, the inference procedure must restrict its search to the parses  $\ell$  which satisfy these weak supervision constraints. The original formulation of the  $\Psi$  factors permitted tractable inference (Hoffmann et al., 2011), but the EXTRACTS function and the  $\Phi$  factors preclude efficient inference. We approximate this maximization using beam search over CCG parses  $\ell$ . For each sentence  $s$ , we perform a beam search to produce  $k = 300$  possible semantic parses. We then check the value of  $\Phi$  for each generated parse and eliminate parses which do not satisfy this syntactic constraint. Finally, we apply EXTRACTS to each parse,

then use the greedy approximate inference procedure from Hoffmann et al. (2011) for the  $\Psi$  factors.

## 4 Building a Grammar for Freebase

We apply the training algorithm from the previous section to produce a semantic parser for a subset of Freebase. This section describes details of the grammar we construct for this task, including the construction of the lexicon  $\Lambda$ , some extensions to the CCG parser, and the features used during training. In this section, we assume access to a knowledge base  $K = (E, C, R, \Delta)$ , a corpus of dependency-parsed sentences  $S$  and a procedure for identifying mentions of entities in sentences.

### 4.1 Constructing the Lexicon $\Lambda$

The first step in constructing the semantic parser is defining a lexicon  $\Lambda$ . We construct  $\Lambda$  by applying simple dependency-parse-based heuristics to sentences in the training corpus. The resulting lexicon  $\Lambda$  captures a variety of linguistic phenomena, including verbs, common nouns (“city”), noun compounds (“California city”) and prepositional modifiers (“city in California”).

The first step in lexicon construction is to use the mention identification procedure to identify all mentions of entities in the sentences  $S$ . This process results in  $(e_1, e_2, s)$  triples, consisting of sentences with two entity mentions. The dependency path between  $e_1$  and  $e_2$  in  $s$  is then matched against the dependency parse patterns in Table 1. Each matched pattern adds one or more lexical entries to  $\Lambda$ .

Each pattern in Table 1 has a corresponding lexical category template, which is a CCG lexical category containing parameters  $e, c$  and  $r$  that are chosen at initialization time. Given the triple  $(e_1, e_2, s)$ , relations  $r$  are chosen such that  $r(e_1, e_2) \in \Delta$ , and categories  $c$  are chosen such that  $c(e_1) \in \Delta$  or  $c(e_2) \in \Delta$ . The template is then instantiated with every combination of these  $e, c$  and  $r$  values.

After instantiating lexical categories for each sentence in  $S$ , we prune infrequent lexical categories to improve parser efficiency. This pruning step is required because the common noun pattern generates a large number of lexical categories, the majority of which are incorrect. Therefore, we eliminate all common noun categories instantiated by fewer than

Part of Speech	Dependency Parse Pattern	Lexical Category Template

Table 1: Dependency parse patterns used to instantiate lexical categories for the semantic parser lexicon  $\Lambda$ . Each pattern is followed by an example phrase that instantiates it. An \* indicates a position that may be filled by multiple consecutive words in the sentence.  $e_1$  and  $e_2$  are the entities identified in the sentence,  $r$  represents a relation where  $r(e_1, e_2)$ , and  $c$  represents a category where  $c(e_1)$ . Each template may be instantiated with multiple values for the variables  $e, c, r$ .

5 sentences in  $S$ . The other rules are less fertile, so we do not need to prune their output.

In addition to these categories, the grammar includes type-changing rules from  $N$  to  $N|N$ . These rules capture noun compounds by allowing nouns to become functions from nouns to nouns. There are several such type-changing rules since the resulting category includes a hidden relation  $r$  between the noun and its modifier (see Table 1). As with lexical categories, the set of type changing rules included in the grammar is determined by matching dependency parse patterns to the training data. Similar rules for noun compounds are used in other CCG parsers (Clark and Curran, 2007).

The instantiated lexicon represents the semantics of words and phrases as conjunctions of predicates from the knowledge base, possibly including existentially quantified variables and  $\lambda$  expressions. The syntactic types  $N$  and  $PP$  are semantically represented as functions from entities to truth values (e.g.,  $\lambda x.\text{CITY}(x)$ ), while sentences  $S$  are statements with no  $\lambda$  terms, such as  $\exists x, y.x = \text{CALIFORNIA} \wedge \text{CITY}(y) \wedge \text{LOCATEDIN}(x, y)$ . Variables in the semantic representation  $(x, y)$  range over entities from the knowledge base. Intuitively, the  $N$  and  $PP$  cate-

gories represent sets of entities, while sentences represent assertions about the world.

## 4.2 Extensions to CCG

The semantic parser is trained using sentences from a web corpus, which contains many out-of-domain words. As a consequence, many of the words encountered during training cannot be represented using the vocabulary of predicates from the knowledge base. To handle these extraneous words, we allow the CCG parser to skip words while parsing a sentence. During parsing, the parser first decides whether to retrieve a lexical category for each word in the sentence. The sentence is then parsed as if only the retrieved lexical categories existed.

## 4.3 Features

The features  $f(\ell, s)$  for our probabilistic CCG contain two sets of features. The first set contains lexical features, which count the number of times each lexical entry is used in  $\ell$ . The second set contains rule application features, which count the number of times each combination rule is applied to each possible set of arguments. An argument is defined by its syntactic and semantic category, and in some cases by the lexical entry which created it. We lex-

icalize arguments for prepositional phrases *PP* and common nouns (initialized by the second rule in Table 1). This lexicalization allows the parser to distinguish between prepositional phrases headed by different prepositions, as well as between different common nouns. All other types are distinguished solely by syntactic and semantic category.

## 5 Evaluation

In this section, we evaluate the performance of a semantic parser for Freebase, trained using our weakly-supervised algorithm. Empirical comparison is somewhat difficult because the most comparable previous work – weakly-supervised relation extraction – uses a shallower semantic representation. Our evaluation therefore has two components: (1) a binary relation extraction task, to demonstrate that the trained semantic parser extracts instances of binary relations with performance comparable to other state-of-the-art systems, and (2) a natural language database query task, to demonstrate the parser’s ability to extract more complex logical forms than binary relation instances, such as logical expressions involving conjunctions of multiple categories and relations with partially shared arguments.

### 5.1 Corpus Construction

Our experiments use a subset of 77 relations<sup>2</sup> from Freebase<sup>3</sup> as the knowledge base and a corpus of web sentences. We constructed the sentence corpus by first sampling sentences from a web crawl and parsing them with MaltParser (Nivre et al., 2006). Long sentences tended to have noisy parses while also rarely expressing relations, so we discarded sentences longer than 10 words. Entities were identified by performing a simple string match between canonical entity names in Freebase and proper noun phrases identified by the parser. In cases where a single noun phrase matched multiple entities, we selected the entity participating in the most relations. The resulting corpus contains 2.5 million  $(e_1, e_2, s)$  triples, from which we reserved 10% for validation and 10% for testing. The validation set was used to estimate performance during algorithm develop-

<sup>2</sup>These relations are defined by a set of MQL queries and potentially traverse multiple relation links.

<sup>3</sup><http://www.freebase.com>

Relation Name	Relation Instances	Sentences
CITYLOCATEDINSTATE	2951	13422
CITYLOCATEDINCOUNTRY	1696	7904
CITYOFPERSONBIRTH	397	440
COMPANIESHEADQUARTEREDHERE	326	432
MUSICARTISTMUSICIAN	251	291
CITYUNIVERSITIES	239	338
CITYCAPITALOFCOUNTRY	123	2529
HASHUSBAND	103	367
PARENTOFPERSON	85	356
HASSPOUSE	81	461

Table 2: Occurrence statistics for the 10 most frequent relations in the training data. “Relation Instances” shows the number of entity tuples  $(e_1, e_2)$  that appear as positive examples for each relation, and “Sentences” shows the total number of sentences in which these tuples appear.

ment, while the test set was used to generate the final experimental results. All triples for each  $(e_1, e_2)$  tuple were placed in the same set.

Approximately 1% of the resulting  $(e_1, e_2, s)$  triples are positive examples, meaning there exists some relation  $r$  where  $r(e_1, e_2) \in \Delta^4$ . To improve training efficiency and prediction performance, we subsample 5% of the negative examples for training, producing a training set of 125k sentences with 27k positive examples. The validation and test sets retain the original positive/negative ratio. Table 2 shows some statistics of the most frequent relations in the test set.

### 5.2 Relation Extraction

The first experiment measures the semantic parser’s ability to extract relations from sentences in our web corpus. We compare our semantic parser to MULTIR (Hoffmann et al., 2011), which is a state-of-the-art weakly supervised relation extractor. This method uses the same weak supervision constraint and parameter estimation procedure, but replaces the semantic parser by a linear classifier. The features for this classifier include the dependency path between the entity mentions, the type of each mention, and the intervening context (Mintz et al., 2009).

Both the semantic parser and MULTIR were trained by running 5 iterations of the structured per-

<sup>4</sup>Note that the positive/negative ratio was much lower without the length filter or entity disambiguation, which is partly why filtering was performed.

Figure 3: Aggregate precision as a function of recall, for MULTIR (Hoffman et al., 2011) and our three semantic parser variants.

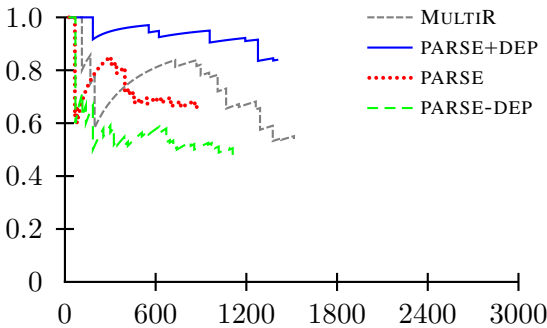

Figure 4: Sentential precision as a function of the expected number of correct extractions for MULTIR (Hoffman et al., 2011) and our three semantic parser variants.

ception algorithm<sup>5</sup>. At test time, both models predicted a relation  $r \in R$  or NONE for each  $(e_1, e_2, s)$  triple in the test set. The parser parses the sentence without considering the entities marked in the sentence, then applies the EXTRACTS function defined in Section 3.1 to identify a relation between  $e_1$  and  $e_2$ . We compare three versions of the semantic parser: PARSE, which is the basic semantic parser, PARSE+DEP which additionally observes the correct dependency parse at test time, and PARSE-DEP which is trained without the syntactic constraint. Note that MULTIR uses the sentence’s dependency parse to construct its feature vector.

Our evaluation considers two performance measures: aggregate and sentential precision/recall. Aggregate precision takes the union of all extracted relation instances  $r(e_1, e_2)$  from the test corpus and compares these instances to Freebase. To pro-

<sup>5</sup>The structured perceptron algorithm does not converge to a parameter estimate, and we empirically found that performance did not improve beyond 5 iterations.

Figure 5: Aggregate precision as a function of recall, ignoring the two most frequent relations, CITYLOCATEDINSTATE and CITYLOCATEDINCOUNTRY.

duce a precision/recall curve, each extracted instance  $r(e_1, e_2)$  is assigned the maximum score over all sentences which extracted it. This metric is easy to compute, but may be inaccurate due to inaccuracies and missing relations in Freebase.

Sentential precision computes the precision of extractions on individual  $(e_1, e_2, s)$  tuples. This metric is evaluated by manually sampling and evaluating 100 test sentences from which a relation was extracted per model. Unfortunately, it is difficult to compute recall for this metric, since the true number of sentences expressing relations is unknown. We instead report precision as a function of the expected number of correct extractions, which is directly proportional to recall.

Figure 3 displays aggregate precision/recall and Figure 4 displays sentential precision/recall for all 4 models. Generally, PARSE behaves like MULTIR with somewhat lower recall. In the sentential evaluation, PARSE+DEP outperforms both PARSE and MULTIR. The difference between PARSE+DEP’s aggregate and sentential precision stems from the fact that PARSE+DEP extracts each relation instance from more sentences than either MULTIR or PARSE. PARSE-DEP has the worst performance in both evaluations, suggesting the importance of syntactic supervision. Precision in the aggregate experiment is low partially due to examples with incorrect entity disambiguation.

We found that the skewed distribution of relation types hides interesting differences between the models. Therefore, we include Figure 5 comparing our syntactically-supervised parsers to MULTIR, ignoring the two most frequent relations (which together

make up over half of all relation instances). Both PARSE and PARSE+DEP are considerably more precise than MULTIR on these less frequent relations because their compositional meaning representation shares parameter strength between relations. For example, the semantic parsers learn that “in” often combines with a city to form a prepositional phrase; the parsers can apply this knowledge to identify city arguments of any relation. However, MULTIR is capable of higher recall, since its dependency parse features can represent syntactic dependencies that cannot be represented by our semantic parsers. This limitation is a consequence of our heuristic lexicon initialization procedure, and could be rectified by a more flexible initialization procedure.

### 5.3 Natural Language Database Queries

The second experiment measures our trained parser’s ability to correctly translate natural language queries into logical queries against Freebase.

To avoid biasing the evaluation, we constructed a test corpus of natural language queries in a data-driven fashion. We searched the test data for sentences with two related entities separated by an “is a” expression. The portion of the sentence before the “is a” expression was discarded and the remainder retained as a candidate query. For example “Jesse is an author from Austin, Texas,” was converted into the candidate query “author from Austin, Texas.” Each candidate query was then annotated with a logical form using categories and relations from the knowledge base; candidate queries without satisfactory logical forms were discarded. We annotated 50 validation and 50 test queries in this fashion. The validation set was used to estimate performance during algorithm development and the test set was used to generate the final results. Example queries with their annotated logical forms are shown in Table 3.

Table 4 displays the results of the query evaluation. For this evaluation, we forced the parser to include every word of the query in the parse. Precision is the percentage of successfully parsed queries for which the correct logical form was predicted. Recall is the percentage of all queries for which the correct logical form was predicted. This evaluation demonstrates that the semantic parser successfully interprets common nouns and identifies multiple relations with shared arguments. The perfor-

Example Query	Logical Form
capital of Russia	$\lambda x. \text{CITYCAPITALOFCOUNTRY}(x, \text{RUSSIA})$
wife of Abraham	$\lambda x. \text{HASHUSBAND}(x, \text{ABRAHAM})$
vocalist from London, England	$\lambda x. \text{MUSICIAN}(x) \wedge \text{PERSONBORNIN}(x, \text{LONDON}) \wedge \text{CITYINCOUNTRY}(\text{LONDON}, \text{ENGLAND})$
home of ConocoPhillips in Canada	$\lambda x. \text{HEADQUARTERS}(\text{CONOCOPhillips}, x) \wedge \text{CITYINCOUNTRY}(x, \text{CANADA})$

Table 3: Example natural language queries and their correct annotated logical form.

	Precision	Recall
PARSE	0.80	0.56
PARSE-DEP	0.45	0.32

Table 4: Precision and recall for predicting logical forms of natural language queries against Freebase. The table compares PARSE, trained with syntactic supervision to PARSE-DEP, trained without syntactic supervision.

mance difference between PARSE and PARSE-DEP also demonstrates the benefit of including syntactic supervision.

Examining the system output, we find two major sources of error. The first is missing lexical categories for uncommon words (e.g., “ex-guitarist”), which negatively impact recall by making some queries unparseable. The second is difficulty distinguishing between relations with similar type signatures, such as CITYLOCATEDINCOUNTRY and CITYCAPITALOFCOUNTRY.

## 6 Related Work

There are many approaches to supervised semantic parsing, including inductive logic programming (Zelle and Mooney, 1996), probabilistic and synchronous grammars (Ge and Mooney, 2005; Wong and Mooney, 2006; Wong and Mooney, 2007; Lu et al., 2008), and automatically learned transformation rules (Kate et al., 2005). This work most closely follows the work on semantic parsing using CCG (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010). These supervised systems are all trained with annotated sentence/logical form pairs; hence these approaches are labor intensive and do not scale to broad domains with large numbers of predicates.

Several recent papers have attempted to reduce the amount of human supervision required to train

a semantic parser. One line of work eliminates the need for an annotated logical form, instead using only the correct answer for a database query (Liang et al., 2011) or even a binary correct/incorrect signal (Clarke et al., 2010). This type of feedback may be easier to obtain than full logical forms, but still requires individually annotated sentences. Other approaches are completely unsupervised, but do not tie the language to an existing meaning representation (Poon and Domingos, 2009). It is also possible to self-train a semantic parser without any labeled data (Goldwasser et al., 2011). However, this approach does not perform as well as more supervised approaches, since the parser’s self-training predictions are not constrained by the correct logical form.

Recent research has produced several weakly supervised relation extractors (Craven and Kumlien, 1999; Mintz et al., 2009; Wu and Weld, 2010; Riedel et al., 2010; Hoffmann et al., 2011). These systems scale up to hundreds of predicates, but have much shallower semantic representations than semantic parsers. For example, these systems cannot be directly used to respond to natural language queries. This work extends weakly supervised relation extraction to produce richer semantic structure, using only slightly more supervision in the form of dependency parses.

## 7 Discussion

This paper presents a method for training a semantic parser using only a knowledge base and a corpus of unlabeled sentences. Our key observation is that multiple forms of weak supervision can be combined to train an accurate semantic parser: *semantic supervision* from a knowledge base of facts, and *syntactic supervision* in the form of a standard dependency parser. We presented an algorithm for training a semantic parser in the form of a probabilistic Combinatory Categorical Grammar, using these two types of weak supervision. We used this algorithm to train a semantic parser for an ontology of 77 Freebase predicates, using Freebase itself as the weak semantic supervision.

Experimental results show that our trained semantic parser extracts binary relations as well as a state-of-the-art weakly supervised relation extractor (Hoffmann et al., 2011). Further experiments

tested our trained parser’s ability to extract more complex meanings from sentences, including logical forms involving conjunctions of multiple relation and category predicates with shared arguments (e.g.,  $\lambda x.MUSICIAN(x) \wedge PERSONBORNIN(x, LONDON) \wedge CITYINCOUNTRY(LONDON, ENGLAND)$ ). To test this capability, we applied the trained parser to natural language queries against Freebase. The semantic parser correctly interpreted 56% of these queries, despite the broad domain and never having seen an annotated logical form. Together, these two experimental analyses suggest that the combination of syntactic and semantic weak supervision is indeed a sufficient basis for training semantic parsers for a diverse range of corpora and predicate ontologies.

One limitation of our method is the reliance on hand-built dependency parse patterns for lexicon initialization. Although these patterns capture a variety of linguistic phenomena, they require manual engineering and may miss important relations. An area for future work is developing an automated way to produce this lexicon, perhaps by extending the recent work on automatic lexicon generation (Kwiatkowski et al., 2010) to the weakly supervised setting. Such an algorithm seems especially important if one wishes to model phenomena such as adjectives, which are difficult to initialize heuristically without generating large numbers of lexical entries.

An elegant aspect of semantic parsing is that it is easily extensible to include more complex linguistic phenomena, such as quantification and events (multi-argument relations). In the future, we plan to increase the expressivity of our parser’s meaning representation to capture more linguistic and semantic phenomena. In this fashion, we can make progress toward broad coverage semantic parsing, and thus natural language understanding.

## Acknowledgments

This research has been supported in part by DARPA under contract number FA8750-09-C-0179, and by a grant from Google. Additionally, we thank Yahoo! for use of their M45 cluster. We also gratefully acknowledge the contributions of our colleagues on the NELL project, Justin Betteridge for collecting the Freebase relations, Jamie Callan and colleagues for the web crawl, and Thomas Kollar and Matt Gardner for helpful comments on earlier drafts of this paper.

## Abstract

This paper proposes cross-lingual language modeling for transcribing source resource-poor languages and translating them into target resource-rich languages if necessary. Our focus is to improve the speech recognition performance of low-resource languages by leveraging the language model statistics from resource-rich languages. The most challenging work of cross-lingual language modeling is to solve the syntactic discrepancies between the source and target languages. We therefore propose syntactic reordering for cross-lingual language modeling, and present a first result that compares inversion transduction grammar (ITG) reordering constraints to IBM and local constraints in an integrated speech transcription and translation system. Evaluations on resource-poor Cantonese speech transcription and Cantonese to resource-rich Mandarin translation tasks show that our proposed approach improves the system performance significantly, up to 3.4% relative WER reduction in Cantonese transcription and 13.3% relative bilingual evaluation understudy (BLEU) score improvement in Mandarin transcription compared with the system without reordering.

## 1 Introduction

Statistical language modeling techniques have achieved remarkable success in speech and language processing (Clarkson and Rosenfeld, 1997; Stolcke, 2002). However, this success largely depends on the availability of a large amount of suitable text data in a language. Without sufficient text data for training,

it is very difficult to build a practical and usable statistical language model. Therefore, most of the advances have been reported in so called *resource-rich* language such as English, Mandarin and Japanese, after creating linguistic resources of these languages at considerable cost. Today there are more than 6000 living languages spoken in the world (Gordon et al., 2005), and most of them have little transcribed texts and are considered as *resource-poor* languages (Nakov and Ng, 2009). Many of these languages are actually spoken by a huge number of speakers (e.g. some Chinese and Indian languages), and thus there is still a great demand to build speech and language processing systems for these languages.

Owing to data scarcity, most often an interpolation (Bellegarda, 2004) of language models between a resource-poor language and a resource-rich language is used in most low-resource ASR systems. Some researchers have proposed transforming resource-rich language models to resource-poor language models by word-level transduction, either in a context-independent or context-dependent manner (Hori et al., 2003; Akita and Kawahara, 2006; Jenson et al., 2009; Neubig et al., 2010). In (Jenson et al., 2009), a simple dictionary based context-independent transduction from a resource-rich language to a resource-poor language is exploited to improve speech recognition of the resource-poor language. In (Hori et al., 2003; Akita and Kawahara, 2006; Neubig et al., 2010), context-dependent transduction is exploited. In their case, the resource-poor language is a spoken language, and the resource-rich language is a written language. They carried out language model transformation since the input speech

is in speaking-style and the output text is in written-style.

Others have investigated cross-lingual information between a resource-poor language and a resource-rich language. In (Khudanpur and Kim, 2002), cross-language cues are used to improve a language model of a resource-poor language. They used cross-lingual unigram probabilities trained from a story-specific parallel corpus of the resource-poor and resource-rich languages. They interpolate the language model of the resource-poor language with those unigram probabilities. In (Kim and Khudanpur, 2003), an n-gram language model in a resource-poor language is interpolated with cross-lingual unigram trigger probabilities. These triggers are word pairs of the resource-poor and resource-rich languages with the highest mutual information across these two languages. Another way of estimating those unigram probabilities is using latent semantic analysis by measuring cosine similarities from a document-aligned corpus for any given word pair (Kim and Khudanpur, 2004).

Both interpolation and word-level transduction approaches fail to meet the challenge of syntactic discrepancies between the resource-poor and resource-rich languages. This syntactic discrepancies exist, for example, even between the Sinitic languages and Indian languages<sup>1</sup> of the same family. Sinitic languages such as Cantonese/Yue, Shanghai/Wu, etc. are officially considered as "dialects" of the standard Chinese Mandarin (or Putonghua)<sup>2</sup>. However, they differ greatly from Mandarin in all aspects and are not mutually comprehensible. For instance, in addition to lexical and pronunciation differences, Cantonese Chinese (Lee, 2011) differs syntactically from Mandarin as well - we found that there are approximately 10% syntactic inversions between sentences of the two forms of Chinese.

We suggest that a better approach than interpolation and word-level transduction is to use *cross-lingual language modeling* with syntactic reorder-

<sup>1</sup>For example, Hindi and Malayalam (Geethakumary, 2002).

<sup>2</sup>Since Cantonese does not have an official written form, there are very few written texts available for training language models. In this paper, we treat Cantonese as a typical resource-poor language and Mandarin as a typical resource-rich language. This language pair will be used for illustration purposes throughout this paper.

ing. A reordering model with reordering constraints, such as ITG constraints (Wu, 1997), IBM constraints (Berger et al., 1996), and local constraints (Kumar and Byrne, 2005) can account for the syntactic differences. It has been shown in (Zens and Ney, 2003; Kanthak et al., 2005; Dreyer et al., 2007) that ITG constraints perform better than other constraints when tackling the reordering between many language pairs. Previous work on weighted finite-state transducer (WFST) based speech translation such as (Casacuberta et al., 2004; Zhou et al., 2005; Zhou et al., 2006; Mathias and Byrne, 2006; Matusov et al., 2006; Saon and Picheny, 2007) only train the reordering model using IBM constraints, local constraints or ad hoc rules. We will use ITG constraints, which have only been applied to text translation tasks before, to model the syntactic differences in cross-lingual language modeling for speech recognition.

We will implement a *cross-lingual language model* using WFSTs, and integrate it into a WFST-based speech recognition search space to give both resource-poor language and resource-rich language transcriptions. This creates an integrated speech transcription and translation framework.

This paper is organized as follows: Section 2 presents our proposed cross-lingual language modeling with syntactic reordering. In Section 3, we discuss speech recognition with cross-lingual language models. Section 4 and 5 give the experimental setup and results. We conclude our work at the end of this paper.

## 2 Cross-lingual Language Modeling with Syntactic Reordering

In automatic speech recognition (ASR), given an observed source speech vector  $X$ , the decoding process searches the best word sequence  $\hat{v}_1^I$  (consists of words  $v_1, v_2, \dots, v_I$ ) by maximizing the posterior probability  $P(v_1^I|X)$ , where  $v_1^I$  is the source transcript representing the transcription of the source speech (see Eq. (1)). According to Bayes' law, we can decompose  $P(v_1^I|X)$  into an acoustic model  $P(X|v_1^I)$  and a language model  $P(v_1^I)$ . If a source language  $L_v$  is a resource-rich language, then the language model  $P(v_1^I)$  can be well estimated from sufficient training texts. However, if the source lan-

language  $L_v$  is a resource-poor language, then the language model  $P(v_1^I)$  cannot be reliably or robustly estimated due to lack of training texts.

$$\begin{aligned}
\hat{v}_1^I &= \arg \max_{v_1^I} P(v_1^I | X) \\
&= \arg \max_{v_1^I} P(X | v_1^I) P(v_1^I) \\
&= \arg \max_{v_1^I} P(X | v_1^I) \sum_{w_1^J} P(v_1^I | w_1^J) P(w_1^J) \\
&\approx \arg \max_{v_1^I} P(X | v_1^I) \max_{w_1^J} P(v_1^I | w_1^J) P(w_1^J)
\end{aligned} \tag{1}$$

Since this paper tackles the language modeling challenge for low-resource speech recognition, here we just assume that the source language  $L_v$  is a resource-poor language. We further assume that there is a target language  $L_w$ , which is a resource-rich language closely related to the language  $L_v$ . In order to improve the language model  $P(v_1^I)$  of the resource-poor language  $L_v$ , we introduce *cross-lingual language modeling* by decomposing the language model  $P(v_1^I)$  into a translation model  $P(v_1^I | w_1^J)$  and a language model  $P(w_1^J)$  of the resource-rich language  $L_w$  (see Eq. (1)).  $w_1^J$  is the target resource-rich language transcript that consists of words  $w_1, w_2, \dots, w_J$ .  $P(v_1^I | w_1^J) P(w_1^J)$  is defined as a *cross-lingual language model*. It leverages the abundant statistics from the language model  $P(w_1^J)$  to improve the language model  $P(v_1^I)$  of the resource-poor language.

The translation model  $P(v_1^I | w_1^J)$  can be estimated by addressing the discrepancies between the resource-poor language  $L_v$  and the resource-rich language  $L_w$ , which can be modeled from a parallel corpus of the  $L_v$  transcript  $v_1^I$  and the  $L_w$  transcript  $w_1^J$ . For the syntactic inversions, we reorder the word or phrase positions of the  $L_w$  language model into those of the  $L_v$  language model. We have observed that most of the words are aligned monotonically between  $L_v$  and  $L_w$  within a phrase. This paper, therefore only considers phrase-level reordering, which effectively preserves the monotonic word sequences within phrases, and significantly reduces the number of reordering paths compared with word-level reordering.

## 2.1 Preprocessing: Phrase Extraction and Segmentation

Our discussion starts with phrase extraction from the parallel corpus. We define a phrase sequence  $\tilde{v}_1^K$  (consists of phrases  $\tilde{v}_1, \tilde{v}_2, \dots, \tilde{v}_K$ ) segmented from the word-level  $L_v$  transcript  $v_1^I$  and  $\tilde{w}_1^K$  (consists of phrases  $\tilde{w}_1, \tilde{w}_2, \dots, \tilde{w}_K$ ) segmented from the word-level  $L_w$  transcript  $w_1^J$ . Furthermore, we define a reordering sequence  $r_1^K$ , of which the detail can be found in Section 2.2.

The phrase-level translation model  $P(v_1^I | w_1^J)$  is decomposed into four components (see Eq. (2)): *segmentation model*  $P(\tilde{w}_1^K | w_1^J)$ , *phrasal reordering model*  $P(r_1^K | \tilde{w}_1^K, w_1^J)$ , *phrase-to-phrase transduction model*  $P(\tilde{v}_1^K | r_1^K, \tilde{w}_1^K, w_1^J)$  and *reconstruction model*  $P(v_1^I | \tilde{v}_1^K, r_1^K, \tilde{w}_1^K, w_1^J)$ . Before presenting each component model, we need to extract two phrase tables for the  $L_v$  transcript and the  $L_w$  transcript, respectively.

$$\begin{aligned}
P(v_1^I | w_1^J) &\approx \max_{\tilde{v}_1^K, r_1^K, \tilde{w}_1^K} P(\tilde{w}_1^K | w_1^J) \cdot \\
&\quad P(r_1^K | \tilde{w}_1^K, w_1^J) \cdot \\
&\quad P(\tilde{v}_1^K | r_1^K, \tilde{w}_1^K, w_1^J) \cdot \\
&\quad P(v_1^I | \tilde{v}_1^K, r_1^K, \tilde{w}_1^K, w_1^J) \tag{2}
\end{aligned}$$

The phrase extraction is based on word-to-word alignments of the parallel corpus. We train word alignments in both directions with GIZA++, and then symmetrize the two alignments using the *refined method* (Och and Ney, 2003). Figure 1 shows an example of word-to-word alignment results between an  $L_v$  transcript (Cantonese) and an  $L_w$  transcript (Mandarin), from which phrase-to-phrase alignments are derived by identifying deletion, substitution, insertion and inversion.

Prior to phrasal reordering, the segmentation model  $P(\tilde{w}_1^K | w_1^J)$  implemented by a segmentation WFST  $S_w$  is applied to segment a word sequence  $w_1^J$  in the  $L_w$  language model into a phrase sequence  $\{\tilde{w}_1, \tilde{w}_2, \dots, \tilde{w}_K\}$ . The maximum number of words that can be segmented into one phrase is controlled by a *segmentation order*  $s$ . An example of  $S_w$  is shown in Figure 3(a1). It segments a word sequence  $\{w_1, w_2, w_3\}$  into a phrase sequence  $\{w_1, w_2-w_3\}$  after performing *composition* (Mohri, 2009) with the target  $L_w$  language model (see Figure 3(b1 & b2))<sup>3</sup>.

<sup>3</sup>The “-” symbol is used to indicate the concatenation of con-

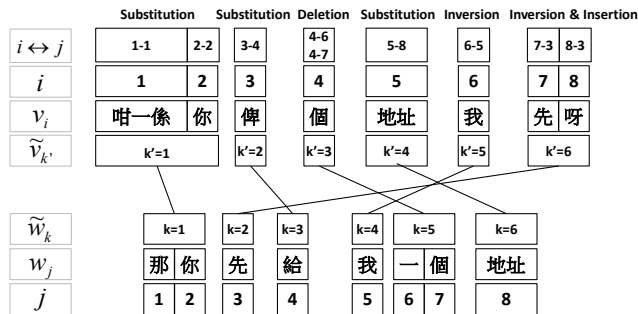

Figure 1: An example (in English: Please give me an address first) of phrase extraction from word-to-word alignments.  $i$  and  $j$  are word indexes.  $k'$  and  $k$  are phrase indexes.  $i \leftrightarrow j$  represents the word-to-word alignment.  $k \leftrightarrow k'$  represents the identified phrase-to-phrase alignment.

## 2.2 Phrasal Reordering Model

Given a phrase sequence  $\{\tilde{w}_1, \tilde{w}_2, \dots, \tilde{w}_K\}$  of the  $L_w$  transcript, the role of the reordering model  $P(r_1^K | \tilde{w}_1^K, w_1^J)$  is to reorder phrase positions of the  $L_w$  transcript into those of the  $L_v$  transcript by permutation of  $\tilde{w}_1^K$  according to a reordering sequence  $\{r_1^K : r_k \in \{1, 2, \dots, K\}, r_k \neq r_{k' \neq k}\}$ . The phrase sequence  $\{\tilde{w}_1, \tilde{w}_2, \dots, \tilde{w}_K\}$  is therefore reordered into  $\{\tilde{w}_{r_1}, \tilde{w}_{r_2}, \dots, \tilde{w}_{r_K}\}$  consequently (see Figure 2 where  $K = 3$ ). Since arbitrary permutations of  $K$  phrases are NP-hard (Knight, 1999), reordering constraints have to be set over  $r_1^K$  to reduce the number of permutations.

There are three reordering constraints widely used in statistical machine translation, namely local constraints, IBM constraints and ITG constraints. Here we would like to point out that this is the first time that reordering constraints have been incorporated into a cross-lingual language model for speech recognition.

### Reordering Constraints

Local constraints make the restriction that one phrase can jump at most  $L - 1$  phrases either forward or backward, where  $L$  is the reordering distance (or window size of permutation)<sup>4</sup>. The generation of  $r_1^K$  under local constraints can be viewed as solving of the following problem (Kløve, 2009):

secutive words forming a phrase.

<sup>4</sup>The concept of reordering distance also applies to other constraints.

How many permutations of  $\{1, 2, \dots, k, \dots, K\}$  satisfy  $|r_k - k| < L$  for all  $k$ ?

IBM constraints, a superset of local constraints (Dreyer et al., 2007), generate permutations  $r_1^K$  deviate from the monotonic phrase order  $\{r_1^K : r_k = k\}$ . More specifically, any phrase position  $r_k$  can be selected from the positions of the first  $m$  yet uncovered phrases (see Eq. (3)). A typical value of  $m$  is 4 (Zens and Ney, 2003), and we write IBM constraints with  $m = 4$  as IBM(4).

$$r_k \in \begin{cases} \{1, 2, \dots, k - 1 + m; r_k \neq r_{k' \neq k}\} \\ \text{if } k \leq K + 1 - m, \\ \{1, 2, \dots, K; r_k \neq r_{k' \neq k}\} \\ \text{if } K + 1 - m < k \leq K. \end{cases} \quad (3)$$

ITG constraints provide a more faithful coverage of syntactic reordering in the parallel data than local constraints and IBM constraints. Our presentation of ITG constraints starts with defining of some permutation sets. Let  $S_K$  be the set of permutations on  $\{1, 2, \dots, K\}$ . A permutation  $r_1^K \in S_K$ , where  $r_1^K = r_1 r_2 \dots r_K$ , contains a subsequence of type  $\tau \in S_M$  if and only if a sequence of indices  $1 \leq i_1 < i_2 < \dots < i_M \leq K$  exists such that  $r_{i_1} r_{i_2} \dots r_{i_M}$  has all the same pairwise comparisons as  $\tau$ . We denote the set of permutations of  $S_K$  not containing subsequences of type  $\tau$  by  $S_K(\tau)$ . If we have sets  $S_K(\tau_1), \dots, S_K(\tau_p)$ , we denote the set  $S_K(\tau_1) \cap \dots \cap S_K(\tau_p)$  by  $S_K(\tau_1, \dots, \tau_p)$  (Barcucci et al., 2000). ITG constraints allow the permutation set  $S_K(3142, 2413)$ , which forbids subsequence of type (3, 1, 4, 2) and its dual (2, 4, 1, 3). Explicitly, ITG constraints avoid any permutation  $r_1^K$  satisfying either  $r_{i_2} < r_{i_4} < r_{i_1} < r_{i_3}$  or  $r_{i_3} < r_{i_1} < r_{i_4} < r_{i_2}$ , where  $1 \leq i_1 < i_2 < i_3 < i_4 \leq K$ . In (Wu, 1997), these forbidden subsequences are called “inside-out” transpositions. They are fairly distorted matchings, and hardly observed in real parallel data.

In order to get an intuitive sense of the reordering capability of those three constraints, we list the number of permutations under local constraints, IBM constraints as well as ITG constraints<sup>5</sup> in Table 1.

<sup>5</sup>Interestingly, when  $K = L$ , the number of permutations under ITG constraints  $N_{ITG} = |S_K(3142, 2413)|$ , and  $|S_K(3142, 2413)|$  equals the  $K - 1$ -th Schröder numbers  $s_{K-1}$  (Ehrenfeucht et al., 1998)

Table 1: Comparison of permutation number under local constraints ( $N_{Local}$ ), IBM constraints ( $N_{IBM(4)}$ ) and ITG constraints ( $N_{ITG}$ ). The comparison is constrained by the phrase number  $K$  and the reordering distance  $L$ .

		K=2	K=3	K=4	K=5	K=6	K=7	K=8	K=9	K=10
L=2	$N_{Local}$	2	3	5	8	13	21	34	55	89
	$N_{IBM(4)}$	2	3	5	8	13	21	34	55	89
	$N_{ITG}$	2	3	5	8	13	21	34	55	89
L=3	$N_{Local}$	2	6	14	31	73	172	400	932	2177
	$N_{IBM(4)}$	2	6	14	31	73	172	400	932	2177
	$N_{ITG}$	2	6	12	25	57	124	268	588	1285
L=4	$N_{Local}$	2	6	24	78	230	675	2069	6404	19708
	$N_{IBM(4)}$	2	6	24	78	230	675	2069	6404	19708
	$N_{ITG}$	2	6	22	52	122	321	885	2304	5880
L=5	$N_{Local}$	2	6	24	120	504	1902	6902	25231	95401
	$N_{IBM(4)}$	2	6	24	96	330	1066	3451	11581	39264
	$N_{ITG}$	2	6	22	90	236	602	1714	5269	16385
L=6	$N_{Local}$	2	6	24	120	720	3720	17304	76110	329462
	$N_{IBM(4)}$	2	6	24	96	384	1374	4718	16275	57749
	$N_{ITG}$	2	6	22	90	394	1108	3014	9038	29618

We can see that given the same  $K$  ( $K \leq 10$ ) and  $L$  ( $L \leq 6$ ), IBM constraints have less permutations than local constraints, and ITG constraints have less permutations than IBM constraints in general (only one exception when  $K = L = 6$ ). These observations indicate that ITG constraints can filter out more unlikely permutations for a fixed reordering distance, resulting in longer distance reordering capability.

Table 1 also tells us that the phrase number  $K$  and the reordering distance  $L$  for any of the constraints cannot be too large for practical implementation. For instance, if  $L = 6$  and  $K$  goes from 6 to 7, the order of magnitude of  $N_{Local}$ ,  $N_{IBM(4)}$  and  $N_{ITG}$  increases from 2 to 3. Hence, phrases for permutation should be selective to cover the most possible re-orderings. If long reordering distances are allowed, unlikely permutations should be pruned so that the memory consumption becomes manageable.

### Reordering Sequence Distribution

So far we have discussed the issue that how to generate permutations for the reordering model using reordering constraints. Another issue is how to parameterize the reordering sequence distribution. Both ITG constraints and other constraints assume

that all permutations are equally probable. However, it makes sense to restrict those non-monotonic reorderings when performing the translation. This not only helps the search of the most likely permutation, but also guides the pruning of unlikely permutations.

$$\begin{aligned}
 P(r_1^K | \tilde{w}_1^K, w_1^J) &= P(r_1) \prod_{k=2}^K P(r_k | r_{k-1}, \tilde{w}_1^K) \\
 &= P(r_1) \prod_{k=2}^K P(r_k | r_{k-1}) \quad (4)
 \end{aligned}$$

We make a first order Markov assumption over the phrasal reordering model  $P(r_1^K | \tilde{w}_1^K, w_1^J)$  (see Eq. (4)). The reordering sequence distribution is parameterized to assign decreasing likelihood to phrase reorderings  $\{\tilde{w}_{r_1}, \tilde{w}_{r_2}, \dots, \tilde{w}_{r_K}\}$  that diverge from the original word order (Och et al., 1999; Kumar et al., 2005). Suppose  $\tilde{w}_{r_k} = w_l^{q'}$  and  $\tilde{w}_{r_{k-1}} = w_q^{q'}$ , the reordering sequence distribution is set as Eq. (5), where  $p_0$  is a tuning factor. We normalize the probabilities  $P(r_k | r_{k-1})$  such that  $\sum_{k'=1, k' \neq r_{k-1}}^K P(r_k = k' | r_{k-1}) = 1$ .

$$\begin{aligned}
 P(r_k | r_{k-1}) &= p_0^{|l-q'-1|} \\
 P(r_1 = k) &= \frac{1}{K}; k \in \{1, 2, \dots, K\} \quad (5)
 \end{aligned}$$

Assume that we have a phrase sequence  $\{\tilde{w}_1, \tilde{w}_2, \tilde{w}_3\}$ , Figure 2 shows the phrasal reordering model implemented by a reordering WFST  $\Omega_r$  under the first order Markov assumption for this phrase sequence.

Figure 3(a2) gives one more example of  $\Omega_r$ , which reorders the phrase sequence  $\{w_1, w_2-w_3\}$  into  $\{w_2-w_3, w_1\}$ <sup>6</sup>. Within the WFST paradigm, reordering models under any of those constraints can be integrated into the cross-lingual language model.

Figure 2: An example of reordering WFST  $\Omega_r$  implementing the phrasal reordering model under the first order Markov assumption.

### 2.3 Phrase-to-Phrase Transduction Model

Once the phrase sequence of the  $L_w$  transcript is reordered into the  $L_v$  transcript order, we use the phrase-to-phrase transduction model specified in Eq. (6) to perform the cross-language transduction. Given sufficient parallel training data, the context-dependent phrase-to-phrase transduction model can be estimated using the GIATI method (Casacuberta and Vidal, 2004). However, for the translation task with scarce training data, the context-dependent transduction probabilities may not be reliably estimated. Therefore, we assume that a phrase  $\tilde{v}_k$  is generated independently by each phrase  $\tilde{w}_{r_k}$ .  $C(\tilde{v}_k, \tilde{w}_{r_k})$  is the number of times that phrase  $\tilde{v}_k$  is aligned to  $\tilde{w}_{r_k}$  in the parallel corpus. This model can be implemented by a WFST  $T_{vw}$  which transduces  $\tilde{v}_k$  to  $\tilde{w}_{r_k}$ . Figure 3(a3) shows an example of  $T_{vw}$  transducing  $v_2-v_3$  to  $w_2-w_3$ .

$$\begin{aligned} P(\tilde{v}_1^K | r_1^K, \tilde{w}_1^K, w_1^J) &= P(\tilde{v}_1^K | r_1^K, \tilde{w}_1^K) \\ &= \prod_{k=1}^K P_k(\tilde{v}_k | \tilde{w}_{r_k}) \\ &= \prod_{k=1}^K \frac{C(\tilde{v}_k, \tilde{w}_{r_k})}{\sum_{\tilde{v}_k} C(\tilde{v}_k, \tilde{w}_{r_k})} \end{aligned} \quad (6)$$

### 2.4 Reconstruction Model

Reconstruction model  $P(v_1^I | \tilde{v}_1^K, r_1^K, \tilde{w}_1^K, w_1^J)$  operates in the opposite direction as the segmentation

<sup>6</sup>For simplicity, reordering sequence distributions are not shown there.

model. It generates a word sequence  $v_1^I$  from a phrase sequence  $\tilde{v}_1^K$ . The reconstruction model can be implemented by a WFST  $R_v$ . An example of  $R_v$  is shown in Figure 3(a4), which reconstructs a phrase  $v_2-v_3$  into a word sequence  $\{v_2, v_3\}$ .

## 3 Speech Recognition with Cross-Lingual Language Models

The translation model  $P(v_1^I | w_1^J)$  can be constructed via WFST *composition* (denoted by  $\circ$ ) (Mohri, 2009) of all the component models as shown in Eq. (7) and Figure 3, where  $\mathcal{T}$  is the final composed WFST that transduces  $v_1^I$  to  $w_1^J$ .

$$\mathcal{T} = R_v \circ T_{vw} \circ \Omega_r \circ S_w \quad (7)$$

The cross-lingual language model  $G_{cl}$  is constructed through composition (see Eq. (8)) of the translation model and a resource-rich language model  $G$ .

$$G_{cl} = \mathcal{T} \circ G = R_v \circ T_{vw} \circ \Omega_r \circ S_w \circ G \quad (8)$$

As the way of integrating a resource-rich language model  $G$  into ASR search space (Mohri et al., 2008), we can integrate the cross-lingual language model  $G_{cl}$  into ASR search space in a globally optimized way as well. The search space can be implemented using a transducer  $ASR$ , which is formulated with a unified WFST approach as shown in Eq. (9). Here  $H$  transduces HMM states to context-dependent phones.  $C$  represents a transduction from context-dependent phones to context-independent phones.  $L$  is a lexicon transducer which maps context-independent phone sequences to word strings restricted to the input symbols of the cross-lingual language model transducer  $G_{cl}$ .

$$ASR = H \circ C \circ L \circ G_{cl} \quad (9)$$

Eq. (9) outputs the recognition result in a resource-rich language. If recognition system requires recognition outputs in a resource-poor language, then the search space should be constructed as Eq. (10), where  $\pi$  is a *projection* (Mohri, 2009) operator which projects the input label to the output label. Before decoding, the recognition transducer  $ASR$  can be optimized by a determinization operation right after each composition.

$$ASR = H \circ C \circ L \circ \pi(G_{cl}) \quad (10)$$

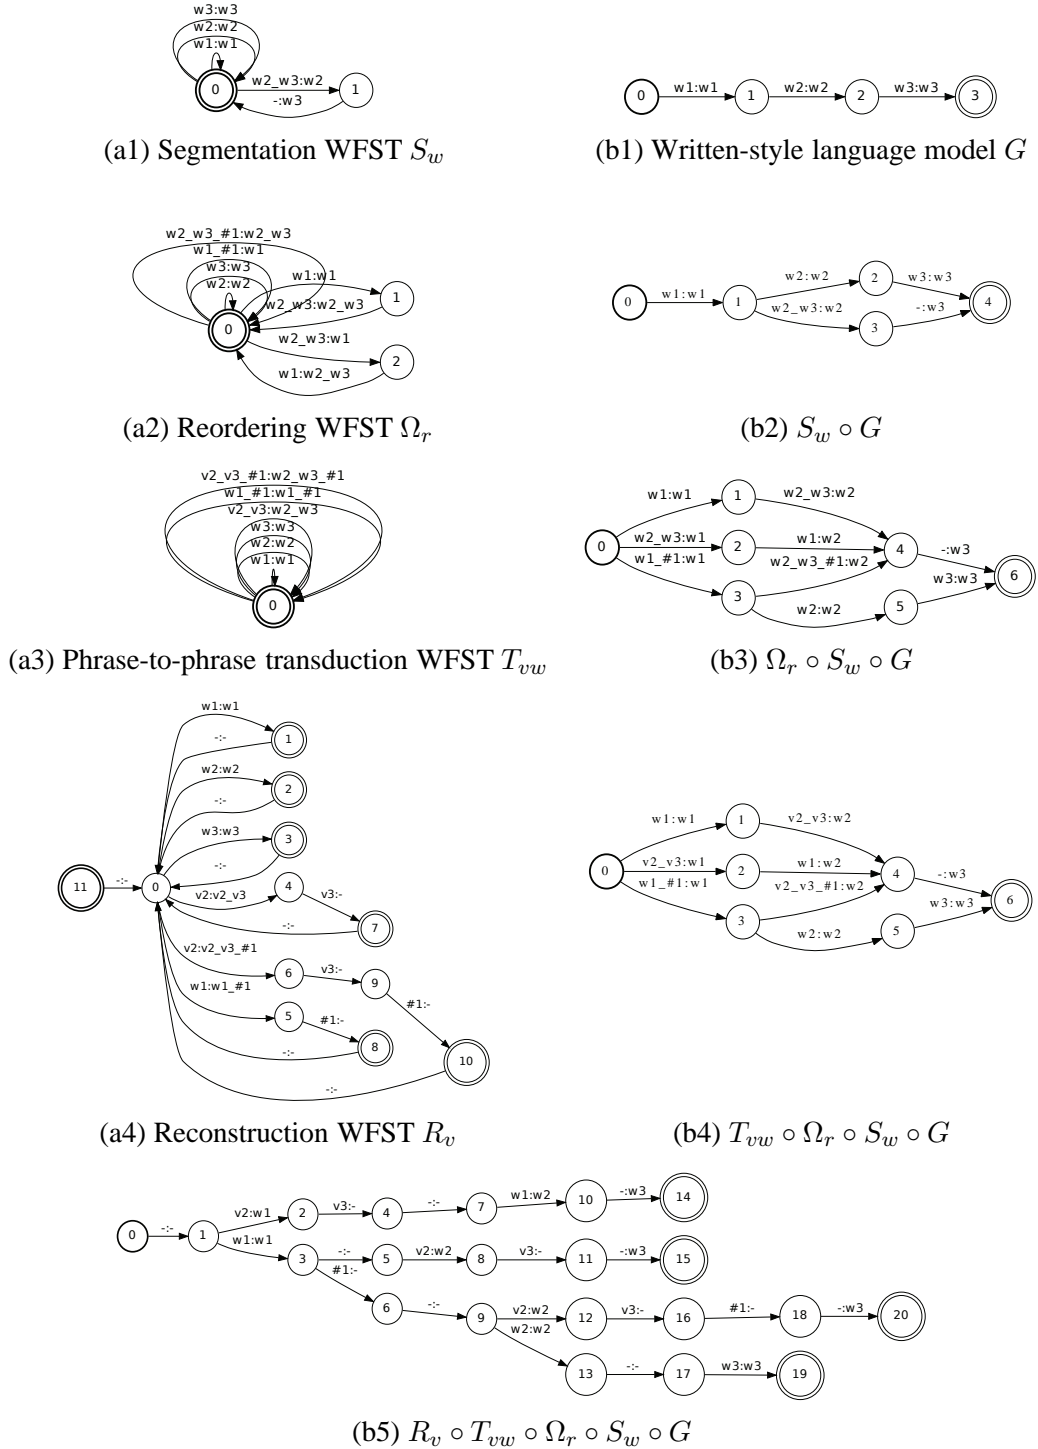

Figure 3: Illustration of constructing a cross-lingual language model via WFSTs: a word sequence  $\{w_1, w_2, w_3\}$  represented by the  $L_w$  language model  $G$  (b1) is segmented into a phrase sequence  $\{w_1, w_2-w_3\}$  (b2);  $\{w_1, w_2-w_3\}$  is reordered into  $\{w_2-w_3, w_1\}$  (b3); phrase  $w_2-w_3$  is transduced to  $v_2-v_3$  (b4); phrase  $v_2-v_3$  is reconstructed into a word sequence  $\{v_2, v_3\}$  (b5).  $w_k$  and  $v_k$  represent  $w_k$  and  $v_k$ , respectively. “-” refers to  $\epsilon$  or null symbol. Auxiliary symbols  $\#1, \#2, \dots$  are used to make the WFST *determinizable* (Mohri, 2009) such that the transducer can be optimized by a *determinization* (Mohri, 2009) operation which significantly reduces the search network size.

## 4 Experimental Setup

### 4.1 Corpus and Model Training

To investigate the performance of our proposed cross-lingual language models, we have chosen Cantonese as a resource-poor language and Mandarin as a resource-rich language. We have collected Cantonese parliamentary speech from the Hong Kong Legislative Council. Currently we only have 4152 parallel transcribed sentences containing 19.4 hours of speech. It is separated into three sets, a training set (11.9 hours, 2700 sentences), a development set (3.7 hours, 788 sentences), and an evaluation set (3.8 hours, 664 sentences). The sentences in the evaluation set are a bit longer than those in the development set. The parallel transcriptions of the training set constitute a parallel corpus, which includes Cantonese transcription (manual transcription) of 106k words and Mandarin transcription (Hansard<sup>7</sup> transcription) of 80k words. The statistics of substitutions, insertions, deletions and inversions identified in the parallel corpus are shown in Table 2. Besides the parallel corpus, we have a set of additional Mandarin transcriptions, which has 31M words.

Table 2: No. of substitutions, insertions, deletions and inversions identified in the parallel corpus with different segmentation order  $s$ .

Segmentation Order	$s = 2$	$s = 3$	$s = 4$	$s = 5$
Substitutions	30921	22723	19011	17106
Insertions	4657	3820	3641	3295
Deletions	1365	1158	1066	1030
Inversions	3000	2876	2814	2779
Total	39943	30577	26532	24210

The training set is used for training an acoustic model (including  $H$  and  $C$ ) using a Maximum Likelihood criterion. It adopts 13 MFCC coefficients, together with 13 delta coefficients and 13 acceleration coefficients as the acoustic features. The acoustic model comprises 73 Hidden Markov Models (HMMs) to represent 70 Cantonese phonemes as well as silence, short pause, and noise. During the acoustic model training, tied-state cross-word triphones are constructed by decision tree clustering.

<sup>7</sup>Hansard is a name of the printed transcripts of parliamentary debates.

The parallel corpus is used for training the translation model  $\mathcal{T}$ . Together with the parallel corpus, the additional Mandarin transcriptions are used for training an interpolated word-level trigram language model  $G$ , where the lexicon size is about 28K. A modified scheme of Kneser-Ney discounting is applied for the language model  $G$  with a back-off threshold of 1 for unigram and 2 for bigram. The cross-lingual language model  $G_{cl}$  can be obtained by composition of  $\mathcal{T}$  and  $G$ .

### 4.2 Decoding and Evaluation Method

Decoding of the speech recognition search space  $ASR$  is performed by  $T^3$  Decoder (Dixon et al., 2009), which is a state-of-the-art WFST-based LVCSR speech decoder. Decoding of  $ASR$  in Eq. (9) gives Mandarin outputs. Decoding of  $ASR$  in Eq. (10) gives Cantonese outputs.

In our experiments, we use the following evaluation criteria:

**WER (word error rate).** The WER is computed as the minimum number of substitution, insertion and deletion operations that have to be performed to convert the generated sentence into the reference sentence (Zens et al., 2004). The WER relates the speech recognition accuracy. The lower WER, the better.

**BLEU (bilingual evaluation understudy) score.** The BLEU score measures the precision of  $n$ -grams (unigrams, bigrams, trigrams and fourgrams) with respect to a reference translation with a penalty for too short sentences (Papineni et al., 2002). The BLEU score reflects the translation accuracy. The larger BLEU score, the better.

We perform WER evaluation of decoding outputs of Eq. (10) and BLEU score evaluation of decoding outputs of Eq. (9) using the evaluation set. The WER evaluation is on the Cantonese output against the Cantonese reference transcription (manual transcription). The BLEU score evaluation is on the Mandarin output against the Mandarin reference transcription (Hansard transcription).

### 4.3 Parameter Settings

The performance of our proposed cross-lingual language models is sensitive to many parameters. Firstly, segmentation order  $s$  affects phrase extraction. The optimal value depends on the language

Table 3: WER and BLEU score for decoding results of  $H \circ C \circ L \circ G$ ,  $H \circ C \circ L \circ \pi(G_{cl})$  without reordering, and  $H \circ C \circ L \circ \pi(G_{cl})$  with reordering under various constraints.

Models	$H \circ C \circ L \circ G$	$H \circ C \circ L \circ \pi(G_{cl})$ $G_{cl} = \mathcal{T}_3 \circ G$ $\mathcal{T}_3 = R_v \circ T_{vw} \circ S_w$	$H \circ C \circ L \circ \pi(G_{cl})$ $G_{cl} = \mathcal{T}_3 \circ G, \mathcal{T}_3 = R_v \circ T_{vw} \circ \Omega_r \circ S_w$		
			Local Constraints	IBM Constraints	ITG Constraints
WER(%)	29.85	27.05	26.35	26.20	26.13
BLEU	N/A	29.23	32.29	32.81	33.12

pair and the size of corpus. Secondly,  $p_0$  in the first order Markov assumption affects the decoding results. Thirdly, the number of reordering permutations or paths are formidable when the reordering distance  $L$  is long as suggested by Table 1. Therefore, we apply histogram pruning to reordering paths, which only maintains top N most likely ones. The development set is used for tuning parameters  $p_0$  and  $N$ .

## 5 Experimental Results

The evaluation results of the proposed cross-lingual language models  $G_{cl}$  with reordering under various constraints are presented in Table 3, where  $G_{cl} = \mathcal{T}_s \circ G = \mathcal{T}_3 \circ G$ .<sup>8</sup> In general, reordering has a significant effect on enhancing the performance of recognition and translation in the sense of WER reduction and BLEU improvement. Compared with the cross-lingual language model without reordering, the cross-lingual language model with reordering under local constraints gives 0.70% absolute WER reduction and 3.06 absolute BLEU improvement. The cross-lingual language model with reordering under IBM constraints gives 0.85% absolute WER reduction and 3.58 absolute BLEU improvement. The cross-lingual language model with reordering under ITG constraints yields the best performance, with 0.92% absolute WER reduction and 3.89 absolute BLEU improvement. All WER improvements pointed out here are statistically significant at 99% confidence according to a two-proportional z-test, and all BLEU improvements are statistically significant at 95% confidence according to a paired student t-test using bootstrap resampling.

<sup>8</sup>We have chosen segment order  $s = 3$  because it works the best in our system.

## 6 Conclusions

We have proposed cross-lingual language modeling with phrase-level syntactic reordering for low-resource speech recognition. The cross-lingual language modeling enriches a resource-poor language model by leveraging the language model from a closely related resource-rich language. It provides an effective method to solve the low-resource language modeling challenge by using a large amount of resource-rich language (e.g. Mandarin) data and a small amount of resource-poor language (e.g. Cantonese) data, as well as some parallel data of resource-poor and resource-rich languages. With a cross-lingual language model, our ASR system can decode speech into transcriptions, either in a resource-poor language or a resource-rich language, using a single WFST-based speech decoder.

We have presented a first end-to-end WFST source to target language transcription and translation system with syntactic reordering and global optimization. Our work is the first to use ITG constraints for the syntactic reordering in such an integrated system. We also did comparative study of ITG constraints, IBM constraints and local constraints in the reordering model, for completeness. We have also presented the determinizable design of each transducer for composing a cross-lingual language model such that we can optimize the search network by determinization. This is crucially important to successfully build a practical integrated system, and, of course, the work is extremely challenging.

Experiments on Cantonese recognition and Cantonese to Mandarin translation tasks have shown that our proposed cross-lingual language model substantially improves the performance of the recognition and translation. The best system gives 12.5% relative WER reduction in Cantonese (resource-poor

language) transcriptions over the system using interpolation. The best reordering model gives 3.4% relative WER reduction and 13.3% relative BLEU score improvement in Mandarin (resource-rich language) transcriptions over the system without reordering. The improvements have been found to be statistically significant.

Even though the objective of our work is for speech recognition, our proposed cross-lingual language modeling can be easily applied to speech translation of other language pairs for efficient direct decoding from source speech to target text.

## 7 Acknowledgments

This work is partially supported by ITS/189/09 and CERG#612211. The authors would like to thank Dr. Tasuku Oonishi for providing access to the  $T^3$  decoder, and thank Prof. Sadaoki Furui and his team for useful discussions. Thanks should go to Yue Yu and Percy Cheung for collecting the Cantonese and Mandarin parallel data. Thanks also go to Ricky Chan for training the Cantonese acoustic model and Dr. Markus Saers for helping on training the GIZA word-to-word alignment models.

## Abstract

We examine the task of resolving complex cases of definite pronouns, specifically those for which traditional linguistic constraints on coreference (e.g., Binding Constraints, gender and number agreement) as well as commonly-used resolution heuristics (e.g., string-matching facilities, syntactic salience) are not useful. Being able to solve this task has broader implications in artificial intelligence: a restricted version of it, sometimes referred to as the Winograd Schema Challenge, has been suggested as a conceptually and practically appealing alternative to the Turing Test. We employ a knowledge-rich approach to this task, which yields a pronoun resolver that outperforms state-of-the-art resolvers by nearly 18 points in accuracy on our dataset.

## 1 Introduction

Despite the significant amount of work on pronoun resolution in the natural language processing community in the past forty years, the problem is still far from being solved. Its difficulty stems in part from its reliance on sophisticated knowledge sources and inference mechanisms. The sentence pair below, which we will subsequently refer to as the *shout* example, illustrates how difficult the problem can be:

- (1a) Ed shouted at Tim because he crashed the car.
- (1b) Ed shouted at Tim because he was angry.

The pronoun *he* refers to *Tim* in 1a and *Ed* in 1b. Humans can resolve the pronoun easily, but state-of-the-art coreference resolvers cannot. The reason is that humans have the kind of *world knowledge*

needed to resolve the pronouns that machines do not. Our world knowledge tells us that if someone is angry, he may shout at other people. Since *Ed* shouted, he should be the one who was angry. Our world knowledge also tells us that we may shout at someone who made a mistake and that crashing a car is a mistake. Combining these two pieces of evidence, we can easily infer that *Tim* crashed the car.

Our goal in this paper is to examine the resolution of *complex* cases of definite pronouns that appear in sentences exemplified by the *shout* example. Specifically, each sentence (1) has two clauses separated by a discourse connective (i.e., the connective appears *between* the two clauses, just like *because* in the *shout* example), where the first clause contains two or more candidate antecedents (e.g., *Ed* and *Tim*), and the second clause contains the target pronoun (e.g., *he*); and (2) the target pronoun agrees in gender, number, and semantic class with each candidate antecedent, but does not have any overlap in content words with any of them. For convenience, we will refer to the target pronoun that appears in this kind of sentences as a *difficult* pronoun.

Note that many traditional linguistic constraints on coreference are no longer useful for resolving difficult pronouns. For instance, syntactic constraints such as the Binding Constraints will not be useful, since the pronoun and the candidate antecedents appear in different clauses separated by a discourse connective; and constraints concerning agreement in gender, number, and semantic class will not be useful, since the pronoun and the candidate antecedents are compatible with respect to all these attributes. Traditionally important clues provided by various

Table 1: Sample twin sentences. The target pronoun in each sentence is italicized, and its antecedent is boldfaced.

string-matching facilities will not be useful either, since the pronoun and its candidate antecedents do not have any words in common.

As in the *shout* example, we ensure that each sentence has a *twin*. Twin sentences were used extensively by researchers in the 1970s to illustrate the difficulty of pronoun resolution (Hirst, 1981). We consider two sentences as twins if (1) they are identical up to and possibly including the discourse connective; and (2) the difficult pronouns in them are lexically identical but have different antecedents. The presence of twins implies that syntactic salience, a commonly-used heuristic in pronoun resolution that prefers the selection of syntactically salient candidate antecedents, may no longer be useful, since the candidate in the subject position is not more likely to be the correct antecedent than the other candidates.

To enable the reader to get a sense of how hard it is to resolve difficult pronouns, Table 1 shows sample twin sentences from our dataset. Note that state-of-the-art pronoun resolvers (e.g., JavaRAP (Qiu et al., 2004), GuiTaR (Poesio and Kabadjov, 2004), as well as those designed by Mitkov (2002) and Charniak and Elsnar (2009)) and coreference resolvers (e.g., BART (Versley et al., 2008), CherryPicker (Rahman and Ng, 2009), Reconcile (Stoyanov et al., 2010), the Stanford resolver (Raghuathan et al., 2010; Lee et al., 2011)) cannot accurately resolve the difficult pronouns in these structurally simple sentences, as they do not have the mechanism to capture the fine distinctions between twin sentences. In other words, when given these sentences, the best that the existing resolvers can do to resolve the pronouns is guessing. This could be surprising to a non-coreference

researcher, but it is indeed the state of the art.

A natural question is: why do existing resolvers not attempt to handle difficult pronouns? One reason could be that these difficult pronouns do not appear frequently in standard evaluation corpora such as MUC, ACE, and OntoNotes (Bagga, 1998; Haghighi and Klein, 2009). In fact, the Stanford coreference resolver (Lee et al., 2011), which won the CoNLL-2011 shared task on coreference resolution, adopts the once-popular rule-based approach, resolving pronouns simply with rules that encode the aforementioned traditional linguistic constraints on coreference, such as the Binding constraints and gender and number agreement.

The infrequency of occurrences of difficult pronouns in these standard evaluation corpora by no means undermines their significance, however. In fact, being able to automatically resolve difficult pronouns has broader implications in artificial intelligence. Recently, Levesque (2011) has argued that the problem of resolving the difficult pronouns in a carefully chosen set of twin sentences, which he refers to as the Winograd Schema Challenge<sup>1</sup>, could serve as a conceptually and practically appealing alternative to the well-known Turing Test (Turing,

<sup>1</sup>Levesque (2011) defines a Winograd Schema as a small reading comprehension test involving the question of which of the two candidate antecedents for the definite pronoun in a given sentence is its correct antecedent. Levesque names this challenge after Winograd because of his pioneering attempt to use a well-known pair of twin sentences — specifically the first pair in Table 1 — to illustrate the difficulty of natural language understanding (Winograd, 1972). Strictly speaking, we are addressing a relaxed version of the Challenge: while Levesque focuses solely on definite pronouns whose resolution requires background knowledge *not* expressed in the words of a sentence, we do not impose such a condition on a sentence.

1950). The reason should perhaps be clear given the above discussion: this is an easy task for a subject who can “understand” natural language but a challenging task for one who can only make intelligent guesses. Levesque believes that “with a very high probability”, anything that can resolve correctly a series of difficult pronouns “is thinking in the full-bodied sense we usually reserve for people”. Hence, being able to make progress on this task enables us to move one step closer to building an intelligent machine that can truly understand natural language.

To sum up, an important contribution of our work is that it opens up a new line of research involving a problem whose solution requires a deeper understanding of a text. With recent advances in knowledge extraction from text, we believe that time is ripe to tackle this problem. It is worth noting that some researchers have focused on other kinds of anaphors that are hard to resolve, including bridging anaphors (e.g., Poesio et al. (2004)) and anaphors referring to abstract entities, such as those realized by verb phrases in dialogs (e.g., Byron (2002), Strube and Müller (2003), Müller (2007)). Nevertheless, to our knowledge, there has been little work that specifically targets difficult pronouns.

Given the complexity of our task, we investigate a variety of sophisticated knowledge sources for resolving difficult pronouns, and combine them via a machine learning approach. Note that there has been a recent surge of interest in extracting world knowledge from online encyclopedias such as Wikipedia (e.g., Ponzetto and Strube (2006, 2007), Poesio et al. (2007)), YAGO (e.g., Bryl et al. (2010), Rahman and Ng (2011), Uryupina et al. (2011)), and Freebase (e.g., Lee et al. (2011)). However, the resulting extractions are primarily IS-A relations (e.g., *Barack Obama* IS-A *U. S. president*), which would not be useful for resolving definite pronouns.

## 2 Dataset Creation

We asked 30 undergraduate students who are not affiliated with this research to compose sentence pairs (i.e., twin sentences) that conform to the constraints specified in the introduction. Each student was also asked to annotate the candidate antecedents, the target pronoun, and the correct antecedent for each sentence she composed. Note that a sentence may

contain multiple pronouns, but exactly one of them — the one explicitly annotated by its author — is the target pronoun. Each sentence pair was cross-checked by one other student to ensure that it (1) conforms to the desired constraints and (2) does not contain pronouns with ambiguous antecedents (in other words, a human should not be confused as to which candidate antecedent is the correct one). At the end of the process, 941 sentence pairs were considered acceptable, and they formed our dataset. These sentences cover a variety of topics, ranging from real events (e.g., Iran’s plan to attack the Saudi ambassador to the U.S.), to events and characters in movies (e.g., Batman and Robin), to purely imaginary situations (e.g., the *shout* example). We partition these sentence pairs into a training set and a test set following a 70/30 ratio.

While not requested by us, the students annotated exactly two candidate antecedents for each sentence. For ease of exposition, we will assume below that there are two candidate antecedents per sentence.

## 3 Machine Learning Framework

Since our goal is to determine which of the two candidate antecedents is the correct antecedent for the target pronoun in each sentence, our system assumes as input the sentence, the target pronoun, and the two candidate antecedents.

We employ machine learning to combine the features derived from different knowledge sources. Specifically, we employ a *ranking-based* approach. Ranking-based approaches have been shown to outperform their classification-based counterparts (Denis and Baldrige, 2007, 2008; Iida et al., 2003; Yang et al., 2003). Given a pronoun and two candidate antecedents, we aim to train a ranking model that *ranks* the two candidates such that the correct antecedent is assigned a higher rank.

More formally, given training sentence  $S_k$  containing target pronoun  $A_k$ , correct antecedent  $C_k$  and incorrect antecedent  $I_k$ , we create two feature vectors,  $\mathbf{x}_{CA_k}$  and  $\mathbf{x}_{IA_k}$ , where  $\mathbf{x}_{CA_k}$  is generated from  $A_k$  and  $C_k$ , and  $\mathbf{x}_{IA_k}$  is generated from  $A_k$  and  $I_k$ . The training set consists of ordered pairs of feature vectors ( $\mathbf{x}_{CA_k}, \mathbf{x}_{IA_k}$ ), and the goal of the training procedure is to acquire a ranker that minimizes the number of violations of pairwise rankings

provided in the training set. We train this ranker using Joachims’ (2002) SVM<sup>light</sup> package. It is worth noting that we do *not* exploit the fact that each sentence has a twin in training or testing.

After training, the ranker can be applied to the test instances, which are created in the same way as the training instances. For each test instance, the target pronoun is resolved to the higher-ranked candidate antecedent.

## 4 Linguistic Features

We derive linguistic features for resolving difficult pronouns from eight components, as described below. To enable the reader to keep track of these features more easily, we summarize them in Table 2.

### 4.1 Narrative Chains

Consider the following sentence:

(2) Ed punished Tim because he tried to escape.

Humans resolve *he* to *Tim* by exploiting the world knowledge that someone who tried to escape is bad and therefore should be punished. Such kind of knowledge can be extracted from *narrative chains*.

Narrative chains are partially ordered sets of events centered around a common *protagonist*, aiming to encode the kind of knowledge provided by *scripts* (Schank and Abelson, 1977). While scripts are hand-written, narrative chains can be learned from unannotated text. Below is a chain learned by Chambers and Jurafsky (2008):

borrow-s invest-s spend-s pay-s raise-s lend-s

As we can see, a narrative chain is composed of a sequence of events (verbs) together with the roles of the protagonist. Here, “s” denotes the subject role, even though a chain can contain a mix of “s” and “o” (the object role). From this chain, we know that the person who borrows something (probably money) may invest, spend, pay, or lend it.

We employ narrative chains to heuristically predict the antecedent for the target pronoun, and encode the prediction as a feature. The heuristic decision procedure operates as follows. Given a sentence, we first determine the event the target pronoun participates in *and* its role in the event. As an example, we determine that in sentence (2) *he* participates in the *try* event and the *escape* event

Component	# Features	Features
Narrative Chains	1	NC
Google	4	G1, G2, G3, G4
FrameNet	4	FN1, FN2, FN3, FN4
Heuristic Polarity	3	HPOL1, HPOL2, HPOL3
Learned Polarity	3	LPOL1, LPOL2, LPOL3
Connective-Based Relation	1	CBR
Semantic Compat.	3	SC1, SC2, SC3
Lexical Features	68,331	antecedent- independent and dependent features

Table 2: Summary of the features described in Section 4.

as a *subject*.<sup>2</sup> Second, we determine the event(s) that the candidate antecedents participate in. In (2), both candidate antecedents participate in the *punish* event. Third, we pair each event participated by each candidate antecedent with each event participated by the pronoun. In our example, we would create two pairs, (*punish, try-s*) and (*punish, escape-s*). Note that *try* and *escape* are associated with the role of the pronoun that we extracted in the first step. Fourth, for each such pair, we extract all the narrative chains containing both elements in the pair from Chambers and Jurafsky’s output.<sup>3</sup> This step results in one chain being extracted, which contains *punish-o* and *escape-s*. In other words, the protagonist in this chain is the subject of an *escape* event and the object of a *punish* event. Fifth, from the extracted chain, we obtain the role played by the pronoun (i.e., the protagonist) in the event in which the candidate antecedents participate. In our example, the pronoun plays an object role in the *punish* event. Finally, we extract the candidate antecedent that plays the extracted role, which in our example is the second antecedent, *Tim*.<sup>4</sup>

We create a binary feature, NC, which encodes this heuristic decision, and compute its value as follows. Assume in the rest of the paper that  $i_1$  and  $i_2$  are the feature vectors corresponding to the first candidate antecedent and the second candidate an-

<sup>2</sup>Throughout the paper, the subject/object of an event refers to its *deep* rather than *surface* subject/object. We determine the grammatical role of an NP using the Stanford dependency parser (de Marneffe et al., 2006) and a set of simple heuristics.

<sup>3</sup>We employ narrative chains of length 12, which are available from <http://cs.stanford.edu/people/nc/schemas/schemas-size12>.

<sup>4</sup>For an alternative way of using narrative chains for coreference resolution, see Irwin et al. (2011).

tecedent, respectively.<sup>5</sup> For our running example, since *Tim* is predicted to be the antecedent of *he*, the value of NC in  $i_2$  is 1, and its value in  $i_1$  is 0. For notational convenience, we write  $NC(i_1)=0$  and  $NC(i_2)=1$ , and will follow this convention when describing the features in the rest of the paper.

Finally, we note that  $NC(i_1)$  and  $NC(i_2)$  will both be set to zero if (1) the pronoun and the antecedents do not participate in events, or (2) no narrative chains can be extracted in step 4 above, or (3) step 4 enables us to extract more than one chain and these chains indicate that the candidate antecedent can have both a subject role and an object role.

## 4.2 Google

Consider the following sentences:

- (3a) Lions eat zebras because they are predators.
- (3b) The knife sliced through the flesh because it was sharp.

Humans resolve *they* to *Lions* in (3a) by exploiting the world knowledge that predators attack and eat other animals. Similarly, humans resolve *it* to *the knife* in (3b) by exploiting the world knowledge that the word *sharp* can be used to describe a knife but not flesh. To acquire this kind of world knowledge, we learn patterns of word usage from the Web by issuing search queries. To facilitate our discussion, let us first introduce some notation. Let a sentence  $S$  be denoted by a triple  $(Z_1, Conn, Z_2)$ , where  $Z_1$  and  $Z_2$  are the clauses preceding and following the discourse connective  $Conn$ , respectively;  $A \in Z_2$  be the pronoun governed by the verb  $V$ ;  $W$  be the sequence of words following  $V$  in  $S$ ; and  $C_1, C_2 \in Z_1$  be the candidate antecedents.

Given a sentence, we generate four queries: (Q1)  $C_1V$ ; (Q2)  $C_2V$ ; (Q3)  $C_1VW$ ; and (Q4)  $C_2VW$ . If  $v$  is a verb-to-be followed by an adjective  $J$ , we generate two more queries: (Q5)  $JC_1$  and (Q6)  $JC_2$ . To exemplify, six queries are generated for (3b): (Q1) “knife was”; (Q2) “flesh was”; (Q3) “knife was sharp”; (Q4) “flesh was sharp”; (Q5) “sharp knife”; and (Q6) “sharp flesh”. On the other hand, only four queries are generated for (3a): (Q1) “lions are”; (Q2)

“zebras are”; (Q3) “lions are predators”; and (Q4) “zebras are predators”.

Using the counts returned by Google for these queries, we create four features, G1, G2, G3, and G4, whose values are determined by Rules 1, 2, 3, and 4, respectively, as described below.

**Rule 1:** if  $\text{count}(Q1) > \text{count}(Q2)$  by at least  $x\%$  then  $G1(i_1)=1$  and  $G1(i_2)=0$ ; else if  $\text{count}(Q2) > \text{count}(Q1)$  by at least  $x\%$  then  $G1(i_2)=1$  and  $G1(i_1)=0$ ; else  $G1(i_1)=G1(i_2)=0$ .

**Rule 2:** if  $\text{count}(Q3) > \text{count}(Q4)$  by at least  $x\%$  then  $G2(i_1)=1$  and  $G2(i_2)=0$ ; else if  $\text{count}(Q4) > \text{count}(Q3)$  by at least  $x\%$  then  $G2(i_2)=1$  and  $G2(i_1)=0$ ; else  $G2(i_1)=G2(i_2)=0$ .

**Rule 3:** if  $\text{count}(Q5) > \text{count}(Q6)$  by at least  $x\%$  then  $G3(i_1)=1$  and  $G3(i_2)=0$ ; else if  $\text{count}(Q6) > \text{count}(Q5)$  by at least  $x\%$  then  $G3(i_2)=1$  and  $G3(i_1)=0$ ; else  $G3(i_1)=G3(i_2)=0$ .

**Rule 4:** if one of  $G1(i_1)$  and  $G1(i_2)$  is 1, then  $G4(i_1)=G1(i_1)$  and  $G4(i_2)=G1(i_2)$ ; else if one of  $G2(i_1)$  and  $G2(i_2)$  is 1, then  $G4(i_1)=G2(i_1)$  and  $G4(i_2)=G2(i_2)$ ; else if one of  $G3(i_1)$  and  $G3(i_2)$  is 1, then  $G4(i_1)=G3(i_1)$  and  $G4(i_2)=G3(i_2)$ ; else  $G4(i_1)=G4(i_2)=0$ .

The role of the threshold  $x$  should be obvious: it ensures that a heuristic decision is made only if the difference between the counts for the two queries are sufficiently large, because otherwise there is no reason for us to prefer one candidate antecedent to the other. In all of our experiments, we set  $x$  to 20.

Note that other researchers have also used lexico-syntactic patterns to generate search queries for bridging anaphora resolution (e.g., Poesio et al. (2004)), other-anaphora resolution (e.g., Modjeska et al. (2003)), and learning selectional preferences for pronoun resolution (e.g., Yang et al. (2005)). However, in each of these three cases, the target *relations* (e.g., the part-whole relation in the case of bridging anaphora resolution, and the subject-verb and verb-object relations in the case of selectional preferences) are specific enough that they can be effectively captured by specific patterns. For example,

<sup>5</sup>The  $n$ th candidate antecedent in a sentence is the  $n$ th annotated NP encountered when processing the sentence in a left-to-right manner. In sentence (2), *Ed* is the first candidate antecedent and *Tim* is the second.

to determine whether *the wheel* is part of *the car* in bridging anaphora resolution, Poesio et al. employ queries of the form “X of Y”, where X and Y would be replaced with *the wheel* and *the car*, respectively. On the other hand, we are not targeting a particular type of relation. Rather, we intend to capture world knowledge like *lions rather than zebras are predators*. Such knowledge may not be expressed as a relation and hence may not be easily captured using specific patterns. For this reason, we need to employ patterns as general as those such as Q3 and Q4.

### 4.3 FrameNet

If we generate search queries as described in the previous subsection for the *shout* example, it is unlikely that Google will return meaningful counts to us. The reason is that both candidate antecedents in the sentence are proper names belonging to the same type (which in this case is PERSON).

However, in some cases, we may be able to generate more meaningful queries from such kind of sentences. Consider the following sentence:

(4) John killed Jim, so he was arrested.

To generate meaningful queries, we make one observation: *John* and *Jim* played different roles in a *kill* event. Hence, we can replace these proper names with their roles. We propose to obtain these roles from FrameNet (Baker et al., 1998). More generally, for each proper name *e* in a given sentence, we (1) determine the event in which *e* is involved (using the Stanford dependency parser); (2) search for the FrameNet frame corresponding to the event as well as *e*’s role in the event; and (3) replace the name with its FrameNet role. In our example, since both names are involved in the *kill* event, we retrieve the FrameNet frame for *kill*. Given that *John* and *Jim* are the subject and object of *kill*, we can extract their semantic roles directly from the frame, which are *killer* and *victim*, respectively.<sup>6</sup> Consequently, we replace the two names with their extracted semantic roles, and generate the search queries from the resulting sentence in the same way as before.

Note that if no frames can be found for the verb in the first clause, no search queries will be generated. After obtaining the query counts, we generate four binary features, FN1, FN2, FN3, FN4, whose values

<sup>6</sup>We heuristically map grammatical roles to semantic roles.

are computed based on the same four heuristic rules that were discussed in the previous subsection.

### 4.4 Heuristic Polarity

Some sentences involve comparing the two candidate antecedents. Consider the following sentences:

(5a) John was defeated by Jim in the election even though he is more popular.

(5b) John was defeated by Jim in the election because he is more popular.

The pronoun *he* refers to *John* in (5a) and *Jim* in (5b). To see how we can design an algorithm for resolving these pronouns, it would be useful to understand how humans resolve them. The phrase *more popular* has a positive sentiment. In (5a), the use of *even though* yields a clause of concession, which flips the polarity of *more popular* (from positive to negative), whereas in (5b), the use of *because* yields a clause of cause, which does not change the polarity of *more popular* (i.e., *more popular* remains positive). Since *more popular* is used to describe *he*, *he* is “better” in (5b) but “worse” in (5a). Now, the word *defeat* has a positive sentiment, and since *Jim* is the *deep subject* of *defeat*, *Jim* is “better” and *John* is “worse”. Finally, in (5b), *he* and *Jim* are “better”, so *he* is resolved to *Jim*; on the other hand, in (5a), *he* and *John* are “worse”, so *he* is resolved to *John*.

We automate this (human) method for resolving pronouns as follows. We begin by determining whether we can assign a *rank value* (i.e., “better” or “worse”) to the pronoun and the two candidate antecedents. For instance, to determine the rank value of the pronoun *A*, we first determine the polarity value  $p_A$  of its *anchor* word  $w_A$ , which is either the verb *v* for which *A* serves as the deep subject, or the adjective modifying *A* if *v* does not exist,<sup>7</sup> using Wilson et al.’s (2005b) subjectivity lexicon.<sup>8</sup> If  $p_A$  is not NEUTRAL, we check whether it can be flipped by the context of  $w_A$ . We consider three kinds of polarity-reversing context: negation, comparative adverb, and discourse connective. Specifically, we determine whether  $w_A$  is negated using the Stanford dependency parser, which explic-

<sup>7</sup>In the sentiment analysis and opinion mining literature,  $(w_A, p_A)$  is known as an opinion-target pair.

<sup>8</sup>The lexicon contains 8221 words, each of which is hand labeled with a polarity of POSITIVE, NEGATIVE, or NEUTRAL.

itly annotates instances of negation; we determine the existence of a comparative adverb (e.g., “more”, “less”) using the POS tag “RBR”; and we determine whether  $A$  exists in a clause headed by a polarity-reversing connective, such as *although*. After flipping  $p_A$  by context, we can infer  $A$ ’s rank value from it. Specifically,  $A$ ’s rank value is “better” if  $p_A$  is positive; “worse” if  $p_A$  is negative; and “cannot be determined” if  $p_A$  is neutral. The polarity values of the two candidate antecedents can be determined in a similar fashion. Note that sometimes we may need to infer rank values. For example, given the sentence “Jane is prettier than Jill”, *prettier* has a positive polarity, so its modifying NP, *Jane*, has a “better” rank, and we can infer that *Jill*’s rank is “worse”.

We create three features, HPOL1, HPOL2, and HPOL3, based on our heuristic polarity determination component. Specifically, if the rank value of the pronoun or the rank value of one or both of the candidate antecedents cannot be determined, the values of all three binary features will be set to zero for both  $i_1$  and  $i_2$ . Otherwise, we compute the values of the three features as follows. To compute HPOL1, which is a binary feature, we (1) employ a heuristic resolution procedure, which resolves the pronoun to the candidate antecedent with the same rank value, and then (2) encode the outcome of this heuristic procedure as the value of HPOL1. For example, since the first candidate antecedent, *John*, is predicted to be the antecedent in (5a),  $\text{HPOL1}(i_1)=1$  and  $\text{HPOL1}(i_2)=0$ . The value of HPOL2 is the concatenation of the polarity values determined for the pronoun and the candidate antecedent. Referring again to (5a),  $\text{HPOL2}(i_1)=\text{positive-positive}$  and  $\text{HPOL2}(i_2)=\text{positive-negative}$ . To compute HPOL3 for a given instance, we simply take its HPOL2 value and append the connective to it. Using (5a) as an example,  $\text{HPOL3}(i_1)=\text{positive-positive-even-though}$  and  $\text{HPOL3}(i_2)=\text{positive-negative-even-though}$ .

#### 4.5 Machine-Learned Polarity

In the previous subsection, we compute the polarity of a word by updating its prior polarity heuristically with contextual information. We hypothesized that polarity could be computed more accurately by employing a sentiment analyzer that can capture richer contextual information. For this reason, we employ

OpinionFinder (Wilson et al., 2005a), which has a pre-trained classifier for annotating the phrases in a sentence with their contextual polarity values.

Given a sentence and the polarity values of the phrases annotated by OpinionFinder, we determine the rank values of the pronoun and the two candidate antecedents by mapping them to the polarized phrases using the dependency relations provided by the Stanford dependency parser. We create three binary features, LPOL1, LPOL2, and LPOL3, whose values are computed in the same way as HPOL1, HPOL2, and HPOL3, respectively, except that the computation here is based on the machine-learned polarity values rather than the heuristically determined polarity values.

#### 4.6 Connective-Based Relations

Consider the following sentences:

- (6a) Google bought Motorola because they want its customer base.
- (6b) Google bought Motorola because they are rich.

Humans resolve *they* to *Google* in (6a) by exploiting the world knowledge that there is a causal relation (signaled by the discourse connective *because*) between the *want* event and the *buy* event. A similar mechanism is used to resolve *they* to *Google* in (6b): from world knowledge we know that there is a causal relation between *rich* and *buy*.

We automate this (human) method for resolving pronouns as follows. First, we gather connective-based relations of this kind from a large, unannotated corpus. In our experiments, we use as our unannotated corpus the documents in three text corpora (namely, BLLIP, Reuters, and English Gigaword), but retain only those sentences that contain a single discourse connective and do not begin with the connective. From these sentences, we collect triples and their frequencies of occurrences in the corpus. Each triple is of the form  $(V, Conn, X)$ , where *Conn* is a discourse connective,  $V$  is a stemmed verb in the clause preceding *Conn*, and  $X$  is a stemmed verb or an adjective in the clause following *Conn*. Each triple essentially denotes a relation between  $V$  and  $X$  expressed by *Conn*. Conceivably, the strength of the relation in a triple increases with its frequency count.

We use the frequency counts of these triples to heuristically predict the correct antecedent for a target pronoun. Given a sentence where *Conn* is the discourse connective, *X* is the stemmed verb governing the target pronoun *A* or the adjective modifying *A* (if *X* is a *to be* verb), and *V* is the stemmed verb governing the candidate antecedents, we retrieve the frequency count of the triple (*V, Conn, X*). If the count is at least 100, we employ a procedure for heuristically selecting the antecedent for the target anaphor. Specifically, if *X* is a verb, then it resolves the target pronoun to the candidate antecedent that has the same grammatical role as the pronoun. However, if *X* is an adjective and the sentence does not involve comparison, then it resolves the target pronoun to the candidate antecedent serving as the subject of *V*.

We create a binary feature, *CBR*, that encodes this heuristic decision. In our running example, the triple (*buy, because, want*) occurs 860 times in our corpus, so the pronoun *they* is resolved to the candidate antecedent that occurs as the subject of *buy*. Hence,  $CBR(i_1)=1$  and  $CBR(i_2)=0$ . However, had the triple occurred less than 100 times, both of these features would have been set to zero.

#### 4.7 Semantic Compatibility

Some of the queries generated by the Google component, such as Q1 and Q2, aim to capture the semantic compatibility between a candidate antecedent, *C*, and the verb governing the target pronoun, *V*. However, using web search queries to estimate semantic compatibility has potential problems, including (1) a *precision* problem: the fact that *C* and *V* appear next to each other in a query does not necessarily imply that a subject-verb relation exists between them; and (2) a *recall* problem: these queries fail to capture subject-verb relations where *C* and *V* are not immediately adjacent to each other.

To address these potential problems, we compute knowledge of selectional preferences from a large, unannotated corpus. As before, we create our unannotated corpus using the documents in BLLIP, Reuters, and English Gigaword. Specifically, we first parse each sentence in the corpus using the Stanford dependency parser. Then, for each stemmed verb *v* and each stemmed noun *n* in the corpus, we collect the following statistics: (1) the

number of times *n* is the subject of *v*; (2) the number of times *n* is the direct object of *v*; (3) the mutual information (MI) of *v* and *n* (with *n* as the subject of *v*); and (4) the MI of *v* and *n* (with *n* as the direct object of *v*).<sup>9</sup>

To understand how we use these statistics to generate features for resolving pronouns, consider the following sentence:

- (7) The man stole the neighbor's bike because he needed one.

Assuming that the target pronoun and its governing verb *V* has grammatical relation *GR*, we create three features, SC1, SC2, and SC3, based on our semantic compatibility component. SC1 encodes the MI value of the head noun of a candidate antecedent and *V* (and *GR*). SC2 is a binary feature whose value indicates which of the candidate antecedents has a larger MI value with *V* (and *GR*). SC3 is the same as SC2, except that MI is replaced with corpus frequency. In other words, SC2 and SC3 employ different measures to heuristically predict the correct antecedent for the target pronoun. If the target pronoun is governed by a *to be* verb, the values of these three features will all be set to zero.

Given our running example, we first retrieve the following corpus-based statistics:  $MI(need:subj, man)=0.6322$ ;  $MI(need:subj, neighbor)=0.3975$ ;  $count(need:subj, man)=474$ ; and  $count(need:subj, neighbor)=68$ . Using these statistics, we can then compute the aforementioned features for our example. Specifically,  $SC1(i_1)=0.6322$ ,  $SC1(i_2)=0.3975$ ,  $SC2(i_1)=1$ ,  $SC2(i_2)=0$ ,  $SC3(i_1)=1$ , and  $SC3(i_2)=0$ .

#### 4.8 Lexical Features

We exploit the coreference-annotated training documents by creating *lexical* features from them. These lexical features can be divided into two categories, depending on whether they are computed based on the candidate antecedents.

Let us begin with the *antecedent-independent* features. Assuming that *W* is an arbitrary word in a sentence *S* that is not part of a candidate antecedent and *Conn* is the connective in *S*, we create three types of binary-valued antecedent-independent features, namely (1) *unigrams*, where we create one

<sup>9</sup>We use the same formula as described in Section 4.2 of Bergsma and Lin (2006) to compute MI values.

feature for each  $W$ ; (2) *word pairs*, where we create features by pairing each  $W$  appearing before  $Conn$  with each  $W$  appearing after  $Conn$ , excluding adjective-noun and noun-adjective pairs<sup>10</sup>; and (3) *word triples*, where we augment each word pair in (2) with  $Conn$ . The value of each feature  $f$  indicates the presence or absence of  $f$  in  $S$ .

Next, we compute the *antecedent-dependent* features. Let (1)  $H_{C_1}$  and  $H_{C_2}$  be the head words of candidate antecedents  $C_1$  and  $C_2$ , respectively; (2)  $V_{C_1}$ ,  $V_{C_2}$ , and  $V_A$  be the verbs governing  $C_1$ ,  $C_2$ , and the target pronoun  $A$ , respectively; and (3)  $J_{C_1}$ ,  $J_{C_2}$ , and  $J_A$  be the adjectives modifying  $C_1$ ,  $C_2$ , and  $A$ , respectively.<sup>11</sup> We create from each candidate antecedent four features, each of which is a word pair. From  $C_1$ , we create  $(H_{C_1}, V_{C_1})$ ,  $(H_{C_1}, J_{C_1})$ ,  $(H_{C_1}, V_A)$ , and  $(H_{C_1}, J_A)$ , all of which will appear in the feature vector corresponding to  $C_1$ . A similar set of four features are created from  $C_2$ . These antecedent-dependent features are all binary-valued.

It is worth mentioning that while we also considered word triples in the connective-based relations component and word pairs in the semantic compatibility component, in those components we determine their usefulness in an unsupervised manner, whereas by employing them as lexical features we determine their usefulness in a supervised manner.

## 5 Evaluation

### 5.1 Experimental Setup

**Dataset.** We report results on the test set, which comprises 30% of our hand-annotated sentence pairs (see Section 2 for details).

**Evaluation metrics.** Results are expressed in terms of accuracy, which is the percentage of correctly resolved target pronouns. We also report the percentages of these pronouns that are (1) not resolved and (2) incorrectly resolved.

### 5.2 Results and Discussion

**The Random baseline.** Our first baseline is a resolver that randomly guesses the antecedent for the

target pronoun in each sentence. Since there are two candidate antecedents per sentence, the Random baseline should achieve an accuracy of 50%.

**The Stanford resolver.** Our second baseline is the Stanford resolver (Lee et al., 2011), which achieves the best performance in the CoNLL 2011 shared task (Pradhan et al., 2011). As a rule-based resolver, it does not exploit any coreference-annotated data.

Recall from Section 3 that our system assumes as input not only a sentence containing a target pronoun but also the two candidate antecedents. To ensure a fair comparison, the same input is provided to this and other baselines. Hence, if the Stanford resolver decides to resolve the target pronoun, it will resolve it to one of the two candidate antecedents. However, if it does not have enough confidence about resolving it, it will leave it unresolved. Its performance on the test set is shown in the “Unadjusted Scores” column in row 1 of Table 3. As we can see, it correctly resolves 40.1% of the pronouns, incorrectly resolves 29.8% of them, and does not make any decision on the remaining 30.1%.

Given that the Random baseline correctly resolves 50% of pronouns and the Stanford resolver correctly resolves only 40.1% of the pronouns, it is tempting to conclude that Stanford does not perform as well as Random. However, recall that Stanford leaves 30.1% of the pronouns unresolved. Hence, to ensure a fairer comparison, we produce “adjusted” scores for the Stanford resolver, where we “force” it to resolve all of the unresolved target pronouns by assuming that probabilistically half of them will be resolved correctly. This adjusted score is shown in the “Adjusted Scores” column in row 1 of Table 3. As we can see, Stanford achieves an accuracy of 55.1%, which is 5.1 points higher than that of Random.

**The Baseline Ranker.** To understand whether the somewhat unsatisfactory Stanford results can be attributed to its inability to exploit the training data, we employ as our third baseline a mention ranker that is trained in the same way as our system (see Section 3), except that it employs 39 commonly-used linguistic features for learning-based coreference resolution (see Table 1 of Rahman and Ng (2009) for a description of these features). Hence, the performance difference between this Baseline Ranker and our system can be attributed entirely

<sup>10</sup>Pairing an adjective  $A$  in one clause with a noun  $N$  in another clause may mislead the learner into thinking that  $N$  is modified by  $A$ , and hence we do not create such pairs.

<sup>11</sup>If  $C_1$ ,  $C_2$ , and  $A$  are not modified by adjectives, no adjective-based features will be created.

Coreference System	Unadjusted Scores			Adjusted Scores		
	Correct	Wrong	No Decision	Correct	Wrong	No Decision
1 Stanford	40.07%	29.79%	30.14%	55.14%	44.86%	0.00%
2 Baseline Ranker	47.70%	47.16%	5.14%	50.27%	49.73%	0.00%
3 Stanford+Baseline Ranker	53.49%	43.12%	3.39%	55.19%	44.77%	0.00%
4 Our system	<b>73.05%</b>	26.95%	0.00%	<b>73.05%</b>	26.95%	0.00%

Table 3: Results of the Stanford resolver, the Baseline Ranker, the Combined resolver, and our system.

to the difference between the two linguistic feature sets. Results of the Baseline Ranker are shown in row 2 of Table 3. Before score adjustment, it correctly resolves 47.7% of the target pronouns, incorrectly resolves 47.2% of them, and leaves the remaining 5.1% unresolved. (Note that we output “no decision” if the ranker assigns the same rank value to both candidate antecedents.) After score adjustment, its accuracy is 50.3%, which is 0.3 points higher than that of Random but statistically indistinguishable from it.<sup>12</sup> On the other hand, its accuracy is 4.9 points lower than that of Stanford, and the difference between their performance is significant. While it seems somewhat surprising that a supervised resolver does not perform as well as a rule-based resolver, neither of them employs knowledge sources that are particularly useful for our dataset. In other words, despite given access to annotated data, the Baseline Ranker may not be able to make effective use of it due to the lack of useful features.

**The Combined resolver.** We create a fourth baseline by combining the Stanford resolver and the Baseline Ranker. The motivation is that the former can provide better precision and the latter can provide better recall by handling “no decision” cases not covered by the former. Note that the Baseline Ranker will be applied to resolve only those pronouns that are left unresolved by Stanford. Results in row 3 of Table 3 show that the adjusted accuracy of this Combined resolver is 55.2%, which is statistically indistinguishable from Stanford’s adjusted accuracy. Hence, these results show that the addition of the Baseline Ranker does not help improve Stanford’s resolution accuracy.

**Our system.** Results of our system, which is trained using the features described in Section 4 in combination with a ranking model, are shown in row 4 of Table 3. As we can see, our system achieves

Feature Type	Correct	Wrong	No Decision
All features	73.05%	26.95%	0.00%
–Narrative Chains	68.97%	31.03%	0.00%
–Google	65.96%	34.04%	0.00%
–FrameNet	72.16%	27.84%	0.00%
–Heuristic Polarity	71.45%	28.55%	0.00%
–Learned Polarity	72.70%	27.30%	0.00%
–Connective-Based Rel.	71.28%	28.72%	0.00%
–Semantic Compat.	71.81%	28.19%	0.00%
–Lexical Features	60.11%	25.35%	14.54%

Table 4: Results of feature ablation experiments.

an accuracy of 73.1%, significantly outperforming the Combined resolver by 17.9 points in accuracy. These results suggest that our features are more useful for resolving difficult pronouns than those commonly used for coreference resolution.

### 5.3 Feature Analysis

In an attempt to gain additional insight into the performance contribution of each of the eight types of features used in our system, we conduct feature ablation experiments. The unadjusted scores of these experiments are shown in Table 4, where each row shows the performance of the model trained on all types of features except for the one shown in that row. For easy reference, the performance of the model trained on all types of features is shown in row 1 of the table.

A few points deserve mention. First, performance drops significantly whichever feature type is removed. This suggests that all eight feature types are contributing positively to overall accuracy. Second, the *Google*-based features and the *Lexical Features* are the most useful, and those generated via *FrameNet* and *Learned Polarity* are the least useful *in the presence* of other feature types. While it is somewhat surprising that *Learned Polarity* is not more useful than *Heuristic Polarity*, we speculate the reason can be attributed to the fact that the corpus on which OpinionFinder was trained was quite different from ours. Finally, even without using the

<sup>12</sup>All statistical significance test results in this paper are obtained using the paired *t*-test, with  $p < 0.05$ .

Feature Type	Correct	Wrong	No Decision
Narrative Chains	30.67%	24.47%	44.86%
Google	33.16%	7.09%	59.75%
FrameNet	7.27%	4.08%	88.65%
Learned Polarity	4.79%	2.66%	92.55%
Heuristic Polarity	7.27%	1.77%	90.96%
Connective-Based Rel.	14.01%	8.69%	77.30%
Semantic Compat.	23.58%	13.12%	63.30%
Lexical Features	56.91%	43.09%	0.00%

Table 5: Results of single-feature coreference models.

*Lexical Features*, our system still outperforms all the baseline resolvers: as can be implied from the last row of Table 4, in the absence of the *Lexical Features*, our resolver achieves an adjusted accuracy of 67.4%, which is only 5.7 points less than that obtained when the full feature set is employed. Hence, while the *Lexical Features* are useful, their importance should not be over-emphasized.

To get a better idea of the utility of each feature type, we conduct another experiment in which we train eight models, each of which employs exactly one type of features. Their unadjusted scores are shown in Table 5. As we can see, *Learned Polarity* has the smallest contribution, whereas the *Lexical Features* have the largest contribution.

#### 5.4 Error Analysis

While our resolver significantly outperforms state-of-the-art resolvers, there is a lot of room for improvement. To help direct future research on the resolution of difficult pronouns, we analyze the major sources of errors made by our resolver.

Our analysis reveals that many of the errors correspond to cases that cannot be handled by any of the eight components of our resolver. To understand these cases, consider first the strengths and weaknesses of *Narrative Chains* and *Google*, the two components that contribute the most to overall performance after *Lexical Features*.

*Google* is especially good at capturing facts, such as *lions are predators* and *zebras are not predators*, helping us correctly resolve sentences such as (5a) and (5b), as well as those in sentence pair (I) in Table 1. However, it may not be good at handling pronouns whose resolution requires an understanding of the connection between the facts or events described in the two clauses of a sentence. The reason is that establishing such a connection requires that we con-

struct a search query composed of information extracted from both clauses, and the resulting, possibly long, query is likely to receive no hit count due to data sparseness. Investigating how to construct such queries while avoiding data sparseness would be an interesting line of future work.

Narrative chains, on the other hand, are useful for capturing the relationship between the events described in the two clauses. However, they are computed over verbs, and therefore cannot capture such a relationship when one or both of the events involved are not described by verbs. For example, narrative chains fail to capture the causal relation between the event expressed by *angry* and *shout* in sentence (1b). It is also worth mentioning that some pronouns that could have been resolved using narrative chains are not owing to the *coverage* and *accuracy* of Chambers and Jurafsky’s (2008) chains, but we believe that these recall and precision problems could be addressed by (1) inducing chains from a larger corpus and (2) using semantic roles rather than grammatical roles in the induction process.

Some resolution errors arise from errors in polarity analysis. This can be attributed to the simplicity of our *Heuristic Polarity* component: determining the polarity of a word based on its prior polarity is too naïve. Fine-grained polarity analysis would be a promising solution to this problem (see Pang and Lee (2008) and Liu (2012) for related work).

## 6 Conclusions

We investigated the resolution of complex cases of definite pronouns, a problem that was under extensive discussion by coreference researchers in the 1970s but has received revived interest owing in part to its relevance to the Turing Test. Our experimental results indicate that it is a challenge for state-of-the-art resolvers, and while we proposed new knowledge sources for addressing this challenge, our resolver still has a lot of room for improvement. In particular, our error analysis indicates that further gains could be achieved via more accurate sentiment analysis and induction of world knowledge from corpora or the Web. In addition, we plan to integrate our resolver into a general-purpose coreference system and evaluate the resulting resolver on standard evaluation corpora such as MUC, ACE, and OntoNotes.

## Acknowledgments

We thank the three anonymous reviewers for their detailed and insightful comments on an earlier draft of the paper. This work was supported in part by NSF Grants IIS-0812261 and IIS-1147644.

## Abstract

Quote extraction and attribution is the task of automatically extracting quotes from text and attributing each quote to its correct speaker. The present state-of-the-art system uses gold standard information from previous decisions in its features, which, when removed, results in a large drop in performance. We treat the problem as a sequence labelling task, which allows us to incorporate sequence features without using gold standard information. We present results on two new corpora and an augmented version of a third, achieving a new state-of-the-art for systems using only realistic features.

## 1 Introduction

News stories are often driven by the quotes made by politicians, sports stars, musicians, and celebrities. When these stories exit the news cycle, the quotes they contain are often forgotten by both readers and journalists. A system that automatically extracts quotes and attributes those quotes to the correct speaker would enable readers and journalists to place news in the context of all comments made by a person on a given topic.

Though quote attribution may appear to be a straightforward task, the simple rule-based approaches proposed thus far have produced disappointing results. Going beyond these to machine learning approaches presents several problems that make quote attribution surprisingly difficult. The main challenge is that while a large portion of quotes can be attributed to a speaker based on simple rules,

the remainder have few or no contextual clues as to who the correct speaker is. Additionally, many quote sequences, such as dialogues, rely on the reader understanding that there is an alternating sequence of speakers, which creates dependencies between attribution decisions made by a classifier.

Elson and McKeown (2010) is the only study that directly uses machine learning in quote attribution, treating the task as a classification task, where each quote is attributed independently of other quotes. To handle conversations and similar constructs they use gold standard information about speakers of previous quotes as features for their model. This is an unrealistic assumption, since gold standard information is not available in practice.

The primary contribution of this paper is that we reformulate quote attribution as a sequence labelling task. This allows us to use sequence features without having to use the unrealistic gold standard features that were used in Elson and McKeown (2010). We experiment with three sequence decoding models including greedy, Viterbi and a linear chain Conditional Random Field (CRF).

Furthermore we present results on two new corpora and an augmented version of a third. The two new corpora are from news articles from the Wall Street Journal and the Sydney Morning Herald respectively, while the third corpus is an extension to the classic literature corpus from Elson and McKeown (2010). Our results show that a quote attribution system using only realistic features is highly feasible for the news domain, with accuracies of 92.4% on the SMH corpus and 84.1% on the WSJ corpus.

## 2 Background

Early work into quote attribution by Zhang et al. (2003) focused on identifying when different characters were talking in children’s stories, so that a speech synthesis system could read the quoted parts in different voices. While they were able to extract quotes with high precision and recall, their attribution accuracy was highly dependent on the document in question, ranging from 47.6% to 86.7%. Mamede and Chaleira (2004) conducted similar research on children’s stories written in Portuguese. Their system proved to be very good at extracting quotes through simple rules, but when using a hand-crafted decision tree to attribute those quotes to a speaker, they achieved an accuracy of only 65.7%.

In the news domain, both Pouliquen et al. (2007) and Sarmiento and Nunes (2009) proposed rule-based systems that work over large volumes of text. Both systems aimed for high precision at the expense of low recall, as their data contained many redundant quotes. More recently, SAPIENS, a French-language quote extraction and attribution system, was developed by de La Clergerie et al. (2011). It conducts a full parse of the text, which allows it to use patterns to extract direct and indirect quotes, as well as the speaker of each quote. Their evaluation found that 19 out of 40 quotes (47.5%) had a correct span and author, while a further 19 had an incorrect author, and 4 had an incorrect span. In related work, Sagot et al. (2010) built a lexicon of French reported speech verbs, and conducted some analysis of different types of quotes.

Glass and Bangay (2007) approached the task with a three stage method. For each quote they first find the nearest speech verb, they then find the grammatical actor of that speech verb, and finally they select the appropriate speaker for that actor. To achieve each of these subtasks they built a model with several manually weighted features that good candidates should possess. For each subtask they then choose the candidate with the largest weighted sum of features. Their full approach yields an accuracy of 79.4% on a corpus of manually annotated fiction books.

Schneider et al. (2010) describe PICTOR, which is principally a quote visualisation tool. Their task was to find direct and indirect quotes, which they

attribute to a text span representing the speaker. To do this they constructed a specialised grammar, which was built with reference to a small development corpus. With a permissive evaluation metric their grammar-based approach yielded 86% recall and 75% precision, however this dropped to 52% recall and 56% precision when measured in terms of completely correct quote-speaker pairs.

The work most similar to ours is the work by Elson and McKeown (2010). Their aim was to automatically identify both quotes and speakers, and then to attribute each quote to a speaker, in a corpus of classic literature that they compiled themselves. To identify potential speakers they used the Stanford NER tagger (Finkel et al., 2005) and a method outlined in Davis et al. (2003) that allowed them to find nominal character references. They then grouped name variants and pronominal mentions into a coreference chain.

To attribute a quote to a speaker they first classified the quotes into categories. Several of the categories have a speaker explicit in their structure, so they attribute quotes to those speakers with no further processing. For the remaining categories, they cast the attribution problem as a binary classification task, where each quote-speaker pair has a “speaker” or “not speaker” label predicted by the classifier. They then reconciled these independent decisions using various techniques to produce a single speaker prediction for each quote. For the simple category predictions they achieved 93-99% accuracy, while for the more complicated categories they achieved 63-64%, with an overall result of 83% accuracy. This compares favourably with their rule-based baseline, which achieved an accuracy of 52%.

While the results of Elson and McKeown (2010) appear encouraging, they are misleading for two reasons. First their corpus does not include quotes where all three annotators chose different speakers. While these quotes include some cases where the annotators chose coreferent spans, it also includes cases of legitimate disagreement about the speaker. An automated system would likely find these cases challenging. Second both their category predictions and machine learning predictions rely on gold standard information from previous quotes, which is not available in practice. In our study we address both these issues.

	Proportion (%)			Accuracy (%)		
	LIT	WSJ	SMH	LIT	WSJ	SMH
Quote-Said-Person	17.9	20.2	3.1	98.9	99.8	99.1
Quote-Person-Said	2.8	6.1	16.6	97.7	97.0	98.5
Other Trigram	0.1	2.3	0.3	66.7	56.2	54.5
Quote-Said-Pronoun	1.9	0.1	0.0	38.6	100.0	0.0
Quote-Pronoun-Said	5.9	8.8	13.5	36.5	92.2	93.9
Other Anaphors	0.1	0.1	0.2	0.0	100.0	62.5
Added*	24.6	28.3	23.9	89.7	76.3	97.5
Backoff	11.0	33.9	32.3	-	-	-
Alone	18.0	0.2	9.7	-	-	-
Conversation*	17.7	0.2	0.3	85.2	0.0	8.3
Total	100.0	100.0	100.0	60.5	57.2	55.8

Table 1: The proportion of quotes in each category and the accuracy of the speaker prediction based on the category. The two categories marked with an asterisk (\*) depend on previous decisions.

### 3 Corpora

We evaluate our methods on two new corpora coming from the news domain, and an augmented version of an existing corpus, which covers classic literature. They are described below.

#### 3.1 Columbia Quoted Speech Attribution Corpus (LIT)

The first corpus we use was originally created by Elson and McKeown (2010). It is a set of excerpts from 11 fictional 19th century works by six well-known authors, split into 18 documents. In total it contains 3,126 quotes annotated with their speakers.

Elson and McKeown used an automated system to find named entity spans and nominal mentions in the text, with the named entities being linked to form a coreference chain (they did not link nominal mentions). The corpus was built using Amazon’s Mechanical Turk, with three annotations per quote. To ensure quality, all annotations from poorly performing annotators were removed, as were quotes where each annotator chose a different speaker. Though excluding some quotes ensures quality annotations, it causes gaps in the quote chains, which is a problem for sequence labelling. Furthermore, the cases where annotators disagreed are likely to be challenging, so removing them from the corpus could make results appear better than they would be in practice.

To rectify this, we conducted additional annotation of the quotes that were excluded by the origi-

nal authors. Two postgraduates annotated 654 additional quotes, with a raw agreement of 79% over 48 double-annotated quotes. Our annotators reported seeing some errors in existing annotations, so we had one annotator check 400 existing annotations for correctness. This additional check found that 92.5% of the quotes were correctly annotated.

#### 3.2 PDTB Attribution Corpus Extension (WSJ)

Our next corpus is an extension to the attribution annotations found in the Penn Discourse TreeBank (PDTB). The original PDTB contains several forms of discourse, including assertions, beliefs, facts, and eventualities. These can be attributed to named entities or to unnamed, pronominal, or implicit sources. Recent work by Pareti (2012) conducted further annotation of this corpus, including reconstructing attributions that were only partially annotated, and introducing additional information. From this corpus we use only direct quotes and the directly quoted portions of mixed quotes, giving us 4,923 quotes.

For the set of potential speakers we use the BBN pronoun coreference and entity type corpus (Weischedel and Brunstein, 2005), with automatically coreferred pronouns. We automatically matched BBN entities to PDTB extension speakers, and included the PDTB speaker where no matching BBN entity could be found. This means an automatic system has an opportunity to find the correct speaker for all quotes in the corpus.

### 3.3 Sydney Morning Herald Corpus (SMH)

We compiled the final corpus from a set of news documents taken from the Sydney Morning Herald website<sup>1</sup>. We randomly selected 965 documents published in 2009 that were not obituaries, opinion pages, advertisements or other non-news stories. To conduct the annotation we employed 11 non-expert annotators via the outsourcing site Freelancer<sup>2</sup>, as well as five expert annotators from our research group. A total of 400 news stories were double-annotated, with at least 33 double-annotated stories per annotator. Raw agreement on the speaker of each quote was high at 98.3%. These documents had already been annotated with named entities as part of a separate research project (Hachey et al., 2012), which includes manually constructed coreference chains. The resulting corpus contains 965 documents, with 3,535 quotes.

### 3.4 Corpus Comparisons

In order to compare the corpora we categorise the quotes into the categories defined by Elson and McKeown (2010), as shown in Table 1. We assigned quotes to these categories by testing (after text preprocessing) whether the quote belonged to each category, in the order shown below:

1. *Trigram* – the quote appears consecutively with a mention of an entity, and a reported speech verb, in any order;
2. *Anaphors* – same as above, except that the mention is a pronoun;
3. *Added* – the quote is in the same paragraph as another quote that precedes it;
4. *Conversation* – the quote appears in a paragraph on its own, and the two paragraphs preceding the current paragraph each contain a single quote, with alternating speakers;
5. *Alone* – the quote is in a paragraph on its own;
6. *Miscellaneous* – the quote matches none of the preceding categories. This category is called “Backoff” in Elson and McKeown (2010).

<sup>1</sup><http://www.smh.com.au>

<sup>2</sup><http://www.freelancer.com>

Unsurprisingly, the two corpora from the news domain share similar proportions of quotes in each category. The main differences are that the SMH uses a larger number of pronouns compared to the WSJ, which tends to use explicit attribution more frequently. The SMH also has a significant proportion of quotes that appear alone in a paragraph, while the WSJ has almost none. Finally, when attributing a quote using a trigram pattern, the SMH mostly uses the Quote-Person-Said pattern, while the WSJ mostly uses the Quote-Said-Person pattern. These differences probably reflect the editorial guidelines of the two newspapers.

The differences between the news corpora and the literature corpus are more substantial. Most notably the LIT corpus has a much higher proportion of quotes that fall into the *Conversation* and *Alone* categories. This is unsurprising as both monologues and dialogues are common in fiction, but are rare in newswire. The two news corpora have more quotes in the *Trigram* and *Backoff* categories.

## 4 Quote Extraction

Quote extraction is the task of finding the spans that represent quotes within a document. There are three types of quotes that can appear:

1. *Direct quotes* appear entirely between quotation marks, and are used to indicate that the speaker said precisely what is written;
2. *Indirect quotes* do not appear between or contain quotation marks, and are used to get the speaker’s point across without implying that the speaker used the exact words of the quote;
3. *Mixed quotes* are indirect quotes that contain a directly quoted portion.

In this work, we limit ourselves to detecting direct quotes and the direct portions of mixed quotes.

To extract quotes we use a regular expression that searches for text between quotation marks. We also deal with the special case of multi-paragraph quotes where one quotation mark opens the quote and every new paragraph that forms part of the quote, with a final quotation mark only at the very end of the quote. This straightforward approach yields over 99% accuracy on all three corpora.

## 5 Quote Attribution

Given a document with a set of quotes and a set of entities, quote attribution is the task of finding the entity that represents the speaker of each quote, based on the context provided by the document. Identifying the correct entity can involve choosing either an entire coreference chain representing an entity, or identifying a specific span of text that represents the entity.

In practice, most applications only need to know which coreference chain represents the speaker, not which particular span in the text. Despite this, the best evidence about which chain is the speaker is found in the context of the individual text spans, and most existing systems aim to get the particular entity span correct. This presents a problem for evaluation, as an incorrect entity span may be identified, but it might still be part of the correct coreference chain. We chose to count attributions as correct if they attributed the quote to the correct coreference chain for both the LIT and SMH corpora, while for the WSJ corpus, where the full coreference chains do not exist, we evaluated an attribution as correct if it was to the correct entity span in the text.

### 5.1 Rule-based Baseline

To establish the effectiveness of our method we built a rule-based baseline system. For each quote it proceeds with the following steps:

1. Search backwards in the text from the end of the sentence the quote appears in for a reported speech verb
2. If the verb is found return the entity mention nearest the verb (ignoring mentions in quotes), in the current sentence or any sentence preceding it
3. If not, return the mention of an entity nearest the end of the quote (ignoring mentions in quotes), in the current sentence or any sentence preceding it

This forms a reasonable baseline as it is able to pick up the quotes that fall into the more simple categories, such as the *Trigram* category and the *Added* category. It is also able to make a guess at the more complicated categories, without using gold standard information as the category predictions do.

## 6 Experimental Setup

We use two classifiers: a logistic regression implementation available in LIBLINEAR (Fan et al., 2008), and a Conditional Random Field (CRF) from CRF-Suite (Okazaki, 2007). Both packages use maximum likelihood estimation with L2 regularisation. We experimented with several values for the coefficient on a development set, but found that it had little impact, so stuck with the default value. All of our machine learning experiments use the same text encoding, which is explained below, and all use the category predictions when they are available.

### 6.1 Text Encoding

We encode our text similarly to Elson and McKeown (2010). The major steps are:

1. Replace all quotes and speakers with special symbols;
2. Replace all reported speech verbs with a symbol. Elson and McKeown (2010) provided us with their list of reported speech verbs;
3. Part-of-Speech (POS) tag the text and remove adjectives, adverbs, and other parts of speech that do not contribute useful information. We used the POS tagger from Curran and Clark (2003);
4. Remove any paragraphs or sentences where no quotes, pronouns or names occur.

All features that will be discussed are calculated with respect to this encoding (e.g. word distance would be the number of words in the encoded text, rather than the number of words in the original text).

### 6.2 Features

In our experiments we use the feature set from Elson and McKeown (2010). The features for a particular pair of target quote ( $q$ ) and target speaker ( $s$ ) are summarised below.

**Distance features** including number of words between  $q$  and  $s$ , number of paragraphs between  $q$  and  $s$ , number of quotes between  $q$  and  $s$ , and number of entity mentions between  $q$  and  $s$

Corpus	Sequence Features		
	Gold	Pred	None
LIT	74.7	49.0	49.6
WSJ	87.3	74.1	82.9
SMH	95.0	85.6	92.4

Table 2: Accuracy results comparing the E&M approach with gold standard, predicted or no sequence features.

**Paragraph features** derived from the 10 paragraphs preceding the quote (including the paragraph the quote is in), includes number of mentions of  $s$ , number of mentions of other speakers, number of words in each paragraph, and number of quotes in each paragraph

**Nearby features** relating to the two tokens either side of  $q$  and  $s$ , includes binary features for each position indicating whether the position is punctuation,  $s$ ,  $q$ , a different speaker, a different quote, or a reported speech verb

**Quote features** about  $q$  itself, including whether  $s$  is mentioned within it, whether other speakers are mentioned within it, how far the quote is from the start of its paragraph and the length in words of  $q$

**Sequence features** that depend on the speakers chosen for the previous quotes, includes number of quotes in the 10 paragraphs preceding and including the paragraph where  $q$  appears that were attributed to  $s$ , and the number that were attributed to other speakers

### 6.3 Elson and McKeown Reimplementation

As part of our study we reproduce the core results of Elson and McKeown (2010) (E&M), as we believe it is a state-of-the-art system. This allows us to determine the effectiveness of our approach when compared to a state-of-the-art approach, and it also allows us to determine how well the E&M approach performs on other corpora. In this section we will briefly summarise the key elements needed to reproduce their work.

The E&M approach makes a binary classification between “speaker” and “not speaker” for up to 15 candidate speakers for each quote. They then reconcile these 15 classifications into one speaker predic-

tion for the quote. While E&M experimented with several different reconciliation methods, we simply chose the speaker with the highest probability attached to its “speaker” label.

We conducted an experiment using our implementation of the E&M method on the original, unaugmented E&M corpus, to see how our result compared with E&M’s 83%. On our test set we achieved 78.2%, however this rose to 82.3% when performing 10-fold cross validation across the whole corpus. Though this is a large difference, it is not necessarily that surprising, as our test set contains documents by authors which are unseen, whereas both the original E&M test set and all the cross validation test sets contain documents by authors that the learner has seen before.

In their work, E&M make a simplifying assumption that all previous attribution decisions were correct. Due to this, their sequence features use gold standard labels from previous quotes, which makes their results unrealistic. In Table 2 we show the effect of replacing the gold standard sequence features with features based on the predicted labels, or with no sequence features at all. All three corpora show a significant drop in accuracy, with the LIT corpus in particular suffering a drop of more than 25%. This motivates our study into including sequence information without using gold standard labels.

## 7 Class Models

We consider two class models for our experiments, which are described in detail below. The binary model is able to take advantage of more data but has less competition between decisions, while the  $n$ -way model has more competition with less data. Both models are used with all the decoding methods, with the exception that the binary model is unsuitable for the CRF experiments.

### 7.1 Binary

When working with  $n$  previous speakers, a binary class model works by predicting  $n$  independent “speaker” versus “not speaker” labels, one for each quote-speaker pair. As the classifications are independent the  $n$  decisions need to be reconciled, as more than one speaker might be predicted. We reconcile the  $n$  decisions by attributing the quote to the

speaker with the highest “speaker” probability. Using a binary class with reconciliation in a greedy decoding model is equivalent to the method in Elson and McKeown (2010), except that the gold standard sequence features are replaced with predicted sequence features.

## 7.2 *n*-way

A key advantage of the binary class model is that when predicting “speaker” versus “not speaker” the classifier only needs to predict one probability, and thus can take into account the evidence of all other quote-speaker pairs. The drawback to the binary model is that the probabilities assigned to the candidate speakers do not need to directly compete against each other. In other words when assigning a binary probability to a candidate speaker, the classifier does not take into account how good the other candidate speakers are.

To rectify these issues we experiment with a single classification for each quote, where the classifier directly decides between up to  $n$  candidate speakers per quote. As speaker-specific evidence is far too sparse, we encode the speakers with their ordinal position backwards from the quote. In other words, the candidate speaker immediately preceding the quote would be labelled “speaker1”, the speaker preceding it would be “speaker2” and so on. The classifier then directly predicts these labels. This representation means that candidate speakers need to directly compete for probability mass, although it has the drawback that the evidence for the higher-numbered speakers is quite sparse.

The features we use for this representation are similar to the features used in the E&M binary model. The key difference is that where there were individual features that were calculated with respect to the speaker, there are now  $n$  features, one for each of the speaker candidates. This allows the model to account for the strength of other candidates when assigning a speaker label.

## 8 Sequence Decoding

We noted in the previous section that the E&M results are based on the unrealistic assumption that all previous quotes were attributed correctly. In this section we outline three sequence decoding ap-

proaches that remove this unrealistic assumption, without removing all of the transition information that it provides. We believe the transition information is important as many quotes have no explicit attribution in the text, and instead rely on the reader understanding something about the sequence of speakers.

For these experiments we regard the set of speaker attributions in a document as the sequence that we want to decode. Each individual state therefore represents a sequence of  $w$  previous attribution decisions, and a decision for the current quote. Obtaining a probability for this state can be done in one of two ways. Either the transition probabilities from state to state can be learned explicitly, or the  $w$  previous attribution decisions can be used to build the sequence features for the current state, which implicitly encodes the transition probabilities.

### 8.1 Greedy Decoding

In sequence decoding the greedy algorithm calculates the probability of each label at a decision point based on the predictions it has already made for previous decisions. More concretely this means we apply a standard classifier at each step, with the sequence features being calculated from the predictions made in previous steps. Greedy decoding is efficient in that it only considers one possible history at each decision point, but it is consequently unable to make trade-offs between good previous choices and good current choices, which means that in general it will not return the optimum sequence of labels. As greedy decoding is an efficient algorithm we do not restrict  $w$ , the number of previous decisions, beyond the 10 paragraph restriction that is already in place.

### 8.2 Viterbi Decoding

Viterbi decoding finds the most probable path through a sequence of decisions. It does this by determining the probabilities of each of the labels at the current decision point, with each of the possible histories of decisions within a given window  $w$ . These probabilities can be multiplied together with the previous decisions to retrieve a joint probability for the entire sequence. The final decision for each quote is then just the speaker which is predicted by the sequence with the largest joint probability.

Although they do not come with probabilities, we chose to include the category predictions in our Viterbi model. As we already know that they are accurate indicators of the speaker we assign them a probability of 100%, which effectively forces the Viterbi decoder to choose the category predictions when they are available. It is worth noting that quotes are only assigned to the *Conversation* category if the two prior quotes had alternating speakers. As such, during the Viterbi decoding the categorisation of the quote actually needs to be recalculated with regard to the two previous attribution decisions. By forcing the Viterbi decoder to choose category predictions when they are available, we get the advantage that quote sequences with no intervening text may be forced into the *Conversation* category, which is typically under-represented otherwise.

Both the sequences using the binary class and the  $n$ -way class can be decoded using the Viterbi algorithm, so we experiment with both class models. We also experiment with varying window sizes ( $w$ ), in order to gain insight into how many previous decisions impact the current decision. Though the Viterbi algorithm is able to find the best sequence of probabilities without the need for an exhaustive search, it can still take an impractical amount of time to run. As such we ignore all but the 10 most promising sequences at each decision point.

### 8.3 Conditional Random Field (CRF) Decoding

The key drawback with the logistic regression experiments described thus far is that the sequence features are trained with gold standard information. This means that during the training phase the sequence features have perfect information about previous speakers and are thus unrealistically good predictors of the final outcome. When the resulting model is used with the less accurate predicted sequence features, it is overconfident about the information those features provide.

We account for this by using a first-order linear chain CRF model, which learns the probabilities of progressing from speaker to speaker more directly. During training the CRF is able to learn the association between features and labels, as well as the chance of transitioning from one label to the next. It also has the advantage of avoiding the label bias problem that would be present in the equivalent Hid-

den Markov Model (Lafferty et al., 2001).

Though the  $n$ -way class model can be used directly in a CRF, the binary class model is more challenging. The main problem is that the “speaker” versus “not speaker” output of the binary classifier does not directly form a meaningful sequence that the CRF can learn over. If the reconciliation step is included it effectively adds an extra layer to the linear chain, making learning more difficult. Due to these difficulties we only use the  $n$ -way class model in our CRF experiments.

## 9 Results

The main result of our experiments with the E&M method is the large drop in accuracy that occurs when the gold standard sequence features are removed, which can be seen in Table 3. When using the binary class model this results in a drop of 25.1% for the LIT corpus, while for the WSJ and SMH corpora the drop is less substantial at 4.4% and 2.6%, respectively. For the LIT corpus the drop is so severe that it actually performs worse than the simple rule-based system. Even more surprisingly, when the predictions from previous decisions are used with a simple greedy decoder, the accuracy drops even further for all three corpora. This indicates that the classifier is putting too much weight on the gold standard sequence features during training, and is misled into making poor decisions when the predicted features are used during test time.

Table 4 shows the results for the  $n$ -way class model. Compared to the binary model, the  $n$ -way class model generally produced lower results, although the results were more stable to changes in parameters and decoders. The only corpus that produced better results with the  $n$ -way class model was the WSJ corpus, which does not have full entity coreference information. This indicates that the  $n$ -way model may be helpful when there is more variability in the choice of entities.

The final results we would like to discuss here are the CRF results. On all three corpora the CRF results are underwhelming. The major issue that we can see when applying a CRF model to this task is that the sequences that it needs to learn over are entire documents. This means that for the LIT corpus the training set consisted of only 12 sequences, while

Corpus	E&M	Rule	No seq.	Greedy	Viterbi		
					<i>w</i> = 1	<i>w</i> = 2	<i>w</i> = 5
LIT	74.7	<b>53.3</b>	49.6	49.0	46.0	49.8	45.9
WSJ	87.3	77.9	82.9	74.1	82.3	<b>83.1</b>	<b>83.1</b>
SMH	95.0	91.2	<b>92.4</b>	85.6	91.7	90.5	84.1

Table 3: Accuracy on test set with the binary class model. Italicised results indicate gold standard information is used. Bold results show the best realistic result for each corpus.

Corpus	Gold seq.	Rule	No seq.	Greedy	Viterbi			CRF
					<i>w</i> = 1	<i>w</i> = 2	<i>w</i> = 5	
LIT	<i>68.6</i>	<b>53.3</b>	47.1	46.7	42.5	46.5	44.4	48.6
WSJ	88.9	77.9	83.6	77.0	<b>84.1</b>	83.7	83.3	79.6
SMH	<i>94.4</i>	<b>91.2</b>	90.0	89.6	89.5	90.1	90.4	91.0

Table 4: Accuracy on test set with the *n*-way class model. Italicised results indicate gold standard information is used. Bold results show the best realistic result for each corpus.

the test set consisted of 6 sequences. With so few sequences it is unsurprising that the CRF model did not perform well. The limited range of the first order linear chain model could also have played a part in the poor performance of the CRF models. However, moving to a higher-order model is problematic as the number of transition probabilities that need to be calculated increases exponentially with the order of the model.

## 10 Conclusion

In this paper, we present the first large-scale evaluation of a quote attribution system on newswire from the 1989 Wall Street Journal (WSJ) and the 2009 Sydney Morning Herald (SMH), as well as comparing against previous work (Elson and McKeown, 2010) on 19th-century literature.

We show that when Elson and McKeown’s unrealistic use of gold-standard history information is removed, accuracy on all three corpora drops substantially. We demonstrate that by treating quote attribution as a sequence labelling task, we can achieve results that are very close to their results on newswire, though not for literature.

In future work, we intend to further explore the sequence features that have a large impact on accuracy, and to find similar features or proxies for the sequence features that would be beneficial. We will also explore other approaches to representing quote

attribution with a CRF. For the task more broadly, it would be beneficial to compare methods of finding indirect and mixed quotes, and to evaluate how well quote attribution performs on those quotes as opposed to just direct quotes.

Our newswire results, 92.4% for the SMH and 84.1% for the WSJ corpus, demonstrate it is possible to develop an accurate and practical quote extraction system. On the LIT corpus our best result was from the simple rule-based system, which yielded 53.3%. It is clear that literature poses an ongoing research challenge.

## Abstract

Supervised hierarchical topic modeling and unsupervised hierarchical topic modeling are usually used to obtain hierarchical topics, such as hLLDA and hLDA. Supervised hierarchical topic modeling makes heavy use of the information from observed hierarchical labels, but cannot explore new topics; while unsupervised hierarchical topic modeling is able to detect automatically new topics in the data space, but does not make use of any information from hierarchical labels. In this paper, we propose a semi-supervised hierarchical topic model which aims to explore new topics automatically in the data space while incorporating the information from observed hierarchical labels into the modeling process, called *Semi-Supervised Hierarchical Latent Dirichlet Allocation (SSHLDA)*. We also prove that hLDA and hLLDA are special cases of SSLDA. We conduct experiments on Yahoo! Answers and ODP datasets, and assess the performance in terms of perplexity and clustering. The experimental results show that predictive ability of SSLDA is better than that of baselines, and SSLDA can also achieve significant improvement over baselines for clustering on the FScore measure.

## 1 Introduction

Topic models, such as latent Dirichlet allocation (LDA), are useful NLP tools for the statistical analysis of document collections and other discrete data.

Furthermore, hierarchical topic modeling is able to obtain the relations between topics — parent-child and sibling relations. Unsupervised hierarchical topic modeling is able to detect automatically new topics in the data space, such as hierarchical Latent Dirichlet Allocation (hLDA) (Blei et al., 2004). hLDA makes use of nested Dirichlet Process to automatically obtain a  $L$ -level hierarchy of topics. Modern Web documents, however, are not merely collections of words. They are usually documents with hierarchical labels – such as Web pages and their placement in hierarchical directories (Ming et al., 2010). Unsupervised hierarchical topic modeling cannot make use of any information from hierarchical labels, thus supervised hierarchical topic models, such as *hierarchical Labeled Latent Dirichlet Allocation (hLLDA)* (Petinot et al., 2011), are proposed to tackle this problem. hLLDA uses hierarchical labels to automatically build corresponding topic for each label, but it cannot find new latent topics in the data space, only depending on hierarchy of labels.

As we know that only about 10% of an iceberg’s mass is seen outside while about 90% of it is unseen, deep down in water. We think that a corpus with hierarchical labels should include not only observed topics of labels, but also there are more latent topics, just like icebergs. hLLDA can make use of the information from labels; while hLDA can explore latent topics. How can we combine the merits of the two types of models into one model?

An intuitive and simple combinational method is like this: first, we use hierarchy of labels as basic hierarchy, called Base Tree (BT); then we use hLDA to build automatically topic hierarchy for each leaf

\*This work was done in National University of Singapore.

†Corresponding author.

node in BT, called Leaf Topic Hierarchy (LTH); finally, we add each LTH to corresponding leaf in the BT and obtain a hierarchy for the entire dataset. We refer the method as Simp-hLDA. The performance of the Simp-hLDA is not so good, as can be seen from the example in Figure 3 (b). The drawbacks are: (i) the leaves in BT do not obtain reasonable and right words distribution, such as “Computers & Internet” node in Figure 3 (b), its topical words, “the to you and a”, is not about “Computers & Internet”; (ii) the non-leaf nodes in BT cannot obtain words distribution, such as “Health” node in Figure 3 (b); (iii) it is a heuristic method, and thus Simp-hLDA has no solid theoretical basis.

To tackle the above drawbacks, we explore the use of probabilistic models for such a task where the hierarchical labels are merely viewed as a part of a hierarchy of topics, and the topics of a path in the whole hierarchy generate a corresponding document. Our proposed generative model learns both the latent topics of the underlying data and the labeling strategies in a joint model, by leveraging on the hierarchical structure of labels and Hierarchical Dirichlet Process.

We demonstrate the effectiveness of the proposed model on large, real-world datasets in the question answering and website category domains on two tasks: the topic modeling of documents, and the use of the generated topics for document clustering. Our results show that our joint, semi-hierarchical model outperforms the state-of-the-art supervised and unsupervised hierarchical algorithms. The contributions of this paper are threefold: (1) We propose a joint, generative semi-supervised hierarchical topic model, i.e. Semi-Supervised Hierarchical Latent Dirichlet Allocation (SSHLDA), to overcome the defects of hLDA and hLLDA while combining their merits. SSHLDA is able to not only explore new latent topics in the data space, but also makes use of the information from the hierarchy of observed labels; (2) We prove that hLDA and hLLDA are special cases of SSHLDA; (3) We develop a gibbs sampling inference algorithm for the proposed model.

The remainder of this paper is organized as follows. We review related work in Section 2. In Section 3, we introduce some preliminaries; while we introduce *SSHLDA* in Section 4. Section 5 details

a gibbs sampling inference algorithm for SSHLDA; while Section 6 presents the experimental results. Finally, we conclude the paper and suggest directions for future research in Section 7.

## 2 Related Work

There have been many variations of topic models. The existing topic models can be divided into four categories: *Unsupervised non-hierarchical topic models*, *Unsupervised hierarchical topic models*, and their corresponding supervised counterparts.

Unsupervised non-hierarchical topic models are widely studied, such as LSA (Deerwester et al., 1990), pLSA (Hofmann, 1999), LDA (Blei et al., 2003), Hierarchical-concept TM (Chemudugunta et al., 2008c; Chemudugunta et al., 2008b), Correlated TM (Blei and Lafferty, 2006) and Concept TM (Chemudugunta et al., 2008a; Chemudugunta et al., 2008b) etc. The most famous one is Latent Dirichlet Allocation (LDA). LDA is similar to pLSA, except that in LDA the topic distribution is assumed to have a Dirichlet prior. LDA is a completely unsupervised algorithm that models each document as a mixture of topics. Another famous model that not only represents topic correlations, but also learns them, is the Correlated Topic Model (CTM). Topics in CTM are not independent; however it is noted that only pairwise correlations are modeled, and the number of parameters in the covariance matrix grows as the square of the number of topics.

However, the above models cannot capture the relation between super and sub topics. To address this problem, many models have been proposed to model the relations, such as Hierarchical LDA (HLDA) (Blei et al., 2004), Hierarchical Dirichlet processes (HDP) (Teh et al., 2006), Pachinko Allocation Model (PAM) (Li and McCallum, 2006) and Hierarchical PAM (HPAM) (Mimno et al., 2007) etc. The relations are usually in the form of a hierarchy, such as the tree or Directed Acyclic Graph (DAG). Blei et al. (2004) proposed the hLDA model that simultaneously learns the structure of a topic hierarchy and the topics that are contained within that hierarchy. This algorithm can be used to extract topic hierarchies from large document collections.

Although unsupervised topic models are suffi-

ciently expressive to model multiple topics per document, they are inappropriate for labeled corpora because they are unable to incorporate the observed labels into their learning procedure. Several modifications of LDA to incorporate supervision have been proposed in the literature. Two such models, Supervised LDA (Blei and McAuliffe, 2007; Blei and McAuliffe, 2010) and DiscLDA (Lacoste-Julien et al., 2008) are first proposed to model documents associated only with a single label. Another category of models, such as the MM-LDA (Ramage et al., 2009b), Author TM (Rosen-Zvi et al., 2004), FlatLDA (Rubin et al., 2011), Prior-LDA (Rubin et al., 2011), Dependency-LDA (Rubin et al., 2011) and Partially LDA (PLDA) (Ramage et al., 2011) etc., are not constrained to one label per document because they model each document as a bag of words with a bag of labels. However, these models obtain topics that do not correspond directly with the labels. Labeled LDA (LLDA) (Ramage et al., 2009a) can be used to solve this problem.

None of these non-hierarchical supervised models, however, leverage on dependency structure, such as parent-child relation, in the label space. For hierarchical labeled data, there are also few models that are able to handle the label relations in data. To the best of our knowledge, only hLLDA (Petinot et al., 2011) and HSLDA (Perotte et al., 2011) are proposed for this kind of data. HSLDA cannot obtain a probability distribution for a label. Although hLLDA can obtain a distribution over words for each label, hLLDA is unable to capture the relations between parent and child node using parameters, and it also cannot detect automatically latent topics in the data space. In this paper, we will propose a generative topic model to tackle these problems of hLLDA.

### 3 Preliminaries

The nested Chinese restaurant process (nCRP) is a distribution over hierarchical partitions (Blei et al., 2004). It generalizes the Chinese restaurant process (CRP), which is a distribution over partitions. The CRP can be described by the following metaphor. Imagine a restaurant with an infinite number of tables, and imagine customers entering the restaurant in sequence. The  $d^{th}$  customer sits at a table accord-

Table 1: Notations used in the paper.

Sym	Description
$V$	Vocabulary (word set), $w$ is a word in $V$
$D$	Document collection
$T_j$	The set of paths in the sub-tree whose root is the $j^{th}$ leaf node in the hierarchy of observed topics
$m$	A document $m$ that consists of words and labels
$\mathbf{w}_m$	The text of document $m$ , $w_i$ is $i^{th}$ words in $\mathbf{w}$
$\mathbf{c}_m$	The topic set of document $m$
$\mathbf{c}_{o_m}$	The set of topics with observed labels for document $m$
$\mathbf{c}_{e_m}$	The set of topics without labels for document $m$
$\mathbf{c}_{e-m}$	The set of latent topics for all documents other than $m$
$\mathbf{z}_{e_m}$	The assignment of the words in the $m^{th}$ document to one of the latent topics
$\mathbf{w}_{e_m}$	The set of the words belonging to one of the latent topics in the $m^{th}$ document
$z_{m,n}$	The assignment of the $n^{th}$ word in the $m^{th}$ document to one of the $L$ available topics
$\mathbf{z}$	The set of $z_{m,n}$ for all words in all documents
$c_i$	A topic in the $i^{th}$ level in the hierarchy
$\theta$	The word distribution set for $Z$ , i.e., $\{\theta\}_{z \in \mathcal{c}}$
$\alpha$	Dirichlet prior of $\theta$
$\delta_{c_i}$	The multinomial distribution over the sub-topics of $c_{i-1}$
$\mu_{c_i}$	Dirichlet prior of $\delta_{c_i}$
$\eta$	Dirichlet prior of $\beta$
$\beta$	The multinomial distribution of words
$\theta_m$	The distributions over topics for document $m$
$\theta$	The set for $\theta_m, m \in \{1, \dots, D\}$

ing to the following distribution,

$$p(c_d = k | c_{1:(d-1)}) \propto \begin{cases} m_k & \text{if } k \text{ is previous occupied} \\ \gamma & \text{if } k \text{ is a new label,} \end{cases} \quad (1)$$

where  $m_k$  is the number of previous customers sitting at table  $k$  and  $\gamma$  is a positive scalar. After  $D$  customers have sat down, their seating plan describes a partition of  $D$  items.

In the nested CRP, imagine now that tables are organized in a hierarchy: there is one table at the first level; it is associated with an infinite number of tables at the second level; each second-level table is associated with an infinite number of tables at the third level; and so on until the  $L^{th}$  level. Each customer enters at the first level and comes out at the  $L^{th}$  level, generating a path with  $L$  tables as she sits in each restaurant. Moving from a table at level  $l$  to one of its subtables at level  $l+1$ , the customer draws following the CRP using Formula (1). In this paper, we will make use of nested CRP to explore latent topics in data space.

To elaborate our model, we first define two concepts. If a model can learn a distribution over words for a label, we refer the topic with a corresponding label as a **labeled topic**. If a model can learn an unseen and latent topic without a label, we refer the

Figure 1: The graphical model of SSHLDA.

topic as a **latent topic**.

#### 4 The Semi-Supervised Hierarchical Topic Model

In this section, we will introduce a semi-supervised hierarchical topic model, i.e., the *Semi-Supervised Hierarchical Latent Dirichlet Allocation* (SSHLDA). SSHLDA is a probabilistic graphical model that describes a process for generating a hierarchical labeled document collection. Like hierarchical Labeled LDA (hLLDA) (Petinot et al., 2011), SSHLDA can incorporate labeled topics into the generative process of documents. On the other hand, like hierarchical Latent Dirichlet Allocation (hLDA) (Blei et al., 2004), SSHLDA can automatically explore latent topic in data space, and extend the existing hierarchy of observed topics. SSHLDA makes use of not only observed topics, but also latent topics.

The graphical model of SSHLDA is illustrated in Figure 1. In the model,  $N$  is the number of words in a document,  $D$  is the total number of documents in a collection,  $M$  is the number of leaf nodes in hierarchical observed nodes,  $c_i$  is a node in the  $i^{th}$  level in the hierarchical tree,  $\eta$ ,  $\alpha$  and  $\mu_{c_i}$  are dirichlet prior parameters,  $\beta_k$  is a distribution over words,  $\theta$  is a document-specific distribution over topics,  $\delta_{c_i}$  is a multinomial distribution over observed sub-topics of topic  $c_i$ ,  $w$  is an observed word,  $z$  is the topic assigned to  $w$ ,  $Dir_k(\cdot)$  is a  $k$ -dimensional Dirichlet distribution,  $T_j$  is a set of paths in the hierarchy of latent topics for  $j^{th}$  leaf node in the hierarchy of ob-

Figure 2: One illustration of SSHLDA. The tree has 5 levels. The shaded nodes are observed topics, and circled nodes are latent topics. The latent topics are generated automatically by SSHLDA model. After learning, each node in this tree will obtain a corresponding probability distribution over words, i.e. a topic.

served topics,  $\gamma$  is a Multi-nomial distribution over paths in the tree. All notations used in this paper are listed in Table 1.

SSHLDA, as shown in Figure 1, assumes the following generative process:

- (1) For each table  $k \in T$  in the infinite tree,
  - (a) Draw a topic  $\beta_k \sim Dir(\eta)$ .
- (2) For each document,  $m \in \{1, 2, \dots, D\}$ 
  - (a) Let  $c_1$  be the root node.
  - (b) For each level  $l \in \{2, \dots, L\}$ :
    - (i) If nodes in this level have been observed, draw a node  $c_l$  from  $Mult(\delta_{c_{l-1}} | \mu_{c_{l-1}})$ .
    - (ii) Otherwise, draw a table  $c_l$  from restaurant  $c_{l-1}$  using Formula (1).
  - (c) Draw an  $L$ -dimensional topic proportion vector  $\theta_m$  from  $Dir(\alpha)$ .
  - (d) For each word  $n \in \{1, \dots, N\}$ :
    - (i) Draw  $z \in \{1, \dots, L\}$  from  $Mult(\theta)$ .
    - (ii) Draw  $w_n$  from the topic associated with restaurant  $c_z$ .

As the example showed in Figure 2, we assume that we have known a hierarchy of observed topics:  $\{A1, A2, A17, A3, A4\}$ , and assume the height of the desired topical tree is  $L = 5$ . All circled nodes are latent topics, and shaded nodes are observed topics. A possible generative process for a document  $m$  can be: It starts from  $A1$ , and chooses node  $A17$  at level 2, and then chooses  $A18$ ,  $A20$  and  $A25$  in the following levels. Thus we obtain a path:  $c_m = \{A1, A17, A18, A20, A25\}$ . After getting the path for  $m$ , SSHLDA generates each word from one of topics in this set of topics  $c_m$ .

## 5 Probabilistic Inference

In this section, we describe a Gibbs sampling algorithm for sampling from the posterior and corresponding topics in the SSSLDA model. The Gibbs sampler provides a method for simultaneously exploring the model parameter space (the latent topics of the whole corpus) and the model structure space (L-level trees).

In SSSLDA, we sample the paths  $\mathbf{c}_m$  for document  $m$  and the per-word level allocations to topics in those paths  $z_{m,n}$ . Thus, we approximate the posterior  $p(\mathbf{c}_m, \mathbf{z}_m | \gamma, \eta, \mathbf{w}, \boldsymbol{\mu})$ . The hyper-parameter  $\gamma$  reflects the tendency of the customers in each restaurant to share tables,  $\eta$  denotes the expected variance of the underlying topics (e.g.,  $\eta \ll 1$  will tend to choose topics with fewer high-probability words),  $\mu_{c_i}$  is the dirichlet prior of  $\delta_{c_i}$ , and  $\boldsymbol{\mu}$  is the set of  $\mu_{c_i}$ .  $w_{m,n}$  denotes the  $n^{\text{th}}$  word in the  $m^{\text{th}}$  document; and  $c_{m,l}$  represents the restaurant corresponding to the  $l^{\text{th}}$ -level topic in document  $m$ ; and  $z_{m,n}$ , the assignment of the  $n^{\text{th}}$  word in the  $m^{\text{th}}$  document to one of the  $L$  available topics. All other variables in the model,  $\theta$  and  $\beta$ , are integrated out. The Gibbs sampler thus assesses the values of  $z_{m,n}$  and  $c_{m,l}$ .

The Gibbs sampler can be divided into two main steps: the sampling of level allocations and the sampling of path assignments.

First, given the values of the SSSLDA hidden variables, we sample the  $c_{m,l}$  variables which are associated with the CRP prior. Noting that  $\mathbf{c}_m$  is composed of  $\mathbf{c}_{o_m}$  and  $\mathbf{c}_{e_m}$ ,  $\mathbf{c}_{o_m}$  is the set of observed topics for document  $m$ , and  $\mathbf{c}_{e_m}$  is the set of latent topics for document  $m$ . The conditional distribution for  $\mathbf{c}_m$ , the  $L$  topics associated with document  $m$ , is:

$$\begin{aligned} p(\mathbf{c}_m | \mathbf{z}, \mathbf{w}, \mathbf{c}_{-m}, \boldsymbol{\mu}) \\ = p(\mathbf{c}_{o_m} | \boldsymbol{\mu}) p(\mathbf{c}_{e_m} | \mathbf{z}_{e_m}, \mathbf{w}_{e_m}, \mathbf{c}_{e_{-m}}) \\ \propto p(\mathbf{c}_{o_m} | \boldsymbol{\mu}) p(\mathbf{w}_{e_m} | \mathbf{c}_{e_m}, \mathbf{w}_{e_{-m}}, \mathbf{z}_{e_m}) \\ p(\mathbf{c}_{e_m} | \mathbf{c}_{e_{-m}}) \end{aligned} \quad (2)$$

where

$$p(\mathbf{c}_{o_m} | \boldsymbol{\mu}) = \prod_{i=0}^{|\mathbf{c}_{o_m}|-1} p(c_{i,m} | \mu_{c_i}) \quad (3)$$

and

$$\begin{aligned} p(\mathbf{w}_{e_m} | \mathbf{c}_{e_m}, \mathbf{w}_{e_{-m}}, \mathbf{z}_{e_m}) \\ = \prod_{l=1}^{|\mathbf{c}_{e_m}|} \left( \frac{\Gamma(n_{c_{e_m,l},-m} + |V|\eta)}{\prod_w \Gamma(n_{c_{e_m,l},-m}^w + \eta)} \times \right. \\ \left. \frac{\prod_w \Gamma(n_{c_{e_m,l},-m}^w + n_{c_{e_m,l},m}^w + \eta)}{\Gamma(n_{c_{e_m,l},-m} + n_{c_{e_m,l},m} + |V|\eta)} \right) \end{aligned} \quad (4)$$

$\mathbf{c}_{e_{-m}}$  is the set of latent topics for all documents other than  $m$ ,  $\mathbf{z}_{e_m}$  is the assignment of the words in the  $m^{\text{th}}$  document to one of the latent topics, and  $\mathbf{w}_{e_m}$  is the set of the words belonging to one of the latent topics in the  $m^{\text{th}}$  document.  $n_{c_{e_m,l},-m}^w$  is the number of instances of word  $w$  that have been assigned to the topic indexed by  $c_{e_m,l}$ , not including those in the document  $m$ .

Second, given the current state of the SSSLDA, we sample the  $z_{m,n}$  variables of the underlying SSSLDA model as follows:

$$\begin{aligned} p(z_{m,n} = j | \mathbf{z}_{-(m,n)}, \mathbf{w}, \mathbf{c}_m, \boldsymbol{\mu}) \\ \propto \frac{n_{-n,j}^m + \alpha}{n_{-n,\cdot}^m + |\mathbf{c}_m|} \cdot \frac{n_{-n,j}^{w_{m,n}} + \eta w_{m,n}}{n_{-(m,n)} + |V|} \end{aligned} \quad (5)$$

Having obtained the full conditional distribution, the Gibbs sampling algorithm is then straightforward. The  $z_{m,n}$  variables are initialized to determine the initial state of the Markov chain. The chain is then run for a number of iterations, each time finding a new state by sampling each  $z_{m,n}$  from the distribution specified by Equation (5). After obtaining individual word assignments  $\mathbf{z}$ , we can estimate the topic multinomials and the per-document mixing proportions. Specifically, the topic multinomials are estimated as:

$$\beta_{\mathbf{c}_{m,j},i} = p(w_i | z_{\mathbf{c}_{m,j}}) = \frac{\eta + n_{z_{\mathbf{c}_{m,j}}}^{w_i}}{|V|\eta + \sum n_{z_{\mathbf{c}_{m,j}}}^i} \quad (6)$$

while the per-document mixing proportions fixed can be estimated as:

$$\theta_{m,j} = \frac{\alpha + n_{\cdot,j}^m}{|\mathbf{c}_m|\alpha + n_{\cdot,\cdot}^m}, j \in 1, \dots, |\mathbf{c}_m| \quad (7)$$

### 5.1 Relation to Existing Models

In this section, we draw comparisons with the current state-of-the-art models for hierarchical topic

modeling (Blei et al., 2004; Petinot et al., 2011) and show that at certain choices of the parameters of our model, these methods fall out as special cases.

Our method generalises not only *hierarchical Latent Dirichlet Allocation* (hLDA), but also *Hierarchical Labeled Latent Dirichlet Allocation* (hLLDA). Our proposed model provides a unified framework allowing us to model hierarchical labels while to explore new latent topics.

**Equivalence to hLDA** As introduced in Section 2, hLDA is a unsupervised hierarchical topic model. In this case, there are no observed nodes, that is, the corpus has no hierarchical labels. This means  $\mathbf{c}_m$  is equal to  $\mathbf{c}_{e_m,m}$ ; meanwhile the factor  $p(\mathbf{c}_{o_m,m}|\boldsymbol{\mu})$  is always equal to one because each document has root node, and this allows us to rewrite Formula (2) as:

$$p(\mathbf{c}_m|\mathbf{z}, \mathbf{w}, \mathbf{c}_{-m}, \boldsymbol{\mu}) \propto p(\mathbf{w}_{c_m}|\mathbf{c}, \mathbf{w}_{-m}, \mathbf{z})p(\mathbf{c}_m|\mathbf{c}_{-m}) \quad (8)$$

which is exactly the same as the conditional distribution for  $\mathbf{c}_m$ , the  $L$  topics associated with document  $m$  in hLDA model. In this case, our model becomes equivalent to the hLDA model.

**Equivalence to hLLDA** hLLDA is a supervised hierarchical topic model, which means all nodes in hierarchy are observed. In this case,  $\mathbf{c}_m$  is equal to  $\mathbf{c}_{o_m,m}$ , and this allows us to rewrite Formula (2) as:

$$p(\mathbf{c}_m|\mathbf{z}, \mathbf{w}, \mathbf{c}_{-m}, \boldsymbol{\mu}) = p(\mathbf{c}_m|\boldsymbol{\mu}) \propto p(\mathbf{c}_{o_m}|\boldsymbol{\mu}) \quad (9)$$

which is exactly the same as the step “Draw a random path assignment  $\mathbf{c}_m$ ” in the generative process for hLLDA. Consequentially, in this sense our model is equivalent to hLLDA.

## 6 Experiments

We demonstrate the effectiveness of the proposed model on large, real-world datasets in the question answering and website category domains on two tasks: the topic modeling of documents, and the use of the generated topics for document clustering.

### 6.1 Datasets

To construct comprehensive datasets for our experiments, we crawled data from two websites. First, we crawled nearly all the questions and associated answer pairs (QA pairs) of two top cat-

Table 2: The statistics of the datasets.

Datasets	#labels	#paths	Max level	#docs
Y_Ans	46	35	4	6,345,786
O_Hlth	6695	6505	10	54939
O_Home	2432	2364	9	24254

egories of Yahoo! Answers: *Computers & Internet* and *Health*. This produced forty-three sub-categories from 2005.11 to 2008.11, and an archive of 6,345,786 QA documents. We refer the Yahoo! Answer data as *Y\_Ans*.

In addition, we first crawled two categories of Open Directory Project (ODP)\*: *Home* and *Health*. Then, we removed all categories whose number of Web sites is less than 3. Finally, for each of Web sites in categories, we submitted the url of each Web site to Google and used the words in the snippet and title of the first returned result to extend the summary of the Web site. We denote the data from the category *Home* as *O\_Home*, and the data from the category *Health* as *O\_Hlth*.

The statistics of all datasets are summarized in Table 2. From this table, we can see that these datasets are very diverse: *Y\_Ans* has much fewer labels than *O\_Hlth* and *O\_Home*, but have much more documents for each label; meanwhile the depth of hierarchical tree for *O\_Hlth* and *O\_Home* can reach level 9 or above.

All experiments are based on the results of models with a burn-in of 10000 Gibbs sampling iterations, symmetric priors  $\alpha = 0.1$  and free parameter  $\eta = 1.0$ ; and for  $\boldsymbol{\mu}$ , we can obtain the estimation of  $\mu_{c_i}$  by fixed-point iteration (Minka, 2003).

### 6.2 Case Study

With topic modeling, the top associated words of topics can be used as good descriptors for topics in a hierarchy (Blei et al., 2003; Blei and McAuliffe, 2010). We show in Figure 3 a pair of comparative example of the proposed model and a baseline model over *Y\_Ans* dataset. The tree-based topic visualizations of Figure 3 (a) and (b) are the results of SShLDA and Simp-hLDA.

We have three major observations from the example: (i) SShLDA is a unified and generative model, after learning, it can obtain a hierarchy of topics;

\*<http://dmoz.org/>

Figure 3: (a) A sub network discovered on *Y.Ans* dataset using SSSLDA, and the whole tree has 74 nodes; (b) A sub network discovered on *Y.Ans* dataset using Simp-hLDA algorithm, and the whole tree has 89 nodes. In both figures, the shaded and squared nodes are observed labels, not topics; the shaded and round nodes are topics with observed labels; blue nodes are topics but without labels and the yellow node is one of leaves in hierarchy of labels. Each topic represented by top 5 terms.

while Simp-hLDA is a heuristic method, and its result is a mixture of label nodes and topical nodes. For example, Figure 3 (b) shows that the hierarchy includes label nodes and topic nodes, and each of labeled nodes just has a label, but label nodes in Figure 3 (a) have their corresponding topics. (ii) During obtaining a hierarchy, SSSLDA makes use of the information from observed labels, thus it can generate a logical, structural hierarchy with parent-child relations; while Simp-hLDA does not incorporate prior information of labels into its generation process, thus although it can obtain a hierarchy, many parent-child pairs have not parent-child relation. For example, in Figure 3 (b), although label “root” is a parent of label “Computers & Internet”, the topical words of label “Computers & Internet” show the topical node is not a child of label “root”. However, in Figure 3 (a), label “root” and “Computers & Internet” has corresponding parent-child relation between their topical words. (iii) In a hierarchy of topics, if a topical node has corresponding label, the label can help people understand descendant topical nodes. For example, when we know node “error files click screen virus” in Figure 3 (a) has its label “Computers & Internet”, we can understand the child topic “hard screen usb power dell” is about

“computer hardware”. However, in Figure 3 (b), the labels in parent nodes cannot provide much information to understand descendant topical nodes because many label nodes have not corresponding right topical words, such as label “Computers & Internet”, its topical words, “the to you and a”, do not reflect the connotation of the label.

These observations further confirm that SSSLDA is better than the baseline model.

### 6.3 Perplexity Comparison

A good topic model should be able to generalize to unseen data. To measure the prediction ability of our model and baselines, we compute the perplexity for each document  $d$  in the test sets. *Perplexity*, which is widely used in the language modeling and topic modeling community, is equivalent algebraically to the inverse of the geometric mean per-word likelihood (Blei et al., 2003). Lower perplexity scores mean better. Our model, SSSLDA, will compare with three state-of-the-art models, i.e. Simp-hLDA, hLDA and hLLDA. Simp-hLDA has been introduced in Section 1, and hLDA and hLLDA has been reviewed in Section 2. We keep 80% of the data collection as the training set and use the remaining collection as the held-out test set. We build the mod-

els based on the train set and compute the perplexity of the test set to evaluate the models. Thus, our goal is to achieve lower perplexity score on a held-out test set. The perplexity of  $M$  test documents is calculated as:

$$\text{perplexity}(D_{test}) = \exp \left\{ -\frac{\sum_{d=1}^M \sum_{m=1}^{N_d} \log p(w_{dm})}{\sum_{d=1}^M N_d} \right\} \quad (10)$$

where  $D_{test}$  is the test collection of  $M$  documents,  $N_d$  is document length of document  $d$  and  $w_{dm}$  is  $m^{\text{th}}$  word in document  $d$ .

We present the results over the *O\_Hlth* dataset in Figure 4. We choose top 3-level labels as observed, and assume other labels are not observed, i.e.  $l = 3$ . From the figure, we can see that the perplexities of SSSLDA, are lower than that of Simp-hLDA, hLDA and hLLDA at different value of the tree height parameter, i.e.  $L \in \{5, 6, 7, 8\}$ . It shows that the performance of SSSLDA is always better than the state-of-the-art baselines, and means that our proposed model can model the hierarchical labeled data better than the state-of-the-art models. We can also obtain similar experimental results over *Y\_Ans* and *O\_Home* datasets, and their detailed description is not included in this paper due to the limitation of space.

#### 6.4 Clustering performance

To evaluate indirectly the performance of the proposed model, we compare the clustering performance of following systems: 1) the proposed model; 2) Simp-hLDA; 3) hLDA; 4) agglomerative clustering algorithm. There are many agglomerative clustering algorithms, and in this paper, we make use of the single-linkage method in a software package called CLUTO (Karypis, 2005) to obtain hierarchies of clusters over our datasets, with words as features. We refer the method as *h-clustering*.

Given a document collection  $DS$  with a  $H$ -level hierarchy of labels, each label in the hierarchy and corresponding documents will be taken as the ground truth of clustering algorithms. The hierarchy of labels denoted as *GT-tree*. The process of evaluation is as follows. First, we choose top  $l$ -level labels in *GT-tree* as an observed hierarchy, i.e. Base Tree (BT), and we need to construct a  $L$ -level hierarchy ( $l < L \leq H$ ) over the documents  $DS$  using a

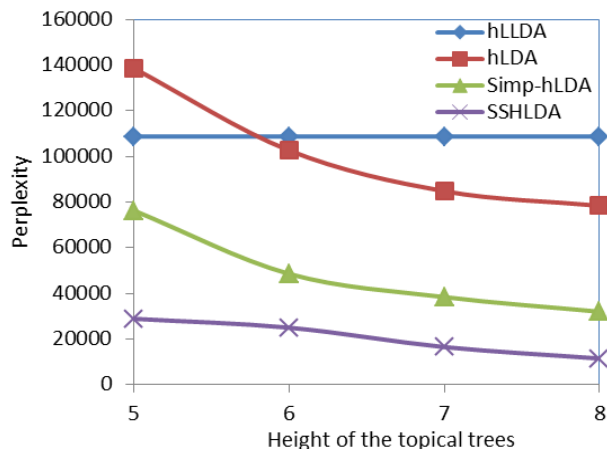

Figure 4: Perplexities of hLLDA, hLDA, Simp-hLDA and SSSLDA. The results are run over the *O\_Hlth* dataset, with the height of the hierarchy of observed labels  $l = 3$ . The X-axis is the height of the whole topical tree ( $L$ ), and Y-axis is the perplexity.

model. The remaining labels in *GT-tree* and corresponding documents are the ground truth classes, each class denoted as  $C_i$ . Then, (i) for h-clustering, we run single-linkage method over the documents  $DS$ . (ii) for Simp-hLDA, hLDA runs on the documents in each leaf-node in BT, and the height parameter is  $(L - l)$  for each hLDA. After training, each document is assigned to top-1 topic according to the distribution over topics for the document. Each topic and corresponding documents forms a new cluster. (iii) for hLDA, hLDA runs on all documents in  $DS$ , and the height parameter is  $L$ . Similar to Simp-hLDA, each document is assigned to top-1 topic. Each topic and corresponding documents forms a new cluster. (iv) for SSSLDA, we set height parameter as  $L$ . After training, each document is also assigned to top-1 topic. Topics and their corresponding documents form a hierarchy of clusters.

##### 6.4.1 Evaluation Metrics

For each dataset we obtain corresponding clusters using the various models described in previous sections. Thus we can use clustering metrics to measure the quality of various algorithms by using a measure that takes into account the overall set of clusters that are represented in the new generated part of a hierarchical tree.

One such measure is the FScore measure, intro-

duced by (Manning et al., 2008). Given a particular class  $C_r$  of size  $n_r$  and a particular cluster  $S_i$  of size  $n_i$ , suppose  $n_{ri}$  documents in the cluster  $S_i$  belong to  $C_r$ , then the FScore of this class and cluster is defined to be

$$F(C_r, S_i) = \frac{2 \times R(C_r, S_i) \times P(C_r, S_i)}{R(C_r, S_i) + P(C_r, S_i)} \quad (11)$$

where  $R(C_r, S_i)$  is the recall value defined as  $n_{ri}/n_r$ , and  $P(C_r, S_i)$  is the precision value defined as  $n_{ri}/n_i$  for the class  $C_r$  and the cluster  $S_i$ . The FScore of the class  $C_r$ , is the maximum FScore value attained at any node in the hierarchical clustering tree  $T$ . That is,

$$F(C_r) = \max_{S_i \in T} F(C_r, S_i). \quad (12)$$

The FScore of the entire clustering solution is then defined to be the sum of the individual class FScore weighted according to the class size.

$$FScore = \sum_{r=1}^c \frac{n_r}{n} F(C_r), \quad (13)$$

where  $c$  is the total number of classes. In general, the higher the FScore values, the better the clustering solution is.

#### 6.4.2 Experimental Results

Each of hLDA, Simp-hLDA and SSHLDA needs a parameter—the height of the topical tree, i.e.  $L$ ; and for Simp-hLDA and SSHLDA, they need another parameter—the height of the hierarchical observed labels, i.e.  $l$ . The h-clustering does not have any height parameters, thus its FScore will keep the same values at different height of the topical tree. With choosing the height of hierarchical labels for *O\_Home* as 4, i.e.  $l = 4$ , the results of our model and baselines with respect to the height of a hierarchy are shown in Figure 5.

From the figure, we can see that our proposed model can achieve consistent improvement over the baseline models at different height, i.e.  $L \in \{5, 6, 7, 8\}$ . For example, the performance of SSHLDA can reach 0.396 at height 5 while the h-clustering, hLDA and hLLDA only achieve 0.295, 0.328 and 0.349 at the same height. The result shows that our model can achieve about 34.2%, 20.7% and 13.5% improvements over h-clustering, hLDA and

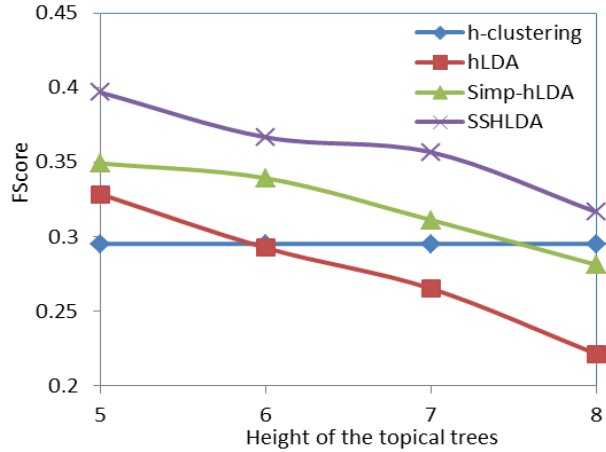

Figure 5: FScore measures of h-clustering, hLDA, Simp-hLDA and SSHLDA. The results are run over the *O\_Home* dataset, with the height of the hierarchy of observed labels  $l = 3$ . The X-axis is the height of the whole topical tree ( $L$ ), and Y-axis is the FScore measure.

hLLDA at height 5. The improvements are significant by t-test at the 95% significance level. We can also obtain similar experimental results over *Y\_Ans* and *O\_Hlth*. However, for the same reason of limitation of space, their detailed descriptions are skipped in this paper.

## 7 Conclusion and Future work

In this paper, we have proposed a semi-supervised hierarchical topic models, i.e. SSHLDA, which aims to solve the drawbacks of hLDA and hLLDA while combine their merits. Specially, SSHLDA incorporates the information of labels into generative process of topic modeling while exploring latent topics in data space. In addition, we have also proved that hLDA and hLLDA are special cases of SSHLDA. We have conducted experiments on the Yahoo! Answers and ODP datasets, and assessed the performance in terms of Perplexity and FScore measure. The experimental results show that the prediction ability of SSHLDA is the best, and SSHLDA can also achieve significant improvement over the baselines on Fscore measure.

In the future, we will continue to explore novel topic models for hierarchical labeled data to further improve the effectiveness; meanwhile we will also apply SSHLDA to other media forms, such as image, to solve related problems in these areas.

## Abstract

Many NLP tasks make predictions that are inherently coupled to syntactic relations, but for many languages the resources required to provide such syntactic annotations are unavailable. For others it is unclear exactly how much of the syntactic annotations can be effectively leveraged with current models, and what structures in the syntactic trees are most relevant to the current task.

We propose a novel method which avoids the need for any syntactically annotated data when predicting a related NLP task. Our method couples latent syntactic representations, constrained to form valid dependency graphs or constituency parses, with the prediction task via specialized factors in a Markov random field. At both training and test time we marginalize over this hidden structure, learning the optimal latent representations for the problem. Results show that this approach provides significant gains over a syntactically uninformed baseline, outperforming models that observe syntax on an English relation extraction task, and performing comparably to them in semantic role labeling.

## 1 Introduction

Many NLP tasks are inherently tied to syntax, and state-of-the-art solutions to these tasks often rely on syntactic annotations as either a source for useful features (Zhang et al., 2006, path features in relation extraction) or as a scaffolding upon which a more narrow, specialized classification can occur (as often done in semantic role labeling). This decou-

pling of the end task from its intermediate representation is sometimes known as the **two-stage** approach (Chang et al., 2010) and comes with several drawbacks. Most notably this decomposition prohibits the learning method from utilizing the labels from the end task when predicting the intermediate representation, a structure which must have some correlation to the end task to provide any benefit.

Relying on intermediate representations that are specifically syntactic in nature introduces its own unique set of problems. Large amounts of syntactically annotated data is difficult to obtain, costly to produce, and often tied to a particular domain that may vary greatly from that of the desired end task. Additionally, current systems often utilize only a small amount of the annotation for any particular task. For instance, performing named entity recognition (NER) jointly with constituent parsing has been shown to improve performance on both tasks, but the only aspect of the syntax which is leveraged by the NER component is the location of noun phrases (Finkel and Manning, 2009). By instead discovering a latent representation jointly with the end task we address all of these concerns, alleviating the need for any syntactic annotations, while simultaneously attempting to learn a latent syntax relevant to both the particular domain and structure of the end task.

We phrase the joint model as factor graph and marginalize over the hidden structure of the intermediate representation at both training and test time, to optimize performance on the end task. Inference is done via loopy belief propagation, making this framework trivially extensible to most graph structures. Computation over latent syntactic rep-

representations is made tractable with the use of special combinatorial factors which implement unlabeled variants of common dynamic-programming parsing algorithms, constraining the hidden representation to realize valid dependency graphs or constituency trees.

We apply this strategy to two common NLP tasks, coupling a model for the end task prediction with latent and general syntactic representations via specialized logical factors which learn associations between latent and observed structure. In comparisons with identical models which observe “gold” syntactic annotations, derived from off-the-shelf parsers or provided with the corpora, we find that our hidden marginalization method is comparable in both tasks and almost every language tested, sometimes significantly outperforming models which observe the true syntax.

The following sections serve as a preliminary, introducing an inventory of factors and variables for constructing factor graph representations of syntactically-coupled NLP tasks. Section 3 explores the benefits of this method on relation extraction (RE), where we compare the use of dependency and constituency structure as latent representations. We then turn to a more established semantic role labeling (SRL) task (§4) where we evaluate across a wide range of languages.

## 2 Latent Pseudo-Syntactic Structure

The models presented in this paper are phrased in terms of variables in an undirected graphical model, Markov random field. More specifically, we implement the model as a factor graph, a bipartite graph composed of factors and variables in which we can efficiently compute the marginal beliefs of any variable set with the sum-product algorithm for cyclic graphs, *loopy belief propagation*. We now introduce the basic variable and factor components used throughout the paper.

### 2.1 Latent Dependency Structure

Dependency grammar is a lexically-oriented syntactic formalism in which syntactic relationships are expressed as dependencies between individual words. Each non-root word specifies another as its head, provided that the resulting structure forms

a valid directed graph, ie. there are no cycles in the graph. Due to the flexibility of this representation it is often used to describe free-word-order languages, and increasingly preferred in NLP for more language-in-use scenarios. A dependency graph can be modeled with the following nodes, as first proposed by Smith and Eisner (2008):

- Let  $\{Link(i, j) : 0 \leq i \leq j \leq n, n \neq j\}$  be  $O(n^2)$  boolean variables corresponding to the possible links in a dependency parse.  $Link(i, j) = \text{true}$  implies that there is a dependency from parent  $i$  to child  $j$ .
- Let  $\{LINK(i, j) : 0 \leq i \leq j \leq n, n \neq j\}$  be  $O(n^2)$  unary factors, each paired with a corresponding  $Link(i, j)$  variable and expressing the independent belief that  $Link(i, j) = \text{true}$ .

### 2.2 Latent Constituency Structure

Alternatively we can describe the more structured constituency formalism by setting up a representation over span variables:

- Let  $\{Span(i, j) : 0 \leq i < j \leq n\}$  be  $O(n^2)$  boolean variables such that  $Span(i, j) = \text{true}$  iff there is a bracket spanning  $i$  to  $j$ <sup>1</sup>.
- Let  $\{SPAN(i, j) : 0 \leq i < j \leq n\}$  be  $O(n^2)$  unary factors, each attached to the corresponding  $Span(i, j)$  variable. These factors score the independent suitability of each span to appear in an unlabeled constituency tree.

All boolean variables presented in this paper will be paired to unary factors in this manner, which we will omit in future descriptions. This encompasses the necessary *representational* structure for both syntactic formalisms, but nothing introduced up to this point guarantees that either of these representations will form a valid tree or DAG.

### 2.3 Combinatorial Factors

Naively constraining these latent representations through the introduction of many interconnected ternary factors is possible, but would likely be computationally intractable. However, as observed in

<sup>1</sup>In practice, we do not need to include variables for spans of width 1 or  $n$ , since they will always be true.

Smith and Eisner (2008), we can encapsulate common dynamic programming algorithms within special-purpose factors to efficiently globally constrain variable configurations. Since the outgoing messages from such factors to a variable can be computed from the factor’s posterior beliefs about that variable, there is no difficulty in exchanging beliefs between these special-purpose factors and the rest of the graph, and inference can proceed using the standard sum-product or max-product belief propagation. Here we present two combinatorial factors that provide efficient ways of constraining the model to fit common syntactic frameworks.

- Let CKYTREE be a global combinatorial factor, as used in previous work in efficient parsing (Naradowsky and Smith, 2012), attached to all the  $Span(i, j)$  variables. This factor contributes a factor of 1 to the model’s score iff the span variables collectively form a legal, binary bracketing and a factor of 0 otherwise. It enforces, therefore, a hard constraint on the variables, computing beliefs via an unlabeled variant of the inside-outside algorithm.
- Let DEP-TREE be a global combinatorial factor, as presented in Smith and Eisner (2008), which attaches to all  $Link(i, j)$  variables and similarly contributes a factor of 1 iff the configuration of  $Link$  variables forms a valid projective dependency graph. A graph is projective if its edges do not cross.

## 2.4 Marginal MAP Inference

It is straightforward to train these latent variable models to maximize the marginal probability of their outputs, conditioning on their inputs, and marginalizing out the latent syntactic variables. To compute feature expectations, we can use marginal inference techniques such as sampling and sum-product belief propagation to compute marginal probabilities.

A knottier problem arises when we want to find the best assignment to the variables of interest while marginalizing out “nuisance” latent variables. This is the problem of **marginal MAP** inference—sometimes known as consensus decoding—which has been shown to be NP-hard and without a polynomial time approximation scheme (Sima’an, 1996;

Casacuberta and Higuera, 2000). In the NLP community, these inference problems often arise when dealing with *spurious ambiguity* where multiple derivations can lead to the same derived structure. In tree substitution grammars, for instance, there may be many ways of combining elementary trees to produce the same output tree; in machine translation, many different elementary phrases or elementary tree pairs might produce the same output string. For syntactic parsing, Goodman (1996) proposed a variational method for summing out spurious ambiguity that was equivalent to minimum Bayes risk decoding (Goel and Byrne, 2000; Kumar and Byrne, 2004) with a constituent-recall loss function. For MT, May and Knight (2006) proposed methods for determinizing tree automata to reduce ambiguity, and Li et al. (2009) proposed a variational method based on n-gram loss functions. More recently, Liu and Ihler (2011) analyzed message-passing algorithms for marginal MAP.

In this paper, we adopt a simple minimum Bayes risk decoding scheme. First, we perform sum-product belief propagation on the full factor graph. Then, we maximize the expected accuracy of the variables of interest, subject to any hard constraints on them (such as mutual exclusion among labels). In some cases with complex combinatorial constraints, this simple MBR scheme has proved more effective than exact decoding over all variables (Auli and Lopez, 2011).

## 3 Relation Extraction

Performing a syntax-based NLP task in most real-world scenarios requires that the incoming data first be parsed using a pre-trained parsing model. For some tasks, like relation extraction, many data sets lack syntactic annotation and these circumstances persist even into the training phase. In this section we explore such scenarios and contrast the use of parser-provided syntactic annotation to marginalizing over latent representations of constituency or dependency syntax. We show the hidden syntactic models are not just competitive with these “oracle” models, but in some configurations can actually outperform them.

Relation extraction is the task of identifying semantic relations between sets of entities in text (as

illustrated in Fig. 1b), and a good proving ground for latent syntactic methods for two reasons. First, because entities share a semantic relationship, under most linguistic analyses these entities will also share some syntactic relation. Indeed, syntactic features have long been an extremely useful source of information for relation extraction systems (Culotta and Sorensen, 2004; Mintz et al., 2009). Secondly, relation extraction has been a common task for pioneering efforts in processing data mined from the internet, and otherwise noisy or out-of-domain data. In particular, large noisily-annotated data sets have been generated by leveraging freely available knowledge bases such as Freebase (Bollacker et al., 2008; Mintz et al., 2009). Such data sets have been utilized successfully for relation extraction from the web (Bunescu and Mooney, 2007).

### 3.1 Model

We present a simple model for representing relational structure, with the only variables present being a set of boolean-valued variables representing an undirected dependency between two entities, and an additional set of boolean label variables representing the type label of the relation.

- Let  $\{Rel(i, j) : 0 \leq i < j \leq n\}$  be  $O(n^2)$  boolean variables such that  $Rel(i, j) = \text{true}$  iff there is a relation spanning  $i$  to  $j$ .
- Let  $\{Rel\text{-Label}(i, j, \lambda) : \lambda \in L, \text{ and } 0 \leq i < j \leq n\}$  be  $O(|L|n^2)$  boolean variables such that  $Rel\text{-Label}(i, j, \lambda) = \text{true}$  iff there is a relation spanning  $i$  to  $j$  with relation type  $\lambda$ .
- Let  $\{ATMOST1(i, j) : 0 \leq i < j \leq n\}$  be  $O(n^2)$  factors, each coordinating the set  $L$  of possible nonterminal variables to the  $Rel$  variable at each  $i, j$  tuple, allowing a  $Rel\text{-Label}$  variable to be  $\text{true}$  iff all other label variables are  $\text{false}$  and  $Rel(i, j) = \text{true}$ .

Here the  $Rel(i, j)$  and  $Rel\text{-Label}(i, j)$  variables simply express the representation of the problem, while the  $ATMOST1$  factors are logical constraints ensuring that only one label will apply to a particular relation.

### 3.2 Coordination Factors

An important contribution of this work is the introduction of a flexible, general framework for connecting the latent and observable partitions of the model. We accomplish this through the use of two additional factors, each expressing the same basic logic, which learn when to coordinate and when to ignore correlations between the latent syntax and the end task. While here we specify binary and ternary versions of these factors, they also generalize to higher dimensions.

- Let  $\{D\text{-CONNECT}(i, j, k) : 0 \leq i < j \leq n; 0 \leq k \leq n\}$  be  $O(n^3)$  factors coordinating any number of dependency syntax  $Link(i, j)$  variables with representational variables on the end task, multiplying in 1 to the model score unless all variables are on, in which case it multiplies a connective potential  $\phi$  derived from its features. Thus it functions logically as a soft NAND factor. In this ternary formulation  $k$  represents a hidden dependency head or pivot which is shared between two syntactic dependencies anchored at the indices of the entities in the relation (as illustrated in Fig. 1).
- Let  $\{C\text{-CONNECT}(i, j) : 0 \leq i < j \leq n\}$  be  $O(n^2)$  factors coordinating syntactic  $Span(i, j)$  and relation arc  $Rel(i, j)$ , identically to  $D\text{-CONNECT}$  but with a 1-to-1 mapping. Intuitively the joint model might learn  $\phi > 1$ , i.e., constituency spans and task prediction relations are more likely to be coterminous.

The difficulty in working with latent dependency syntax is that we posit that the RE variables do not share a 1-to-1 mapping with variables in the hidden representation. We expect instead, according to linguistic intuition, that a relation between entities at position  $i$  and  $j$  in the sentence should have corresponding syntactic dependencies but that they are likely to realize this by sharing the same head word (as depicted in Fig.1), a word whose identity should help label the relation. Therefore we introduce a special coordination factor,  $D\text{-CONNECT}$  as a ternary factor to capture the relationship between pairs of latent syntactic variables and a single relation variable, pivoting on the same unknown head word.

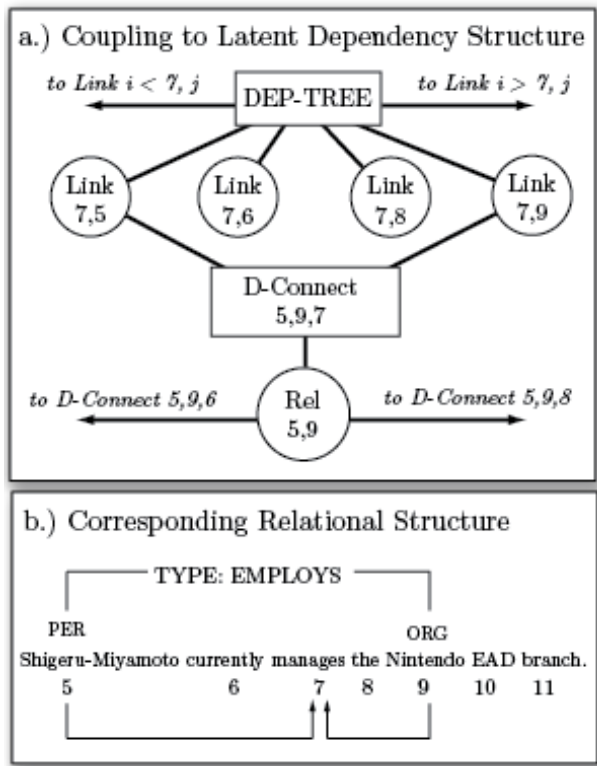

Figure 1: Latent Dependency coupling for the RE task. The D-CONNECT factor expresses ternary connection relations because the shared head word of the proposed relation is unknown. As is convention, variables are represented by circles, factors by rectangles.

We introduce six model scenarios.

- **Baseline**, simply the arc-factored model consisting only of *Rel* and corresponding *Label* variables for each entity. Features on the relation factors, which are common to all model configurations, are combinations of lexical information (i.e., the words that form the entity, the pos-tags of the entities, etc.) as well as the distance between the relation. This is a lightweight model and generally does not attempt to exhaustively leverage all possible proven sources of useful features (Zhou et al., 2005) towards a higher absolute score, but rather to serve as a point of comparison to the models which rely on syntactic information.
- **Baseline-Ent**, a variant of **Baseline** with additional features which include combinations of mention type, entity type, and entity sub-type.

- **Oracle D-Parse**, in which we also instantiate a full set of latent dependency syntax variables, and connect them to the baseline model using D-CONNECT factors. Syntax variables are clamped to their true values.
- **Oracle C-Parse**, the constituency syntax analogue of **Oracle D-Parse**.
- **Hidden D-Parse**, which is an extension of **Oracle D-Parse** in which we connect all syntax variables to a DEP-TREE factor, syntax variables are unobserved, and are learned jointly with the end task. The features for latent syntax are a subset of those used in dependency parsing (McDonald et al., 2005).
- **Hidden C-Parse**, the constituency syntax analogue of **Hidden D-Parse**. The feature set is similar but bigrams are taken over the words defining the constituent span, rather than the words defining the head/modifier relation.

Coordination factor features for the syntactically-informed models are particularly important. This became evident in initial experiments where the baseline was often able to outperform the hidden syntactic model. However, inclusion of entity and mention label features into the connection factors provides the model with greater reasoning over when to coordinate or ignore the relation predictions with the underlying syntax. These are a proper subset of the **Baseline-Ent** features.

### 3.3 Data

We evaluate these models using the 2005 Automatic Content Extraction (ACE) data set (Walker, 2006), using the English (dual-annotated) and Chinese (solely annotator #1 data set) sections. Each corpus is annotated with entity mentions—tagged as PER, ORG, LOC, or MISC—and, where applicable, what type of relation exists between them (e.g., coarse: PHYS; fine: Located). But like most corpora available for the task, the burden of acquiring corresponding syntactic annotation is left to the researcher. In this situation it is common to turn to existing pre-trained parsing models.

We generate our data by first splitting the raw text paragraphs into sentences. Chinese sentences

ACE Results												
Model	English						Chinese

Table 1: Relation Extraction Results. Models using hidden constituency syntax provide significant gains over the syntactically-uniformed baseline model in both languages, but the advantages of the latent syntax were mitigated on the smaller Chinese data set.

are also tokenized according to Penn Chinese Treebank standards (Xue et al., 2005). The sentences are then tagged and parsed using the Stanford CoreNLP tools, using the standard pre-trained models for tagging (Toutanova and Manning, 2000), and the factored parsing model of Klein and Manning (2002). The distributed grammar is trained on a variety of sources, including the standard Wallstreet Journal corpus, but also biomedical, translation, and questions. We then apply entity and relation annotations noisily to the data, collapsing multi-word entities into one term. We filter out sentences with fewer than two entities (and are thus incapable of containing relations) and sentences with more than 40 words (to keep the parses more reliable). This yields 6966 sentences for English data, but unfortunately only 747 sentences for the Chinese. Nine of every ten sentences comprise the training set, with every tenth sentence reserved for test.

### 3.4 Results

We train all models using 20 iterations of stochastic gradient descent, each with a maximum of 10 BP iterations (though in practice we find convergence to often occur much earlier). The results are presented in Table 1, showing precision, recall, and F-measure for both labeled and unlabeled prediction. For English, not only is the hidden marginalization method a suitable replacement for the syntactic trees provided by pre-trained, state-of-the-art models, but in both configurations we find that inducing an optimal hidden structure is preferable to the parser-produced annotations. On Chinese, where the data set is atypically small, we still observe improved performance

over the baseline in the constituency-based model though it is not able to match the observed syntax model.

Despite the intuition that both entities occupy roles as modifiers of the same verb, we find that the **Hidden D-Parse** model often fails to recover the correct latent structure, and that even when successful dependency parses are observed, the head word is often not uniquely indicative of the relation type (as *known* is not strongly correlated with the relation type EMPLOYEES in the phrase: *Shigeru Miyamoto, best known for his work at the video game company Nintendo*). Hence when it comes to relation extraction, at least on our relatively small data sets, we find the simplest approach to latent syntactic structure is the best.

We now turn to the task of semantic role labeling to evaluate this method on a more established hand-annotated data set, and a more varied set of languages.

## 4 Semantic Role Labeling

The task of semantic role labeling (SRL) aims to detect and label the semantic relationships between particular words, most commonly verbs (referred to in the domain as *predicates*), and their *arguments* (Meza-Ruiz and Riedel, 2009).

In a manner similar to RE, there is a strong correlation between the presence of an SRL relation and there existing an underlying syntactic dependency, though this is not always expressed as directly as a 1-to-1 correspondence. This has historically motivated a reliance on syntactic annotation, and some of the most successful methods have simply applied

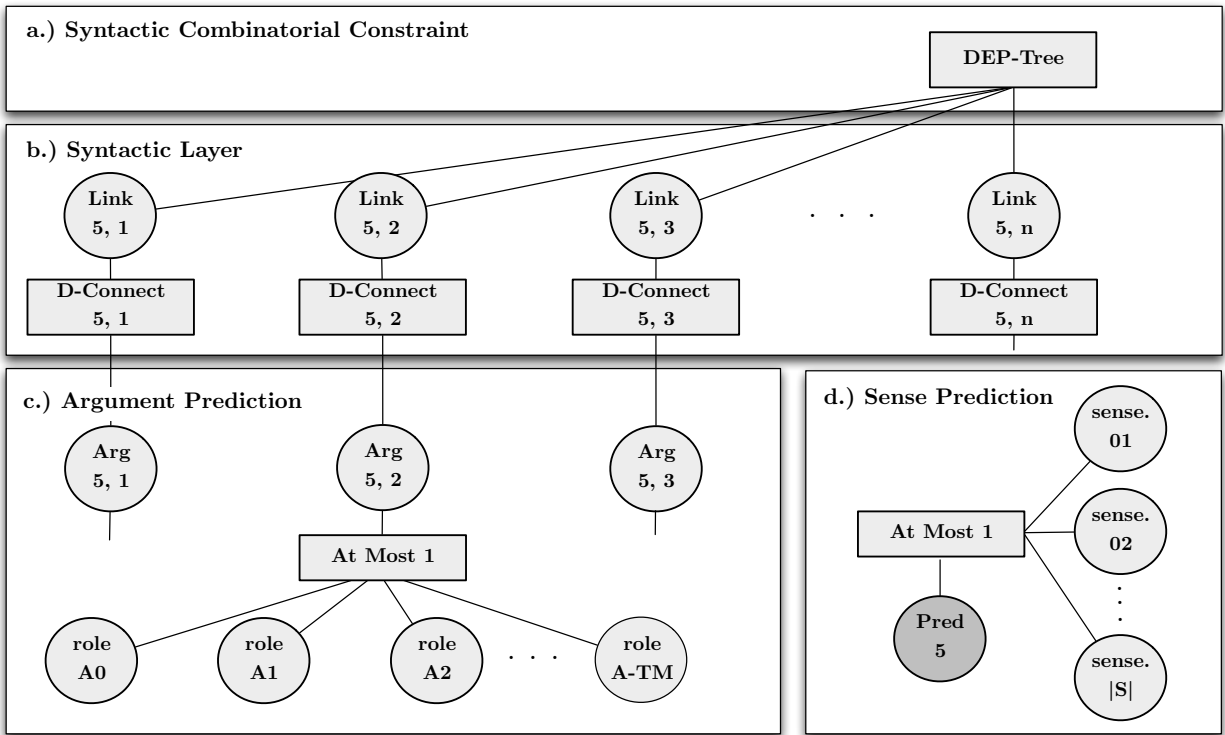

Figure 2: A tiered graphic representing the three different SRL model configurations. The baseline system is described in the bottom (c & d), the separate panels highlighting the independent predictions of this model: sense labels are assigned in an entirely separate process from argument prediction. Pruning in the model takes place primarily in this tier, since we observe true predicates we only instantiate over these indices. The middle tier (b.) illustrates the syntactic representation layer, and the connective factors between syntax and SRL. In the observed syntax model the *Link* variables are clamped to their correct values, with no need for a factor to coordinate them to form a valid tree. Finally, the hidden model comprises all layers, including a combinatorial syntactic constraint (a.) over syntactic variables. In this scenario all labels in (b.) are hidden at both training and test time.

feature-rich classifiers to the parsed trees. Related work has recognized the large annotation burden the task demands, but aimed to keep the syntactic annotations and induce semantic roles (Lang and Lapata, 2010). In this section we will take the opposite approach, disregarding the syntactic annotations which we argue are more costly to acquire, as they require more formal linguistic training to produce.

#### 4.1 Model

We present a simple, flexible model for SRL in which sense predictions are made independently of the rest of the model, and argument predictions are made independently of each other. The model structure is composed as depicted in Fig. 2.

- Let  $\{Arg(i, j) : 0 \leq i < j \leq n\}$  be  $O(n^2)$  boolean variables such that  $Arg(i, j) = \text{true}$

iff predicate  $i$  takes token  $j$  as an argument.

- Let  $\{Role(i, j, \lambda) : \lambda \in L, \text{ and } 0 \leq i < j \leq n\}$  be  $O(|L|n^2)$  boolean variables such that  $Role(i, j, \lambda) = \text{true}$  iff  $Arg(i, j)$  is true and takes the role label  $\lambda$ .
- Let  $\{Sense(i, \sigma) : \sigma \in S, \text{ and } 0 \leq i \leq n\}$  be  $O(|S|n)$  boolean variables such that  $Sense(i, \sigma) = \text{true}$  iff predicate  $i$  has sense  $\sigma$ .

##### 4.1.1 Features

At the coarsest level both the SRL and RE models are specifying binary predictions between a pair of indices in the sentence, and a set of labels for each dependency that happens to be true. Similarly we use almost identical features in SRL as we did in

Figure 3: Examining the learned hidden representation for SRL. In this example the syntactic dependency arcs derived from gold standard syntactic annotations (*left*) are entirely disjoint from the correct predicate/arguments pairs (shown in the heatmaps by the squares outlined in black), and the observed syntax model fails to recover any of the correct predictions. In contrast, the hidden model structure (*right*) learns a representation that closely parallels the desired end task predictions, helping it recover three of the four correct SRL predictions (shaded arcs: red corresponds to a correct prediction, with true labels GA, KARA, etc.), and providing some evidence towards the fourth. The dependency tree corresponding to the hidden structure is derived by edge-factored decoding: dependency variables whose beliefs  $> 0.5$  are classified as true (though some arcs not relevant to the SRL predictions are omitted for clarity).

RE, with the sole exception that we incorporate the observable lemma and morphological features into bigrams on predicate/argument pairs. For sense prediction we rely only on unigram features taken in a close ( $w = 2$ ) window of the target predicate.

For the coordinating factors we use subsets of combinations of word, part-of-speech, and capitalization features taken between head and argument, and concatenate these with the distance and direction between the predicate and argument. We do not find the performance of the system to be as sensitive to which features are present in the coordinating factors as we did in the RE task.

## 4.2 Data

We evaluate our SRL model using the data set developed for the CoNLL 2009 shared task competition

(Hajič et al., 2009), which features seven languages and provides an ideal opportunity to measure the ability of the hidden structure to generalize across languages of disparate origin and varied characteristics. It also provides the opportunity to observe a variety of different annotation styles and biases, some of which our model was able to uncover as ill-suited to common models for the task. The data itself provides word, lemma, part-of-speech, and morphological feature information, along with gold dependency parses. Words which denote predicates are identified, and their (train time) arguments are provided. They are also annotated with a sense label for each predicate, which is scored as an additional SRL dependency. Thus the task involves predicting for each predicate a set of argument dependencies and the sense label associated with that predicate.

Table 2: SRL Results. The hidden model excels on the unlabeled prediction results, often besting the scores obtained using the parses distributed with the CoNLL data sets. These gains did not always translate to the labeled task where poor sense prediction hindered absolute performance.

### 4.3 Results

We evaluate across a set of model configurations analogous to before. All experiments used 30 iterations of SGD with a Gaussian prior, and a max 10 iterations of BP to compute the marginals for each example. In comparison to the CoNLL competition entries (Table 2, rightmost columns) our syntactically-informed models generally fall in the middle of the rankings. This is not surprising given the independent predictions of the model and the very general, language universal assumptions we have made in the model structure and feature sets. However, in terms of gauging the usefulness of the hidden syntactic marginalization method the results are extremely compelling, with only marginal differences between the performance of the observed-syntax model, especially relative to the baseline.

And despite the simplicity of the model, we still manage to perform at state-of-the-art levels in a few instances, sometimes outperforming most of the competition entries without observing any syntax. The performance on Chinese is an example of this,

with our system outperforming all but the best system, and the hidden syntactic model only slightly behind.

Abstracting away from the performance comparisons against other systems, the unlabeled results are the more revealing evidence for the use of hidden syntactic structure. Here the average hidden model score (88.89) almost outperforms the observed syntax model (90.22, and vs. 66.80 baseline), mostly due to the large margins on the unlabeled Japanese scores. The strong independence between sense prediction and argument prediction hinders performance on the labeled task, but on all languages we find an extremely significant improvement exploiting hidden syntactic structure in comparison to the baseline system—the hidden model recovers more than 92% of the gap between the baseline and the observed syntax model. It is also interesting to note that in the shared task competition the two languages which systems lost the most performance between their parsing F1 and their SRL F1 were Japanese and German. As illustrated in Fig. 3, the corre-

spondence between syntax and SRL are extremely, and systematically, poor. In this example our hidden structure model was able to assign strong beliefs to the latent syntactic variables which correspond to the correct predicate/argument pairs, allowing it to correctly identify three of the four SRL arguments when the joint model failed to recover one.

## 5 Related Work

This work is perhaps mostly closely related to the Learning over Constrained Latent Representations (LCLR) framework of Chang et al. (2010). Their abstract problem formulation is identical: both paradigms seek to couple the end task to an intermediate representation which is not accessible to the learning algorithm. However much of the intent, scale, and methodology is different. LCLR aims to provide a flexible latent structure for increasing the representational power of the model in a useful way, and is demonstrated on tasks and domains where data availability is not a key concern. In contrast, while our hidden structure models may outperform their observed syntax counterparts, our focus is as much on alleviating the burden of procuring large amounts of syntactic annotation as it is about increasing the expressiveness of the model. To that end we constrain a more sophisticated latent representation and couple it to highly structured output predictions, opposed to binary classification problems. In methodology, we perform the more computationally intensive marginalization operation instead of maximizing.

Marginalization of hidden structure is also fundamental to other work, and featured most prominently in generative Bayesian latent variable models (Teh et al., 2006). Our approach is trained discriminatively, affording the use of very rich feature sets and the prediction of partial structures without needing to specify a full derivation. Similar approaches have been used in more linear latent variable CRF-based models (McCallum et al., 2005), but these must only marginalize only over hidden states of a much more compact representation. Naively extending this to tree-based constraints would often be computationally inefficient, and we avoid intractability through the encapsulation of much of the dynamic programming machinery into specialized factors. Moreover,

using loopy belief propagation means that the inference method is not closely coupled to the task structure, and need not change when applying this method to other types of graphs.

## 6 Conclusion

We have presented a novel method of coupling syntactically-oriented NLP tasks to combinatorially-constrained hidden syntactic representations, and have shown that marginalizing over this latent representation not only provides significant improvements over syntactically-uninformed baselines, but occasionally improves performance when compared to systems which observe syntax. On the task of relation extraction we find that a constituency representation provides the most improvement over the baseline, while in the SRL domain our model is extremely competitive with the best reported results on Chinese, and outperforms the model using the provided parses on German and Japanese.

We believe this method delivers very promising results in our presented tasks, opening the door to new lines of research examining what types of constraints and what configurations of hidden structure are most beneficial for particular tasks and languages. Moreover, we present one type of coordinating factor, as both D-CONNECT and C-CONNECT logically express a soft NAND function, but more sophisticated coupling schemes are another natural direction to pursue. Finally, we use sum-product variant of belief propagation inference, but more specialized inference schemes may show additional benefits.

## Abstract

Past work on learning part-of-speech taggers from tag dictionaries and raw data has reported good results, but the assumptions made about those dictionaries are often unrealistic: due to historical precedents, they assume access to information about labels in the raw and test sets. Here, we demonstrate ways to learn hidden Markov model taggers from incomplete tag dictionaries. Taking the MIN-GREEDY algorithm (Ravi et al., 2010) as a starting point, we improve it with several intuitive heuristics. We also define a simple HMM emission initialization that takes advantage of the tag dictionary and raw data to capture both the openness of a given tag and its estimated prevalence in the raw data. Altogether, our augmentations produce improvements to performance over the original MIN-GREEDY algorithm for both English and Italian data.

## 1 Introduction

Learning accurate part-of-speech (POS) taggers based on plentiful labeled training material is generally considered a solved problem. The best taggers obtain accuracies of over 97% for English newswire text in the Penn Treebank, which can be considered as an upper-bound that matches human performance on the same task (Manning, 2011). However, as Manning notes, this story changes as soon as one is working with different assumptions and data, including having less training data, different kinds of training data, other languages, and other domains. Such POS tagging work has been plentiful and includes efforts to induce POS tags without labels (Christodoulopoulos et al., 2010); learn from

POS-tag dictionaries (Ravi et al., 2010), incomplete dictionaries (Hasan and Ng, 2009) and human-constructed dictionaries (Goldberg et al., 2008); bootstrap taggers for a language based on knowledge about other languages (Das and Petrov, 2011), and creating supervised taggers for new, challenging domains such as Twitter (Gimpel et al., 2011).

Here, we focus on learning from tag dictionaries. This is often characterized as unsupervised or weakly supervised training. We adopt the terminology *type-supervised* training to distinguish it from unsupervised training from raw text and supervised training from word tokens labeled with their parts-of-speech. Work on type-supervision goes back to (Merialdo, 1994), who introduced the still standard procedure of using a bigram Hidden Markov Model (HMM) trained via Expectation Maximization.

Early research appeared to show that learning from types works nearly as well as learning from tokens, with researchers in the 1990s obtaining accuracies up to 96% on English (e.g. Kupiec (1992)). However, the tag dictionaries in these cases were obtained from labeled tokens. While replicating earlier experiments, Banko and Moore (2004) discovered that performance was highly dependent on cleaning tag dictionaries using statistics gleaned from the *tokens*. This greatly simplifies the job of a type-supervised HMM: it no longer must entertain entries for uncommon word-tag pairs (or mistaken pairs due to annotation errors), which otherwise stand on equal footing with the common ones. When the full, noisy tag dictionary was employed, Banko and Moore found accuracies dropped from 96% to 77%.

Banko and Moore's observations spurred a new line of research that sought to improve performance in the face of full, noisy dictionaries; see Ravi and

Knight (2009) for an overview. The highest accuracy achieved to date under these assumptions is 91.6% (Ravi et al., 2010). However, as is often noted (including by the authors themselves), many papers that work on learning taggers from tag dictionaries make unrealistic assumptions about the tag dictionaries they use as input (Toutanova and Johnson, 2008; Ravi and Knight, 2009; Hasan and Ng, 2009). For example, tag dictionaries are typically constructed with every token-tag pair in the data, including those that appear only in the test set. This means that the evaluation of these taggers does not measure how they perform on sentences that contain unseen words or unseen word-tag pairs, a likely occurrence in real use of a trained tagger.

We show that it is possible to achieve good tagging accuracy using a noisy and incomplete tag dictionary that has no access to the tags of the raw and test data and no access to the tag frequency information of the labeled training data from which the dictionary is drawn. We build on Ravi et al.’s (2010) model minimization approach, which reduces dictionary noise by greedily approximating the minimum set of tag bigrams needed to cover the raw data and exploits that information as a constraint on the initialization of the model before running EM. We extend their method in four distinct ways.

1. Enable the algorithm to be used with incomplete dictionaries by exploiting the type-based information provided by the tag dictionary and raw text to initialize EM, and by training a standard supervised HMM on the output of EM.
2. Improve the greedy procedure to find a better minimized set of tag-tag bigrams.
3. Modify the method to return only the set of bigrams required to tag sentences instead of keeping all bigrams chosen by minimization.
4. Exploit the paths found during minimization as a direct initialization for EM.

Together, these improvements make it possible to use model minimization in a realistic context, and obtain higher performance: on English, results go from 63.5% for a vanilla HMM to 82.1% for an HMM that uses strategies to deal with unknowns, then to 85.0% with Ravi and Knight’s minimization and finally to 88.5% with our enhancements.

## 2 Supervision for HMMs

Hidden Markov Models (HMMs) are well-known generative probabilistic sequence models commonly used for POS-tagging. The probability of a tag sequence given a word sequence is determined from the product of emission and transition probabilities:

$$P(t|w) \propto \prod_{i=1}^N P(w_i|t_i) \cdot P(t_i|t_{i-1})$$

HMMs can be trained directly from labeled data by calculating maximum likelihood estimates or from incomplete data using Expectation Maximization (EM) (Dempster et al., 1977). We use both strategies in this work: EM is used to estimate models that can automatically label raw tokens, and then a new HMM is estimated from that auto-labeled data.

### 2.1 Token-supervised training

We use a simple but effective smoothing regime to account for unknown words and unseen tag-tag transitions. For emissions:

$$P(w_i|t_i) = \frac{C(t_i, w_i) + \alpha(t_i)P_{uni}(w_i)}{C(t_i) + \alpha(t_i)}$$

where  $P_{uni}(w_i)$  is the unigram probability of  $w_i$ , and  $\alpha(t_i)$  is a tag specific amount of mass for smoothing. We use one-count smoothing (Chen and Goodman, 1996), where  $\alpha(t_i)$  is based on the number of words that occur with  $t_i$  once:

$$\alpha(t_i) = |w_i : C(t_i, w_i) = 1|$$

Since open-class tags occur more frequently with words that appear once, they will reserve more mass for unknown words than closed-class tags will. The transition distributions are smoothed in a similar fashion:

$$P(t_i|t_{i-1}) = \frac{C(t_{i-1}, t_i) + \lambda(t_{i-1})P_{uni}(t_i)}{C(t_{i-1}) + \lambda(t_{i-1})}$$

$$\lambda(t_{i-1}) = |t_i : C(t_{i-1}, t_i) = 1|$$

This simple scheme is quite effective: an HMM trained on the Penn Treebank sections 0-18 and evaluated on sections 19-21 and smoothed in this way obtains 96.5% accuracy. We do not use gold standard labels elsewhere for this paper, but do use this model on the output of type-supervised HMMs.

## 2.2 Type-supervised training

We are primarily interested in learning taggers from tag dictionaries combined with unlabeled text. As is standard, we use EM to iteratively estimate the transition and emission probability parameters to maximize the likelihood of unlabeled data. It is known, however, that EM has particular problems learning a good HMM for POS tagging (Johnson, 2007; Ravi and Knight, 2009). One reason is that EM generally tries to learn probability distributions that are fairly uniform while POS tag frequencies are quite skewed. For example, “a” appears in the training data with seven different tags, but 99.9% of “a” tokens are determiners. Thus, the accuracy of anything approaching a uniform distribution for “a” tags will suffer greatly. In the context of unsupervised POS tagging models, modeling this distinction greatly improves results (Moon et al., 2010). Here, we can simply exploit the tag dictionary and raw data.

An initial set of parameters for the transitions and emissions must be supplied as the input to EM. Given just a tag dictionary, the simplest initialization is to set all tag transitions to be uniform, ranging over all tag continuations, while for emissions, a uniform distribution over all words that occur with the tag is assigned. This may be appropriate when a complete tag dictionary is available, including complete information for words that appear only in the test data. This is because there will never be any unknown words during model estimation or inference. Likewise, there will never be a situation where the tag dictionary rules out all possible tag transitions between two adjacent tokens in training or testing. As a result, no smoothing is needed in this scenario.

The problem with this is that estimating a model based on type-supervision requires raw text, and if we have an incomplete tag dictionary, some of the words in that text will be missing from the tag dictionary. In a Bayesian setting, priors provide mass for such tokens; models are estimated using either Gibbs sampling or variational inference (Johnson, 2007). However, we use vanilla EM here; as a consequence, once a parameter is zero, it is always zero. We thus need to ensure that mass is reserved for words outside the tag dictionary at the start of EM. (For transitions, uniform distributions are sufficient since the set of tags is closed.)

## 2.3 Emission probability initialization

The simplest way to initialize the emission distributions is to assign a count of one to every entry in the tag dictionary, and one count for unknowns. Then, during each iteration of EM, the expectation step is able to estimate new non-zero counts for all possible emissions encountered in the raw corpus. This basic strategy allows one to train an HMM with EM using only an incomplete tag dictionary and raw text. However, this basic approach for emission probabilities produces bad unknown-word probabilities. Specifically, if for each tag we simply assume one count for each entry in the tag dictionary and one count for unknowns and then normalize, the probability of an unknown word having a specific tag is inversely correlated with the number of word types associated with the tag in the tag dictionary. In other words, a tag that appears with a smaller number of distinct words will be seen by the HMM as being a better candidate tag for an unknown word. Unfortunately this is the opposite behavior we want since closed-class tags like *determiner* and *preposition* are bad candidates for tagging novel words.

For type-supervised training, we can do much better. Note that  $C(w, t)$  comes in two varieties:  $w$  is either found in the tag dictionary (known word types), or it is not (unknown word types). We refer to the later as td-unknown: these are words that occur in the raw word sequence used for EM but which do not occur in the tag dictionary. These are thus different unknowns from words have not been observed in the dictionary or in the raw set but which may be encountered at test time. Computing the full  $C(w, t)$  is necessary since we want  $P(w|t)$  to cover known and td-unknown words. We must thus determine both  $C_{known}(w, t)$  and  $C_{unktd}(w, t)$ .

First, we focus on calculating  $C_{known}(w, t)$ . If a word  $w$  appears  $C(w)$  times in the raw corpus, and is seen with  $|TD(w)|$  tags in the tag dictionary, then assume for each  $t$  in  $TD(w)$ :

$$C_{known}(w, t) = C(w) / |TD(w)|$$

and  $C_{known}(w, t) = 0$  for all other  $t$ . In other words, we split  $C(w)$ , the count of  $w$  tokens in the corpus, evenly among each of  $w$ 's possible tags. This provides us with an estimate of the true  $C(w, t)$  by approximating the portion of the counts of each word

type that may be associated with that tag. Note that while this will give us zeros for any words that don't appear in the raw corpus, this is not a problem because EM training is based only on that corpus.

Second, we look at td-unknown word types: those in the raw data that are *not* found in the tag dictionary. Given the value  $P(unk_{td}|t)$  for the likelihood of an unknown word given a tag  $t$ , we can compute estimated counts  $C_{unk_{td}}(w, t)$  for a td-unknown word  $w$  using

$$C_{unk_{td}}(w, t) = C(w) \cdot P(unk_{td}|t)$$

where  $C(w)$ , again, comes from the raw corpus. This has the effect of spreading  $C(w)$ , the count of tokens of that unknown word  $w$ , across all of the possible tags, with each tag receiving a proportion of the total count as determined by  $P(unk_{td}|t)$ .

The challenge, then, is to compute  $P(unk_{td}|t)$ . For this, we have two potential sources of knowledge, the tag dictionary and the raw token sequence, each telling us complementary information.

First, the tag dictionary tells us about the openness of a tag—the likelihood that an unseen word will have that label—based on our previously-discussed intuition that we are more likely to see a new word with a tag that is known to be associated with many words already. Thus, we can estimate  $P_{td}(unk_{td}|t)$  by simply normalizing the  $|TD(t)|$  values:

$$P_{td}(unk_{td}|t) = \frac{|TD(t)|^2}{\sum_{t' \in Tags} |TD(t')|^2}$$

We exaggerate the differences between tags by squaring the  $|TD(t)|$  terms to draw an even larger distinction between open and closed class types.

Unfortunately, if we calculate an estimated word count directly from this using  $C_{unk_{td}}(w, t) = C(w) \cdot P_{td}(unk_{td}|t)$ , the  $C_{unk_{td}}(w, t)$  values would be taken without any regard to the overall likelihood of tag  $t$ . Since  $C_{known}(NN)$  is very high,  $C_{unk_{td}}(NN)$  will seem very low by comparison. Likewise, since  $C_{known}(RB)$  is much lower,  $C_{unk_{td}}(RB)$  will seem very high by comparison.

$P(unk_{td}|t)$  must account for the overall likelihood of  $t$  so that the  $C_{unk_{td}}(w, t)$  values will be scaled appropriately according to the overall likelihood of  $t$ . For this, we use our second knowledge source: the raw data. Based on the  $C_{known}(w, t)$

values as given above, the raw data tells us about the overall expectation of a word having a particular tag. From this, we can estimate the tag distribution for known words:  $C_{known}(t) = \sum_{w' \in V} C_{known}(w', t)$  and then normalize to get  $P_{known}(t)$ .

Finally, we need to combine  $P_{td}(unk_{td}|t)$  and  $P_{known}(t)$  into a single  $P(unk_{td}|t)$  that accounts for both the openness of a tag and its overall prevalence. We would like this combination to use the high  $P_{known}(NN)$  to boost  $P(unk_{td}|NN)$  and the low  $P_{known}(RB)$  to dampen  $P(unk_{td}|RB)$ . So, we compute and normalize:

$$P(unk_{td}|t) \propto \frac{|TD(t)|^2}{\sum_{t' \in Tags} |TD(t')|^2} \cdot P_{known}(t)$$

## 2.4 Auto-supervised post-EM smoothing

The initialization accounting for td-unknown words given above allows EM to be run on the raw token sequence, but it provides no probability for words that are truly unseen (in either the tag dictionary or the raw data). Consequently, any novel words in the test set will have zero emission probabilities, leading to extremely low unknown-word accuracies.

To overcome this problem, we perform a simple post-processing step after EM, which we refer to as **auto-supervised** training. We take the HMM trained by EM and use it to label the raw corpus. This gives us an automatically-labeled corpus that can be used for standard *supervised* training (without EM) to produce a new HMM. The effect of this post-processing step is to smooth the counts learned from EM onto any new words encountered during testing. This procedure significantly improves the ability of the HMM to label unknown words.

As a final note, it would of course be possible to use other models at this stage, such as a Conditional Random Field (Lafferty et al., 2001).

## 3 Enhancing MIN-GREEDY

As was discussed above, one of the major problems for type-supervised POS-tagger training with EM is a tag dictionary with low-frequency entries such as the word “a” being associated with the *foreign word* tag when nearly all of its instances are as a determiner. To avoid the need for manually pruning the tag dictionary, Ravi and Knight (2009)

Figure 1: MIN-GREEDY graph showing a state in the first phase. Numbered, solid arrows: order of chosen bigrams; dotted: potential choices.

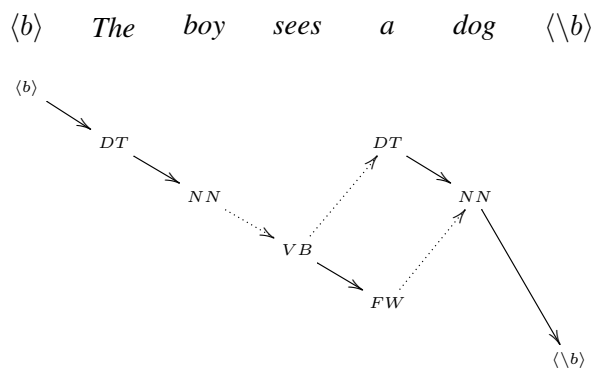

Figure 2: Start of the second MIN-GREEDY phase.

proposed that low-probability tags might be automatically filtered from the tag dictionary through a model minimization procedure applied to the raw text and constrained by the full tag dictionary. Ravi et al. (2010) develop a faster approach for model minimization using a greedy algorithm that they call MIN-GREEDY. It is this algorithm that we extend.

### 3.1 The original MIN-GREEDY algorithm

The MIN-GREEDY algorithm starts by initializing a graph with a vertex for each possible tag of each token in the raw data. The set of possible tags for each token is the set of tags associated with that word in the tag dictionary. Special *sentence start* and *sentence end* vertices are added to the graph for each sentence to mark its beginning and end. Unlike Ravi et al. (2010), we allow for an incomplete tag dictionary, meaning that our scenario has the additional complication that the tag set for some raw-corpus

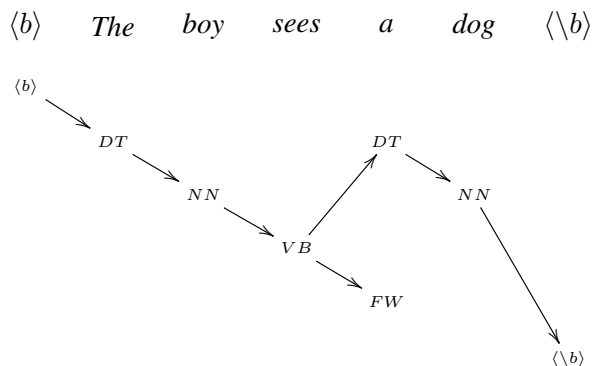

Figure 3: Potential MIN-GREEDY conclusion.

words will not be known. For these words, the full set of tags is used. Note that this increases the ambiguity and overall number of edges in the graph.

The MIN-GREEDY algorithm works in three phases: Greedy Set Cover, Greedy Path Completion, and Iterative Model-Fitting. In the first two phases, the algorithm chooses tag bigrams that form the edges of the graph. The goal of these phases is to select a set of edges that is sufficient to allow a path through every sentence in the raw corpus. The algorithm greedily selects these edges in an attempt to quickly approximate the minimal set of tag bigrams needed to accomplish this goal. In the final phase, the algorithm runs several iterations of EM in order to fit the bigram set to the raw data.

In the first phase, Greedy Set Cover, the algorithm selects tag bigrams in an effort to *cover* all of the word tokens. A word token is considered *covered* if there is at least one tag bigram edge connected to at least one of its vertices. At each iteration, the algorithm examines the entire graph, across all sentences, to find the tag bigram that, if added, would maximize the number of newly covered words.

Consider the graph in Figure 1. Assume, for the example, that this sentence comprises the entire raw corpus. At the start of the first phase, no tag bigrams are selected. On the first iteration, the algorithm chooses the tag bigram DT→NN because this tag bigram describes two edges for a total of four words newly covered: *The*, *boy*, *a*, and *dog*. On the second iteration, there are only three word tokens left uncovered: the start symbol, *sees*, and the end symbol. At this point, as the figure shows, there are five tag bigrams that would each result in covering one addi-

tional token. Since there are no tag bigrams whose choosing would result in covering more than one additional token, the algorithm randomly chooses one of these five. The algorithm iterates like this until all words are covered, as in, for example, Figure 2.

The second phase of the MIN-GREEDY algorithm, Greedy Path Completion, seeks to fill *holes* in the tag paths found in the graph. A *hole* is a potential edge that, if added, would connect two existing edges. At each iteration, the algorithm finds the tag bigram that, if selected, would maximize the number of holes that would be filled across all raw sentences.

The example graph in Figure 2 shows a potential start of the second phase. At this point, there are three tag bigrams that each fill one hole if selected, and the algorithm randomly selects one. Iteration continues until there is a complete tag path through each sentence in the raw corpus. One potential resolution for the example is given in Figure 3.

Once a set of tag bigrams has been generated that allows for a complete tag path through every sentence of the raw corpus, MIN-GREEDY begins its final phase: Iterative Model-Fitting. In this phase, the algorithm trains a succession of type-supervised HMM models. Each iteration trains an HMM and then uses it to tag the raw corpus, the result of which is used to prepare inputs for the next iteration.

Iterative Model-Fitting begins with the minimized set of bigrams returned from the second phase of MIN-GREEDY. This set is used as a hard constraint on the allowable tag bigrams during type-supervised HMM training. While EM is running, the only tag transitions that are counted are those that fall into the minimized tag bigram set; all other transition counts are ignored. Once an HMM has been trained, it is immediately used to tag the raw corpus, producing a set of auto-labeled sentences. For the second iteration of the phase, we extract a constrained tag dictionary from the auto-labeled corpus by simply taking every word/tag pair appearing in the data. This new tag dictionary is a subset of the original, full, tag dictionary, and hopefully has fewer low-frequency entries that would cause problems for EM.

We use this constrained tag dictionary to again perform type-supervised HMM training, but without any constraints on the allowable tag bigrams. This produces our third HMM. Using this HMM, we can, again, tag the raw corpus, producing another set of

auto-labeled sentences. We can then extract the set of tag bigrams appearing in this data to produce a new set of tag transition constraints, similar to what was returned by the second phase. With this set of tag transition constraints, and the full tag dictionary, we can perform another round of type-supervised HMM training, and repeat the entire process.

The third MIN-GREEDY phase continues iterating, alternating between training an HMM using a constrained set of tag transitions and training one using a constrained tag dictionary. The size of the set of constrained tag bigrams produced is tracked on each iteration, and the algorithm is considered to have converged when this value changes by less than five percent. The final result of the MIN-GREEDY algorithm is a trained HMM.

The evaluation of the MIN-GREEDY algorithm, as described in Ravi et al. (2010), was performed only for scenarios with a complete tag dictionary (including all raw and test word types). As such, no techniques were described for handling unknown words. Because we are interested in the more realistic scenario of an incomplete tag dictionary, we augment the original MIN-GREEDY setup with the smoothing techniques described above.

### 3.2 Improving tag bigram selection

One of the major problems with the MIN-GREEDY algorithm is that its heuristics for choosing the next tag bigram frequently result in many-way ties. In the first two phases of MIN-GREEDY, the greedy procedure looks for the tag bigram that will have the most positive impact. In the Greedy Set Cover phase this means choosing the tag bigram that would cover the most new tokens, and in the Greedy Path Completion phase this means choosing the tag bigram that would fill the most holes. However, it is frequently the case that there are many distinct tag bigrams that would cover the most new tokens or fill the most holes, leaving the MIN-GREEDY algorithm with no choice but to randomly select from these options. Since there are frequently cases of having many dozens of options, it is clear that some of those choices *must* be better than others, even though MIN-GREEDY does not make a distinction and considers them all to be equally good choices.

Consider the example in Figure 1 representing a possible state of the minimization graph. To have

reached this stage, tag bigram  $DT \rightarrow NN$  would have been chosen since it covered the highest number of tokens: four. Additionally,  $\langle b \rangle \rightarrow DT$  and  $NN \rightarrow \langle \backslash b \rangle$  could have been chosen as the second and third tag bigrams since they tied for the most new tokens covered: one. For the state shown in this figure, there is only one uncovered token, *sees*, but three tag bigrams that cover it. Since each of these tag bigrams covers exactly one new word, they are all considered by MIN-GREEDY to be equally good choices as the next tag bigram for inclusion, and the algorithm will choose one at random. However, it should be clear that the  $VB \rightarrow FW$  tag bigram is wrong while the other two would lead to a correct answer. As such, we would like for the algorithm to avoid choosing  $VB \rightarrow FW$ , and to pick one of the others.

In order to push the algorithm into choosing the right tag bigrams in these otherwise ambiguous situations, we have added an additional criterion to the bigram-choosing heuristic: after narrowing down the set of tag bigrams to those that cover the most new tokens, we further narrow the choice of bigrams by minimizing the number of new word-type/tag pairs that would be added to the result. Consider our example. If we choose the tag bigram  $NN \rightarrow VB$  or  $VB \rightarrow DT$ , then exactly one new word-type/tag pair would be added to our result: *sees*/ $VB$  (since *boy*/ $NN$  and *a*/ $DT$  would already have been added by the incorporation of previous selected tag bigrams). By contrast if we choose the tag bigram  $VB \rightarrow FW$  then *two* new word-type/tag pairs would be added: *sees*/ $VB$  and *a*/ $FW$ .

Minimizing the number of new word/tag pairs added by the algorithm has two main advantages. First, it keeps the selected bigrams focused on the same vertices, which results in fewer holes that the Greedy Path Completion phase must deal with. Secondly, it keeps the selected bigrams focused on more common tags for each word type, such as *a*/ $DT$ , and keeps it away from rare tags, such as *a*/ $FW$ .

### 3.3 Only tag bigrams on minimization paths

As was described above, the output of MIN-GREEDY's second stage is a minimized set of tag bigrams which is used as a constraint on the first iteration of the third stage, Iterative Model-Fitting. However, in order to determine when to stop adding new bigrams during the first two phases, the MIN-

GREEDY algorithm must try to find complete tag paths through each sentence in the raw corpus, stopping once a tag path has been found for each one. While the algorithm is trying to select only the tag bigrams that are necessary for a complete tagging, it happens frequently that bigrams are selected that are not actually used on any tag path.

Consider the example shown in Figure 3. The graph has a complete path through the sentence, but also contains an extraneous edge,  $VB \rightarrow FW$ , that is not used on the path. Assuming that this tag bigram is not used on the tag path of any other sentence, it can safely be removed from the resultant set to produce a smaller set of tag bigrams, getting us even closer to the minimized set that we desire.

To find the set of tag bigrams excluding these extraneous edges, we modify the MIN-GREEDY algorithm. During the first and second phases of the algorithm, we check all raw data sentences for a completed path after each tag bigram is selected. If a completed path is found for a sentence, we store that path immediately. Once a path is found for every sentence, we extract the set of bigrams used on these paths, and pass that set, instead of the full set of selected bigrams, to the third phase of the algorithm.

Note that it is important that we store the completed paths as soon as they are completed. Since sentences are completed at different stages, and more tag bigrams are selected after some of these sentences are complete, it is inevitable that some sentences will end up with multiple complete tag paths by the end of the second phase. However, we seek only the *first* such path. Tag bigrams are selected in order of their impact, so bigrams selected earlier are better and should be preferred. Considering again the example in Figure 3, based on the frequency of the tags, it is likely that, given the presence of other sentences in the raw corpus, the tag path including bigrams  $VB \rightarrow DT$  and  $DT \rightarrow NN$  would be found before the one including  $VB \rightarrow FW$  and  $FW \rightarrow NN$ . Since they are more frequent bigrams, we would want to keep the first path even if the second is completed at a later time.

The result of this improvement is a smaller, cleaner minimized tag bigram set to be delivered to the third phase of MIN-GREEDY.

Scenario	Total	Known	Unk.
0. Random baseline (choose tag randomly from tag dictionary)	63.53	65.49	2.38
1. HMM baseline (simple EM with tag dictionary and raw text)	69.20	71.42	0.27
2. HMM baseline + auto-supervised training	82.33	83.67	40.46
3. HMM baseline + auto-supervised training + emission initialization	82.05	83.27	44.31

### 3.4 EM initialization with minimization output

As a final improvement to MIN-GREEDY, we took the set of completed tag paths returned from the second phase of the algorithm, as described in the previous section, and used them as labeled data to initialize an HMM for EM training.

Since we modified MIN-GREEDY to produce a set of completed tag paths for sentences, we can take this to be a complete set of labels for the raw corpus. Furthermore, since we were careful about storing paths as soon as they become completed by the minimization process, and the tag bigrams are chosen in order of frequency, there will be more high-frequency bigrams than low-frequency. As a result, this labeling will contain good tag transitions and token labelings. As such, the labeled data produced by the second phase provides useful information beyond a simple set of sufficient bigrams: it contains legitimate frequency information that can be used to initialize the HMM. We, therefore, initialize an HMM directly from this data to start EM.

## 4 Evaluation<sup>1</sup>

**English data.** We evaluate on the Penn Treebank (Marcus et al., 1993). In all cases we use the first 47,996 tokens of section 16 as our raw data, sections 19–21 as our development set, and perform the final evaluation on sections 22–24.

<sup>1</sup>Source code, scripts, and data to reproduce the results presented here can be found at [github.com/dhgarrette/type-supervised-tagging-2012emnlp](https://github.com/dhgarrette/type-supervised-tagging-2012emnlp)

We evaluate two differently sized tag dictionaries. The first is extracted directly from sections 00–15 (751,059 tokens) and the second from sections 00–07 (379,908 tokens). The former contains 39,087 word types, 45,331 word/tag entries, a per-type ambiguity of 1.16 and yields a per-token ambiguity of 2.21 on the raw corpus (treating unknown words as having all 45 possible tags). The latter contains 26,652 word types, 30,662 word/tag entries, a per-type ambiguity of 1.15 and yields a per-token ambiguity of 2.03 on the raw corpus. In both cases, every word/tag pair found in the relevant sections was used in the tag dictionary: no pruning was performed.

**Italian data.** As a second evaluation, we use the TUT corpus (Bosco et al., 2000). To verify that our approach is language-independent without the need for specific tuning, we executed our tests on the Italian data without any trial runs, parameter modifications, or other changes. We divided the TUT data, taking the first half of each of the five sections as input to the tag dictionary, the next quarter as raw data, and the last quarter as test data. All together, the tag dictionary was constructed from 41,000 tokens consisting of 7,814 word types, 8,370 word/tag pairs, per-type ambiguity of 1.07 and a per-token ambiguity of 1.41 on the raw data. The raw data consisted of 18,574 tokens and the test contained 18,763 tokens.

**Results** We ran eleven experiments for each data set with results shown in Tables 1 and 2. All scores are reported as the percentage of tokens for which the correct tag was assigned. Accuracy is shown as

Scenario	PTB (00-07)			TUT		
	Total	Known	Unk.	Total	Known	Unk.

Table 2: Tagging accuracy using PTB sections 00-07 and TUT to build the tag dictionary. *Known* word types are those appearing in the tag dictionary. Scenario numbers correspond to Table 1.

the Total (all word types), Known (word types found in the tag dictionary), and Unknown (word types not found in the tag dictionary).

Experiments 1–3 evaluate our smoothing techniques applied directly to the task of type-supervised HMM training with EM, without MIN-GREEDY. The basic HMM consistently beats the baseline random tagger, the auto-supervision technique makes an enormous improvement for both known and unknown words, and the the emission initialization yields a sizable improvement for unknown words.

Experiments 4–6 evaluated our reimplementations of MIN-GREEDY. We start with the most basic level of smoothing needed to work in a type-supervised scenario. For the smaller PTB tag dictionary and the TUT data, MIN-GREEDY actually has lower performance than the HMM alone. This indicates that if the tag dictionary has a low degree of ambiguity, then MIN-GREEDY can make the situation worse. However, with our smoothing techniques, we regain similar improvements as with the HMM.

Finally we performed experiments evaluating combinations of our improvements to MIN-GREEDY. Scenarios 7–9 show each improvement taken in turn. Scenario 10 shows the results for using all three improvements. For the English data, the best results are found when all the improvements are used. When taken individually, the bigram choice heuristic and HMM initialization from minimization output each consistently outperform the improved-

MIN-GREEDY baseline on English. However, restricting the tag bigrams to that in the minimization-tagged output causes problems in the smaller PTB scenario, presumably falling to a local maximum like MIN-GREEDY that the other improvements are able to help the algorithm avoid.

Though the accuracy improvements are less than for English, the Italian results show that our MIN-GREEDY enhancements make an appreciable difference for a language and dataset for which the approaches considered were run sight unseen.

**Error analysis** One of the primary goals of model minimization is to automatically eliminate low-probability entries from the tag dictionary that might confuse the EM algorithm (Ravi et al., 2010). In order to see how well our techniques are able to identify and eliminate these unlikely word/tag pairs, we analyzed the tagging errors from each experiment. In doing so, we discovered that the two of the most problematic words for the EM algorithm are “a” and “in”. We ran further experiments to explore what was happening with those words. The results, using PTB sections 00–07 are shown in Table 3.

In PTB sections 00-07 the word “a” appears 7630 times and with 7 different tags. This includes 7621 occurrences with tag DT, 3 with tag SYM (symbol), and 1 time with LS (list item marker). As such, we would want the HMM to lean heavily toward tag DT when tagging the token “a”. Unfortunately, the rare tags confuse the EM procedure and end up with dis-

tok	model output	tokens tagged by scenario					
		3	6	7	8	9	10
a	DT	32	4	4	4	2424	2425
	LS	1531	0	0	0	0	0
	SYM	731	2356	2305	2356	0	0
in	IN	12	15	2024	4	2042	2047
	FW	1922	1910	0	0	0	0
	RP	20	27	0	2037	0	0

Table 3: Number of times, for the words “a” and “in”, the tagger trained by the particular scenario selected the given tag. Experiments used PTB sections 00-07 for the initial tag dictionary. Scenario numbers correspond to Table 1.

proportionately high probabilities. Our experiment training an HMM without minimization (scenario 3) resulted in 1531 “a” tokens being tagged LS, 731 as SYM, and only 32 tagged as DT.

The situation is similar with the word “in”, which appears 6155 times with 5 different tags in the 8 sections. Of these, 6073 occurrences are tagged IN (preposition), 63 are RP (particle), and 1 is FW (foreign word). Again, EM without minimization is confused by the rare tokens, assigning FW 1922 times and IN 12 times.

The minimization procedure attempts to overcome this problem by removing unlikely tags from the tag dictionary automatically. As is shown in Table 3, MIN-GREEDY without our enhancements is able to reject the problematic LS as a tag for “a”, but unable to do so for SYM, resulting in 2356 tokens tagged SYM and only 4 tagged DT. Similarly, MIN-GREEDY is unable to reject FW as a tag for “in”.

Our enhancements to MIN-GREEDY improve the situation. More careful choosing of bigrams during minimization results in the avoidance of LS and FW (but not SYM) for “a” as well as FW and RP for “in”. Restricting the tag bigrams output from MIN-GREEDY to just those on tag paths avoids LS and FW for “a” and FW for “in”. Finally, using the tagged sentences from MIN-GREEDY as noisy supervision for EM initialization eliminates all rare tags, as does the use of all three enhancements together.

## 5 Conclusion

Our results show it is possible to create accurate POS-taggers using type-supervision with incom-

plete tag dictionaries by extending the MIN-GREEDY algorithm of Ravi et al. (2010). The most useful change we made to the MIN-GREEDY procedure was the implementation of a better heuristic for picking tag bigrams. An intuitive and straightforward emission initialization provides the necessary basis to run EM on a given raw token sequence. Using EM output on this raw sequence as auto-labeled material to a supervised HMM then proves highly effective for generalization to new texts containing previously unseen word types.

Vaswani et al (2010) explore the use of minimum description length principles in a Bayesian model as a way of capturing model minimization, inspired by the MIN-GREEDY algorithm. The advantage there is that only a single objective function needs to be optimized, rather than having initialization followed by an iterative back and forth with pruning of tag-tag pairs. Our own next steps are to move in a similar direction to explore the possibilities for encoding the intuitions we developed for initialization and minimization as a single generative model.

Goldberg et al. (2008) note that fixing noisy dictionaries by hand is actually quite feasible, and suggest that effort should focus on exploiting human knowledge rather than just algorithmic improvements. We agree; however, our ultimate motivation is to use this work to tackle bootstrapping from very small tag dictionaries or dictionaries obtained from linguists or resources other than a corpus, and for tag sets that are more ambiguous (e.g., supertagging for CCGbank (Hockenmaier and Steedman, 2007)). Such efforts require automatic *expansion* of tag dictionaries, which then need be constrained based on available raw token sequences using methods such as those explored here. In this respect, the somewhat idiosyncratic noise in the corpus-derived dictionaries used here make a good test.

## Abstract

In this paper, we investigate different usages of feature representations in the web person name disambiguation task which has been suffering from the mismatch of vocabulary and lack of clues in web environments. In literature, the latter receives less attention and remains more challenging. We explore the feature space in this task and argue that collecting person specific evidences from a corpus level can provide a more reasonable and robust estimation for evaluating a feature's importance in a given web page. This can alleviate the *lack of clues* where discriminative features can be reasonably weighted by taking their corpus level importance into account, not just relying on the current local context. We therefore propose a topic-based model to exploit the person specific global importance and embed it into the person name similarity. The experimental results show that the corpus level topic information provides more stable evidences for discriminative features and our method outperforms the state-of-the-art systems on three WePS datasets.

## 1 Introduction

Resolving ambiguity associated with person names found on the Web is a key challenge in many Internet applications, such as information retrieval, question answering, open information extraction, automatic knowledge acquisition (Wu and Weld, 2008) and so on. For example, if you want to know more about a guy named *George Foster* and feed Yahoo! with his name, the results are not satisfactory where you get

more than 40 different persons named *George Foster* scattering in the top 100 returned pages. None of the dominant search engines currently helps users group those returned pages into clusters according to whether they refer to the same person. Users thus have to either read those pages carefully or adjust their queries by adding extra modifiers. This motivates an intensive study in automatically resolving person name ambiguity in various web applications.

However, resolving web person name ambiguity is not a trivial task. Due to the difficulties in figuring out or predicting the number of namesakes in the returned pages, the task has been investigated in an unsupervised learning fashion in the literature, which is apparently different from the traditional word sense disambiguation or entity linking/disambiguation tasks, where the inventories of candidate word senses or entities are usually known given the target word or entity mention.

A general framework for this task can be formulated as first extracting various features from the web pages, and then grouping these pages into several clusters each of which is assumed to represent one specific person. Despite of the inevitably noisy nature of web data, a key challenge is how to handle the data sparsity problem which we mean as: **mismatch of vocabulary** and **lack of clues**. The former refers to the case that two web pages may describe the same person but use different words thus the word overlap between them are small. Various features, including entities, biographical information, URL, etc., have been introduced to bridge the gap (Mann and Yarowsky, 2003; Kalashnikov et al., 2008a; Ikeda et al., 2009; Jiang et al., 2009),

and external knowledge resources are also employed to capture the semantic relationship between entities (Han and Zhao, 2009, 2010). However, a more challenging scenario is that there are few clues available in the web pages. For example, there is a page mentioning a nutritionist *Emily Bender* in WePS2 dataset (Javier et al., 2009). Throughout the whole page we can find only one word, *nutrition*, related to her identification, while other pages about the nutritionist in the dataset contain substantial materials about her profession and job. In this case, current efforts, focusing on either feature engineering or background knowledge, are incapable to exploiting these limited clues from the current page to the whole *Emily Bender* document set, where *nutrition*, as an important feature for recognizing a nutritionist, should be paid more attention.

As far as we know, there is less work focusing on exploring person specific information to relieve the *lack of clues* problem. Traditional vector space model (VSM) is most widely used to accommodate various features, but it ignores any relations between them (Mann and Yarowsky, 2003; Ikeda et al., 2009). Beyond bag-of-features, two kinds of features are explored, co-occurrences of entities and Wikipedia based semantic relationship between entities, both of which provide a reasonable relatedness for entity pairs. More recent works adopt one of these relationships (Jiang et al., 2009; Kalashnikov et al., 2008a; Han and Zhao, 2009). Han and Zhao try to model both aspects, but their co-occurrence estimation, estimated from held-out resources, fails to capture the person specific importance for a feature, which is crucial to enhance limited clues in a corpus level, e.g., the significance of *nutrition* for *Emily Bender* in WePS1 dataset.

In this paper, we explore different usages of features and propose an approach which mines cross document information to capture the person specific importance for a feature. Specifically, we construct a semantic graph from Wikipedia concepts appearing in all documents that contain the target name (which we refer to *name observation set*), then group them into several topics and further weight each feature by considering both the relatedness of the feature to its corresponding topic and the importance of this topic in the current name observation set. By incorporating both the Wikipedia and topic information into

our person name similarity, our model exploits both Wikipedia based background knowledge and person specific importance. We argue that the corpus level importance provides more stable evidences for discriminative features in various scenarios, especially the tough case. We compared our model with the state of the arts on three WePS datasets (from the First and Second Web People Search Clustering Task), and our experiments show that our model consistently outperforms other competitive models on all three datasets.

In the rest of this paper, we first review related work, and in Section 3, show how we exploit the person specific importance in our disambiguation model. Experiment results are discussed in Section 4. We conclude this paper in Section 5.

## 2 Related Work

Web person name ambiguity resolution can be formally defined as follows: Given a set of web pages  $\{d_1, d_2, \dots, d_n\}$ , where each page  $d_i$  ( $i = 1, \dots, n$ ) contains an ambiguous name  $N$  which may correspond to several persons holding this name among these pages. The disambiguation system should group these name observations into  $j$  cluster  $\{c_1, c_2, \dots, c_j\}$  each of which is expected to contain web pages about the same person.

As mentioned before, the task is usually formulated in a unsupervised fashion, including two steps: feature extraction and person clustering. Most research efforts so far have been made to the former, exploring various features according to specific applications, while the second step is currently dominated by hierarchical agglomerative clustering (HAC). According to the reliance of extra knowledge resources, existing works can be categorized into non-resource methods and resource-based methods. Non-resource methods extract various local features from the context of ambiguous names, and compute the similarity between feature vectors. These features include plain words (Bagga and Baldwin, 1998), biographical information (Mann and Yarowsky, 2003; Niu et al., 2004), named entities, compound key phrases, hyperlinks (Ikeda et al., 2009), etc. The similarity between namesakes are usually measured by the cosine similarity (Bagga and Baldwin, 1998), or other graph based met-

rics(Iria et al., 2007; Kalashnikov et al., 2008a; Jiang et al., 2009). Those methods pay more attention to extracting informative features and their co-occurrences, but they usually treat the features locally, and ignore the semantic relatedness of features beyond the current document.

Resource-based approaches, on the other hand, can leverage external resources to benefit from rich background knowledge, which is crucial to remedy the data sparsity problem. The employed resources include raw texts available on the web and online encyclopedias. Kalashnikov et al. and Yiming et al. use extra web corpora to obtain co-occurrences between named entities. Rao et al. use Google Snippets to provide more contexts. By employing Wikipedia, the largest online encyclopedia, rich background knowledge about the semantic relatedness between entities can be leveraged to improve the disambiguation performance, and relieve the coverage problem, to some extent. Bunescu and Pasca and Cucerzan utilize Wikipedia’s category hierarchy to disambiguate entities, while Pilz uses Wikipedia’s link information. Han and Zhao adopt Wikipedia semantic relatedness to compute the similarity between name observations. They also combine multiple knowledge sources and capture explicit semantic relatedness between concepts and implicit semantic relationship embedded in a semantic graph simultaneously(Han and Zhao, 2010).

Most approaches discussed above explore various features in the current page or rely on external knowledge resources to bridge the vocabulary gap, but pay less attention to the *lack of clues* since they ignore the person specific evidence in the current corpus level. Our model focuses on solving the data sparsity problem by utilizing other web pages in the same name observation set to provide a robust but person specific weighting for discriminative features beyond the current document alone. In terms of extra resources, the Wikipedia based model (WS) by Han and Zhao (2009) is close to our model. The WS model uses Wikipedia to capture the relationship between entities in the local context to bridge the vocabulary gap, but it is incapable to evaluate the importance of a feature with regarding to the target name, hence is unable to make use of limited clues in the current web page. Our method captures person specific evidences by generating topics from

all concepts in the current name observation set and weighting a feature accordingly. In this case, discriminative features that are sparse in the current page can be globally weighted so as to provide a more accurate and stable person name similarity.

### 3 The Model

Our model consists of three steps: feature extraction, topic generation and name disambiguation. For an ambiguous name, we first extract three types of features and construct a semantic graph from all Wikipedia concepts extracted from the current name observation set. We then collect global person specific evidences by clustering these concepts on the graph into different topics, which in turn are used to weight each concept by considering the importance of its corresponding topic in the current name observation set and its highly related neighbors in both the topic and its local context. At last, we incorporate the proposed topic representation into the person name similarity function and adopt the hierarchical agglomerative clustering (HAC) algorithm to group these web pages.

#### 3.1 Feature Extraction

We extract features from the contexts of ambiguous names, including Wikipedia concepts, named entities and biographical information, such as email addresses, phone numbers and birth years.

**Wikipedia Concept Extraction** Each concept in Wikipedia is described by an article containing hyperlinks to other concepts which are supposed to related to the current one. All the linking relations in Wikipedia construct a huge semantic graph, where we can mine rich semantic relationship between concepts(David and Ian, 2008). We collect Wikipedia concepts from all web pages in the dataset by comparing all n-grams (up to 8) from the dataset to Wikipedia anchor text dictionary and checking whether it is a Wikipedia concept surface form. We further prune the extracted concepts according to their keyphraseness(Mihalcea and Csomai, 2007). Initially, each concept is weighted according to its average semantic relatedness(David and Ian, 2008) with other concepts in the current page.

**Named Entity and Biographical Information Extraction** Although Wikipedia concepts can pro-

vide rich background knowledge, they suffer from the limited coverage. It is common that some discriminative features are not likely to be found in Wikipedia, such as names of infamous people or organizations, email addresses, phone numbers, etc. We therefore extract two extra kinds of features, named entities that do not appear in the Wikipedia anchor text dictionary, and biographical information. We use Stanford Named Entity Recognizer (Finkel et al., 2005) to collect named entities which are not in the Wikipedia list. We use regular expressions to extract email address, phone numbers and birth years. For convenience, we will also call concept features for Wikipedia concept features and non-concept features for the other two in the rest of this paper.

### 3.2 Topic Generation and Weighting Scheme

Now we proceed to describe the key step of our model, topic generation and weighting strategy. The purpose of introducing topics into our model is to exploit the corpus level importance of a feature for a given name so that we will not miss any discriminative features which are few in the current name observation but have shown significant importance over the whole name observation set.

**Graph Construction** In our model, we capture the topic structure through a semantic graph. Specifically, for each name observation set, we connect all Wikipedia concepts appearing in the current observation set by their pairwise semantic relatedness (David and Ian (2008)) to form a semantic graph.

The constructed graph is usually very dense since any pair of unrelated concepts would be connected by a small semantic relatedness resulting in many light-weighted or even meaningless edges. We therefore propose to prune some light-weighted edges to make the graph stable and easier to harvest reasonable topics. We use the following strategies to prune the graph:

- If an edge's weight is lower than a predefined threshold, it will be pruned.
- If two vertices of an edge do not co-occur in any web page of the current observation set, then this edge will be pruned.

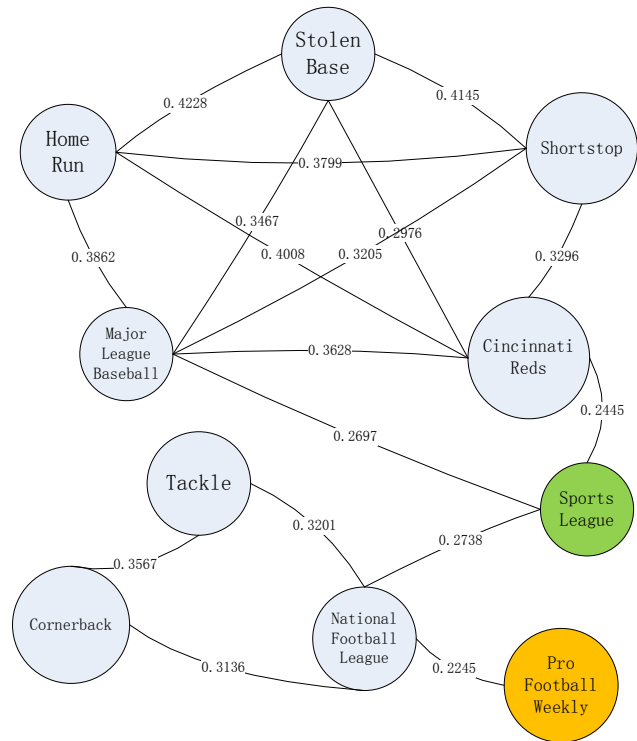

Figure 1: An abridged example of the semantic graph for *George Foster*. The green node *Sports League* is a hub node, and the yellow node *Pro Football Weekly* is an outlier.

The second rule is set to be strict and is proposed to handle the following circumstance. Some general concepts, such as swimming, football, basketball and golf, will be measured highly related with each other by Wikipedia semantic relatedness and thus are very likely to be grouped into one topic, however, they are discriminative on their own when disambiguating different persons. For example, the concept *swimming* is discriminative enough to distinguish Russian swimmer Popov from basketball player Popov. So it is not a good idea to group these concepts into one topic. The proposed co-occurrence rule is based on the above observation that it is rare that such kind of general concepts, e.g., swim and basketball, often co-occur with each other when talking about one specific person. After the pruning step, for each ambiguous name, we get a semantic graph from all Wikipedia concepts extracted in this name observation set. Figure 1 illustrates an abridged version of a semantic graph for *George Foster*.

**Graph Clustering** Considering the graph construction strategy we use, it is more suitable for us to group the concepts on the graph into several topics using a density-based clustering model.

We choose SCAN algorithm Xu et al. (2007) to perform the clustering step. The SCAN algorithm utilizes a neighborhood structure to measure the similarity between two vertices. If a vertex has a minimal of  $\mu$  neighbors with a similarity larger than  $\varepsilon$ , it is called a *core*. The algorithm<sup>1</sup> starts from a random vertex in a graph, examining whether it is a core or not. If yes, the algorithm will expand a cluster from this vertex recursively, otherwise the vertex will be assigned either a hub node or an outlier depending on the number of its neighboring clusters. A hub node connects to more than one cluster, while an outlier connects to one or no cluster. Take the semantic graph in Figure 1 for example, the node *Sports League* is a hub node, while the node *Pro Football Weekly* is an outlier. Finally, all concepts in the graph are grouped into  $K + 2$  parts ( $K$  is the number of the clusters, and is determined automatically), including  $K$  clusters, the set of hub nodes and the set of outliers.

One problem of applying SCAN in our work is that it is originally designed for unweighted graphs. We have to adapt it to our weighted graph by modifying the similarity function between two nodes as follows:

$$sim(c_1, c_2) = \alpha \times \frac{sim_{nb}(c_1, c_2)}{1 + \alpha} + \frac{sr(c_1, c_2)}{1 + \alpha} \quad (1)$$

and  $sim_{nb}(c_1, c_2)$  is defined as:

$$sim_{nb}(c_1, c_2) = \frac{\sum_{c \in N(c_1) \cap N(c_2)} \frac{sr(c_1, c) + sr(c_2, c)}{2}}{|N(c_1) \cup N(c_2)|}$$

where  $N(c)$  is the neighbor set of concept  $c$ . This new similarity function contains two parts: the neighborhood similarity and the semantic relatedness between two concepts. We combine them using a linear combination, where  $\alpha$  is a weight tuned during training.

**Topic Generation** Now we will map the clustering results into different topics. Intuitively, each

<sup>1</sup>We omit the details of SCAN for brevity, and refer interested reader to Xu et al. (2007) for more details.

cluster will be treated as a topic. However, we found that hub nodes usually correspond to general concepts which may be related to many topics, but with a loose relatedness. We thus *distribute* each general concept into its every related topic, but with a lower weight to distinguish from ordinary concepts in this topic.

Outliers may be concepts which are far away from main themes of the corpus, or noise concepts. We calculate the average semantic relatedness of an outlier with its neighbor concepts that belong to one topic. If the result is lower than a threshold, this outlier will be discarded, otherwise it will be treated as a non-concept feature.

Now we are able to map the clustering results into different topics. Intuitively, each cluster will be treated as a topic. However, we found that hub nodes usually correspond to general concepts, e.g., *education* or *public*, which may be related to many topics, but with a loose relatedness. We thus *distribute* each general concept into its every related topic, but with a lower weight to distinguish from ordinary concepts in this topic. Outliers are found to contain concepts which are far away from main topics of the document set and look like noise concepts. We therefore calculate the average semantic relatedness of an outlier node with its neighboring concepts which belong to some topics. If the average relatedness is lower than a threshold, this node will be discarded, otherwise it will be treated as a non-concept feature.

**Weighting Topics** After generating all topics, we should weight each topic according to its importance in the current name observation set as well as the quality of the topic (cluster). Intuitively, if most concepts in the topic are considered to be discriminative in the current name set and they are closely related to each other, this topic should be weighted as important. By properly weighting the generated topics, we can capture the importance of a concept reliably in the corpus level (in the current name observation set) rather than in the current page solely.

Before we weight a topic, we first explain how we re-weight a hub concept in a topic since our initial feature weighting scheme (Han and Zhao, 2009) works on individual web page, lacks cross document information and is likely to over-estimate the impor-

tance of a hub node (general concept) by assigning a higher weight. Suppose a hub node  $h$  connects to a topic  $t$  with  $n$  neighbors, namely  $c_1, c_2, \dots, c_n$ . The similarity between this hub node and the topic is computed by averaging the semantic relatedness between this hub node and these  $n$  neighbors:

$$sim(h, t) = \frac{1}{n} \sum_{i=1}^n sr(h, c_i). \quad (2)$$

We then update the weight of this hub node by considering its similarity with this topic:  $w_t(h) = w(h) \times sim(h, t)$  from which we can see that the hub node receives a lower weight than before indicating that it is not as important as ordinary concepts in a topic.

Now we proceed to weight the topic  $t$  by taking into account the frequencies of its concepts and the coherence between the concepts and their neighborhood in topic  $t$ :

$$w(t) = \frac{\sum_{i=1}^n f(c_i)}{n} \times \frac{\sum_{i=1}^n n\_coh(c_i, t)}{n} \quad (3)$$

where topic  $t$  contains  $n$  concepts  $\{c_1, c_2, \dots, c_n\}$ ,  $f(c)$  is the frequency of concept  $c$  over current name observation set, specially, when  $c$  is a hub node concept, we will distribute its frequency according to equation (2), having  $f_t(c) = f(c)sim(c, t)$ . And  $n\_coh(c, t)$  is the neighborhood coherence of concept  $c$  with topic  $t$ , defined as:

$$n\_coh(c, t) = \frac{\sum_{q \in N(c) \cap t} sr(q, c)}{|N(c) \cap t|} \quad (4)$$

where  $N(c)$  is the neighboring node set of concept  $c$ .

By incorporating corpus level concept frequencies into topic weighting, discriminative concepts that are sparse in one document and suppressed by conventional models can benefit from their corpus level importance as well as their coherence in related topics.

### 3.3 Clustering Person Name Observations

Now the remaining key step is to compute the similarity between two name observations. The similarity proposed in GRAPE(Jiang et al., 2009) measures two documents by bridge tags (common features) shared by two document graphs. Specifically,

Jiang et al. utilize *cohesion* to weight a bridge tag in a document. The more bridge tags two documents share, the stronger the cohesion of each bridge tag is, and in turn the more similar the two documents are.

However, this similarity bears a shortcoming that the bridge tags shared by the two documents require an exact match of features, which does not take any semantic relatedness into consideration. If two web pages mentioning the same person but have few features in common, the GRAPE similarity may not work properly. We, therefore, propose a new similarity measure combining topic similarity, topic based connectivity strength and GRAPE's connectivity strength.

### Matching Topics to Person Name Observations

We first describe how to match the generated topics to different name observations. In order to avoid unreliable estimation, we only match a topic to a name observation when they share at least one concept. To measure the relatedness between a topic and a name observation, we formulate this similarity as the weighted average of semantic relatedness between each concept from one side and its closely related counterpart from the other side, defined as:

$$sim(A \rightarrow B) = \frac{\sum_{a \in A} w_A(a) \times w_B(b_a) \times sr(a, b_a)}{\sum_{a \in A} w_A(a) \times w_B(b_a)} \quad (5)$$

$$sim(A, B) = (sim(A \rightarrow B) + sim(B \rightarrow A))/2,$$

where  $A$  can be a topic and  $B$  a name observation or vice versa,  $b_a$  is a concept in  $B$  that is most related to concept  $a$ ,  $w_A(a)$  represents the weight of concept  $a$  estimated by the averaged relatedness between  $a$  and other concepts in  $A$ .

**Person Name Similarity** Now we describe the first component in our proposed measure: topic similarity, which is calculated through the common topics shared by the two name observations,  $o_1$  and  $o_2$ :

$$TSm(o_1, o_2) = \sum_{t \in T(o_1, o_2)} sim(o_1, t) \times sim(o_2, t) \times sim(o_1 \cap t, o_2 \cap t) \times w(t) \quad (6)$$

where  $T(o_1, o_2)$  contains all common topics of  $o_1$  and  $o_2$ ,  $w(t)$  is the weight of topic  $t$  estimated using

equation (3), both  $sim(o_i, t)$  and  $sim(o_1 \cap t, o_2 \cap t)$  measure the similarity between two concept sets and can be estimated using equation (5). The underlying idea of the equation is, if two name observations share more and closer common topics, and also these topics receive higher weights according to the current name observation set, then the two observations should be more related to each other.

Specifically, the factor  $sim(o_1 \cap t, o_2 \cap t)$  is designed to measure the fine relatedness between  $o_1$  and  $o_2$  given the topic  $t$ . Sometimes, both  $o_1$  and  $o_2$  are mapped to  $t$  and both close to this topic, but in fact they depict different aspects of  $t$  since some of our topics are more general thus include several aspects. The comparison of their intersections will provide a more detailed view for their similarity.

Inspired by the use of bridge tags in GRAPE(Jiang et al., 2009), we propose to capture the connection strength between concept sets by the means of our topics. We consider common topics as the bridge tags and define our topic based connectivity strength between two name observations as:

$$TCS(o_1, o_2) = \frac{1}{2} \sum_{t \in T(o_1, o_2)} sim(o_1 \cap t, o_2 \cap t) \times (Cohs(o_1, t) + Cohs(o_2, t)) \quad (7)$$

Note that we still need  $sim(o_1 \cap t, o_2 \cap t)$  to capture the fine differences inside a topic.  $Cohs(o, t)$  is a cohesion measure to capture the relatedness between non-concept features in  $o$  and concept features in  $t$ , defined as:

$$Cohs(o, t) = \sum_{c \in o \cap t} w(t) \times \sum_{q \in EB(o)} occ(c, q) f_o(c) f_o(q) \quad (8)$$

where  $EB(o)$  contains all non-concept features in  $o$  (e.g., non-Wikipedia entities and biographical information),  $occ(c, q)$  is the co-occurring number of concept  $c$  and feature  $q$ ,  $f_o(q)$  is the relative frequency of  $q$  in observation  $o$ . It is easy to find that a higher cohesion can be achieved by larger overlap between  $o$  and  $t$ , higher topic weight and more co-occurrences of concept features in  $t$  and other features in  $o$ .

The third part is the original connectivity strength defined in GRAPE(Jiang et al., 2009):  $CS(o_1, o_2)$ , calculated using plain features without topics (we

omit the details for brevity). Finally, we linearly combine equation (6), (7) and  $CS(o_1, o_2)$  into the person name similarity function as:

$$S(o_1, o_2) = \alpha_1 \times TSm(o_1, o_2) + \alpha_2 \times TCS(o_1, o_2) + (1 - \alpha_1 - \alpha_2) \times CS(o_1, o_2) \quad (9)$$

where  $\alpha_1$  and  $\alpha_2$  are optimized during training.

This final similarity function will then be embedded into a normal HAC algorithm to group the web pages into different namesakes where we compute the centroid-based distance between clusters(Mann and Yarowsky, 2003).

## 4 Experiments

We compare our model with competitive baselines on three WePS datasets. In the following, we first describe the experimental setup, and then discuss the their performances.

### 4.1 Data

**Wikipedia Data** Wikipedia offers free copies of all available data to interested users in their website. We used the one released in March 6th, 2009 in our experiments. We identified over 4,000,000 highly connected concepts in this dump; each concept links to 10 other concepts in average.

**WePS Datasets** We used three datasets in our experiments, WePS1 Training and Testing (Artiles et al., 2007), WePS2 Testing (Javier et al., 2009). These datasets collected names from three different resources including Wikipedia names, program committee of a computer science conference and US census. Each name were queried in Yahoo! Search and top  $N$  result pages (100 pages in WePS1 and 150 pages in WePS2) were obtained and manually labeled.

### 4.2 Baselines

We compare our model TM with four baseline methods: (1)VSM: traditional vector space model with cosine similarity. We use features extracted in Section 3.1 and weight them using TFIDF. The documents are grouped using standard HAC algorithm. (2)GRAPE(Jiang et al., 2009): we re-implement the state-of-the-art system which outperforms any models that do not use extra knowledge resources reported in WePS1 and WePS2. (3)WS: the Wikipedia

Semantic method(Han and Zhao, 2009). This system uses Wikipedia to enhance the results of name disambiguation. (4)SSR: the Structural Semantic relatedness model(Han and Zhao, 2010) creates a semantic graph to re-calculate the semantic relatedness between features, and captures both explicit semantic relations and implicit structural semantic knowledge. We also build two variants of TM: TM-nTW which removes topic weighting to examine what effect the topic weighting strategy can make and whether it can provide a person specific evidence and TM-nCP which does not use co-occurring information to prune the semantic graph to examine whether the pruning is effective.

### 4.3 Parameters

There are several parameters to be tuned in our model. In the SCAN algorithm, we use default parameters according to (Xu et al., 2007) with an exception: the weight  $\alpha$  is tuned exhaustively to be 0.2. Note that the number of topics are automatically decided by SCAN. The semantic graph pruning threshold is set to 0.27 tuned on a held out set. The smoothing parameters in equation (9) are:  $\alpha_1 = 0.3$ ,  $\alpha_2 = 0.2$  which are tuned using cross validation. Optimization of some parameters will be addressed in detail in the following subsection. In HAC, all optimal merging thresholds are selected by applying leave-one-out cross validation.

### 4.4 Results and Discussion

We adopt the same evaluation process as (Han and Zhao, 2009), and evaluating these models using Purity, Inverse Purity and the F-measure (also used in WePS Task Artiles et al. (2007)). The overall performance is shown in Table 1, and the best scores are in boldface.

Let us first look at our model and its variants, TM-nTW and TM-nCP. By introducing the corpus level topic weighting scheme, our model improves in average 1.6% consistently over all datasets. Recall that our topic weightings are obtained over the whole name observation set beyond local context, this improvement indicates that this corpus level person specific evidences render the person similarity more reasonably than that of single document. On the other hand, by pruning the semantic graph, our model improves averagely 1.3% over TM-nCP. This

Table 1: Web person name disambiguation results on all three WePS datasets

WePS1 Training			
Method	P	IP	FMeasure
VSM	0.86	0.86	0.85
GRAPE	<b>0.93</b>	0.90	<b>0.91</b>
WS	0.88	0.89	0.87
SSR	0.82	<b>0.92</b>	0.85
TM-nTW	0.91	0.89	0.90
TM-nCP	0.92	0.90	<b>0.91</b>
TM	<b>0.93</b>	0.91	<b>0.91</b>
WePS1 Testing			
Method	P	IP	FMeasure
VSM	0.79	0.85	0.81
GRAPE	0.93	0.83	0.87
WS	0.88	<b>0.90</b>	0.88
SSR	0.85	0.83	0.84
TM-nTW	0.93	0.85	0.88
TM-nCP	0.92	0.86	0.88
TM	<b>0.94</b>	0.86	<b>0.90</b>
WePS2 Testing			
Method	P	IP	FMeasure
VSM	0.82	0.87	0.83
GRAPE	0.88	<b>0.90</b>	0.89
WS	0.85	0.89	0.86
SSR	0.89	0.84	0.86
TM-nTW	0.92	0.87	0.89
TM-nCP	<b>0.93</b>	0.88	0.90
TM	<b>0.93</b>	0.89	<b>0.91</b>

shows that our co-occurrence based pruning strategy can help render the semantic graph with less noisy edges, thus generate more reasonable topics.

Generally, our proposed model works best consistently over all three datasets. Our method gains 9.3% improvement on average in three datasets compared with VSM, 1.7% improvement compared to GRAPE, 3.8% over WS and 6.7% over SSR. We also performed significance testing on F-measures: the differences between our model and other models are significant. We notice there are many noisy or short web pages which lead to inaccurate concept extraction, but this cross document evidences, to some extent, can remedy this. In the *Emily Bender* example, our system correctly groups the odd page, which contains limited clues, into the *nutritionist* cluster,

while the rest, excluding WS and SSR, failed. Surprisingly, SSR combines both kinds of relations and implicit structural knowledge, but performs in the same bulk with VSM in WePS1 training set. We think the reason may be that some name observation sets are too small to estimate non-concept relatedness via random walk. In WePS1 training set, many names in this dataset contains several namesakes, each of which corresponds to a few web pages. In this case, our corpus level weighting scheme and WS show no advantage over GRAPE which considers word co-occurrences solely. From the results, we can also find that there is no clear winner between GRAPE and WS. The former does not use Wikipedia relatedness but only includes local relationship, and performs even slightly better than WS in WePS2, which indicates that non-Wikipedia concepts are important disambiguation features as well.

#### 4.5 Parameter Optimization

In this subsection, we discuss the optimization of several parameters in the proposed method. In total we need to set four parameters. The first one is the edge pruning threshold during graph construction; the second one is the weight  $\alpha$  in SCAN algorithm; the third one and the fourth one are the combination parameters in the final similarity function. We will address the first two in the following. The last two combination parameters are tuned by exhaustively searching the space and omitted here for brevity.

First, we configure the pruning threshold. Intuitively, larger threshold can prune more unimportant edges and improve the disambiguation performance. However, if the threshold is too large, we may prune important edges and harm the results. The F-measure of our method with respect to the pruning threshold is plotted in Figure 2.

From Figure 2, we can know that in all three data sets, a pruning threshold of 0.27 will lead to the best performance. Both increasing and decreasing of this pruning threshold will cause a decline of the F-Measure, because they will either leave more noisy light-weighted edges or prune some important edges.

Secondly, we configure the neighborhood similarity weight. The larger this weight is, the more neighborhood information can influence the similarity between two nodes in the semantic graph. We plot the

Figure 2: The F-Measure v.s. the edge pruning threshold on three data sets.

Figure 3: The F-Measure v.s. the neighborhood similarity weight on three data sets.

performance of our method regarding to the neighborhood similarity weight in Figure 3.

From Figure 3, we know that for the WePS 1 Testing and WePS2 Testing data sets, a neighborhood similarity weight of 0.2 can result in the best performance, but for WePS 1 Training set, the weight for the best performance is 0.6. In fact, when the neighborhood similarity weight varies from 0 to 1, the difference between the best and worst performance are less than 0.01, which indicates that neighborhood similarity is as considerable as semantic relatedness.

## 5 Conclusion and Future Work

In this paper, we explore the feature space in the web person name disambiguation task and propose a topic-based model which exploits corpus level person specific evidences to handle the data sparsity challenges, especially the case that limited evidences can be collected from the local context. In particular, we harvest topics from wikipedia concepts appearing in the name observation set, and weight a concept based on both the relatedness of the concept to its corresponding topic and the importance of this topic in the current name observation set, so that some discriminative but sparse features can obtain more reliable weights. Experimental results show that our weighting strategy does its job and the proposed model outperforms the-state-of-the-art systems. Our current work utilizes the topic information shared in one name observation set but is incapable to handle sparse name set, which needs more accurate relation extraction inside the name observations. Jointly modeling entity linking and person (entity) disambiguation tasks will be an interesting direction where the two tasks are closely related and usually need to be considered at the same time. Investigating the person name disambiguation task in different web applications will also be of great importance, e.g., disambiguating a name in streaming data or during knowledge base construction. In addition, graphical model, which has been studied in academic author disambiguation, may be a good choice to cope with the noises and non-standard forms in web data.

## Acknowledgments

We would like to thank Yidong Chen, Wei Wang and Tinghua Wang for their useful discussions and the anonymous reviewers for their helpful comments which greatly improved the work and the presentation. ## Abstract

This paper proposes a method for learning a discriminative parser for machine translation reordering using only aligned parallel text. This is done by treating the parser’s derivation tree as a latent variable in a model that is trained to maximize reordering accuracy. We demonstrate that efficient large-margin training is possible by showing that two measures of reordering accuracy can be factored over the parse tree. Using this model in the pre-ordering framework results in significant gains in translation accuracy over standard phrase-based SMT and previously proposed unsupervised syntax induction methods.

## 1 Introduction

Finding the appropriate word ordering in the target language is one of the most difficult problems for statistical machine translation (SMT), particularly for language pairs with widely divergent syntax. As a result, there is a large amount of previous research that handles the problem of reordering through the use of improved reordering models for phrase-based SMT (Koehn et al., 2005), hierarchical phrase-based translation (Chiang, 2007), syntax-based translation (Yamada and Knight, 2001), or pre-ordering (Xia and McCord, 2004).

In particular, systems that use source-language syntax allow for the handling of long-distance reordering without large increases in

decoding time. However, these require a good syntactic parser, which is not available for many languages. In recent work, DeNero and Uszkoreit (2011) suggest that unsupervised grammar induction can be used to create source-sentence parse structure for use in translation as a part of a pre-ordering based translation system.

In this work, we present a method for inducing a parser for SMT by training a discriminative model to maximize reordering accuracy while treating the parse tree as a latent variable. As a learning framework, we use online large-margin methods to train the model to directly minimize two measures of reordering accuracy. We propose a variety of features, and demonstrate that learning can succeed when no linguistic information (POS tags or parse structure) is available in the source language, but also show that this linguistic information can be simply incorporated when it is available. Experiments find that the proposed model improves both reordering and translation accuracy, leading to average gains of 1.2 BLEU points on English-Japanese and Japanese-English translation without linguistic analysis tools, or up to 1.5 BLEU points when these tools are incorporated. In addition, we show that our model is able to effectively maximize various measures of reordering accuracy, and that the reordering measure that we choose has a direct effect on translation results.

## 2 Preordering for SMT

Machine translation is defined as transformation of source sentence  $F = f_1 \dots f_J$  to target sentence  $E = e_1 \dots e_I$ . In this paper, we take

---

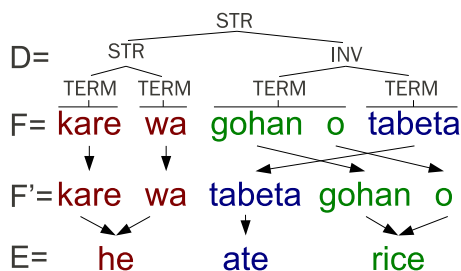

Figure 1: An example with a source sentence  $F$  reordered into target order  $F'$ , and its corresponding target sentence  $E$ .  $D$  is one of the BTG derivations that can produce this ordering.

the pre-ordering approach to machine translation (Xia and McCord, 2004), which performs translation as a two step process of reordering and translation (Figure 1). Reordering first deterministically transforms  $F$  into  $F'$ , which contains the same words as  $F$  but is in the order of  $E$ . Translation then transforms  $F'$  into  $E$  using a method such as phrase-based SMT (Koehn et al., 2003), which can produce accurate translations when only local reordering is required.

This general framework has been widely studied, with the majority of works relying on a syntactic parser being available in the source language. Reordering rules are defined over this parse either through machine learning techniques (Xia and McCord, 2004; Zhang et al., 2007; Li et al., 2007; Genzel, 2010; Dyer and Resnik, 2010; Khalilov and Sima'an, 2011) or linguistically motivated manual rules (Collins et al., 2005; Xu et al., 2009; Carpuat et al., 2010; Isozaki et al., 2010b). However, as building a parser for each source language is a resource-intensive undertaking, there has also been some interest in developing reordering rules without the use of a parser (Rottmann and Vogel, 2007; Tromble and Eisner, 2009; DeNero and Uszkoreit, 2011; Visweswariah et al., 2011), and we will follow this thread of research in this paper.

In particular, two methods deserve mention for being similar to our approach. First, DeNero and Uszkoreit (2011) learn a reordering model through a three-step process of bilingual grammar induction, training a monolingual parser to reproduce the induced trees, and training

a reordering model that selects a reordering based on this parse structure. In contrast, our method trains the model in a single step, treating the parse structure as a latent variable in a discriminative reordering model. In addition Tromble and Eisner (2009) and Visweswariah et al. (2011) present models that use binary classification to decide whether each pair of words should be placed in forward or reverse order. In contrast, our method uses traditional context-free-grammar models, which allows for simple parsing and flexible parameterization, including features such as those that utilize the existence of a span in the phrase table. Our work is also unique in that we show that it is possible to directly optimize several measures of reordering accuracy, which proves important for achieving good translations.<sup>1</sup>

### 3 Training a Reordering Model with Latent Derivations

In this section, we provide a basic overview of the proposed method for learning a reordering model with latent derivations using online discriminative learning.

#### 3.1 Space of Reorderings

The model we present here is based on the bracketing transduction grammar (BTG, Wu (1997)) framework. BTGs represent a binary tree derivation  $D$  over the source sentence  $F$  as shown in Figure 1. Each non-terminal node can either be a straight (STR) or inverted (INV) production, and terminals (TERM) span a non-empty substring  $f$ .<sup>2</sup>

The ordering of the sentence is determined by the tree structure and the non-terminal labels STR and INV, and can be built bottom-up. Each subtree represents a source substring  $f$  and its reordered counterpart  $f'$ . For each terminal node, no reordering occurs and  $f$  is equal to  $f'$ .

<sup>1</sup>The semi-supervised method of Katz-Brown et al. (2011) also optimizes reordering accuracy, but requires manually annotated parses as seed data.

<sup>2</sup>In the original BTG framework used in translation, terminals produce a bilingual substring pair  $f/e$ , but as we are only interested in reordering the source  $F$ , we simplify the model by removing the target substring  $e$ .

For each non-terminal node spanning  $f$  with its left child spanning  $f_1$  and its right child spanning  $f_2$ , if the non-terminal symbol is STR, the reordered strings will be concatenated in order as  $f' = f'_1 f'_2$ , and if the non-terminal symbol is INV, the reordered strings will be concatenated in inverted order as  $f' = f'_2 f'_1$ .

We define the space of all reorderings that can be produced by the BTG as  $\mathcal{F}'$ , and attempt to find the best reordering  $\hat{F}'$  within this space.<sup>3</sup>

### 3.2 Reorderings with Latent Derivations

In order to find the best reordering  $\hat{F}'$  given only the information in the source side sentence  $F$ , we define a scoring function  $S(F'|F)$ , and choose the ordering of maximal score:

$$\hat{F}' = \arg \max_{F'} S(F'|F).$$

As our model is based on reorderings licensed by BTG derivations, we also assume that there is an underlying derivation  $D$  that produced  $F'$ . As we can uniquely determine  $F'$  given  $F$  and  $D$ , we can define a scoring function  $S(D|F)$  over derivations, find the derivation of maximal score

$$\hat{D} = \arg \max_D S(D|F)$$

and use  $\hat{D}$  to transform  $F$  into  $F'$ .

Furthermore, we assume that the score  $S(D|F)$  is the weighted sum of a number of feature functions defined over  $D$  and  $F$

$$S(D|F, \mathbf{w}) = \sum_i w_i \phi_i(D, F)$$

where  $\phi_i$  is the  $i$ th feature function, and  $w_i$  is its corresponding weight in weight vector  $\mathbf{w}$ .

Given this model, we must next consider how to learn the weights  $\mathbf{w}$ . As the final goal of our model is to produce good reorderings  $F'$ , it is natural to attempt to learn weights that will allow us to produce these high-quality reorderings.

<sup>3</sup>BTGs cannot reproduce all possible reorderings, but can handle most reorderings occurring in natural translated text (Haghighi et al., 2009).

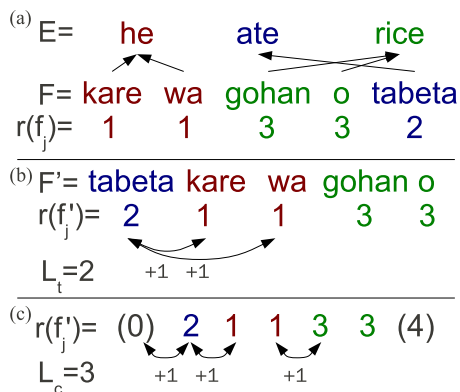

Figure 2: An example of (a) the ranking function  $r(f_j)$ , (b) loss according to Kendall's  $\tau$ , (c) loss according to chunk fragmentation.

## 4 Evaluating Reorderings

Before we explain the learning algorithm, we must know how to distinguish whether the  $F'$  produced by the model is good or bad. This section explains how to calculate oracle reorderings, and assign each  $F'$  a *loss* and an *accuracy* according to how well it reproduces the oracle.

### 4.1 Calculating Oracle Orderings

In order to calculate reordering quality, we first define a ranking function  $r(f_j|F, A)$ , which indicates the relative position of source word  $f_j$  in the proper target order (Figure 2 (a)). In order to calculate this ranking function, we define  $A = \mathbf{a}_1, \dots, \mathbf{a}_J$ , where each  $\mathbf{a}_j$  is a set of the indices of the words in  $E$  to which  $f_j$  is aligned.<sup>4</sup> Given these alignments, we define an ordering function  $\mathbf{a}_{j_1} < \mathbf{a}_{j_2}$  that indicates that the indices in  $\mathbf{a}_{j_1}$  come before the indices in  $\mathbf{a}_{j_2}$ . Formally, we define this function as “the first index in  $\mathbf{a}_{j_1}$  is at most the first index in  $\mathbf{a}_{j_2}$ , similarly for the last index, and either the first or last index in  $\mathbf{a}_{j_1}$  is less than that of  $\mathbf{a}_{j_2}$ .”

Given this ordering, we can sort every alignment  $\mathbf{a}_j$ , and use its relative position in the sentence to assign a rank to its word  $r(f_j)$ . In

<sup>4</sup>Null alignments require special treatment. To do so, we can place unaligned brackets and quotes directly before and after the spans they surround, and attach all other unaligned words to the word directly to the right for head-initial languages (e.g. English), or left for head-final languages (e.g. Japanese).

the case of ties, where neither  $\mathbf{a}_{j_1} < \mathbf{a}_{j_2}$  nor  $\mathbf{a}_{j_2} < \mathbf{a}_{j_1}$ , both  $f_{j_1}$  and  $f_{j_2}$  are assigned the same rank. We can now define measures of re-ordering accuracy for  $F'$  by how well it arranges the words in order of ascending rank. It should be noted that as we allow ties in rank, there are multiple possible  $F'$  where all words are in strictly ascending order, which we will call *oracle* orderings.

## 4.2 Kendall’s $\tau$

The first measure of reordering accuracy that we will consider is Kendall’s  $\tau$  (Kendall, 1938), a measure of pairwise rank correlation which has been proposed for evaluating translation re-ordering accuracy (Isozaki et al., 2010a; Birch et al., 2010) and pre-ordering accuracy (Talbot et al., 2011). The fundamental idea behind the measure lies in comparisons between each pair of elements  $f'_{j_1}$  and  $f'_{j_2}$  of the reordered sentence, where  $j_1 < j_2$ . Because  $j_1 < j_2$ ,  $f'_{j_1}$  comes before  $f'_{j_2}$  in the reordered sentence, the ranks should be  $r(f'_{j_1}) \leq r(f'_{j_2})$  in order to produce the correct ordering.

Based on this criterion, we first define a loss  $L_t(F')$  that will be higher for orderings that are further from the oracle. Specifically, we take the sum of all pairwise orderings that do not follow the expected order

$$L_t(F') = \sum_{j_1=1}^{J-1} \sum_{j_2=j_1+1}^J \delta(r(f'_{j_1}) > r(f'_{j_2}))$$

where  $\delta(\cdot)$  is an indicator function that is 1 when its condition is true, and 0 otherwise. An example of this is given in Figure 2 (b).

To calculate an accuracy measure for ordering  $F'$ , we first calculate the maximum loss for the sentence, which is equal to the total number of non-equal rank comparisons in the sentence<sup>5</sup>

$$\max_{F'} L_t(F') = \sum_{j_1=1}^{J-1} \sum_{j_2=j_1+1}^J \delta(r(f'_{j_1}) \neq r(f'_{j_2})). \quad (1)$$

<sup>5</sup>The traditional formulation of Kendall’s  $\tau$  assumes no ties in rank, and thus the maximum loss can be calculated as  $J(J-1)/2$ .

Finally, we use this maximum loss to normalize the actual loss to get an accuracy

$$A_t(F') = 1 - \frac{L_t(F')}{\max_{\tilde{F}'} L_t(\tilde{F}')},$$

which will take a value between 0 (when  $F'$  has maximal loss), and 1 (when  $F'$  matches one of the oracle orderings). In Figure 2 (b),  $L_t(F') = 2$  and  $\max_{\tilde{F}'} L_t(\tilde{F}') = 8$ , so  $A_t(F') = 0.75$ .

## 4.3 Chunk Fragmentation

Another measure that has been used in evaluation of translation accuracy (Banerjee and Lavie, 2005) and pre-ordering accuracy (Talbot et al., 2011) is chunk fragmentation. This measure is based on the number of chunks that the sentence needs to be broken into to reproduce the correct ordering, with a motivation that the number of continuous chunks is equal to the number of times the reader will have to jump to a different position in the reordered sentence to read it in the target order. One way to measure the number of continuous chunks is considering whether each word pair  $f'_j$  and  $f'_{j+1}$  is discontinuous (the rank of  $f'_{j+1}$  is not equal to or one greater than  $f'_j$ )

$$\text{DISCONT}(f'_j, f'_{j+1}) = \delta(r(f'_j) \neq r(f'_{j+1}) \wedge r(f'_j) + 1 \neq r(f'_{j+1}))$$

and sum over all word pairs in the sentence to create a sentence-based loss

$$L_c(F') = \sum_{j=1}^{J-1} \text{DISCONT}(f'_j, f'_{j+1}) \quad (2)$$

While this is the formulation taken by previous work, we found that this under-penalizes bad reorderings of the first and last words of the sentence, which can contribute to the loss only once, as opposed to other words which can contribute to the loss twice. To account for this, when calculating the chunk fragmentation score, we additionally add two sentence boundary words  $f_0$  and  $f_{J+1}$  with ranks  $r(f_0) = 0$  and  $r(f_{J+1}) = 1 + \max_{f'_j \in F'} r(f'_j)$  and redefine the summation in Equation (2) to consider these words (e.g. Figure 2 (c)).

```

procedure WEIGHTUPDATE( $F, A, \mathbf{w}$ )
   $\mathcal{D} \leftarrow \text{parse}(F, \mathbf{w})$  ▷ Create parse forest
   $\dot{D} \leftarrow \underset{D \in \mathcal{D}}{\text{argmax}} S(D|F, \mathbf{w}) + L(D|F, A)$ 
▷ Find the model parse
   $\hat{D} \leftarrow \underset{D \in \mathcal{D}}{\text{argmin}} L(D|F, A) - \alpha S(D|F, \mathbf{w})$ 
▷ Find the oracle parse
  if  $L(\hat{D}|F, A) \neq L(\dot{D}|F, A)$  then
     $\mathbf{w} \leftarrow \beta(\mathbf{w} + \gamma(\phi(\hat{D}, F) - \phi(\dot{D}, F)))$ 
▷ Perform weight update
  end if
end procedure

```

Figure 3: An online update for sentence  $F$ , alignment  $A$ , and weight vector  $\mathbf{w}$ .  $\alpha$  is a very small constant, and  $\beta$  and  $\gamma$  are defined by the update strategy.

Similarly to Kendall’s  $\tau$ , we can also define an accuracy measure between 0 and 1 using the maximum loss, which will be at most  $J + 1$ , which corresponds to the total number of comparisons made in calculating the loss<sup>6</sup>

$$A_c(F') = 1 - \frac{L_c(F')}{J + 1}.$$

In Figure 2 (c),  $L_c(F') = 3$  and  $J + 1 = 6$ , so  $A_c(F') = 0.5$ .

## 5 Learning a BTG Parser for Reordering

Now that we have a definition of loss over reorderings produced by the model, we have a clear learning objective: we would like to find reorderings  $F'$  with low loss. The learning algorithm we use to achieve this goal is motivated by discriminative training for machine translation systems (Liang et al., 2006), and extended to use large-margin training in an online framework (Watanabe et al., 2007).

### 5.1 Learning Algorithm

Learning uses the general framework of large-margin online structured prediction (Crammer et al., 2006), which makes several passes through the data, finding a derivation with high model score (the *model* parse) and a derivation with

<sup>6</sup>It should be noted that for sentences of length one or sentences with tied ranks, the maximum loss may be less than  $J + 1$ , but for simplicity we use this approximation.

minimal loss (the *oracle* parse), and updating  $\mathbf{w}$  if these two parses diverge (Figure 3).

In order to create both of these parses efficiently, we first create a parse forest encoding a large number of derivations  $\mathcal{D}_i$  according to the model scores. Next, we find the model parse  $\dot{D}_i$ , which is the parse in the forest  $\mathcal{D}_i$  that maximizes the sum of the model score and the loss  $S(D_k|F_k, \mathbf{w}) + L(D_k|F_k, A_k)$ . It should be noted that here we are considering not only the model score, but also the derivation’s loss. This is necessary for loss-driven large-margin training (Crammer et al., 2006), and follows the basic intuition that during training, we would like to make it easier to select negative examples with large loss, causing these examples to be penalized more often and more heavily.

We also find an oracle parse  $\hat{D}_i$ , which is selected solely to minimize the loss  $L(D_k|F_k, A_k)$ . One important difference between the model we describe here and traditional parsing models is that the target derivation  $\hat{D}_k$  is a latent variable. Because many  $D_k$  achieve a particular reordering  $F'$ , many reorderings  $F'$  are able to minimize the loss  $L(F'_k|F_k, A_k)$ . Thus it is necessary to choose a single oracle derivation to treat as the target out of many equally good reorderings. DeNero and Uszkoreit (2011) resolve this ambiguity with four features with empirically tuned scores before training a monolingual parser and reordering model. In contrast, we follow previous work on discriminative learning with latent variables (Yu and Joachims, 2009), and break ties within the pool of oracle derivations by selecting the derivation with the largest model score. From an implementation point of view, this can be done by finding the derivation that minimizes  $L(D_k|F_k, A_k) - \alpha S(D_k|F_k, \mathbf{w})$ , where  $\alpha$  is a constant small enough to ensure that the effect of the loss will always be greater than the effect of the score.

Finally, if the model parse  $\dot{D}_k$  has a loss that is greater than that of the oracle parse  $\hat{D}_k$ , we update the weights to increase the score of the oracle parse and decrease the score of the model parse. Any criterion for weight updates may be used, such as the averaged perceptron (Collins, 2002) and MIRA (Crammer et al., 2006), but

we opted to use Pegasus (Shalev-Shwartz et al., 2007) as it allows for the introduction of regularization and relatively stable learning.

To perform this full process, given a source sentence  $F_k$ , alignment  $A_k$ , and model weights  $\mathbf{w}$  we need to be able to efficiently calculate scores, calculate losses, and create parse forests for derivations  $D_k$ , the details of which will be explained in the following sections.

## 5.2 Scoring Derivation Trees

First, we must consider how to efficiently assign scores  $S(D|F, \mathbf{w})$  to a derivation or forest during parsing. The most standard and efficient way to do so is to create local features that can be calculated based only on the information included in a single node  $d$  in the derivation tree. The score of the whole tree can then be expressed as the sum of the scores from each node:

$$\begin{aligned} S(D|F, \mathbf{w}) &= \sum_{d \in D} S(d|F, \mathbf{w}) \\ &= \sum_{d \in D} \sum_i w_i \phi_i(d, F). \end{aligned}$$

Based on this restriction, we define a number of features that can be used to score the parse tree. To ease explanation, we represent each node in the derivation as  $d = \langle s, l, c, c + 1, r \rangle$ , where  $s$  is the node’s symbol (STR, INV, or TERM), while  $l$  and  $r$  are the leftmost and rightmost indices of the span that  $d$  covers.  $c$  and  $c + 1$  are the rightmost index of the left child and leftmost index of the right child for non-terminal nodes.

All features are intersected with the node label  $s$ , so each feature described below corresponds to three different features (or two for features applicable to only non-terminal nodes).

- $\phi_{lex}$ : Identities of words in positions  $f_l, f_r, f_c, f_{c+1}, f_{l-1}, f_{r+1}, flfr$ , and  $f_c f_{c+1}$ .
- $\phi_{class}$ : Same as  $\phi_{lex}$ , but with words abstracted to classes. We use the 50 classes automatically generated by Och (1999)’s method that are calculated during alignment in standard SMT systems.
- $\phi_{balance}$ : For non-terminals, features indicating whether the length of the left span

$(c - l + 1)$  is lesser than, equal to, or greater than the length of the right span  $(r - c)$ .

- $\phi_{table}$ : Features, bucketed by length, that indicate whether “ $f_l \dots f_r$ ” appears as a contiguous phrase in the SMT training data, as well as the log frequency of the number of times the phrase appears total and the number of times it appears as a contiguous phrase (DeNero and Uszkoreit, 2011). Phrase length is limited to 8, and phrases of frequency one are removed.
- $\phi_{pos}$ : Same as  $\phi_{lex}$ , but with words abstracted to language-dependent POS tags.
- $\phi_{cfg}$ : Features indicating the label of the spans  $f_l \dots f_r, f_l \dots f_c$ , and  $f_{c+1} \dots f_r$  in a supervised parse tree, and the intersection of the three labels. When spans do not correspond to a span in the supervised parse tree, we indicate “no span” with the label “X” (Zollmann and Venugopal, 2006).

Most of these features can be calculated from only a parallel corpus, but  $\phi_{pos}$  requires a POS tagger and  $\phi_{cfg}$  requires a full syntactic parser in the source language. As it is preferable to have a method that is applicable in languages where these tools are not available, we perform experiments both with and without the features that require linguistic analysis tools.

## 5.3 Finding Losses for Derivation Trees

The above features  $\phi$  and their corresponding weights  $\mathbf{w}$  are all that are needed to calculate scores of derivation trees at test time. However, during training, it is also necessary to find model parses according to the loss-augmented scoring function  $S(D|F, \mathbf{w}) + L(D|F, A)$  or oracle parses according to the loss  $L(D|F, A)$ . As noted by Taskar et al. (2003), this is possible if our losses can be factored in the same way as the feature space. In this section, we demonstrate that the loss  $L(d|F, A)$  for the evaluation measures we defined in Section 4 can (mostly) be factored over nodes in a fashion similar to features.

### 5.3.1 Factoring Kendall’s $\tau$

For Kendall’s  $\tau$ , in the case of terminal nodes,  $L_t(d = \langle \text{TERM}, l, r \rangle | F, A)$  can be calculated by performing the summation in Equation (1). We can further define this sum recursively and use memoization for improved efficiency

$$L_t(d|F, A) = L_t(\langle \text{TERM}, l, r - 1 \rangle | F, A) + \sum_{j=l}^{r-1} \delta(r(f_j) > r(f_r)). \quad (3)$$

For non-terminal nodes, we first focus on straight non-terminals with parent node  $d = \langle \text{STR}, l, c, c + 1, r \rangle$ , and left and right child nodes  $d_l = \langle s_l, l, lc, lc + 1, c \rangle$  and  $d_r = \langle s_r, c + 1, rc, rc + 1, r \rangle$ . First, we note that the loss for the subtree rooted at  $d$  can be expressed as

$$L_t(d|F, A) = L_t(d_l|F, A) + L_t(d_r|F, A) + \sum_{j_1=l}^c \sum_{j_2=c+1}^r \delta(r(f_{j_1}) > r(f_{j_2})).$$

In other words, the subtree’s total loss can be factored into the loss of its left subtree, the loss of its right subtree, and the additional loss contributed by comparisons between the words spanning both subtrees. In the case of inverted terminals, we must simply reverse the comparison in the final sum to be  $\delta(r(f_{j_1}) < r(f_{j_2}))$ .

### 5.3.2 Factoring Chunk Fragmentation

Chunk fragmentation loss can be factored in a similar fashion. First, it is clear that the loss for the terminal nodes can be calculated efficiently in a fashion similar to Equation (3). In order to calculate the loss for non-terminals  $d$ , we note that the summation in Equation (2) can be divided into the sum over the internal bi-grams in the left and right subtrees, and the bi-gram spanning the reordered trees

$$L_c(d|F, A) = L_c(d_l|F, A) + L_c(d_r|F, A) + \text{DISCONT}(f'_c, f'_{c+1}).$$

However, unlike Kendall’s  $\tau$ , this equation relies not on the ranks of  $f_c$  and  $f_{c+1}$  in the original sentence, but on the ranks of  $f'_c$  and  $f'_{c+1}$  in the reordered sentence. In order to keep track

of these values, it is necessary to augment each node in the tree to be  $d = \langle s, l, c, c + 1, r, tl, tr \rangle$  with two additional values  $tl$  and  $tr$  that indicate the position of the leftmost and rightmost words after reordering. Thus, a straight non-terminal parent  $d$  with children  $d_l = \langle s_l, l, lc, lc + 1, c, tl, tlr \rangle$  and  $d_r = \langle s_r, c + 1, rc, rc + 1, r, trl, tr \rangle$  will have loss as follows

$$L_c(d|F, A) = L_c(d_l|F, A) + L_c(d_r|F, A) + \text{DISCONT}(f_{tlr}, f_{trl})$$

with a similar calculation being possible for inverted non-terminals.

## 5.4 Parsing Derivation Trees

Finally, we must be able to create a parse forest from which we select model and oracle parses. As all feature functions factor over single nodes, it is possible to find the parse tree with the highest score in  $O(J^3)$  time using the CKY algorithm. However, when keeping track of target positions for calculation of chunk fragmentation loss, there are a total of  $O(J^5)$  nodes, an unreasonable burden in terms of time and memory. To overcome this problem, we note that this setting is nearly identical to translation using synchronous CFGs with an integrated bigram LM, and thus we can employ cube-pruning to reduce our search space (Chiang, 2007).

## 6 Experiments

Our experiments test the reordering and translation accuracy of translation systems using the proposed method. As reordering metrics, we use Kendall’s  $\tau$  and chunk fragmentation (Talbot et al., 2011) comparing the system  $F'$  and oracle  $F'$  calculated with manually created alignments. As translation metrics, we use BLEU (Papineni et al., 2002), as well as RIBES (Isozaki et al., 2010a), which is similar to Kendall’s  $\tau$ , but evaluated on the target sentence  $E$  instead of the reordered sentence  $F'$ . All scores are the average of three training runs to control for randomness in training (Clark et al., 2011).

For translation, we use Moses (Koehn et al., 2007) with lexicalized reordering (Koehn et al., 2005) in all experiments. We test three types

	en-ja				ja-en			
	Chunk	$\tau$	BLEU	RIBES	Chunk	$\tau$	BLEU	RIBES

Table 1: The number of sentences and words for training and testing the reordering model (RM), translation model (TM), and language model (LM).

of pre-ordering: original order with  $F' \leftarrow F$  (ORIG), pre-orderings learned using the 3-step process of DeNero and Uszkoreit (2011) (3-STEP), and the proposed model with latent derivations (LADER).<sup>7</sup> Except when stated otherwise, LADER was trained to minimize chunk fragmentation loss with a cube pruning stack pop limit of 50, and the regularization constant of  $10^{-3}$  (chosen through cross-validation).

We test our systems on Japanese-English and English-Japanese translation using data from the Kyoto Free Translation Task (Neubig, 2011). We use the training set for training translation and language models, the development set for weight tuning, and the test set for testing (Table 1). We use the designated development and test sets of manually created alignments as training data for the reordering models, removing sentences of more than 60 words.

As default features for LADER and the monolingual parsing and reordering models in 3-STEP, we use all the features described in Section 5.2

<sup>7</sup>Available open-source: <http://phontron.com/lader>

except  $\phi_{pos}$  and  $\phi_{cfg}$ . In addition, we test systems with  $\phi_{pos}$  and  $\phi_{cfg}$  added. For English, we use the Stanford parser (Klein and Manning, 2003) for both POS tagging and CFG parsing. For Japanese, we use the KyTea tagger (Neubig et al., 2011) for POS tagging,<sup>8</sup> and the EDA word-based dependency parser (Flannery et al., 2011) with simple manual head-rules to convert a dependency parse to a CFG parse.

## 6.1 Effect of Pre-ordering

Table 2 shows reordering and translation results for ORIG, 3-STEP, and LADER. It can be seen that the proposed LADER outperforms the baselines in both reordering and translation.<sup>9</sup> There are a number of reasons why LADER outperforms 3-STEP. First, the pipeline of 3-STEP suffers from error propagation, with errors in monolingual parsing and reordering resulting in low overall accuracy.<sup>10</sup> Second, as Section 5.1 describes, LADER breaks ties between oracle parses based on model score, allowing easy-to-reproduce model parses to be chosen during training. In fact, LADER generally found trees that followed from syntactic constituency, while 3-STEP more often used terminal nodes

<sup>8</sup>In addition, following the example of Sudoh et al. (2011a)’s reordering rules, we lexicalize all particles.

<sup>9</sup>It should be noted that our results for 3-STEP are significantly worse than those of DeNero and Uszkoreit (2011). Likely reasons include a 20x difference in training data size, the fact that we are using naturally translated text as opposed to text translated specifically to create word alignments, or differences in implementation.

<sup>10</sup>When using oracle parses, chunk accuracy was up to 81%, showing that parsing errors are highly detrimental.

	en-ja				ja-en			
	Chunk	$\tau$	BLEU	RIBES	Chunk	$\tau$	BLEU	RIBES
$L_c$	<b>73.19</b>	78.44	<b>23.11</b>	69.86	<b>75.14</b>	<b>79.14</b>	<b>19.54</b>	<b>66.93</b>
$L_t$	70.37	79.57	22.57	69.47	72.51	78.93	18.52	66.26
$L_c + L_t$	72.55	<b>80.58</b>	<b>22.89</b>	<b>70.34</b>	74.44	<b>79.82</b>	19.21	<b>66.48</b>

Table 3: Results for systems trained to optimize chunk fragmentation ( $L_c$ ) or Kendall’s  $\tau$  ( $L_t$ ).

that spanned constituent boundaries (as long as the phrase frequency was high). Finally, as Section 6.2 shows in detail, the ability of LADER to maximize reordering accuracy directly allows for improved reordering and translation results.

It can also be seen that incorporating POS tags or parse trees improves accuracy of both LADER and 3-STEP, particularly for English-Japanese, where syntax has proven useful for pre-ordering, and less so for Japanese-English, where syntactic pre-ordering has been less successful (Sudoh et al., 2011b).

We also tested Moses’s implementation of hierarchical phrase-based SMT (Chiang, 2007), which achieved BLEU scores of 23.21 and 19.30 for English-Japanese and Japanese-English respectively, approximately matching LADER in accuracy, but with a significant decrease in decoding speed. Further, when pre-ordering with LADER and hierarchical phrase-based SMT were combined, BLEU scores rose to 23.29 and 19.69, indicating that the two techniques can be combined for further accuracy improvements.

## 6.2 Effect of Training Loss

Table 3 shows results when one of three losses is optimized during training: chunk fragmentation ( $L_c$ ), Kendall’s  $\tau$  ( $L_t$ ), or the linear interpolation of the two with weights chosen so that both losses contribute equally ( $L_t + L_c$ ). In general, training successfully maximizes the criterion it is trained on, and  $L_t + L_c$  achieves good results on both measures. We also find that  $L_c$  and  $L_c + L_t$  achieve the best translation results, which is in concert with Talbot et al. (2011), who find chunk fragmentation is better correlated with translation accuracy than Kendall’s  $\tau$ . This is an important result, as methods such as that of Tromble and Eisner (2009) optimize pairwise

word comparisons equivalent to  $L_t$ , which may not be optimal for translation.

## 6.3 Effect of Automatic Alignments

Table 4 shows the difference between using manual and automatic alignments in the training of LADER. LADER is able to improve over the ORIG baseline in all cases, but when equal numbers of manual and automatic alignments are used, the reorderer trained on manual alignments is significantly better. However, as the number of automatic alignments is increased, accuracy improves, approaching that of the system trained on a smaller number of manual alignments.

## 7 Conclusion

We presented a method for learning a discriminative parser to maximize reordering accuracy for machine translation. Future work includes application to other language pairs, development of more sophisticated features, investigation of probabilistic approaches to inference, and incorporation of the learned trees directly in tree-to-string translation.

## Acknowledgments

We thank Isao Goto, Tetsuo Kiso, and anonymous reviewers for their helpful comments, and Daniel Flannery for helping to run his parser.

## Abstract

The training of most syntactic SMT approaches involves two essential components, word alignment and monolingual parser. In the current state of the art these two components are mutually independent, thus causing problems like lack of rule generalization, and violation of syntactic correspondence in translation rules. In this paper, we propose two ways of re-training monolingual parser with the target of maximizing the consistency between parse trees and alignment matrices. One is targeted self-training with a simple evaluation function; the other is based on training data selection from forced alignment of bilingual data. We also propose an auxiliary method for boosting alignment quality, by symmetrizing alignment matrices with respect to parse trees. The best combination of these novel methods achieves 3 Bleu point gain in an IWSLT task and more than 1 Bleu point gain in NIST tasks.

## 1 Introduction

There are many varieties in syntactic statistical machine translation (SSMT). Apart from a few attempts to use synchronous parsing to produce the tree structure of both source language (SL) and target language (TL) simultaneously, most SSMT approaches make use of monolingual parser to produce the parse tree(s) of the SL and/or TL sentences, and then link up the information of the two languages through word alignment. In the current state of the art, word aligner and monolingual parser are trained and applied separately. On the one hand, an average word aligner does not consider the syntax information of both languages, and the output links may violate syntactic correspondence. That is, some SL words

yielded by a SL parse tree node may not be traced to, via alignment links, some TL words with legitimate syntactic structure. On the other hand, parser design is a monolingual activity and its impact on MT is not well studied (Ambati, 2008). Many good translation rules may thus be filtered by a good monolingual parser.

In this paper we will focus on the translation task from Chinese to English, and the string-to-tree SSMT model as elaborated in (Galley et al., 2006). There are two kinds of translation rules in this model, minimal rules, and composed rules, which are composition of minimal rules. The minimal rules are extracted from a special kind of nodes, known as frontier nodes, on TL parse tree. The concept of frontier node can be illustrated by Figure 1, which shows two partial bilingual sentences with the corresponding TL sub-trees and word alignment links. The TL words yielded by a TL parse node can be traced to the corresponding SL words through alignment links. In the diagram, each parse node is represented by a rectangle, showing the phrase label, span, and complement span respectively. The span of a TL node  $N$  is defined as the minimal contiguous SL string that covers all the SL words reachable from  $N$ . The complement span of  $N$  is the union of spans of all the nodes that are neither descendants nor ancestors of  $N$  (c.f. Galley et al., 2006). A frontier node is a node of which the span and the complement span do not overlap with each other. In the diagram, frontier nodes are grey in color. Frontier node is the key in the SSMT model, as it identifies the bilingual information which is consistent with both the parse tree and alignment matrix.

There are two major problems in the SSMT model. The first one is the violation of syntactic

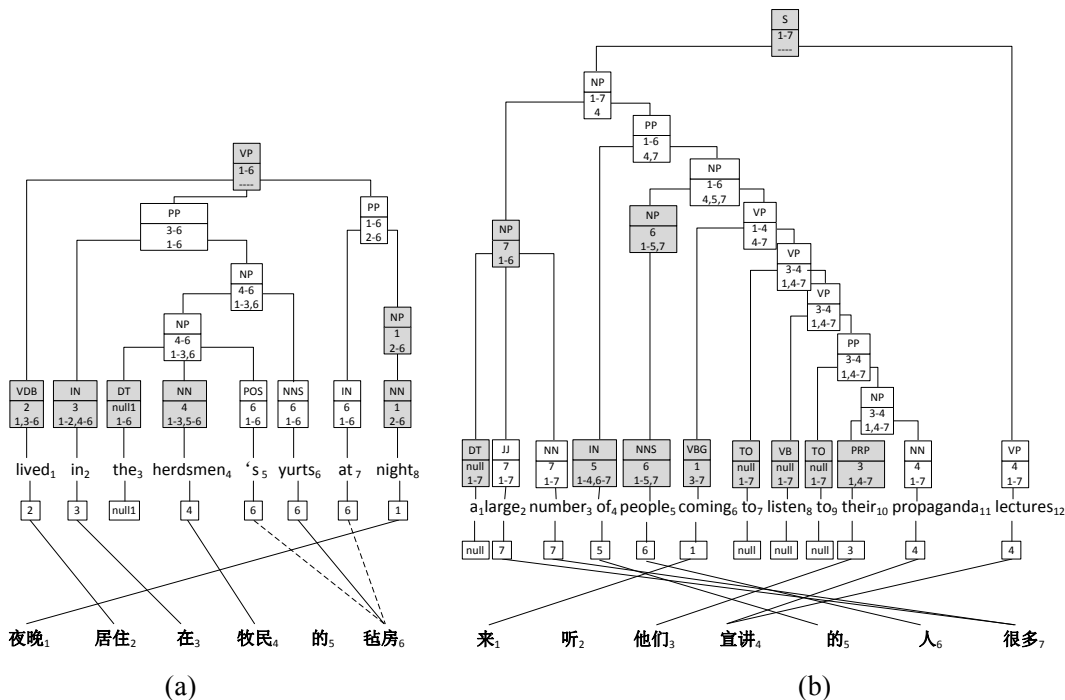

Figure 1. Two example partial bilingual sentences with word alignment and syntactic tree for the target sentence. All the nodes in gray are frontier nodes. Example (a) contains two error links (in dashed line), and the syntactic tree for the target sentence of example (b) is wrong.

structure by incorrect alignment links, as shown by the two dashed links in Figure 1(a). These two incorrect links hinder the extraction of a good minimal rule “毡房<sub>7</sub> → NNS(yurts)” and that of a good composed rule “牧民<sub>4</sub>, 的<sub>5</sub> → NP(DT(the), NN(herdsmen), POS('s))”. By and large, incorrect alignment links lead to translation rules that are large in size, few in number, and poor in generalization ability (Fossum et al, 2008). The second problem is parsing error, as shown in Figure 1(b). The incorrect POS tagging of the word “lectures” causes a series of parsing errors, including the absence of the noun phrase “NP(NN(propaganda), NN(lectures))”. These parsing errors hinder the extraction of good rules, such as “宣讲<sub>4</sub> → NP(NN(propaganda), NN(lectures))”.

Note that in Figure 1(a), the parse tree is correct, and the incorrect alignment links might be fixed if the aligner takes the parse tree into consideration. Similarly, in Figure 1(b) some parsing errors might be fixed if the parser takes into consideration the correct alignment links about “propaganda” and

“lecture”. That is, alignment errors and parsing might be fixed if word aligner and parser are not mutually independent.

In this paper, we emphasize more on the correction of parsing errors by exploiting alignment information. The general approach is to re-train a parser with parse trees which are the most consistent with alignment matrices. Our first strategy is to apply the idea of targeted self-training (Katz-Brown et al., 2011) with the simple evaluation function of frontier set size. That is to re-train the parser with the parse trees which give rise to the largest number of frontier nodes. The second strategy is to apply forced alignment (Wuebker et al., 2010) to bilingual data and select the parse trees generated by our SSMT system for re-training the parser. Besides, although we do not invent a new word aligner exploiting syntactic information, we propose a new method to symmetrize the alignment matrices of two directions by taking parse tree into consideration.

## 2 Parser Re-training Strategies

Most monolingual parsers used in SSMT are trained upon certain tree bank. That is, a parser is trained with the target of maximizing the agreement between its decision on syntactic structure and that decision in the human-annotated parse trees. As mentioned in Section 1, monolingual syntactic structure is not necessarily suitable for translation, and sometimes the bilingual information in word alignment may help the parser find out the correct structure. Therefore, it is desirable if there is a way to re-train a parser with bilingual information.

What is needed includes a framework of parser re-training, and a data selection strategy that maximizes the consistency between parse tree and alignment matrix. Our two solutions will be introduced in the next two subsections respectively.

### 2.1 Targeted Self-Training with Frontier Set Based Evaluation (TST-FS)

The first solution is based on targeted self-training (TST) (Katz-Brown et al., 2011). In standard self-training, the top one parse trees produced by the current parser are taken as training data for the next round, and the training objective is still the correctness of monolingual syntactic structure. In targeted self-training, the training objective shifts to certain external evaluation function. For each sentence, the n-best parse trees from the current parser are re-ranked in accordance with this external evaluation function, and the top one of the re-ranked candidates is then selected as training data for the next round. The key of targeted self-training is the definition of this external evaluation function.

As shown by the example in Figure 1(b), an incorrect parse tree is likely to hinder the extraction of good translation rules, because the number of frontier nodes in the incorrect tree is in general smaller than that in the correct tree. Consider the example in Figure 2, which is about the same partial bilingual sentence as in Figure 1(b). Although both parse trees do not have the correct syntactic structure, the tree in Figure 2 has more frontier nodes, leads to more valid translation rules, and is therefore more preferable.

This example suggests a very simple external evaluation function, viz. the size of frontier set. Given a bilingual sentence, its alignment matrix,

Figure 2. The parse tree selected by TST-FS for the example in Figure 1(b)

and the N-best parse trees of the TL sentence, we will calculate the number of frontier nodes for each parse tree, and re-rank the parse trees in its descending order. The new top one parse tree is selected as the training data for the next round of targeted self-training of the TL parser. In the following we will call this approach as targeted self-training with frontier set based evaluation (TST-FS).

Note that the size of the N-best list should be kept small. It is because sometimes a parse tree with an extremely mistaken structure happens to have perfect match with the alignment matrix, thereby giving rise to nearest the largest frontier set size. It is empirically found that a 5-best list of parse trees is already sufficient to significantly improve translation performance.

### 2.2 Forced Alignment-based Parser Re-Training (FA-PR)

If we doubt that the parse tree from a monolingual parser is not appropriate enough for translation purpose, then it seems reasonable to consider using the parse tree produced by an SSMT system to re-train the parser. A naïve idea is simply to run an SSMT system over some SL sentences and retrieve the by-product TL parse trees for re-training the monolingual parser. The biggest problem of this naïve approach is that the translation by an MT system is often a 'weird' TL sentence, and thus the associated parse tree is of little use in improving the parser.

Forced alignment (Wuebker et al., 2010) of bilingual data is a much more promising approach.

When applied to SSMT, given a bilingual sentence, it performs phrase segmentation of the SL side, parsing of the TL side, and word alignment of the bilingual sentence, using the full translation system as in decoding. It finds the best decoding path that generates the TL side of the bilingual sentence, and the parse tree of the TL sentence is also obtained as a by-product. The parse trees from forced alignment are suitable for re-training the monolingual parser.

Here is the simple iterative re-training algorithm. First we have a baseline monolingual parser and plug it into an SSMT system. Then perform forced alignment, using the SSMT system, of some bilingual data and obtain the parse trees as new training data for the parser. The new parser can then be applied again to do the second round of forced alignment. This iteration of forced alignment followed by parser re-training is kept going until some stopping criterion is met. In the following we will call this approach as forced alignment based parser re-training (FA-PR).

---

**Algorithm 1** Forced Alignment Based Parser Re-Training (FA-PR)

---

- step1:  $t = 0; Pars_0 = Pars_{init}$ .
  - step2: Use parser  $Pars_t$  to parse target sentences of training data, and build a SSMT systems  $SYS_t$ .
  - step3: Perform forced alignment on training data with  $SYS_t$  to get parse trees  $Trees_{FAPR}$  for target sentence of training data.
  - step4: Train a new parser  $Pars_{FAPR}$  with  $Trees_{FAPR}$ .
  - step5:  $t = t + 1; Pars_t = Pars_{FAPR}$ .
  - Step6: Go to step 2, until performance of  $SYS_t$  on development data drops, or a preset limit is reached.
- 

There are a few important implementation details of FA-PR. Forced alignment is guaranteed to obtain a parse tree if all translation rules are kept and no pruning is performed during decoding. Yet in reality an average MT system applies pruning during translation model training and decoding, and a lot of translation rules will then be discarded. In order to have more parse trees be considered by forced alignment, we keep all translation rules and relax pruning constraints in the decoder, viz.

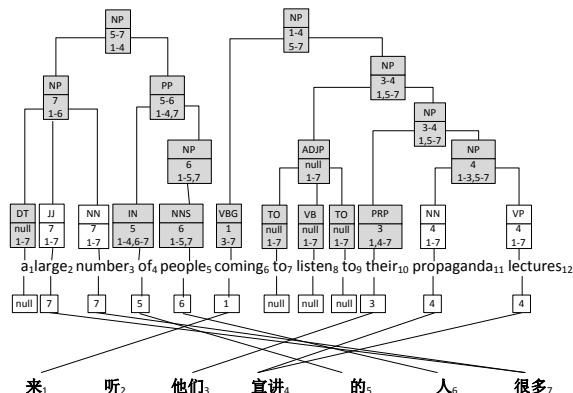

Figure 3. The parse tree selected by FA-PR for the example in Figure 1(b)

enlarge the stack size of each cell in the chart from 50 to 150.

Another measure to guarantee the existence of a decoding path in forced alignment is to allow part of a SL or TL sentence translate to null. Consider the example in Figure 1(b). We also add a null alignment for any span of the source and target sentences to handle the null translation scenario. It is easy to add a null translation candidate for a span of the source sentence during decoding, but not easy for target spans. For example, suppose the best translation candidate for the source span "来<sub>1</sub> NP的<sub>5</sub>人<sub>6</sub>很多<sub>7</sub>" is "a large number of people coming NP", and the best translation candidate for "听<sub>2</sub>他们<sub>3</sub>宣讲<sub>4</sub>" is "their propaganda lectures", there is no combination of candidates from two n-best translation lists which can match a sequence in the given target part, so we add a translation candidate ("to listen to ") generated from null, whose syntactic label can be any label (decided according to the translated context, which is "ADJP" here). The feature weights for the added null alignment are set to be very small, so as to avoid the competition with the normal candidates. In order to generate normal trees with not so many null alignment sub-trees for the target sentence (such trees are not suitable for parser re-training), only target spans with less than 4 words can align to null, and such null-aligned sub-tree can only be added no more than 3 times.

With all the mentioned modification of the forced alignment, the partial target tree generated using forced alignment for the example in Figure 1(b) is shown in Figure 3. We can see that even

with an incorrect sub-tree, more useful rules can be extracted, compared with the baseline sub-tree and the sub-tree generated from TST-FS.

### 3 Word Alignment Symmetrization

The most widely used word aligners in MT, like HMM and IBM Models (Och and Ney, 2003), are directional aligners. Such aligner produces one set of alignment matrices for the SL-to-TL direction and another set for the TL-to-SL direction. Symmetrization refers to the combination of these two sets of alignment matrices.

The most popular method of symmetrization is intersect-diag-grow (IDG). Given a bilingual sentence and its two alignment matrices  $A_{ST}$  and  $A_{TS}$ , IDG starts with all the links in  $A_{ST} \cap A_{TS}$ . Then IDG considers each link in  $A_{ST} \cup A_{TS} - (A_{ST} \cap A_{TS})$  in turn. A link is added if its addition does not make some phrase pairs overlap. Although IDG is simple and efficient, and has been shown to be effective in phrase-based SMT, it is problematic in SSMT, as illustrated by the example in section 1.

#### 3.1 Intersect-Diag-Syntactic-Grow (IDSG)

We propose a new symmetrization method, Intersect-Diag-Syntactic-Grow (IDSG), which is an adaptation of IDG but also taking syntactic information in consideration. It is sketched in Algorithm 2.

---

#### Algorithm 2 Intersect-Diag-Syntactic-Grow

---

- step1: Generate all the candidate links  $A_{candi}$  using IDG.
- step2: Select the one which can generate the biggest frontier set:

$$l = \operatorname{argmax}_{l' \in A_{candi}} (\text{frontierSize}(A \cup l', \text{Tree}))$$

- step3: Add  $l$  to  $A$ , and repeat step 1, until no new link can be added.
- 

Like IDG, IDSG starts with all the links in  $A_{ST} \cap A_{TS}$  and its main task is to add links selected from  $A_{candi} = A_{ST} \cup A_{TS} - (A_{ST} \cap A_{TS})$ . IDSG is also subject to the constraints of IDG. The new criterion in link selection in IDSG is specified in Step 2. Given a parse tree of the TL side of the bilingual sentence, in each iteration IDSG considers the change of frontier set size caused by

Figure 4, the alignment generated by IDSG for the example in Figure 1(a)

the addition of each link in  $A_{candi}$ . The link leading to the maximum number of frontier nodes is added (and removed from  $A_{candi}$ ). This process continues until no more links can be added.

In sum, IDSG add links in an order which take syntactic structure into consideration, and the link with the least violation of the syntactic structure is added first.

For the example in Figure 1(a), IDSG succeeds in discarding the two incorrect links, and produces the final alignment and frontier set as shown in Figure 4. Note that IDSG still fails to produce the correct link (the<sub>3</sub>, 牧民<sub>4</sub>), since this link does not appear in  $A_{candi}$  at all.

#### 3.2 Combining TST-FS/FA-PR and IDSG

Parser re-training aims to improve a parser with alignment matrix while IDSG aims to improve alignment matrix with parse tree. It is reasonable to combine them, and there are two alternatives of the combination, depending on the order of application. That is, we could either improve alignment matrix by IDSG and then re-train parser with the better alignment, or re-train parser and then improve alignment matrix with better syntactic information. Either alternative can be arranged into an iterative training routine, but empirically it is found that only one round of parser re-training before or after only one round of IDSG is already enough.

## 4 Experiment

In this section, we conduct experiments on Chinese to English translation task to test our proposed methods of parser re-training and word alignment symmetrization. The evaluation method is the case insensitive IBM BLEU-4 (Papineni et al., 2002). Significant testing is carried out using bootstrap re-sampling method proposed by Koehn (2004) with a 95% confidence level.

### 4.1 Parser and SMT Decoder

The syntactic parser we used in this paper is Berkeley parser, with the grammar trained on WSJ corpus, and the training method follows Petrov and Klein (2007). Our SMT decoder is an in-house implementation of string-to-tree decoder. The features we used are standard used features, such as translation probabilities, lexical weights, language model probabilities and distortion probability. The feature weights are tuned using the minimum error rate training (MERT) (Och, 2003).

### 4.2 Experiment Data Setting and Baselines

We test our method with two data settings: one is IWSLT data set, the other is NIST data set.

	dev8+dialog	dev9
Baseline	50.58	49.85

Table 1. Baselines for IWSLT data set

	NIST'03	NIST'05	NIST'08
Baseline	37.57	36.44	24.87

Table 2. Baselines for NIST data set

Our IWSLT data is the IWSLT 2009 dialog task data set. The training data include the BTEC and SLDB training data. The training data contains 81k sentence pairs, 655k Chinese words and 806k English words. The language model is 5-gram language model trained with the English sentences in the training data. We use the combination of dev8 and dialog as development set, and dev9 as test set. The TL sentences of the training data with the selected/generated trees are used as the training data to re-train the parser. To get the baseline of this setting, we run IDG to combine the bi-direction alignment generated by Giza++ (Och Ney, 2003), and run Berkeley parser (Petrov and

Klein, 2007) to parse the target sentences. With the baseline alignments and syntactic trees, we extract rules and calculate features. The baseline results are shown in Table 1.

For the NIST data set, the bilingual training data we used is NIST 2008 training set excluding the Hong Kong Law and Hong Kong Hansard. The training data contains 354k sentence pairs, 8M Chinese words and 10M English words, and is also the training data for our parser re-training. The language model is 5-gram language model trained with the Giga-Word corpus plus the English sentences in the training data. The development data to tune the feature weights of our decoder is NIST 2003 evaluation set, and test sets are NIST 2005 and 2008 evaluation sets. The baseline for NIST data is got in a similar way with for IWSLT, which are shown in Table 2 .

### 4.3 Results of TST-FS/ FA-PR

The parser re-training strategies TST-FS and FA-PR are tested with two baselines, one is the default parser without any re-training and another is standard self-training (SST). All three re-training approaches are based on the same bilingual datasets as used in translation model training. The MT performances on IWSLT and NIST by the four approaches are shown in Table 3 and 4 respectively.

It can be seen that just standard self-training does improve translation performance, as re-training on the TL side of bilingual data is a kind of domain adaptation (from WSJ to IWSLT/NIST). But targeted self-training achieves more noticeable improvement, almost twice as much as standard self-training. This confirms the value of word alignment information in parser re-training. Finally, the even larger improvement of FA-PR than TST-FS shows that merely increasing the number of frontier nodes is not enough. Some frontier nodes are of poor quality, and the frontier nodes found in forced alignment are more suitable.

It can also be seen that the improvement in IWSLT is larger than that in NIST. The first reason is that both WSJ and NIST are of the news domain and of formal writing style, whereas IWSLT is of the tourist domain and of colloquial style. Therefore any improvement from the default parser, which is trained on WSJ, is expected to be smaller in the NIST case. Another reason is that, since the

IWSLT dataset is much smaller, the impact of more and better rules is more obvious.

Note that the figures in Table 3 and 4 are about parser re-training for only one iteration. It is found that, more iteration do not lead to further significant improvement. The forced alignment of bilingual training data does not obtain a full decoding path for every bilingual sentence. It is because, although all translation rules are kept, there is still pruning during decoding. Only 64% of the IWSLT dataset and 53% of the NIST dataset can be successfully forced-aligned. In general, the longer the bilingual sentence, the less likely forced alignment is successful, and that is why a lower proportion of NIST can be forced-aligned.

#### 4.4 Symmetrization

The new symmetrization method IDSG is compared with the baseline method IDG.

	dev8+dialog	dev9	# Rules
IDG	50.58	49.85	515K
IDSG	<b>52.71</b> (+2.31)	<b>51.80</b> (+2.05)	626K

Table 5. MT performance of symmetrization methods on IWSLT data set. The results in bold type are significantly better than the performance of IDG.

	NIST'03	NIST'05	NIST'08	#Rules
IDG	37.57	36.44	24.87	3,376K
IDSG	38.15 (+0.58)	<b>37.07</b> (+0.63)	<b>25.67</b> (+0.80)	4,109K

Table 6. MT performance of symmetrization methods on NIST data. The results in bold type are significantly better than the performance of IDG.

As shown by the results in Table 5 and 6, IDSG enlarges the set of translation rules by more than 20%, thereby improving translation performance significantly. As in parser re-training, the improvement in the IWSLT task is larger than that in the NIST task. Again, it is because the IWSLT dataset is very small and so the effect of rule table size is more obvious.

	dev8+dialog	dev9	# Rules
Baseline	50.58	49.85	515K
SST	<b>52.04</b> (+1.46)	<b>51.26</b> (+1.41)	574K
TST-FS	<b>52.75</b> (+2.17)	<b>52.51</b> (+2.66)	572K
FA-PR	<b>53.31</b> (+2.73)	<b>52.8</b> (+2.95)	591K

Table 3. MT performance of parser re-training strategies on IWSLT data set. The results in bold type are significantly better than the baseline.

	NIST'03	NIST'05	NIST'08	#Rules
Baseline	37.57	36.44	24.87	3,376K
SST	37.98 (+0.41)	36.79 (+0.35)	25.30 (+0.43)	3,462K
TST-FS	<b>38.42</b> (+0.85)	<b>37.39</b> (+0.95)	<b>25.79</b> (+0.92)	3,642K
FA-PR	<b>38.74</b> (+1.17)	<b>37.69</b> (+1.25)	<b>25.89</b> (+1.02)	3,976K

Table 4. MT performance of parser re-training strategies on NIST data set. The results in bold type are significantly better than the baseline.

#### 4.5 Methods combined

As mentioned in section 3.2, parser re-training and the new symmetrization method can be combined in two different ways, depending on the order of application. Table 7 and 8 show the experiment results of combining FA-PR with IDSG.

It can be seen that either way of the combination is better than using FA-PR or IDSG alone. Yet there is no significant difference between the two kinds of combination.

The best result is a gain of more than 3 Bleu points on IWSLT and that of more than 1 Bleu point on NIST.

## 5 Related Works

There are a lot of attempts in improving word alignment with syntactic information (Cherry and Lin, 2006; DeNero and Klein, 2007; Hermjakob, 2009) and in improving parser with alignment information (Burkett and Klein, 2008). Yet strictly speaking all these attempts aim to improve the

parser/aligner itself rather than the translation model.

To improve the performance of syntactic machine translation, Huang and Knight (2006) proposed a method incorporating a handful of relabeling strategies to modify the syntactic trees structures. Ambati and Lavie (2008) restructured target parse trees to generate highly isomorphic target trees that preserve the syntactic boundaries of constituents aligned in the original parse trees. Wang et al., (2010) proposed to use re-structuring and re-labeling to modify the parser tree. The re-structuring method uses a binarization method to enable the reuse of sub-constituent structures, and the linguistic and statistical re-labeling methods to handle the coarse nonterminal problem, so as to enhance generalization ability. Different from the previous work of modifying tree structures with post-processing methods, our methods try to learn a suitable grammar for string-to-tree SMT models, and directly produce trees which are consistent with word alignment matrices.

Instead of modifying the parse tree to improve machine translation performance, many methods were proposed to modify word alignment by taking syntactic tree into consideration, including deleting incorrect word alignment links by a discriminative model (Fossum et al., 2008), re-aligning sentence pairs using EM method with the rules extracted with initial alignment (Wang et al., 2010), and removing ambiguous alignment of functional words with constraint from chunk-level information during rule extraction (Wu et al., 2011). Unlike all these pursuits, to generate a consistent word alignment, our method modifies the popularly used IDG symmetrization method to make it suitable for string-to-tree rule extraction, and our method is much simpler and faster than the previous works.

## 6 Conclusion

In this paper we have attempted to improve SSMT by reducing the errors introduced by the mutual independence between monolingual parser and word aligner. Our major contribution is the strategies of re-training parser with the bilingual information in alignment matrices. Either of our proposals of targeted self-training with frontier set size as evaluation function and forced alignment based re-training is more effective than baseline

parser or standard self-training of parser. As an auxiliary method, we also attempted to improve alignment matrices by a new symmetrization method.

In future, we will explore more alternatives in integrating parsing information and alignment information, such as discriminative word alignment using a lot of features from parser.

# Transforming Trees to Improve Syntactic Convergence

David Burkett and Dan Klein

Computer Science Division

University of California, Berkeley

{dburkett, klein}@cs.berkeley.edu

## Abstract

We describe a transformation-based learning method for learning a sequence of monolingual tree transformations that improve the agreement between constituent trees and word alignments in bilingual corpora. Using the manually annotated English Chinese Translation Treebank, we show how our method automatically discovers transformations that accommodate differences in English and Chinese syntax. Furthermore, when transformations are learned on automatically generated trees and alignments from the same domain as the training data for a syntactic MT system, the transformed trees achieve a 0.9 BLEU improvement over baseline trees.

## 1 Introduction

Monolingually, many Treebank conventions are more or less equally good. For example, the English WSJ treebank (Marcus et al., 1993) attaches verbs to objects rather than to subjects, and it attaches prepositional modifiers outside of all quantifiers and determiners. The former matches most linguistic theories while the latter does not, but to a monolingual parser, these conventions are equally learnable. However, once bilingual data is involved, such treebank conventions entail constraints on rule extraction that may not be borne out by semantic alignments. To the extent that there are simply divergences in the syntactic structure of the two languages, it will often be impossible to construct syntax trees that are simultaneously in full agreement with monolingual linguistic theories and with the alignments between sentences in both languages.

To see this, consider the English tree in Figure 1a, taken from the English side of the English Chinese Translation Treebank (Bies et al., 2007). The

lowest VP in this tree is headed by ‘select,’ which aligns to the Chinese verb ‘挑选.’ However, ‘挑选’ also aligns to the other half of the English infinitive, ‘to,’ which, following common English linguistic theory, is outside the VP. Because of this violating alignment, many syntactic machine translation systems (Galley et al., 2004; Huang et al., 2006) won’t extract any translation rules for this constituent. However, by applying a simple transformation to the English tree to set up the infinitive as its own constituent, we get the tree in Figure 1b, which may be less well-motivated linguistically, but which corresponds better to the Chinese-mediated semantics and permits the extraction of many more syntactic MT rules.

In this work, we develop a method based on *transformation-based learning* (Brill, 1995) for automatically acquiring a sequence of tree transformations of the sort in Figure 1. Once the transformation sequence has been learned, it can be deterministically applied to any parsed sentences, yielding new parse trees with constituency structures that agree better with the bilingual alignments yet remain consistent across the corpus. In particular, we use this method to learn a transformation sequence for the English trees in a set of English to Chinese MT training data. In experiments with a string-to-tree translation system, we show resulting improvements of up to 0.9 BLEU.

A great deal of research in syntactic machine translation has been devoted to handling the inherent syntactic divergence between source and target languages. Some systems attempt to model the differences directly (Yamada and Knight, 2001; Eisner, 2003), but most recent work focuses on reducing the sensitivity of the rule-extraction procedure to the constituency decisions made by 1-best syntactic parsers, either by using forest-based methods

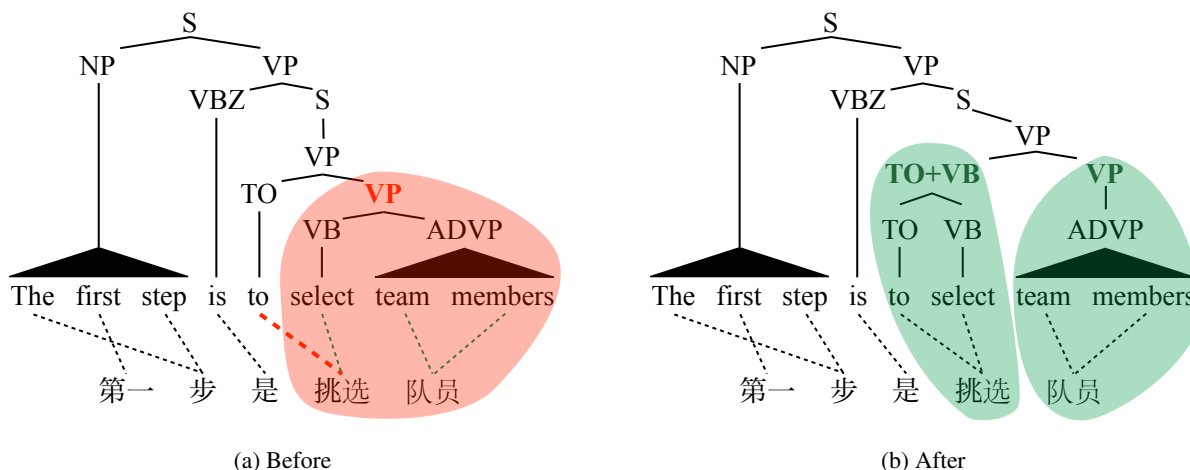

Figure 1: An example tree transformation merging a VB node with the TO sibling of its parent VP. Before the transformation (a), the bolded VP cannot be extracted as a translation rule, but afterwards (b), both this VP and the newly created TO+VB node are extractable.

for learning translation rules (Mi and Huang, 2008; Zhang et al., 2009), or by learning rules that encode syntactic information but do not strictly adhere to constituency boundaries (Zollmann et al., 2006; Marton and Resnik, 2008; Chiang, 2010). The most closely related MT system is that of Zhao et al. (2011), who train a rule extraction system to transform the subtrees that make up individual translation rules using a manually constructed set of transformations similar to those learned by our system.

Instead of modifying the MT system to work around the input annotations, our system modifies the input itself in order to improve downstream translation. Most systems of this sort learn how to modify word alignments to agree better with the syntactic parse trees (DeNero and Klein, 2007; Fossum et al., 2008), but there has also been other work directly related to improving agreement by modifying the trees. Burkett et al. (2010) train a bilingual parsing model that uses bilingual agreement features to improve parsing accuracy. More closely related to the present work, Katz-Brown et al. (2011) retrain a parser to directly optimize a word reordering metric in order to improve a downstream machine translation system that uses dependency parses in a preprocessing reordering step. Our system is in the same basic spirit, using a proxy evaluation metric (agreement with alignments; see Section 2 for details) to improve performance on a downstream translation

task. However, we are concerned more generally with the goal of creating trees that are more compatible with a wide range of syntactically-informed translation systems, particularly those that extract translation rules based on syntactic constituents.

## 2 Agreement

Our primary goal in adapting parse trees is to improve their agreement with a set of external word alignments. Thus, our first step is to define an *agreement score* metric to operationalize this concept.

Central to the definition of our agreement score is the notion of an *extractable node*. Intuitively, an extractable English<sup>1</sup> tree node (also often called a “frontier node” in the literature), is one whose span aligns to a contiguous span in the foreign sentence.

Formally, we assume a fixed word alignment  $a = \{(i, j)\}$ , where  $(i, j) \in a$  means that English word  $i$  is aligned to foreign word  $j$ . For an English span  $[k, \ell]$  (inclusive), the set of aligned foreign words is:

$$fset([k, \ell]) = \{j \mid \exists i : k \leq i \leq \ell; (i, j) \in a\}$$

We then define the aligned foreign span as:

$$fspan([k, \ell]) = [\min(fset([k, \ell])), \max(fset([k, \ell]))]$$

<sup>1</sup>For expositional clarity, we will refer to “English” and “foreign” sentences/trees, but our definitions are in no way language dependent and apply equally well to any language pair.

The aligned English span for a given foreign span  $[s, t]$  is defined analogously:

$$\begin{aligned} eset([s, t]) &= \{i \mid \exists j : s \leq j \leq t; (i, j) \in a\} \\ espan([s, t]) &= [\min(eset([s, t])), \max(eset([s, t]))] \end{aligned}$$

Finally, we define  $[k, \ell]$  to be extractable if and only if it has at least one word alignment and its aligned foreign span aligns back to a subspan of  $[k, \ell]$ :

$$fset([k, \ell]) \neq \emptyset \wedge espan(fspan([k, \ell])) \subseteq [k, \ell]$$

With this definition of an extractable span, we can now define the agreement score  $g_a(t)$  for an English tree  $t$ , conditioned on an alignment  $a$ :<sup>2</sup>

$$g_a(t) = \sum_{\substack{[k, \ell] \in t: \\ |[k, \ell]| > 1}} sign([k, \ell]) \quad (1)$$

Where

$$sign([k, \ell]) = \begin{cases} 1 & [k, \ell] \text{ is extractable} \\ -1 & \text{otherwise} \end{cases}$$

Importantly, the sum in Equation 1 ranges over all *unique* spans in  $t$ . This is simply to make the metric less gameable, preventing degenerate solutions such as an arbitrarily long chain of unary productions over an extractable span. Also, since all individual words are generated by preterminal part-of-speech nodes, the sum skips over all length 1 spans.

As a concrete example of agreement score, we can return to Figure 1. The tree in Figure 1a has 6 unique spans, but only 5 are extractable, so the total agreement score is  $5 - 1 = 4$ . After the transformation, though, the tree in Figure 1b has 6 extractable spans, so the agreement score is 6.

### 3 Transformation-Based Learning

Transformation-based learning (TBL) was originally introduced via the Brill part-of-speech tagger (Brill, 1992) and has since been applied to a wide variety of NLP tasks, including binary phrase structure bracketing (Brill, 1993), PP-attachment disambiguation (Brill and Resnik, 1994), base NP chunking (Ramshaw and Marcus, 1995), dialogue act tagging (Samuel et al., 1998), and named entity recognition (Black and Vasilakopoulos, 2002).

<sup>2</sup>Unextractable spans are penalized in order to ensure that space is saved for the formation of extractable ones.

The generic procedure is simple, and requires only four basic inputs: a set of training sentences, an initial state annotator, an inventory of atomic transformations, and an evaluation metric. First, you apply the initial state annotator (here, the source of original trees) to your training sentences to ensure that they all begin with a legal annotation. Then, you test each transformation in your inventory to see which one will yield the greatest improvement in the evaluation metric if applied to the training data. You greedily apply this transformation to the full training set and then repeat the procedure, applying transformations until some stopping criterion is met (usually either a maximum number of transformations, or a threshold on the marginal improvement in the evaluation metric).

The output of the training procedure is an ordered set of transformations. To annotate new data, you simply label it with the same initial state annotator and then apply each of the learned transformations in order. This process has the advantage of being quite fast (usually linear in the number of transformations and the length of the sentence; for parsing, the cost will typically be dominated by the cost of the initial state annotator), and, unlike the learned parameters of a statistical model, the set of learned transformations itself can often be of intrinsic linguistic interest.

For our task, we have already defined the evaluation metric (Section 2) and the initial state annotator will either be the gold Treebank trees or a Treebank-trained PCFG parser. Thus, to fully describe our system, it only remains to define the set of possible tree transformations.

### 4 Tree Transformations

The definition of an atomic transformation consists of two parts: a rewrite rule and the triggering environment (Brill, 1995). Tree transformations are best illustrated visually, and so for each of our transformation types, both parts of the definition are represented schematically in Figures 2-7. We have also included a real-world example of each type of transformation, taken from the English Chinese Translation Treebank.

Altogether, we define six types of tree transformations. Each class of transformation takes be-

Figure 2: ARTICULATE transformations.

tween two and four syntactic category arguments, and most also take a DIRECTION argument that can have the value *left* or *right*.<sup>3</sup> We refer to the nodes in the schematics whose categories are arguments of the transformation definition as *participating* nodes. Basically, a particular transformation is triggered anywhere in a parse tree where all participating nodes appear in the configuration shown. The exact rules for the triggering environment are:

1. Each participating node must appear in the schematically illustrated relationship to the others. The non-participating nodes in the schematic do not have to appear. Similarly, any number of additional nodes can appear as siblings, parents, or children of the explicitly illustrated nodes.
2. Any node that will gain a new child as a result of the transformation must already have at least one nonterminal child. We have drawn the schematics to reflect this, so this condition is

<sup>3</sup>To save space, the schematic for each of these transformations is only shown for the *left* direction, but the *right* version is simply the mirror image.

equivalent to saying that any participating node that is drawn with children must have a phrasal syntactic category (i.e. it cannot be a POS).

3. Repeated mergings are not allowed. That is, the newly created nodes that result from an ARTICULATE or ADOPT transformation cannot then participate as the LEFT or RIGHT argument of a subsequent ARTICULATE transformation or as the AUNT or TARGET argument of a subsequent ADOPT transformation. This is simply to prevent the unrestrained proliferation of new syntactic categories.

The rewrite rule for a transformation is essentially captured in the corresponding schematic. Additional nodes that do not appear in the schematic are generally handled in the obvious way: unillustrated children or parents of illustrated nodes remain in place, while unillustrated siblings of illustrated nodes are handled identically to their illustrated siblings. The only additional part of the rewrite that is not shown explicitly in the schematics is that if the node in the PARENT position of a TRANSFER or ADOPT transformation is left childless by the transformation (be-

cause the TARGET node was its only child), then it is deleted from the parse tree. In the case of a transformation whose triggering environment appears multiple times in a single tree, transformations are always applied leftmost/bottom-up and exhaustively.<sup>4</sup>

In principle, our transformation inventory consists of all possible assignments of syntactic categories to the arguments of each of the transformation types (subject to the triggering environment constraints). In practice, though, we only ever consider transformations whose triggering environments appear in the training corpus (including new triggering environments that appear as the result of earlier transformations). While the theoretical space of possible transformations is exponentially large, the set of transformations we actually have to consider is quite manageable, and empirically grows substantially sublinearly in the size of the training set.

## 5 Results and Analysis

There are two ways to use this procedure. One is to apply it to the entire data set, with no separate training phase. Given that the optimization has no notion of gold transformations, this procedure is roughly like an unsupervised learner that clusters its entire data. Another way is to learn annotations on a subset of data and apply it to new data. We choose the latter primarily for reasons of efficiency and simplicity: many common use cases are easiest to manage when annotation systems can be trained once offline and then applied to new data as it comes in.

Since we intend for our system to be used as a pre-trained annotator, it is important to ensure that the learned transformation sequence achieves agreement score gains that generalize well to unseen data. To minimize errors that might be introduced by the noise in automatically generated parses and word alignments, and to maximize reproducibility, we conducted our initial experiments on the English Chinese Translation Treebank. For this dataset, the initial state annotations (parse trees) were manually created by trained human annotators, as were the word alignments used to compute the agreement

<sup>4</sup>The transformation is repeatedly applied at the lowest, leftmost location of the parse tree where the triggering environment appears, until the triggering environment no longer appears anywhere in the tree.

Figure 8: Transformation results on the English Chinese Translation Treebank. The value plotted is the average (per-sentence) improvement in agreement score over the baseline trees.

Transformations	Total Spans	Extractable Spans	Agreement Score
0	13.15	9.78	6.40
10	12.57	10.36	8.15
50	13.41	11.38	9.35
200	14.03	11.96	9.89
1584	14.58	12.36	10.15
2471	14.65	12.35	10.06

Table 1: Average span counts and agreement scores on the English Chinese Translation Treebank development set. The highest agreement score was attained at 1584 transformations, but most of the improvement happened much earlier.

score.<sup>5</sup> The data was divided into training/dev/test using the standard Chinese parsing split; we trained the system on the training set (2261 sentences after filtering out sentences with missing annotations), and evaluated on the development set (223 sentences after filtering).

The improvements in agreement score are shown in Figure 8, with a slightly more detailed breakdown at a few fixed points in Table 1. While the system was able to find up to 2471 transformations that improved the training set agreement score, the majority of the improvement, and especially the majority of the improvement that generalized to the test set,

<sup>5</sup>The annotation guidelines for the English side of this Treebank are similar, though not identical, to those for the WSJ Treebank.

Table 2: The first 20 learned transformations, excluding those that only merged punctuation or conjunctions with adjacent phrases. The first 5 are illustrated in Figure 9.

was achieved within the first 200 or so transformations. We also see from Table 1 that, though the first few transformations deleted many non-extractable spans, the overall trend was to produce more finely articulated trees, with the full transformation sequence increasing the number of spans by more than 10%.

As discussed in Section 3, one advantage of TBL is that the learned transformations can themselves often be interesting. For this task, some of the highest scoring transformations did uninteresting things like conjoining conjunctions or punctuation, which are often either unaligned or aligned monotonically with adjacent phrases. However, by filtering out all ARTICULATE transformations where either the LEFT or RIGHT argument is “CC”, “-RRB-”, “;”, or “.” and taking the top 20 remaining transformations, we get the list in Table 2, the first 5 of which are also illustrated in Figure 9. Some of these (e.g. #1, #7, #10) are additional ways of creating new spans when English and Chinese phrase structures roughly agree, but many others do recover known differences

in English and Chinese syntax. For example, many of these transformations directly address compound verb forms in English, which tend to align to single words in Chinese: #3 (past participle constructions), #4 (infinitive), #6 (all), and #17 (present perfect). We also see differences between English and Chinese internal NP structure (e.g. #9, #12, #13).

## 6 Machine Translation

The ultimate goal of our system is to improve the agreement between the automatically generated parse trees and word alignments that are used as training data for syntactic machine translation systems. Given the amount of variability between the outputs of different parsers and word aligners (or even the same systems with different settings), the best way to improve agreement is to learn a transformation sequence that is specifically tuned for the same annotators (parsers and word aligners) we are evaluating with. In particular, we found that though training on the English Chinese Translation Treebank produces clean, interpretable rules, preliminary experiments showed little to no improvement from using these rules for MT, primarily because actual alignments are not only noisier but also systematically different from gold ones. Thus, all rules used for MT experiments were learned from automatically annotated text.

For our Chinese to English translation experiments, we generated word alignments using the Berkeley Aligner (Liang et al., 2006) with default settings. We used an MT pipeline that conditions on target-side syntax, so our initial state annotator was the Berkeley Parser (Petrov and Klein, 2007), trained on a modified English treebank that has been adapted to match standard MT tokenization and capitalization schemes.

As mentioned in Section 5, we could, in principle train on all 500k sentences of our MT training data. However, this would be quite slow: each iteration of the training procedure requires iterating through all  $n$  training sentences<sup>6</sup> once for each of the  $m$  candidate transformations, for a total cost of  $O(nm)$  where  $m$  grows (albeit sublinearly) with  $n$ . Since the

<sup>6</sup>By using a simple hashing scheme to keep track of triggering environments, this cost can be reduced greatly but is still linear in the number of training sentences.

(a) ARTICULATE(S,NP,VP)

(b) FLATTENINCONTEXT(PP,NP,IN,right)

(c) PROMOTE(VP,VP,VBN,left)

(d) ADOPT(VP,TO,VP,VB,left)

(e) ADOPT(PP,VBG,PP,IN,left)

Figure 9: Illustrations of the top 5 transformations from Table 2.

most useful transformations almost by definition are ones that are triggered the most frequently, any reasonably sized training set is likely to contain them, and so it is not actually likely that dramatically increasing the size of the training set will yield particularly large gains.

Thus, to train our TBL system, we extracted a random subset of 3000 sentences to serve as a training set.<sup>7</sup> We also extracted an additional 1000 sentence test set to use for rapidly evaluating agreement score generalization. Figure 10 illustrates the improvements in agreement score for the automatically annotated data, analogous to Figure 8. The same general patterns hold, although we do see that the automatically annotated data is more idiosyncratic and so more than twice as many transformations are learned before training set agreement stops improving, even though the training set sizes are roughly the same.<sup>8</sup> Furthermore, test set generalization in the automatic annotation setting is a little bit worse, with later transformations tending to actually hurt test set agreement.

For our machine translation experiments, we used the string-to-tree syntactic pipeline included in the current version of Moses (Koehn et al., 2007). Our training bitext was approximately 21.8 million words, and the sentences and word alignments were the same for all experiments; the only difference between each experiment was the English trees, for which we tested a range of transformation sequence prefixes (including a 0-length prefix, which just yields the original trees, as a baseline). Since the transformed trees tended to be more finely articulated, and increasing the number of unique spans often helps with rule extraction (Wang et al., 2007), we equalized the span count by also testing binarized versions of each set of trees, using the left-branching and right-branching binarization scripts included with Moses.<sup>9</sup>

We tuned on 1000 sentence pairs and tested on

<sup>7</sup>The sentences were shorter on average than those in the English Chinese Translation Treebank, so this training set contains roughly the same number of words as that used in the experiments from Section 5.

<sup>8</sup>Note that the training set improvement curves don't actually flatten out because training halts once no improving transformation exists.

<sup>9</sup>Binarized trees are guaranteed to have  $k - 1$  unique spans for sentences of length  $k$ .

Figure 10: Transformation results on a subset of the MT training data. The training and test sets are disjoint in order to measure how well the learned transformation sequence generalizes. Once again, we plot the average improvement over the baseline trees. Though 5151 transformations were learned from the training set, the maximum test set agreement was achieved at 630 transformations, with an average improvement of 2.60.

642 sentence pairs from the NIST MT04 and MT05 data sets, using the BLEU metric (Papineni et al., 2001). As discussed by Clark et al. (2011), the optimizer included with Moses (MERT, Och, 2003) is not always particularly stable, and results (even on the tuning set) can vary dramatically across tuning runs. To mitigate this effect, we first used the Moses training scripts to extract a table of translation rules for each set of English trees. Then, for each rule table, we ran MERT 11 times and selected the parameters that achieved the maximum tuning BLEU to use for decoding the test set.

Table 3 shows the results of our translation experiments. The best translation results are achieved by using the first 139 transformations, giving a BLEU improvement of more than 0.9 over the strongest baseline.

## 7 Conclusion

We have demonstrated a simple but effective procedure for learning a tree transformation sequence that improves agreement between parse trees and word alignments. This method yields clear improvements in the quality of Chinese to English translation, showing that by manipulating English syntax to converge with Chinese phrasal structure, we improve our ability to explicitly model the types of

Transformations	Agrmnt Score	BLEU		
		None	Left	Right
0	5.36	31.66	31.81	31.84
32	7.17	32.41	32.17	32.06
58	7.42	32.18	32.68*	32.37
139	7.81	32.20	32.60*	<b>32.77*</b>
630	7.96	32.48	32.06	32.22
5151	7.89	32.13	31.84	32.12

Table 3: Machine translation results. Agreement scores are taken from the test data used to generate Figure 10. Note that using 0 transformations just yields the original baseline trees. The transformation sequence cutoffs at 32, 58, and 139 were chosen to correspond to marginal training (total) agreement gain thresholds of 50, 25, and 10, respectively. The cutoff at 630 was chosen to maximize test agreement score and the cutoff at 5151 maximized training agreement score. Column headings for BLEU scores (“None,” “Left,” “Right”) refer to the type of binarization used after transformations. Entries marked with a “\*” show a statistically significant difference ( $p < 0.05$ ) from the strongest (right-binarized) baseline, according to the paired bootstrap (Efron and Tibshirani, 1994).

structural relationships between languages that syntactic MT systems are designed to exploit, even if we lose some fidelity to the original monolingual annotation standards in the process.

# Learning Constraints for Consistent Timeline Extraction

David McClosky and Christopher D. Manning

Natural Language Processing Group  
Computer Science Department  
Stanford University, Stanford, CA, USA  
{mcclosky, manning}@stanford.edu

## Abstract

We present a distantly supervised system for extracting the temporal bounds of *fluents* (relations which only hold during certain times, such as *attends school*). Unlike previous pipelined approaches, our model does not assume independence between each fluent or even between named entities with known connections (parent, spouse, employer, etc.). Instead, we model what makes timelines of fluents consistent by learning cross-fluent constraints, potentially spanning entities as well. For example, our model learns that someone is unlikely to start a job at age two or to marry someone who hasn't been born yet. Our system achieves a 36% error reduction over a pipelined baseline.

## 1 Introduction

Many information extraction (IE) systems traditionally extracted just relations, but a great many real world relations such as *attends school* or *has spouse* vary over time. To capture this, some recent IE systems have extended their focus from relations to *fluents* (relations combined with temporal bounds). This can be seen in the temporal slot filling track in the TAC-KBP 2011 shared task (Ji et al., 2011). A direct application of this work is the automatic improvement of online resources such as Freebase and Wikipedia infoboxes. Indirect applications include question answering systems.

Fluents can be grouped together to form timelines (see Figure 1 for an example) and provide easily capturable consistency constraints. Our goal is

Figure 1: A timeline of two named entities. Each time span represents a *fluent* (a relation with temporal bounds). Temporal bounds are denoted by spans on the timeline. Fluents can create links between entities (e.g., marriage).

to learn these constraints and use them to produce more accurate timelines of significant events for people and organizations. For example, it is common knowledge that someone cannot attend a school if they haven't been born yet. Constraints on consistent timelines do not need to be hard constraints, though: it is rare, although possible, to become the CEO of a company at the age of 21.

Despite the rich constraints on valid timelines, there is relatively little work on exploiting these constraints for mutual disambiguation. Many existing systems extract different parts of a timeline separately and use heuristics to combine them. These heuristics tend to optimize only local consistency (within a single fluent) but ignore more global constraints across fluents (e.g., attending a school before being born) or across fluents of two linked entities (e.g., attending a school before the school was founded). In this work, we explore using joint inference to enforce these constraints. We show that these techniques can yield substantial improvements. Additionally, our general approach is not specific to extracting temporal boundaries of fluents. It could easily be applied to other IE systems which

employ independent extractions followed by heuristics to improve consistency.

## 2 The timelining task

As a basis for our task, we first describe the Temporal KBP task (Ji et al., 2011). As input, one is given a list of *queries*, a database of example fluents, and source documents. Queries are named entities (people or organizations) with their gold relations but no temporal bounds. The database consists of training entities with their fluents, including known temporal bounds for each fluent. Example fluents can be seen in Table 1. Note that the database may be incomplete. In addition to missing fluents for an entity, some temporal bounds may be missing from the database; missing bounds are unfortunately indistinguishable from unbounded ranges. As a result, we can only trust concrete temporal boundaries in the database. Source documents consist of raw text from news, blogs, and Wikipedia articles. For each fluent, systems must output their predicted temporal bounds, along with references to source documents to provide provenance.

Our task is a variation of the Temporal KBP task. In our case, the database is a collection of Freebase<sup>1</sup> entities and their fluents, merged with Wikipedia infoboxes. Each entity has a unique ID, allowing us to avoid some coreference issues (though there can still be issues in document retrieval). In Temporal KBP, the temporal representation allows for upper and lower bounds on both the event start and end:  $\langle s_l, s_u, e_l, e_u \rangle$  where  $s_l \leq start \leq s_u$ ,  $e_l \leq end \leq e_u$ . However, it is difficult to obtain these bounds without manual annotation. As a result, we opted for the simpler representation which can be easily found in databases like Freebase. Our temporal representation is limited to bounds of the form  $\langle start, end \rangle$  where either can be unbounded or unknown (both represented as  $\pm\infty$ ).

Our set of fluents is closely related to those in the Temporal KBP task. Our goal was to use as much temporal information as possible, with the hope of each fluent providing additional potential constraints. While we omit the *resides in* and *member of* fluents,<sup>2</sup> we add several others. For

people and organizations, we add a special fluent, *lifespan*, which doesn't take a slot value.<sup>3</sup> A list of fluents we use are listed in Table 3.

## 3 Model

To operate on a set of queries, we first collect candidate temporal expression mentions for each fluent from our source documents. This limits us to using temporal expression mentions which appear near fluent mentions in text. It also ensures that we can provide provenance for each temporal boundary assertion. This process is described in §3.1.

Our model contains two components, both of which assign probabilities to timelines. The *classifier component* determines how each candidate temporal expression mention connects to its fluent (§3.2). For example, the mention may indicate the START of the fluent, the END, both its START AND END (for instantaneous events), or be UNRELATED. These connections involve relations between temporal expression mentions and relations and we refer to them as *metarelations*.<sup>4</sup> For features, the classifier uses the surrounding textual and syntactic context of temporal expression and fluent mentions. Each classification decision is made independently, allowing for inconsistency at multiple levels (within a fluent, across fluents, or across entities). However, using joint inference, the classifier component can determine the best overall span for each fluent.

The *consistency component* learns what makes timelines consistent (§3.3). It is similar in nature to a language model for timelines instead of sentences. Given a candidate timeline, the consistency component estimates its probability of occurring. This is done by decomposing timelines into a series of *questions* (such as “did the entity go to school before starting a job?”) and learning the probabilities of different answers from training data.

Unlike the classifier component, the consistency component is blind to the underlying text in the source documents. The two components work together to find a global timeline that is both based on textual evidence and coherent across entities using with temporal bounds.

<sup>3</sup>Note that this is a relation in the non-temporal KBP task.

<sup>4</sup>Other metarelations are possible under more complex temporal representations. For example, Artiles et al. (2011) uses the HOLDS metarelation.

<sup>1</sup><http://freebase.org>

<sup>2</sup>This is because these fluents are rarely present in Freebase

Entity	Relation	Slot value	Temporal bounds
Jon Stewart /en/jon_stewart	<i>lifespan</i>	—	[1962-11-28, +∞)
Jon Stewart /en/jon_stewart	<i>has parent</i>	Donald Leibowitz /en/donald_leibowitz	[1962-11-28, +∞)
Jon Stewart /en/jon_stewart	<i>attends school</i>	College of William and Mary /en/college_of_william_and_mary	(−∞, 1984]
Jon Stewart /en/jon_stewart	<i>has spouse</i>	Tracey McShane /en/tracy_mcshane	[2000-11, +∞)

Table 1: Example relations with their temporal bounds. Freebase IDs are shown in `monospace`. Note that temporal bounds differ in their resolution (some are days of the year, others are only years). Some bounds are unknown (e.g., the start of the *attends school* fluent) and indistinguishable from unbounded. The *lifespan* fluent is a unary relation.

joint inference (note that they are trained independently). The inference process is described in §3.4.

### 3.1 Temporal expression retrieval

Given a fluent, we search for all textual mentions of the fluent and collect nearby temporal expression mentions. These temporal expressions are used as candidate boundaries for the fluent in later steps. The search process assumes that if a fluent’s entity and slot value co-occur in a sentence,<sup>5</sup> that sentence is typically a positive example of the fluent.<sup>6</sup> This is sometimes known as *distant supervision* (Craven and Kumlien, 1999; Mintz et al., 2009). We use the Stanford Core NLP suite (Toutanova et al., 2003; Finkel et al., 2005; Klein and Manning, 2003; Lee et al., 2011) to annotate each document with POS and NER tags, parse trees, and coreference chains. On top of this, we apply a rule-based temporal expression extractor (Chang and Manning, 2012). Since we have coreference links, we also search documents for anything coreferent with the fluent’s entity.

The temporal expression extractor handles most standard date and time formats. For each document, one can provide an optional reference time. For underspecified dates, the reference time is used to

<sup>5</sup>While we limit our scope to sentences in this work, it is trivial to extend this to larger regions such as paragraphs.

<sup>6</sup>The *lifespan* fluent requires special handling. Ideally, its candidates would be provided by a relation extraction mention detector (e.g., a KBP system). For this work, we use the gold *lifespan* bounds as slot values for the purpose of document retrieval. While this does heavily bias the system towards using gold bounds, the system still must predict the correct associations (START, END, etc.) making the *lifespan* fluent non-trivial.

resolve these dates to full expressions if possible. Some of our documents are news articles, where we use the publication date as the reference time. Other documents, e.g., Wikipedia articles, are undated and we typically omit a reference time for these. We exclude dates which are not uniquely resolvable (e.g., “September 15th,” when the reference date is unknown) since our task requires us to output unambiguous dates.

We create training datums by computing the metarelation between each temporal expression and its gold fluent. For example, for the temporal expression mention “September 15th, 1981” and gold *lifespan* relation that spans [1981-09-15, +∞), we would assign the START metarelation. As a heuristic, we allow for underspecified matches. Thus, both “1981” and “September 1981” would have the START metarelation but “September 2nd, 1981” would be assigned UNRELATED.

### 3.2 Classifier component

We use a classifier to determine the nature of the link between fluents and candidate temporal expression mentions. Our classifier (a standard multi-class maximum entropy classifier) learns a function  $C : (t, f) \rightarrow \mathcal{M}$  where  $t$  is a temporal expression mention,  $f = \langle \text{entity, relation name, slot value} \rangle$  is a fluent from the database, and  $\mathcal{M}$  is the set of the four possible metarelations.

Features for the classifier include many of those in Artiles et al. (2011). These include standard relation extraction features such as the dependency paths between the temporal expression and the entity or slot value. We use both the original depen-

dependency paths and their collapsed Stanford Dependencies forms (de Marneffe and Manning, 2008). We include the lengths of each path and, if the path is shorter than four edges, the grammatical relations, words, POS tags, and NER labels along the path. We extract the same sorts of features from surface paths (i.e., the words and tags between the entity and the temporal expression) if the path is five tokens or shorter. For temporal expressions, we include their century and decade as features. These features act as a crude prior over when valid temporal expressions occur. There are also features for the precision of the temporal expression (year only, has month, and has day). Lastly, we include the relation name itself as a feature.

Previous work (Artiles et al., 2011) heuristically aggregates the hard decisions from their classifier to create a locally consistent span. The *basic aggregation model* (described in §4.2) is similar to their method. In contrast, our method uses the likelihood of complete spans to ensure both boundaries are consistent with the text.

To calculate the likelihood of a specific temporal span for a fluent  $f$ , we represent the span as a series of metarelations and take the product of their probabilities. For example, if the candidate span is  $[1981-09-15, +\infty)$  and we have two temporal expressions, “September 15th, 1981” and “2012”:

$$\begin{aligned} P(\text{span}(f) = [1981-09-15, +\infty) \mid f) = \\ P(C(\text{“September 15th, 1981”}, f) = \text{START}) \times \\ P(C(\text{“2012”}, f) = \text{UNRELATED}) \end{aligned}$$

This can easily be extended to calculating the joint probability of an entire timeline, represented as a list of  $\langle \text{fluent}, \text{span} \rangle$  pairs:

$$P_{CC}(\langle f_1, s_1 \rangle, \dots) = \prod_i P(\text{span}(f_i) = s_i \mid f_i)$$

We refer to this model as the Combined Classifier (CC) since it uses the probabilities of all timelines boundaries rather than aggregating hard local decisions.

### 3.3 Consistency component

While distant supervision can be used to create implicit negative examples for the classifier component

(time expressions marked as UNRELATED), we do not have an equivalent technique to reliably create negative examples for the consistency component (examples of inconsistent timelines). Instead, we only have positive examples of consistent timelines from the database. As a result, we must treat predicting consistency as a density estimation rather than a classification problem.

Our consistency component is designed to be as general as possible – it does not even include basic constraints about timelines such as “starts are before ends.” Instead, we provide several simple templates for temporal constraints to allow it to learn these basic tendencies as well as more complex ones. Examples include whether one typically goes to school first or starts their first job, how many jobs people typically have at one time, or if it is possible to marry someone who hasn’t been born yet.

We achieve this by decomposing timelines into a series of probabilistic events, or *questions*. As an example, one question about the timeline shown in Table 1 is whether Jon Stewart graduated from the College of William and Mary BEFORE marrying Tracey McShane, i.e.,  $\text{end}(\text{attends school}) < \text{start}(\text{has spouse})$ . In this case, the answer is “yes.” More generally, we can apply the BEFORE template to all boundaries of all fluents:  $\text{boundary}_1(\text{fluent}_1) < \text{boundary}_2(\text{fluent}_2)$ . We use templates like these (denoted by SMALL CAPS) to generate all possible questions to ask about a specific entity.

Other questions can be asked at the fluent level rather than the boundary level (Allen, 1983). One set of fluent level questions asks whether two fluents’ spans OVERLAP. For example, in Table 1, Jon Stewart’s *lifespan* OVERLAPS with the span of his *has spouse* fluent. Other sets of fluent level questions ask whether the span of a fluent completely CONTAINS the span of another one, whether a fluent is COMPLETELY BEFORE another fluent, and whether two fluents TOUCH (the start of one fluent is the same as the end of another).

Since all of these questions involve ordering but ignore the actual differences in time, we create one more set of questions asking whether two boundaries are WITHIN a certain number of years:

$$|\text{boundary}_1(\text{fluent}_1) - \text{boundary}_2(\text{fluent}_2)| \leq K$$

for  $K \in \{1, 2, 4, 8, 16\}$ . The aim is to approximate the typical lengths of a single fluent or amount of time between boundaries from different fluents.

There is nothing which requires that the fluents in question come from a single entity. Thus, we can trivially ask questions about two entities which are linked by a fluent. For example, since Jon Stewart is linked to Tracey McShane by the *has spouse* fluent (Table 1), we could ask the question of whether Jon Stewart’s *lifespan* OVERLAPS Tracey McShane’s *lifespan*. We can ask any type of question about two linked entities and distinguish the questions by prefixing them with the nature of the link (*has spouse* in this case).

Note that not all questions can be answered since they may rely on comparing unknown values. This is because (for our setup) infinite values are indistinguishable from unknown values. For example, the start of the Jon Stewart’s *attends school* fluent is undefined in the database, but clearly not actually  $-\infty$ . Thus, we add a third possible answer to each question: unknown. The answers to boundary level questions are defined only if both boundaries are finite. Fluent level questions have known answers as long as both fluents have at least one finite value.

To train our model, we gather the answers to questions over all the fluents from training entities. Each question forms a multinomial over the three possible values (yes, no, unknown). To determine the probability of a complete timeline:

$$P_{consistency}(timeline) = \prod_{(q,a) \in Q(timeline)} \begin{cases} (1-c)P_{\theta}(a | q) & q \text{ is old} \\ c & q \text{ is new} \end{cases}$$

where  $Q(\cdot)$  generates all possible  $\langle question, answer \rangle$  pairs which are consistent with the fluents in the timeline,  $\theta$  is a vector of the model parameters, and  $c$  is a smoothing parameter (described below).

To learn the model parameters, we start by using maximum-likelihood estimation for these multinomials from training entities. However, some smoothing is required since new entities may contain previously unseen answers to existing questions. To address this, we apply add- $\lambda$  smoothing to each multinomial,  $P_{\theta}(a | q)$ . Additionally, it is possible to see entirely new questions when we see

a new combination of fluent types. We reserve an amount of probability mass for new questions,  $c$ .  $c$  and  $\lambda$  are estimated in turn by picking the value that maximizes the likelihood of the timeline made by the development entities.

To adjust the weight of the consistency component relative to the classifier component, we take the geometric mean of the likelihood using the total number of questions,  $|Q(t)|$ , as the exponent and raise the resulting mean to an exponent,  $\beta$ . This is necessary since the two components essentially operate on different scales. The Joint Classifier with Consistency (JCC) model calculates the score of a timeline,  $t$ , according to both components:

$$score_{JCC}(t) = P_{CC}(t) \left[ P_{consistency}(t)^{\frac{\beta}{|Q(t)|}} \right]$$

### 3.4 Inference

Inference for the CC model is relatively simple: Simply pick the most likely span for each fluent. Since it assumes all fluents are independent, the bounds for each fluent can be inferred separately. To perform inference on a specific fluent, we consider all of its possible temporal spans, limited by the temporal expression mentions found by the retrieval system (§3.1). Each possible span assigns one of the four metarelations to each candidate temporal expression for the fluent. For example, if we found only the temporal expression mention “1981” for a specific fluent, there are four possible spans:

UNRELATED:	$(-\infty, +\infty)$
START:	$[1981-01-01, +\infty)$
END:	$(-\infty, 1981-12-31]$
START AND END:	$[1981-01-01, 1981-12-31]$

Note that when we assign “1981” as a start, we use the earliest possible time (January 1st) while when we assign it as an end, we use the latest possible time (December 31st). Of course, we typically have multiple candidate temporal expressions and thus potentially many more than four possible spans. All temporal expression mentions that resolve to the same time are grouped together, since it wouldn’t make sense to assign “August 28th, 2010” one metarelation and a different one to “8/28/2010.”

Joint inference for the JCC model is a little more involved since the consistency model does not assume independence across fluents. Thus, we need

to apply techniques like Gibbs sampling or random-restart hillclimbing (RRHC) to determine the optimal temporal spans for each fluent. For our task, the two methods obtain similar performance while RRHC requires many fewer iterations so our discussion focuses on the latter. RRHC involves looping over all fluents in our testing entities, shuffling the order of the fluents at the beginning of each pass. We maintain a working timeline,  $t$ , with our current guesses of the spans for each fluent. For each fluent and span  $\langle f, s \rangle \in t$ , we pick the optimal span for  $f$ :

$$s^* = \arg \max_{s' \in S(f)} \text{score}_{JCC}(t_{s'})$$

where  $S(f)$  determines all possible temporal spans for the fluent  $f$  and  $t_{s'} = (t \cup \langle f, s' \rangle) - \langle f, s \rangle$  is a copy of  $t$  where  $s'$  is the span for  $f$  instead of  $s$ . After selecting  $s^*$ , we add it to our timeline:  $t_{new} = (t \cup \langle f, s^* \rangle) - \langle f, s \rangle$ . Rather than calculating the score of the full timeline, we can save time by using only the relevant fluents in  $t_{s'}$ . For example, if our fluent is the *has spouse* fluent for Jon Stewart, we include all the fluents involving Jon Stewart and any relevant linked entities. In this case, we also include all the fluents for Tracey McShane.

Each round of RRHC consists of two passes through the fluents we are inferring: An  $\arg \max$  pass followed by a randomization pass where we randomly choose spans for a random fraction of the fluents. When finished, we return the highest scoring timeline seen during either of these passes.

## 4 Experiments

We evaluate our models (CC and JCC) according to their ability to predict the temporal bounds of fluents from Freebase. This is similar to the Diagnostic Track in the Temporal KBP task, where gold relations are provided as inputs. We provide three baselines for comparison, discussed further in §4.2. To form our database, we scraped a random sample of people and organization entities from Freebase using their API. Since our consistency model has limited effect if entities do not have any links to other entities, we restrict our attention to entities linked to at least one other entity – this eliminates a large

portion of possible entities. Our corpus<sup>7</sup> consists of 8,450 entities for training, 1,072 for development, and 1,067 for test. Entities have approximately 2.0 fluents on average.

From experiments on the development set, we set the relative strength of the consistency component  $\beta = 10$ . For the JCC model, we perform three runs for each experiment with different random seeds. Each experiment performs 10 rounds of RRHC,<sup>8</sup> initializing from an empty timeline.

### 4.1 Evaluation metric

Our evaluation metric is adapted from the Temporal KBP metric (Ji et al., 2011) to work with 2-tuples for temporal representations rather than the 4-tuples in Temporal KBP. The metric favors tighter bounds on fluents while giving partial credit. All dates need to be given at day resolution. Thus, for gold fluents with only year- or month-level resolution, we treat them as their earliest (for starts) or latest (for ends) possible day. To score a boundary, we take the difference between the predicted and gold values: If they're both unbounded ( $\pm\infty$ ), the boundary's score is 1. If only one is unbounded, the score is 0. If both are finite, the score is  $1/(1 + |d|)$  where  $d$  is the difference between the values in years. To score a fluent, we average the scores of its start and end boundaries. In rare cases, we have multiple spans for the same relation (e.g., Elizabeth Taylor married Richard Burton twice). In these cases, we give systems the benefit of the doubt and greedily align fluents in such a way as to maximize the metric. The total metric computes the score of each fluent divided by the number of fluents. The official metric includes precision and recall components, but since our setup provides gold relations, our precision and recall are equal. This allows us to report a single number.

### 4.2 Baselines and oracle

The simplest baseline is the *null* baseline, proposed in Surdeanu et al. (2011). This baseline assumes that all fluents are unbounded in their spans. The purpose

<sup>7</sup><http://nlp.stanford.edu/~mcclosky/data/freebase-temporal-relations.tar.gz>

<sup>8</sup>There was no significant difference in accuracy between running 10 and 200 rounds of RRHC.

Figure 2: Performance of models and baselines on development data while varying amount of training data. Not pictured: The *null* baseline at 58.8%.

of this baseline is primarily to show the approximate minimal value for the temporal metric.

We provide two other baselines to describe heuristic methods of aggregating the hard decisions from the classifier function  $C$  learned in §3.2. These are unlike the CC model which uses the soft decisions of  $C$ . Both of these baselines maintain lists of possible starts and ends for each fluent. If the classifier assigns START AND END, we add the candidate temporal expression to both. The first baseline, *basic aggregation*, is along the same lines as the aggregation method used in Artiles et al. (2011), a state-of-the-art system. Our baseline assigns the earliest start and the latest end as the bounds for each fluent, assigning  $\pm\infty$  for empty lists. The second baseline, *basic aggregation (modes)*, is the same except that it uses the mode from each list.

To determine the best possible score given our temporal expression retrieval system, we calculate the oracle score by assigning each fluent the span which maximizes the temporal metric. The oracle score can differ from a perfect score since we can only use candidate temporal expressions as values for a fluent if (a) mentions of the fluent are retrievable in our source documents, (b) the temporal expression mention appears nearby, and (c) our temporal expression extractor is able to recognize it correctly. Nevertheless, it is still a reasonable upper bound in our setting.

Model	Dev	Test
Oracle	78.1	75.2
<b>Joint Classifier with Consistency</b>	<b>76.1</b>	<b>72.2</b>
Combined Classifier	75.8	71.5
Basic aggregation (modes)	75.3	71.2
Basic aggregation	74.7	70.5
<i>null</i> baseline	58.8	55.6

Table 2: Performance of systems on development and test divisions. The Joint classifier with Consistency is the average of three runs with negligible variance ( $\sigma \approx 0.02$ ).

### 4.3 Results

We present the performance of our models, baselines, and the oracle in Figure 2 while varying the percentage of training entities. The JCC model (76.1% on development with 100% training entities) is consistently the best non-oracle system. Its gains are larger when the amount of training data is low. This is presumably because the classifier suffers from insufficient data and the consistency component is able to learn consistency rules to recover from this. Both the CC and JCC models outperform the basic aggregation models. This shows the value of incorporating all marginal probabilities. On the test set (Table 2), the JCC model performs even better in comparison to the simple models, despite the test set being clearly more difficult than the development set. In this case, the JCC achieves a 36% error reduction over the basic aggregation model.<sup>9</sup> On the official KBP entities, the oracle score is 92%. Since we use a different set of entities, there is a mismatch between our entities and the source documents resulting in a lower oracle score. Addressing this is future work.

## 5 Discussion

Table 3 shows the performance of four systems and baselines on individual fluent types. The JCC model derives most of its improvement from the two *lifespan* fluents and other high frequency fluents. The *lifespan* fluents provide the most room for improvement since they tend to contain non-*null* values a reasonable amount of the time (note how these relations have a large gap between their ora-

<sup>9</sup>This counts errors relative to the oracle score since we treat the retrieval system as fixed in this work.

Fluent	Count	Model					
		<i>null</i>	Basic	Basic (modes)	CC	JCC	Oracle
organization: <i>lifespan</i>	266	49.2	71.0	70.7	71.1	71.7	73.4
organization: <i>top employees</i>	150	88.0	88.0	88.0	88.0	88.0	88.3
organization: <i>founders</i>	31	0.0	5.4	5.4	10.8	11.1	16.3
organization: <i>acquires company</i>	14	21.4	21.4	21.4	21.4	21.4	38.5
person: <i>lifespan</i>	806	28.6	63.1	64.6	65.6	66.1	69.1
person: <i>has spouse</i>	582	92.2	92.1	92.1	92.2	92.3	93.1
person: <i>attends school</i>	107	97.7	97.7	97.7	97.7	98.1	98.1
person: <i>has job</i>	85	78.8	79.4	79.4	78.8	78.8	80.3
person: <i>holds government position</i>	45	16.7	19.7	19.7	19.7	19.7	25.1
person: <i>romantic partner</i>	5	50.0	52.9	52.9	52.9	52.9	71.2

Table 3: Fluent-level performance of models and baselines on development data. Scores are calculated with the temporal metric. CC stands for Combined Classifier and JCC for Joint Classifier with Consistency. The JCC model obtains most of its benefits on the two *lifespan* relations. For *attends school*, it is the only system able to achieve oracle-level performance. The *null* baseline is especially strong for several fluents since these tend to be unbounded or (more likely) missing their values in Freebase. The two basic aggregation models differ primarily on their predictions for the *lifespan* fluents.

cle and *null* scores). Additionally, the *lifespan* fluent is always present for entities while other fluents are sparser. For *attends school*, JCC is the only system able to achieve oracle-level performance. No system improves on the *null* baseline for *acquires company*. This is likely due to its sparsity.

Inspecting the multinomials in the consistency component, we can see that the model learns reasonable answers to questions such as whether an entity “was born before getting married?” (yes: 14.8%, no: 0.04%),<sup>10</sup> “died before their parents were born?” (yes: 0.3%, no: 53.7%) and “finished a job before starting a job (not necessarily the same one)?” (yes: 72.5%, no: 20.5%). Despite some unavoidable noise in the data, it is clear these constraints are useful.

## 6 Related work

There is a large body of related work that focuses on ordering events or classifying temporal relations between them (Ling and Weld, 2010; Yoshikawa et al., 2009; Chambers and Jurafsky, 2008; Mani et al., 2006, *inter alia*). Much of this work uses the Allen interval relations (Allen, 1983) which richly describe partial orderings of fluents. We use several of these as fluent-level question templates.

Joint inference has been applied successfully

<sup>10</sup>Percentages for “unknown” are omitted here.

to other NLP problems (Roth and Yih, 2004; Toutanova et al., 2008; Martins et al., 2009; Chang et al., 2010; Koo et al., 2010; Berant et al., 2011). Two recent examples in information extraction include using Markov Logic for temporal ordering (Ling and Weld, 2010) and using dual-decomposition for event extraction (Riedel and McCallum, 2011).

Our work is closest to Temporal KBP slot filling systems. The CUNY and UNED systems (Artiles et al., 2011; Garrido et al., 2011) for this task used classifiers to determine the relation between temporal expressions and fluents. These systems use the hard decisions from the classifier and combine the decisions by finding a span that includes all temporal expressions. In contrast, our system uses the classifier’s marginal probabilities along with the consistency component to incorporate global consistency constraints. Other participants used rule-based and pattern matching approaches (Byrne and Dunnion, 2011; Surdeanu et al., 2011; Burman et al., 2011).

Outside of Temporal KBP, there are several works on the task of extracting fluents from text. Wang et al. (2011) which uses label propagation, a graph-based semi-supervised method to extend positive and negative seed examples over the graph. Talukdar et al. (2012) apply a similar approach by aggregating local classification decisions using tempo-

ral constraints (e.g., mutual exclusion, containment, and succession) and joint inference. One key difference is that their constraints are included as input rather than learned by the system.

## 7 Conclusion and future Work

Joint inference can be effectively applied to the task of inferring timelines about named entities. Rather than using hard coded heuristics, our model learns and applies consistency constraints which capture inter-entity and cross-entity rules. Simple inference techniques such as random-restart hillclimbing score well and run efficiently. Both of our models (CC and JCC) obtain a substantial error reductions over simpler heuristics-based consistency approaches.

The overall framework can easily be applied to other information extraction tasks. Rather than listing rules for consistency, these can be learned and enforced via joint inference. While simple joint inference methods such as random-restart hillclimbing and Gibbs sampling worked well in our case, more complex inference methods may be required with more elaborate constraints.

A prime direction for future work is combining our model with a probabilistic relation extraction system. This could be accomplished by using the marginal probabilities on the extracted relations and multiplying them with the probabilities from the classifier and consistency components. Inference would require an additional step which could add or drop candidate fluents. Furthermore, the consistency component can be extended with new question types to incorporate non-temporal constraints as well.

## Abstract

Because the real world evolves over time, numerous relations between entities written in presently available texts are already obsolete or will potentially evolve in the future. This study aims at resolving the intricacy in consistently compiling relations extracted from text, and presents a method for identifying constancy and uniqueness of the relations in the context of supervised learning. We exploit massive time-series web texts to induce features on the basis of time-series frequency and linguistic cues. Experimental results confirmed that the time-series frequency distributions contributed much to the recall of constancy identification and the precision of the uniqueness identification.

## 1 Introduction

We have witnessed a number of success stories in acquiring semantic relations between entities from ever-increasing text on the web (Pantel and Pennacchiotti, 2006; Banko et al., 2007; Suchanek et al., 2007; Wu et al., 2008; Zhu et al., 2009; Mintz et al., 2009; Wu and Weld, 2010). These studies have successfully revealed to us millions of relations between real-world entities, which have been proven to be beneficial in solving knowledge-rich problems such as question answering and textual entailment (Ferrucci et al., 2010).

\*This work was conducted while the first author was a graduate student at University of Tokyo.

There exists, however, a great challenge to compile consistently relations extracted from text by these methods, because they assume a simplifying assumption that relations are time-invariant. In other words, they implicitly disregard the fact that statements in texts actually reflect the state of the world at the time when they were written, which follows that relations extracted from such texts eventually become outdated as the real world evolves over time.

Let us consider that relations are extracted from the following sentences:<sup>1</sup>

- (1) a. 1Q84 *is written by* Haruki Murakami.
- b. Moselle river *flows through* Germany.
- c. U.S.'s *president is* George Bush.
- d. Pentax *sells* K-5, a digital SLR.

Here, italicized predicates represent the relations, while underlined entities are their arguments. The relations in statements 1a and 1b are true across time, so we can simply accumulate all the relation instances. The relations in 1c and 1d in contrast evolve over time. The relation written in 1c becomes outdated when the other person takes the position, so we need to supersede it when a new relation is extracted from text (e.g., U.S.'s president is Barack Obama). For the relation in 1d, we do not always need to supersede it with a new relation.

This study is motivated from the above consider-

<sup>1</sup>Since our task settings are language-independent, we hereafter employ English examples as much as possible to widen the potential readership of the paper, although we conducted experiments with relations between entities in Japanese.

ations and proposes a method for identifying constancy and uniqueness of relations in order to select an appropriate strategy to maintain relation instances extracted from text. For example, the relations written in statements 1a and 1b are constant, while those in 1c and 1d are non-constant; the relation in 1c is unique,<sup>2</sup> whereas the relation in 1d is non-unique. With these properties of relations in mind, we can accumulate constant relations while appropriately superseding non-constant, unique relations with newly acquired relations.

We locate each identification task in the context of supervised classification. The key challenge in solving these classification tasks is how to induce an effective feature that identifies unique, non-constant relations (statement 1c) that seemingly appear as non-unique relations on text (statement 1b). We exploit massive time-series web text to observe actual evolutions of relation instances and induce features from the relation instances taken from a time sliding window and linguistic cues modifying the predicate and arguments of the target relation.

We evaluated our method on 1000 relations extracted from 6-year’s worth of Japanese blog posts with 2.3-billion sentences. We have thereby confirmed that the features induced from this time-series text contributed much to improve the classification accuracy.

The main contributions of this paper are twofold:

- We have introduced a novel task for identifying constancy relations. Since most of the existing studies assume that relations are time-invariant as discussed by Weikum et al. (2011), non-constant relations prevalent in their outcome incur a serious problem in maintaining the acquired relations. The notion of constancy is meant to resolve this stalemate.
- We have for the first time demonstrated the usefulness of a time-series text in relation acquisition and confirmed its impact in the two relation classification tasks. The features induced from the time-series text have greatly contributed to the accuracy of the classification based on uniqueness as well as the recall of the classification based on constancy.

<sup>2</sup>This kind of relation is referred to as functional relation in the literature (Ritter et al., 2008; Lin et al., 2010).

Constant	Non-constant
<b>arg1</b> was born in <b>arg2</b>	<b>arg1</b> ’s president is <b>arg2</b>
<b>arg1</b> is a father of <b>arg2</b>	<b>arg1</b> belongs to <b>arg2</b>
<b>arg1</b> is written by <b>arg2</b>	<b>arg1</b> lives in <b>arg2</b>

Table 1: Examples of constant, non-constant relations.

The remainder of this paper is structured as follows. Section 2 introduces the two properties of relations (constancy and uniqueness) and then defines the task setting of this study. Sections 3 and 4 describe the features induced from time-series text for constancy and uniqueness classification, respectively. Section 5 reports experimental results. Section 6 addresses work related to this study. Section 7 concludes this study and mentions future work.

## 2 Classification of Relations based on Constancy and Uniqueness

### 2.1 Constancy and uniqueness

We introduce two properties of relations: *constancy* and *uniqueness*.

A relation is *constant* if, for most values of *arg1*, the value of *arg2* is independent of time (Table 1). For example,  $\langle \mathbf{arg1} \text{ was born in } \mathbf{arg2} \rangle$  is a constant relation since one’s birthplace never changes. On the other hand,  $\langle \mathbf{arg1} \text{ ’s president is } \mathbf{arg2} \rangle$  is an example of non-constant relations. This can be checked by noting that, for example, the president of the United States was Barack Obama in 2011 but was previously George Bush and Bill Clinton before him.

A relation is *unique* if, for most values of *arg1*, there exists, at any given point in time, only one value of *arg2* that satisfies the relation (Table 2). For example,  $\langle \mathbf{arg1} \text{ was born in } \mathbf{arg2} \rangle$  is obviously a unique relation. The relation  $\langle \mathbf{arg1} \text{ is headquartered in } \mathbf{arg2} \rangle$  is also unique, while it is non-constant. Notice that there is usually only one headquarters at any point in time, although the location of a headquarters can change. In contrast, the relation  $\langle \mathbf{arg1} \text{ is funded by } \mathbf{arg2} \rangle$  is a non-unique relation since it is likely that there exist more than one funder.

### 2.2 Discussion

Both constancy and uniqueness are properties that usually, not always, hold for most, not all, of the *arg1*’s values. To see this, let us examine the relation  $\langle \mathbf{arg1} \text{ ’s president is } \mathbf{arg2} \rangle$ . Although this relation is

Unique	Non-unique
<b>arg1</b> was born in <b>arg2</b>	<b>arg1</b> is funded by <b>arg2</b>
<b>arg1</b> is headquartered in <b>arg2</b>	<b>arg1</b> consists of <b>arg2</b>
<b>arg1</b> 's president is <b>arg2</b>	<b>arg1</b> borders on <b>arg2</b>

Table 2: Examples of unique and non-unique relations.

non-constant and unique (Table 1 and 2), it is still possible to find exceptional cases. For example, a country might exist in which the president has never changed; a country might have more than one president at the same time during civil war. However, since such situations are rare, the relation  $\langle \mathbf{arg1}$ 's president is  $\mathbf{arg2} \rangle$  is considered as neither constant nor non-unique.

The above discussion implies that the constancy and uniqueness of relations can not be determined completely objectively. We, nevertheless, claim that these properties of relations are intuitively acceptable and thus they can be identified with moderate agreement by different people (see section 5).

### 2.3 Task and our approach

This paper explores classifying given relations on the basis of constancy and uniqueness. We treat the problem as two independent binary classification tasks, and train supervised classifiers.

The technical challenge we address in this paper is how to design features for the two tasks. Section 3 presents features based on time-series frequency and linguistic cues for classifying constant and non-constant relations. Similarly, section 4 presents analogous features for classifying unique and non-unique relations.

## 3 Features for Constancy Classification

### 3.1 Time-series frequency

It is intuitive to identify constant relations by comparing frequency distributions over  $\mathbf{arg2}$  in different time periods. This idea leads us to use frequency estimates from time-series text as features.

**Time-series text** For a time-series text, we used Japanese blog posts that had been gathered from Feb. 2006 to Sep. 2011 (68 months). These data include 2.3 billions of sentences. These posts were aggregated on a monthly basis by using time stamps attached with them, i.e., the unit of time is one month

Figure 1: Time-series frequency distribution of  $\langle \mathbf{arg1} \text{ belongs to } \mathbf{arg2} \rangle$  when  $\mathbf{arg1}$  takes Keisuke Honda.

in our corpus.

**Basic idea** For constant relations (e.g.,  $\langle \mathbf{arg1} \text{ was born in } \mathbf{arg2} \rangle$ ), we can expect that the frequency distributions over  $\mathbf{arg2}$  for a given  $\mathbf{arg1}$  (e.g., *Mozart*) are similar to each other irrespective of the time windows that are used to estimate frequency.

In the case of non-constant relations (e.g.,  $\langle \mathbf{arg1} \text{ belongs to } \mathbf{arg2} \rangle$ ), on the other hand, the frequency distributions over  $\mathbf{arg2}$  for a given  $\mathbf{arg1}$  significantly differ depending on the time window. For example, Figure 1 illustrates the frequency distributions of  $\mathbf{arg2}$ s for  $\langle \mathbf{arg1} \text{ belongs to } \mathbf{arg2} \rangle$  in which  $\mathbf{arg1}$  takes Keisuke Honda, a famous football player. We can clearly observe that due to Keisuke Honda being sold from VVV Venlo to CSKA Moscow, the distributions differ greatly between 2008 and 2010.

As is evident from the above discussions, the stability/change in the distribution over  $\mathbf{arg2}$  is a good indicator of constant/non-constant relations. The following subsection addresses how to encode such information as features.

**Feature computation** Let us examine using as features the cosine similarity between frequency distributions over  $\mathbf{arg2}$ . Averaging such similarities over representative values of  $\mathbf{arg1}$ , we have

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \cos(F_{w_1}(r, e), F_{w_2}(r, e)),$$

where  $r$  is a relation (e.g.,  $\langle \mathbf{arg1}$ 's president is  $\mathbf{arg2} \rangle$ ),  $e$  is a named entity (e.g., *United States*) appearing in  $\mathbf{arg1}$ , and  $F_w(r, e)$  is the frequency distribution over  $\mathbf{arg2}$  when  $\mathbf{arg1}$  takes  $e$ . The subscripts

$w_1$  and  $w_2$  denote the time window (e.g., from Jan. 2011 to Feb. 2011) used to estimate the frequency distribution.  $\mathcal{E}_N(r)$  denotes a set of top  $N$  frequent entities appearing in  $\text{arg1}$ . We use the entire time-series text to obtain  $\mathcal{E}_N(r)$ .

Unfortunately, this idea is not suitable for our purpose. The problem is that it is not clear how to determine the two time windows,  $w_1$  and  $w_2$ . To identify non-constant relations,  $\text{arg2}$  must have different values in the two time periods. Such time windows are, however, impossible to know of in advance.

We propose avoiding this difficulty by using average, maximum and minimum similarity over all possible time windows:

$$\begin{aligned} & \frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \text{ave}_{w_1, w_2 \in \mathcal{W}_T} \cos(F_{w_1}(r, e), F_{w_2}(r, e)), \\ & \frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \max_{w_1, w_2 \in \mathcal{W}_T} \cos(F_{w_1}(r, e), F_{w_2}(r, e)), \\ & \frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \min_{w_1, w_2 \in \mathcal{W}_T} \cos(F_{w_1}(r, e), F_{w_2}(r, e)), \end{aligned}$$

where  $\mathcal{W}_T$  is a set of all time windows of the size  $T$ . For example, if we set  $T$  to 3 (months) in the 68-month’s worth of blog posts,  $\mathcal{W}_T$  consists of 66 ( $= 68 - 3 + 1$ ) time windows. Although we still have to specify the number of entities  $N$  and the window size  $T$ , this is not a serious problem in practice. We set  $N$  to 100. We use four window sizes (1, 3, 6, and 12 months) and induce different features for each window size. As a result, we have 12 real-valued features.

### 3.2 Linguistic cues

This subsection presents two types of linguistically-motivated features for discriminating between constant and non-constant relations.

**Nominal modifiers** We observe that non-constant relations could be indicated by some nominal modifiers:

- (2) a. George Bush, *ex*-president of USA.
- b. Lincoln is the *first* president of the USA.

The use of the prefix *ex*- and the adjective *first* implies that the president changes, and hence the relation  $\langle \text{arg1} \text{ ’s president is arg2} \rangle$  is not constant.

---

前 (ex-), 現 (present), 次期 (next), 元 (former), 新 (new),
旧 (old), 歴代 (successive), 初代 (first), 初 (first)

---

Table 3: Japanese prefixes and adjectives indicating non-constant relations. The translations are provided in the parentheses.

We propose making use of such modifiers as features. Although the above examples are in English, we think modifiers also exist that have similar meanings in other languages including Japanese, our target language.

Our new features are induced as follows:

- First, we manually list eight nominal modifiers that indicate the non-constancy (Table 3).
- Next, we extract nouns from a relation to be classified (e.g., *president*), and count the frequency with which each modifier modifies those nouns. We use the same blog posts as in section 3.1 for counting the frequency. Since time information is not important in this case, the frequency is simply accumulated over the entire time span.
- We then generate eight features, one for each of the eight modifiers. The value of the features is one if the frequency exceeds threshold  $\theta_1$ ,<sup>3</sup> otherwise it is zero. Note that the value of this feature is always zero if the relation includes no nouns.

**Tense and aspect** Tense and aspect of verbs are also important indicators of the non-constancy:

- (3) The U.S. president *was* George Bush.

If a relation, such as  $\langle \text{arg1} \text{ ’s president is arg2} \rangle$ , can often be rephrased in the past tense as in (3), it is likely to be, if not always, a non-constant relation.

It is, fortunately, straightforward to recognize tense and aspect in Japanese, because they are expressed by attaching suffixes to verbs. In this study, we use three common suffixes: “た”, “ている”, and “てる”. The first suffix expresses past tense, while the other two express present continuous or progressive aspects depending on context.

<sup>3</sup> $\theta_1 = 10$  in our experiment.

A given relation is transformed into different forms by attaching the suffixes to a verb in the relation, and their frequencies are counted. By using the frequency estimates, we generate three new features, each of which corresponds to one of the three suffixes. The value of the new features is one if the frequency exceeds threshold  $\theta_2$ ,<sup>4</sup> otherwise it is zero.

The frequency is counted in the same way as in the case of the nominal modifiers. The value of this feature is always zero if the relation includes no verbs.

## 4 Features for Uniqueness Classification

This section provides features for identifying unique relations. These features are also based on the time-series text and linguistic cues, as in the case of constancy classification.

### 4.1 Time-series frequency

**Number of entity types** A straightforward approach to identifying unique relations is, for a given  $\text{arg1}$ , to count the number of entity types appearing in  $\text{arg2}$  (Lin et al., 2010). For unique relations, the number of entity types should be one in an ideal noiseless situation. Even if the estimate is contaminated by noise, a small number of entity types can still be considered to indicate the uniqueness of the relation.

A shortcoming of such a simple approach is that it never considers the (non-)constancy of relations. Presume counting the number of entity types in  $\text{arg2}$  of the relation  $\langle \text{arg1 is headquartered in arg2} \rangle$ , which is non-constant and unique. If we use large size of time window to obtain counts, we will observe multiple types of entities in  $\text{arg2}$ , not because the relation is non-unique, but because it is non-constant. This problem cannot be resolved by trivially using very small windows, since a time window that is too small in turn causes a data sparseness problem.

This problem is attributed to the difficulty in determining the appropriate size of the time window. We tackle this problem by using the same technique presented in section 3.1. Specifically, we use the fol-

<sup>4</sup> $\theta_2 = 3000$  in our experiment.

lowing three measures as features:

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \text{ave}_{w \in \mathcal{W}_T} \# \text{type}(F_w(r, e)),$$

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \text{max}_{w \in \mathcal{W}_T} \# \text{type}(F_w(r, e)),$$

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \text{min}_{w \in \mathcal{W}_T} \# \text{type}(F_w(r, e)),$$

where the function  $\# \text{type}(\cdot)$  denotes the number of entity types appearing in  $\text{arg2}$ .

**Ratio of entity frequency** Since it is not reliable enough to use only the number of entity types, we also exploit the frequency of the entity. Let  $e_{1st}$  and  $e_{2nd}$  be the most and the second most frequent entities found in  $\text{arg2}$ . If the frequency of  $e_{1st}$  is much larger than that of  $e_{2nd}$ , the relation is likely to be constant.

To encode this intuition, the following measures are used as features:

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \text{ave}_{w \in \mathcal{W}_T} \frac{f_w(e, r, e_{1st})}{f_w(e, r, e_{2nd})}$$

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \text{max}_{w \in \mathcal{W}_T} \frac{f_w(e, r, e_{1st})}{f_w(e, r, e_{2nd})}$$

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \text{min}_{w \in \mathcal{W}_T} \frac{f_w(e, r, e_{1st})}{f_w(e, r, e_{2nd})}$$

where the  $f_w(e, r, e')$  is the frequency of the relation  $r$  in which  $\text{arg1}$  and  $\text{arg2}$  take  $e$  and  $e'$ , respectively. The subscript  $w$  denotes the time window.

### 4.2 Linguistic cues

Coordination structures and some keywords indicate non-unique relations:

- (4) a. France borders on *Italy and Spain*.
- b. France borders on *Italy etc*.

The coordination structure in the first example implies an entity can border on more than one entity, and hence the relation  $\langle \text{arg1 borders on arg2} \rangle$  is not unique. The keyword *etc*. in the second example also indicates the non-uniqueness.

と, とか, や, やら, だの, なり, か

Table 4: List of Japanese particles that are used to form coordination structures.

To capture this intuition, we introduce two types of linguistic features for classifying unique and non-unique relations. The first feature checks whether entities in `arg2` form coordination structures. The feature is fired if the number of times that coordination structures are found in `arg2` exceeds threshold  $\theta_3$ .<sup>5</sup> Coordination structures are identified by a list of Japanese particles, which roughly correspond to *and* or *or* in English (Table 4). If two entities are connected by one of those particles, they are seen as forming a coordination structure.

The second feature exploits such keywords as *etc.* for identifying non-unique relations. We list four Japanese keywords that have similar meaning to the English word *etc.*, and induce another binary feature<sup>6</sup>. The feature is fired if the number of times that an entity in `arg2` is followed by one of the four keywords exceeds threshold  $\theta_3$ .

## 5 Experiments and discussions

We built labeled data and examine the classification performance of the proposed method. We also analyzed the influence of window size  $T$  on the performance, as well as major errors caused by our method.

### 5.1 Data

We built a dataset for evaluation by extracting relations from the time-series text (section 3.1) and then manually annotating 1000 relations. The detailed procedure is as follows.

First, we parsed the time-series text and extracted as relation dependency paths connecting two named entities. We used J.DepP,<sup>7</sup> an efficient shift-reduce parser with feature sequence trie (Yoshinaga and Kitsuregawa, 2009; Yoshinaga and Kitsuregawa, 2010), for parsing. All Japanese words that conjugate were normalized into standard forms.

<sup>5</sup> $\theta_3 = 10$  in our experiment.

<sup>6</sup>The keywords we used are 等, ら, たち, and 達.

<sup>7</sup><http://www.tkl.iis.u-tokyo.ac.jp/~ynaga/jdepp/>

Figure 2: Recall-precision curve (constancy classification).

Then, annotators were asked to label 1000 relations as not only constant or non-constant but also unique or non-unique. Three annotators were assigned to each relation, and the goldstandard label is determined by majority vote. The Fleiss kappa (Fleiss, 1971) was 0.346 for constancy classification and was 0.428 for uniqueness classification. They indicate fair and moderate agreement, respectively (Landis and Koch, 1977).

We have briefly investigated the relations whose labels assigned by the annotators conflicted. The major cause was that the annotators sometimes assumed different types of named entities as values of arguments. A typical case in which this problem arises is that the relation has polysemous meanings, e.g.,  $\langle \mathbf{arg1}$  was born in  $\mathbf{arg2} \rangle$ , or a vague meaning, e.g.,  $\langle \mathbf{arg1}$  makes  $\mathbf{arg2} \rangle$ . For example, `arg2` of  $\langle \mathbf{arg1}$  was born in  $\mathbf{arg2} \rangle$  can be filled with different types of entities such as date and place. We can address this problem by typing arguments (Lin et al., 2010).

### 5.2 Result

Using the dataset, we performed 5-fold cross-validation for both classification tasks. We used the passive-aggressive algorithm for our classifier (Crammer et al., 2006).

**Constancy classification** Figure 2 illustrates the recall-precision curve in constancy classification. Because we are unaware of any previous methods for classifying constant and non-constant relations, a simple method based on the cosine similarity was

Figure 3: Recall-precision curve (uniqueness classification).

used as a baseline:

$$\frac{1}{N} \sum_{e \in \mathcal{E}_N(r)} \cos(F_{w_1}(r, e), F_{w_2}(r, e)),$$

where the time windows  $w_1$  and  $w_2$  are determined as the first and last month in which the relation  $r$  is observed. A given relation is classified as non-constant if the above similarity exceeds a threshold. The recall-precision curve was drawn by changing the threshold.

The results demonstrated that our method outperforms the baseline. This indicates the effectiveness of using time-series frequency and linguistic cues as features.

The poor performance of the baseline was mainly due to data sparseness. Since the baseline method is dependent on the frequency estimates obtained from only two months of texts, it is less reliable than the proposed method.

**Uniqueness classification** Figure 3 illustrates the recall-precision curve in uniqueness classification. As a baseline we implemented the method proposed by Lin et al. (2010). While they have presented three methods (KLFUNC, KLDIFF, and their average), we report the results of the last one because it performed the best among the three in our experiment.

From the figure, we can again see that the proposed method outperforms the baseline method. Lin’s method is similar to ours, but differs in that they do not exploit time-series information at all.

Figure 4: Comparison with the methods varying a value of  $N$  for constancy classification.

Figure 5: Comparison with the methods varying a value of  $N$  for uniqueness classification.

We hence conclude time-series information is useful for classifying not only constant but also unique relations.

### 5.3 Investigation into the number of entities, $N$

We ranged the value of  $N$  in  $\{2, 10, 20, 100\}$ . Setting  $N$  to a larger value yields the better recall for constancy classification and the better precision for uniqueness classification (Figures 4 and 5). These results meet our expectations, since features derived from frequency distributions of  $\text{arg2}$  over various  $\text{arg1}$ s capture the generic nature of the target relation.

Figure 6: Comparison with the methods using only a single value of  $T$  for constancy classification.

Figure 7: Comparison with the methods using only a single value of  $T$  for uniqueness classification.

#### 5.4 Investigation into the window size, $T$

Our method uses multiple time windows of different sizes (i.e., different values of  $T$ ) to induce features, as detailed in sections 3.1 and 4.1. To confirm the effect of this technique, we investigated the performance when we use only a single value of  $T$  (Figures 6 and 7).

The results in the uniqueness classification task demonstrated that our method achieves better overall results than the methods using a single value of  $T$ . We can therefore consider that using multiple values of  $T$  as features is a reasonable strategy. On the other hand, we could not confirm the effect of using multiple time windows of different sizes in the constancy classification task.

#### 5.5 Error analysis

We randomly selected and analyzed 200 misclassified relations for both tasks. The analysis revealed four types of errors.

**Paraphrases** We observed that constant relations are prone to be miss-classified as non-constant when more than one paraphrase appear in  $\text{arg2}$  and thus the value of  $\text{arg2}$  is pretended to change. For example, America was also referred to as USA or United States of America. A similar problem was observed for unique relations as well.

**Topical bias** Topics mentioned in the blog posts are sometimes biased, and such bias can have a negative effect on classification, especially when a relation takes a small number of entity types in  $\text{arg2}$  for given  $\text{arg1}$ . For example, Jaden Smith, who is one of Will Smith’s sons, is frequently mentioned in our time-series text because he co-starred with his father in a movie, while Will Smith’s other sons never appeared in our text. We consider this a possible reason for our method wrongly identifying  $\langle \text{arg1}$ ’s son is  $\text{arg2} \rangle$  as a unique relation.

**Short-/Long-term evolution** Since we have aggregated on a monthly basis the 6-year’s worth of blog posts, the induced features cannot capture evolutions that occur in shorter or longer intervals. For example, consider relation  $\langle \text{arg1}$  beats  $\text{arg2} \rangle$  taking Real Madrid as  $\text{arg1}$ . Since Real Madrid usually have more than one football match in a month, they can beat several teams in a month, which misleads the classifier to recognize the relation as non-unique. Similarly when a relation takes more than 6 years to evolve, it will be regarded as constant.

#### Reference to past, future, or speculative facts

The blog authors sometimes refer to relations that do not occur around when they write their posts; such relations actually occurred in the past, will occur in the future, or even speculative. Since our method exploits the time stamps attached to the posts to associate the relations with time, those relations introduce noises in the frequency distributions. Although our robust feature induction could in most cases avoid an adverse effect caused by these noises, they sometimes led to misclassification.

## 6 Related Work

In recent years, much attention has been given to extracting relations from a massive amount of textual data, especially the web (cf. section 1). Most of those studies, however, explored just extracting relations from text. Only a few studies, as described below, have discussed classifying those relations.

There has been no previous work on identifying the constancy of relations. The most relevant research topic is the temporal information extraction (Verhagen et al., 2007; Verhagen et al., 2010; Ling and Weld, 2010; Wang et al., 2010; Hovy et al., 2012). This is the task of extracting from textual data an event and the time it happened, e.g., Othello was written by Shakespeare in 1602. Such temporal information alone is not sufficient for identifying the constancy of relations, while we think it would be helpful.

On the other hand, the uniqueness of relations has so far been discussed in some studies. Ritter et al. (2008) have pointed out the importance of identifying unique relations for various NLP tasks such as contradiction detection, quantifier scope disambiguation, and synonym resolution. They proposed an EM-style algorithm for scoring the uniqueness of relations. Lin et al. (2010) also proposed three algorithms for identifying unique relations. While those studies discussed the same problem as this paper, they did not point out the importance of the constancy in identifying unique relations (cf. section 4.1).

## 7 Conclusion

This paper discussed that the notion of constancy is essential in compiling relations between entities extracted from real-world text and proposed a method for classifying relations on the basis of constancy and uniqueness. The time-series web text was fully exploited to induce frequency-based features from time-series frequency distribution on relation instances as well as language-based features tailored for individual classification tasks. Experimental results confirmed that the frequency-based features contributed much to the precision and recall in both identification tasks.

We will utilize the identified properties of the relations to adopt an appropriate strategy to compile

their instances. We also plan to start a spin-off research that acquires paraphrases by grouping values of *arg2s* for each value of *arg1* in a constant, unique relation.

We consider that the notion of constancy will even be beneficial in acquiring world knowledge, other than relations between entities, from text; we aim at extending the notion of constancy to other types of knowledge involving real-world entities, such as concept-instance relations.

# No Noun Phrase Left Behind: Detecting and Typing Unlinkable Entities

## Abstract

Entity linking systems link noun-phrase mentions in text to their corresponding Wikipedia articles. However, NLP applications would gain from the ability to detect and type all entities mentioned in text, including the long tail of entities not prominent enough to have their own Wikipedia articles. In this paper we show that once the Wikipedia entities mentioned in a corpus of textual assertions are linked, this can further enable the detection and fine-grained typing of the unlinkable entities. Our proposed method for detecting unlinkable entities achieves 24% greater accuracy than a Named Entity Recognition baseline, and our method for fine-grained typing is able to propagate over 1,000 types from linked Wikipedia entities to unlinkable entities. Detection and typing of unlinkable entities can increase yield for NLP applications such as typed question answering.

## 1 Introduction

A key challenge in machine reading (Etzioni et al., 2006) is to identify the entities mentioned in text, and associate them with appropriate background information such as their type. Consider the sentence “Some people think that pineapple juice is good for vitamin C.” To analyze this sentence, a machine should know that “pineapple juice” refers to a beverage, while “vitamin C” refers to a nutrient.

Entity linking (Bunescu and Paşca, 2006; Cucerzan, 2007) addresses this problem by linking noun phrases within the sentence to entries in a large, fixed entity catalog (almost always

example noun phrases	status
“apple juice” “orange juice” “ <b>prune juice</b> ” “ <b>wheatgrass juice</b> ”	present <b>absent</b>
“radiation exposure” “workplace stress” “ <b>asbestos exposure</b> ” “ <b>financial stress</b> ”	present <b>absent</b>
“IJCAI” “OOPSLA” “ <b>EMNLP</b> ” “ <b>ICAPS</b> ”	present <b>absent</b>

Table 1: Wikipedia has entries for prominent entities, while missing tail and new entities of the same types.

Wikipedia). Thus, entity linking has a limited and somewhat arbitrary range. In our example, systems by (Ferragina and Scaiella, 2010) and (Ratinov et al., 2011) both link “vitamin C” correctly, but link “pineapple juice” to “pineapple.” “Pineapple juice” is not entity linked as a beverage because it is not prominent enough to have its own Wikipedia entry. As Table 1 shows, Wikipedia often has prominent entities, while missing tail and new entities of the same types.<sup>1</sup> (Wang et al., 2012) notes that there are more than 900 different active shoe brands, but only 82 exist in Wikipedia. In scenarios such as intelligence analysis and local search, non-Wikipedia entities are often the most important.

Hence, we introduce the *unlinkable noun phrase problem*: Given a noun phrase that does not link into Wikipedia, return whether it is an entity, as well its fine-grained semantic types. Deciding if a non-Wikipedia noun phrase is an entity is challenging because many of them are not entities (e.g., “Some people,” “an addition” and “nearly half”). Predict-

<sup>1</sup>The same problem occurs with Freebase, which is also missing the same Table 1 entities.

ing semantic types is a challenge because of the diversity of entity types in general text. In our experiments, we utilized the Freebase type system, which contains over 1,000 semantic types.

The first part of this paper proposes a novel method for detecting entities by observing that entities often have different usage-over-time characteristics than non-entities. Evaluation shows that our method achieves 24% relative accuracy gain over a NER baseline. The second part of this paper shows how instance-to-instance class propagation (Kozareva et al., 2011) can be adapted and scaled to semantically type general noun-phrase entities using types from linked entities, by leveraging over one million different possible textual relations.

Contributions of our research include:

- We motivate and introduce the *unlinkable noun phrase problem*, which extends previous work in entity linking.
- We propose a novel method for discriminating entities from arbitrary noun phrases, utilizing features derived from Google Books ngrams.
- We adapt and scale instance-to-instance class propagation in order to associate types with non-Wikipedia entities.
- We implement and evaluate our methods, empirically verifying improvement over appropriate baselines.

## 2 Background

In this section we provide an overview of entity linking, how we entity link our data set, and describe how our problem and approach differ from related areas such as NER and Web extraction.

### 2.1 Entity Linking

Given text, the task of entity linking (Bunescu and Paşca, 2006; Cucerzan, 2007; Milne and Witten, 2008; Kulkarni et al., 2009) is to identify the Wikipedia entities within the text, and mark them with which Wikipedia entity they correspond to. Entity linking elevates us from plain text into meaningful *entities* that have properties, semantic types, and relationships with each other. Other entity catalogs can be used in place of Wikipedia, especially in domain-specific contexts, but general purpose linking systems all use Wikipedia because of its broad

general coverage, and to leverage its article texts and link structure during the linking process.

A problem we observed when using entity linking systems is that despite containing over 3 million entities, Wikipedia does not cover a significant number of entities. This occurs with entities that are not prominent enough to have their own dedicated article and with entities that are very new. For example, Facebook has over 600 million users, and each of them could be considered an entity. The REVERB extractor (Fader et al., 2011) on the ClueWeb09 Web corpus found over 1.4 billion noun phrases participating in textual relationships, and a sizable portion of these noun phrases are entities. While recent research has used NIL features to determine whether they are being asked to link an entity not in Wikipedia (Dredze et al., 2010; Ploch, 2011), there has been no research on whether given noun phrases that are *unlinkable* (for not being in Wikipedia) are entities, and how to make them usable if they are.

Our goal is to address this problem of learning whether non-Wikipedia noun phrases are entities, and assigning semantic types to them to make them useful. We begin with a corpus of 15 million “(noun phrase subject, textual relation, noun phrase object)” assertions from the Web that were extracted by REVERB (Fader et al., 2011).<sup>2</sup> REVERB already filters out relative pronouns, WHO-adverbs, and existential “there” noun phrases that do not make meaningful arguments. We then employ standard entity linking techniques including string matching, prominence priors (Fader et al., 2009), and context matching (Bunescu and Paşca, 2006) to link the noun phrase subjects into Wikipedia.

In this manner, we were able to entity link the noun phrase subject of 9,699,967 extractions, while the remaining 5,028,301 extractions had no matches (mostly due to no close string matches). There were 1,401,713 distinct noun phrase subjects in the 5 million extractions that had no matches. These are the *unlinkable* noun phrases we will study here.

### 2.2 Named Entity Recognition

Named Entity Recognition (NER) is the task of identifying named entities in text. A key difference between our final goals and NER is that in the con-

<sup>2</sup>available at <http://reverb.cs.washington.edu>

text of entity linking and Wikipedia, there are many more entities than just the *named* entities. For example, “apple juice” and “television” are Wikipedia entities (with Wikipedia articles), but are not traditional named entities. Still, as named entities do comprise a sizable portion of our *unlinkable* noun phrases, we compare against a NER baseline in our entity detection step.

Fine-grained NER (Sekine and Nobata, 2004; Lee et al., 2007) has studied scaling NER to up to 200 semantic types. This differs from our semantic typing of unlinked entities because our approach assumes access to corpora-level relationships between a large set of linked entities (with semantic types) and the unlinked entities. As a result we are able to propagate 1,339 Freebase semantic types from the linked entities to the unlinked entities, which is substantially more types than fine-grained NER.

### 2.3 Extracting Entity Sets

There is a line of research in using Web extraction (Etzioni et al., 2005) and entity set expansion (Pantel et al., 2009) to extract lists of typed entities from the Web (e.g., a list of every city). Our problem instead focuses on determining whether any individual noun phrase is an entity, and what semantic types it holds. Given a noun phrase representing a person name, we return that this is a person entity even if it is not in a list of people names harvested from the Web.

## 3 Architecture

Our goal is: given (1) a large set of linked assertions  $L$  and (2) a large set of unlinked assertions  $U$ , for each unlinkable noun phrase subject  $n \in U$ , predict: (1) whether  $n$  is an entity, and if so, then (2) the set of Freebase semantic types for  $n$ . For  $L$  we use the 9.7 million assertions whose *subject* argument we were able to link in Section 2.1, and for  $U$  we use the 5 million assertions that we could not link.

We divide the system into two components. The first component (described in Section 4) takes any unlinkable noun phrase and outputs whether it is an entity. All  $n \in U$  classified as entities are placed in a set  $E$ . The second component (described in Section 5) uses  $L$  and  $U$  to predict the semantic types for each entity  $e \in E$ .

Figure 1: Usage over time in Google books for the noun phrase “Prices quoted” (e.g., from “Prices quoted are for 2 adults”) which is not an entity.

Figure 2: Usage over time for the unlinkable noun phrase “Soluble fibre,” which is an entity. The best fit line has steeper slope compared to Figure 1.

## 4 Detecting Unlinkable Entities

This first task takes in any *unlinkable* noun phrase and outputs whether it is an entity. There is a long history of discussion in analytic philosophy literature on the question of what exists (e.g., (Quine, 1948)). We adopt a more pragmatic view, defining an “entity” as a noun phrase that could have a Wikipedia-style article if there were no notability or newness considerations, and which would have semantic types. We are interested in entities that could help populate an entity store. “EMNLP 2012” is an example of an entity, while “The method” and “12 cats” are examples of noun phrases that are not entities. This is challenging because at a surface level, many entities and non-entities look similar: “Sex and the City” is an entity, while “John and David” is not. “Eminem” is an entity, while “Youd” (a typo from “You’d”) is not.

We address this task by training a classifier with features primarily derived from a timestamped corpus. An intuition here is that when considering only unlinkable noun phrases, usage patterns across

Figure 3: Plot of  $R^2$  vs  $Slope$  for the usage over time of a collection of noun phrases selected for illustrative purposes. Many of the non-entities occur at lower  $Slope$  and higher  $R^2$ , while the entities often have higher slope and/or lower  $R^2$ . “Bluetooth technology” actually has even higher slope, but was adjusted left to fit in this figure.

time often differ for entities and non-entities. Noun phrase entities that are observed in text going back hundreds of years (e.g., “Europe”) almost all have their own Wikipedia entries, so in unlinkable noun phrase space, the remaining noun phrases that are observed in text going back hundreds of years tend to be all the textual references and expressions that are not entities. We plan to use this signal to help separate the entities from the non-entities.

#### 4.1 Classifier Features

We use the Google Books ngram corpus (Michel et al., 2010), which contains timestamped usage of 1-grams through 5-grams in millions of digitized books for each year from 1500 to 2007.<sup>3</sup> We use ngram match count values from case-insensitive matching. To avoid sparsity anomalies we observed in years before 1740, we use the data from 1740 onward. While it has not been used for our task before, this corpus is a rich resource that enables reasoning about knowledge (Evans and Foster, 2011) and

<sup>3</sup>available at <http://books.google.com/ngrams/datasets>

understanding semantic changes of words over time (Wijaya and Yeniterzi, 2011). Talukdar et al. (2012) recently used it to effectively temporally scope relational facts.

Our first feature is the  $slope$  of the least-squares best fit line for usage over time. For example, if a term appears 25 times in books in 1950, 30 times in 1951, ..., 100 times in 2007, then we compute the straight line that best fits  $\{(1950, 25), (1951, 31), \dots, (2007, 100)\}$ , and examine the slope. We have observed cases of non-entity noun phrases (e.g., Figure 1) having lower slopes than entity noun phrases (e.g., Figure 2). Note that we do not normalize match counts by yearly total frequency, but we do normalize counts for each term to range from 0 to 1 (setting the max count for each term to 1) to avoid bias from entity prominence. To capture the current usage, in cases where there exists a  $\geq 5$  year gap in usage of a term we only use the data after the gap.

Another feature is the  $R^2$  fit of the best fit line. Higher  $R^2$  indicates that the data is closer to a straight line. Figure 3 plots  $R^2$  vs  $Slope$  values

Figure 4: *UsageSinceYear* of example unlinked terms.

for some sample noun phrases. We observed that along with their lower *Slope*, the non-entities often also had higher  $R^2$ , indicating that their usage does not vary wildly from year to year. This contrasts with certain entities (e.g., “FY 99” for “Fiscal Year 1999”) whose usage sometimes varied sharply from year to year based on their prominence in those specific years.

A third feature is *UsageSinceYear*, which finds the year from when a term last started continually being used. For example, a *UsageSinceYear* value of 1920 would indicate that the term was used in books every year from 1920 through 2007. Figure 4 shows examples of where various terms fall along this dimension.

From the books ngram corpus, we also calculate features for: *PercentProperCaps* - the percentage of case-insensitive matches for the term where all words began with a capital letter, *PercentExactMatch* - the percentage of case-insensitive matches for the term that matched the capitalization in the assertion exactly, and *Frequency* - the total number of case-insensitive occurrences of the term in the book ngrams data, summed across all years, which reflects prominence. Last, we also include a simple *numeric* feature to detect the presence of leading numeric words (e.g., “5” in “5 days” or “Three” in “Three choices”).

## 4.2 Evaluation

From the corpus of 15 million REVERB assertions, there were 1.4 million unlinked noun phrases including 17% unigrams, 51% bigrams, 21% trigrams, and 11% 4-grams or longer. Bigrams comprise over half the noun phrases and the books bigram data is a self-contained download that is easier to obtain and store

system	correctly classified
Majority class baseline	50.4%
Named Entity Recognition	63.3%
<i>Slope</i> feature only	61.1%
<i>PUF</i> feature combination	69.1%
<i>ALL</i> features	78.4%

Table 2: Our classifier using all features (*ALL*) outperforms majority class and NER baselines.

than the full books ngram corpus, so we focus on bigrams in our evaluation. In a random sample of unlinked bigrams, we found that 73% were present in the books ngram data (65% exact match, 8% case-insensitive match only), while 27% were not (these were mostly entities or errors with non-alphabetic characters). Coverage is a greater issue with longer ngrams (e.g., there are many more possible 5-grams than bigrams, so any individual 5-gram is less likely to reach the minimum threshold to be included in the books data), but as mentioned earlier, only 11% of unlinkable noun phrases were 4-grams or longer.

We randomly sampled 250 unlinked bigrams that had books ngram data, and asked 2 annotators to label each as “entity,” “non-entity,” or “unclear.” Our goal is to separate noun phrases that are clearly entities (e.g., “prune juice”) from those that are clearly not entities (e.g., “prices quoted”), rather than to debate phrases that may be in some entity store definitions but not others, so we asked the annotators to choose “unclear” when there was any doubt. There were 151 bigrams that both annotators believed to be very clear labels, including 69 that both annotators labeled as entities, 70 that both annotators labeled as non-entities, and 12 with label disagreement. Cohen’s kappa was 0.84, indicating excellent agreement. Our experiment is now to separate the 69 clear entities from the 70 clear non-entities.

For experiment baselines we use the majority class baseline *MAJ*, as well as a Named Entity Recognition baseline *NER*. For *NER* we used the Illinois Named Entity Tagger (Ratinov and Roth, 2009) on the highest setting (that achieved 90.5  $F_1$  score on the CoNLL03 shared task). *NER* expects a sentence, so we use the longest assertion in the corpus that the noun phrase was observed in. We evaluate several combinations of our features to test dif-

ferent aspects of our system: *Slope* uses only *Slope*, *PUF* uses *PercentProperCaps* + *UsageSinceYear* + *Frequency*, and *ALL* uses all features. We evaluate using the WEKA J48 Decision Tree on default settings, with leave-one-out cross validation.

Table 2 shows the results. *MAJ* correctly classifies 50.4% of instances, *NER* correctly classifies 63.3% and *ALL* correctly classifies 78.4%.

### 4.3 Analysis

Overall, 78.4% correctly classified instances is fairly strong performance on this task. By using the described features, our classifier was able to detect and filter many of the non-entity noun phrases in this scenario. Compared to the 63.3% of *NER*, it is an absolute gain of 15.1%, a relative gain of 24%, and a reduction in error of 41.1% (from 36.7% to 21.6%). Student’s *t*-test at 95% confidence verified that the difference was significant.

We found that while low *Slope* (especially with higher  $R^2$ ) often indicated non-entity, there were numerous cases where higher *Slope* did not necessarily indicate entity. For example, the noun phrase “several websites” has fairly sharp slope, but still does not denote a clear entity. In these cases, the addition of other features can serve as additional useful signal. One error from *ALL* is the term “Analyst estimates,” which the annotators labeled as a non-entity, but which occasionally appears in text (especially titles) as “Analyst Estimates,” and is a relatively recent phrase. *NER* misses entities such as “synthetic cubism” and “hunter orange” that occur in our data but are not traditional named entities. We observed that while none of our features achieves over 70% accuracy by themselves, they perform well in conjunction with each other.

## 5 Propagating Semantic Types

This second task uses a set of linked assertions  $L$  and set of unlinked assertions  $U$  to predict the semantic types for each entity  $e \in E$ . If the previous step output that “Sun Microsystems” is likely to be an entity, then the goal of this step is to further predict that it has the Freebase types such as *organization* and *software developer*.

From  $L$  we use the set of linked entities and the textual relations they occur with. For example,  $L$

might contain that the entity *Microsoft* links to a particular Wikipedia article, and also that it occurs with textual relations such as “has already announced” and “has released updates for.” For each Wikipedia-linked entity in  $L$ , we further look up its exact set of Freebase types.<sup>4</sup> From  $U$  we obtain the set of textual relations that each  $e \in E$  is in the domain of. We now have a large set of class-labeled instances (all entities in  $L$ ), a large set of unlabeled instances ( $E$ ), and a method to connect the unlabeled instances with the class-labeled instances (via any shared textual relations), so we cast this task as an instance-to-instance class propagation problem (Kozareva et al., 2011) for propagating class labels from labeled to unlabeled instances.

We build on the recent work of Kozareva et al. (2011), and adapt their approach to leverage the scale and resources of our scenario. While they use only one type of edge between instances, namely shared presence in the high precision *DAP* pattern (Hovy et al., 2009), our final system uses 1.3 million textual relations from  $|L \cup U|$ , corresponding to 1.3 million potential edge types. Their evaluation involved only 20 semantic classes, while we use all 1,339 Freebase types covered by our entities in  $L$ .

There is a rich history of other approaches for predicting semantic types. (Talukdar et al., 2008) and (Talukdar and Pereira, 2010) model relationships between instances and classes, but our unlinked entities do not come with any class information. Pattern-based approaches (Paşca, 2004; Pantel and Ravichandran, 2004) are popular, but (Kozareva et al., 2011) notes that they “are constraint to the information matched by the pattern and often suffer from recall,” meaning that they do not cover many instances. Classifiers have also been trained for fine-grained semantic typing, but for noticeably fewer types than we work with. (Rahman and Ng, 2010) studied hierarchical and collective classification using 92 types, and FIGER (Ling and Weld, 2012) recently used an adapted perceptron for multi-class multi-label classification into 112 types.

### 5.1 Algorithm

Given an entity  $e$ , our algorithm involves: (1) finding the textual relations that  $e$  is in the domain of, (2)

<sup>4</sup>data available at <http://download.freebase.com/wex>

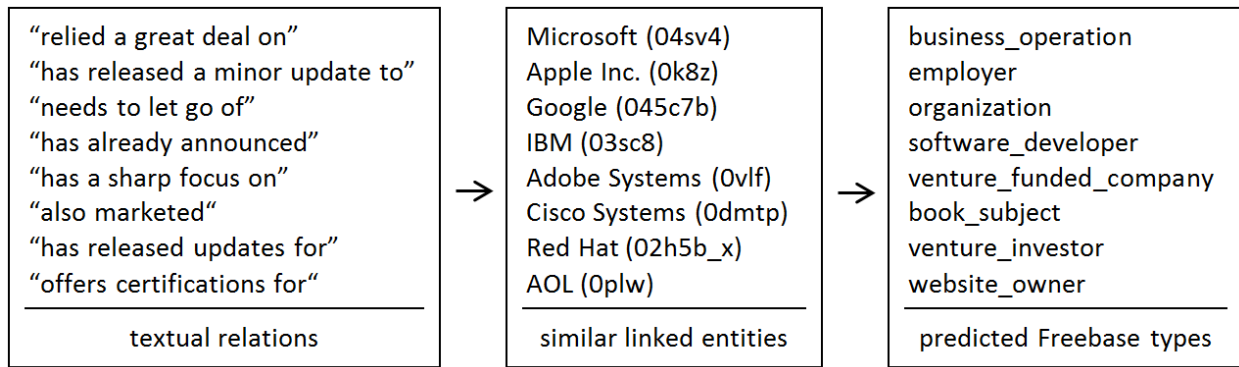

Figure 5: This example illustrates the set of Freebase type predictions for the noun phrase “Sun Microsystems.” We predict the semantic type of a noun phrase by: (1) finding the textual relations it is in the domain of, (2) finding linked entities that are also in the domain of those textual relations, and (3) observing their semantic types.

finding linked entities that are also in the domain of those textual relations, and then (3) predicting types by observing the types of those linked entities. Figure 5 illustrates how we would predict the semantic types of the noun phrase “Sun Microsystems.”

**Find Relations:** Obtain the set  $R$  of all textual relations in  $U$  that  $e$  is in the domain of. For example, if  $U$  contains the assertion “(Sun Microsystems, has released a minor update to, Java 1.4.2),” then the textual relation “has released a minor update to” should be added to  $R$  when typing “Sun Microsystems.”

**Find Similar Entities:** Find the linked entities in  $L$  that are in the domain of the most relations in  $R$ . In our example, entities such as “Microsoft” and “Apple Inc.” have the greatest overlap in textual relations because they are most often in the domain of the same textual relations, e.g., (“Microsoft, has released a minor update to, Windows Live Essentials”). Create a set  $S$  of the entities that share the most textual relations. We found keeping 10 similar entities ( $|S| = 10$ ) is generally enough to predict the original entity’s types in the final step.

**Predict Types:** Return the most frequent Freebase types of the entities in  $S$  as the prediction. To avoid penalizing very small types, if there are  $n$  instances of semantic class  $C$  in  $S$ , then we rank  $C$  using a type score  $T(n, C, S) = \max(n/|S|, n/|C|)$ , which we found to perform better than  $T(n, C, S) = \text{avg}(n/|S|, n/|C|)$ . For “Sun Microsystems,” *business operation* was the top predicted type because all entities in  $S$  were observed to include *business operation* type.

## 5.2 Edge Validity

This algorithm will only be effective if entities that share textual relation strings are more likely to be of the same semantic types. To verify this, we sampled 30,000 linked entities from  $L$  that had at least 30 textual relations each, and associated each with their 30 most frequent relations. From the 900 million possible entity pairs, we then randomly sample 500 entity pairs that shared exactly  $k$  out of 30 relations, for each  $k$  from 0 to 15. At each  $k$  we then use our sampled pairs to estimate the probability that any two entities sharing exactly  $k$  relations (out of their 30 possible) will share at least one type.

The results are shown in Figure 6. We found that entities sharing more textual relations were in fact more likely to have semantic types in common. Two entities that shared exactly 0 of 30 textual relations were only 11% likely to share a semantic type, while two entities that shared exactly 10 of 30 relations were 80% likely to share a semantic type. This validates our use of textual relations as a signal-bearing edge in instance-to-instance class propagation.

## 5.3 Weighting Textual Relations

The algorithm as currently described treats all textual relations equally, when in reality some are stronger signal to entity type than others. For example, two entities in the domain of the “came with” relation often will not share semantic types, but two entities in the domain of the “autographed” relation will almost always share a type. To capture this intuition, we define relation weight  $w(r)$  as the observed probability (among the linked entities) that two en-

Figure 6: Entities that share more textual relations are more likely to have semantic types in common.

entities will share a Freebase type if they both occur in the domain of  $r$ . If  $D(r)$  = all entities observed in the domain of relation  $r$  and  $T(e)$  = all Freebase types listed for entity  $e$ , then weight  $w(r)$  of a textual relation string  $r$  is:

$$w(r) = \sum_{e_1, e_2 \in D(r), e_1 \neq e_2} \frac{I(e_1, e_2)}{|D(r)| \cdot (|D(r)| - 1)}$$

$$I(e_1, e_2) = \begin{cases} 1, & \text{if } |T(e_1) \cap T(e_2)| > 0 \\ 0, & \text{otherwise.} \end{cases}$$

Table 3 shows examples of high weight relations, and Table 4 shows low weight relations. We now modify the *Find Similar Entities* step such that if a linked entity shares a set of relations  $Q$  with the entity being typed, then it receives a score which considers all shared relations  $q \in Q$  but uses the high weight relations more. On a development set we found that a score of  $\sum_{q \in Q} 10^{4 \cdot w(q)}$  was effective, as higher weight signifies much stronger signal. This score then determines which entities to place in  $S$ .

## 5.4 Evaluation

The goal of the evaluation is to judge how well our method can predict the Freebase semantic types of entities in our scenario. Our linked entities covered 1,339 Freebase types, including many interesting types such as *computer operating system*, *religious text*, *airline* and *baseball team*. Human judges would have trouble manually annotating new entities with all these types because there are too many to keep in mind and understand the characteristics

“is a highway in”
“is a university located in”
“became the president of”
“turned down the role of”
“has an embassy in”

Table 3: Example relations found to have high weight.

“comes with”
“is a generic term for”
“works best on”
“can be made from”
“is almost identical to”

Table 4: Example relations found to have low weight.

of. Instead, we automatically generate testing data by sampling entities from  $L$ , and then test on ability to recover the actual Freebase types (which we know).

We sample a *HEAD* set of distinct 500 Freebase entities (drawn randomly from our set of linked extractions), and a *TAIL* set of 500 entities (drawn randomly from our set of linked entities). An entity that occurs in many extractions is more likely to be in *HEAD* than *TAIL*. Our sampling also picks only entities that occur with at least 10 relations, which is appropriate for the Web scenario where more instances can always be queried for.

For baselines we use random baseline  $B_{Random}$  and a frequency baseline  $B_{Frequency}$  which always returns types in order of their frequency among all linked entities (e.g., always *person*, then *location*, etc). We evaluate our system without relation weighting ( $S_{NoWeight}$ ) and also with relation weighting ( $S_{Weighted}$ ). For  $S_{Weighted}$  we leave all the test set entities out when calculating global relation weights. Our metrics are *Precision at 1* and  $F_1$  score. Precision at 1 measures how often the top returned type is a correct type, and is useful for applications that want one type per entity.  $F_1$  measures how well the method recovers the full set of Freebase types (for each test case we graph precision/recall and take the max  $F_1$ ), and is useful for applications such as typed question answering.

Table 5 shows the results.  $B_{Random}$  performs poorly because there are so many semantic types, and very few of them are correct for each test case.  $B_{Frequency}$  performs slightly better on *TAIL* than *HEAD* because *TAIL* contains more entities of the most frequent types.  $S_{NoWeight}$  performance

	HEAD		TAIL	
	Prec@1	F <sub>1</sub>	Prec@1	F <sub>1</sub>
<b>B<sub>Random</sub></b>	0.008	0.028	0.004	0.023
<b>B<sub>Frequency</sub></b>	0.244	0.302	0.298	0.322
<b>S<sub>NoWeight</sub></b>	0.542 <sup>†</sup>	0.465 <sup>†</sup>	0.510 <sup>†</sup>	0.456 <sup>†</sup>
<b>S<sub>Weighted</sub></b>	0.610 <sup>‡</sup>	0.521 <sup>‡</sup>	0.598 <sup>‡</sup>	0.522 <sup>‡</sup>

Table 5: Evaluation on HEAD and TAIL, 500 elements each. <sup>†</sup> indicates statistical significance over **B<sub>Frequency</sub>**, and <sup>‡</sup> over both **B<sub>Frequency</sub>** and **S<sub>NoWeight</sub>**. Significance is measured using the Student’s *t*-test at 95% confidence. The top type predicted by our **S<sub>Weighted</sub>** method is correct about 60% of the time, while the top type predicted by the **B<sub>Frequency</sub>** baseline is correct under 30% of the time.

is statistically significant above all baselines, and *S<sub>Weighted</sub>* is statistically significant over *S<sub>NoWeight</sub>* on both test sets and metrics.

## 5.5 Analysis

*S<sub>Weighted</sub>* was successful at recovering the correct Freebase types of many entities. For example, it finds that “Atherosclerosis” is a *medical risk factor* by connecting it to “obesity” and “diabetes,” that “Supernatural” is a *TV program* and a *Netflix title* by connecting it to “House” and “30 Rock,” and that “America West” is an *aircraft owner* and an *airline* by connecting it to “Etihad Airways” and “China Eastern Airlines.” While precision at 1 around 60% may not be high enough yet for certain applications, it is significantly better than competing approaches, which are under 30%, and we hope that our values can serve as a non-trivial baseline on this task for future systems.

One example where *S<sub>Weighted</sub>* made some mistakes is *fictional characters*. Many *fictional characters* participate in a textual relations that make them look like *people* (e.g., “was born on”), but predicting that they belong to *people* class is incorrect. Some performance hit was also due to entity linking errors. From an assertion like “The Four Seasons is located in Hamamatsu,” our entity linker (and other entity linkers we tried) prefer linking “The Four Seasons” to Vivaldi’s music composition rather than the hotel chain. We are then unable to recover *music composition* type from relations like “is located in.” Our algorithm relies on accurate entity linking in *L*, but there is a precision/recall tradeoff to consider here because it also benefits from higher coverage of entities and relations in *L*.

As a general reference for performance of state-of-the-art fine-grained entity classification, the

FIGER system (Ling and Weld, 2012) for classifying into 112 types reported *F<sub>1</sub>* scores ranging from 0.471 to 0.693 in their experiments. It is important to note that these numbers are not directly comparable to us because they used different data, different (and fewer) types, and different evaluation methodology.

## 6 Discussion

This paper presented an approach for working with non-Wikipedia entities in text. Consider the following possibilities for a noun phrase in a text corpus:

**Wikipedia Entity:** (e.g., “Computer Science,” “South America,” “apple juice”) - Entity linking techniques can identify and type these.

**Non-Wikipedia, Non-Entity:** (e.g., “strange things,” “Early studies,” “A link”) - Our classifier from Section 4 is able to filter these.

**Non-Wikipedia, Entity:** (e.g., “Safflower oil,” “prune juice,” “Amazon UK”) - We identify these as entities, then propagate semantic types to them. Our technique finds that “Safflower oil” occurs with high weight relations such as “is sometimes used to treat” and “can be substituted for,” making it similar to linked entities such as “Phentermine” and “Dandelion,” and then correctly predicts semantic types including *food ingredient* and *medical treatment*.

### 6.1 Typed Question Answering

From our set of 15 million assertions, we found and typed many non-Wikipedia entities. In *food* while Wikipedia has “crab meat,” we find it is missing others such as “rabbit meat” and “goat milk.” In *job titles* it has “scientist” and “lawyer,” but we find it is missing “PhD student,” “fashion designer,” and others. We find many of the *people* and *employers* not

prominent enough for Wikipedia.

One application of this research is to increase the yield of applications such as Typed Question Answering (Buscaldi and Rosso, 2006). For example, consider the query “What *computer game* is a lot of fun?” A search for assertions matching “\* is a lot of fun” in the data yields around 1,000 results such as “camping,” “David Sedaris” and “Hawaii.” Entity linking allows us to identify just the *computer games* in Wikipedia that match the query, such as “Civilization.” However, around 400 query matches could not be entity linked. Our noun-phrase classifier filters out non-entities such as “actual play,” “Just this” and “Two kids.” After predicting types for the matches that did not get filtered, we find additional non-Wikipedia *computer games* that match the query, including “Cooking Dash,” “Delicious Deluxe” and “Slingo Supreme.”

## 7 Future Work

An area we are continuing to improve the system on is *textual ambiguity*. For example, an unlinked noun phrase might simultaneously be the name of a *film*, a *car*, and a *person*. Instead of outputting that the noun phrase holds all of those types, a stronger output would be to realize that the noun phrase is ambiguous, determine how many senses it has, and determine which sense is being referred to in each instance. We have ideas for how to detect ambiguous entities using mutual exclusion (Carlson, 2010) and functional relations. For example, if we predict that a noun phrase has *film* and *car* types but we also observe in our linked instances that these types are mutually exclusive, then this is good evidence that the noun phrase refers to multiple terms.

We also plan to continue improving our techniques, as there is still plenty of room for improvement on both subtasks. For detecting new entities, we are interested in seeing if timestamped Twitter data could be analyzed to increase both recall and precision. For predicting semantic types, (Kozareva et al., 2011) proposed additional techniques which we have not fully explored. Also, we can incorporate additional signals such as shared term heads when they are available, in order to help find terms that are likely to share types. Last, we would like to feed back our system output to improve system

performance. For example, non-entity noun phrases that make it to the typing step might lead to particular predicted type distributions that indicate an error occurred earlier in the process.

## 8 Conclusion

In this paper we showed that while entity linking cannot link to entities outside of Wikipedia, once a large text corpus has been entity linked, the presence and content of the existing links can be leveraged to help detect and semantically type the non-Wikipedia entities as well. We designed techniques for detecting whether unlinked noun phrases are entities, and if they are, then propagating semantic types to them from the linked entities. In our evaluations, we showed that our techniques achieve statistically significant improvement over baseline methods.

Our research here takes initial steps toward a future where the vast universe of entities that are not prominent enough to include in manually-authored knowledge bases is analyzed automatically instead of being left behind.

## Acknowledgements

University of British Columbia

Vancouver, BC, V6T 1Z4, Canada

## Abstract

We propose a complete probabilistic discriminative framework for performing sentence-level discourse analysis. Our framework comprises a discourse segmenter, based on a binary classifier, and a discourse parser, which applies an optimal CKY-like parsing algorithm to probabilities inferred from a Dynamic Conditional Random Field. We show on two corpora that our approach outperforms the state-of-the-art, often by a wide margin.

## 1 Introduction

Automatic discourse analysis has been shown to be critical in several fundamental Natural Language Processing (NLP) tasks including text generation (Prasad et al., 2005), summarization (Marcu, 2000b), sentence compression (Sporleder and Lapata, 2005) and question answering (Verberne et al., 2007). Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), one of the most influential theories of discourse, posits a tree representation of a discourse, known as a Discourse Tree (DT), as exemplified by the sample DT shown in Figure 1. The leaves of a DT correspond to contiguous atomic text spans, also called Elementary Discourse Units (EDUs) (three in the example). The adjacent EDUs are connected by a *rhetorical* relation (e.g., ELABORATION), and the resulting larger text spans are recursively also subject to this relation linking. A span linked by a rhetorical relation can be either a NUCLEUS or a SATELLITE depending on how central the message is to the author. Discourse analysis in RST involves two subtasks: (i) breaking the

text into EDUs (known as *discourse segmentation*) and (ii) linking the EDUs into a labeled hierarchical tree structure (known as *discourse parsing*).

Figure 1: Discourse structure of a sentence in RST-DT.

Previous studies on discourse analysis have been quite successful in identifying what machine learning approaches and what features are more useful for automatic discourse segmentation and parsing (Soricut and Marcu, 2003; Subba and Eugenio, 2009; duVerle and Prendinger, 2009). However, all the proposed solutions suffer from at least one of the following two key limitations: first, they make strong independence assumptions on the structure and the labels of the resulting DT, and typically model the construction of the DT and the labeling of the relations separately; second, they apply a greedy, sub-optimal algorithm to build the structure of the DT.

In this paper, we propose a new *sentence-level* discourse parser that addresses both limitations. The crucial component is a probabilistic discriminative parsing model, expressed as a Dynamic Conditional Random Field (DCRF) (Sutton et al., 2007). By representing the *structure* and the *relation* of each discourse tree constituent jointly and by explicitly capturing the *sequential* and *hierarchical* dependencies between constituents of a discourse tree, our DCRF model does not make any independence assumption among these properties. Furthermore, our

parsing model supports a bottom-up parsing algorithm which is non-greedy and provably optimal.

The discourse parser assumes that the input text has been already segmented into EDUs. As an additional contribution of this paper, we propose a novel discriminative approach to discourse segmentation that not only achieves state-of-the-art performance, but also reduces the time and space complexities by using fewer features. Notice that the combination of our segmenter with our parser forms a complete probabilistic discriminative framework for performing sentence-level discourse analysis.

Our framework was tested in a series of experiments. The empirical evaluation indicates that our approach to discourse parsing outperforms the state-of-the-art by a wide margin. Moreover, we show this to be the case on two very different genres: news articles and instructional how-to-do manuals.

In the rest of the paper, after discussing related work, we present our discourse parser. Then, we describe our segmenter. The experiments and the corpora we used are described next, followed by a discussion of the key results and some error analysis.

## 2 Related work

Automatic discourse analysis has a long history; see (Stede, 2011) for a detailed overview. Soricut and Marcu (2003) present the publicly available SPADE<sup>1</sup> system that comes with probabilistic models for *sentence-level* discourse segmentation and parsing based on lexical and syntactic features derived from the lexicalized syntactic tree of a sentence. Their parsing algorithm finds the most probable DT for a sentence, where the probabilities of the constituents are estimated by their parsing model. A constituent (e.g., `ATTRIBUTE-NS[(1,2),3]` in Figure 1) in a DT has two components, first, the *label* denoting the relation and second, the *structure* indicating which spans are being linked by the relation. The nuclearity statuses of the spans are built into the relation labels (e.g., `NS[(1,2),3]` means that span (1,2) is the NUCLEUS and it comes before span 3 which is the SATELLITE). SPADE is limited in several ways. It makes an independence assumption between the label and the structure while modeling a constituent, and it ignores the sequential and

hierarchical dependencies between the constituents in the parsing model. Furthermore, SPADE relies only on lexico-syntactic features, and it follows a *generative* approach to estimate the model parameters for the segmentation and the parsing models. SPADE was trained and tested on the RST-DT corpus (Carlson et al., 2002), which contains human-annotated discourse trees for news articles.

Subsequent research addresses the question of how much syntax one really needs in discourse analysis. Sporleder and Lapata (2005) focus on discourse chunking, comprising the two subtasks of segmentation and non-hierarchical nuclearity assignment. More specifically, they examine whether features derived via part of speech (POS) and chunk taggers would be sufficient for these purposes. Their results on RST-DT turn out to be comparable to SPADE without using any features from the syntactic tree. Later, Fisher and Roark (2007) demonstrate over 4% absolute “performance gain” in segmentation, by combining the features extracted from the syntactic tree with the ones derived via taggers. Using quite a large number of features in a binary log-linear model they achieve the state-of-the-art segmentation performance on the RST-DT test set.

On the different genre of *instructional manuals*, Subba and Eugenio (2009) propose a shift-reduce parser that relies on a classifier to find the appropriate relation between two text segments. Their classifier is based on Inductive Logic Programming (ILP), which learns first-order logic rules from a large set of features including the linguistically rich *compositional semantics* coming from a semantic parser. They show that the compositional semantics improves the classification performance. However, their discourse parser implements a greedy approach (hence not optimal) and their classifier disregards the sequence and hierarchical dependencies.

Using RST-DT, Hernault et al. (2010) present the HILDA system that comes with a segmenter and a parser based on Support Vector Machines (SVMs). The segmenter is a binary SVM classifier which relies on the same lexico-syntactic features used in SPADE, but with more context. The discourse parser builds a DT iteratively utilizing two SVM classifiers in each iteration: (i) a binary classifier decides which of the two adjacent spans to link, and (ii) a multi-class classifier then connects the se-

<sup>1</sup><http://www.isi.edu/licensed-sw/spade/>

lected spans with the appropriate relation. They use a very large set of features in their parser. However, taking a radically-greedy approach, they model structure and relations separately, and ignore the sequence dependencies in their models.

Recently, there has been an explosion of interest in Conditional Random Fields (CRFs) (Lafferty et al., 2001) for solving structured output classification problems, with many successful applications in NLP including syntactic parsing (Finkel et al., 2008), syntactic chunking (Sha and Pereira, 2003) and discourse chunking (Ghosh et al., 2011) in Penn Discourse Treebank (Prasad et al., 2008). CRFs being a discriminative approach to sequence modeling (i.e., directly models the conditional  $p(\mathbf{y}|\mathbf{x}, \Theta)$ ), have several advantages over its generative counterparts such as Hidden Markov Models (HMMs) and Markov Random Fields (MRFs), which first model the joint  $p(\mathbf{y}, \mathbf{x}|\Theta)$ , then infer the conditional  $p(\mathbf{y}|\mathbf{x}, \Theta)$ . Key advantages include the ability to incorporate arbitrary overlapping local and global features, and the ability to relax strong independence assumptions. It has been advocated that CRFs are generally more accurate since they do not “waste effort” modeling complex distributions (i.e.,  $p(\mathbf{x})$ ) that are not relevant for the target task (Murphy, 2012).

### 3 The Discourse Parser

Assuming that a sentence is already segmented into a sequence of EDUs  $e_1, e_2, \dots, e_n$  manually or by an automatic segmenter (see Section 4), the discourse parsing problem is to decide which spans to connect (i.e., *structure* of the DT) and which relations (i.e., *labels* of the internal nodes) to use in the process of building the hierarchical DT. To build the DTs effectively, a common assumption is that they are *binary trees* (Soricut and Marcu, 2003; duVerle and Prendinger, 2009). That is, multi-nuclear relations (e.g., LIST, JOINT, SEQUENCE) involving more than two EDUs are mapped to a hierarchical right-branching binary tree. For example, a flat  $LIST(e_1, e_2, e_3, e_4)$  is mapped to a right-branching binary tree  $LIST(e_1, LIST(e_2, LIST(e_3, e_4)))$ .

Our discourse parser has two components. The first component, the *parsing model*, assigns a probability to every possible DT. The second component, the *parsing algorithm*, finds the most probable DT

among the candidate discourse trees.

#### 3.1 Parsing Model

A DT can be represented as a set of constituents of the form  $R[i, m, j]$ , which denotes a rhetorical relation  $R$  that holds between the span containing EDUs  $i$  through  $m$ , and the span containing EDUs  $m+1$  through  $j$ . For example, the DT in Figure 1 can be written as  $\{\text{ELABORATION-NS}[1,1,2], \text{ATTRIBUTE-NS}[1,2,3]\}$ . Notice that a relation  $R$  also indicates the nuclearity assignments of the spans being connected, which can be one of NUCLEUS-SATELLITE (NS), SATELLITE-NUCLEUS (SN) and NUCLEUS-NUCLEUS (NN).

Given the model parameters  $\Theta$  and a candidate DT  $T$ , for all the constituents  $c$  in  $T$ , our parsing model estimates the *conditional probability*  $P(c|C, \Theta)$ , which specifies the joint probability of the relation  $R$  and the structure  $[i, m, j]$  associated with the constituent  $c$ , given that  $c$  has a set of sub-constituents  $C$ . For instance, for the DT shown in Figure 1, our model would estimate  $P(R'[1, 1, 2]|\Theta)$ ,  $P(R'[2, 2, 3]|\Theta)$ ,  $P(R'[1, 2, 3]|R''[1, 1, 2], \Theta)$  etc. for all  $R'$  and  $R''$  ranging on the set of relations. In what follows we describe our probabilistic parsing model to compute all these conditional probabilities  $P(c|C, \Theta)$ . We will demonstrate how our approach not only models the structure and the relation jointly, but it also captures *linear sequence dependencies* and *hierarchical dependencies* between constituents of a DT.

Our novel parsing model is the Dynamic Conditional Random Field (DCRF) (Sutton et al., 2007) shown in Figure 2. A DCRF is a generalization of linear-chain CRFs to represent complex interaction between labels, such as when performing multiple labeling tasks on the same sequence. The *observed* nodes  $W_j$  in the figure are the text spans. A text span can be either an EDU or a concatenation of a sequence of EDUs. The *structure* nodes  $S_j \in \{0, 1\}$  in the figure represent whether text spans  $W_{j-1}$  and  $W_j$  should be connected or not. The *relation* nodes  $R_j \in \{1 \dots M\}$  denote the discourse relation between spans  $W_{j-1}$  and  $W_j$ , given that  $M$  is the total number of relations in our relation set. Notice that we now model the structure and the relation jointly and also take the sequential dependencies between adjacent constituents into consideration.

Figure 2: A Dynamic CRF as a discourse parsing model.

We can obtain the conditional probabilities of the constituents (i.e.,  $P(c|C, \Theta)$ ) of all candidate DTs for a sentence by applying the DCRF parsing model recursively at different levels, and by computing the posterior marginals of the relation-structure pairs. To illustrate, consider the example sentence in Figure 1 where we have three EDUs  $e_1, e_2$  and  $e_3$ . The DCRF model for the first level is shown in Figure 3(a), where the (observed) EDUs are the spans in the span sequence. Given this model, we obtain the probabilities of the constituents  $R[1, 1, 2]$  and  $R[2, 2, 3]$  by computing the posterior marginals  $P(R_2, S_2=1|e_1, e_2, e_3, \Theta)$  and  $P(R_3, S_3=1|e_1, e_2, e_3, \Theta)$ , respectively. At the second level (see Figure 3(b)), there are two possible span sequences  $(e_{1:2}, e_3)$  and  $(e_1, e_{2:3})$ . In the first sequence, EDUs  $e_1$  and  $e_2$  are linked into a larger span, and in the second one, EDUs  $e_2$  and  $e_3$  are connected into a larger span. We apply our DCRF model to the two possible span sequences and obtain the probabilities of the constituents  $R[1, 2, 3]$  and  $R[1, 1, 3]$  by computing the posterior marginals  $P(R_3, S_3=1|e_{1:2}, e_3, \Theta)$  and  $P(R_{2:3}, S_{2:3}=1|e_1, e_{2:3}, \Theta)$ , respectively.

Figure 3: DCRF model applied to the sequences at different levels in the example in Fig. 1. (a) A sequence at the first level (b) Two possible sequences at the second level.

To further clarify the process, let us assume that the sentence contains four EDUs  $e_1, e_2, e_3$  and  $e_4$ . At the first level (Figure 4(a)), there is only one possible span sequence to which we apply our DCRF model.

We obtain the probabilities of the constituents  $R[1, 1, 2]$ ,  $R[2, 2, 3]$  and  $R[3, 3, 4]$  by computing the posterior marginals  $P(R_2, S_2=1|e_1, e_2, e_3, e_4, \Theta)$ ,  $P(R_3, S_3=1|e_1, e_2, e_3, e_4, \Theta)$  and  $P(R_4, S_4=1|e_1, e_2, e_3, e_4, \Theta)$ , respectively. At the second level (Figure 4(b)), there are three possible sequences  $(e_{1:2}, e_3, e_4)$ ,  $(e_1, e_{2:3}, e_4)$  and  $(e_1, e_2, e_{3:4})$ . When the DCRF model is applied to the sequence  $(e_{1:2}, e_3, e_4)$ , we obtain the probabilities of the constituent  $R[1, 2, 3]$  by computing the posterior marginal  $P(R_3, S_3=1|e_{1:2}, e_3, e_4, \Theta)$ . Likewise, the posterior marginals  $P(R_{2:3}, S_{2:3}=1|e_1, e_{2:3}, e_4, \Theta)$  and  $P(R_4, S_4=1|e_1, e_{2:3}, e_4, \Theta)$  in the DCRF model applied to the sequence  $(e_1, e_{2:3}, e_4)$  represents the probabilities of the constituents  $R[1, 1, 3]$  and  $R[2, 3, 4]$ , respectively. Similarly, we attain the probabilities of the constituent  $R[2, 2, 4]$  from the DCRF model applied to the sequence  $(e_1, e_2, e_{3:4})$  by computing the posterior marginal  $P(R_{3:4}, S_{3:4}=1|e_1, e_2, e_{3:4}, \Theta)$ . At the third level (Figure 4(c)), there are three possible sequences  $(e_{1:3}, e_4)$ ,  $(e_1, e_{2:4})$  and  $(e_{1:2}, e_{3:4})$ , to which we apply our model and acquire the probabilities of the constituents  $R[1, 3, 4]$ ,  $R[1, 1, 4]$  and  $R[1, 2, 4]$  by computing their respective posterior marginals.

Figure 4: DCRF model applied to the sequences at different levels of a discourse tree. (a) A sequence at the first level, (b) Three possible sequences at the second level, (c) Two possible sequences at the third level.

Our DCRF model is designed using MALLET (McCallum, 2002). In order to avoid overfitting we regularize the DCRF model with  $l_2$  regularization and learn the model parameters using the limited-memory BFGS (L-BFGS) fitting algorithm. Since exact inference can be intractable in DCRF models,

we perform approximate inference (to compute the posterior marginals) using tree-based reparameterization (Wainwright et al., 2002).

### 3.1.1 Features Used in the Parsing Model

Crucial to parsing performance is the set of features used, as summarized in Table 1. Note that these features are defined on two consecutive spans  $W_{j-1}$  and  $W_j$  of a span sequence. Most of the features have been explored in previous studies. However, we improve some of these as explained below.

**Organizational** features encode useful information about the surface structure of a sentence as shown by (duVerle and Prendinger, 2009). We measure the length of the spans in terms of the number of EDUs and *tokens* in it. However, in order to better adjust to the length variations, rather than computing their absolute numbers in a span, we choose to measure their *relative numbers* with respect to their total numbers in the sentence. For example, in a sentence containing three EDUs, a span containing two of these EDUs will have a relative EDU number of 0.67. We also measure the *distances* of the spans from the beginning and to the end of the sentence in terms of the number of EDUs.

#### 8 organizational features

- Relative number of EDUs in *span 1* and *span 2*.
- Relative number of tokens in *span 1* and *span 2*.
- Distances of span 1 in EDUs to the *beginning* and to the *end*.
- Distances of span 2 in EDUs to the *beginning* and to the *end*.

#### 8 N-gram features

- Beginning* and *end* lexical N-grams in span 1.
- Beginning* and *end* lexical N-grams in span 2.
- Beginning* and *end* POS N-grams in span 1.
- Beginning* and *end* POS N-grams in span 2.

#### 5 dominance set features

- Syntactic labels of the *head* node and the *attachment* node.
- Lexical heads of the *head* node and the *attachment* node.
- Dominance relationship* between the two text spans.

#### 2 contextual features

- Previous* and *next* feature vectors.

#### 2 substructure features

- Root nodes of the *left* and *right* rhetorical subtrees.

Table 1: Features used in the DCRF parsing model.

Discourse connectives (e.g., *because*, *but*), when present, signal rhetorical relations between two text segments (Knott and Dale, 1994; Marcu, 2000a). However, previous studies (e.g., Hernault et al. (2010), Biran and Rambow (2011)) suggest that an

empirically acquired lexical N-gram dictionary is more effective than a fixed list of connectives, since this approach is domain independent and capable of capturing non-lexical cues such as punctuations. To build the *lexical N-gram* dictionary empirically from the training corpus we consider the first and last  $N$  tokens ( $N \in \{1, 2\}$ ) of each span and rank them according to their mutual information<sup>2</sup> with the two labels, *Structure* and *Relation*. Intuitively, the most informative cues are not only the most frequent, but also the ones that are indicative of the labels in the training data (Blitzer, 2008). In addition to the lexical N-grams we also encode *POS* tags of the first and last  $N$  tokens ( $N \in \{1, 2\}$ ) as features.

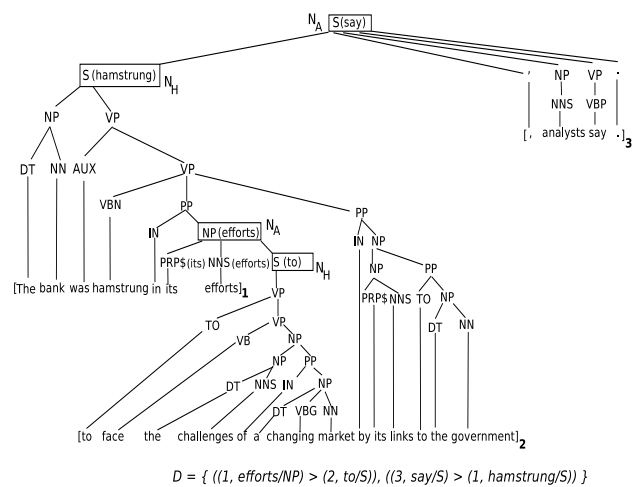

Figure 5: A discourse segmented lexicalized syntactic tree. Boxed nodes form the dominance set  $D$ .

**Dominance set** extracted from the Discourse Segmented Lexicalized Syntactic Tree (DS-LST) (Soricut and Marcu, 2003) has been shown to be a very effective feature in SPADE. Figure 5 shows the DS-LST for our running example (see Figure 1 and 3). In a DS-LST, each EDU except the one with the root node must have a *head node*  $N_H$  that is attached to an *attachment node*  $N_A$  residing in a separate EDU. A dominance set  $D$  (shown at the bottom of Figure 5 for our example) contains these *attachment* points of the EDUs in a DS-LST. In addition to the syntactic and lexical information of the head and attachment nodes, each element in  $D$  also represents a dominance relationship between the EDUs involved. The EDU with  $N_A$  dominates the EDU with  $N_H$ . In or-

<sup>2</sup>In contrast, HILDA ranks the N-grams by frequencies.

der to extract dominance set features for two consecutive spans  $e_{i:j}$  and  $e_{j+1:k}$ , we first compute  $D$  from the DS-LST of the sentence. We then extract the element from  $D$  that holds across the EDUs  $j$  and  $j + 1$ . In our running example, for the spans  $e_1$  and  $e_2$  (Figure 3(a)), the relevant dominance set element is  $(1, efforts/NP) > (2, to/S)$ . We encode the syntactic labels and lexical heads of  $N_H$  and  $N_A$  and the dominance relationship (i.e., which of the two spans is dominating) as features in our model.

We also incorporate more **contextual** information by including the above features computed for the neighboring span pairs in the current feature vector.

We incorporate *hierarchical dependencies* between constituents in a DT by means of the **substructure** features. For the two adjacent spans  $e_{i:j}$  and  $e_{j+1:k}$ , we extract the roots of the rhetorical subtrees spanning over  $e_{i:j}$  (left) and  $e_{j+1:k}$  (right). In our example (see Figure 1 and Figure 3 (b)), the root of the rhetorical subtree spanning over  $e_{1:2}$  is ELABORATION-NS. However, this assumes the presence of a labeled DT which is not the case when we apply the parser to a new sentence. This problem can be easily solved by looping twice through building the model and the parsing algorithm (described below). We first build the model without considering the substructure features. Then we find the optimal DT employing our parsing algorithm. This intermediate DT will now provide labels for the substructures. Next we can build a new, more accurate model by including the substructure features, and run again the parsing algorithm to find the final optimal DT.

### 3.2 Parsing Algorithm

Our parsing model above assigns a conditional probability to every possible DT constituent for a sentence, the job of the parsing algorithm is to find the most probable DT. Formally, this can be written as,

$$DT^* = \underset{DT}{\operatorname{argmax}} P(DT|\Theta)$$

Our discourse parser implements a probabilistic CKY-like bottom-up algorithm for computing the most likely parse of a sentence using dynamic programming; see (Jurafsky and Martin, 2008) for a description. Specifically, with  $n$  number of EDUs in a sentence, we use the upper-triangular portion of the  $n \times n$  Dynamic Programming Table (DPT). The cell  $[i, j]$  in the DPT represents the span containing EDUs  $i$  through  $j$  and stores the

probability of a constituent  $R[i, m, j]$ , where  $m = \underset{i \leq k \leq j}{\operatorname{argmax}} P(R[i, k, j])$ .

In contrast to HILDA which implements a greedy algorithm, our approach finds a DT that is globally optimal. Our approach is also different from SPADE’s implementation. SPADE first finds the *tree structure* that is globally optimal, then it assigns the most probable *relations* to the internal nodes. More specifically, the cell  $[i, j]$  in SPADE’s DPT stores the probability of a constituent  $R[i, m, j]$ , where  $m = \underset{i \leq k \leq j}{\operatorname{argmax}} P([i, k, j])$ . Disregarding the relation label  $R$  while building the DPT, this approach may find a tree that is **not** globally optimal.

## 4 The Discourse Segmenter

Our discourse parser above assumes that the input sentences have been already segmented into EDUs. Since it has been shown that discourse segmentation is a primary source of inaccuracy for discourse parsing (Soricut and Marcu, 2003), we have developed our own segmenter, that not only achieves state-of-the-art performance as shown later, but also reduces the time complexity by using fewer features.

Our segmenter implements a binary classifier to decide for each word (except the last word) in a sentence, whether to put an EDU boundary *after* that word. We use a Logistic Regression (LR) (i.e., discriminative) model with  $l_2$  regularization and learn the model parameters using the L-BFGS algorithm, which gives quadratic convergence rate. To avoid overfitting, we use 5-fold cross validation to learn the regularization strength parameter from the training data. We also use a simple *bagging* technique (Breiman, 1996) to deal with the sparsity of *boundary* tags. Note that, our first attempt at this task implemented a linear-chain CRF model to capture the sequence dependencies between the tags in a discriminative way. However, the binary LR classifier, using the same features, not only outperforms the CRF model, but also reduces the space complexity.

### 4.1 Features Used in the Segmentation Model

Our set of features for discourse segmentation are mostly inspired from previous studies but used in a novel way as we describe below.

Our first subset of features which we call *SPADE features*, includes the lexico-syntactic patterns ex-

tracted from the lexicalized syntactic tree for the given sentence. These features replicates the features used in SPADE, but used in a discriminative way. To decide on an EDU boundary after a token  $w_k$ , we find the lowest constituent in the lexicalized syntactic tree that spans over tokens  $w_i \dots w_j$  such that  $i \leq k < j$ . The production that expands this constituent in the tree and its different variations, form the feature set. For example in Figure 5, the production  $NP(efforts) \rightarrow PRP\$(its)NNS(efforts)\uparrow S(to)$  and its different variations depending on whether they include the lexical heads and how many non-terminals (up to two) to consider before and after the potential EDU boundary ( $\uparrow$ ), are used to determine the existence of a boundary after the word *efforts* (see (Fisher and Roark, 2007) for details). SPADE uses these features in a generative way, meaning that, it inserts an EDU boundary if the relative frequency (i.e., Maximum Likelihood Estimate (MLE)) of a potential boundary given the production in the training corpus is greater than 0.5. If the production has not been observed frequently enough, it uses its other variations to perform further smoothing. In contrast, we compute the MLE estimates for a production and its other variations, and use those as features with/without binarizing the values.

Shallow syntactic parse (or *Chunk*) and *POS* tags have been shown to possess valuable cues for discourse segmentation (Fisher and Roark, 2007). For example, it is less likely that an EDU boundary occurs within a chunk. We, therefore, annotate the tokens of a sentence with chunk and POS tags by a state-of-the-art tagger<sup>3</sup> and encode these as features.

EDUs are normally multi-word strings. Thus, a token near the beginning or end of a sentence is unlikely to be the end of a segment. Therefore, for each token we include its *relative position* in the sentence and *distances* to the beginning and end as features.

It is unlikely that two consecutive tokens are tagged with EDU boundaries. We incorporate *contextual* information for a token by including the above features computed for its neighboring tokens.

We also experimented with different N-gram ( $N \in \{1, 2, 3\}$ ) features extracted from the token sequence, POS sequence and chunk sequence. However, since such features did not improve the seg-

mentation accuracy on the development set, they were excluded from our final set of features.

## 5 Experiments

### 5.1 Corpora

To demonstrate the generality of our model, we experiment with two different genres. First, we use the standard *RST-DT* corpus (Carlson et al., 2002) that contains discourse annotations for 385 Wall Street Journal news articles from the Penn Treebank (Marcus et al., 1994). Second, we use the *Instructional* corpus developed by Subba and Eugenio (2009) that contains discourse annotations for 176 instructional how-to-do manuals on home-repair.

The RST-DT corpus is partitioned into a training set of 347 documents (7673 sentences) and a test set of 38 documents (991 sentences), and 53 documents (1208 sentences) have been (doubly) annotated by two human annotators, based on which we compute the human agreement. We use the human-annotated syntactic trees from Penn Treebank to train SPADE in our experiments using RST-DT as done in (Soricut and Marcu, 2003). We extracted a sentence-level DT from a document-level DT by finding the subtree that exactly spans over the sentence. By our count, 7321 sentences in the training set, 951 sentences in the test set and 1114 sentences in the doubly-annotated set have a well-formed DT in RST-DT. The Instructional corpus contains 3430 sentences in total, out of which 3032 have a well-formed DT. This forms our sentence-level corpora for discourse parsing. However, the existence of a well-formed DT is not a necessity for discourse segmentation, therefore, we do not exclude any sentence in our discourse segmentation experiments.

### 5.2 Experimental Setup

We perform our experiments on discourse parsing in RST-DT with the 18 coarser relations (see Figure 6) defined in (Carlson and Marcu, 2001) and also used in SPADE and HILDA. By attaching the nuclearity statuses (i.e., NS, SN, NN) to these relations we get 39 distinct relations<sup>4</sup>. Our experiments on the Instructional corpus consider the same 26 primary relations (e.g., GOAL:ACT, CAUSE:EFFECT, GENERAL-SPECIFIC) used in

<sup>3</sup><http://cogcomp.cs.illinois.edu/page/software>

<sup>4</sup>Not all relations take all the possible nuclearity statuses.

(Subba and Eugenio, 2009) and also treat the reversals of non-commutative relations as separate relations. That is, PREPARATION-ACT and ACT-PREPARATION are two different relations. Attaching the nuclearity statuses to these relations gives 70 distinct relations in the Instructional corpus.

We use SPADE as our baseline model and apply the same modifications to its default setting as described in (Fisher and Roark, 2007), which delivers improved performance. Specifically, in testing, we replace the Charniak parser (Charniak, 2000) with a more accurate reranking parser (Charniak and Johnson, 2005). We use the reranking parser in all our models to generate the syntactic trees. This parser was trained on the sections of the Penn Treebank not included in the test set. For a fair comparison, we apply the same canonical lexical head projection rules (Magerman, 1995; Collins, 2003) to lexicalize the syntactic trees as done in SPADE and HILDA. Note that, all the previous works described in Section 2, report their models’ performance on a particular test set of a specific corpus. To compare our results with the previous studies, we test our models on those specific test sets. In addition, we show more general performance based on 10-fold cross validation.

### 5.3 Parsing based on Manual Segmentation

First, we present the results of our discourse parser based on *manual* segmentation. The parsing performance is assessed using the unlabeled (i.e., span) and labeled (i.e., nuclearity, relation) precision, recall and F-score as described in (Marcu, 2000b, page 143). For brevity, we report only the F-scores in Table 2. Notice that, our parser (DCRF) consistently outperforms SPADE (SP) on the RST-DT test set<sup>5</sup>. Especially, on relation labeling, which is the hardest among the three tasks, we get an absolute F-score improvement of 9.5%, which represents a relative error rate reduction of 29.3%. Our F-score of 77.1 in relation labeling is also close to the human agreement (i.e., F-score of 83.0) on the doubly-annotated data. Our results on the RST-DT test set are consistent with the mean scores over 10-folds, when we perform 10-fold cross validation on RST-DT.

The improvement is even larger on the Instructional corpus, where we compare our mean results

<sup>5</sup>The improvements are statistically significant ( $p < 0.01$ ).

over 10-folds with the results reported in Subba and Eugenio (S&E) (2009) on a test set<sup>6</sup>, giving absolute F-score improvements of 4.8%, 15.5% and 10.6% in span, nuclearity and relations, respectively. Our parser reduces the errors by 67.6%, 54.6% and 28.6% in span, nuclearity and relations, respectively.

	RST-DT				Instructional	
	Test set		10-fold	Doubly	S&E	10-fold
Scores	SP	DCRF	DCRF	Human	ILP	DCRF
Span	93.5	<b>94.6</b>	93.7	95.7	92.9	<b>97.7</b>
Nuc.	85.8	<b>86.9</b>	85.2	90.4	71.8	<b>87.2</b>
Rel.	67.6	<b>77.1</b>	75.4	83.0	63.0	<b>73.6</b>

Table 2: Parsing results using *manual* segmentation.

If we compare the performance of our model on the two corpora, we see that our model is more accurate in finding the right tree structure (see Span) on the Instructional corpus. This may be due to the fact that sentences in the Instructional domain are relatively short and contain fewer EDUs than sentences in the News domain, thus making it easier to find the right tree structure. However, when we compare the performance on the relation labeling task, we observe a decrease on the Instructional corpus. This may be due to the small amount of data available for training and the imbalanced distribution of a large number of discourse relations in this corpus.

To analyze the features, Table 3 presents the parsing results on the RST-DT test set using different subsets of features. Every new subset of features appears to improve the accuracy. More specifically, when we add the *organizational* features with the *dominance set* features (see  $S_2$ ), we get about 2% absolute improvement in nuclearity and relations. With *N-gram* features ( $S_3$ ), the gain is even higher; 6% in relations and 3.5% in nuclearity, demonstrating the utility of the N-gram features. This is consistent with the findings of (duVerle and Prendinger, 2009; Schilder, 2002). Including the *Contextual* features ( $S_4$ ), we get further 3% and 2.2% improvements in nuclearity and relations, respectively. Notice that, adding the *substructure* features ( $S_5$ ) does not help much in sentence-level parsing, giving only

<sup>6</sup>Subba and Eugenio (2009) report their results based on an arbitrary split between a training set and a test set. We asked the authors for their particular split. However, since we could not obtain that information, we compare our model’s performance based on 10-fold cross validation with their reported results.

an improvement of 0.8% in relations. Therefore, one may choose to avoid using this computationally expensive feature in time-constrained scenarios. However, in the future, it will be interesting to see its importance in document-level parsing with large trees.

Scores	$S_1$	$S_2$	$S_3$	$S_4$	$S_5$
Span	91.3	92.1	93.3	94.6	94.6
Nuclearity	78.2	80.3	83.8	86.8	86.9
Relation	66.2	68.1	74.1	76.3	77.1

Table 3: Parsing results based on manual segmentation using different subsets of features on RST-DT test set. Feature subsets  $S_1 = \{\text{Dominance set}\}$ ,  $S_2 = \{\text{Dominance set, Organizational}\}$ ,  $S_3 = \{\text{Dominance set, Organizational, N-gram}\}$ ,  $S_4 = \{\text{Dominance set, Organizational, N-gram, Contextual}\}$ ,  $S_5 (\text{all}) = \{\text{Dominance set, Organizational, N-gram, Contextual, Substructure}\}$ .

#### 5.4 Evaluation of the Discourse Segmenter

We evaluate the segmentation accuracy with respect to the intra-sentential segment boundaries following (Fisher and Roark, 2007). Specifically, if a sentence contains  $n$  EDUs, which corresponds to  $n - 1$  intra-sentence segment boundaries, we measure the model’s ability to correctly identify these  $n - 1$  boundaries. Human agreement for this task is quite high (F-score of 98.3) on RST-DT.

Table 4 shows the results of different models in (P)recision, (R)ecall, and (F)-score on the two corpora. We compare our model’s (LR) results with HILDA (HIL), SPADE (SP) and the results reported in Fisher and Roark (F&R) (2007) on the RST-DT test set. HILDA gives the weakest performance<sup>7</sup>. Our results are also much better than SPADE<sup>8</sup>, with an absolute F-score improvement of 4.9%, and comparable to the results of F&R, even though we use fewer features. Furthermore, we perform 10-fold cross validation on both corpora and compare with SPADE. However, SPADE does not come with a training module for its segmenter. We reimplemented this module and verified it on the RST-DT test set. Due to the lack of human-annotated syntactic trees in the *Instructional* corpus, we train SPADE in this corpus using the syntactic trees produced

<sup>7</sup>Note that, the high segmentation accuracy reported in (Hernault et al., 2010) is due to a less stringent evaluation metric.

<sup>8</sup>The improvements are statistically significant ( $p < 2.4e-06$ )

by the reranking parser. Our model delivers absolute F-score improvements of 3.8% and 8.1% on the RST-DT and the Instructional corpora, respectively, which is statistically significant in both cases ( $p < 3.0e-06$ ). However, when we compare our results on the two corpora, we observe a substantial decrease in performance on the Instructional corpus. This could be due to a smaller amount of data in this corpus and the inaccuracies in the syntactic parser and taggers, which are trained on news articles.

	RST-DT						Instructional	
	Test Set				10-fold		10-fold	10-fold
	HIL	SP	F&R	LR	SP	LR	SP	LR
P	77.9	83.8	<b>91.3</b>	88.0	83.7	<b>87.5</b>	65.1	<b>73.9</b>
R	70.6	86.8	89.7	<b>92.3</b>	86.2	<b>89.9</b>	82.8	<b>89.7</b>
F	74.1	85.2	<b>90.5</b>	90.1	84.9	<b>88.7</b>	72.8	<b>80.9</b>

Table 4: Segmentation results of different models.

#### 5.5 Parsing based on Automatic Segmentation

In order to evaluate our full system, we feed our discourse parser the output of our discourse segmenter. Table 5 shows the F-score results. We compare our results with SPADE on the RST-DT test set. We achieve absolute F-score improvements of 3.6%, 3.4% and 7.4% in span, nuclearity and relation, respectively. These improvements are statistically significant ( $p < 0.001$ ). Our system, therefore, reduces the errors by 15.5%, 11.4%, and 17.6% in span, nuclearity and relations, respectively. These results are also consistent with the mean results over 10-folds.

Scores	RST-DT			Instructional
	Test set		10-fold	10-fold
	SPADE	DCRF	DCRF	DCRF
Span	76.7	<b>80.3</b>	78.7	71.9
Nuclearity	70.2	<b>73.6</b>	72.2	64.3
Relation	58.0	<b>65.4</b>	64.2	54.8

Table 5: Parsing results using *automatic* segmentation.

For the Instructional corpus, the last column of Table 5 shows the mean 10-fold cross validation results. We cannot compare with S&E because no results were reported using an automatic segmenter. However, it is interesting to observe how much our full system is affected by an automatic segmenter on both RST-DT and the Instructional corpus (see Table 2 and Table 5). Nevertheless, taking into account the segmentation results in Table 4, this is

not surprising because previous studies (Soricut and Marcu, 2003) have already shown that automatic segmentation is the primary impediment to high accuracy discourse parsing. This demonstrates the need for a more accurate segmentation model in the Instructional genre. A promising future direction would be to apply effective domain adaptation methods (e.g., *easyadapt* (Daume, 2007)) to improve the segmentation performance in the Instructional domain by leveraging the rich data in RST-DT.

## 5.6 Error Analysis and Discussion

The results in Table 2 suggest that given a manually segmented discourse, our sentence-level discourse parser finds the unlabeled (i.e., span) discourse tree and assigns the nuclearity statuses to the spans at a performance level close to human annotators. We, therefore, look more closely into the performance of our parser on the hardest task of *relation labeling*.

Figure 6 shows the confusion matrix for the relation labeling task using manual segmentation on the RST-DT test set. The relation labels are ordered according to their frequency in the RST-DT training set and represented by their initial letters. For example, EL represents ELABORATION and CA represents CAUSE. In general, errors can be explained by two different phenomena acting together: (i) the frequency of the relations in the training data, and (ii) the semantic (or pragmatic) similarity between the relations. The most frequent relations (e.g., ELABORATION) tend to confuse the less frequent ones (e.g., SUMMARY), and the relations which are semantically similar (e.g., CAUSE, EXPLANATION) confuse each other, making it hard to distinguish for the computational models. Notice that, the confusions caused by JOINT appears to be high considering its frequency. The confusion between JOINT and TEMPORAL may be due to the fact that both of these coarser relations<sup>9</sup> contain finer relations (i.e., *list* in JOINT and *sequence* in TEMPORAL), which are semantically similar, as pointed out by Carlson and Marcu (2001). The confusion between JOINT and BACKGROUND may be explained by their different (semantic vs. pragmatic) interpretation in the RST theory (Stede, 2011, page 85).

<sup>9</sup>JOINT is actually not a relation, but is characterized by juxtaposition of two EDUs without a relation.

Figure 6: Confusion matrix for the relation labels on the RST-DT test set. Y-axis represents *true* and X-axis represents *predicted* labels. The relation labels are TOPIC-COMMENT, EVALUATION, SUMMARY, MANNER-MEANS, COMPARISON, EXPLANATION, CONDITION, TEMPORAL, CAUSE, ENABLEMENT, BACKGROUND, CONTRAST, JOINT, SAME-UNIT, ATTRIBUTION, ELABORATION.

Based on these observations we will pursue two ways to improve our discourse parser. We need a more robust (e.g., *bagging*) method to deal with the imbalanced distribution of relations, along with a better representation of semantic knowledge. For example, *compositional semantics* (Subba and Eugenio, 2009) and *subjectivity* (Somasundaran, 2010) can be quite relevant for identifying relations.

## 6 Conclusion

In this paper, we have described a complete probabilistic discriminative framework for performing sentence-level discourse analysis. Experiments indicate that our approach outperforms the state-of-the-art on two corpora, often by a wide margin.

In ongoing work, we plan to generalize our DCRF-based parser to multi-sentential text and also verify to what extent parsing and segmentation can be jointly performed. A longer term goal is to extend our framework to also work with graph structures of discourse, as recommended by several recent discourse theories (Wolf and Gibson, 2005). Once we achieve similar performance on graph structures, we will perform extrinsic evaluation to determine their relative utility for various NLP tasks.

## Abstract

Previous work on paraphrase extraction using parallel or comparable corpora has generally not considered the documents' discourse structure as a useful information source. We propose a novel method for collecting paraphrases relying on the sequential event order in the discourse, using multiple sequence alignment with a semantic similarity measure. We show that adding discourse information boosts the performance of sentence-level paraphrase acquisition, which consequently gives a tremendous advantage for extracting phrase-level paraphrase fragments from matched sentences. Our system beats an informed baseline by a margin of 50%.

## 1 Introduction

It is widely agreed that identifying paraphrases is a core task for natural language processing, including applications like document summarization (Barzilay et al., 1999), Recognizing Textual Entailment (Dagan et al., 2005), natural language generation (Zhao et al., 2010; Ganitkevitch et al., 2011), and machine translation (Marton et al., 2009). As a consequence, many methods have been proposed for generating large paraphrase resources (Lin and Pantel, 2001; Szpektor et al., 2004; Dolan et al., 2004). One of the intuitively appropriate data sources for such collections are parallel or comparable corpora: if two texts are translations of the same foreign document, or if they describe the same underlying scenario, they should contain a reasonable number of sentence pairs that convey the same meaning.

Most approaches that extract paraphrases from parallel texts employ some type of pattern match-

ing: sentences with the same meaning are assumed to share many n-grams (Barzilay and Lee, 2003; Callison-Burch, 2008, among others), many words in their context (Barzilay and McKeown, 2001) or certain slots in a dependency path (Lin and Pantel, 2001; Szpektor et al., 2004). Discourse structure has only marginally been considered for this task: For example, Dolan et al. (2004) extract the first sentences from comparable articles and take them as paraphrases. Another approach (Deléger and Zweigenbaum, 2009) matches similar paragraphs in comparable texts, creating smaller comparable documents for paraphrase extraction.

We believe that discourse structure delivers important information for the extraction of paraphrases. Sentences that play the same role in a certain discourse and have a similar discourse context can be paraphrases, even if a semantic similarity model does not consider them very similar. This extends the widely applied distributional hypothesis to the discourse level: According to the distributional hypothesis, entities are similar if they share similar contexts. In our case, entities are whole sentences, and contexts are discourse units.

Based on this assumption, we propose a novel method for collecting paraphrases from parallel texts using discourse information. We create a new type of parallel corpus by collecting multiple summaries for several TV show episodes. The discourse structures of those summaries are easy to compare: they all contain the events in the same order as they have appeared on the screen. This allows us to take sentence order as event-based discourse structure, which is highly parallel for recaps of the same episode.

In its first step, our system uses a sequence align-

ment algorithm combined with a state-of-the-art similarity measure. The approach outperforms informed baselines on the task of sentential paraphrase identification. The usage of discourse information even contributes more to the final performance than the sentence similarity measure.

As second step, we extract phrase-level paraphrase fragments from the matched sentences. This step relies on the alignment algorithm's output, and we show that discourse information makes a big difference for the precision of the extraction. We then add more discourse-based information by preprocessing the text with a coreference resolution system, which results in additional performance improvement.

The paper is structured as follows: first we summarize related work (Sec. 2), and then we give an overview over our perspective on the task and sketch our system pipeline (Sec. 3). The following two sections describe the details of the sentence matching step (Sec. 4) and the subsequent paraphrase fragment extraction (Sec. 5). We present both automatic and manual evaluation of the two system components (Sec. 6). Finally, we conclude the paper and give some hints for future work (Sec. 7).

## 2 Related Work

Previous paraphrase extraction approaches can be roughly characterized under two aspects: 1) data source and 2) granularity of the output.

Both parallel corpora and comparable corpora have been quite well studied. Barzilay and McKeown (2001) use different English translations of the same novels (i.e., monolingual parallel corpora), while others (Quirk et al., 2004) experiment on multiple sources of the same news/events, i.e., monolingual comparable corpora. Commonly used (candidate) comparable corpora are news articles written by different news agencies within a limited time window (Wang and Callison-Burch, 2011). Other studies focus on extracting paraphrases from large bilingual parallel corpora, which the machine translation (MT) community provides in many varieties. Bannard and Callison-Burch (2005) as well as Zhao et al. (2008) take one language as the pivot and match two possible translations in the other languages as paraphrases if they share a common pivot

phrase. As parallel corpora have many alternative ways of expressing the same foreign language concept, large quantities of paraphrase pairs can be extracted.

The paraphrasing task is also strongly related to cross-document event coreference resolution, which is tackled by similar techniques used by the available paraphrasing systems (Bagga and Baldwin, 1999; Tomadaki and Salway, 2005).

Most work in paraphrase acquisition has dealt with sentence-level paraphrases, e.g., (Barzilay and McKeown, 2001; Barzilay and Lee, 2003; Dolan et al., 2004; Quirk et al., 2004). Our approach for sentential paraphrase extraction is related to the one introduced by Barzilay and Lee (2003), who also employ multiple sequence alignment (MSA). However, they use MSA at the sentence level rather than at the discourse level.

We take some core ideas from our previous work on mining script information (Regneri et al., 2010). In this earlier work, we focused on event structures and their possible realizations in natural language. The corpus used in those experiments were short crowd-sourced descriptions of everyday tasks written in bullet point style. We aligned them with a hand-crafted similarity measure that was specifically designed for this text type. In this current work, we target the general task of extracting paraphrases for events rather than the much more specific script-related task. The current approach uses a domain-independent similarity measure instead of a specific hand-crafted similarity score and is thus applicable to standard texts.

From an applicational point of view, sentential paraphrases are difficult to use in other NLP tasks. At the phrasal level, interchangeable patterns (Shinyama et al., 2002; Shinyama and Sekine, 2003) or inference rules (Lin and Pantel, 2001) are extracted. In both cases, each pattern or rule contains one or several slots, which are restricted to certain type of words, e.g., named entities (NE) or content words. They are quite successful in NE-centered tasks, like information extraction, but their level of generalization or coverage is insufficient for applications like Recognizing Textual Entailment (Dinu and Wang, 2009).

The research on *general* paraphrase fragment extraction at the sub-sentential level is mainly based

on phrase pair extraction techniques from the MT literature. Munteanu and Marcu (2006) extract sub-sentential translation pairs from comparable corpora using the log-likelihood-ratio of word translation probability. Quirk et al. (2007) extract fragments using a generative model of noisy translations. Our own work (Wang and Callison-Burch, 2011) extends the first idea to paraphrase fragment extraction on monolingual parallel and comparable corpora. Our current approach also uses word-word alignment, however, we use syntactic dependency trees to compute *grammatical* fragments. Our use of dependency trees is inspired by the constituent-tree-based experiments of Callison-Burch (2008).

### 3 Paraphrases and Discourse

Previous approaches have shown that comparable texts provide a good basis for paraphrase extraction. We want to show that discourse structure is highly useful for precise and high-yield paraphrase collection from such corpora. Consider the following (made-up) example:

- (1) [House keeps focusing on his aching leg.<sub>1.1</sub>.] [The psychiatrist suggests him to get a hobby <sub>1.2</sub>.] [House joins a cooking class.<sub>1.3</sub>]
- (2) [He tells him that the Ibuprofen is not helping with the pain.<sub>2.1</sub>.] [Nolan tells House to take up a hobby.<sub>2.2</sub>] [Together with Wilson he goes to a cookery course.<sub>2.3</sub>]

Read as a whole, it is clear that the two texts describe the same three events, in the same order, and thus, e.g., 1.2 and 2.2 are paraphrases. However, they share very few n-grams, nor named entities. We determine three factors that can help to identify such paraphrases:

1. Consider the **sequence of events**. A system which recognizes that the three sentence pairs occur in the same sequential event order would have a chance of actually matching the sentences.
2. Do **coreference resolution**. To determine which *sentence parts* actually carry the same meaning, pronoun resolution is essential (e.g., to match “suggest him” and “tells House”).

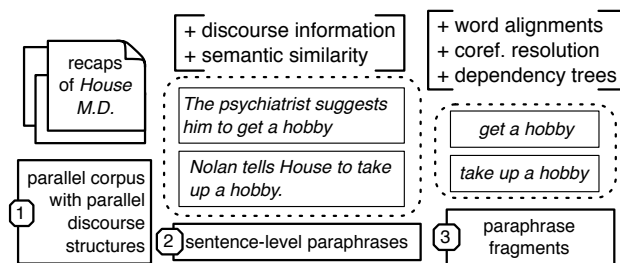

Figure 1: System pipeline

3. Try a generic **sentence similarity model**. Pattern matching or n-gram overlap might not be sufficient to solve this problem.

Our system pipeline is sketched in Fig. 1:

1. **Create a corpus:** First, we create a comparable corpus of texts with *highly comparable discourse structures*. Complete discourse structures like in the RST Discourse Treebank (Carlson et al., 2002) may be very useful for paraphrase computation, however, they are hard to obtain. Discourse annotation is difficult and work-intensive, and full-blown automatic discourse parsers are neither robust nor very precise. To circumvent this problem, we assemble documents that have parallel discourse structures by default: We compile multiple plot summaries of TV show episodes. The textual order of those summaries typically mirrors the underlying event order of the episodes, in the same sequence they happened on screen. We take sentence sequences of recaps as parallel discourse structures.
2. **Extract sentence-level paraphrases:** Our system finds sentence pairs that are either paraphrases themselves, or at least contain paraphrase fragments. This procedure crucially relies on discourse knowledge: A Multiple Sequence Alignment (MSA) algorithm matches sentences if both their inherent *semantic similarities* and the overall similarity score of their *discourse contexts* are high enough.
3. **Extract paraphrase fragments:** Sentence-level paraphrases may be too specific for further domain-independent applications, as they

row	recap 1	recap 2	recap 3	recap 4	recap 5

Figure 2: Excerpt from an alignment table for 5 exemplary recaps of Episode 2 (Season 6).

contain specific NEs (e.g. “House”) or time references. Thus we take a necessary second step and extract finer-grained paraphrase *fragments* from the sentence pairs matched in step 2. The resulting matched phrases should be grammatical and interchangeable regardless of context. We propose and compare different fragment extraction algorithms.

The remainder of the paper shows how both of the paraphrasing steps benefit from using a corpus with highly parallel discourse structures: The system components employ discourse information either directly by using MSA (step 1) or coreference resolution (step 2), or indirectly, because using MSA in step 1 results in a high precision gain for the subsequent second step.

#### 4 Sentence Matching with MSA

This section explains how we apply MSA to extract sentence-level paraphrases from a comparable corpus. As our input data, we manually collect recaps for *House M.D.* episodes from different sources on the web<sup>1</sup>. *House* episodes have an intermediate length (~45 min), which results in recaps of a con-

<sup>1</sup>e.g. <http://house.wikia.com> – for a detailed list of URLs, please check the supplementary material or contact the authors.

venient size (40 to 150 sentences). The result is one comparable document collection per episode. We applied a sentence splitter (Gillick, 2009) to the documents and treat them as sequences of sentences for further processing.

**Sequence alignment** takes as its input two sequences consisting of elements of some alphabet, and an alphabet-specific score function  $c_m$  over pairs of sequence elements. For insertions and deletions, the algorithm additionally takes gap costs ( $c_{gap}$ ). Multiple Sequence Alignment generalizes pairwise alignment to arbitrarily many sequences. MSA has its main application area in bioinformatics, where it is used to identify equivalent parts of DNA (Durbin et al., 1998). Our alphabet consists of sentences, and a sequence is an ordered sentence list constituting a recap.

A Multiple Sequence Alignment results in a table like Fig. 2. Each column contains the sentences of one recap, possibly intermitted with gaps (“⊘”), and each row contains at least one non-gap. If two sentences end up in the same row, they are *aligned*; we take aligned sentence to be paraphrases. Aligning a sentence with a gap can be thought of as an insertion or deletion. Each alignment has a *score* which is the sum of all scores for substitutions and all costs for insertions and deletions. Informally, the alignment

score is the sum of all scores for each pair of cells  $(c_1, c_2)$ , if  $c_1$  and  $c_2$  are in the same row. If either  $c_1$  or  $c_2$  is a gap, the pair’s score is  $c_{gap}$ . If both cells contain sentences, the score is  $c_m(c_1, c_2)$ .

Fern and Stevenson (2009) showed that sophisticated similarity measures improve paraphrasing, so we apply a state-of-the-art vector space model (Thater et al., 2011) as our score function. The vector space model provides contextualized similarities of words, i.e. the vector of each word is disambiguated by the context the current instance occurs in.  $c_m(c_1, c_2)$  returns the model’s similarity score for  $c_1$  and  $c_2$ .

We re-implement a standard MSA algorithm (Needleman and Wunsch, 1970) which approximates the best MSA given the input sequences,  $c_m$  and  $c_{gap}$ . This algorithm recursively aligns two sequences at a time, treating the resulting alignment as a new sequence. This does not necessarily result in the globally optimal alignment, because the order in which sequences are aligned can change the final output. Given this constraint, the algorithm finds the best alignment, which - in our case - is the alignment with the maximal score. Intuitively, we are looking for the alignment where the most similar sentences with the most similar preceding and trailing contexts end up as paraphrases.

## 5 Paraphrase Fragment Extraction

Taking the output of the sentence alignment as input, we next extract shorter phrase-level paraphrases (*paraphrase fragments*) from the matched sentence pairs. We try different algorithms for this step, all relying on word-word alignments.

### 5.1 Preprocessing

Before extracting paraphrase fragments, we first preprocess all documents as follows:

**Stanford CoreNLP**<sup>2</sup> provides a set of natural language analysis tools. We use the part-of-speech (POS) tagger, the named-entity recognizer, the parser (Klein and Manning, 2003), and the coreference resolution system (Lee et al., 2011). In particular, the dependency structures of the parser’s output are used for VP-

<sup>2</sup><http://nlp.stanford.edu/software/corenlp.shtml>

fragment extraction (Sec. 5.3). The output from the coreference resolution system is used to cluster all mentions referring to the same entity and to select one as the *representative* mention. If the representative mention is not a pronoun, we modify the original texts by replacing all pronoun mentions in the cluster with the syntactic head of the representative mention. Note that the coreference resolution system is applied to each recap as a whole.

**GIZA++** (Och and Ney, 2003) is a widely used word aligner for MT systems. We amend the input data by copying identical word pairs 10 times and adding them as additional ‘sentence’ pairs (Byrne et al., 2003), in order to emphasize the higher alignment probability between identical words. We run GIZA++ for bi-directional word alignment and obtain a lexical translation table.

### 5.2 Fragment Extraction

As mentioned in Sec. 2, we choose to use alignment-based approaches to this task, which allows us to use many existing MT techniques and tools. We mainly follow our previous approach (Wang and Callison-Burch, 2011), which is a modified version of an approach by Munteanu and Marcu (2006) on translation fragment extraction. We briefly review the three-step procedure here and refer the reader to the original paper for more details:

1. Establish word-word alignment between each sentence pair using GIZA++;
2. Smooth the alignment based on lexical occurrence likelihood;
3. Extract fragment pairs using different heuristics, e.g., non-overlapping n-grams, chunk boundaries, or dependency trees.

After obtaining a lexical translation table by running GIZA++, for each word pair,  $w_1$  and  $w_2$ , we use both positive and negative lexical associations for the alignment, which are defined as the conditional probabilities  $p(w_1|w_2)$  and  $p(w_1|\neg w_2)$ , respectively. The resulting alignment can be further constrained by a modified longest common substring (LCS) algorithm, which takes sequences of

words instead of letters as input. Smoothing (step 2) is done for each word by taking the average score of it and its four neighbor words. All the word alignments (excluding stop-words) with positive scores are selected as candidate fragment elements.

Provided with the candidate fragment elements, we previously (Wang and Callison-Burch, 2011) used a chunker<sup>3</sup> to finalize the output fragments, in order to follow the linguistic definition of a (*para-*) *phrase*. We extend this step in the current system by applying a dependency parser to constrain the boundary of the fragments (Sec. 5.3). Finally, we filter out trivial fragment pairs, such as identical or the original sentence pairs.

### 5.3 VP-fragment Extraction

To obtain more grammatical output fragments, we add another layer of linguistic information to our input sentences. Based on the dependency parses produced during preprocessing, we extract phrases containing verbs and their complements. More precisely, we match two phrases if their respective subtrees  $t_1$  and  $t_2$  satisfy the following conditions:

- The subtrees mirror a complete subset of the GIZA++ word alignment, i.e., all words aligned to a given word in  $t_1$  are contained in  $t_2$ , and vice versa. For empty alignments, we require an overlap of at least one lemma (ignoring stop words).
- The root nodes of  $t_1$  and  $t_2$  have the same roles within their trees, e.g., we match clauses with an `xcomp`-label only with other `xcomp`-labelled clauses.
- Both  $t_1$  and  $t_2$  contain at least one verb with at least one complement. To enhance recall, we additionally extract complete prepositional phrases.
- We exclude trivial fragment pairs that are prefixes or suffixes of each other (or identical).

The main advantage of this approach lies in the output’s grammaticality, because the subtrees always match complete phrases. This method also functions as a filtering mechanism for mistakenly aligned sentences: If only the two sentence nodes are returned

<sup>3</sup>We use the same OpenNLP chunker (<http://opennlp.sourceforge.net/>) for consistency.

as possible matching partners, the pair is discarded from the results.

## 6 Evaluation

We evaluate both sentential paraphrase matching and paraphrase fragment extraction using manually labelled gold standards (provided in the supplementary material). We collect recaps for all 20 episodes of season 6 of *House M.D.*, taking 8 summaries per episode (the supplementary material contains a list of all URLs). This results in 160 documents containing 14735 sentences. For evaluation, we use all episodes except no. 2, which is held out for parameter optimizations and other development purposes.

### 6.1 Sentential Paraphrase Evaluation

To evaluate sentence matching, we adapt the baselines from our earlier work (Regneri et al., 2010) and create a new gold standard. We compute precision, recall and accuracy of our main system and suggest baselines that separately show the influence of both the MSA and the semantic scoring function.

#### Gold-Standard

We aim to create an evaluation set that contains a sufficient amount of genuine paraphrases. Finding such sentence pairs with random sampling and manual annotation is infeasible: There are more than 200,000,000 possible sentence pairs, and we expect less than 1% of them to be paraphrases. We thus sample pairs that either the system or the baselines recognized as paraphrases and try to create an evaluation set that is not biased towards the actual system or any of the baselines. The evaluation set consists of 2000 sentence pairs: 400 that the system recognized as paraphrases, 400 positively labelled pairs for each of the three baselines (described in the following section) and 400 randomly selected pairs. For the final evaluation, we compute precision, recall, f-score and accuracy for our main system and each baseline on this set.

Two annotators labelled each sentence pair ( $S_1, S_2$ ) with one of the following labels:

1. **paraphrases:**  $S_1$  and  $S_2$  refer to exactly the same event(s).
2. **containment:**  $S_1$  contains all the event information mentioned in  $S_2$ , but refers to at least

one additional event, or vice versa.

3. **related:**  $S_1$  and  $S_2$  overlap in at least one event reference, but both refer to at least one additional event.
4. **unrelated:**  $S_1$  and  $S_2$  do not overlap at all.

This scheme has a double purpose: The main objective is judging whether two sentences contain paraphrases (1-3) or if they are unrelated (4). We use this coarser distinction for system evaluation by collapsing the categories 1-3 in one *paraphrase<sub>coll</sub>* category. Secondly, the annotation shows how well the sentences fit each other’s content (1 vs. 2&3), and how much work needs to be done to extract the sentence parts with the same meaning (2 vs. 3).

The inter-annotator agreement according to Cohen’s Kappa (Cohen, 1960) is  $\kappa = 0.55$  (“moderate agreement”). The distinction between *unrelated* cases and elements of *paraphrase<sub>coll</sub>* reaches  $\kappa = 0.71$  (“substantial agreement”). For the final gold standard, a third annotator resolved all conflict cases.

Among all gold standard sentence pairs, we find 158 *paraphrases*, 238 *containment* cases, 194 *related* ones and 1402 *unrelated*. We had to discard 8 sentence pairs because one of the items was invalid or empty. The high proportion of ‘unrelated’ cases results from the 400 random pairs and the low precision of the baselines. Looking at the paraphrases, 27% of the 590 instances in the *paraphrase<sub>coll</sub>* category are proper paraphrases, and 73% of them contain additional information that does not belong to the paraphrased part.

## Experimental Setup

We compute precision, recall and f-score with respect to the gold standard (paraphrases are members of *paraphrase<sub>coll</sub>*), taking f-score as follows:

$$f\text{-score} = \frac{2 * \textit{precision} * \textit{recall}}{\textit{precision} + \textit{recall}}$$

We also compute accuracy as the overall fraction of correct labels (negative and positive ones).

Our main system uses MSA (denoted by MSA afterwards) with vector-based similarities (VEC) as a

scoring function. The gap costs are optimized for f-score, resulting in  $c_{gap} = 0$ .<sup>4</sup>

To show the contribution of MSA’s structural component and compare it to the vector model’s contribution, we create a second MSA-based system that uses MSA with BLEU scores (Papineni et al., 2002) as scoring function (MSA+BLEU). BLEU establishes the average 1-to-4-gram overlap of two sentences. The gap costs for this baseline were optimized separately, ending up with  $c_{gap} = 1$ .

In order to quantify the contribution of the alignment, we create a discourse-unaware baseline by dropping the MSA and using a state-of-the-art clustering algorithm (Noack, 2007) fed with the vector space model scores (CLUSTER+VEC). The algorithm partitions the set of sentences into paraphrase clusters such that the most similar sentences end up in one cluster. This does not require any parameter tuning.

We also show a baseline that uses the clustering algorithm with BLEU scores (CLUSTER+BLEU). The comparison of this baseline with the other clustering-baseline that uses vector similarities helps to underline the sentence similarities’ advantage compared to pure word overlap. Note that the CLUSTER+BLEU system resembles popular n-gram overlap measures for paraphrase classification.

We also show the results completely random label assignment, which constitutes a lower bound for the baselines and the system.

## Results

Overall, our system extracts 20379 paraphrase pairs. Tab. 1 shows the evaluation results on our gold-standard.

The MSA based system variants outperform the two clustering baselines significantly (all levels refer to  $p = 0.01$  and were tested with a resampling test (Edgington, 1986)).

The clustering baselines perform significantly better than a random baseline, especially considering recall. The more elaborated vector-space measure even gives 10% more in precision and accuracy, and overall 14% more in f-score. This is al-

<sup>4</sup>Gap costs directly influence precision and recall: “cheap” gaps lead to a more restrictive system with higher precision, and more expensive gaps give more recall. We chose f-score as our objective.

<i>System</i>	<i>Prec.</i>	<i>Recall</i>	<i>F-score</i>	<i>Acc.</i>
RANDOM	0.30	0.49	0.37	0.51
CLUSTER+BLEU	0.35	0.63	0.45	0.54
CLUSTER+VEC	0.40	0.68	0.51	0.61
MSA+BLEU	0.73	<b>0.74</b>	<b>0.73</b>	0.84
MSA+VEC	<b>0.79</b>	0.66	0.72	<b>0.85</b>

Table 1: Results for sentence matching.

ready a remarkable improvement compared to the random baseline, and still a significant one compared to CLUSTER+BLEU.

Adding structural knowledge with MSA improves the clustering’s accuracy performance by 24% (CLUSTER+VEC vs. MSA+VEC), precision even goes up by 39%.

Intuitively we expected the MSA-based systems to end up with a higher recall than the clustering baselines, because sentences can be matched even if their similarity is moderate or low, but their discourse context is highly similar. However, this is only the case for the system using BLEU scores, but not for the system based on the vector space model. One possible explanation lies in picking f-score as objective for the optimization of the gap costs for MSA: For the naturally more restrictive word overlap measure, this leads to a more recall-oriented system with a low threshold for aligning sentences, whereas the gap costs for the vector-based system favors a more restrictive alignment with more precise results.

The comparison of the two MSA-based systems highlights the great benefit of using structural knowledge: Both MSA+BLEU and MSA+VEC have comparable f-scores and accuracy. The advantage from using the vector-space model that is still obvious for the clustering baselines is nearly evened out when adding discourse knowledge as a backbone. However, the vector model still results in nominally higher precision and accuracy.

It is hard to do a direct comparison with state-of-the-art paraphrase recognition systems, because most are evaluated on different corpora, e.g., the Microsoft paraphrase corpus (Dolan and Brockett, 2005, MSR). We cannot apply our system to the MSR corpus, because we take complete texts as in-

put, while the MSR corpus solely delivers sentence pairs. While the MSR corpus is larger than our collection, the wording variations in its paraphrase pairs are usually lower than for our examples. Thus the final numbers of previous approaches might be vaguely comparable with our results: Das and Smith (2009) present two systems reaching f-scores of 0.82 and 0.83, with a precision of 0.75 and 0.80. Both precision and f-scores of our msa-based systems lie within the same range. Heilman and Smith (2010) introduce a recall-oriented system, which reaches an f-score of 0.81 by a precision of 0.76. Compared to this system, our approach results in better precision values.

All further computations bases on the system using MSA and the vector space model (MSA+VEC), because it achieves the highest precision and accuracy values.

## 6.2 Paraphrase Fragment Evaluation

We also manually evaluate precision on paraphrase fragments, and additionally describe the *productivity* of the different setups, providing some intuition about the methods’ recall.

### Gold-Standard

We randomly collect 150 fragment pairs for each of the five system configurations (explained in the following section). Each fragment pair  $(f_1, f_2)$  is annotated with one of the following categories:

1. **paraphrases:**  $f_1$  and  $f_2$  convey the same meaning, i.e., they are well-formed and good matches on the content level.
2. **related:**  $f_1$  and  $f_2$  overlap in their meaning, but one or both phrases have additional unmatched information.
3. **irrelevant:**  $f_1$  and  $f_2$  are unrelated.

This labeling scheme again assesses precision as well as paraphrase granularity. For precision rating, we collapse categories 1&2 into one *paraphrase<sub>coll</sub>* category. Each pair is labelled by two annotators, who were shown both the fragments and the whole sentences they originate from. Overall, the raters had an agreement of  $\kappa = 0.67$  (“substantial agreement”), which suggests that the task was easier than sentence level annotation. The agreement for the

distinction between the *paraphrase<sub>coll</sub>* categories and *irrelevant* instances reaches a level of  $\kappa = 0.88$  (also “substantial agreement”). All conflicts were again adjudicated by a third annotator. Overall, the gold standard contains 190 paraphrases, 258 *related* pairs and 302 *irrelevant* instances. Unlike previous approaches to fragment extraction, we do not evaluate *grammaticality*, given that the VP-fragment method implicitly constrains the output fragments to be complete phrases.

### Configurations & Results

We take the output of the sentence matching system MSA+VEC as input for paraphrase fragment extraction. As detailed in Sec. 5, our core fragment module uses the word-word alignments provided by GIZA++ and uses a chunker for fragment extraction. We successively enrich this core module with more information, either by longest common substring (LCS) matching or by operating on dependency trees (VP). In addition, we evaluate the influence of coreference resolution by preprocessing the input to the best performing configuration with pronoun resolution (COREF).

We mainly compute precision for this task, as the recall of paraphrase fragments is difficult to define. However, we do include a measure we call *productivity* to indicate the algorithm’s completeness. It is defined as the ratio between the number of resulting fragment pairs and the number of sentence pairs used as input.

<i>Extraction Method</i>	<i>Precision</i>	<i>Productivity</i>
MSA	0.57	<b>0.76</b>
MSA+LCS	0.45	0.30
MSA+VP	0.81	0.42
<b>MSA+VP+COREF</b>	<b>0.84</b>	0.45

Table 2: Results of paraphrase fragment extraction.

Tab. 2 shows the evaluation results. We reach our best precision by using the VP-fragment heuristics, which is still more productive than the LCS method. The grammatical filter gives us a higher precision compared to the purely alignment-based approaches. Enhancing the system with coreference resolution raises the score even further. We

cannot directly compare this performance to other systems, as all other approaches have different data sources. However, precision is usually manually evaluated, so the figures are at least indicative for a comparison with previous work: One state-of-the-art system introduced by Zhao et al. (2008) extracts paraphrase fragments from bilingual parallel corpora and reaches a precision of 0.67. We found the same number using our previous approach (Wang and Callison-Burch, 2011), which is roughly equivalent to our core module. Our approach outperforms both by 17% with similar estimated productivity.

As a final comparison, we show how the performance of the sentence matching methods directly affects the fragment extraction. We use the VP-based fragment extraction system (VP), and compare the performances by using either the outputs from our main system (MSA+VP) or alternatively the baseline that replaces MSA with a clustering algorithm (CLUSTER+VP). Both variants use the vector-based semantic similarity measure.

<i>Sentence matching</i>	<i>Precision</i>	<i>Productivity</i>
CLUSTER+VP	0.31	0.04
<b>MSA+VP</b>	<b>0.81</b>	<b>0.42</b>

Table 3: Impact of MSA on fragment extraction

As shown in Tab. 3, the precision gain from using MSA becomes tremendous during further processing: We beat the baseline by 50% here, and productivity increases by a factor of 10. This means that the baseline produces on average 0.01 good fragment pairs per matched sentence pair, and the final system extracts 0.3 of them. Those numbers show that for any application that acquires paraphrases of arbitrary granularity, sequential event information provides an invaluable source to achieve a lean paraphrasing method with high precision.

### 6.3 Example output

Fig. 3 shows exemplary results from our system pipeline, using the VP-FRAGMENTS method with full coreference resolution on the sentence pairs extracted by MSA. The results reflect the importance of discourse information for this task: Sentences are correctly matched in spite of not having common de-

	Sentence 1 [ <i>with fragment 1</i> ]	Sentence 2 [ <i>with fragment 2</i> ]
1	Taub meets House for dinner and claims [ <i>that Rachel had a pottery class</i> ].	Taub shows up for his dinner with House without Rachel, explaining [ <i>that she's at a ceramics class</i> ].
2	House doesn't want her to go and she doesn't want to go either, but [ <i>she can't leave her family</i> ].	Lydia admits that she doesn't want to leave House but [ <i>she has to stay with her family</i> ].
3	Thirteen is in a cab to the airport when she finds out that [ <i>her trip had been canceled</i> ].	Hadley discovers that [ <i>her reservation has been canceled</i> ].
4	Nash asks House [ <i>for the extra morphine</i> ].	The patient is ready [ <i>for more morphine</i> ].
5	House comes in to tell Wilson that Tucker has cancer and [ <i>shows him the test results</i> ].	House comes in and [ <i>informs Wilson that the tests have proven positive</i> ]: Tucker has cancer.
6	Foreman tells him [ <i>to confide in Cameron</i> ].	When Chase points out they can't move Donny without alerting Cameron, Foreman tells Chase [ <i>to be honest with his wife</i> ].
7	Thirteen breaks [ <i>into the old residence</i> ] and tells Taub that she realizes that he's been with Maya.	Taub and Thirteen break [ <i>into Ted's former residence</i> ].
8	He finds [ <i>a darkened patch on his right foot near the big toe</i> ].	House finally finds [ <i>a tumorous mole on his toe</i> ].

Figure 3: Example results; fragments extracted from aligned sentences are bracketed and *emphasized*.

pendency patterns (e.g., Example 4) or sharing many n-grams (6-8). Additionally, the coreference resolution allows us to match *Rachel* (1) and *Wilson* (5) to the correct corresponding pronouns. All examples show that this technique of matching sentence could even help to make coreference resolution better, because we can easily identify *Cameron* with *his wife*, *Lydia* with the respective pronouns, *Nash* with *The Patient* or the nickname *Thirteen* with *Hadley*, the character's actual name.

## 7 Conclusion and Future Work

We presented our work on paraphrase extraction using discourse information, on a corpus consisting of recaps of TV show episodes. Our approach first uses MSA to extract sentential paraphrases, which are then further processed to compute finer-grained paraphrase fragments using dependency trees and pronoun resolution. The experimental results show great advantages from using discourse information, beating informed baselines and performing competitively with state-of-the-art systems.

For future work, we plan to use MSA to align single clauses rather than whole sentences. This can also help to define the fragment boundaries more clearly. Additionally, we plan to generalize

the method for other parallel texts by preprocessing them with a temporal classifier. In a more advanced step, we will also use the aligned paraphrases to help resolving discourse structure, e.g. for coreference resolution, which could lead to a high-performance bootstrapping system. In a long-term view, it would be interesting to see how aligned discourse trees could help to extract paraphrases from arbitrary parallel text.

# Generating Non-Projective Word Order in Statistical Linearization

Bernd Bohnet Anders Björkelund Jonas Kuhn Wolfgang Seeker Sina Zarriß

Institut für Maschinelle Sprachverarbeitung

University of Stuttgart

{bohnetbd, anders, jonas, seeker, zarriessa}@ims.uni-stuttgart.de

## Abstract

We propose a technique to generate non-projective word orders in an efficient statistical linearization system. Our approach predicts *liftings* of edges in an unordered syntactic tree by means of a classifier, and uses a projective algorithm for tree linearization. We obtain statistically significant improvements on six typologically different languages: English, German, Dutch, Danish, Hungarian, and Czech.

## 1 Introduction

There is a growing interest in language-independent data-driven approaches to natural language generation (NLG). An important subtask of NLG is surface realization, which was recently addressed in the 2011 Shared Task on Surface Realisation (Belz et al., 2011). Here, the input is a linguistic representation, such as a syntactic dependency tree lacking all precedence information, and the task is to determine a natural, coherent linearization of the words.

The standard data-driven approach is to traverse the dependency tree deciding locally at each node on the relative order of the head and its children. The shared task results have proven this approach to be both effective and efficient when applied to English.

Figure 1: A non-projective example from the CoNLL 2009 Shared Task data set for parsing (Hajič et al., 2009).

However, the approach can only generate projective word orders (which can be drawn without any crossing edges). Figure 1 shows a non-projective word order: the edge connecting the extracted *wh*-pronoun with its head crosses another edge. Once *what* has been ordered relative to *achieve*, there are no ways of inserting intervening material. In this case, only ungrammatical linearizations can be produced from the unordered input tree:

- (1) a. \*It is federal support should try to what achieve
- b. \*It is federal support should try to achieve what
- c. \*It is try to achieve what federal support should

Although rather infrequent in English, non-projective word orders are quite common in languages with a less restrictive word order. In these languages, it is often possible to find a grammatically correct *projective* linearization for a given input tree, but discourse coherence, information structure, and stylistic factors will often make speakers prefer some non-projective word order.<sup>1</sup> Figure 2 shows an object fronting example from German where the edge between the subject and the finite verb crosses the edge between the object and the full verb. Various other constructions, such as extraposition of (relative) clauses or scrambling, can lead to non-projectivity. In languages where word order is driven to an even larger degree by information structure, such as Czech and Hungarian, non-projectivity can likewise result from various ordering decisions. These phenomena have been studied extensively in

<sup>1</sup>A categorization of non-projective edges in the Prague Dependency Treebank (Böhmová et al., 2000) is presented in Hajičová et al. (2004).

the linguistic literature, and for certain languages, work on rule-based generation has addressed certain aspects of the problem.

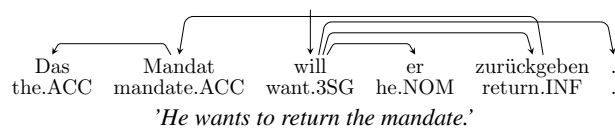

Figure 2: German object fronting with complex verb introducing a non-projective edge.

In this paper, we aim for a general data-driven approach that can deal with various causes for non-projectivity and will work for typologically different languages. Our technique is inspired by work in data-driven multilingual parsing, where non-projectivity has received considerable attention. In pseudo-projective parsing (Kahane et al., 1998; Nivre and Nilsson, 2005), the parsing algorithm is restricted to projective structures, but the issue is side-stepped by converting non-projective structures to projective ones prior to training and application, and then restoring the original structure afterwards.

Similarly, we split the linearization task in two stages: initially, the input tree is modified by lifting certain edges in such a way that new orderings become possible even under a projectivity constraint; the second stage is the original, projective linearization step. In parsing, projectivization is a deterministic process that lifts edges based on the linear order of a sentence. Since the linear order is exactly what we aim to produce, this deterministic conversion cannot be applied before linearization. Therefore, we use a statistical classifier as our initial lifting component. This classifier has to be trained on suitable data, and it is an empirical question whether the projective linearizer can take advantage of this preceding lifting step.

We present experiments on six languages with varying degrees of non-projective structures: English, German, Dutch, Danish, Czech and Hungarian, which exhibit substantially different word order properties. Our approach achieves significant improvements on all six languages. On German, we also report results of a pilot human evaluation.

## 2 Related Work

An important concept for tree linearization are *word order domains* (Reape, 1989). The domains are bags of words (constituents) that are not allowed to be discontinuous. A straightforward method to obtain the word order domains from dependency trees and to order the words in the tree is to use each word and its children as domain and then to order the domains and contained words recursively. As outlined in the introduction, the direct mapping of syntactic trees to domains does not provide the possibility to obtain all possible correct word orders.

Linearization systems can be roughly distinguished as either rule-based or statistical systems. In the 2011 Shared Task on Surface Realisation (Belz et al., 2011), the top performing systems were all statistical dependency realizers (Bohnet et al., 2011; Guo et al., 2011; Stent, 2011).

Grammar-based approaches map dependency structures or phrase structures to a tree that represents the linear precedence. These approaches are mostly able to generate non-projective word orders. Early work was nearly exclusively applied to phrase structure grammars (e.g. (Kathol and Pollard, 1995; Rambow and Joshi, 1994; Langkilde and Knight, 1998)). Concerning dependency-based frameworks, Bröker (1998) used the concept of word order domains to separate surface realization from linear precedence trees. Similarly, Duchier and Debusmann (2001) differentiate Immediate Dominance trees (ID-trees) from Linear Precedence trees (LP-trees). Gerdes and Kahane (2001) apply a hierarchical topological model for generating German word order. Bohnet (2004) employs graph grammars to map between dependency trees and linear precedence trees represented as hierarchical graphs. In the frameworks of HPSG, LFG, and CCG, a grammar-based generator produces word order candidates that might be non-projective, and a ranker is used to select the best surface realization (Cahill et al., 2007; White and Rajkumar, 2009).

Statistical methods for linearization have recently become more popular (Langkilde and Knight, 1998; Ringger et al., 2004; Filippova and Strube, 2009; Wan et al., 2009; He et al., 2009; Bohnet et al., 2010; Guo et al., 2011). They typically work by traversing the syntactic structure either bottom-up (Filip-

pova and Strube, 2007; Bohnet et al., 2010) or top-down (Guo et al., 2011; Bohnet et al., 2011). These linearizers are mostly applied to English and do not deal with non-projective word orders. An exception is Filippova and Strube (2007), who contribute a study on the treatment of preverbal and postverbal constituents for German focusing on constituent order at the sentence level. The work most similar to ours is that of Gamon et al. (2002). They use machine-learning techniques to lift edges in a pre-processing step to a surface realizer. Their objective is the same as ours: by lifting, they avoid crossing edges. However, contrary to our work, they use phrase-structure syntax and focus on a limited number of cases of crossing branches in German only.

### 3 Lifting Dependency Edges

In this section, we describe the first of the two stages in our approach, namely the classifier that lifts edges in dependency trees. The classifier we aim to train is meant to predict liftings on a given unordered dependency tree, yielding a tree that, with a perfect linearization, would not have any non-projective edges.

#### 3.1 Preliminaries

The dependency trees we consider are of the form displayed in Figure 1. More precisely, all words (or nodes) form a rooted tree, where every node has exactly one parent (or *head*). Edges point from head to dependent, denoted in the text by  $h \rightarrow d$ , where  $h$  is the head and  $d$  the dependent. All nodes directly or transitively depend on an artificial root node (depicted in Figure 1 as the incoming edge to *is*).

We say that a node  $a$  *dominates* a node  $d$  if  $a$  is an ancestor of  $d$ . An edge  $h \rightarrow d$  is *projective* iff  $h$  dominates all nodes in the linear span between  $h$  and  $d$ . Otherwise it is *non-projective*. Moreover, a dependency tree is projective iff all its edges are projective. Otherwise it is non-projective.

A *lifting* of an edge  $h \rightarrow d$  (or simply of the node  $d$ ) is an operation that replaces  $h \rightarrow d$  with  $g \rightarrow d$ , given that there exists an edge  $g \rightarrow h$  in the tree, and undefined otherwise (i.e. the dependent  $d$  is reattached to the head of its head).<sup>2</sup> When the lifting

<sup>2</sup>The undefined case occurs only when  $d$  depends on the root, and hence cannot be lifted further; but these edges are by definition projective, since the root dominates the entire tree.

operation is applied  $n$  successive times to the same node, we say the node was lifted  $n$  *steps*.

#### 3.2 Training

During training we make use of the projectivization algorithm described by Nivre and Nilsson (2005). It works by iteratively lifting the shortest non-projective edges until the tree is projective. Here, shortest edge refers to the edge spanning over the fewest number of words. Since finding the shortest edge relies on the linear order, instead of lifting the shortest edge, we lift non-projective edges ordered by depth in the tree, starting with the deepest nested edge. A lifted version of the tree from Figure 1 is shown in Figure 3. The edge of *what* has been lifted three steps (the original edge is dotted), and the tree is no longer non-projective.

Figure 3: The sentence from Figure 1, where *what* has been assigned a new head (solid line). The original edge is dotted.

We model the edge lifting problem as a multi-class classification problem and consider nodes one at a time and ask the question “*How far should this edge be lifted?*”, where classes correspond to lifting 0, 1, 2, ...,  $n$  steps. To create training instances we use the projectivization algorithm mentioned above. We traverse the nodes of the tree sorted by depth. For multiple nodes at the same depth, ties are broken by linear order, i.e. for multiple nodes at the same depth, the leftmost is visited first. When a node is visited, we create a training instance out of it. Its class is determined by the number of steps it would be lifted by the projectivization algorithm given the linear order (in most cases the class corresponds to no lifting, since most edges are projective). As we traverse the nodes, we also execute the liftings (if any) and update the tree on the fly.

The training instances derived are used to train a logistic regression classifier using the LIBLINEAR package (Fan et al., 2008). The features used for the lifting classifier are described in Table 1. Since we use linear classifiers, our feature set also contains conjunctions of atomic features. The features

Atomic features	
$\forall x \in \{w, w_p, w_{gp}, w_{ch}, w_s, w_{un}\}$	morph( $x$ ), label( $x$ ), lemma( $x$ ), PoS( $x$ )
$\forall x \in \{w_{gc}, w_{ne}, w_{co}\}$	label( $x$ ), lemma( $x$ ), PoS( $x$ )
Complex features	
$\forall x \in \{w, w_p, w_{gp}\}$	lemma( $x$ )+PoS( $x$ ), label( $x$ )+PoS( $x$ ), label( $x$ )+lemma( $x$ )
$\forall x \in \{w_{ch}, w_s, w_{un}\}, y = w$	lemma( $x$ )+lemma( $y$ ), PoS( $y$ )+lemma( $x$ ), PoS( $y$ )+lemma( $x$ )
$\forall x \in \{w, w_p, w_{gp}\}, y = \text{HEAD}(x)$	lemma( $x$ )+lemma( $y$ ), lemma( $x$ )+PoS( $y$ ), PoS( $x$ )+lemma( $y$ )
$\forall x \in \{w, w_p, w_{gp}\}, y = \text{HEAD}(x), z = \text{HEAD}(y)$	PoS( $x$ )+PoS( $y$ )+PoS( $z$ ), label( $x$ )+label( $y$ )+label( $z$ )
$\forall x \in \{w_{ch}, w_s, w_{un}\}, y = \text{HEAD}(x), z = \text{HEAD}(y)$	PoS( $x$ )+PoS( $y$ )+PoS( $z$ ), label( $x$ )+label( $y$ )+label( $z$ )
Non-binary features	
$\forall x \in \{w, w_p, w_{gp}\}$	SUBTREESIZE( $x$ ), RELSUBTREESIZE( $x$ )

Table 1: Features used for lifting.  $w$  refers to the word (dependent) in question. And with respect to  $w$ ,  $w_p$  is the parent;  $w_{gp}$  is the grandparent;  $w_{ch}$  are children;  $w_s$  are siblings;  $w_{un}$  are uncles (i.e. children of the grandparent, excluding the parent);  $w_{gc}$  are grandchildren;  $w_{ne}$  are nephews (i.e. grandchildren of the parent that are not children of  $w$ );  $w_{co}$  are cousins (i.e. grandchildren of the grandparent that are not  $w$  or siblings of  $w$ ). The non-binary feature functions refer to: SUBTREESIZE – the absolute number of nodes below  $x$ , RELSUBTREESIZE – the relative size of the subtree rooted at  $x$  with respect to the whole tree.

involve the lemma, dependency edge label, part-of-speech tag, and morphological features of the node in question, and of several neighboring nodes in the dependency tree. We also have a few non-binary features that encode the size of the subtree headed by the node and its ancestors.

We ran preliminary experiments to determine the optimal architecture. First, other ways of modeling the liftings are conceivable. To find new reattachment points, Gamon et al. (2002) propose two other ways, both using a binary classifier: applying the classifier to each node  $x$  along the path to the root asking “Should  $d$  be reattached to  $x$ ?”; or lifting one step at a time and applying the classifier iteratively until it says stop. They found that the latter outperformed the former. We tried this method, but found that it was inferior to the multi-class model and more frequently over- or underlifted.

Second, to avoid data sparseness for infrequent lifting distances, we introduce a maximum number of liftings. We found that a maximum of 3 gave the best performance. In the pseudocode below, we refer to this number as *maxsteps*.<sup>3</sup> This means that we are able to predict the correct lifting for most (but not all) of the non-projective edges in our data sets (cf. Table 3).

Third, as Nivre and Nilsson (2005) do for pars-

ing, we experimented with marking edges that were lifted by indicating this on the edge labels. In the case of parsing, this step is necessary in order to reverse the liftings in the parser output. In our case, it could potentially be beneficial for both the lifting classifier, and for the linearizer. However, we found that marking liftings at best gave similar results as not marking, so we kept the original labels without marking.

### 3.3 Decoding

In the decoding stage, an unordered tree is given and the goal is to lift edges that would be non-projective with respect to the gold linear order. Similarly to how training instances are derived, the decoding algorithm traverses the tree bottom-up and visits every node once. Ties between nodes at the same depth are broken in an arbitrary but deterministic way. When a node is visited, the classifier is applied and the corresponding lifting is executed. Pseudocode is given in Algorithm 1.<sup>4</sup>

Different orderings of nodes at the same depth can lead to different lifts. The reason is that liftings are applied immediately and this influences the features when subsequent nodes are considered. For instance, consider two sibling nodes  $n_i$  and  $n_j$ . If  $n_i$  is visited before  $n_j$ , and  $n_i$  is lifted, this means

<sup>3</sup>During training, nodes that are lifted further than *maxsteps* are assigned to the class corresponding to *maxsteps*. This approach worked better than ignoring the training instance or treating it as a non-lifting (i.e. a lifting of 0 steps).

<sup>4</sup>The MIN function is used to guarantee that the edge is not lifted beyond the root node of the tree. This does not happen in practice though, since the feature set of the classifier include features that implicitly encode the proximity to the root node.

that at the time we visit  $n_j$ ,  $n_i$  is no longer a sibling of  $n_j$ , but rather an uncle. An obvious extension of the decoding algorithm presented above is to apply beam search. This allows us to consider  $n_j$  both in the context where  $n_i$  has been lifted and when it has not been lifted.

```

1 N ← NODES(T)
2 SORT-BY-DEPTH-BREAK-TIES-ARBITRARILY(N, T)
3 foreach node ∈ N do
4   feats ← EXTRACT-FEATURES(node, T)
5   steps ← CLASSIFY(feats)
6   steps ← MIN(steps, ROOT-DIST(node))
7   LIFT(node, T, steps)
8 return T

```

Algorithm 1: Greedy decoding for lifting.

Pseudocode for the beam search decoder is given in Algorithm 2. The algorithm keeps an agenda of trees to explore as each node is visited. For every node, it clones the current tree and applies every possible lifting. Every tree also has an associated score, which is the sum of the scores of each lifting so far. The score of a lifting is defined to be the log probability returned from the logistic classifier. After exploring all trees in the agenda, the  $k$ -best new trees from the beam are extracted and put back into the agenda. When all nodes have been visited, the best tree in the agenda is returned. For the experiments the beam size ( $k$  in Algorithm 2) was set to 20.

```

1 N ← NODES(T)
2 SORT-BY-DEPTH-BREAK-TIES-ARBITRARILY(N, T)
3 Tscore ← 0
4 Agenda ← {T}
5 foreach node ∈ N do
6   Beam ← ∅
7   foreach tree ∈ Agenda do
8     feats ← EXTRACT-FEATURES(node, tree)
9     m ← MIN(maxsteps, ROOT-DIST(node))
10    foreach s ∈ 0..maxsteps do
11      t ← CLONE(tree)
12      score ← GET-LIFT-SCORE(feats, s)
13      tscore = tscore + score
14      LIFT(node, t, s)
15      Beam ← Beam ∪ {t}
16   Agenda ← EXTRACTKBEST(Beam, k)
17 return EXTRACTKBEST(Agenda, 1)

```

Algorithm 2: Beam decoding for lifting.

While beam search allows us to explore the search space somewhat more thoroughly, a large number of

possibilities remain unaccounted for. Again, consider the sibling nodes  $n_i$  and  $n_j$  when  $n_i$  is visited before  $n_j$ . The beam allows us to consider  $n_j$  both when  $n_i$  is lifted and when it is not. However, the situation where  $n_j$  is visited *before*  $n_i$  is still never considered. Ideally, all permutations of nodes at the same depth should be explored before moving on. Unfortunately this leads to a combinatorial explosion of permutations, and exhaustive search is not tractable. As an approximation, we create two orderings and run the beam search twice. The difference between the orderings is that in the second one all ties are reversed. As this *bibeam* consistently improved over the beam in Algorithm 2, we only present these results in Section 5 (there denoted simply *Beam*).

## 4 Linearization

A linearizer searches for the optimal word order given an unordered dependency tree, where the optimal word order is defined as the single reference order of the dependency tree in the gold standard. We employ a statistical linearizer that is trained on a corpus of pairs consisting of unordered dependency trees and their corresponding sentences. The linearization method consists of the following steps:

**Creating word order domains.** In the first step, we build the word order domains  $d_h$  for all nodes  $h \in y$  of a dependency tree  $y$ . A domain is defined as a node and all of its direct dependents. For example, the tree shown in Figure 3 has the following domains:  $\{it, be, should\}$ ,  $\{what, support, should, try\}$ ,  $\{federal, support\}$ ,  $\{try, to\}$ ,  $\{to, achieve\}$

If an edge was lifted before the linearization, the lifted node will end up in the word order domain of its new head rather than in the domain of its original head. This way, the linearizer can deduce word orders that would result in non-projective structures in the non-lifted tree.

**Ordering the words of the domains.** In the second step, the linearizer orders the words of each domain. The position of a subtree is determined by the position of the head of the subtree in the enclosing domain. Algorithm 3 shows the tree linearization algorithm. In our implementation, the linearizer traverses the tree either top-down or bottom-up.

```

1 // T is the dependency tree with lifted nodes
2 beam-size ← 1000
3 for h ∈ T do
4   domainh ← GET-DOMAIN(T,h)
5   // initialize the beam with a empty word list
6   Agendah ← (ε)
7   foreach w ∈ domainh do
8     // beam for extending word order lists
9     Beam ← ()
10    foreach l ∈ Agendah do
11      // clone list l and append the word w
12      if w ∉ l then
13        l' ← APPEND(l,w)
14        Beam ← Beam ⊕ l'
15        score[l'] ← COMPUTE-SCORE(l')
16    if |Beam| > beam-size then
17      SORT-LISTS-DESCENDING-TO-
18      SCORE(Beam,score)
19      Agendah ← SUBLIST(0,beam-size,Beam)
20    else
21      Agendah ← Beam
22    foreach l ∈ Beam do
23      SCOREg[l] ← SCORE[l] +
24      GLOBAL-SCORE(l)
25  Agendah ← Beam
26 return Beam

```

Algorithm 3: Dependency Tree Linearization.

The linearization algorithm initializes the word order beam ( $agenda_h$ ) with an empty order ( $\epsilon$ ) (line 6). It then iterates over the words of a domain (lines 7-20). In the first iteration, the algorithm clones and extends the empty word order list ( $\epsilon$ ) by each word of the sentence (line 12-15). If the beam ( $beam$ ) exceeds a certain size ( $beam-size$ ), it is sorted by score and pruned to maximum beam size ( $beam-size$ ) (lines 16-20). The following example illustrates the extensions of the beam for the top domain shown in Figure 3.

```

Iter. agendabe
0: (ε)
1: ((it) (be) (should))
2: ((it be) (it should) (be it) (be should) ...)

```

The beam enables us to apply features that encode information about the first tokens and the last token, which are important for generating, e.g. the word order of questions, i. e. if the last token is a question mark then the sentence should probably be a question (cf. feature set shown in Table 2). Furthermore, the beam enables us to generate alternative linearizations. For this, the algorithm iterates over the alter-

native word orders of the domains in order to assemble different word orders on the sentence level.<sup>5</sup> Finally, when traversing the tree bottom-up, the algorithm has to use the different orders of the already ordered subtrees as context, which also requires a search over alternative word orders of the domains.

**Training of the Linearizer.** We use MIRA (Crammer et al., 2006) for the training of the linearizer. The classifier provides a score that we use to rank the alternative word orders. Algorithm 3 calls two functions to compute the score: *compute-score* (line 15) for features based on pairs of words and trigrams and *compute-global-score* for features based on word patterns of a domain. Table 2 shows the feature set for the two functions. In the case that the linearization of a word order domain is incorrect the algorithm updates its weight vector  $w$ . The following equation shows the update function of the weight vector:

$$w = w + \tau_h(\phi(d_h, T, x_g) - \phi(d_h, T, x_p))$$

We update the weight vector  $w$  by adding the difference of the feature vector representation of the correct linearization  $x_g$  and the wrongly predicted linearization  $x_p$ , multiplied by  $\tau$ .  $\tau$  is the passive-aggressive update factor as defined below. The suffered  $loss_h$  is  $\phi(d_h, T, x_p) - \phi(d_h, T, x_g)$ .

$$\tau = \frac{loss_h}{\|\phi(d_h, T, x_g) - \phi(d_h, T, x_p)\|^2}$$

**Creating the word order of a sentence.** The linearizer traverses the tree either top-down or bottom-up and assembles the results in the surface order. The bottom-up linearization algorithm can take into account features drawn from the already ordered subtrees while the top-down algorithm can employ as context only the unordered nodes. However, the bottom-up algorithm additionally has to carry out a search over the alternative linearization of the subdomains, as different orders of the subdomain provide different context features. This leads to a higher linearization time. We implemented both, but could only find a rather small accuracy difference. In the following, we therefore present results only for the top-down method.

<sup>5</sup>The beam also makes it possible to employ a generative language model to rerank alternative linearizations.

Atomic features	
<b>For nodes</b> $w \in domain_h$	lemma( $w$ ), label( $w$ ), PoS( $w$ ), num-children( $w$ ), num-grandchildren( $w$ ), label-children( $w$ ), PoS-children( $w$ )

<b>For trigrams</b> $(w_1, w_2, w_3) \in domain_h$	feat <sub>3</sub> : lemma( $w_1$ )+lemma( $w_2$ )+lemma( $w_3$ ) feat <sub>4</sub> : PoS( $w_1$ )+PoS( $w_2$ )+PoS( $w_3$ )+head( $w_1, w_2, w_3$ ) feat <sub>5</sub> : label( $w_1$ )+label( $w_2$ )+label( $w_3$ )+PoS( $w_1$ )+head( $w_1, w_2, w_3$ )
<b>For sentence</b> $s$	feat <sub>6</sub> : label( $w_1$ )+label( $w_{n-1}$ )+lemma( $head$ )+lemma( $w_1$ )+lemma( $w_{n-1}$ ) feat <sub>7</sub> : PoS( $w_1$ )+PoS( $w_2$ )+PoS( $w_3$ )+PoS( $w_{n-1}$ )+PoS( $w_{n-2}$ )+PoS( $w_{n-3}$ )+contains-?( $s$ )

Table 2: Exemplified features used for scoring linearizations of a word order domain (see Algorithm 3). Atomic features which represent properties of a node or a domain are conjoined into feature vectors of different lengths. Linearizations are scored based on bigrams, trigrams, and global sentence-level features.

## 5 Experiments

We conduct experiments on six European languages with varying degrees of word order restrictions: While English word order is very restrictive, Czech and Hungarian exhibit few word order constraints. Danish, Dutch, and German (so-called V2, i.e. verb-second, languages) show a relatively free word order that is however more restrictive than in Hungarian or Czech. The English and the Czech data are from the CoNLL 2009 Shared Task data sets (Hajič et al., 2009). The Danish and the Dutch data are from the CoNLL 2006 Shared Task data sets (Buchholz and Marsi, 2006). For Hungarian, we use the Hungarian Dependency Treebank (Vincze et al., 2010), and for German, we use a dependency conversion by Seeker and Kuhn (2012).

	# sent's	np sent's	np edges	np $\leq 3$ lifts
English	39,279	7.63 %	0.39%	98.39%
German	36,000	28.71%	2.34%	94.98%
Dutch	13,349	36.44%	5.42%	99.80%
Danish	5,190	15.62 %	1.00%	96.72%
Hungarian	61,034	15.81%	1.45%	99.82%
Czech	38,727	22.42%	1.86%	99.84%

Table 3: Size of training sets, percentage of non-projective (np) sentences and edges, percentage of np edges covered by 3 lifting steps.

Table 3 shows the sizes of the training corpora and the percentage of non-projective sentences and edges in the data. Note that the data sets for Dan-

ish and Dutch are quite small. English has the least percentage of non-projective edges. Czech, German, and Dutch show the highest percentage of non-projective edges. The last column shows the percentage of non-projective edges that can be made projective by at most 3 lifting steps.

### 5.1 Setup

In our two-stage approach, we first train the lifting classifier. The results for this classifier are reported in Section 5.2.

Second, we train the linearizer on the output of the lifting classifier. To assess the impact of the lifting technique on linearization, we built four systems on each language: **(a)** a linearizer trained on the original, non-lifted dependency structures (*No-lift*), two trained on the automatically lifted edges (comparing **(b)** the beam and **(c)** greedy decoding), **(d)** one trained on the oracle, i.e. gold-lifted structures, which gives us an upper bound for the lifting technique. The linearization results are reported in Section 5.3.

In this two-stage setup, we have the problem that, if we re-apply the lifting classifier on the data it was trained on, the input for the linearizer will be better during training than during testing. To provide realistic training data for the linearizer, we make a 10-fold cross-validation of the lifting classifier on the training set, and use this as training data for the linearizer. The lifting classifier that is applied to the test set is trained on the entire training set.

## 5.2 Lifting results

To evaluate the performance of the lifting classifier, we present precision, recall, and F-measure results for each language. We also compute the percentage of sentences that were handled perfectly by the lifting classifier. Precision and recall are defined the usual way in terms of true positives, false positives, and false negatives, where true positives are edges that should be lifted and were lifted correctly; false positives are edges that should not be lifted but were *and* edges that should be lifted and were lifted, but were reattached in the wrong place; false negatives are edges that should be lifted but were not.

The performance of both the greedy decoder and the bibeam decoder are shown in Table 4. The scores are taken on the cross-validation on the training set, as this provides more reliable figures. The scores are micro-averaged, i.e. all folds are concatenated and compared to the entire training set.

Although the major evaluation of the lifting is given by the performance of the linearizer, Table 4 gives us some clues about the lifting. We see that precision is generally much higher than recall. We believe this is related to the fact that some phenomena encoded by non-projective edges are more systematic and thus easier to learn than others (e. g. wh-extraction vs. relative clause extraposition). We also find that beam search consistently yields modest increases in performance.

	Greedy				Beam			
	P	R	F1	Perfect	P	R	F1	Perfect
Eng	77.31	50.45	61.05	95.76	78.85	50.63	61.66	95.83
Ger	72.33	63.59	67.68	81.91	72.05	64.41	68.02	81.97

Dan	85.90	58.55	69.64	92.76	85.90	58.55	69.64	92.74
Hun	72.60	61.61	66.66	88.46	73.06	64.77	68.67	88.73
Cze	77.79	55.00	64.44	86.28	77.31	55.68	64.74	86.33

Table 4: Precision, recall, F-measure and perfect projection results for the lifting classifier.

## 5.3 Linearization Results and Discussion

We evaluate the linearizer with standard metrics: n-gram overlap measures (BLEU, NIST), edit distance (Edit), and the proportion of exactly linearized sentences (Exact). As a means to assess the impact of lifting more precisely, we propose the word-based measure  $Exact_{lift}$  which only looks at the words with an incoming lifted edge. The  $Exact_{lift}$  score

then corresponds to the percentage of these words that has been realized in the exact same position as in the original sentence.

Lang $Lift$	BLEU	NIST	Edit	Exact	$Exact_{lift}$	$N_{lift}$
Eng $Nolift$	0.911	15.09	0.922	56.40	0.00	0
Eng $Greedy$	0.914	15.10	0.923	57.27	59.87	152
Eng $Beam$	0.916	15.11	0.925	58.48	62.82	156
Eng $Oracle$	0.923	15.14	0.928	60.73	70.42	240
Ger $Nolift$	0.792	13.76	0.844	40.4	0.00	0
Ger $Greedy$	0.811	13.86	0.864	42.9	55.21	480

Table 5: Performance of linearizers using different liftings,  $Exact_{lift}$  is the exact match for words with an incoming lifted edge,  $N_{lift}$  is the total number of lifted edges.

The results are presented in Table 5. On each language, the predicted liftings significantly improve on the non-lifted baseline (except the greedy decoding in English).<sup>6</sup> The differences between the beam and the greedy decoding are not significant. The scores on the oracle liftings suggest that the impact of lifting on linearization is heavily language-dependent: It is highest on the V2-languages, and somewhat smaller on English, Hungarian, and Czech. This is not surprising since the V2-languages (especially German and Dutch) have the highest proportion of non-projective edges and sentences (see Table 3). On the other hand, English has a very small number of non-projective edges, such that the BLEU score (which captures the n-gram level) reflects the improvement by only

<sup>6</sup>We used a t-test, with  $\alpha = 0.01$ .

a small increase. However, note that, on the sentence level, the percentage of exactly regenerated sentences increases by 2 points which suggests that a non-negligible amount of non-projective sentences can now be generated more fluently.

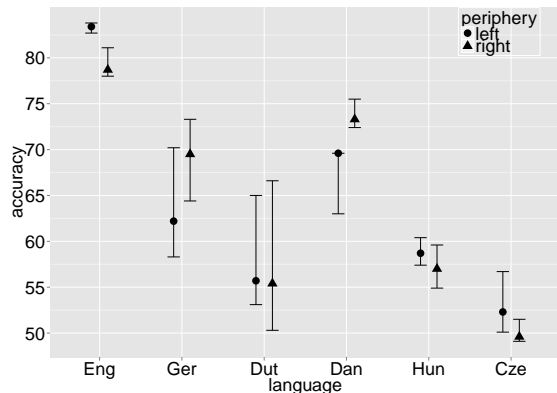

Figure 4: Accuracy for the linearization of the sentences' left and right periphery, the bars are upper and lower bounds of the non-lifted and the gold-lifted baseline.

The  $\text{Exact}_{\text{lift}}$  measure refines this picture: The linearization of the non-projective edges is relatively exact in English, and much less precise in Hungarian and Czech where  $\text{Exact}_{\text{lift}}$  is even low on the gold-lifted edges. The linearization quality is also quite moderate on Dutch where the lifting leads to considerable improvements. These tendencies point to some important underlying distinctions in the non-projective word order phenomena over which we are generalizing: In certain cases, the linearization seems to systematically follow from the fact that the edge has to be lifted, such as *wh*-extraction in English (Figure 1). In other cases, the non-projective linearization is just an alternative to other grammatical, but maybe less appropriate, realizations, such as the *prefield*-occupation in German (Figure 2).

Since a lot of non-projective word orders affect the clause-initial or clause-final position, we evaluate the exact match of the left periphery (first three words) and the right periphery (last three words) of the sentence. The accuracies obtained are plotted in Figure 4, where the lower and upper bars correspond to the lower and upper bound from the non-lifted and the gold-lifted baseline. It clearly emerges from this figure that the range of improvements obtainable from lifting is closely tied to the general

linearization quality, and also to word order properties of the languages. Thus, the range of sentences affected by the lifting is clearly largest for the V2-languages. The accuracies are high, but the ranges are small for English, whereas the accuracies are low and the ranges quite small for Czech and Hungarian.

System	BLEU	NIST
(Bohnet et al., 2011) (ranked 1st)	0.896	13.93
(Guo et al., 2011) (ranked 2nd)	0.862	13.68
Baseline-Non-Lifted + LM	0.896	13.94
Beam-Lifted + LM	0.901	13.96

Table 6: Results on the development set of the 2011 Shared Task on Surface Realisation data, (the test set was not officially released).

We also evaluated our linearizer on the data of 2011 Shared Task on Surface Realisation, which is based on the English CoNLL 2009 data (like our previous evaluations) but excludes information on morphological realization. For training and evaluation, we used the exact set up of the Shared Task. For the morphological realization, we used the morphological realizer of Bohnet et al. (2010) that predicts the word form using shortest edit scripts. For the language model (LM), we use a 5-gram model with Kneser-Ney (Kneser and Ney, 1995) smoothing derived from 11 million sentences of the Wikipedia.

In Table 6, we compare our two linearizers (with and without lifting) to the two top systems of the 2011 Shared Task on Surface Realisation, (Bohnet et al., 2011) and (Guo et al., 2011). Without the lifting, our system reaches a score comparable to the top-ranked system in the Shared Task. With the lifting, we get a small<sup>7</sup> but statistically significant improvement in BLEU such that our system reaches a higher score than the top ranked systems. This shows that the improvements we obtain from the lifting carry over to more complex generation tasks which include morphological realization.

#### 5.4 Human Evaluation

We have carried out a pilot human evaluation on the German data in order to see whether human judges prefer word orders obtained from the lifting-based

<sup>7</sup>Remember that English has the least percentage of non-projective edges in our data sets, which are however important to linearize correctly (see Figure 1).

linearizer. In particular, we wanted to check whether the lifting-based linearizer produces more natural word orders for sentences that had a non-projective tree in the corpus, and maybe less natural word orders on originally projective sentences. Therefore, we divided the evaluated items into originally projective and non-projective sentences.

We asked four annotators to judge 60 sentence pairs comparing the lifting-based against the non-lifted linearizer using the toolkit by Kow and Belz (2012). All annotators are students, two of them have a background in linguistics. The items were randomly sampled from the subset of the development set containing those sentences where the linearizers produced different surface realizations. The items are subdivided into 30 originally projective and 30 originally non-projective sentences.

For each item, we presented the original context sentence from the corpus and the pair of automatically produced linearizations for the current sentence. The annotators had to decide on two criteria: (i) which sentence do they prefer? (ii) how fluent is that sentence? In both cases, we used continuous sliders as rating tools, since humans seem to prefer them (Belz and Kow, 2011). For the first criterion, the slider positions were mapped to values from -50 (preference for left sentence) to 50 (preference for right sentence). If the slider position is zero, both sentences are equally preferred. For the second criterion, the slider positions were mapped to values from 0 (absolutely broken sentence) to 100 (perfectly fluent sentence).

Sentences	Scores	Equal	Lifted	Non-lifted
	% selected	44.58%	35.0%	20.42%
All	Fluency	56.14	75.77	72.78
	Preference	0	34.75	31.06
	% selected	29.63%	58.33%	12.04%
Non- Proj.	Fluency	43.06	76.27	68.85
	Preference	0	37.52	24.46
	% selected	56.82%	15.91%	27.27%
Proj.	Fluency	61.72	74.29	74.19
	Preference	0	26.43	33.44

Table 7: Results from human evaluation.

Table 7 presents the results averaged over all sentences, as well as for the subsets of non-projective and projective sentences. We report the percentage of items where the judges selected both, the lifted, or non-lifted sentence, alongside with the average flu-

ency score (0-100) and preference strength (0-50).

On the entire set of items, the judges selected both sentences in almost half of the cases. However, on the subset of non-projective sentences, the lifted version is clearly preferred and has a higher average fluency and preference strength. The percentage of zero preference items is much higher on the subset of projective sentences. Moreover, the average fluency of the zero preference items is remarkably higher on the projective sentences than on the non-projective subset. We conclude that humans have a strong preference for lifting-based linearizations on non-projective sentences. We attribute the low fluency score on the non-projective zero preference items to cases where the linearizer did not get a correct lifting or could not linearize the lifting correctly such that the lifted and the non-lifted version were not appropriate. On the other hand, incorrect liftings on projective sentences do not necessarily seem to result in deprecated linearizations, which leads to the high percentage of zero preferences with a good average fluency on this subset.

## 6 Conclusion

We have presented a novel technique to linearize sentences for a range of languages that exhibit non-projective word order. Our approach deals with non-projectivity by lifting edges in an unordered input tree which can then be linearized by a standard projective linearization algorithm.

We obtain significant improvements for the lifting-based linearization on English, German, Dutch, Danish, Czech and Hungarian, and show that lifting has the largest impact on the V2-languages. In a human evaluation carried out on German we also show that human judges clearly prefer lifting-based linearizations on originally non-projective sentences, and, on the other hand, that incorrect liftings do not necessarily result in bad realizations of the sentence.

## Acknowledgments

This work was funded by the Deutsche Forschungsgemeinschaft (DFG) via the SFB 732 "Incremental Specification in Context". We would also like to thank Anna Häty and our four annotators for their contribution to the human evaluation.

# Learning Syntactic Categories Using Paradigmatic Representations of Word Context

Mehmet Ali Yatbaz      Enis Sert      Deniz Yuret

{myatbaz,esert,dyuret}@ku.edu.tr

## Abstract

We investigate paradigmatic representations of word context in the domain of unsupervised syntactic category acquisition. Paradigmatic representations of word context are based on potential substitutes of a word in contrast to syntagmatic representations based on properties of neighboring words. We compare a bigram based baseline model with several paradigmatic models and demonstrate significant gains in accuracy. Our best model based on Euclidean co-occurrence embedding combines the paradigmatic context representation with morphological and orthographic features and achieves 80% many-to-one accuracy on a 45-tag 1M word corpus.

## 1 Introduction

Grammar rules apply not to individual words (e.g. dog, eat) but to syntactic categories of words (e.g. noun, verb). Thus constructing syntactic categories (also known as lexical or part-of-speech categories) is one of the fundamental problems in language acquisition.

Syntactic categories represent groups of words that can be substituted for one another without altering the grammaticality of a sentence. Linguists identify syntactic categories based on semantic, syntactic, and morphological properties of words. There is also evidence that children use prosodic and phonological features to bootstrap syntactic category acquisition (Ambridge and Lieven, 2011). However there is as yet no satisfactory computational model that can match human performance. Thus identify-

ing the best set of features and best learning algorithms for syntactic category acquisition is still an open problem.

Relationships between linguistic units can be classified into two types: syntagmatic (concerning positioning), and paradigmatic (concerning substitution). Syntagmatic relations determine which units can combine to create larger groups and paradigmatic relations determine which units can be substituted for one another. Figure 1 illustrates the paradigmatic vs syntagmatic axes for words in a simple sentence and their possible substitutes.

In this study, we represent the paradigmatic axis directly by building *substitute vectors* for each word position in the text. The dimensions of a substitute vector represent words in the vocabulary, and the magnitudes represent the probability of occurrence in the given position. Note that the substitute vector for a word position (e.g. the second word in Fig. 1) is a function of the context only (i.e. “the ... cried”), and does not depend on the word that does actually appear there (i.e. “man”). Thus substi-

Figure 1: Syntagmatic vs. paradigmatic axes for words in a simple sentence (Chandler, 2007).

tute vectors represent *individual word contexts*, not word types. We refer to the use of features based on substitute vectors as *paradigmatic representations of word context*.

Our preliminary experiments indicated that using context information alone without the identity or the features of the target word (e.g. using dimensionality reduction and clustering on substitute vectors) has limited success and modeling the co-occurrence of word and context types is essential for inducing syntactic categories. In the models presented in this paper, we combine paradigmatic representations of word context with features of co-occurring words within the co-occurrence data embedding (CODE) framework (Globerson et al., 2007; Maron et al., 2010). The resulting embeddings for word types are split into 45 clusters using k-means and the clusters are compared to the 45 gold tags in the 1M word Penn Treebank Wall Street Journal corpus (Marcus et al., 1999). We obtain many-to-one accuracies up to .7680 using only distributional information (the identity of the word and a representation of its context) and .8023 using morphological and orthographic features of words improving the state-of-the-art in unsupervised part-of-speech tagging performance.

The high probability substitutes reflect both semantic and syntactic properties of the context as seen in the example below (the numbers in parentheses give substitute probabilities):

*“Pierre Vinken, 61 years old, will join the board as a nonexecutive director Nov. 29.”*

**the:** its (.9011), the (.0981), a (.0006), . . .

**board:** board (.4288), company (.2584), firm (.2024), bank (.0731), . . .

Top substitutes for the word “the” consist of words that can act as determiners. Top substitutes for “board” are not only nouns, but specifically nouns compatible with the semantic context.

This example illustrates two concerns inherent in all distributional methods: (i) words that are generally substitutable like “the” and “its” are placed in separate categories (DT and PRP\$) by the gold standard, (ii) words that are generally not substitutable like “do” and “put” are placed in the same category

(VB). Freudenthal et al. (2005) point out that categories with unsubstitutable words fail the standard linguistic definition of a syntactic category and children do not seem to make errors of substituting such words in utterances (e.g. “*What do you want?*” vs. \**What put you want?*”). Whether gold standard part-of-speech tags or distributional categories are better suited to applications like parsing or machine translation can be best decided using extrinsic evaluation. However in this study we follow previous work and evaluate our results by comparing them to gold standard part-of-speech tags.

Section 2 gives a detailed review of related work. Section 3 describes the dataset and the construction of the substitute vectors. Section 4 describes co-occurrence data embedding, the learning algorithm used in our experiments. Section 5 describes our experiments and compares our results with previous work. Section 6 gives a brief error analysis and Section 7 summarizes our contributions. All the data and the code to replicate the results given in this paper is available from the authors’ website at <http://goo.gl/RoqEh>.

## 2 Related Work

There are several good reviews of algorithms for unsupervised part-of-speech induction (Christodoulopoulos et al., 2010; Gao and Johnson, 2008) and models of syntactic category acquisition (Ambridge and Lieven, 2011).

This work is to be distinguished from supervised part-of-speech disambiguation systems, which use labeled training data (Church, 1988), unsupervised disambiguation systems, which use a dictionary of possible tags for each word (Merialdo, 1994), or prototype driven systems which use a small set of prototypes for each class (Haghighi and Klein, 2006). The problem of induction is important for studying under-resourced languages that lack labeled corpora and high quality dictionaries. It is also essential in modeling child language acquisition because every child manages to induce syntactic categories without access to labeled sentences, labeled prototypes, or dictionary constraints.

Models of unsupervised part-of-speech induction fall into two broad groups based on the information they utilize. Distributional models only use word

types and their context statistics. Word-feature models incorporate additional morphological and orthographic features.

## 2.1 Distributional models

Distributional models can be further categorized into three subgroups based on the learning algorithm. The first subgroup represents each word type with its context vector and clusters these vectors accordingly (Schütze, 1995). Work in modeling child syntactic category acquisition has generally followed this clustering approach (Redington et al., 1998; Mintz, 2003). The second subgroup consists of probabilistic models based on the Hidden Markov Model (HMM) framework (Brown et al., 1992). A third group of algorithms constructs a low dimensional representation of the data that represents the empirical co-occurrence statistics of word types (Globerston et al., 2007), which is covered in more detail in Section 4.

**Clustering:** Clustering based methods represent context using neighboring words, typically a single word on the left and a single word on the right called a “frame” (e.g., **the dog is; the cat is**). They cluster word types rather than word tokens based on the frames they occupy thus employing one-tag-per-word assumption from the beginning (with the exception of some methods in (Schütze, 1995)). They may suffer from data sparsity caused by infrequent words and infrequent contexts. The solutions suggested either restrict the set of words and set of contexts to be clustered to the most frequently observed, or use dimensionality reduction. Redington et al. (1998) define context similarity based on the number of common frames bypassing the data sparsity problem but achieve mediocre results. Mintz (2003) only uses the most frequent 45 frames and Biemann (2006) clusters the most frequent 10,000 words using contexts formed from the most frequent 150-200 words. Schütze (1995) and Lamar et al. (2010b) employ SVD to enhance similarity between less frequently observed words and contexts. Lamar et al. (2010a) represent each context by the currently assigned left and right tag (which eliminates data sparsity) and cluster word types using a soft k-means style iterative algorithm. They report the best clustering result to date of .708 many-to-one accuracy

on a 45-tag 1M word corpus.

**HMMs:** The prototypical bitag HMM model maximizes the likelihood of the corpus  $w_1 \dots w_n$  expressed as  $P(w_1|c_1) \prod_{i=2}^n P(w_i|c_i)P(c_i|c_{i-1})$  where  $w_i$  are the word tokens and  $c_i$  are their (hidden) tags. One problem with such a model is its tendency to distribute probabilities equally and the resulting inability to model highly skewed word-tag distributions observed in hand-labeled data (Johnson, 2007). To favor sparse word-tag distributions one can enforce a strict one-tag-per-word solution (Brown et al., 1992; Clark, 2003), use sparse priors in a Bayesian setting (Goldwater and Griffiths, 2007; Johnson, 2007), or use posterior regularization (Ganchev et al., 2010). Each of these techniques provide significant improvements over the standard HMM model: for example Gao and Johnson (2008) show that sparse priors can gain from 4% (.62 to .66 with a 1M word corpus) in cross-validated many-to-one accuracy. However Christodoulopoulos et al. (2010) show that the older one-tag-per-word models such as (Brown et al., 1992) outperform the more sophisticated sparse prior and posterior regularization methods both in speed and accuracy (the Brown model gets .68 many-to-one accuracy with a 1M word corpus). Given that close to 95% of the word occurrences in human labeled data are tagged with their most frequent part of speech (Lee et al., 2010), this is probably not surprising; one-tag-per-word is a fairly good first approximation for induction.

## 2.2 Word-feature models

One problem with the algorithms in the previous section is the poverty of their input features. Of the syntactic, semantic, and morphological information linguists claim underlie syntactic categories, context vectors or bitag HMMs only represent limited syntactic information in their input. Experiments incorporating morphological and orthographic features into HMM based models demonstrate significant improvements. (Clark, 2003; Berg-Kirkpatrick and Klein, 2010; Blunsom and Cohn, 2011) incorporate similar orthographic features and report improvements of 3, 7, and 10% respectively over the baseline Brown model. Christodoulopoulos et al. (2010) use prototype based features as described in (Haghighi and Klein, 2006) with automatically in-

duced prototypes and report an 8% improvement over the baseline Brown model. Christodoulopoulos et al. (2011) define a type-based Bayesian multinomial mixture model in which each word instance is generated from the corresponding word type mixture component and word contexts are represented as features. They achieve a .728 MTO score by extending their model with additional morphological and alignment features gathered from parallel corpora. To our knowledge, nobody has yet tried to incorporate phonological or prosodic features in a computational model for syntactic category acquisition.

### 2.3 Paradigmatic representations

Sahlgren (2006) gives a detailed analysis of paradigmatic and syntagmatic relations in the context of word-space models used to represent word meaning. Sahlgren’s paradigmatic model represents word types using co-occurrence counts of their frequent neighbors, in contrast to his syntagmatic model that represents word types using counts of contexts (documents, sentences) they occur in. Our substitute vectors do not represent word types at all, but *contexts of word tokens* using probabilities of likely substitutes. Sahlgren finds that in word-spaces built by frequent neighbor vectors, more nearest neighbors share the same part-of-speech compared to word-spaces built by context vectors. We find that representing the paradigmatic axis more directly using substitute vectors rather than frequent neighbors improve part-of-speech induction.

Our paradigmatic representation is also related to the second order co-occurrences used in (Schütze, 1995). Schütze concatenates the left and right context vectors for the target word type with the left context vector of the right neighbor and the right context vector of the left neighbor. The vectors from the neighbors include potential substitutes. Our method improves on his foundation by using a 4-gram language model rather than bigram statistics, using the whole 78,498 word vocabulary rather than the most frequent 250 words. More importantly, rather than simply concatenating vectors that represent the target word with vectors that represent the context we use S-CODE to model their co-occurrence statistics.

### 2.4 Evaluation

We report many-to-one and V-measure scores for our experiments as suggested in (Christodoulopoulos et al., 2010). The many-to-one (MTO) evaluation maps each cluster to its most frequent gold tag and reports the percentage of correctly tagged instances. The MTO score naturally gets higher with increasing number of clusters but it is an intuitive metric when comparing results with the same number of clusters. The V-measure (VM) (Rosenberg and Hirschberg, 2007) is an information theoretic metric that reports the harmonic mean of homogeneity (each cluster should contain only instances of a single class) and completeness (all instances of a class should be members of the same cluster). In Section 6 we argue that homogeneity is perhaps more important in part-of-speech induction and suggest MTO with a fixed number of clusters as a more intuitive metric.

## 3 Substitute Vectors

In this study, we predict the part of speech of a word in a given context based on its substitute vector. The dimensions of the substitute vector represent words in the vocabulary, and the entries in the substitute vector represent the probability of those words being used in the given context. Note that the substitute vector is a function of the context only and is indifferent to the target word. This section details the choice of the data set, the vocabulary and the estimation of substitute vector probabilities.

The Wall Street Journal Section of the Penn Treebank (Marcus et al., 1999) was used as the test corpus (1,173,766 tokens, 49,206 types). The treebank uses 45 part-of-speech tags which is the set we used as the gold standard for comparison in our experiments. To compute substitute probabilities we trained a language model using approximately 126 million tokens of Wall Street Journal data (1987-1994) extracted from CSR-III Text (Graff et al., 1995) (we excluded the test corpus). We used SRILM (Stolcke, 2002) to build a 4-gram language model with Kneser-Ney discounting. Words that were observed less than 20 times in the language model training data were replaced by UNK tags, which gave us a vocabulary size of 78,498. The perplexity of the 4-gram language model on the test cor-

pus is 96.

It is best to use both left and right context when estimating the probabilities for potential lexical substitutes. For example, in “*He lived in San Francisco suburbs.*”, the token *San* would be difficult to guess from the left context but it is almost certain looking at the right context. We define  $c_w$  as the  $2n - 1$  word window centered around the target word position:  $w_{-n+1} \dots w_0 \dots w_{n-1}$  ( $n = 4$  is the  $n$ -gram order). The probability of a substitute word  $w$  in a given context  $c_w$  can be estimated as:

$$\begin{aligned} P(w_0 = w | c_w) &\propto P(w_{-n+1} \dots w_0 \dots w_{n-1}) (1) \\ &= P(w_{-n+1}) P(w_{-n+2} | w_{-n+1}) \\ &\quad \dots P(w_{n-1} | w_{-n+1}^{n-2}) \quad (2) \\ &\approx P(w_0 | w_{-n+1}^{-1}) P(w_1 | w_{-n+2}^0) \\ &\quad \dots P(w_{n-1} | w_0^{n-2}) \quad (3) \end{aligned}$$

where  $w_i^j$  represents the sequence of words  $w_i w_{i+1} \dots w_j$ . In Equation 1,  $P(w | c_w)$  is proportional to  $P(w_{-n+1} \dots w_0 \dots w_{n+1})$  because the words of the context are fixed. Terms without  $w_0$  are identical for each substitute in Equation 2 therefore they have been dropped in Equation 3. Finally, because of the Markov property of  $n$ -gram language model, only the closest  $n - 1$  words are used in the experiments.

Near the sentence boundaries the appropriate terms were truncated in Equation 3. Specifically, at the beginning of the sentence shorter  $n$ -gram contexts were used and at the end of the sentence terms beyond the end-of-sentence token were dropped.

For computational efficiency only the top 100 substitutes and their unnormalized probabilities were computed for each of the 1,173,766 positions in the test set<sup>1</sup>. The probability vectors for each position were normalized to add up to 1.0 giving us the final substitute vectors used in the rest of this study.

<sup>1</sup>The substitutes with unnormalized log probabilities can be downloaded from <http://goo.gl/jzKH0>. For a description of the FASTSUBS algorithm used to generate the substitutes please see <http://arxiv.org/abs/1205.5407v1>. FASTSUBS accomplishes this task in about 5 hours, a naive algorithm that looks at the whole vocabulary would take more than 6 days on a typical 2012 workstation.

## 4 Co-occurrence Data Embedding

The general strategy we follow for unsupervised syntactic category acquisition is to combine features of the context with the identity and features of the target word. Our preliminary experiments indicated that using the context information alone (e.g. clustering substitute vectors) without the target word identity and features had limited success.<sup>2</sup> It is the co-occurrence of a target word with a particular type of context that best predicts the syntactic category. In this section we review the unsupervised methods we used to model co-occurrence statistics: the Co-occurrence Data Embedding (CODE) method (Globerson et al., 2007) and its spherical extension (S-CODE) introduced by (Maron et al., 2010).

Let  $X$  and  $Y$  be two categorical variables with finite cardinalities  $|X|$  and  $|Y|$ . We observe a set of pairs  $\{x_i, y_i\}_{i=1}^n$  drawn IID from the joint distribution of  $X$  and  $Y$ . The basic idea behind CODE and related methods is to represent (embed) each value of  $X$  and each value of  $Y$  as points in a common low dimensional Euclidean space  $\mathbf{R}^d$  such that values that frequently co-occur lie close to each other. There are several ways to formalize the relationship between the distances and co-occurrence statistics, in this paper we use the following:

$$p(x, y) = \frac{1}{Z} \bar{p}(x) \bar{p}(y) e^{-d_{x,y}^2} \quad (4)$$

where  $d_{x,y}^2$  is the squared distance between the embeddings of  $x$  and  $y$ ,  $\bar{p}(x)$  and  $\bar{p}(y)$  are empirical probabilities, and  $Z = \sum_{x,y} \bar{p}(x) \bar{p}(y) e^{-d_{x,y}^2}$  is a normalization term. If we use the notation  $\phi_x$  for the point corresponding to  $x$  and  $\psi_y$  for the point corresponding to  $y$  then  $d_{x,y}^2 = \|\phi_x - \psi_y\|^2$ . The log-likelihood of a given embedding  $\ell(\phi, \psi)$  can be

<sup>2</sup>A 10-nearest-neighbor supervised baseline using cosine distance between substitute vectors gives .7213 accuracy. Clustering substitute vectors using various distance metrics and dimensionality reduction methods give results inferior to this upper bound.

expressed as:

$$\begin{aligned} \ell(\phi, \psi) &= \sum_{x,y} \bar{p}(x, y) \log p(x, y) & (5) \\ &= \sum_{x,y} \bar{p}(x, y) (-\log Z + \log \bar{p}(x) \bar{p}(y) - d_{x,y}^2) \\ &= -\log Z + \text{const} - \sum_{x,y} \bar{p}(x, y) d_{x,y}^2 \end{aligned}$$

The likelihood is not convex in  $\phi$  and  $\psi$ . We use gradient ascent to find an approximate solution for a set of  $\phi_x, \psi_y$  that maximize the likelihood. The gradient of the  $d_{x,y}^2$  term pulls neighbors closer in proportion to the empirical joint probability:

$$\frac{\partial}{\partial \phi_x} \sum_{x,y} -\bar{p}(x, y) d_{x,y}^2 = \sum_y 2\bar{p}(x, y) (\psi_y - \phi_x) \quad (6)$$

The gradient of the  $Z$  term pushes neighbors apart in proportion to the estimated joint probability:

$$\frac{\partial}{\partial \phi_x} (-\log Z) = \sum_y 2p(x, y) (\phi_x - \psi_y) \quad (7)$$

Thus the net effect is to pull pairs together if their estimated probability is less than the empirical probability and to push them apart otherwise. The gradients with respect to  $\psi_y$  are similar.

S-CODE (Maron et al., 2010) additionally restricts all  $\phi_x$  and  $\psi_y$  to lie on the unit sphere. With this restriction,  $Z$  stays around a fixed value during gradient ascent. This allows S-CODE to substitute an approximate constant  $\tilde{Z}$  in gradient calculations for the real  $Z$  for computational efficiency. In our experiments, we used S-CODE with its sampling based stochastic gradient ascent algorithm and smoothly decreasing learning rate.

## 5 Experiments

In this section we present experiments that evaluate substitute vectors as representations of word context within the S-CODE framework. Section 5.1 replicates the bigram based S-CODE results from (Maron et al., 2010) as a baseline. The S-CODE algorithm works with discrete inputs. The substitute vectors as described in Section 3 are high dimensional and continuous. We experimented with two approaches to use substitute vectors in a discrete setting. Section 5.2 presents an algorithm that

partitions the high dimensional space of substitute vectors into small neighborhoods and uses the partition id as a discrete context representation. Section 5.3 presents an even simpler model which pairs each word with a random substitute. When the left-word – right-word pairs used in the bigram model are replaced with word – partition-id or word – substitute pairs we see significant gains in accuracy. These results support our running hypothesis that paradigmatic features, i.e. potential substitutes of a word, are better determiners of syntactic category compared to left and right neighbors. Section 5.4 explores morphologic and orthographic features as additional sources of information and its results improve the state-of-the-art in the field of unsupervised syntactic category acquisition.

Each experiment was repeated 10 times with different random seeds and the results are reported with standard errors in parentheses or error bars in graphs. Table 1 summarizes all the results reported in this paper and the ones we cite from the literature.

### 5.1 Bigram model

In (Maron et al., 2010) adjacent word pairs (bigrams) in the corpus are fed into the S-CODE algorithm as  $X, Y$  samples. The algorithm uses stochastic gradient ascent to find the  $\phi_x, \psi_y$  embeddings for left and right words in these bigrams on a single 25-dimensional sphere. At the end each word  $w$  in the vocabulary ends up with two points on the sphere, a  $\phi_w$  point representing the behavior of  $w$  as the left word of a bigram and a  $\psi_w$  point representing it as the right word. The two vectors for  $w$  are concatenated to create a 50-dimensional representation at the end. These 50-dimensional vectors are clustered using an instance weighted k-means algorithm and the resulting groups are compared to the correct part-of-speech tags. Maron et al. (2010) report many-to-one scores of .6880 (.0016) for 45 clusters and .7150 (.0060) for 50 clusters (on the full PTB45 tag-set). If only  $\phi_w$  vectors are clustered without concatenation we found the performance drops significantly to about .62.

To make a meaningful comparison we re-ran the bigram experiments using our default settings and obtained a many-to-one score of .7314 (.0096) and the V-measure is .6558 (.0052) for 45 clusters. The following default settings were used: (i) each word

Distributional Models	MTO	VM	Models with Additional Features	MTO	VM
(Lamar et al., 2010a)	.708	-	(Clark, 2003)*	.712	.655
(Brown et al., 1992)*	.678	.630	(Christodoulopoulos et al., 2011)	.728	.661
(Goldwater et al., 2007)	.632	.562	(Berg-Kirkpatrick and Klein, 2010)	.755	-
(Ganchev et al., 2010)*	.625	.548	(Christodoulopoulos et al., 2010)	.761	.688
(Maron et al., 2010)	.688 (.0016)	-	(Blunsom and Cohn, 2011)	.775	.697
Bigrams (Sec. 5.1)	.7314 (.0096)	.6558 (.0052)	Substitutes and Features (Sec. 5.4)	.8023 (.0070)	.7207 (.0041)
Partitions (Sec. 5.2)	.7554 (.0055)	.6703 (.0037)			
Substitutes (Sec. 5.3)	.7680 (.0038)	.6822 (.0029)			

Table 1: Summary of results in terms of the MTO and VM scores. Standard errors are given in parentheses when available. Starred entries have been reported in the review paper (Christodoulopoulos et al., 2010). Distributional models use only the identity of the target word and its context. The models on the right incorporate orthographic and morphological features.

was kept with its original capitalization, (ii) the learning rate parameters were adjusted to  $\varphi_0 = 50$ ,  $\eta_0 = 0.2$  for faster convergence in log likelihood, (iii) the number of s-code iterations were increased from 12 to 50 million, (iv) k-means initialization was improved using (Arthur and Vassilvitskii, 2007), and (v) the number of k-means restarts were increased to 128 to improve clustering and reduce variance.

## 5.2 Random partitions

Instead of using left-word – right-word pairs as inputs to S-CODE we wanted to pair each word with a paradigmatic representation of its context to get a direct comparison of the two context representations. To obtain a discrete representation of the context, the random-partitions algorithm first designates a random subset of substitute vectors as centroids to partition the space, and then associates each context with the partition defined by the closest centroid in cosine distance. Each partition thus defined gets a unique id, and word ( $X$ ) – partition-id ( $Y$ ) pairs are given to S-CODE as input. The algorithm cycles through the data until we get approximately 50 million updates. The resulting  $\phi_x$  vectors are clustered using the k-means algorithm (no vector concatenation is necessary). Using default settings (64K random partitions, 25 s-code dimensions,  $Z = 0.166$ ) the many-to-one accuracy is .7554 (.0055) and the V-measure is .6703 (.0037).

To analyze the sensitivity of this result to our specific parameter settings we ran a number of experiments where each parameter was varied over a range of values.

Figure 2 gives results where the number of initial

Figure 2: MTO is not sensitive to the number of partitions used to discretize the substitute vector space within our experimental range.

random partitions is varied over a large range and shows the results to be fairly stable across two orders of magnitude.

Figure 3 shows that at least 10 embedding dimensions are necessary to get within 1% of the best result, but there is no significant gain from using more than 25 dimensions.

Figure 4 shows that the constant  $\tilde{Z}$  approximation can be varied within two orders of magnitude without a significant performance drop in the many-to-one score. For uniformly distributed points on a 25 dimensional sphere, the expected  $Z \approx 0.146$ . In the experiments where we tested we found the real  $Z$  always to be in the 0.140-0.170 range. When the constant  $\tilde{Z}$  estimate is too small the attraction in Eq. 6 dominates the repulsion in Eq. 7 and all points tend to converge to the same location. When  $\tilde{Z}$  is too high, it prevents meaningful clusters from coalesc-

Figure 3: MTO falls sharply for less than 10 S-CODE dimensions, but more than 25 do not help.

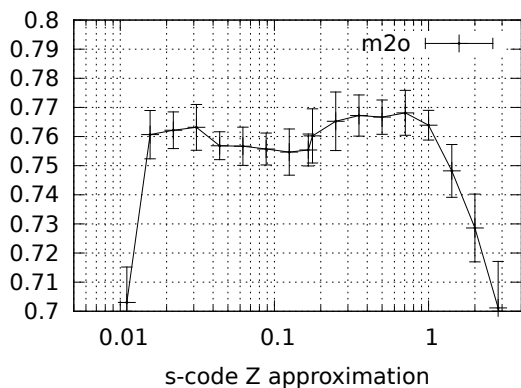

Figure 4: MTO is fairly stable as long as the  $\tilde{Z}$  constant is within an order of magnitude of the real  $Z$  value.

ing.

We find the random partition algorithm to be fairly robust to different parameter settings and the resulting many-to-one score significantly better than the bigram baseline.

### 5.3 Random substitutes

Another way to use substitute vectors in a discrete setting is simply to sample individual substitute words from them. The random-substitutes algorithm cycles through the test data and pairs each word with a random substitute picked from the pre-computed substitute vectors (see Section 3). We ran the random-substitutes algorithm to generate 14 million word ( $X$ ) – random-substitute ( $Y$ ) pairs (12 substitutes for each token) as input to S-CODE. Clustering the resulting  $\phi_x$  vectors yields a many-to-one score of .7680 (.0038) and a V-measure of

.6822 (.0029).

This result is close to the previous result by the random-partition algorithm, .7554 (.0055), demonstrating that two very different discrete representations of context based on paradigmatic features give consistent results. Both results are significantly above the bigram baseline, .7314 (.0096). Figure 5 illustrates that the random-substitute result is fairly robust as long as the training algorithm can observe more than a few random substitutes per word.

Figure 5: MTO is not sensitive to the number of random substitutes sampled per word token.

### 5.4 Morphological and orthographic features

Clark (2003) demonstrates that using morphological and orthographic features significantly improves part-of-speech induction with an HMM based model. Section 2 describes a number other approaches that show similar improvements. This section describes one way to integrate additional features to the random-substitute model.

The orthographic features we used are similar to the ones in (Berg-Kirkpatrick et al., 2010) with small modifications:

- Initial-Capital: this feature is generated for capitalized words with the exception of sentence initial words.
- Number: this feature is generated when the token starts with a digit.
- Contains-Hyphen: this feature is generated for lowercase words with an internal hyphen.

- Initial-Apostrophe: this feature is generated for tokens that start with an apostrophe.

We generated morphological features using the unsupervised algorithm Morfessor (Creutz and Lagus, 2005). Morfessor was trained on the WSJ section of the Penn Treebank using default settings, and a perplexity threshold of 300. The program induced 5 suffix types that are present in a total of 10,484 word types. These suffixes were input to S-CODE as morphological features whenever the associated word types were sampled.

In order to incorporate morphological and orthographic features into S-CODE we modified its input. For each word – random-substitute pair generated as in the previous section, we added word – feature pairs to the input for each morphological and orthographic feature of the word. Words on average have 0.25 features associated with them. This increased the number of pairs input to S-CODE from 14.1 million (12 substitutes per word) to 17.7 million (additional 0.25 features on average for each of the 14.1 million words).

Using similar training settings as the previous section, the addition of morphological and orthographic features increased the many-to-one score of the random-substitute model to .8023 (.0070) and V-measure to .7207 (.0041). Both these results improve the state-of-the-art in part-of-speech induction significantly as seen in Table 1.

## 6 Error Analysis

Figure 6 is the Hinton diagram showing the relationship between the most frequent tags and clusters from the experiment in Section 5.4. In general the errors seem to be the lack of completeness (multiple large entries in a row), rather than lack of homogeneity (multiple large entries in a column). The algorithm tends to split large word classes into several clusters. Some examples are:

- Titles like Mr., Mrs., and Dr. are split from the rest of the proper nouns in cluster (39).
- Auxiliary verbs (10) and the verb “say” (22) have been split from the general verb clusters (12) and (7).

- Determiners “the” (40), “a” (15), and capitalized “The”, “A” (6) have been split into their own clusters.
- Prepositions “of” (19), and “by”, “at” (17) have been split from the general preposition cluster (8).

Nevertheless there are some homogeneity errors as well:

- The adjective cluster (5) also has some noun members probably due to the difficulty of separating noun-noun compounds from adjective modification.
- Cluster (6) contains capitalized words that span a number of categories.

Most closed-class items are cleanly separated into their own clusters as seen in the lower right hand corner of the diagram. The completeness errors are not surprising given that the words that have been split are not generally substitutable with the other members of their Penn Treebank category. Thus it can be argued that metrics that emphasize homogeneity such as MTO are more appropriate in this context than metrics that average homogeneity and completeness such as VM as long as the number of clusters is controlled.

## 7 Contributions

Our main contributions can be summarized as follows:

- We introduced substitute vectors as paradigmatic representations of word context and demonstrated their use in syntactic category acquisition.
- We demonstrated that using paradigmatic representations of word context and modeling co-occurrences of word and context types with the S-CODE learning framework give superior results when compared to a baseline bigram model.
- We extended the S-CODE framework to incorporate morphological and orthographic features and improved the state-of-the-art in unsupervised part-of-speech induction to 80% many-to-one accuracy.

Figure 6: Hinton diagram comparing most frequent tags and clusters.

- All our code and data, including the substitute vectors for the one million word Penn Treebank Wall Street Journal dataset, is available at the authors' website at <http://goo.gl/RoqEh>.

## Abstract

We apply two new automated semantic evaluations to three distinct latent topic models. Both metrics have been shown to align with human evaluations and provide a balance between internal measures of information gain and comparisons to human ratings of coherent topics. We improve upon the measures by introducing new aggregate measures that allows for comparing complete topic models. We further compare the automated measures to other metrics for topic models, comparison to manually crafted semantic tests and document classification. Our experiments reveal that LDA and LSA each have different strengths; LDA best learns descriptive topics while LSA is best at creating a compact semantic representation of documents and words in a corpus.

## 1 Introduction

Topic models learn bags of related words from large corpora without any supervision. Based on the words used within a document, they mine topic level relations by assuming that a single document covers a small set of concise topics. Once learned, these topics often correlate well with human concepts. For example, one model might produce topics that cover ideas such as government affairs, sports, and movies. With these unsupervised methods, we can extract useful semantic information in a variety of tasks that depend on identifying unique topics or concepts, such as distributional semantics (Jurgens and Stevens, 2010), word sense induction (Van de Cruys and Apidianaki, 2011; Brody and Lapata, 2009), and information retrieval (Andrzejewski and Buttler, 2011).

When using a topic model, we are primarily concerned with the degree to which the learned topics match human judgments and help us differentiate between ideas. But until recently, the evaluation of these models has been ad hoc and application specific. Evaluations have ranged from fully automated intrinsic evaluations to manually crafted extrinsic evaluations. Previous extrinsic evaluations have used the learned topics to compactly represent a small fixed vocabulary and compared this distributional space to human judgments of similarity (Jurgens and Stevens, 2010). But these evaluations are hand constructed and often costly to perform for domain-specific topics. Conversely, intrinsic measures have evaluated the amount of information encoded by the topics, where perplexity is one common example (Wallach et al., 2009), however, Chang et al. (2009) found that these intrinsic measures do not always correlate with semantically interpretable topics. Furthermore, few evaluations have used the same metrics to compare distinct approaches such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), Latent Semantic Analysis (LSA) (Landauer and Dutnais, 1997), and Non-negative Matrix Factorization (NMF) (Lee and Seung, 2000). This has made it difficult to know which method is most useful for a given application, or in terms of extracting useful topics.

We now provide a comprehensive and automated evaluation of these three distinct models (LDA, LSA, NMF), for automatically learning semantic topics. While these models have seen significant improvements, they still represent the core differences between each approach to modeling topics. For our evaluation, we use two recent automated coherence measures (Mimno et al., 2011; Newman et al., 2010)

originally designed for LDA that bridge the gap between comparisons to human judgments and intrinsic measures such as perplexity. We consider several key questions:

1. How many topics should be learned?
2. How many learned topics are useful?
3. How do these topics relate to often used semantic tests?
4. How well do these topics identify similar documents?

We begin by summarizing the three topic models and highlighting their key differences. We then describe the two metrics. Afterwards, we focus on a series of experiments that address our four key questions and finally conclude with some overall remarks.

## 2 Topic Models

We evaluate three latent factor models that have seen widespread usage:

1. Latent Dirichlet Allocation
2. Latent Semantic Analysis with Singular Value Decomposition
3. Latent Semantic Analysis with Non-negative Matrix Factorization

Each of these models were designed with different goals and are supported by different statistical theories. We consider both LSA models as topic models as they have been used in a variety of similar contexts such as distributional similarity (Jurgens and Stevens, 2010) and word sense induction (Van de Cruys and Apidianaki, 2011; Brody and Lapata, 2009). We evaluate these distinct models on two shared tasks (1) grouping together similar words while separating unrelated words and (2) distinguishing between documents focusing on different concepts.

We distill the different models into a shared representation consisting of two sets of learned relations: how words interact with topics and how topics interact with documents. For a corpus with  $\mathcal{D}$  documents and  $\mathcal{V}$  words, we denote these relations in terms of  $\mathcal{T}$  topics as

- (1) a  $\mathcal{V} \times \mathcal{T}$  matrix,  $W$ , that indicates the strength each word has in each topic, and
- (2) a  $\mathcal{T} \times \mathcal{D}$  matrix,  $H$ , that indicates the strength each topic has in each document.

$\mathcal{T}$  serves as a common parameter to each model.

### 2.1 Latent Dirichlet Allocation

Latent Dirichlet Allocation (Blei et al., 2003) learns the relationships between words, topics, and documents by assuming documents are generated by a particular probabilistic model. It first assumes that there are a fixed set of topics,  $\mathcal{T}$  used throughout the corpus, and each topic  $z$  is associated with a multinomial distribution over the vocabulary  $\Phi_z$ , which is drawn from a Dirichlet prior  $Dir(\beta)$ . A given document  $D_i$  is then generated by the following process

1. Choose  $\Theta_i \sim Dir(\alpha)$ , a topic distribution for  $D_i$
2. For each word  $w_j \in D_i$ :
  - (a) Select a topic  $z_j \sim \Theta_i$
  - (b) Select the word  $w_j \sim \Phi_{z_j}$

In this model, the  $\Theta$  distributions represent the probability of each topic appearing in each document and the  $\Phi$  distributions represent the probability of words being used for each topic. These two sets of distributions correspond to our  $H$  and  $W$  matrices, respectively. The process above defines a generative model; given the observed corpus, we use collapsed Gibbs sampling implementation found in Mallet<sup>1</sup> to infer the values of the latent variables  $\Phi$  and  $\Theta$  (Griffiths and Steyvers, 2004). The model relies only on two additional hyper parameters,  $\alpha$  and  $\beta$ , that guide the distributions.

### 2.2 Latent Semantic Analysis

Latent Semantic Analysis (Landauer and Dutnais, 1997; Landauer et al., 1998) learns topics by first forming a traditional term by document matrix used in information retrieval and then smoothing the counts to enhance the weight of informative words. Based on the original LSA model, we use the Log-Entropy transform. LSA then decomposes this smoothed, term by document matrix in order to generalize observed relations between words and documents. For both LSA models, we used implementations found in the S-Space package.<sup>2</sup>

Traditionally, LSA has used the Singular Value Decomposition, but we also consider Non-negative Matrix Factorization as we've seen NMF applied in similar situations (Pauca et al., 2004) and others

Table 1: Top 10 words from several high and low quality topics when ordered by the UCI Coherence Measure. Topic labels were chosen in an ad hoc manner only to briefly summarize the topic’s focus.

have found a connection between NMF and Probabilistic Latent Semantic Analysis (Ding et al., 2008), an extension to LSA. We later refer to these two LSA models simply as SVD and NMF to emphasize the difference in factorization method.

**Singular Value Decomposition** decomposes  $M$  into three smaller matrices

$$M = U\Sigma V^T$$

and minimizes Frobenius norm of  $M$ ’s reconstruction error with the constraint that the rows of  $U$  and  $V$  are orthonormal eigenvectors. Interestingly, the decomposition is agnostic to the number of desired dimensions. Instead, the rows and columns in  $U$  and  $V^T$  are ordered based on their descriptive power, i.e. how well they remove noise, which is encoded by the diagonal singular value matrix  $\Sigma$ . As such, reduction is done by retaining the first  $\mathcal{T}$  rows and columns from  $U$  and  $V^T$ . For our generalization, we use  $W = U\Sigma$  and  $H = \Sigma V^T$ . We note that values in  $U$  and  $V^T$  can be both negative and positive, preventing a straightforward interpretation as unnormalized probabilities

**Non-negative Matrix Factorization** also factorizes  $M$  by minimizing the reconstruction error, but with only one constraint: the decomposed matrices consist of only non-negative values. In this respect, we can consider it to be learning an unnormalized probability distributions over topics. We use the

original Euclidean least squares definition of NMF<sup>3</sup>. Formally, NMF is defined as

$$M = WH$$

where  $H$  and  $W$  map directly onto our generalization. As in the original NMF work, we learn these unnormalized probabilities by initializing each set of probabilities at random and update them according to the following iterative update rules

$$W = W \frac{MH^T}{WHH^T} \quad H = H \frac{W^T M}{W^T W H}$$

### 3 Coherence Measures

Topic Coherence measures score a single topic by measuring the degree of semantic similarity between high scoring words in the topic. These measurements help distinguish between topics that are semantically interpretable topics and topics that are artifacts of statistical inference, see Table 1 for examples ordered by the UCI measure. For our evaluations, we consider two new coherence measures designed for LDA, both of which have been shown to match well with human judgements of topic quality: (1) The UCI measure (Newman et al., 2010) and (2) The UMass measure (Mimno et al., 2011).

Both measures compute the coherence of a topic as the sum of pairwise distributional similarity

<sup>3</sup>We note that the alternative KL-Divergence form of NMF has been directly linked to PLSA (Ding et al., 2008)

scores over the set of topic words,  $V$ . We generalize this as

$$\text{coherence}(V) = \sum_{(v_i, v_j) \in V} \text{score}(v_i, v_j, \epsilon)$$

where  $V$  is a set of word describing the topic and  $\epsilon$  indicates a smoothing factor which guarantees that *score* returns real numbers. (We will be exploring the effect of the choice of  $\epsilon$ ; the original authors used  $\epsilon = 1$ .)

**The UCI metric** defines a word pair’s score to be the pointwise mutual information (PMI) between two words, i.e.

$$\text{score}(v_i, v_j, \epsilon) = \log \frac{p(v_i, v_j) + \epsilon}{p(v_i)p(v_j)}$$

The word probabilities are computed by counting word co-occurrence frequencies in a sliding window over an external corpus, such as Wikipedia. To some degree, this metric can be thought of as an external comparison to known semantic evaluations.

**The UMass metric** defines the score to be based on document co-occurrence:

$$\text{score}(v_i, v_j, \epsilon) = \log \frac{D(v_i, v_j) + \epsilon}{D(v_j)}$$

where  $D(x, y)$  counts the number of documents containing words  $x$  and  $y$  and  $D(x)$  counts the number of documents containing  $x$ . Significantly, the UMass metric computes these counts over the *original corpus* used to train the topic models, rather than an external corpus. This metric is more intrinsic in nature. It attempts to confirm that the models learned data known to be in the corpus.

## 4 Evaluation

We evaluate the quality of our three topic models (LDA, SVD, and NMF) with three experiments. We focus first on evaluating aggregate coherence methods for a complete topic model and consider the differences between each model as we learn an increasing number of topics. Secondly, we compare coherence scores to previous semantic evaluations.

Lastly, we use the learned topics in a classification task and evaluate whether or not coherent topics are equally informative when discriminating between documents.

For all our experiments, we trained our models on 92,600 New York Times articles from 2003 (Sandhaus, 2008). For all articles, we removed stop words and any words occurring less than 200 times in the corpus, which left 35,836 unique tokens. All documents were tokenized with OpenNLP’s MaxEnt<sup>4</sup> tokenizer. For the UCI measure, we compute the PMI between words using a 20 word sliding window passed over the WaCkypedia corpus (Baroni et al., 2009). In all experiments, we compute the coherence with the top 10 words from each topic that had the highest weight, in terms of LDA and NMF this corresponds with a high probability of the term describing the topic but for SVD there is no clear semantic interpretation.

### 4.1 Aggregate methods for topic coherence

Before we can compare topic models, we require an aggregate measure that represents the quality of a complete model, rather than individual topics. We consider two aggregates methods: (1) the average coherence of all topics and (2) the entropy of the coherence for all topics. The average coherence provides a quick summarization of a model’s quality whereas the entropy provides an alternate summarization that differentiates between two interesting situations. Since entropy measures the complexity of a probability distribution, it can easily differentiate between uniform distributions and multimodal, distributions. This distinction is relevant when users prefer to have roughly uniform topic quality instead of a wide gap between high- and low-quality topics, or vice versa. We compute the entropy by dropping the *log* and  $\epsilon$  factor from each scoring function.

Figure 1 shows the average coherence scores for each model as we vary the number of topics. These average scores indicate some simple relationships between the models: LDA and NMF have approximately the same performance and both models are consistently better than SVD. All of the models quickly reach a stable average score at around 100 topics. This initially suggests that learning more

<sup>4</sup><http://incubator.apache.org/opennlp/>

Figure 1: Average Topic Coherence for each model

Figure 2: Entropy of the Topic Coherence for each model

topics neither increases or decreases the quality of the model, but Figure 2 indicates otherwise. While the entropy for the UMass score stays stable for all models, NMF produces erratic entropy results under the UCI score as we learn more topics. As entropy is higher for even distributions and lower for all other distributions, these results suggest that the NMF is learning topics with drastically different levels of quality, i.e. some with high quality and some with very low quality, but the average coherence over all topics do not account for this.

Low quality topics may be composed of highly unrelated words that can't be fit into another topic, and in this case, our smoothing factor,  $\epsilon$ , may be ar-

tificially increasing the score for unrelated words. Following the practice of the original use of these metrics, in Figures 1 and 2 we set  $\epsilon = 1$ . In Figure 3, we consider  $\epsilon = 10^{-12}$ , which should significantly reduce the score for completely unrelated words. Here, we see a significant change in the performance of NMF, the average coherence decreases dramatically as we learn more topics. Similarly, performance of SVD drops dramatically and well below the other models. In figure 4 we lastly compute the average coherence using only the top 10% most coherence topics with  $\epsilon = 10^{-12}$ . Here, NMF again performs on par with LDA. With the top 10% topics still having a high average coherence but the full set

Figure 3: Average Topic Coherence with  $\epsilon = 10^{-12}$

Figure 4: Average Topic Coherence of the top 10% topics with  $\epsilon = 10^{-12}$

of topics having a low coherence, NMF appears to be learning more low quality topics once it’s learned the first 100 topics, whereas LDA learns fewer low quality topics in general.

## 4.2 Word Similarity Tasks

The initial evaluations for each coherence measure asked human judges to directly evaluate topics (Newman et al., 2010; Mimno et al., 2011). We expand upon this comparison to human judgments by considering word similarity tasks that have often been used to evaluate distributional semantic spaces (Jurgens and Stevens, 2010). Here, we use the learned topics as generalized semantics describ-

ing our knowledge about words. If a model’s topics generalize the knowledge accurately, we would expect similar words, such as “cat” and “dog”, to be represented with a similar set of topics. Rather than evaluating individual topics, this similarity task considers the knowledge within the entire set of topics, the topics act as more compact representation for the known words in a corpus.

We use the Rubenstein and Goodenough (1965) and Finkelstein et al. (2002) word similarity tasks. In each task, human judges were asked to evaluate the similarity or relatedness between different sets of word pairs. Fifty-One Evaluators for the Rubenstein and Goodenough (1965) dataset were given 65 pairs

Figure 5: Word Similarity Evaluations for each model

Figure 7: Correlation between topic coherence and topic ranking in classification

of words and asked to rate their similarity on a scale from 0 to 4, where a higher score indicates a more similar word pair. Finkelstein et al. (2002) broadens the word similarity evaluation and asked 13 to 16 different subjects to rate 353 word pairs on a scale from 0 to 10 based on their relatedness, where relatedness includes similarity and other semantic relations. We can evaluate each topic model by computing the cosine similarity between each pair of words in the evaluate set and then compare the model's ratings to the human ratings by ranked correlation. A high correlation signifies that the topics closely model human judgments.

Figure 5 displays the results. SVD and LDA

both surpass NMF on the Rubenstein & Goodenough test while SVD is clearly the best model on the Finklestein et. al test. While our first experiment showed that SVD was the worst model in terms of topic coherence scores, this experiment indicates that SVD provides an accurate, stable, and reliable approximation to human judgements of similarity and relatedness between word pairs in comparison to other topic models.

### 4.3 Coherence versus Classification

For our final experiment, we examine the relationship between topic coherence and classification accuracy for each topic model. We suspect that highly

Figure 8: Comparison between topic coherence and topic rank with 500 topics

Figure 6: Classification accuracy for each model

coherent topics, and coherent topic models, will perform better for classification. We address this question by performing a document classification task using the topic representations of documents as input features and examine the relationship between topic coherence and the usefulness of the corresponding feature for classification.

We trained each topic model with all 92,600 New York Times articles as before. We use the section labels provided for each article as class labels, where each label indicates the on-line section(s) under which the article was published and should thus be related to the topics contained in each article. To reduce the noise in our data set we narrow down the articles to those that have only one label and whose

label is applied to at least 2000 documents. This results in 57,696 articles with label distributions listed in Table 2. We then represent each document using columns in the topic by document matrix  $H$  learned for each topic model.

Label	Count	Label	Count
New York and Region	11219	U.S.	3675
Paid Death Notices	11152	Arts	3437
Opinion	8038	World	3330
Business	7494	Style	2137
Sports	7214		

Table 2: Section label counts for New York Times articles used for classification

For each topic model trained on  $N$  topics, we performed stratified 10-fold cross-validation on the 57,696 labeled articles. In each fold, we build an automatically-sized bagged ensemble of unpruned CART-style decision trees (Banfield et al., 2007) on 90% of the dataset<sup>5</sup>, use that ensemble to assign labels to the other 10%, and measure the accuracy of that assignment. Figure 6 shows the average classification accuracy over all ten folds for each model. Interestingly, SVD has slightly, but statistically significantly, higher accuracy results than both NMF and LDA. Furthermore, performance quickly increases

<sup>5</sup>The precise choice of the classifier scheme matters little, as long as it is accurate, speedy, and robust to label noise; all of which is true of the choice here.

and plateaus with well under 50 topics.

Our bagged decision trees can also determine the importance of each feature during classification. We evaluate the strength of each topic during classification by tracking the number of times each node in our decision trees observe each topic, please see (Caruana et al., 2006) for more details. Figure 8 plot the relationship between this feature ranking and the topic coherence for each topic when training LDA, SVD, and NMF on 500 topics. Most topics for each model provide little classification information, but SVD shows a much higher rank for several topics with a relatively higher coherence score. Interestingly, for all models, the most coherent topics are not the most informative. Figure 7 plots a more compact view of this same relationship: the Spearman rank correlation between classification feature rank and topic coherence. NMF shows the highest correlation between rank and coherence, but none of the models show a high correlation when using more than 100 topics. SVD has the lowest correlation, which is probably due to the model’s overall low coherence yet high classification accuracy.

## 5 Discussion and Conclusion

Through our experiments, we made several exciting and interesting discoveries. First, we discovered that the coherence metrics depend heavily on the smoothing factor  $\epsilon$ . The original value, 1.0 created a positive bias towards NMF from both metrics even when NMF generated incoherent topics. The high smoothing factor also gave a significant increase to SVD scores. We suspect that this was not an issue in previous studies with the coherence measures as LDA prefers to form topics from words that co-occur frequently, whereas NMF and SVD have no such preferences and often create low quality topics from completely unrelated words. Therefore, we suggest a smaller  $\epsilon$  value in general.

We also found that the UCI measure often agreed with the UMass measure, but the UCI-entropy aggregate method induced more separation between LSA, SVD, and NMF in terms of topic coherence. This measure also revealed the importance of the smoothing factor for topic coherence measures.

With respects to human judgements, we found that coherence scores do not always indicate a bet-

ter representation of distributional information. The SVD model consistently out performed both LDA and NMF models, which each had higher coherence scores, when attempting to predict human judgements of similarity.

Lastly, we found all models capable of producing topics that improved document classification. At the same time, SVD provided the most information during classification and outperformed the other models, which again had more coherent topics. Our comparison between topic coherence scores and feature importance in classification revealed that relatively high quality topics, but not the most coherent topics, drive most of the classification decisions, and most topics do not affect the accuracy.

Overall, we see that each topic model paradigm has it’s own strengths and weaknesses. Latent Semantic Analysis with Singular Value Decomposition fails to form individual topics that aggregate similar words, but it does remarkably well when considering all the learned topics as similar words develop a similar topic representation. These topics similarly perform well during classification. Conversely, both Non Negative Matrix factorization and Latent Dirichlet Allocation learn concise and coherent topics and achieved similar performance on our evaluations. However, NMF learns more incoherent topics than LDA and SVD. For applications in which a human end-user will interact with learned topics, the flexibility of LDA and the coherence advantages of LDA warrant strong consideration. All of code for this work will be made available through an open source project.<sup>6</sup>

## Abstract

Phrase-based machine translation models have shown to yield better translations than Word-based models, since phrase pairs encode the contextual information that is needed for a more accurate translation. However, many phrase pairs do not encode any relevant context, which means that the translation event encoded in that phrase pair is led by smaller translation events that are independent from each other, and can be found on smaller phrase pairs, with little or no loss in translation accuracy. In this work, we propose a relative entropy model for translation models, that measures how likely a phrase pair encodes a translation event that is derivable using smaller translation events with similar probabilities. This model is then applied to phrase table pruning. Tests show that considerable amounts of phrase pairs can be excluded, without much impact on the translation quality. In fact, we show that better translations can be obtained using our pruned models, due to the compression of the search space during decoding.

## 1 Introduction

Phrase-based Machine Translation Models (Koehn et al., 2003) model  $n$ -to- $m$  translations of  $n$  source words to  $m$  target words, which are encoded in phrase pairs and stored in the translation model. This approach has an advantage over Word-based Translation Models (Brown et al., 1993), since translating multiple source words allows the context for each source word to be considered during trans-

lation. For instance, the translation of the English word “in” by itself to Portuguese is not obvious, since we do not have any context for the word. This word can be translated in the context of “in (the box)” to “dentro”, or in the context of “in (China)” as “na”. In fact, the lexical entry for “in” has more than 10 good translations in Portuguese. Consequently, the lexical translation entry for Word-based models splits the probabilistic mass between different translations, leaving the choice based on context to the language model. On the other hand, in Phrase-based Models, we would have a phrase pair  $p(\textit{in the box}, \textit{dentro da caixa})$  and  $p(\textit{in china}, \textit{na china})$ , where the words “in the box” and “in China” can be translated together to “dentro da caixa” and “na China”, which substantially reduces the ambiguity. In this case, both the translation and language models contribute to find the best translation based on the local context, which generally leads to better translations.

However, not all words add the same amount of contextual information. Using the same example for “in”, if we add the context “(hid the key) in”, it is still not possible to accurately identify the best translation for the word “in”. The phrase extraction algorithm (Ling et al., 2010) does not discriminate which phrases pairs encode contextual information, and extracts all phrase pairs with consistent alignments. Hence, phrases that add no contextual information, such as,  $p(\textit{hid the key in}, \textit{escondeu a chave na})$  and  $p(\textit{hid the key in}, \textit{escondeu a chave dentro})$  are extracted. This is undesirable because we are populating translation models with redundant phrase pairs, whose translations can be obtained using com-

binations of other phrases with the same probabilities, namely  $p(\text{hid the key, escondeu a chave})$ ,  $p(\text{in, dentro})$  and  $p(\text{in, na})$ . This is a problem that is also found in language modeling, where large amounts of redundant higher-order n-grams can make the model needlessly large. For backoff language models, multiple pruning strategies based on relative entropy have been proposed (Seymore and Rosenfeld, 1996) (Stolcke, 1998), where the objective is to prune n-grams in a way to minimize the relative entropy between the model before and after pruning.

While the concept of using relative entropy for pruning is not new and frequently used in backoff language models, there are no such models for machine translation. Thus, the main contribution of our work is to propose a relative entropy pruning model for translation models used in Phrase-based Machine Translation. It is shown that our pruning algorithm can eliminate phrase pairs with little or no impact in the predictions made in our translation model. In fact, by reducing the search space, less search errors are made during decoding, which leads to improvements in translation quality.

This paper is organized as follows. We describe and contrast the state of the art pruning algorithms in section 2. In section 3, we describe our relative-entropy model for machine translation. Afterwards, in section 4, we apply our model for pruning in Phrase-based Machine Translation systems. We perform experiments with our pruning algorithm based on phrase pair independence and analyse the results in section 5. Finally, we conclude in section 6.

## 2 Phrase Table Pruning

Phrase table pruning algorithms are important in translation, since they efficiently reduce the size of the translation model, without having a large negative impact in the translation quality. This is especially relevant in environments where memory constraints are imposed, such as translation systems for small devices like cellphones, and also when time constraints for the translation are defined, such as online Speech-to-Speech systems.

### 2.1 Significance Pruning

A relevant reference in phrase table pruning is the work of (Johnson and Martin, 2007), where it is shown that a significant portion of the phrase table can be discarded without a considerable negative impact on translation quality, or even positive one. This work computes the probability, named p-value, that the joint occurrence event of the source phrase  $s$  and target phrase  $t$  occurring in same sentence pair happens by chance, and are actually statistically independent. Phrase pairs that have a high p-value, are more likely to be spurious and more prone to be pruned. This work is followed in (Tomeh et al., 2009), where phrase pairs are treated discriminately based on their complexity. Significance-based pruning has also been successfully applied in language modeling in (Moore and Quirk, 2009).

Our work has a similar objective, but instead of trying to predict the independence between the source and target phrases in each phrase pair, we attempt to predict the independence between a phrase pair and other phrase pairs in the model.

### 2.2 Relevance Pruning

Another proposed approach (Matthias Eck and Waibel, 2007) consists at collecting usage statistics for phrase pairs. This algorithm decodes the training corpora and extracts the number of times each phrase pair is used in the 1-best translation hypothesis. Thus, phrase pairs that are rarely used during decoding are excluded first during pruning.

This method considers the relationship between phrase pairs in the model, since it tests whether the decoder is more prone to use some phrase pairs than others. However, it leads to some undesirable pruning choices. Let us consider a source phrase “the box in China” and 2 translation hypotheses, where the first hypothesis uses the phrase translation  $p(\text{the key in China, a chave na China})$  with probability 70%, and the second hypothesis uses two phrase translations  $p(\text{the key, a chave})$  and  $p(\text{in China, na China})$  with probability 65%. This approach will lean towards pruning the phrase pairs in the second hypothesis, since the decoder will use the first hypothesis. This is generally not desired, since the 2 smaller phrase pairs can be used to translate the same source sentence with a small probab-

ity loss (5%), even if the longer phrase is pruned. On the other hand, if the smaller phrases are pruned, the longer phrase can not be used to translate smaller chunks, such as “the key in Portugal”. This matter is aggravated due to the fact that the training corpora is used to decode, so longer phrase pairs will be used more frequently than when translating unseen sentences, which will make the model more biased into pruning shorter phrase pairs.

### 3 Relative Entropy Model For Phrase-based Translation Models

In this section, we shall define our entropy model for phrase pairs. We start by introducing some notation to distinguish different types of phrase pairs and show why some phrase pairs are more redundant than others. Afterwards, we illustrate our notion of relative entropy between phrase pairs. Then, we describe our entropy model, its computation and its application to phrase table pruning.

#### 3.1 Atomic and Composite Phrase Pairs

We discriminate between 2 types of phrase pairs: atomic phrase pairs and composite phrase pairs.

Atomic phrase pairs define the smallest translation units, such that given an atomic phrase pair that translates from  $s$  to  $t$ , the same translation cannot be obtained using any combination of other phrase pairs. Removing these phrase pairs reduces the range of translations that our model is capable of translating and also the possible translations.

Composite phrase pairs define translations of a given sequence of words that can also be obtained using atomic or other smaller composite phrase pairs. Each combination is called a derivation or translation hypothesis. Removing these phrase pairs does not change the amount of sentences that the model can translate, since all translations encoded in these phrases can still be translated using other phrases, but these will lead to different translation probabilities.

Considering table 1, we can see that atomic phrases encode one elementary translation event, while composite phrases encode joint events that are encoded in atomic phrase pairs. If we look at the source phrase “in”, there is a multitude of possible translations for this word in most target languages.

Taking Portuguese as the target language, the probability that “in” is translated to “em” is relatively low, since it can also be translated to “no”, “na”, “dentro”, “dentro de” and many others.

However, if we add another word such as “Portugal” forming “in Portugal”, it is more likely that “in” is translated to “em”. Thus, we define the joint event of “in” translating to “em” ( $A_1$ ) and “Portugal” to “Portugal” ( $B_1$ ), denoted as  $A_1 \cap B_1$ , in the phrase pair  $p(\text{in Portugal}, \text{em Portugal})$ . Without this phrase pair it is assumed that these are independent events with probability given by  $P(A_1)P(B_1)$ <sup>1</sup>, which would be 10%, leading to a 60% reduction. In this case, it would be more likely, that *in Portugal* is translated to *no Portugal* or *na Portugal*, which would be incorrect.

Some words, such as “John”, forming “John in”, do not influence the translations for the word “in”, since it can still be translated to “em”, “no”, “na”, “dentro” or “dentro de” depending on the word that follows. By definition, if the presence of phrase  $p(\text{John}, \text{John})$  does not influence the translation of  $p(\text{in}, \text{em})$  and viceversa, we can say that probability of the joint event  $P(A_1 \cap C_1)$  is equal to the product of the probabilities of the events  $P(A_1)P(C_1)$ .

If we were given a choice of pruning either the composite phrase pairs  $p(\text{John in}, \text{John em})$  or  $p(\text{in Portugal}, \text{em Portugal})$ , the obvious choice would be the former, since the probability of the event encoded in that phrase pair is composed by 2 independent events, in which case the decoder will inherently consider the hypothesis that “John in” is translated to “John em” with the same probability. In another words, the model’s predictions even, without this phrase pair will remain the same.

The example above shows an extreme case, where the event encoded in the phrase pair  $p(\text{John in}, \text{John em})$  is decomposed into independent events, and can be removed without changing the model’s prediction. However, finding and pruning phrase pairs that are independent, based on smaller events is impractical, since most translation events are not strictly independent. However, many phrase pairs can be replaced with derivations using smaller phrases with a small loss in the model’s pre-

<sup>1</sup>For simplicity, we assume at this stage that no reordering model is used

Phrase Pair	Prob	Event
Atomic Phrase Pairs		
in → em	10%	$A_1$
in → na	20%	$A_2$
in → no	20%	$A_3$
in → dentro	5%	$A_4$
in → dentro de	5%	$A_5$
Portugal → Portugal	100%	$B_1$
John → John	100%	$C_1$
Composite Phrase Pairs		
in Portugal → em Portugal	70%	$A_1 \cap B_1$
John in → John em	10%	$C_1 \cap A_1$
John in → John na	20%	$C_1 \cap A_2$
John in → John no	20%	$C_1 \cap A_3$
John in → John dentro	5%	$C_1 \cap A_4$
John in → John dentro de	5%	$C_1 \cap A_5$

Table 1: Phrase Translation Table with associated events

dictions.

Hence, we would like to define a metric for phrase pairs that allows us evaluate how discarding each phrase pair will affect the pruned model’s predictions. By removing phrase pairs that can be derived using smaller phrase pairs with similar probability, it is possible to discard a significant portion of the translation model, while minimizing the impact on the model’s predictions.

### 3.2 Relative Entropy Model for Machine Translation

For each phrase pair  $p_a$ , we define the supporting set  $SP(p_a(s, t)) = S_1, \dots, S_k$ , where each element  $S_i = p_i, \dots, p_j$  is a distinct derivation of  $p_a(s, t)$  that translates  $s$  to  $t$ , with probability  $P(S_i) = P(p_i) \times \dots \times P(p_j)$ . A phrase pair can have multiple elements in its supporting set. For instance, the phrase pair  $p(\text{John in Portugal}, \text{John em Portugal})$ , has 3 elements in the support set:

- $S_1 = \{p(\text{John}, \text{John}), p(\text{in}, \text{em}), p(\text{Portugal}, \text{Portugal})\}$
- $S_2 = \{p(\text{John}, \text{John}), p(\text{in Portugal}, \text{em Portugal})\}$
- $S_3 = \{p(\text{John in}, \text{John em}), p(\text{Portugal}, \text{Portugal})\}$

$S_1$ ,  $S_2$  and  $S_3$  encode 3 different assumptions about the event of translating “John in Portugal” to “John em Portugal”.  $S_1$  assumes that the event is composed by 3 independent events  $A_1$ ,  $B_1$  and  $C_1$ ,  $S_2$  assumes that  $A_1$  and  $B_1$  are dependent, and

groups them into a single composite event  $A_1 \cap B_1$ , which is independent from  $C_1$ , and  $S_3$  groups  $A_1$  and  $C_1$  independently from  $B_1$ . As expected, the event encoded in the phrase pair  $p$  itself is  $A_1 \cap B_1 \cap C_1$ , which assumes that  $A_1$ ,  $B_1$  and  $C_1$  are all dependent. We can see that if any of the events  $S_1$ ,  $S_2$  or  $S_3$  has a “similar probability” as the event coded in the phrase pair, we can remove this phrase pair with a minimal impact in the phrase prediction.

To formalize our notion of “similar probability”, we apply the relative entropy or the Kullback-Leibler divergence, and define the divergence between a pruned translation model  $P_p(s, t)$  and the unpruned model  $P(s, t)$  as:

$$D(P_p||P) = - \sum_{s,t} P(s, t) \log \frac{P_p(t|s)}{P(t|s)} \quad (1)$$

Where  $\frac{P_p(t|s)}{P(t|s)}$ , measures the deviation from the probability emission from the pruned model and the original probability from the unpruned model, for each source-target pair  $s, t$ . This is weighted by the frequency that the pair  $s, t$  is observed, given by  $P(s, t)$ .

Our objective is to minimize  $D(P_p||P)$ , which can be done locally by removing phrase pairs  $p(s, t)$  with the lowest values for  $-P(s, t) \log \frac{P_p(t|s)}{P(t|s)}$ . Ideally, we would want to minimize the relative entropy for all possible source and target sentences, rather than all phrases in our model. However, minimizing such an objective function would be intractable due to reordering, since the probability assigned to a phrase pair in a sentence pair by each model would depend on the positioning of all other phrase pairs used in the sentence. Because of these dependencies, we would not be able to reduce this problem to a local minimization problem. Thus, we assume that all phrase pairs have the same probability regardless of their context in a sentence.

Thus, our pruning algorithm takes a threshold  $\delta$  and prunes all phrase pairs that fail to meet the following criteria:

$$-P(s, t) \log \frac{P_p(t|s)}{P(t|s)} > \delta \quad (2)$$

The main components of this function is the ratio between the emission from the pruned model and

unpruned models given by  $\frac{P_p(t|s)}{P(t|s)}$ , and the weight given to each  $s, t$  pair given by  $P(s, t)$ . In the remainder of this section, we will focus on how to model each of these components in equation 2.

### 3.3 Computing $P(s, t)$

The term  $P(s, t)$  can be seen as a weighting function for each  $s, t$  pair. There is no obvious optimal distribution to model  $P(s, t)$ . In this work, we apply 2 different distributions for  $P(s, t)$ . First, a uniform distribution, where all phrases are weighted equally. Secondly, a multinomial function defined as:

$$P(s, t) = \frac{N(s, t)}{N} \quad (3)$$

where  $N$  is the number of sentence pairs in the parallel data, and  $N(s, t)$  is the number of sentence pairs where  $s$  was observed in the source sentence and  $t$  was observed in the target sentence. Using this distribution, the model is more biased in pruning phrase pairs with  $s, t$  pairs that do not occur frequently.

### 3.4 Computing $\frac{P_p(t|s)}{P(t|s)}$

The computation of  $\frac{P_p(t|s)}{P(t|s)}$  depends on how the decoder adapts when a phrase pair is pruned from the model. In the case of back-off language models, this can be solved by calculating the difference of the logs between the n-gram estimate and the back-off estimate. However, a translation decoder generally functions differently. In our work, we will assume that the decoding will be performed using a Viterbi decoder, such as MOSES (Koehn et al., 2007), where the translation with the highest score is chosen.

In the example above, where  $s$ ="John in Portugal" and  $t$ ="John em Portugal", the decoder would choose the derivation with the highest probability from  $s$  to  $t$ . Using the unpruned model, the possible derivations are either using phrase  $p(s, t)$  or one element of its support set  $S_1, S_2$  or  $S_3$ . On the other hand, on the pruned model where  $p(s, t)$  does not exist, only  $S_1, S_2$  and  $S_3$  can be used. Thus, given a  $s, t$  pair one of three situations may occur. First, if the probability of the phrase pair  $p(s, t)$  is lower than the highest probability element in  $SP(p(s, t))$ , then both the models will choose that element, in which case,  $\frac{P_p(t|s)}{P(t|s)} = 1$ . This can happen, if we define

features that penalize longer phrase pairs, such as lexical weighting, or if we apply smoothing (Foster et al., 2006). Secondly, if the probability of  $p(s, t)$  is equal to the most likely element in  $SP(p(s, t))$ , regardless of whether the unpruned model chooses to use  $p(s, t)$  or that element, the probability emissions of the pruned and unpruned model will be identical. Thus, for this case  $\frac{P_p(t|s)}{P(t|s)} = 1$ . Finally, if the probability of  $p(s, t)$  is higher than other possible derivations, the unpruned model will choose to emit the probability of  $p(s, t)$ , while the pruned model will emit the most likely element in  $SP(p(s, t))$ . Hence, the probability loss between the 2 models, will be the ratio between the probability of  $p(s, t)$  and the probability of the most likely element in  $SP(p(s, t))$ .

From the example above, we can generalize the function for  $\frac{P_p(t|s)}{P(t|s)}$  as:

$$\frac{\prod_{p' \in \text{argmax}(SP(p(s, t)))} P(p')}{P(p(s, t))} \quad (4)$$

Where  $P(p(s, t))$  denotes the probability of  $p(s, t)$  and  $\prod_{p' \in \text{argmax}(SP(p(s, t)))} P(p')$  the most likely sequence of phrasal translations that translates  $s$  to  $t$ , with the probability equal to the product of all phrase translation probabilities in that sequence.

Replacing in equation 2, our final condition that must be satisfied for keeping a phrase pair is:

$$-P(s, t) \log \frac{\prod_{p' \in \text{argmax}(SP(p(s, t)))} P(p')}{P(p(s, t))} > \delta \quad (5)$$

## 4 Application for Phrase-based Machine Translation

We will now show how we apply our entropy pruning model in the state-of-the-art phrase-based translation system MOSES and describe the problems that need to be addressed during the implementation of this model.

### 4.1 Translation Model

The translation model in Moses is composed by a phrase translation model and a phrase reordering model. The first one models, for each phrase pair  $p(s, t)$ , the probability of translating the  $s$  to  $t$  by combining multiple features  $\phi_i$ , weighted by

$w_i^T$ , as  $P_T(p) = \prod_{i=1}^n \phi_i(p)^{w_i^T}$ . The reordering model is similar, but models the local reordering between  $p$ , given the previous and next phrase according to the target side,  $p_P$  and  $p_N$ , or more formally,  $P_R(p|p_P, p_N) = \prod_{i=1}^m \psi_i(p|p_P, p_P)^{w_i^R}$

## 4.2 Building the Support Set

Essentially, implementing our model is equivalent to calculating the components described in equation 5. These are  $P(s, t)$ ,  $P(p(s|t))$  and  $\text{argmax}(SP(p(s, t)))$ . Calculating the uniform distribution and multinomial distributions for  $P(s, t)$  is simple, the uniform distribution just assumes the same value for all  $s$  and  $t$ , and the multinomial distribution can be modeled by extracting counts from the parallel corpora.

Calculating  $P(s|t)$  is also trivial, since it only involves calculating  $P_T(p(s, t))$ , which can be done by retrieving the translation features of  $p$  and applying the weights for each feature.

The most challenging task is to calculate  $\text{argmax}(SP(p(s, t)))$ , which is similar to the decoding task in machine translation, where we need to find the best translation  $\hat{t}$  for a sentence  $s$ , that is,  $\hat{t} = \text{argmax}_t P(s|t)P(t)$ . In practice, we are not searching in the space of possible translations, but in the space of possible derivations, which are sequences of phrase translations  $p_1(s_1, t_1), \dots, p_n(s_n, t_n)$  that can be applied to  $s$  to generate an output  $t$  with the score given by  $P(t) \prod_{i=1}^n P(s_i, t_i)$ .

Our algorithm to determine  $SP(p(s, t))$  can be described as an adaptation to the decoding algorithm in Moses, where we restrict the search space to the subspace  $SP(p(s, t))$ , that is, our search space is only composed by derivations that output  $t$ , without using  $p$  itself. This can be done using the forced decoding algorithm proposed in (Schwartz, 2008). Secondly, the score of a given translation hypothesis does not depend on the language model probability  $P(t)$ , since all derivations in this search space have the same  $t$ , thus we discard this probability from the score function. Finally, rather than using beam search, we exhaustively search all the search space, to reduce the hypothesis of incurring a search error at this stage. This is possible, since phrase pairs are generally smaller than text (less than 8 words), and because we are constraining the search space to  $t$ , which is an order of magnitude smaller than the reg-

ular search space with all possible translations.

## 4.3 Pruning Algorithm

The algorithm to generate a pruned translation model is shown in 1. We iterate over all phrase pairs  $p_1(s_1, t_1), \dots, p_n(s_n, t_n)$ , decode using our forced decoding algorithm from  $s_i$  to  $t_i$ , to obtain the best path  $S$ . If no path is found then it means that the  $p_i$  is atomic. Then, we prune  $p_i$  based on condition 5.

---

### Algorithm 1 Independence Pruning

   **end if**  
   **if**  $score \leq \delta$  **then**  
      $prune(p_i)$   
   **end if**  
**end for**  
**return** pruned model

---

The main bottle neck in this algorithm is finding  $\text{argmax}(SP(p_i))$ . While this appears relatively simple and similar to a document decoding task, the size of our task is on a different order of magnitude, since we need to decode every phrase pair in the translation model, which might not be tractable for large models with millions of phrase pairs. We address this problem in section 5.3.

Another problem with this algorithm is that the decision to prune each phrase pair is made assuming that all other phrase pairs will remain in the model. Thus, there is a chance a phrase pair  $p_1$  is pruned because of a derivation using  $p_2$  and  $p_3$  that leads to the same translation. However, if  $p_3$  also happens to be pruned, such a derivation will no longer be possible. One possible solution to address this problem is to perform pruning iteratively, from the smallest phrase pairs (number of words) and increase the size at each iteration. However, we find this undesirable, since the model will be biased into removing smaller phrase pairs, which are generally more useful, since they can be used in multiple derivation to replace larger phrase pairs. In the example above, the model

would eliminate  $p_3$  and keep  $p_1$ , yet the best decision could be to keep  $p_3$  and remove  $p_1$ , if  $p_3$  is also frequently used in derivations of other phrase pairs. Thus, we leave the problem of finding the best set of phrases to prune as future work.

## 5 Experiments

We tested the performance of our system under two different environments. The first is the small scale DIALOG translation task for IWSLT 2010 evaluation (Paul et al., 2010) using a small corpora for the Chinese-English language pair (henceforth referred to as “IWSLT”). The second one is a large scale test using the complete EUROPARL (Koehn, 2005) corpora for the Portuguese-English language pair, which we will denote by “EUROPARL”.

### 5.1 Corpus

The IWSLT model was trained with 30K training sentences. The development corpus and test corpus were taken from the evaluation dataset in IWSLT 2006 (489 tuning and 500 test sentences with 7 references). The EUROPARL model was trained using the EUROPARL corpora with approximately 1.3M sentence pairs, leaving out 1K sentences for tuning and another 1K sentences for tests.

### 5.2 Setup

In the IWSLT experiment, word alignments were generated using an HMM model (Vogel et al., 1996), with symmetric posterior constraints (V. Graça et al., 2010), using the Geppetto toolkit<sup>2</sup>. This setup was used in the official evaluation in (Ling et al., 2010). For the EUROPARL experiment the word alignments were generated using IBM model 4. In both experiments, the translation model was built using the phrase extraction algorithm (Paul et al., 2010), with commonly used features in Moses (Ex: probability, lexical weighting, lexicalized reordering model). The optimization of the translation model weights was done using MERT tuning (Och, 2003) and the results were evaluated using BLEU-4.

### 5.3 Pruning Setup

Our pruning algorithm is applied after the translation model weight optimization with MERT. We gener-

ate multiple translation models by setting different values for  $\delta$ , so that translation models of different sizes are generated at intervals of 5%. We also run the significance pruning (Johnson and Martin, 2007) algorithm in these conditions.

While the IWSLT translation model has only 88,424 phrase pairs, for the EUROPARL experiment, the translation model was composed by 48,762,372 phrase pairs, which had to be decoded. The average time to decode each phrase pair using the full translation model is 4 seconds per sentence, since the table must be read from disk due to its size. This would make translating 48M phrase pairs unfeasible. To address this problem, we divide the phrase pairs in the translation model into blocks of  $K$  phrase pairs, that are processed separately. For each block, we resort to the approach used in MERT tuning, where the model is filtered to only include the phrase pairs that are used for translating tuning sentences. We filter each block with phrase pairs from  $K$  to  $2K$  with the source sentences  $s_K, \dots, s_{2K}$ . Furthermore, since we are force decoding using the target sentences, we also filter the remaining translation models using the target sentences  $t_K, \dots, t_{2K}$ . We used blocks of 10,000 phrase pairs and each filtered table was reduced to less than 1% of the translation table on average, reducing the average decoding time to 0.03 seconds per sentence. Furthermore, each block can be processed in parallel allowing multiple processes to be used for the task, depending on the resources that are available.

### 5.4 Results

Figure 1 shows the BLEU results for different sizes of the translation model for the IWSLT experiment using the uniform and multinomial distributions for  $P(s, t)$ . We observe that there is a range of values from 65% to 95% where we actually observe improvements caused by our pruning algorithm, with the peak at 85% for the uniform distribution, where we improve from 15.68 to 15.82 (0.9% improvement). Between 26% and 65%, the BLEU score is lower than the baseline at 100%, with the minimum at 26% with 15.54, where only atomic phrase pairs remain and both the multinomial and uniform distribution have the same performance, obviously. This is a considerable reduction in phrase table size by sacrificing 0.14 BLEU points. Regarding the com-

<sup>2</sup><http://code.google.com/p/geppetto/>

Figure 1: Results for the IWSLT experiment. The x-axis shows the percentage of the phrase table used. The BLEU scores are shown in the y-axis. Two distributions for  $P(s, t)$  were tested Uniform and Multinomial.

comparison between the uniform and multinomial distribution, we can see that both distributions yield similar results, specially when a low number of phrase pairs is pruned. In theory, the multinomial distribution should yield better results, since the pruning model will prefer to prune phrase pairs that are more likely to be observed. However, longer phrase pairs, which tend compete with other long phrase pairs on which get pruned first. These phrase pairs generally occur only once or twice, so the multinomial model will act similarly to the uniform model regarding longer phrase pairs. On the other hand, as the model size reduces, we can see that using multinomial distribution seems to start to improve over the uniform distribution.

The comparison between our pruning model and pruning based on significance is shown in table 2. These models are hard to compare, since not all phrase table sizes can be obtained using both metrics. For instance, the significance metric can either keep or remove all phrase pairs that only appear once, leaving a large gap of phrase table sizes that cannot be attained. In the EUROPARL experiment the sizes of the table suddenly drops from 60% to 8%. The same happens with our metric that cannot distinguish atomic phrase pairs. In the EUROPARL experiment, we cannot generate phrase tables with sizes smaller than 15%. Thus, we only show results at points where both algorithms can produce a phrase table.

Significant improvements are observed in the

Table size	Significance Pruning	Entropy (u) Pruning	Entropy (m) Pruning
<b>IWSLT</b>			
57K (65%)	14.82	15.77	<b>15.78</b>
71K (80%)	15.14	15.76	<b>15.77</b>
80K (90%)	15.31	<b>15.73</b>	15.72
88K (100%)	15.68	15.68	15.68
<b>EUROPARL</b>			
29M (60%)	28.64	28.82	<b>28.91</b>
34M (70%)	28.84	28.94	<b>28.99</b>
39M (80%)	28.86	<b>28.99</b>	<b>28.99</b>
44M (90%)	28.91	29.00	<b>29.02</b>
49M (100%)	29.18	29.18	29.18

Table 2: Comparison between Significance Pruning (Significance Pruning) and Entropy-based pruning using the uniform (Entropy (u) Pruning) and multinomial distributions (Entropy (m) Pruning).

IWSLT experiment, where significance pruning does not perform as well. On the other hand, on the EUROPARL experiment, our model only achieves slightly higher results. We believe that this is related by the fact the EUROPARL corpora is generated from automatically aligning documents, which means that there are misaligned sentence pairs. Thus, many spurious phrase pairs are extracted. Significance pruning performs well under these conditions, since the measure is designed for this purpose. In our metric, we do not have any means for detecting spurious phrase pairs, in fact, spurious phrase pairs are probably kept in the phrase table, since each distinct spurious phrase pair is only extracted once, and thus, they have very few derivations in its support set. This suggests, that the significance score can be integrated in our model to improve our model, which we leave as future work.

Figure 2: Translation order in for different reordering starting from left to right.

We believe that in language pairs such as Chinese-

English with large distance reorderings between phrases are more prone to search errors and benefit more from our pruning algorithm. To illustrate this, let us consider the source sentence “John married in Portugal”, and translating either using the blocks “John”, “married” and “in Portugal” or the blocks “John”, “married in”, “Portugal”, the first hypothesis would be much more viable, since the word “Portugal” is more relevant as the context for the word “in”. Thus, the key choice for the decoder is to decide whether to translate using “married” with or without “in”, and it is only able to predict that it is better to translate “married” by itself until it finds that “in” is better translated with “Portugal”. Thus, a search error occurs if the hypothesis where “married” is translated by itself is removed. In figure 2, we can see the order that blocks are considered for different reorderings, starting from left to right. In a), we illustrate the case for a monotonous translation. We observe that the correct decision between translating “married in” or just “married” is found immediately, since the blocks “Portugal” and “in Portugal” are considered right afterwards. In this case, it is unlikely that the hypothesis using “married” is removed. However, if we consider that due to reordering, “John” is translated after “married” and before “Portugal”, which is shown in b). Then, the correct decision can only be found after considering “John”. In this case, “John” does not have many translations, so the likelihood of eliminating the correct hypothesis. However, if there were many translations for John, it is highly likely that the correct partial hypothesis is eliminated. Furthermore, the more words exist between “married” and “Portugal”, the more likely will the correct hypothesis not exist when we reach “Portugal”. By pruning the hypothesis “married in” a priori, we contribute in preventing such search errors.

We observe that some categories of phrase pairs that are systematically pruned, but these cannot be generalized in rules, since there are many exceptions. The most obvious type of phrase pairs are phrases with punctuations, such as “谢谢.” to “thanks .” and “. 谢谢” to “thanks .”, since “.” is translated independently from most contextual words. However, this rule should not be generalized, since in some cases “.” is a relevant contextual marker. For instance, the word “please” is translated

to “请” in the sentence ‘open the door, please.’ and translated to “使高兴” in “please my advisors”. Another example are sequences of numbers, which are generally translated literally. For instance, “八(8) 三(3) 八(8)” is translated to “eight three eight” (Ex: “room eight three eight”). Thus, phrase pairs for number sequences can be removed, since those numbers can be translated one by one. However, for sequences such as “一(1) 八(8)”, we need a phrase pair to represent this specifically. This is because “一(1)” can be translated to “one”, but also to “a”, “an”, “single”. Other exceptions include “一(1) 一(1)”, which tends to be translated as “eleven”, and which tends to be translated to “o”, rather than “zero” in sequences (“room eleven o five”).

## 6 Conclusions

We present a pruning algorithm for Machine Translation based on relative entropy, where we assess whether the translation event encoded in a phrase pair can be decomposed into combinations of events encoded in other phrase pairs. We show that such phrase pairs can be removed from the translation model with little negative impact or even a positive one in the overall translation quality. Tests show that our method yields comparable or better results with state of the art pruning algorithms.

As future work, we would like to combine our approach with significance pruning, since both approaches are orthogonal and address different issues. We also plan to improve the pruning step of our algorithm to find the optimal set of phrase pairs to prune given the pruning threshold.

The code used in this work will be made available.

# A Systematic Comparison of Phrase Table Pruning Techniques

Richard Zens and Daisy Stanton and Peng Xu

Google Inc.  
{zens, daisy, xp}@google.com

## Abstract

When trained on very large parallel corpora, the phrase table component of a machine translation system grows to consume vast computational resources. In this paper, we introduce a novel pruning criterion that places phrase table pruning on a sound theoretical foundation. Systematic experiments on four language pairs under various data conditions show that our principled approach is superior to existing ad hoc pruning methods.

## 1 Introduction

Over the last years, statistical machine translation has become the dominant approach to machine translation. This is not only due to improved modeling, but also due to a significant increase in the availability of monolingual and bilingual data. Here are just two examples of very large data resources that are publicly available:

- The Google Web 1T 5-gram corpus available from the Linguistic Data Consortium consisting of the 5-gram counts of about one trillion words of web data.<sup>1</sup>
- The 10<sup>9</sup>-French-English bilingual corpus with about one billion tokens from the Workshop on Statistical Machine Translation (WMT).<sup>2</sup>

These enormous data sets yield translation models that are expensive to store and process. Even with

modern computers, these large models lead to a long experiment cycle that hinders progress. The situation is even more severe if computational resources are limited, for instance when translating on handheld devices. Then, reducing the model size is of the utmost importance.

The most resource-intensive components of a statistical machine translation system are the language model and the phrase table. Recently, compact representations of the language model have attracted the attention of the research community, for instance in Talbot and Osborne (2007), Brants et al. (2007), Pauls and Klein (2011) or Heafield (2011), to name a few. In this paper, we address the other problem of any statistical machine translation system: large phrase tables.

Johnson et al. (2007) has shown that large portions of the phrase table can be removed without loss in translation quality. This motivated us to perform a systematic comparison of different pruning methods. However, we found that many existing methods employ ad-hoc heuristics without theoretical foundation.

The pruning criterion introduced in this work is inspired by the very successful and still state-of-the-art language model pruning criterion based on entropy measures (Stolcke, 1998). We motivate its derivation by stating the desiderata for a good phrase table pruning criterion:

- **Soundness:** The criterion should optimize some well-understood information-theoretic measure of translation model quality.

<sup>1</sup>LDC catalog No. LDC2006T13

<sup>2</sup><http://www.statmt.org/wmt11/translation-task.html>

- **Efficiency:** Pruning should be fast, i. e., run linearly in the size of the phrase table.
- **Self-containedness:** As a practical consideration, we want to prune phrases from an existing phrase table. This means pruning should use only information contained in the model itself.
- **Good empirical behavior:** We would like to be able to prune large parts of the phrase table without significant loss in translation quality.

Analyzing existing pruning techniques based on these objectives, we found that they are commonly deficient in at least one of them. We thus designed a novel pruning criterion that not only meets these objectives, it also performs very well in empirical evaluations.

The **novel contributions** of this paper are:

1. a systematic description of existing phrase table pruning methods.
2. a new, theoretically sound phrase table pruning criterion.
3. an experimental comparison of several pruning methods for several language pairs.

## 2 Related Work

The most basic pruning methods rely on probability and count cutoffs. We will cover the techniques that are implemented in the Moses toolkit (Koehn et al., 2007) and the Pharaoh decoder (Koehn, 2004) in Section 3. We are not aware of any work that analyzes their efficacy in a systematic way. It is thus not surprising that some of them perform poorly, as our experimental results will show.

The work of Johnson et al. (2007) is promising as it shows that large parts of the phrase table can be removed without affecting translation quality. Their pruning criterion relies on statistical significance tests. However, it is unclear how this significance-based pruning criterion is related to translation model quality. Furthermore, a comparison to other methods is missing. Here we close this gap and perform a systematic comparison. The same idea of significance-based pruning was exploited in (Yang and Zheng, 2009; Tomeh et al., 2009) for hierarchical statistical machine translation.

A different approach to phrase table pruning was undertaken by Eck et al. (2007a; 2007b). They rely on usage statistics from translating sample data, so it is not self-contained. However, it could be combined with the methods proposed here.

Another approach to phrase table pruning is triangulation (Chen et al., 2008; Chen et al., 2009). This requires additional bilingual corpora, namely from the source language as well as from the target language to a third bridge language. In many situations this does not exist or would be costly to generate.

Duan et al. (2011), Sanchis-Trilles et al. (2011) and Tomeh et al. (2011) modify the phrase extraction methods in order to reduce the phrase table size. The work in this paper is independent of the way the phrase extraction is done, so those approaches are complementary to our work.

## 3 Pruning Using Simple Statistics

In this section, we will review existing pruning methods based on simple phrase table statistics. There are two common classes of these methods: absolute phrase table pruning and relative phrase table pruning.
