## Preface by General and Program Chairs

It is our pleasure to welcome you to the EMNLP-CoNLL 2012 conference, a joint meeting of the Conference on Empirical Methods in Natural Language Learning (EMNLP) and the Conference on Computational Natural Language Learning (CoNLL). After the successful first collaboration in 2007, EMNLP-CoNLL 2012 is being jointly organized by the SIGDAT and SIGNLL special interest groups of the Association of Computational Linguistics.

This time, EMNLP-CoNLL is co-located with, and immediately after ACL's 50th anniversary conference. The choice of the location is an opportunity for the ACL community to return to the beautiful Jeju Island, Korea, following a seven-year hiatus since the Second International Joint Conference on Natural Language Processing (IJCNLP 2005) was held here.

Out of 606 submissions received by EMNLP-CoNLL this year, a total of 36 submissions were eventually withdrawn or rejected without review. From the remaining submissions, 99 were accepted for oral presentation and 40 for poster presentation, for a combined acceptance rate of 24.8%. As in recent editions of EMNLP, authors were given the opportunity to provide supplementary material in conjunction with their submissions, which the program committee could but was not required to take into account during reviewing. Also as in recent editions, authors of accepted papers were offered an additional page in the camera-ready version of their submissions, so that comments received from reviewers could be more easily addressed.

The papers submitted to the conference were subject to a rigorous reviewing process, made possible by efforts of a team of 525 primary and 66 secondary reviewers, acting under the guidance of 22 area chairs. Presence of unsupported claims, or failure to properly compare with previous work, were likely serious obstacles, on the path from initial submission to acceptance and then publication in our proceedings. Luckily, our preface has a guaranteed placement in the proceedings. Therefore, without access to insider data and impressions from previous editions of the conference, we will still go on a limb here, and make the unsupported claim that our team of area chairs has been the greatest. That their expertise, dedication and willingness to go beyond the call of duty had a positive impact on a timely reviewing process and a high-quality conference program, would be an understatement. It has been a pleasure to interact and work with our area chairs.

The schedule of our conference is strengthened by two invited speakers, Eric Xing and Patrick Pantel, who we were very happy to have accept our invitation; and by the CoNLL Shared Task, an annual tradition for the CoNLL conferences. This year's CoNLL Shared Task is Modeling Multilingual Unrestricted Coreference in OntoNotes, and its proceedings and detailed schedule are available separately.

We would like to thank all authors who submitted to our conference, for their willingness to share their knowledge with the rest of us. It may take a few weeks or many years, for the knowledge distilled into the present proceedings to have a measurable impact on our field and beyond. An impact that would not be possible without countless hours spent by authors, from developing ideas to running experiments to building usable systems - steps that often fail, and sometimes succeed.

We would also like to thank all members of the program committee, for their willingness to offer

feedback that sometimes reaches extraordinary levels of detail and value to authors. To recognise some of the most dedicated reviewers, we include the Best Reviewer awards a little later in these proceedings.

Naoaki Okazaki, Publications Chair, deserves our special thanks. He brought in a healthy dose of rigor to the planning and preparation of not only this proceedings but also conference materials, matched only by his dedication to deliver under tight scheduling constraints.

If the combination of oral presentations, posters and invited talks that make up EMNLP-CoNLL 2012 is considered a success, it is because it benefited from the touch of many people. Francesco Figari easily kept tabs on our salvos of large and small requests for updates to our conference website. Rich Gerber, Paolo Gai and the larger team managing the conference submission system were quick to offer answers to all our questions. The publication chairs and local arrangements committee of ACL 2012, including Michael White, Maggie Li, Jong Park and especially Gary Geunbae Lee, covered significant tasks on behalf of EMNLP-CoNLL, all with a smile. Chin-Yew Lin, Miles Osborne, Eric Fosler-Lussier, Dekang Lin, Rada Mihalcea, Regina Barzilay, Ulrich Germann and David Yarowsky offered high-level advice or answered detailed questions, drawing upon their experience as organizers of previous ACL-sponsored conferences.

We are grateful to our sponsors (Baidu, Google and Microsoft), for their support of best paper awards and support of student travel in particular, and the financial well-being of the conference in general. It has been an honor to be of service to the conference, for which we would like to thank the community and those who offered us this opportunity. We hope that you enjoy the conference, and have a productive and pleasant stay in South Korea!

Jun'ichi Tsujii, General Chair

James Henderson and Marius Paşca, Program Chairs

**General Chair:**

Jun'ichi Tsujii, Microsoft Research Asia

**Program Chairs:**

James Henderson, Xerox Research Centre Europe

Marius Paşca, Google

**Area Chairs:**

Eugene Agichtein, Emory University

Yejin Choi, Stony Brook University

Hal Daumé III, University of Maryland

Doug Downey, Northwestern University

Chris Dyer, Carnegie Mellon University

Adrià de Gispert, University of Cambridge

Julia Hirschberg, Columbia University

Anna Korhonen, University of Cambridge

Bing Liu, University of Illinois at Chicago

Hwee Tou Ng, National University of Singapore

Patrick Pantel, Microsoft Research

Marco Pennacchiotti, Yahoo! Labs

Slav Petrov, Google

Simone Paolo Ponzetto, Sapienza University of Rome

John Prager, IBM Research

Chris Quirk, Microsoft Research

Sebastian Riedel, University of Massachusetts at Amherst

Hiroya Takamura, Tokyo Institute of Technology

Partha Talukdar, Carnegie Mellon University

Kristina Toutanova, Microsoft Research

Reut Tsarfaty, Uppsala University

Marilyn Walker, University of California at Santa Cruz

**Publication Chair:**

Naoaki Okazaki, Tohoku University

## **Program Committee: Reviewers:**

Ahmed Abbasi, Robert Abbott, Omri Abend, Meni Adler, Mikhail Ageev, Lars Ahrenberg, Hua Ai, Cem Akkaya, Pranav Anand, Alina Andreevskaia, Ion Androustopoulos, Eiji Aramaki, Yoav Artzi, Abhishek Arun, Nicholas Asher, Giuseppe Attardi, Necip Fazil Ayan,

Anton Bakalov, Alexandra Balahur, Niranjan Balasubramanian, Timothy Baldwin, Carmen Banea, Ritwik Banerjee, Mohit Bansal, Roy Bar-Haim, Kedar Belare, Anja Belz, Paul Bennett, Stefan Benus, Taylor Berg-Kirkpatrick, Nicola Bertoldi, Justin Betteridge, Chandra Sekhar Bhagavathula, Aditya Bhargava, Jiang Bian, Chris Biemann, Dan Bikel, Alexandra Birch, Arianna Bisazza, Graeme Blackwood, Sasha Blair-Goldensohn, Jim Blevins, Michael Bloodgood, Phil Blunsom, Bernd Bohnet, Ester Boldrini, Antal van den Bosch, Elizabeth Boschee, Jan Botha, Alexandre Bouchard-Côté, Jordan Boyd-Graber, Thorsten Brants, Ulf Brefeld, Chris Brew, Ted Briscoe, Razvan Bunescu, David Burkett, Bill Byrne, Donna Byron,

**Program Committee: Secondary Reviewers:**

Gabor Angeli, Gerlof Bouma, Steven Burrows, Paula Carvalho, Diego Ceccarelli, Janara Christensen, Eric Corlett, Bart Desmet, Frank Ferraro, Tiziano Flati, Francisco Guzman, Yifan He, Dirk Hovy, Rubén Izquierdo, Jiarong Jiang, Tetsuo Kiso, Effi Levi, Baichuan Li, Nedim Lipka, Lemao Liu, Jeff Lund, Pierre Magistry, Thang Luong Minh, Makoto Miwa, Abdelrahman Mohamed, Taesun Moon, Tanmoy Mukherjee, Ryo Nagata, Franco Maria Nardini, Viet-An Nguyen, Gozde Ozbal, Wang Pidong, Barbara Plank, Quentin Pleple, Natalia Ponomareva, Vladimir Popescu, Daniel Preotiuc, Ju Qi, Kyle Rawlins, Majid Razmara, Nils Reiter, Joseph Le Roux, Benoît Sagot, Mohammad Salameh, Baskaran Sankaran, Uma Sawant, Roy Schwartz, Aliaksei Severyn, Kathrin Spreyer, Gabriele Tolomei, Olga Uryopina, Rakesh Varna, Zhiyang Wang, Zhuoran Wang, Jonny Weese, Michael Wick, Wei Xu, Haiqin Yang, Xuchen Yao, Mo Yu, Yintao Yu, Jiajun Zhang, Bo Zhao, Shanheng Zhao, Tu Zhaopeng, Chao Zhou

## **Invited Talks:**

### **“On Learning Sparse Structured Input-Output Models”**

**Eric Xing, Carnegie Mellon University**

In many modern problems across areas such as natural language processing, computer vision, and social media inference, one is often interested in learning a Sparse Structured Input-Output Model (SIOM), in which the input variables of the model such as lexicons in a document bear rich structures due to the syntactic and semantic dependences between them in the text; and the output variables such as the elements in a multi-way classification, a parse, or a topic representation are also structured because of their interrelatedness. A SIOM can nicely capture rich structural properties in the data and in the problem, but it also raises severe computational and theoretical challenge on sparse, consistent, and tractable model identification and inference.

In this talk, I will present models, algorithms, and theories that learn Sparse SIOMs of various kinds in very high dimensional input/output space, with fast and highly scalable optimization procedures, and strong statistical guarantees. I will demonstrate application of our approach to problems in large-scale text classification, topic modeling, and dependency parsing.

### **“The Appification of the Web and the Renaissance of Conversational User Interfaces”**

**Patrick Pantel, Microsoft Research**

The appification of the Web is triggering a fundamental shift in how users access information. We are moving from centralized access points, such as search engines, towards highly specialized, and yet fragmented, functionalities in disconnected apps. This talk explores an entity-centric conversational interface as a mechanism to overcome this fragmentation, highlighting the numerous associated NLP challenges and opportunities that lie ahead.

Consider mobile scenarios, where the traditional search engine paradigm is being cannibalized by search and browse functionalities built directly into specialized apps. For example, while users can search for restaurants and products using their mobile browser, they are increasingly turning directly to applications such as Yelp, Urbanspoon and Amazon. However, interoperability between applications and lacking generalized interfaces to their functionalities pose serious scalability challenges. In this talk, we argue for an entity-centric conversational interface in which natural user interactions with entities are paired with actions that can be performed on the entities, thus enabling the brokering of web pages and applications that can satisfy the intended action. In this vision, the broker is aware of all entities and actions of interest to its users, understands the intent of the user, and provides direct actionable results through APIs with external providers satisfying the intent. The user saves clicks and time to accomplish her intended action and can discover related actions. New revenue streams open up from paid action placement and lead generation opportunities. At the forefront of this direction are a number of NLP challenges in the areas of entity recognition, entity linking, knowledge extraction, intent recognition, and dialog modeling, to name a few.

We end by proposing one particular technique for learning and mapping user intents in a search interface. In an annotation study conducted over a traffic sample of web usage logs, we found that a large proportion of user queries involve actions on entities, calling for an automatic approach to identifying relevant actions for entity-bearing queries. We pose the problem of finding actions

that can be performed on entities as the problem of doing probabilistic inference in a graphical model that captures how entity-bearing information requests are generated. Given a large collection of real-world queries and clicks from a commercial search engine, the models are learned efficiently through maximum likelihood estimation using an EM algorithm. Given a new query, inference enables the recommendation of a set of pertinent actions and providers. We propose an evaluation methodology for measuring the relevance of our recommended actions, and show empirical evidence of the quality and the diversity of the discovered actions.

**Best Reviewer Awards:**

Hua Ai	Ion Androutsopoulos	Yoav Artzi	Mohit Bansal
Aditya Bhargava	Graeme Blackwood	Sasha Blair-Goldensohn	David Burkett
Marie Candito	Marine Carpuat	Xavier Carreras	Soumen Chakrabarti

## Table of Contents

<i>Syntactic Transfer Using a Bilingual Lexicon</i> Greg Durrett, Adam Pauls and Dan Klein .....	1
<i>Regularized Interlingual Projections: Evaluation on Multilingual Transliteration</i> Jagadeesh Jagarlamudi and Hal Daume III .....	12
<i>Bilingual Lexicon Extraction from Comparable Corpora Using Label Propagation</i> Akihiro Tamura, Taro Watanabe and Eiichiro Sumita .....	24
<i>Lexical Differences in Autobiographical Narratives from Schizophrenic Patients and Healthy Controls</i> Kai Hong, Christian G. Kohler, Mary E. March, Amber A. Parker and Ani Nenkova .....	37
<i>Streaming Analysis of Discourse Participants</i> Benjamin Van Durme .....	48
<i>Detecting Subgroups in Online Discussions by Modeling Positive and Negative Relations among Participants</i> Ahmed Hassan, Amjad Abu-Jbara and Dragomir Radev .....	59
<i>Generative Goal-Driven User Simulation for Dialog Management</i> Aciel Eshky, Ben Allison and Mark Steedman .....	71
<i>Optimising Incremental Dialogue Decisions Using Information Density for Interactive Systems</i> Nina Dethlefs, Helen Hastie, Verena Rieser and Oliver Lemon .....	82
<i>Mixed Membership Markov Models for Unsupervised Conversation Modeling</i> Michael J. Paul .....	94
<i>An Entity-Topic Model for Entity Linking</i> Xianpei Han and Le Sun .....	105
<i>Linking Named Entities to Any Database</i> Avirup Sil, Ernest Cronin, Penghai Nie, Yinfei Yang, Ana-Maria Popescu and Alexander Yates .....	116
<i>Towards Efficient Named-Entity Rule Induction for Customizability</i> Ajay Nagesh, Ganesh Ramakrishnan, Laura Chiticariu, Rajasekar Krishnamurthy, Ankush Dharkar and Pushpak Bhattacharyya .....	128
<i>Active Learning for Imbalanced Sentiment Classification</i> Shoushan Li, Shengfeng Ju, Guodong Zhou and Xiaojun Li .....	139
<i>A Weakly Supervised Model for Sentence-Level Semantic Orientation Analysis with Multiple Experts</i> Lizhen Qu, Rainer Gemulla and Gerhard Weikum .....	149

<i>Collocation Polarity Disambiguation Using Web-based Pseudo Contexts</i> Yanyan Zhao, Bing Qin and Ting Liu .....	160
<i>Aligning Predicates across Monolingual Comparable Texts using Graph-based Clustering</i> Michael Roth and Anette Frank .....	171
<i>Local and Global Context for Supervised and Unsupervised Metonymy Resolution</i> Vivi Nastase, Alex Judea, Katja Markert and Michael Strube .....	183
<i>Learning Verb Inference Rules from Linguistically-Motivated Evidence</i> Hila Weisman, Jonathan Berant, Idan Szpektor and Ido Dagan .....	194
<i>Spectral Dependency Parsing with Latent Variables</i> Paramveer Dhillon, Jordan Rodu, Michael Collins, Dean Foster and Lyle Ungar .....	205
<i>A Phrase-Discovering Topic Model Using Hierarchical Pitman-Yor Processes</i> Robert Lindsey, William Headden and Michael Stipicevic .....	214
<i>A Bayesian Model for Learning SCFGs with Discontiguous Rules</i> Abby Levenberg, Chris Dyer and Phil Blunsom .....	223
<i>Multiple Aspect Summarization Using Integer Linear Programming</i> Kristian Woodsend and Mirella Lapata .....	233
<i>Minimal Dependency Length in Realization Ranking</i> Michael White and Rajakrishnan Rajkumar .....	244
<i>Framework of Automatic Text Summarization Using Reinforcement Learning</i> Seonggi Ryang and Takeshi Abekawa .....	256
<i>Large Scale Decipherment for Out-of-Domain Machine Translation</i> Qing Dou and Kevin Knight .....	266
<i>N-gram-based Tense Models for Statistical Machine Translation</i> Zhengxian Gong, Min Zhang, Chew Lim Tan and Guodong Zhou .....	276
<i>Source Language Adaptation for Resource-Poor Machine Translation</i> Pidong Wang, Preslav Nakov and Hwee Tou Ng .....	286
<i>Exploiting Reducibility in Unsupervised Dependency Parsing</i> David Mareček and Zdeněk Žabokrtský .....	297
<i>Improving Transition-Based Dependency Parsing with Buffer Transitions</i> Daniel Fernández-González and Carlos Gómez-Rodríguez .....	308
<i>Generalized Higher-Order Dependency Parsing with Cube Pruning</i> Hao Zhang and Ryan McDonald .....	320
<i>Universal Grapheme-to-Phoneme Prediction Over Latin Alphabets</i> Young-Bum Kim and Benjamin Snyder .....	332

<i>Name Phylogeny: A Generative Model of String Variation</i> Nicholas Andrews, Jason Eisner and Mark Dredze .....	344
<i>Syntactic Surprisal Affects Spoken Word Duration in Conversational Contexts</i> Vera Demberg, Asad Sayeed, Philip Gorinski and Nikolaos Engonopoulos .....	356
<i>Why Question Answering using Sentiment Analysis and Word Classes</i> Jong-Hoon Oh, Kentaro Torisawa, Chikara Hashimoto, Takuya Kawada, Stijn De Saeger, Jun'ichi Kazama and You Wang .....	368
<i>Natural Language Questions for the Web of Data</i> Mohamed Yahya, Klaus Berberich, Shady Elbassuoni, Maya Ramanath, Volker Tresp and Gerhard Weikum .....	379
<i>Answering Opinion Questions on Products by Exploiting Hierarchical Organization of Consumer Reviews</i> Jianxing Yu, Zheng-Jun Zha and Tat-Seng Chua .....	391
<i>Locally Training the Log-Linear Model for SMT</i> Lemao Liu, Hailong Cao, Taro Watanabe, Tiejun Zhao, Mo Yu and Conghui Zhu .....	402
<i>Iterative Annotation Transformation with Predict-Self Reestimation for Chinese Word Segmentation</i> Wenbin Jiang, Fandong Meng, Qun Liu and Yajuan Lü .....	412
<i>Automatically Constructing a Normalisation Dictionary for Microblogs</i> Bo Han, Paul Cook and Timothy Baldwin .....	421
<i>Unsupervised PCFG Induction for Grounded Language Learning with Highly Ambiguous Supervision</i> Joohyun Kim and Raymond Mooney .....	433
<i>Forced Derivation Tree based Model Training to Statistical Machine Translation</i> Nan Duan, Mu Li and Ming Zhou .....	445
<i>Multi-instance Multi-label Learning for Relation Extraction</i> Mihai Surdeanu, Julie Tibshirani, Ramesh Nallapati and Christopher D. Manning .....	455
<i>An “AI readability” Formula for French as a Foreign Language</i> Thomas François and Cédric Fairon .....	466
<i>Dynamic Programming for Higher Order Parsing of Gap-Minding Trees</i> Emily Pitler, Sampath Kannan and Mitchell Marcus .....	478
<i>Joint Entity and Event Coreference Resolution across Documents</i> Heeyoung Lee, Marta Recasens, Angel Chang, Mihai Surdeanu and Dan Jurafsky .....	489
<i>Joint Chinese Word Segmentation, POS Tagging and Parsing</i> Xian Qian and Yang Liu .....	501

<i>Translation Model Based Cross-Lingual Language Model Adaptation: from Word Models to Phrase Models</i>	
Shixiang Lu, Wei Wei, Xiaoyin Fu and Bo Xu .....	512
<i>Open Language Learning for Information Extraction</i>	
Mausam, Michael Schmitz, Stephen Soderland, Robert Bart and Oren Etzioni .....	523
<i>Modelling Sequential Text with an Adaptive Topic Model</i>	
Lan Du, Wray Buntine and Huidong Jin .....	535
<i>A Comparison of Vector-based Representations for Semantic Composition</i>	
William Blacoe and Mirella Lapata .....	546
<i>Exploiting Chunk-level Features to Improve Phrase Chunking</i>	
Junsheng Zhou, Weiguang Qu and Fen Zhang .....	557
<i>A Beam-Search Decoder for Grammatical Error Correction</i>	
Daniel Dahlmeier and Hwee Tou Ng .....	568
<i>A Statistical Relational Learning Approach to Identifying Evidence Based Medicine Categories</i>	
Mathias Verbeke, Vincent Van Asch, Roser Morante, Paolo Frasconi, Walter Daelemans and Luc De Raedt .....	579
<i>Lyrics, Music, and Emotions</i>	
Rada Mihalcea and Carlo Strapparava .....	590
<i>Assessment of ESL Learners' Syntactic Competence Based on Similarity Measures</i>	
Su-Youn Yoon and Suma Bhat .....	600
<i>A Unified Approach to Transliteration-based Text Input with Online Spelling Correction</i>	
Hisami Suzuki and Jianfeng Gao .....	609
<i>Excitatory or Inhibitory: A New Semantic Orientation Extracts Contradiction and Causality from the Web</i>	
Chikara Hashimoto, Kentaro Torisawa, Stijn De Saeger, Jong-Hoon Oh and Jun'ichi Kazama .....	619
<i>Enlarging Paraphrase Collections through Generalization and Instantiation</i>	
Atsushi Fujita, Pierre Isabelle and Roland Kuhn .....	631
<i>Concurrent Acquisition of Word Meaning and Lexical Categories</i>	
Afra Alishahi and Grzegorz Chrupala .....	643
<i>Do Neighbours Help? An Exploration of Graph-based Algorithms for Cross-domain Sentiment Classification</i>	
Natalia Ponomareva and Mike Thelwall .....	655
<i>Learning Lexicon Models from Search Logs for Query Expansion</i>	
Jianfeng Gao, Shasha Xie, Xiaodong He and Alnur Ali .....	666

<i>Joint Inference for Event Timeline Construction</i>	
Quang Do, Wei Lu and Dan Roth .....	677
<i>Three Dependency-and-Boundary Models for Grammar Induction</i>	
Valentin I. Spitzkovsky, Hiyan Alshawi and Daniel Jurafsky .....	688
<i>Exploring Adaptor Grammars for Native Language Identification</i>	
Sze-Meng Jojo Wong, Mark Dras and Mark Johnson .....	699
<i>Discovering Diverse and Salient Threads in Document Collections</i>	
Jennifer Gillenwater, Alex Kulesza and Ben Taskar .....	710
<i>Generalizing Sub-sentential Paraphrase Acquisition across Original Signal Type of Text Pairs</i>	
Aurélien Max, Houda Bouamor and Anne Vilnat .....	721
<i>Parse, Price and Cut—Delayed Column and Row Generation for Graph Based Parsers</i>	
Sebastian Riedel, David Smith and Andrew McCallum .....	732
<i>Domain Adaptation for Coreference Resolution: An Adaptive Ensemble Approach</i>	
Jian Bo Yang, Qi Mao, Qiao Liang Xiang, Ivor Wai-Hung Tsang, Kian Ming Adam Chai and Hai Leong Chieu .....	744
<i>Weakly Supervised Training of Semantic Parsers</i>	
Jayant Krishnamurthy and Tom Mitchell .....	754
<i>Cross-Lingual Language Modeling with Syntactic Reordering for Low-Resource Speech Recognition</i>	
Ping Xu and Pascale Fung .....	766
<i>Resolving Complex Cases of Definite Pronouns: The Winograd Schema Challenge</i>	
Altaf Rahman and Vincent Ng .....	777
<i>A Sequence Labelling Approach to Quote Attribution</i>	
Timothy O’Keefe, Silvia Pareti, James R. Curran, Irena Koprinska and Matthew Honnibal ...	790
<i>SSHLDA: A Semi-Supervised Hierarchical Topic Model</i>	
Xian-Ling Mao, Zhao-Yan Ming, Tat-Seng Chua, Si Li, Hongfei Yan and Xiaoming Li .....	800
<i>Improving NLP through Marginalization of Hidden Syntactic Structure</i>	
Jason Naradowsky, Sebastian Riedel and David Smith .....	810
<i>Type-Supervised Hidden Markov Models for Part-of-Speech Tagging with Incomplete Tag Dictionaries</i>	
Dan Garrette and Jason Baldridge .....	821
<i>Explore Person Specific Evidence in Web Person Name Disambiguation</i>	
Liwei Chen, Yansong Feng, Lei Zou and Dongyan Zhao .....	832
<i>Inducing a Discriminative Parser to Optimize Machine Translation Reordering</i>	
Graham Neubig, Taro Watanabe and Shinsuke Mori .....	843

<i>Re-training Monolingual Parser Bilingually for Syntactic SMT</i>	
Shujie Liu, Chi-Ho Li, Mu Li and Ming Zhou .....	854
<i>Transforming Trees to Improve Syntactic Convergence</i>	
David Burkett and Dan Klein .....	863
<i>Learning Constraints for Consistent Timeline Extraction</i>	
David McClosky and Christopher D. Manning .....	873
<i>Identifying Constant and Unique Relations by using Time-Series Text</i>	
Yohei Takaku, Nobuhiro Kaji, Naoki Yoshinaga and Masashi Toyoda .....	883
<i>No Noun Phrase Left Behind: Detecting and Typing Unlinkable Entities</i>	
Thomas Lin, Mausam and Oren Etzioni .....	893
<i>A Novel Discriminative Framework for Sentence-Level Discourse Analysis</i>	
Shafiq Joty, Giuseppe Carenini and Raymond Ng .....	904
<i>Using Discourse Information for Paraphrase Extraction</i>	
Michaela Regneri and Rui Wang .....	916
<i>Generating Non-Projective Word Order in Statistical Linearization</i>	
Bernd Bohnet, Anders Björkelund, Jonas Kuhn, Wolfgang Seeker and Sina Zarriess .....	928
<i>Learning Syntactic Categories Using Paradigmatic Representations of Word Context</i>	
Mehmet Ali Yatbaz, Enis Sert and Deniz Yuret .....	940
<i>Exploring Topic Coherence over Many Models and Many Topics</i>	
Keith Stevens, Philip Kegelmeyer, David Andrzejewski and David Buttler .....	952
<i>Entropy-based Pruning for Phrase-based Machine Translation</i>	
Wang Ling, João Graça, Isabel Trancoso and Alan Black .....	962
<i>A Systematic Comparison of Phrase Table Pruning Techniques</i>	
Richard Zens, Daisy Stanton and Peng Xu .....	972
<i>Probabilistic Finite State Machines for Regression-based MT Evaluation</i>	
Mengqiu Wang and Christopher D. Manning .....	984
<i>An Empirical Investigation of Statistical Significance in NLP</i>	
Taylor Berg-Kirkpatrick, David Burkett and Dan Klein .....	995
<i>Employing Compositional Semantics and Discourse Consistency in Chinese Event Extraction</i>	
Peifeng Li, Guodong Zhou, Qiaoming Zhu and Libin Hou .....	1006
<i>Reading The Web with Learned Syntactic-Semantic Inference Rules</i>	
Ni Lao, Amarnag Subramanya, Fernando Pereira and William W. Cohen .....	1017
<i>Ensemble Semantics for Large-scale Unsupervised Relation Extraction</i>	
Bonan Min, Shuming Shi, Ralph Grishman and Chin-Yew Lin .....	1027

<i>Forest Reranking through Subtree Ranking</i>	
Richard Farkas and Helmut Schmid .....	1038
<i>Parser Showdown at the Wall Street Corral: An Empirical Investigation of Error Types in Parser Output</i>	
Jonathan K. Kummerfeld, David Hall, James R. Curran and Dan Klein .....	1048
<i>Extending Machine Translation Evaluation Metrics with Lexical Cohesion to Document Level</i>	
Billy T. M. Wong and Chunyu Kit .....	1060
<i>Fast Large-Scale Approximate Graph Construction for NLP</i>	
Amit Goyal, Hal Daume III and Raul Guerra .....	1069
<i>Building a Lightweight Semantic Model for Unsupervised Information Extraction on Short Listings</i>	
Doo Soon Kim, Kunal Verma and Peter Yeh .....	1081
<i>Sketch Algorithms for Estimating Point Queries in NLP</i>	
Amit Goyal, Hal Daume III and Graham Cormode .....	1093
<i>Monte Carlo MCMC: Efficient Inference by Approximate Sampling</i>	
Sameer Singh, Michael Wick and Andrew McCallum .....	1104
<i>On Amortizing Inference Cost for Structured Prediction</i>	
Vivek Srikumar, Gourab Kundu and Dan Roth .....	1114
<i>Exact Sampling and Decoding in High-Order Hidden Markov Models</i>	
Simon Carter, Marc Dymetman and Guillaume Bouchard .....	1125
<i>PATTY: A Taxonomy of Relational Patterns with Semantic Types</i>	
Ndapandula Nakashole, Gerhard Weikum and Fabian Suchanek .....	1135
<i>Training Factored PCFGs with Expectation Propagation</i>	
David Hall and Dan Klein .....	1146
<i>A Coherence Model Based on Syntactic Patterns</i>	
Annie Louis and Ani Nenkova .....	1157
<i>Language Model Rest Costs and Space-Efficient Storage</i>	
Kenneth Heafield, Philipp Koehn and Alon Lavie .....	1169
<i>Document-Wide Decoding for Phrase-Based Statistical Machine Translation</i>	
Christian Hardmeier, Joakim Nivre and Jörg Tiedemann .....	1179
<i>Left-to-Right Tree-to-String Decoding with Prediction</i>	
Yang Feng, Yang Liu, Qun Liu and Trevor Cohn .....	1191
<i>Semantic Compositionality through Recursive Matrix-Vector Spaces</i>	
Richard Socher, Brody Huval, Christopher D. Manning and Andrew Y. Ng .....	1201
<i>Polarity Inducing Latent Semantic Analysis</i>	
Wen-tau Yih, Geoffrey Zweig and John Platt .....	1212

<i>First Order vs. Higher Order Modification in Distributional Semantics</i>	
Gemma Boleda, Eva Maria Vecchi, Miquel Cornudella and Louise McNally .....	1223
<i>Learning-based Multi-Sieve Co-reference Resolution with Knowledge</i>	
Lev Ratinov and Dan Roth .....	1234
<i>Joint Learning for Coreference Resolution with Markov Logic</i>	
Yang Song, Jing Jiang, Wayne Xin Zhao, Sujian Li and Houfeng Wang .....	1245
<i>Resolving “This-issue” Anaphora</i>	
Varada Kolhatkar and Graeme Hirst .....	1255
<i>Entity based Q&amp;A Retrieval</i>	
Amit Singh .....	1266
<i>Constructing Task-Specific Taxonomies for Document Collection Browsing</i>	
Hui Yang .....	1278
<i>Besting the Quiz Master: Crowdsourcing Incremental Classification Games</i>	
Jordan Boyd-Graber, Brianna Satinoff, He He and Hal Daume III .....	1290
<i>Multi-Domain Learning: When Do Domains Matter?</i>	
Mahesh Joshi, Mark Dredze, William W. Cohen and Carolyn Rose .....	1302
<i>Biased Representation Learning for Domain Adaptation</i>	
Fei Huang and Alexander Yates .....	1313
<i>Unambiguity Regularization for Unsupervised Learning of Probabilistic Grammars</i>	
Kewei Tu and Vasant Honavar .....	1324
<i>Extracting Opinion Expressions with semi-Markov Conditional Random Fields</i>	
Bishan Yang and Claire Cardie .....	1335
<i>Opinion Target Extraction Using Word-Based Translation Model</i>	
Kang Liu, Liheng Xu and Jun Zhao .....	1346
<i>Word Salad: Relating Food Prices and Descriptions</i>	
Victor Chahuneau, Kevin Gimpel, Bryan R. Routledge, Lily Scherlis and Noah A. Smith ...	1357
<i>Learning to Map into a Universal POS Tagset</i>	
Yuan Zhang, Roi Reichart, Regina Barzilay and Amir Globerson .....	1368
<i>Part-of-Speech Tagging for Chinese-English Mixed Texts with Dynamic Features</i>	
Jiayi Zhao, Xipeng Qiu, Shu Zhang, Feng Ji and Xuanjing Huang .....	1379
<i>Wiki-ly Supervised Part-of-Speech Tagging</i>	
Shen Li, João Graça and Ben Taskar .....	1389
<i>Joining Forces Pays Off: Multilingual Joint Word Sense Disambiguation</i>	
Roberto Navigli and Simone Paolo Ponzetto .....	1399

<i>A New Minimally-Supervised Framework for Domain Word Sense Disambiguation</i>	
Stefano Faralli and Roberto Navigli .....	1411
<i>Grounded Models of Semantic Representation</i>	
Carina Silberer and Mirella Lapata .....	1423
<i>Improved Parsing and POS Tagging Using Inter-Sentence Consistency Constraints</i>	
Alexander Rush, Roi Reichart, Michael Collins and Amir Globerson .....	1434
<i>Unified Dependency Parsing of Chinese Morphological and Syntactic Structures</i>	
Zhongguo Li and Guodong Zhou .....	1445
<i>A Transition-Based System for Joint Part-of-Speech Tagging and Labeled Non-Projective Dependency Parsing</i>	
Bernd Bohnet and Joakim Nivre .....	1455
<i>Identifying Event-related Bursts via Social Media Activities</i>	
Xin Zhao, Baihan Shu, Jing Jiang, Yang Song, Hongfei Yan and Xiaoming Li .....	1466
<i>User Demographics and Language in an Implicit Social Network</i>	
Katja Filippova .....	1478
<i>Revisiting the Predictability of Language: Response Completion in Social Media</i>	
Bo Pang and Sujith Ravi .....	1489
<i>Supervised Text-based Geolocation Using Language Models on an Adaptive Grid</i>	
Stephen Roller, Michael Speriosu, Sarat Rallapalli, Benjamin Wing and Jason Baldrige ...	1500
<i>A Discriminative Model for Query Spelling Correction with Latent Structural SVM</i>	
Huizhong Duan, Yanen Li, ChengXiang Zhai and Dan Roth .....	1511
<i>Characterizing Stylistic Elements in Syntactic Structure</i>	
Song Feng, Ritwik Banerjee and Yejin Choi .....	1522

# Conference Program

Thursday, July 12, 2012

## Session 1-AM-0P: Opening

09:00-09:15 Opening Remarks

## Session 1-AM-1P: Plenary Session: Invited Talk

Session Chair: James Henderson

09:15-10:30 Invited Talk: On Learning Sparse Structured Input-Output Models (Eric Xing, Carnegie Mellon University)

10:30-11:00 Coffee Break

## Session 1-AM-2A: Machine Translation: Bilingual Lexicons and Alignment

Session Chair: David Chiang

11:00-11:30 *Syntactic Transfer Using a Bilingual Lexicon*  
Greg Durrett, Adam Pauls and Dan Klein

11:30-12:00 *Regularized Interlingual Projections: Evaluation on Multilingual Transliteration*  
Jagadeesh Jagarlamudi and Hal Daume III

12:00-12:30 *Bilingual Lexicon Extraction from Comparable Corpora Using Label Propagation*  
Akihiro Tamura, Taro Watanabe and Eiichiro Sumita

## Session 1-AM-2B: Social Media: Author Style and Attribution

Session Chair: Janyce Wiebe

11:00-11:30 *Lexical Differences in Autobiographical Narratives from Schizophrenic Patients and Healthy Controls*  
Kai Hong, Christian G. Kohler, Mary E. March, Amber A. Parker and Ani Nenkova

11:30-12:00 *Streaming Analysis of Discourse Participants*  
Benjamin Van Durme

12:00-12:30 *Detecting Subgroups in Online Discussions by Modeling Positive and Negative Relations among Participants*  
Ahmed Hassan, Amjad Abu-Jbara and Dragomir Radev

**Thursday, July 12, 2012 (continued)**

**Session 1-AM-2C: Dialogue and Interactive Systems**

Session Chair: Michael White

- 11:00-11:30 *Generative Goal-Driven User Simulation for Dialog Management*  
Aciel Eshky, Ben Allison and Mark Steedman
- 11:30-12:00 *Optimising Incremental Dialogue Decisions Using Information Density for Interactive Systems*  
Nina Dethlefs, Helen Hastie, Verena Rieser and Oliver Lemon
- 12:00-12:30 *Mixed Membership Markov Models for Unsupervised Conversation Modeling*  
Michael J. Paul

**Session 1-AM-2D: Information Extraction: Entity Disambiguation**

Session Chair: Raymond Mooney

- 11:00-11:30 *An Entity-Topic Model for Entity Linking*  
Xianpei Han and Le Sun
- 11:30-12:00 *Linking Named Entities to Any Database*  
Avirup Sil, Ernest Cronin, Penghai Nie, Yinfei Yang, Ana-Maria Popescu and Alexander Yates
- 12:00-12:30 *Towards Efficient Named-Entity Rule Induction for Customizability*  
Ajay Nagesh, Ganesh Ramakrishnan, Laura Chiticariu, Rajasekar Krishnamurthy, Ankush Dharkar and Pushpak Bhattacharyya
- 12:30-14:00 Lunch

**Session 1-PM-1A: Sentiment Analysis**

Session Chair: Bing Liu

- 14:00-14:30 *Active Learning for Imbalanced Sentiment Classification*  
Shoushan Li, Shengfeng Ju, Guodong Zhou and Xiaojun Li
- 14:30-15:00 *A Weakly Supervised Model for Sentence-Level Semantic Orientation Analysis with Multiple Experts*  
Lizhen Qu, Rainer Gemulla and Gerhard Weikum
- 15:00-15:30 *Collocation Polarity Disambiguation Using Web-based Pseudo Contexts*  
Yanyan Zhao, Bing Qin and Ting Liu

**Thursday, July 12, 2012 (continued)**

**Session 1-PM-1B: Semantics: Nouns, Verbs and Predicates**

Session Chair: Rada Mihalcea

- 14:00-14:30 *Aligning Predicates across Monolingual Comparable Texts using Graph-based Clustering*  
Michael Roth and Anette Frank
- 14:30-15:00 *Local and Global Context for Supervised and Unsupervised Metonymy Resolution*  
Vivi Nastase, Alex Judea, Katja Markert and Michael Strube
- 15:00-15:30 *Learning Verb Inference Rules from Linguistically-Motivated Evidence*  
Hila Weisman, Jonathan Berant, Idan Szpektor and Ido Dagan

**Session 1-PM-1C: Machine Learning: Latent Models**

Session Chair: Alexandre Klementiev

- 14:00-14:30 *Spectral Dependency Parsing with Latent Variables*  
Paramveer Dhillon, Jordan Rodu, Michael Collins, Dean Foster and Lyle Ungar
- 14:30-15:00 *A Phrase-Discovering Topic Model Using Hierarchical Pitman-Yor Processes*  
Robert Lindsey, William Headden and Michael Stipicevic
- 15:00-15:30 *A Bayesian Model for Learning SCFGs with Discontiguous Rules*  
Abby Levenberg, Chris Dyer and Phil Blunsom

**Session 1-PM-1D: Summarization**

Session Chair: Dragomir Radev

- 14:00-14:30 *Multiple Aspect Summarization Using Integer Linear Programming*  
Kristian Woodsend and Mirella Lapata
- 14:30-15:00 *Minimal Dependency Length in Realization Ranking*  
Michael White and Rajakrishnan Rajkumar
- 15:00-15:30 *Framework of Automatic Text Summarization Using Reinforcement Learning*  
Seonggi Ryang and Takeshi Abekawa
- 15:30-16:00 Coffee Break

**Thursday, July 12, 2012 (continued)**

**Session 1-PM-2A: Machine Translation**

Session Chair: Xiong Deyi

16:00-16:30 *Large Scale Decipherment for Out-of-Domain Machine Translation*

Qing Dou and Kevin Knight

16:30-17:00 *N-gram-based Tense Models for Statistical Machine Translation*

Zhengxian Gong, Min Zhang, Chew Lim Tan and Guodong Zhou

17:00-17:30 *Source Language Adaptation for Resource-Poor Machine Translation*

Pidong Wang, Preslav Nakov and Hwee Tou Ng

**Session 1-PM-2B: Dependency Parsing**

Session Chair: Emily Pitler

16:00-16:30 *Exploiting Reducibility in Unsupervised Dependency Parsing*

David Mareček and Zdeněk Žabokrtský

16:30-17:00 *Improving Transition-Based Dependency Parsing with Buffer Transitions*

Daniel Fernández-González and Carlos Gómez-Rodríguez

17:00-17:30 *Generalized Higher-Order Dependency Parsing with Cube Pruning*

Hao Zhang and Ryan McDonald

**Session 1-PM-2C: Phonemes, Words and Speech**

Session Chair: Pascale Fung

16:00-16:30 *Universal Grapheme-to-Phoneme Prediction Over Latin Alphabets*

Young-Bum Kim and Benjamin Snyder

16:30-17:00 *Name Phylogeny: A Generative Model of String Variation*

Nicholas Andrews, Jason Eisner and Mark Dredze

17:00-17:30 *Syntactic Surprisal Affects Spoken Word Duration in Conversational Contexts*

Vera Demberg, Asad Sayeed, Philip Gorinski and Nikolaos Engonopoulos

**Thursday, July 12, 2012 (continued)**

**Session 1-PM-2D: Question Answering**

Session Chair: Alessandro Moschitti

- 16:00-16:30 *Why Question Answering using Sentiment Analysis and Word Classes*  
Jong-Hoon Oh, Kentaro Torisawa, Chikara Hashimoto, Takuya Kawada, Stijn De Saeger, Jun'ichi Kazama and Yiou Wang
- 16:30-17:00 *Natural Language Questions for the Web of Data*  
Mohamed Yahya, Klaus Berberich, Shady Elbassuoni, Maya Ramanath, Volker Tresp and Gerhard Weikum
- 17:00-17:30 *Answering Opinion Questions on Products by Exploiting Hierarchical Organization of Consumer Reviews*  
Jianxing Yu, Zheng-Jun Zha and Tat-Seng Chua
- 17:30-18:00 Break

**Session 1-PM-3P: Poster Session and Reception (18:00-22:00)**

*Locally Training the Log-Linear Model for SMT*

Lemao Liu, Hailong Cao, Taro Watanabe, Tiejun Zhao, Mo Yu and Conghui Zhu

*Iterative Annotation Transformation with Predict-Self Reestimation for Chinese Word Segmentation*

Wenbin Jiang, Fandong Meng, Qun Liu and Yajuan Lü

*Automatically Constructing a Normalisation Dictionary for Microblogs*

Bo Han, Paul Cook and Timothy Baldwin

*Unsupervised PCFG Induction for Grounded Language Learning with Highly Ambiguous Supervision*

Joohyun Kim and Raymond Mooney

*Forced Derivation Tree based Model Training to Statistical Machine Translation*

Nan Duan, Mu Li and Ming Zhou

*Multi-instance Multi-label Learning for Relation Extraction*

Mihai Surdeanu, Julie Tibshirani, Ramesh Nallapati and Christopher D. Manning

*An "AI readability" Formula for French as a Foreign Language*

Thomas François and Cédric Fairon

**Thursday, July 12, 2012 (continued)**

*Dynamic Programming for Higher Order Parsing of Gap-Minding Trees*

Emily Pitler, Sampath Kannan and Mitchell Marcus

*Joint Entity and Event Coreference Resolution across Documents*

Heeyoung Lee, Marta Recasens, Angel Chang, Mihai Surdeanu and Dan Jurafsky

*Joint Chinese Word Segmentation, POS Tagging and Parsing*

Xian Qian and Yang Liu

*Translation Model Based Cross-Lingual Language Model Adaptation: from Word Models to Phrase Models*

Shixiang Lu, Wei Wei, Xiaoyin Fu and Bo Xu

*Open Language Learning for Information Extraction*

Mausam, Michael Schmitz, Stephen Soderland, Robert Bart and Oren Etzioni

*Modelling Sequential Text with an Adaptive Topic Model*

Lan Du, Wray Buntine and Huidong Jin

*A Comparison of Vector-based Representations for Semantic Composition*

William Blacoe and Mirella Lapata

*Exploiting Chunk-level Features to Improve Phrase Chunking*

Junsheng Zhou, Weiguang Qu and Fen Zhang

*A Beam-Search Decoder for Grammatical Error Correction*

Daniel Dahlmeier and Hwee Tou Ng

*A Statistical Relational Learning Approach to Identifying Evidence Based Medicine Categories*

Mathias Verbeke, Vincent Van Asch, Roser Morante, Paolo Frasconi, Walter Daelemans and Luc De Raedt

*Lyrics, Music, and Emotions*

Rada Mihalcea and Carlo Strapparava

*Assessment of ESL Learners' Syntactic Competence Based on Similarity Measures*

Su-Youn Yoon and Suma Bhat

**Thursday, July 12, 2012 (continued)**

*A Unified Approach to Transliteration-based Text Input with Online Spelling Correction*  
Hisami Suzuki and Jianfeng Gao

*Excitatory or Inhibitory: A New Semantic Orientation Extracts Contradiction and Causality from the Web*

Chikara Hashimoto, Kentaro Torisawa, Stijn De Saeger, Jong-Hoon Oh and Jun'ichi Kazama

*Enlarging Paraphrase Collections through Generalization and Instantiation*

Atsushi Fujita, Pierre Isabelle and Roland Kuhn

*Concurrent Acquisition of Word Meaning and Lexical Categories*

Afra Alishahi and Grzegorz Chrupala

*Do Neighbours Help? An Exploration of Graph-based Algorithms for Cross-domain Sentiment Classification*

Natalia Ponomareva and Mike Thelwall

*Learning Lexicon Models from Search Logs for Query Expansion*

Jianfeng Gao, Shasha Xie, Xiaodong He and Alnur Ali

*Joint Inference for Event Timeline Construction*

Quang Do, Wei Lu and Dan Roth

*Three Dependency-and-Boundary Models for Grammar Induction*

Valentin I. Spitzkovsky, Hiyun Alshawi and Daniel Jurafsky

*Exploring Adaptor Grammars for Native Language Identification*

Sze-Meng Jojo Wong, Mark Dras and Mark Johnson

*Discovering Diverse and Salient Threads in Document Collections*

Jennifer Gillenwater, Alex Kulesza and Ben Taskar

*Generalizing Sub-sentential Paraphrase Acquisition across Original Signal Type of Text Pairs*

Aurélien Max, Houda Bouamor and Anne Vilnat

*Parse, Price and Cut—Delayed Column and Row Generation for Graph Based Parsers*

Sebastian Riedel, David Smith and Andrew McCallum

**Thursday, July 12, 2012 (continued)**

*Domain Adaptation for Coreference Resolution: An Adaptive Ensemble Approach*

Jian Bo Yang, Qi Mao, Qiao Liang Xiang, Ivor Wai-Hung Tsang, Kian Ming Adam Chai and Hai Leong Chieu

*Weakly Supervised Training of Semantic Parsers*

Jayant Krishnamurthy and Tom Mitchell

*Cross-Lingual Language Modeling with Syntactic Reordering for Low-Resource Speech Recognition*

Ping Xu and Pascale Fung

*Resolving Complex Cases of Definite Pronouns: The Winograd Schema Challenge*

Altaf Rahman and Vincent Ng

*A Sequence Labelling Approach to Quote Attribution*

Timothy O'Keefe, Silvia Paretì, James R. Curran, Irena Koprinska and Matthew Honnibal

*SSHLDA: A Semi-Supervised Hierarchical Topic Model*

Xian-Ling Mao, Zhao-Yan Ming, Tat-Seng Chua, Si Li, Hongfei Yan and Xiaoming Li

*Improving NLP through Marginalization of Hidden Syntactic Structure*

Jason Naradowsky, Sebastian Riedel and David Smith

*Type-Supervised Hidden Markov Models for Part-of-Speech Tagging with Incomplete Tag Dictionaries*

Dan Garrette and Jason Baldridge

*Explore Person Specific Evidence in Web Person Name Disambiguation*

Liwei Chen, Yansong Feng, Lei Zou and Dongyan Zhao

**Friday, July 13, 2012**

**Session 2-AM-1P: Plenary Session: Invited Talk**

Session Chair: Marius Pasca

09:15-10:30 Invited Talk: The Application of the Web and the Renaissance of Conversational User Interfaces (Patrick Pantel, Microsoft Research)

10:30-11:00 Coffee Break

**Session 2-AM-2A: Machine Translation: Role of Syntax**

Session Chair: Qun Liu

11:00-11:30 *Inducing a Discriminative Parser to Optimize Machine Translation Reordering*  
Graham Neubig, Taro Watanabe and Shinsuke Mori

11:30-12:00 *Re-training Monolingual Parser Bilingually for Syntactic SMT*  
Shujie Liu, Chi-Ho Li, Mu Li and Ming Zhou

12:00-12:30 *Transforming Trees to Improve Syntactic Convergence*  
David Burkett and Dan Klein

**Session 2-AM-2B: Information Extraction: Temporally-Aware Extraction**

Session Chair: Jong-Hoon Oh

11:00-11:30 *Learning Constraints for Consistent Timeline Extraction*  
David McClosky and Christopher D. Manning

11:30-12:00 *Identifying Constant and Unique Relations by using Time-Series Text*  
Yohei Takaku, Nobuhiro Kaji, Naoki Yoshinaga and Masashi Toyoda

12:00-12:30 *No Noun Phrase Left Behind: Detecting and Typing Unlinkable Entities*  
Thomas Lin, Mausam and Oren Etzioni

**Friday, July 13, 2012 (continued)**

**Session 2-AM-2C: Discourse and Generation**

Session Chair: Anette Frank

- 11:00-11:30 *A Novel Discriminative Framework for Sentence-Level Discourse Analysis*  
Shafiq Joty, Giuseppe Carenini and Raymond Ng
- 11:30-12:00 *Using Discourse Information for Paraphrase Extraction*  
Michaela Regneri and Rui Wang
- 12:00-12:30 *Generating Non-Projective Word Order in Statistical Linearization*  
Bernd Bohnet, Anders Björkelund, Jonas Kuhn, Wolfgang Seeker and Sina Zarriess

**Session 2-AM-2D: CoNLL Shared Task**

Session Chair: Sameer Pradhan

- 11:00-12:30 CoNLL Shared Task Session
- 12:30-13:45 Lunch
- 13:45-14:30 SIGDAT and SIGNLL Business Meetings

**Session 2-PM-1A: Semantics: Words and Topics**

Session Chair: Roi Reichart

- 14:30-15:00 *Learning Syntactic Categories Using Paradigmatic Representations of Word Context*  
Mehmet Ali Yatbaz, Enis Sert and Deniz Yuret
- 15:00-15:30 *Exploring Topic Coherence over Many Models and Many Topics*  
Keith Stevens, Philip Kegelmeyer, David Andrzejewski and David Buttler

**Friday, July 13, 2012 (continued)**

**Session 2-PM-1B: Machine Translation: Pruning**

Session Chair: Kevin Knight

14:30-15:00 *Entropy-based Pruning for Phrase-based Machine Translation*

Wang Ling, João Graça, Isabel Trancoso and Alan Black

15:00-15:30 *A Systematic Comparison of Phrase Table Pruning Techniques*

Richard Zens, Daisy Stanton and Peng Xu

**Session 2-PM-1C: Evaluation**

Session Chair: Billy Tak-Ming Wong

14:30-15:00 *Probabilistic Finite State Machines for Regression-based MT Evaluation*

Mengqiu Wang and Christopher D. Manning

15:00-15:30 *An Empirical Investigation of Statistical Significance in NLP*

Taylor Berg-Kirkpatrick, David Burkett and Dan Klein

**Session 2-PM-1D: CoNLL Shared Task**

Session Chair: Alessandro Moschitti

14:30-15:30 CoNLL Shared Task Session

15:30-16:00 Coffee Break

**Session 2-PM-2A: Information Extraction: Relation and Event Extraction**

Session Chair: Mausam

16:00-16:30 *Employing Compositional Semantics and Discourse Consistency in Chinese Event Extraction*

Peifeng Li, Guodong Zhou, Qiaoming Zhu and Libin Hou

16:30-17:00 *Reading The Web with Learned Syntactic-Semantic Inference Rules*

Ni Lao, Amarnag Subramanya, Fernando Pereira and William W. Cohen

17:00-17:30 *Ensemble Semantics for Large-scale Unsupervised Relation Extraction*

Bonan Min, Shuming Shi, Ralph Grishman and Chin-Yew Lin

**Friday, July 13, 2012 (continued)**

**Session 2-PM-2B: Parsing Models and Evaluation**

Session Chair: Ivan Titov

- 16:00-16:30 *Forest Reranking through Subtree Ranking*  
Richard Farkas and Helmut Schmid
- 16:30-17:00 *Parser Showdown at the Wall Street Corral: An Empirical Investigation of Error Types in Parser Output*  
Jonathan K. Kummerfeld, David Hall, James R. Curran and Dan Klein
- 17:00-17:30 *Extending Machine Translation Evaluation Metrics with Lexical Cohesion to Document Level*  
Billy T. M. Wong and Chunyu Kit

**Session 2-PM-2C: Large-Scale NLP Algorithms**

Session Chair: Benjamin van Durme

- 16:00-16:30 *Fast Large-Scale Approximate Graph Construction for NLP*  
Amit Goyal, Hal Daume III and Raul Guerra
- 16:30-17:00 *Building a Lightweight Semantic Model for Unsupervised Information Extraction on Short Listings*  
Doo Soon Kim, Kunal Verma and Peter Yeh
- 17:00-17:30 *Sketch Algorithms for Estimating Point Queries in NLP*  
Amit Goyal, Hal Daume III and Graham Cormode

**Session 2-PM-2D: Machine Learning: Inference**

Session Chair: Jennifer Gillenwater

- 16:00-16:30 *Monte Carlo MCMC: Efficient Inference by Approximate Sampling*  
Sameer Singh, Michael Wick and Andrew McCallum
- 16:30-17:00 *On Amortizing Inference Cost for Structured Prediction*  
Vivek Srikumar, Gourab Kundu and Dan Roth
- 17:00-17:30 *Exact Sampling and Decoding in High-Order Hidden Markov Models*  
Simon Carter, Marc Dymetman and Guillaume Bouchard

**Saturday, July 14, 2012**

**Session 3-AM-1P: Plenary Session**

Session Chair: Jun'ichi Tsujii

- 09:00-09:30 *PATY: A Taxonomy of Relational Patterns with Semantic Types*  
Ndapandula Nakashole, Gerhard Weikum and Fabian Suchanek
- 09:30-10:00 *Training Factored PCFGs with Expectation Propagation*  
David Hall and Dan Klein
- 10:00-10:30 *A Coherence Model Based on Syntactic Patterns*  
Annie Louis and Ani Nenkova
- 10:30-11:00 Coffee Break

**Session 3-AM-2A: Machine Translation: Decoding**

Session Chair: Preslav Nakov

- 11:00-11:30 *Language Model Rest Costs and Space-Efficient Storage*  
Kenneth Heafield, Philipp Koehn and Alon Lavie
- 11:30-12:00 *Document-Wide Decoding for Phrase-Based Statistical Machine Translation*  
Christian Hardmeier, Joakim Nivre and Jörg Tiedemann
- 12:00-12:30 *Left-to-Right Tree-to-String Decoding with Prediction*  
Yang Feng, Yang Liu, Qun Liu and Trevor Cohn

**Saturday, July 14, 2012 (continued)**

**Session 3-AM-2B: Distributional and Compositional Semantics**

Session Chair: Bo Pang

- 11:00-11:30 *Semantic Compositionality through Recursive Matrix-Vector Spaces*  
Richard Socher, Brody Huval, Christopher D. Manning and Andrew Y. Ng
- 11:30-12:00 *Polarity Inducing Latent Semantic Analysis*  
Wen-tau Yih, Geoffrey Zweig and John Platt
- 12:00-12:30 *First Order vs. Higher Order Modification in Distributional Semantics*  
Gemma Boleda, Eva Maria Vecchi, Miquel Cornudella and Louise McNally

**Session 3-AM-2C: Discourse: Coreference Resolution**

Session Chair: Mihai Surdeanu

- 11:00-11:30 *Learning-based Multi-Sieve Co-reference Resolution with Knowledge*  
Lev Ratinov and Dan Roth
- 11:30-12:00 *Joint Learning for Coreference Resolution with Markov Logic*  
Yang Song, Jing Jiang, Wayne Xin Zhao, Sujian Li and Houfeng Wang
- 12:00-12:30 *Resolving “This-issue” Anaphora*  
Varada Kolhatkar and Graeme Hirst

**Session 3-AM-2D: Information Retrieval**

Session Chair: Jianfeng Gao

- 11:00-11:30 *Entity based Q&A Retrieval*  
Amit Singh
- 11:30-12:00 *Constructing Task-Specific Taxonomies for Document Collection Browsing*  
Hui Yang
- 12:00-12:30 *Besting the Quiz Master: Crowdsourcing Incremental Classification Games*  
Jordan Boyd-Graber, Brianna Satinoff, He He and Hal Daume III
- 12:30-14:00 Lunch

**Saturday, July 14, 2012 (continued)**

**Session 3-PM-1A: Machine Learning: Transfer and Biases**

Session Chair: Benjamin Snyder

# Syntactic Transfer Using a Bilingual Lexicon

Greg Durrett, Adam Pauls, and Dan Klein

Computer Science Division

University of California, Berkeley

{gdurrett, adpauls, klein}@cs.berkeley.edu

## Abstract

We consider the problem of using a bilingual dictionary to transfer lexico-syntactic information from a resource-rich source language to a resource-poor target language. In contrast to past work that used bitexts to transfer analyses of specific sentences at the token level, we instead use features to transfer the behavior of words at a type level. In a discriminative dependency parsing framework, our approach produces gains across a range of target languages, using two different low-resource training methodologies (one weakly supervised and one indirectly supervised) and two different dictionary sources (one manually constructed and one automatically constructed).

## 1 Introduction

Building a high-performing parser for a language with no existing treebank is still an open problem. Methods that use no supervision at all (Klein and Manning, 2004) or small amounts of manual supervision (Haghighi and Klein, 2006; Cohen and Smith, 2009; Naseem et al., 2010; Berg-Kirkpatrick and Klein, 2010) have been extensively studied, but still do not perform well enough to be deployed in practice. Projection of dependency links across aligned bitexts (Hwa et al., 2005; Ganchev et al., 2009; Smith and Eisner, 2009) gives better performance, but crucially depends on the existence of large, in-domain bitexts. A more generally applicable class of methods exploits the notion of universal part of speech tags (Petrov et al., 2011; Das and

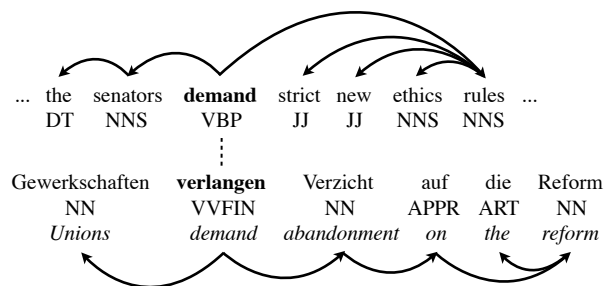

Figure 1: Sentences in English and German both containing words that mean “demand.” The fact that the English *demand* takes nouns on its left and right indicates that the German *verlangen* should do the same, correctly suggesting attachments to *Verzicht* and *Gewerkschaften*.

Petrov, 2011) to train parsers that can run on any language with no adaptation (McDonald et al., 2011) or unsupervised adaptation (Cohen et al., 2011). While these universal parsers currently constitute the highest-performing methods for languages without treebanks, they are inherently limited by operating at the coarse POS level, as lexical features are vital to supervised parsing models.

In this work, we consider augmenting delexicalized parsers by transferring syntactic information through a bilingual lexicon at the word type level. These parsers are delexicalized in the sense that, although they receive target language words as input, their feature sets do not include indicators on those words. This setting is appropriate when there is too little target language data to learn lexical features directly. Our main approach is to add features which are lexical in the sense that they compute a function of specific target language words, but are still un-

lexical in the sense that all lexical knowledge comes from the bilingual lexicon and training data in the source language.

Consider the example English and German sentences shown in Figure 1, and suppose that we wish to parse the German side without access to a German treebank. A delexicalized parser operating at the part of speech level does not have sufficient information to make the correct decision about, for example, the choice of subcategorization frame for the verb *verlangen*. However, *demand*, a possible English translation of *verlangen*, takes a noun on its left and a noun on its right, an observation that in this case gives us the information we need. We can fire features in our German parser on the attachments of *Gewerkschaften* and *Verzicht* to *verlangen* indicating that similar-looking attachments are attested in English for an English translation of *verlangen*. This allows us to exploit fine-grained lexical cues to make German parsing decisions even when we have little or no supervised German data; moreover, this syntactic transfer is possible even in spite of the fact that *demand* and *verlangen* are not observed in parallel context.

Using type-level transfer through a dictionary in this way allows us to decouple the lexico-syntactic projection from the data conditions under which we are learning the parser. After computing feature values using source language resources and a bilingual lexicon, our model can be trained very simply using any appropriate training method for a supervised parser. Furthermore, because the transfer mechanism is just a set of features over word types, we are free to derive our bilingual lexicon either from bitext or from a manually-constructed dictionary, making our method strictly more general than those of McDonald et al. (2011) or Täckström et al. (2012), who rely centrally on bitext. This flexibility is potentially useful for resource-poor languages, where a human-curated bilingual lexicon may be broader in coverage or more robust to noise than a small, domain-limited bitext. Of course, it is an empirical question whether transferring type level information about word behavior is effective; we show that, indeed, this method compares favorably with other transfer mechanisms used in past work.

The actual syntactic information that we transfer consists of purely monolingual lexical attachment

statistics computed on an annotated source language resource.<sup>1</sup> While the idea of using large-scale summary statistics as parser features has been considered previously (Koo et al., 2008; Bansal and Klein, 2011; Zhou et al., 2011), doing so in a projection setting is novel and forces us to design features suitable for projection through a bilingual lexicon. Our features must also be flexible enough to provide benefit even in the presence of cross-lingual syntactic differences and noise introduced by the bilingual dictionary.

Under two different training conditions and with two different varieties of bilingual lexicons, we show that our method of lexico-syntactic projection does indeed improve the performance of parsers that would otherwise be agnostic to lexical information. In all settings, we see statistically significant gains for a range of languages, with our method providing up to 3% absolute improvement in unlabeled attachment score (UAS) and 11% relative error reduction.

## 2 Model

The projected lexical features that we propose in this work are based on lexicalized versions of features found in MSTParser (McDonald et al., 2005), an edge-factored discriminative parser. We take MSTParser to be our underlying parsing model and use it as a testbed on which to evaluate the effectiveness of our method for various data conditions.<sup>2</sup> By instantiating the basic MSTParser features over coarse parts of speech, we construct a state-of-the-art delexicalized parser in the style of McDonald et al. (2011), where feature weights can be directly transferred from a source language or languages to a desired target language. When we add projected lexical features on top of this baseline parser, we do so in a way that does not sacrifice this generality: while our new features take on values that are language-specific, they interact with the model at a language-independent level. We therefore have the best of

<sup>1</sup>Throughout this work, we will use English as the source language, but it is possible to use any language for which the appropriate bilingual lexicons and treebanks exist. One might expect to find the best performance from using a source language closely related to the target.

<sup>2</sup>We train MSTParser using the included implementation of MIRA (Crammer and Singer, 2001) and use projective decoding for all experiments described in this paper.

Figure 2: Computation of features on a dependency arc. DELEX features are indicators over characteristics of dependency links that do not involve the words in the sentence. PROJ features are real-valued analogues of DELEX features that do contain words. We form a query from each stipulated set of characteristics, compute the values of these queries heuristically, and then fire a feature based on each query’s signature. Signatures indicate which attachment properties were considered, which part of the query was lexicalized (shown by brackets here), and the POS of the query word. This procedure yields a small number of real-valued features that still capture rich lexico-syntactic information.

two worlds in that our features can be learned on any treebank or treebanks that are available to us, but still exploit highly specific lexical information to achieve performance gains over using coarse POS features alone.

## 2.1 DELEX Features

Our DELEX feature set consists of all of the unlexicalized features in MSTParser, only lightly modified to improve performance for our setting. McDonald et al. (2005) present three basic types of such features, ATTACH, INBETWEEN, and SURROUNDING, which we apply at the coarse POS level. The ATTACH features for a given dependency link consist of indicators of the tags of the head and modifier, separately as well as together. The INBETWEEN and SURROUNDING features are indicators on the tags of the head and modifier in addition to each intervening tag in turn (INBETWEEN) or various combinations of tags adjacent to the head or modifier (SURROUNDING).<sup>3</sup>

MSTParser by default also includes a copy of each of these indicator features conjoined with the direction and distance of the attachment it denotes. These extra features are important to getting

<sup>3</sup>As in Koo et al. (2008), our feature set contains more backed-off versions of the SURROUNDING features than are described in McDonald et al. (2005).

good performance out of the baseline model. We slightly modify the conjunction scheme and expand it with additional backed-off conjunctions, since these changes lead to features that empirically transfer better than the MSTParser defaults. Specifically, we use conjunctions with attachment direction (left or right), coarsened distance,<sup>4</sup> and attachment direction and coarsened distance combined.

We emphasize again that these baseline features are entirely standard, and all the DELEX feature set does is recreate an MSTParser-based analogue of the direct transfer parser described by McDonald et al. (2011).

## 2.2 PROJ Features

We will now describe how to compute our projected lexical features, the PROJ feature set, which constitutes the main contribution of this work. Recall that we wish our method to be as general as possible and work under many different training conditions; in particular, we wish to be able to train our model on only existing treebanks in other languages when no target language trees are available (discussed in Section 3.3), or on only a very small target language treebank (Section 3.4). It would greatly increase the power of our model if we were able to include target-language-lexicalized versions of the ATTACH

<sup>4</sup>Our five distance buckets are {1, 2, 3–5, 6–10, 11+}.

features, but these are not learnable without a large target language treebank. We instead must augment our baseline model with a relatively small number of features that are nonetheless rich enough to transfer the necessary lexical information.

Our overall approach is sketched in Figure 2, where we show the features that fire on two proposed edges in a German dependency parse. Features on an edge in MSTParser incorporate a subset of observable properties about that edge’s head, modifier, and context in the sentence. For sets of properties that do not include a lexical item, such as VERB→NOUN, we fire an indicator feature from the DELEX feature set. For those that do include a lexical item, such as *verlangen*→NOUN, we form a *query*, which resembles a lexicalized indicator feature. Rather than firing the query as an indicator feature directly, which would result in a model parameter for each target word, we fire a broad feature called an *signature* whose value reflects the specifics of the query (computation of these values is discussed in Section 2.2.2). For example, we abstract *verlangen*→NOUN to [VERB]→CHILD, with square brackets indicating the element that was lexicalized. Section 2.2.1 discusses this coarsening in more detail. The signatures are agnostic to individual words and even the language being parsed, so they can be learned on small amounts of data or data from other languages.

Our signatures allow us to instantiate features at different levels of granularity corresponding to the levels of granularity in the DELEX feature set. When a small amount of target language data is present, the variety of signatures available to us means that we can learn language-specific transfer characteristics: for example, nouns tend to follow prepositions in both French and English, but the ordering of adjectives with respect to nouns is different. We also have the capability to train on languages other than our target language, and while this is expected to be less effective, it can still teach us to exploit some syntactic properties, such as similar verb attachment configurations if we train on a group of SVO languages distinct from a target SVO language. Therefore, our feature set manages to provide the training procedure with choices about how much syntactic information to transfer at the same time as it prevents overfitting and provides language independence.

## 2.2.1 Query and Signature Types

A query is a subset of the following pieces of information about an edge: parent word, parent POS, child word, child POS, attachment direction, and binned attachment distance. It must contain exactly one word.<sup>5</sup> We experimented with properties from INBETWEEN and SURROUNDING features as well, but found that these only helped under some circumstances and could lead to overfitting.<sup>6</sup>

A signature contains the following three pieces of information:

1. The non-empty subset of attachment properties included in the query
2. Whether we have lexicalized on the parent or child of the attachment, indicated by brackets
3. The part of speech of the included word

Because either the parent or child POS is included in the signature, there are three meaningful properties to potentially condition on, of which we must select a nonempty subset. Some multiplication shows that we have  $7 \times 2 \times 13 = 182$  total PROJ features.

As an example, the queries

*verlangen* → NOUN  
*verlangen* → ADP  
*sprechen* → NOUN

all share the signature [VERB]→CHILD, but

*verlangen* → NOUN,RIGHT  
*Verzicht* → ADP  
 VERB → *Verzicht*

have [VERB]→CHILD,DIR, [ADP]→CHILD, and PARENT→[NOUN] as their signatures, respectively.

The level of granularity for signatures is a parameter that simply must be engineered. We found some benefit in actually instantiating two signatures for every query, one as described above and one that

<sup>5</sup>Bilexical features are possible in our framework, but we do not use them here, so for clarity we assume that each query has one associated word.

<sup>6</sup>One hypothesis is that features looking at the sentence context are more highly specialized to a given language, since they examine the parent, the child, *and* one or more other parts of speech or words.

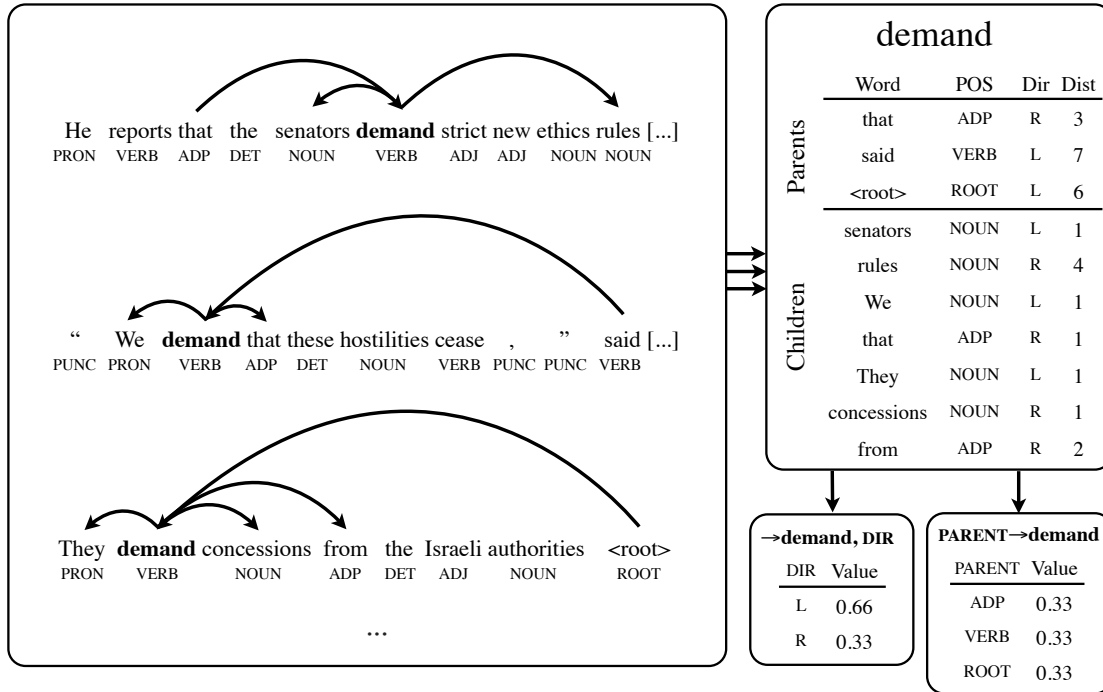

Figure 3: Computation of query values. For each occurrence of a given source word, we tabulate the attachments it takes part in (parents and children) and record their properties. We then compute relative frequency counts for each possible query type to get source language scores, which will later be projected through the dictionary to obtain target language feature values. Only two query types are shown here, but values are computed for many others as well.

does not condition on the part of speech of the word in the signature. One can also imagine using more refined signatures, but we found that this led to overfitting in the small training scenarios under consideration.

## 2.2.2 Query Value Estimation

Each query is given a value according to a generative heuristic that involves the source training data and the probabilistic bilingual lexicon.<sup>7</sup> For a particular signature, a query can be written as a tuple  $(x_1, x_2, \dots, w_t)$  where  $w_t$  is the target language query word and the  $x_i$  are the values of the included language-independent attachment properties. The value this feature takes is given by a simple generative model: we imagine generating the attachment properties  $x_i$  given  $w_t$  by first generating a source

<sup>7</sup>Lexicons such as those produced by automatic aligners include probabilities natively, but obviously human-created lexicons do not. For these dictionaries, we simply assume that each word translates with uniform probability into each of its possible translations. Tweaking this method did not substantially change performance.

word  $w_s$  from  $w_t$  based on the bilingual lexicon, then jointly generating the  $x_i$  conditioned on  $w_s$ . Treating the choice of source translation as a latent variable to be marginalized out, we have

$$\begin{aligned} \text{value} &= p(x_1, x_2, \dots | w_t) \\ &= \sum_{w_s} p(w_s | w_t) p(x_1, x_2, \dots | w_s) \end{aligned}$$

The first term of the sum comes directly from our probabilistic lexicon, and the second we can estimate using the maximum likelihood estimator over our source language training data:

$$p(x_1, x_2, \dots | w_s) = \frac{c(x_1, x_2, \dots, w_s)}{c(w_s)} \quad (1)$$

where  $c(\cdot)$  denotes the count of an event in the source language data.

The final feature value is actually the logarithm of this computed value, with a small constant added before the logarithm is taken to avoid zeroes.

## 3 Experiments

### 3.1 Data Conditions

Before we describe the details of our experiments, we sketch the data conditions under which we evaluate our method. As described in Section 1, there is a continuum of lightly supervised parsing methods from those that make no assumptions (beyond what is directly encoded in the model), to those that use a small set of syntactic universals, to those that use treebanks from resource-rich languages, and finally to those that use both existing treebanks and bitexts.

Our focus is on parsing when one does not have access to a full-scale target language treebank, but one does have access to realistic auxiliary resources. The first variable we consider is whether we have access to a small number of target language trees or only pre-existing treebanks in a number of other languages; while not our actual target language, these other treebanks can still serve as a kind of proxy for learning which features generally transfer useful information (McDonald et al., 2011). We notate these conditions with the following shorthand:

**BANKS:** Large treebanks in other target languages

**SEED:** Small treebank in the right target language

Previous work on essentially unsupervised methods has investigated using a small number of target language trees (Smith and Eisner, 2009), but the behavior of supervised models under these conditions has not been extensively studied. We will see in Section 3.4 that with only 100 labeled trees, even our baseline model can achieve performance equal to or better than that of the model of McDonald et al. (2011). A single linguist could plausibly annotate such a number of trees in a short amount of time for a language of interest, so we believe that this is an important setting in which to show improvement, even for a method primarily intended to augment unsupervised parsing.

In addition, we consider two different sources for our bilingual lexicon:

**AUTOMATIC:** Extracted from bitext

**MANUAL:** Constructed from human annotations

Both bitexts and human-curated bilingual dictionaries are more widely available than complete treebanks. Bitexts can provide rich information about

lexical correspondences in terms of how words are used in practice, but for resource-poor languages, parallel text may only be available in small quantities, or be domain-limited. We show results of our method on bilingual dictionaries derived from both sources, in order to show that it is applicable under a variety of data conditions and can successfully take advantage of such resources as are available.

### 3.2 Datasets

We evaluate our method on a range of languages taken from the CoNLL shared tasks on multilingual dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007). We make use of dependency treebanks for Danish, German, Greek, Spanish, Italian, Dutch, Portuguese, and Swedish, all from the 2006 shared task.

For our English resource, we use 500,000 English newswire sentences from English Gigaword version 3 (Graff et al., 2007), parsed with the Berkeley Parser (Petrov et al., 2006) and converted to a dependency treebank using the head rules of Collins (1999).<sup>8</sup> Our English test set (used in Section 3.4) consists of the first 300 sentences of section 23 of the Penn treebank (Marcus et al., 1993), preprocessed in the same way. Our model does not use gold fine-grained POS tags, but we do use coarse POS tags deterministically generated from the provided gold fine-grained tags in the style of Berg-Kirkpatrick and Klein (2010) using the mappings of Petrov et al. (2011).<sup>9</sup> Following McDonald et al. (2011), we strip punctuation from all treebanks for the results of Section 3.3. All results are given in terms of unlabeled attachment score (UAS), ignoring punctuation even when it is present.

We use the Europarl parallel corpus (Koehn, 2005) as the bitext from which to extract the AUTOMATIC bilingual lexicons. For each target language, we produce one-to-one alignments on the English-target bitext by running the Berkeley Aligner (Liang et al., 2006) with five iterations of IBM Model 1 and

<sup>8</sup>Results do not degrade much if one simply uses Sections 2-21 of the Penn treebank instead. Coverage of rare words in the treebank is less important when a given word must also appear in the bilingual lexicon as the translation of an observed German word in order to be useful.

<sup>9</sup>Note that even in the absence of gold annotation, such tags could be produced from bitext using the method of (Das and Petrov, 2011) or could be read off from a bilingual lexicon.

Table 1: Evaluation of features derived from AUTOMATIC and MANUAL bilingual lexicons when trained on a concatenation of non-target-language treebanks (the BANKS setting). Values reported are UAS for sentences of all lengths in the standard CoNLL test sets, with punctuation removed from training and test sets. Daggers indicate statistical significance computed using bootstrap resampling; a single dagger indicates  $p < 0.1$  and a double dagger indicates  $p < 0.05$ . We also include the baseline results of McDonald et al. (2011) and Täckström et al. (2012) and improvements from their best methods of using bitext and lexical information. These results are not directly comparable to ours, as indicated by \* and \*\*. However, we still see that the performance of our type-level transfer method approaches that of bitext-based methods, which require complex bilingual training for each new language.

five iterations of the HMM aligner with agreement training. Our lexicon is then read off based on relative frequency counts of aligned instances of each word in the bitext.

We also use our method on bilingual dictionaries constructed in a more conventional way. For this purpose, we scrape our MANUAL bilingual lexicons from English Wiktionary (Wikimedia Foundation, 2012). We mine entries for English words that explicitly have foreign translations listed as well as words in each target language that have English definitions. We discard all translation entries where the English side is longer than one word, except for constructions of the form “to VERB”, where we manually remove the “to” and allow the word to be defined as the English infinitive. Finally, because our method requires a dictionary with probability weights, we assume that each target language word translates with uniform probability into any of the candidates that we scrape.

### 3.3 BANKS

We first evaluate our model under the BANKS data condition. Following the procedure from McDonald et al. (2011), for each language, we train both our DELEX and DELEX+PROJ features on a concatenation of 2000 sentences from each other CoNLL training set, plus 2000 sentences from the Penn

Treebank. Again, despite the values of our PROJ queries being sensitive to which language we are currently parsing, the signatures are language independent, so discriminative training still makes sense over such a combined treebank. Training our PROJ features on the non-English treebanks in this concatenation can be understood as trying to learn which lexico-syntactic properties transfer “universally,” or at least transfer broadly within the families of languages we are considering.

Table 1 shows the performance of the DELEX feature set and the DELEX+PROJ feature set using both AUTOMATIC and MANUAL bilingual lexicons. Both methods provide positive gains across the board that are statistically significant in the vast majority of cases, though MANUAL is slightly less effective; we postpone until Section 4.1 the discussion of the shortcomings of the MANUAL lexicon.

We include for reference the baseline results of McDonald et al. (2011) and Täckström et al. (2012) (multi-direct transfer and no clusters) and the improvements from their best methods using lexical information (multi-projected transfer and cross-lingual clusters). We emphasize that these results are *not* directly comparable to our own, as we have different training data (and even different training languages) and use a different underlying parsing model (MSTParser instead of a transition-based

Table 2: Evaluation of features derived from AUTOMATIC and MANUAL bilingual lexicons when trained on various small numbers of target language trees (the SEED setting). Values reported are UAS for sentences of all lengths on our enlarged CoNLL test sets (see text); each value is based on 50 sampled training sets of the given size. Daggers indicate statistical significance as described in the text. Statistical significance is not reported for averages.

parser (Nivre, 2008)). However, our baseline is competitive with theirs,<sup>10</sup> demonstrating that we have constructed a state-of-the-art delexicalized parser. Furthermore, our method appears to approach the performance of previous bitext-based methods, and because of its flexibility and the freedom from complex cross-lingual training for each new language, it can be applied in the MANUAL case as well, a capability which neither of the other methods has.

### 3.4 SEED

We now turn our attention to the SEED scenario, where a small number of target language trees are available for each language we consider. While it is imaginable to continue to exploit the other treebanks in the presence of target language trees, we found that training our DELEX features on the seed treebank alone gave higher performance than any

attempt to also use the concatenation of treebanks from the previous section. This is not too surprising because, with this number of sentences, there is already good monolingual coverage of coarse POS features, and attempting to train features on other languages can be expected to introduce noise into otherwise accurate monolingual feature weights.

We train our DELEX+PROJ model with both AUTOMATIC and MANUAL lexicons on target language training sets of size 100, 200, and 400, and give results for each language in Table 2. The performance of parsers trained on small numbers of trees can be highly variable, so we create multiple treebanks of each size by repeatedly sampling from each language’s train treebank, and report averaged results. Furthermore, this evaluation is not on the standard CoNLL test sets, but is instead on those test sets with a few hundred unused training sentences added, the reason being that some of the CoNLL test sets are very small (fewer than 200 sentences) and appeared

<sup>10</sup>The baseline of Täckström et al. (2012) is lower because it is trained only on English rather than on many languages.

to give highly variable results. To compute statistical significance, we draw a large number of bootstrap samples for each training set used, then aggregate all of their sufficient statistics in order to compute the final  $p$ -value. We see that our DELEX+PROJ method gives statistically significant gains at the 95% level over DELEX for nearly all language and training set size pairs, giving on average a 9% relative error reduction in the 400-tree case.

Because our features are relatively few in number and capture heuristic information, one question we might ask is how well they can perform in a non-projection context. In the last line of the table, we report gains that are achieved when PROJ features computed from parsed Gigaword are used directly on English, with no intermediate dictionary. These are not comparable to the other values in the table because we are using our projection strategy monolingually, which removes the barriers of imperfect lexical correspondence (from using the lexicon) and imperfect syntactic correspondence (from projecting). As one might expect, the gains on English are far higher than the gains on other languages. This indicates that performance is chiefly limited by the need to do cross-lingual feature adaptation, not inherently low feature capacity. We delay further discussion to Section 4.2.

One surprising thing to note is that the gains given by our PROJ features are in some cases larger here than in the BANKS setting. This result is slightly counterintuitive, as our baseline parsers are much better in this case and so we would expect diminished returns from our method. We conclude that accurately learning which signatures transfer between languages is important, and it is easier to learn good feature weights when some target language data is available. Further evidence supporting this hypothesis is the fact that the gains are larger and more significant on larger training set sizes.

## 4 Discussion

### 4.1 AUTOMATIC versus MANUAL

Overall, we see that gains from using our MANUAL lexicons are slightly lower than those from our AUTOMATIC lexicons. One might expect higher performance because scraped bilingual lexicons are not prone to some of the same noise that exists in auto-

	AUTOMATIC		MANUAL	
	Voc	OCC	Voc	OCC
DA	324K	0.91	22K	0.64
DE	320K	0.89	58K	0.55
EL	196K	0.94	23K	0.43
ES	165K	0.89	206K	0.74
IT	158K	0.91	78K	0.65
NL	251K	0.87	50K	0.72
PT	165K	0.85	46K	0.53
SV	307K	0.93	28K	0.60

Table 3: Lexicon statistics for all languages for both sources of bilingual lexicons. “Voc” indicates vocabulary size and “OCC” indicates open-class coverage, the fraction of open-class tokens in the test treebanks with entries in our bilingual lexicon.

matic aligners, but this is empirically not the case. Rather, as we see in Table 3, the low recall of our MANUAL lexicons on open-class words appears to be a possible culprit. The coverage gap between these and the AUTOMATIC lexicons is partially due to the inconsistent structure of Wiktionary: inflected German and Greek words often do not have their own pages, so we miss even common morphological variants of verb forms in those languages. The inflected forms that we do scrape are also mapped to the English base form rather than the corresponding inflected form in English, which introduces further noise. Coverage is substantially higher if we translate using stems only, but this did not empirically lead to performance improvements, possibly due to conflating different parts of speech with the same base form.

One might hypothesize that our uniform weighting scheme in the MANUAL lexicon is another source of problems, and that bitext-derived weights are necessary to get high performance. This is not the case here. Truncating the AUTOMATIC dictionary to at most 20 translations per word and setting the weights uniformly causes a slight performance drop, but is still better than our MANUAL lexicon. This further demonstrates that these problems are more a limitation of our dictionary than our method. English Wiktionary is not designed to be a bilingual dictionary, and while it conveniently provided an easy way for us to produce lexicons for a wide array

Figure 4: Example of a German tree and a parallel English sentence with high levels of syntactic divergence. The English verb *want* takes fundamentally different children than *wollen* does, so properties of the sort we present in Section 2.2 will not transfer effectively.

of languages, it is not the resource that one would choose if designing a parser for a specific target language. Bilingual is not necessary for our approach to work, and results on the AUTOMATIC lexicon suggest that our type-level transfer method can in fact do much better given a higher quality resource.

## 4.2 Limitations

While our method does provide consistent gains across a range of languages, the injection of lexical information is clearly not sufficient to bridge the gap between unsupervised and supervised parsers. We argued in Section 3.4 that the cross-lingual transfer step of our method imposes a fundamental limitation on how useful any such approach can be, which we now investigate further.

In particular, any syntactic divergence, especially inconsistent divergences like head switching, will limit the utility of transferred structure. Consider the German example in Figure 4, with a parallel English sentence provided. The English tree suggests that *want* should attach to an infinitival *to*, which has no correlate in German. Even disregarding this, its grandchild is the verb *continue*, which is realized in the German sentence as the adverb *weiter*. While it is still broadly true that *want* and *wollen* both have verbal elements located to their right, it is less clear how to design features that can still take advantage of this while working around the differences we have described. Therefore, a gap between the per-

formance of our features on English and the performance of our projected features, as is observed in Table 2, is to be expected in the absence of a more complete model of syntactic divergence.

## 5 Conclusion

In this work, we showed that lexical attachment preferences can be projected to a target language at the type level using only a bilingual lexicon, improving over a delexicalized baseline parser. This method is broadly applicable in the presence or absence of target language training trees and with bilingual lexicons derived from either manually-annotated resources or bitexts. The greatest improvements arise when the bilingual lexicon has high coverage and a number of target language trees are available in order to learn exactly what lexico-syntactic properties transfer from the source language.

In addition, we showed that a well-tuned discriminative model with the correct features can achieve good performance even on very small training sets. While unsupervised and existing projection methods do feature great versatility and may yet produce state-of-the-art parsers on resource-poor languages, spending time constructing small supervised resources appears to be the fastest method to achieve high performance in these settings.

## Abstract

In this paper, we address the problem of building a multilingual transliteration system using an interlingual representation. Our approach uses international phonetic alphabet (IPA) to learn the interlingual representation and thus allows us to use any word and its IPA representation as a training example. Thus, our approach requires only monolingual resources: a *phoneme dictionary* that lists words and their IPA representations.<sup>1</sup> By adding a phoneme dictionary of a new language, we can readily build a transliteration system into any of the existing previous languages, without the expense of all-pairs data or computation. We also propose a regularization framework for learning the interlingual representation, which accounts for language specific phonemic variability, and thus it can find better mappings between languages. Experimental results on the name transliteration task in five diverse languages show a maximum improvement of 29% accuracy and an average improvement of 17% accuracy compared to a state-of-the-art baseline system.

## 1 Introduction

Because of the wide usage of English, many natural language processing (NLP) tasks have bilingual resources from English into other languages. For example, significantly larger parallel texts are available

<sup>1</sup>It is arguable that getting words and their IPA representation require knowledge about both words and IPA symbols, but it still is specific to one language and, in this sense, we refer to it as a monolingual resource.

between English and other languages. Similarly, bilingual dictionaries and transliteration data sets are more accessible from a language into English than into a different language. This situation has caused the NLP community to develop approaches which use a resource rich language ( $Q$  say English) as pivot to build resources/applications between a new language pair  $P$  and  $R$ . Previous studies in machine translation (Utiyama and Isahara, 2007; Paul and Sumita, 2011), transliteration (Khapra et al., 2010), and dictionary mining (Saralegi et al., 2011) show that these bridge language approaches perform competitively with approaches that use resources between  $P$  and  $R$ . In this paper, we propose a regularization framework for bridge language approaches and show its effectiveness for name transliteration task. The key idea of our approach is that it accounts for language specific variation in the bridge language resources (i.e. between  $P \leftrightarrow Q$  and  $Q \leftrightarrow R$ ) and aims to minimize this variation as much as possible. Though our technique is general, for clarity we describe it in the context of named entity (NE) transliteration.

Named entity (NE) transliteration involves transliterating a name in one language into another language and is shown to be crucial for machine translation (MT) (Knight and Graehl, 1998; Al-Onaizan and Knight, 2002; Hermjakob et al., 2008; Li et al., 2009) and cross-lingual information retrieval (CLIR) (AbdulJaleel and Larkey, 2003; Mandl and Womser-Hacker, 2005; Udupa et al., 2009). There exists a large body of literature in transliteration, especially in the bilingual setting, well summarized by Ravi and Knight (2009). We

English		Bulgarian	
Word	IPA	Word	IPA
bashful	/ˈbæʃfəl/	шибам	/ˈʃibəm/
tuesday	/ˈtuːzdeɪ/	лук	/luk/
craft	/kræft/	как	/kak/
book	/bʊk/	музей	/mʊˈzej/
head	/hɛd/	спека	/spɛˈkɔ/

Table 1: Example phoneme dictionaries in English and Bulgarian. The English translations for the Bulgarian words are switch, onion, how, museum, and spekle.

summarize the approaches that are most relevant to us in Sec. 5. In this paper, we operate in the context of transliteration mining (Klementiev and Roth, 2006; Sproat et al., 2006) where we assume that we are given a source language name and a list of target language candidate transliterations and the task is to identify the correct transliteration.

Given a set of  $l$  languages, we address the problem of building a transliteration system between every pair of languages. A straight forward supervised learning approach would require training data of name pairs between every pair of languages (Knight and Graehl, 1998) or a set of common names transliterated from every language into a pivot language. Though it is relatively easy to obtain names transliterated into a pivot language (such as English), it is unlikely that such data sets contain the same names. Bridge language approaches overcome the need for common names and build transliteration systems for resource poor languages (Khapra et al., 2010). However, such approaches still require training data consisting of bilingual name transliterations (orthographic name-to-name mappings). In this paper, we relax the need for name transliterations by using international phonetic alphabet (IPA) in a manner akin to a “bridge language.”

## 2 IPA for Transliteration

We assume that we have a list of words and their IPA representations in each of the  $l$  languages. The words in different languages need not have any relationship to each other. Table 1 shows few words and their IPA representations in English and Bulgarian languages. We refer to the set of (word, IPA) pairs as *phoneme dictionary* in this paper. Notice that the common symbols in the IPA sequences indicate a

vague phonetic correspondence between the character sequences of English and Bulgarian. For example, both the words ‘bashful’ and ‘шибам’ have the symbol ‘ʃ’ in their IPA sequences which indicate a possible mapping between the character sequences ‘sh’ and ‘ш’.

The use of IPA as the bridge language offers multiple advantages. As shown in Table 1, it allows us to include any (word, IPA) pair in the training data and thus it relaxes the need for name pairs as the training data. Since we only need a phoneme dictionary in each language, our approach does not require any bilingual resources to build the transliteration system. Moreover, since our training data can contain any word (not only the NEs), it is easier to obtain such a resource, for e.g. the phoneme dictionaries obtained from Wiktionary contain at least 2000 words in 21 languages and we will see in Sec. 6 that we can build a decent transliteration system with 2000 words.<sup>2</sup> Finally, unlike other transliteration approaches, by simply adding a phoneme dictionary of  $(l + 1)$ <sup>st</sup> language we can readily get a transliteration system into any of the existing  $l$  languages and thus avoid the need for all-pairs data or computation.

Using IPA as the bridge language poses some new challenges such as the language specific phonemic inventory. For example, Mandarin doesn’t have /v/, so it is frequently substituted with /w/ or /f/. Similarly, !Xóõ (Southern Khoisan, spoken in Botswana) has 122 consonants, mostly consisting of a large inventory of different word-initial click sounds (Haspelmath et al., 2005), many of which do not exist in any other documented languages. Besides this language specific phonemic inventory, names have different IPA representations in different languages. For example, as shown in Table 2, the IPA sequences for ‘China’ in English and Dutch have common IPA symbols but the English IPA sequence has additional symbols. Moreover, a name can have multiple pronunciations with in a language, e.g. ‘France’ has two different IPA sequences in English (Table 2).

In order to handle this phonemic diversity, our method explicitly models language-specific variability and attempts to minimize this phonemic variability.

<sup>2</sup>In our experiments, we consider languages with small (2000) and big (>30K) phoneme dictionaries.

Word	IPA sequence
China	/ˈtʃaɪ.nə/ (En), /ˈʃina/ (Du), /ˈçi:na:/ (De)
America	/əˈmɛrɪkə/ (En), /aˈmɛ.ri.kə/ (Ro)
France	/ˈfɹɑ:ns/ (En), /ˈfɹænts/ (En), /fʁɑ̃s/ (Fr)

Table 2: IPA sequences of few words in different languages indicated using language codes in the parenthesis (‘En’ for English, ‘Du’ for Dutch, ‘De’ for German, ‘Ro’ for Romanian, and ‘Fr’ for French).

ity as much as possible. At a high level, our approach uses the phoneme dictionaries of each language to learn mapping functions into an interlingual representation (also referred as common subspace). Subsequently, given a pair of languages, a query name in one of the languages and a list of candidate transliterations in the other language, we use the mapping functions of those two language to identify the correct name transliteration. The mapping functions explicitly model the language specific variability and thus account for fine grained differences. Our experimental results on four language pairs from two different language families show a maximum improvement of 29% accuracy and an average improvement of 17% accuracy compared to a state-of-the-art baseline approach. An important advantage of our approach is that, it extends easily to more than two languages and in fact adding phoneme dictionary from a different, but related, language improves the accuracies of a given language pair. Our main contributions are: 1) building a transliteration system using (word, IPA) pairs and hence using only monolingual resources and 2) proposing a regularization framework which is more general and applies to other bridge language applications such as lexicon mining (Mann and Yarowsky, 2001).

### 3 Low Dimensional Projections

Our approach is inspired by the Canonical Correlation Analysis (CCA) (Hotelling, 1936) and its application to transliteration mining (Udupa and Khapra, 2010).

First, we convert the phoneme dictionary of each language into feature vectors, i.e. we convert each word into a feature vector of n-gram character sequences and similarly, we also, convert the IPA representations into feature vectors of n-gram IPA

symbol sequences. For example, if we use unigram and bigram sequences as features, then the feature vectors of ‘head’ and its IPA sequence ‘hed’ are given by  $\{h, e, a, d, \#h, he, ea, ad, d\}$  and  $\{h, \varepsilon, d, \#h, h\varepsilon, \varepsilon d, d\}$ . For brevity, we refer to the spaces of n-gram character and IPA symbol sequences as character and phonemic spaces respectively. The character space is specific to each language while the phonemic space is shared across all the languages. Since we use IPA as bridge, even though two languages share orthography (e.g. English and French) it is irrelevant for our approach.

Then, for each language, we find mappings ( $A_i$  and  $U_i$ ) from the character and phonemic spaces into a common  $k$ -dimensional subspace such that the correct transliterations lie closer to each other in this subspace. Before moving into the details of our approach, we will describe the notation and then give an overview of the process by which our approach finds the transliteration.

#### 3.1 Notation

Let  $\mathbf{x}_i^{(m)} \in \mathbb{R}^{d_i}$  and  $\mathbf{p}_i^{(m)} \in \mathbb{R}^c$  be the feature vectors of the  $m^{th}$  word and its IPA sequence in the  $i^{th}$  ( $1 \dots l$ ) language, where  $d_i$  is the size (i.e. no. of features) of the character space of the language and  $c$  is the size of the common phonemic space. Let  $X_i$  ( $d_i \times n_i$ ) and  $P_i$  ( $c \times n_i$ ) denote the  $i^{th}$  language data matrices with  $\mathbf{x}_i^{(m)}$  and  $\mathbf{p}_i^{(m)}$   $m = 1 \dots n_i$  as the columns respectively. We consistently use subscript to indicate the language and superscript to indicate the index of an example point.

#### 3.2 Method Overview

During the training stage, for each language, we find mappings (or projection directions)  $A_i \in \mathbb{R}^{(d_i \times k)}$  and  $U_i \in \mathbb{R}^{(c \times k)}$  from the character and phonemic spaces into a  $k$ -dimensional subspace (or an interlingual representation) such that a name gets mapped to the *same*  $k$ -dimensional vector irrespective of the language. That is, given a name  $\mathbf{x}_i$  it gets mapped to the vector  $A_i^T \mathbf{x}_i$  and similarly its IPA sequence  $\mathbf{p}_i$  gets mapped to  $U_i^T \mathbf{p}_i$ . During the testing stage, given a name  $\mathbf{x}_i$  in the source ( $i^{th}$ ) language, we find its transliteration in the target ( $j^{th}$ ) language  $\mathbf{x}_j$  by solving the following decoding problem:

$$\arg \min_{\mathbf{x}_j} L(\mathbf{x}_i, \mathbf{x}_j) \quad (1)$$

Figure 1: A single name (Gandhi) is shown in all the input feature spaces. The alignment between the character and phonemic space is indicated with double dimensional arrows. Bridge-CCA uses a single mapping function  $U$  from the phonemic space into the common subspace (the 2-dimensional green space at the top), whereas our approach uses two mapping functions  $U_1$  and  $U_2$ , one for each language, to map the IPA sequences into the common subspace.

where  $L(\mathbf{x}_i, \mathbf{x}_j)$  is given by

$$\min_{\mathbf{p} \in \mathbb{R}^c} \|A_i^T \mathbf{x}_i - U_i^T \mathbf{p}\|^2 + \|A_j^T \mathbf{x}_j - U_j^T \mathbf{p}\|^2 \quad (2)$$

This formulation uses the source language mappings ( $A_i$  and  $U_i$ ) to find the IPA sequence  $\mathbf{p}$  that is closest to the source name and then uses it, along with the target language mappings ( $A_j$  and  $U_j$ ), to identify the correct transliteration from a list of candidate transliterations.

At a high level, existing bridge language approaches such as Bridge-CCA (Khapra et al., 2010) assume that  $U_i \equiv U_j$  thus ignoring the language specific variation. To understand its implication consider the example shown in Fig. 1. The middle portion of the Fig. shows the name Gandhi (represented as point) in the character spaces of English and Hindi, three-dimensional spaces, and its IPA sequences in the phonemic space (the two-

dimensional space in the middle). Notice that, because of the phonemic variation, the same name is represented by two distinct points in the common phonemic space.<sup>3</sup> Now, since Bridge-CCA uses a single mapping function for both the IPA sequences, it fails to map these two distinct points into a common point in the interlingual subspace.

Our new formulation, as explained above, relaxes this hard constraint and learns different mapping functions ( $U_i$  and  $U_j$ ) and hence our approach can potentially map both the distinct IPA sequences into a single point. As a result our approach successfully handles the language specific phonemic variation. At the same time we constrain the projection directions such that they behave similarly for the phonemic sounds that are observed in majority of the languages. In the example shown in Fig. 1, our model (called Regularized Projections) finds two different mapping functions  $U_1$  and  $U_2$ , one for each language, from the phonemic space into the common two-dimensional space at the bottom.

### 3.3 Regularized Projections

In this section we first formulate the problem of finding the mapping functions ( $A_i$  and  $U_i$ ) of each language as an optimization problem. In the following section (Sec. 4), we develop a method for solving the optimization problem and also derive closed form solution for the prediction problem given in Eq. 1. For simplicity, we describe our approach in terms of single projection vectors,  $\mathbf{a}_i \in \mathbb{R}^{d_i}$  and  $\mathbf{u}_i \in \mathbb{R}^c$ , rather than full matrices, but the generalization is trivial.

Inspired by the Canonical Correlation Analysis (CCA) (Hotelling, 1936), we find projection directions in the character and phonemic spaces of each language such that, after projection, a word is closer to its aligned IPA sequence. To understand this, assume that we have a name (say ‘‘Barack Obama’’) in all the languages<sup>4</sup> and its feature vectors are given by  $\mathbf{x}_i$  and  $\mathbf{p}_i$   $i = 1 \dots l$  in the character and phone-

<sup>3</sup>In reality, as explained in the previous section, the phonemic variation that is commonly observed is that different features are triggered for different languages. But for visualization purpose, we showed the IPA sequences as if they differ in the feature values.

<sup>4</sup>Our model does not require same names in different languages; this is used only for easier understanding.

mic spaces respectively. Then, we might try to find projection directions  $\mathbf{a}_i$  in each language and  $\mathbf{u}$  in the common phonemic space such that:

$$\arg \min_{\mathbf{a}_i, \mathbf{u}} \sum_{i=1}^l \left( \langle \mathbf{x}_i, \mathbf{a}_i \rangle - \langle \mathbf{p}_i, \mathbf{u} \rangle \right)^2 \quad (3)$$

where  $\langle \cdot, \cdot \rangle$  denotes the dot product between two vectors. This model assumes that the projection direction  $\mathbf{u}$  is same for the phonemic space of all the languages. This is a hard constraint and does not handle the language specific variability as discussed in the previous section. We model the language specificity by relaxing this hard constraint.

In our model, intuitively, the parameters corresponding to the phonemic sounds that occur in majority of the languages are shared across the languages while the parameters of the language specific sounds are modeled per each language. This is achieved by modeling the projection directions of the  $i^{\text{th}}$  language phonemic space  $\mathbf{u}_i \leftarrow \mathbf{u} + \mathbf{r}_i$ . The vector  $\mathbf{u} \in \mathbb{R}^c$  is common to the phonemic spaces of all the languages and thus handles sounds that are observed in multiple languages while  $\mathbf{r}_i \in \mathbb{R}^c$ , the residual vector, is specific to each language and accounts for the language specific phonemic variations. Then the new formulation is given by:

$$\arg \min_{\mathbf{a}_i, \mathbf{u}, \mathbf{r}_i} \sum_{i=1}^l \left\| \langle \mathbf{x}_i, \mathbf{a}_i \rangle - \langle \mathbf{p}_i, \mathbf{u} + \mathbf{r}_i \rangle \right\|^2 + \lambda \langle \mathbf{p}_i, \mathbf{r}_i \rangle^2$$

where  $\lambda$  is the residual parameter. The first term of this summation ensures that a word and its IPA sequence gets mapped to closer points in the subspace while the second term forces the residual vectors to be as small as possible. By enforcing the residual vectors to be small, this formulation encourages the sounds that occur in majority of the languages to be accounted by  $\mathbf{u}$  and the sounds that are specific to the given language by  $\mathbf{r}_i$ . The final optimization problem is obtained by summing these terms over all the examples and all the languages and is given by:

$$\begin{aligned} \min_{\mathbf{a}_i, \mathbf{u}, \mathbf{r}_i} \sum_{i=1}^l \left( \frac{\|X_i^T \mathbf{a}_i - P_i^T (\mathbf{u} + \mathbf{r}_i)\|^2}{n_i} + \lambda \|P_i^T \mathbf{r}_i\|^2 \right) \quad (4) \\ \text{s.t. } \sum_{i=1}^l \frac{1}{n_i} \|X_i^T \mathbf{a}_i\|^2 = 1 \text{ and } \sum_{i=1}^l \frac{1}{n_i} \|P_i^T \mathbf{u}\|^2 = 1 \end{aligned}$$

The constraints of the above optimization problem avoid the trivial solution of setting all the vectors to zero and are referred to as length constraints.

## 4 Model Optimization

In this section, we derive the solutions for the optimization problems presented in the previous section.

### 4.1 Training the Model

We follow the standard procedure of forming the Lagrangian and setting its derivative to zero. The Lagrangian  $\mathcal{L}$  of the optimization problem in Eq. 4 is given by:

$$\begin{aligned} \mathcal{L} = \sum_i \frac{1}{n_i} \|X_i^T \mathbf{a}_i - P_i^T (\mathbf{u} + \mathbf{r}_i)\|^2 + \lambda \sum_i \|P_i^T \mathbf{r}_i\|^2 \\ + \alpha \left( \sum_i \frac{1}{n_i} \|X_i^T \mathbf{a}_i\|^2 - 1 \right) + \beta \left( \sum_i \frac{1}{n_i} \|P_i^T \mathbf{u}\|^2 - 1 \right) \end{aligned}$$

where  $\alpha$  and  $\beta$  are Lagrangian multipliers corresponding to the length constraints. Differentiating  $\mathcal{L}$  with respect to  $\mathbf{a}_i$ ,  $\mathbf{r}_i$  and  $\mathbf{u}$  and setting the derivatives to zero yields the following equations, respectively:

$$\begin{aligned} (1 + \alpha) X_i X_i^T \mathbf{a}_i - X_i P_i^T \mathbf{r}_i &= X_i P_i^T \mathbf{u} \\ -P_i X_i^T \mathbf{a}_i + (1 + \lambda n_i) P_i P_i^T \mathbf{r}_i &= -P_i P_i^T \mathbf{u} \end{aligned}$$

$$\sum_i \frac{1}{n_i} (P_i X_i^T \mathbf{a}_i - P_i P_i^T \mathbf{r}_i) = (1 + \beta) \sum_i \frac{1}{n_i} P_i P_i^T \mathbf{u}$$

We can rewrite these equations in matrix form, as shown in Eqs. 5 and 6, since the solution becomes clear in this form. For brevity, let  $E_i = (1 + \alpha) X_i X_i^T$ ,  $F_i = -X_i P_i^T$  and  $G_i = (1 + \lambda n_i) P_i P_i^T$ . Then,  $\mathbf{u}$  can be solved for using the generalized eigenvalue problem shown in Eq. 7. This step involves computing an inverse of a  $(d_i + c)$  matrix and an eigenvalue problem of size  $c$  which can be expensive since solving each of these problems involve cubic time. This can be reduced further into a problem of smaller size by using inverse of a partitioned matrix as shown in Eq. 8. This identity reduces the matrix inverse computation from a problem of size  $d_i + c$  into two smaller problems of size  $d_i$  and  $c$  each. This reduces the time complexity considerably since the inverse computation is cubic in the size of the matrix.

$$\begin{bmatrix} (1+\alpha)X_iX_i^T & -X_iP_i^T \\ -P_iX_i^T & (1+\lambda n_i)P_iP_i^T \end{bmatrix} \begin{bmatrix} \mathbf{a}_i \\ \mathbf{r}_i \end{bmatrix} = \begin{bmatrix} X_iP_i^T \\ -P_iP_i^T \end{bmatrix} \mathbf{u} \quad (5)$$

$$\sum_i \frac{1}{n_i} \begin{bmatrix} P_iX_i^T & -P_iP_i^T \end{bmatrix} \begin{bmatrix} \mathbf{a}_i \\ \mathbf{r}_i \end{bmatrix} = (1+\beta) \sum_i \frac{1}{n_i} P_iP_i^T \mathbf{u} \quad (6)$$

$$\sum_i \frac{1}{n_i} \begin{bmatrix} -F_i^T & \frac{-G_i}{1+\lambda n_i} \end{bmatrix} \begin{bmatrix} E_i & F_i \\ F_i^T & G_i \end{bmatrix}^{-1} \begin{bmatrix} -F_i \\ -G_i \\ \frac{-G_i}{1+\lambda n_i} \end{bmatrix} \mathbf{u} = (1+\beta) \sum_i \frac{1}{n_i} P_iP_i^T \mathbf{u} \quad (7)$$

$$\text{If } M_i = (E_i - F_iG_i^{-1}F_i^T)^{-1}, \text{ then } \begin{bmatrix} E_i & F_i \\ F_i^T & G_i \end{bmatrix}^{-1} = \begin{bmatrix} M_i & -M_iF_iG_i^{-1} \\ -G_i^{-1}F_i^TM_i & G_i^{-1} + G_i^{-1}F_i^TM_iF_iG_i^{-1} \end{bmatrix} \quad (8)$$

Substituting Eq. 8 into Eq. 7 and further simplifying results in the following eigenvalue problem for solving  $\mathbf{u}$ :

$$\sum_i \frac{G_i + (\lambda n_i)^2 F_i^T M_i F_i}{n_i(1 + \lambda n_i)^2} \mathbf{u} = (1 + \beta) \sum_i \frac{P_i P_i^T}{n_i} \mathbf{u}$$

where  $M_i = (E_i - F_iG_i^{-1}F_i^T)^{-1}$ . Notice that the term  $E_i = (1+\alpha)X_iX_i^T$  depends on the Lagrangian multiplier  $\alpha$ . Because of this, we cannot solve for both the parameters and the Lagrangian multipliers at the same time. One possible approach is to do an alternate optimization over the parameters and Lagrangian multipliers, but in this paper we fix  $\alpha$  and solve for  $\mathbf{u}$ . The value of  $\alpha$  denotes the correlation and its maximum value is 1. In practice, we often observe that the top few correlations take the value of 1. Based on this observation we fix the value of  $\alpha$  to 1 (Sec. 6).

Subsequently, we use  $\mathbf{u}$  to solve for  $\mathbf{a}_i$  and  $\mathbf{r}_i$  as follows:

$$\mathbf{a}_i = -\frac{\lambda n_i M_i F_i}{1 + \lambda n_i} \mathbf{u} \quad (9)$$

$$\mathbf{r}_i = \frac{\lambda n_i G_i^{-1} F_i^T M_i F_i - I}{1 + \lambda n_i} \mathbf{u} \quad (10)$$

In order to increase the stability of the system we regularize  $G_i$  and  $E_i$  by adding  $\tau I$ . We use the top  $k$  eigenvectors  $\mathbf{u}$  and their corresponding  $\mathbf{a}_i$  and  $\mathbf{r}_i$  vectors as columns and form the mappings  $U$ ,  $A_i$  and  $R_i$  respectively. These mappings are used in predicting the transliteration of a name in one language into any other language, which will be described in the following section.

## 4.2 Transliteration Mining (Prediction)

During the testing phase, given a source name and a list of candidate transliterations, we solve the decoding problem shown in Eq. 1 to find the appropriate target language transliteration. Formally, given a word  $\mathbf{x}_i$  in  $i^{\text{th}}$  language we find its transliteration into  $j^{\text{th}}$  language  $\mathbf{x}_j$ , by solving the optimization problem shown in Eq. 1, where  $U_i = U + R_i$  and  $U_j = U + R_j$ . Similar to the previous case, the closed form solution can be found by computing the first derivative with respect to the unknown phoneme sequence and the target language transliteration and setting it to zero. First, the IPA sequence  $\mathbf{p}^*$  that minimizes  $L(\mathbf{x}_i, \mathbf{x}_j)$  is given by:

$$\mathbf{p}^* = C_{ij}^{-1} (U_i A_i^T \mathbf{x}_i + U_j A_j^T \mathbf{x}_j) \quad (11)$$

where  $C_{ij} = U_i U_i^T + U_j U_j^T$ . We substitute this back in Eq. 2 and then solve for  $\mathbf{x}_j$ , the best transliteration in the  $j^{\text{th}}$  language, as:

$$A_j (I - U_j^T C_{ij}^{-1} U_j) A_j^T \mathbf{x}_j = A_j U_j^T C_{ij}^{-1} U_i A_i^T \mathbf{x}_i \quad (12)$$

Since  $U_i$  and  $U_j$  are not full rank matrices, to increase the numerical stability of the prediction step, we use  $C_{ij} = U_i U_i^T + U_j U_j^T + 0.001 I$  where  $I$  is an identity matrix. Notice that this solution doesn't depend on the  $\mathbf{p}^*$  and hence we don't need to compute it explicitly.

## 5 Related Work

There is a large body of the literature in named entity transliteration, so we will describe only the most relevant ones to our approach. In transliteration, generative approaches aim to generate the target language

transliteration of a given source name (Knight and Graehl, 1998; Jung et al., 2000; Haizhou et al., 2004; Al-Onaizan and Knight, 2002) while discriminative approaches assume a list of target language names, obtained from other sources, and try to identify the correct transliteration (Klementiev and Roth, 2006; Sproat et al., 2006). The effectiveness of the discriminative approaches depend on the list of target language candidates. Sproat et al. (2006) report an oracle accuracy of 85%, but it depends on the source of the candidate transliterations. Nevertheless, all these approaches require either bilingual name pairs or phoneme sequences to learn to transliterate between two languages. Thus, if we want to build a transliteration system between every pair of languages in a given set of languages then these approaches need resources between every pair of languages which can be prohibitive.

Bridge language approaches propose an alternative and use a resource rich language such as English as common language (Khapra et al., 2010) but they still need bilingual resources. Moreover Bridge-CCA (Khapra et al., 2010) uses a single mapping function for the phonemic space of all the languages and thus it can not handle language specific variability. In the original setting, authors use English as the pivot and since the feature space of English is fixed, irrespective of the target language, this may not be a serious concern but it becomes crucial when we use IPA as the bridge language.

Approaches that map words in different languages into the common phonemic space have also been well studied. But most of these approaches use language specific resources such as CMU pronunciation dictionary (Gao et al., 2004) or a carefully constructed cost matrices for addition, substitution, and deletion of phonemes between a pair of languages (Tao et al., 2006; Yoon et al., 2007). Variants of soundex algorithm (Odel and Russel, 1918) such as Kodex (Kang and Choi, 2000) use hand constructed consonant to soundex code tables for name transliteration. Similar to our approach these variants only require soundex mappings of a new language to build transliteration system, but our model does not require explicit mapping between n-gram characters and the IPA symbols instead it learns them automatically using phoneme dictionaries. Alternatively unsupervised approaches have also been explored

(Ravi and Knight, 2009), but their accuracies are fairly low compared to the supervised and weekly supervised approaches.

## 6 Experiments

Our experiments are designed to evaluate the following three aspects of our model, and of our approach to transliteration in general:

**IPA as bridge:** Unlike other phonemic based approaches (Sec. 5), we do not *explicitly* model the phoneme modifications between pairs of languages. Moreover, the phoneme dictionary in each language is crawled from Wiktionary (Sec. 6.1), which is likely to be noisy. So, the first aspect we want to evaluate is the effectiveness of using IPA as the bridge language. Here, we also compare our method with other bridge language approaches and establish the importance of modeling language specific variance.

**Multilinguality:** In our method, simply adding a phoneme dictionary of a new language allows us to extend our transliteration system into any of the existing languages. We evaluate the effect of data from a different, but related, languages on a transliteration system between a given pair.

**Complementarity:** Using IPA as bridge language allows us to build transliteration system into resource poor languages. But we also want to evaluate whether such an approach can help improving a transliteration system trained directly on bilingual name-pairs.

### 6.1 Data Sets

We use data sets from five languages in order to evaluate the effectiveness of our approach. The phoneme dictionaries (list of words and their IPA representations as shown in Table 1) are obtained from Wiktionary. The Wiktionary dump downloaded in October 2011 has at least 2000 (word, IPA) pairs in 21 languages which also includes some resource poor languages (e.g. Armenian, Taiwanese, Turkish, etc.).

In principle, our method allows us to build transliteration system into any of these language pairs without any additional information. But, in this paper, we use English (En), Bulgarian (Bg), Russian (Ru), French (Fr), and Romanian (Ro) for eval-

	En.	Bg.	Ru.	Fr.	Ro.
Train	31K	36K	1141	36K	5211
Dev.	–	1264	2000	2717	430
Test	–	1264	2000	2717	431
# Features	5000	3998	2900	5000	3465

Table 3: Statistics of different data sets. Training data is monolingual phoneme dictionaries while development/test sets are bilingual name pairs between English and the respective language.

uation purposes, as they suffice to showcase all the three aspects mentioned in the previous section. Table 3 shows the sizes of phoneme dictionaries used for training the models. The phoneme dictionaries of English, Bulgarian, and Russian contain more than 30K (word,IPA) pairs while the remaining two languages have smaller phoneme dictionaries. The development and test sets between English and the remaining language pairs are obtained from geonames data base.<sup>5</sup> These are geographic location names from different countries written in multiple languages.

## 6.2 Experimental Setup

We convert the phoneme dictionaries of each language into feature vectors. We use unigram and bigram features in the phonemic space and unigram, bigram and trigram features in the character space. An example for feature generation is shown in Sec. 3. After converting the data into feature vectors, we retain the most frequent 5000 features. We only keep the frequent 5000 features since we observed, elsewhere, that including infrequent features leads CCA based methods to learn projection directions with perfect correlations which are not effective for downstream applications. The last row of Table 3 shows the number of features in the character space of each of the languages. The phonemic space is common to all the languages and has 3777 features. Though the phonemic features are common to all the languages, as discussed in Sec. 2, only a subset of features will be observed in a given language. For example, in our data sets, of the total 3777 common phonetic features only 3312, 882, and 1009 features are observed in English, Bulgarian,

<sup>5</sup><http://www.geonames.org/>

Figure 2: Performance of transliteration system with residual parameter  $\lambda$  on English-Bulgarian development data set.

and Russian languages respectively. This indicates the diversity in the phonemic inventory of different languages.

We compare our approach against Bridge-CCA, a state-of-the-art bridge language transliteration system which is known to perform competitively with other discriminative approaches (Khapra et al., 2010). We use the phoneme dictionaries in each language to train our approach, as well as the baseline system. The projection directions learnt during the training are used to find the transliteration for a test name as described in Sec. 4.2. We report the performance in terms of the accuracy (exact match) of the top ranked transliteration and the mean reciprocal rank (MRR) of the correct transliteration. We find transliterations in both the directions (i.e. target language transliterations given a source name and vice versa) and report average accuracies. The regularization parameter ( $\tau$ ) and the size of the interlingual representation ( $k$ ) in both our approach and Bridge-CCA are tuned on the development set.

## 6.3 Description of Results

In this section we report experimental results on the three aspects mentioned above.

### 6.3.1 IPA as Bridge

Fig. 2 shows the performance of our system with the residual parameter  $\lambda$  (in Eq. 4) on the develop-

		En-Bg		En-Ru		En-Fr		En-Ro	
		Acc.	MRR	Acc.	MRR	Acc.	MRR	Acc.	MRR

2	Ours (cosine)	67.68	76.52	45.07	53.63	42.45	53.06	74.13	81.28
3	Ours (Eq. 12)	83.70	88.32	63.47	73.01	70.68	78.13	77.38	<b>84.22</b>
4	Ours (cosine + Multi.)	68.91	77.44	49.15	57.20	42.55	53.02	77.49	84.04
5	Ours (Eq. 12 + Multi.)	<b>84.45</b>	<b>88.43</b>	<b>66.70</b>	<b>75.85</b>	<b>71.09</b>	<b>78.43</b>	<b>77.49</b>	84.04

Table 4: Results of our approach and the baseline system on the test set. The second block shows the results when our approach is trained only on phoneme dictionaries of the language pair, the third block shows results when we include other language data as well.

ment data set. When  $\lambda$  is small, the model does not attempt to constrain the projection directions  $U_i$ 's and hence they tend to map names to completely unrelated vectors. As we increase the residual parameter, it forces the residual vectors ( $R_i$ ) to be smaller and thus the subspaces identified for each language are closely tied together. Thus, it models the commonalities across languages and also the language specific variability. Based on the performance curves on the development data, we fix  $\lambda = 50$  in the rest of the experiments.

Table 4 shows the results of Bridge-CCA and our approach on the four language pairs. We report the results of our approach with the decoding proposed in Sec. 4.2 and a simple cosine similarity measure in the common-subspace, i.e.  $\cos(A_i^T \mathbf{x}_i, A_j^T \mathbf{x}_j)$ . Comparison of the accuracies in rows 1, 2 and 3, shows that simply using cosine similarity performs almost same as the Bridge-CCA approach. However, using the decoding suggested in Eq. 12 gives significant improvements. To understand why the cosine angle between  $A_i^T \mathbf{x}_i$  and  $A_j^T \mathbf{x}_j$  is not the appropriate measure, assume that the vectors  $\mathbf{x}_i$  and  $\mathbf{x}_j$  are feature vectors of same name in two languages and let  $\mathbf{p}$  be its true IPA representation. Then, since our model learns projection directions such that  $A_i^T \mathbf{x}_i \approx U_i^T \mathbf{p}$ ,

$$\cos(A_i^T \mathbf{x}_i, A_j^T \mathbf{x}_j) = \cos((U_i + R_i)^T \mathbf{p}, (U_j + R_j)^T \mathbf{p})$$

The additional residual matrices  $R_i$  and  $R_j$  make the cosine measure inappropriate. At the same time, our model forces the residual matrices to be small and this is probably the reason why it performs competitively with the Bridge-CCA. On the other hand, our decoding method, as shown in Eq. 1, in-

tegrates over the best possible phoneme sequence and thus yields significant improvements. In the rest of the paper, we report results with the decoding in Eq. 12 unless specified explicitly. Our approach achieves a maximum improvement of 29.13% accuracy over Bridge-CCA in English-French and on an average it achieves 17.17% and 15.19% improvement in accuracy and MRR respectively. Notice that even though our Russian phoneme dictionary has only 1141 (word, IPA) pairs, our approach is able to achieve an accuracy of 63.47% and an MRR of 73% indicating that the correct name transliteration is, on an average, at rank 1 or 2.

### 6.3.2 Multilinguality

The fourth and fifth rows of Table 4 also show the multilingual results. In particular, we train our system on data from the three languages En, Bg, and Ru and test it on En-Bg and En-Ru test sets. Similarly, we train a different system on data from En, Fr and Ro and evaluate it on En-Fr and En-Ro test sets. We split the languages based on the language family, Russian and Bulgarian are Slavonic languages while French and Romanian are Romance languages, and expect that languages in same family have similar pronunciations. Comparing the performance of our system with and without the multilingual data set, it is clear that having data from other languages helps improve the accuracy.

### 6.3.3 Complementarity

In the final experiment, we want to compare the performance of our approach, which uses only monolingual resources, with a transliteration system trained using bilingual name pairs. We train a CCA based transliteration system (Udupa and Khapra,

	En-Bg		En-Fr	
	Acc.	MRR	Acc.	MRR
CCA	95.57	96.76	95.82	96.67
Ours+CCA	95.69	96.90	96.14	96.90
$\Delta$ Err	2.7%	4.2%	7.5%	6.8%
Ours+CCA(t)	95.80	96.95	96.34	97.04
$\Delta$ Err	5.4%	5.8%	12.3%	11.3%

Table 5: Comparison with a system trained on bilingual name pairs. The (t) in the third row indicates parameters are tuned for test set. We also show the percentage error reduction achieved by a linear combination of our approach and CCA.

2010) on a training data of 3792 and 8151 location name pairs. Notice that the training and test data for this system are from the same domain and thus it has an additional advantage over our approach, which is trained on whatever happens to be on Wiktionary.

The second row of Table 5 shows the results of CCA on English-Bulgarian and English-French language pairs. CCA achieves high accuracies even though the training data is relatively small, most likely because of the domain match between training and test data sets. As another baseline, we tried using Google machine translation API to transliterate the English names of the En-Bg test set. We hoped that since these are names, the translation engine would simply transliterate them and return the result. Of the output, we observed that about 500 names are passed through the MT system unchanged and so we ignore them. On the remaining names, it achieved an accuracy of 76.15% and the average string edit distance of the returned transliteration to the true transliteration is about 3.74. These accuracies are not directly comparable to the results shown in Table 5 because, presumably, it is a transliteration generation system unlike CCA which is a transliteration mining approach. For lack fair comparison, we don't report the accuracies of the Google transliteration output in Table 5.

Table 5 also shows the results of our system when combined with the CCA approach. For a given English word, we score the candidate transliterations using our approach and then linearly combine their scores with the scores assigned by CCA. We perform a line search between  $[0, 1]$  for the appropriate weight combination. The third and fourth rows of

Table 5 show the results of the linear combination when the weight is tuned for the development and test sets respectively. The improvements, though not significant, are encouraging and suggest that a sophisticated way of combining these different systems may yield significant improvements. This experiment shows that a transliteration system trained on word and IPA representations can actually augment a system trained on bilingual name pairs leading to an improved performance.

## 7 Conclusion

In this paper we proposed a regularization technique for the bridge language approaches and showed its effectiveness on the name transliteration task. Our approach learns interlingual representation using only monolingual resources and hence can be used to build transliteration system between resource poor languages. We show that, by accounting the language specific phonemic variation, we can get a significant improvements. Our experimental results suggest that a transliteration system built using IPA data can also help improve the accuracy of a transliteration system trained on bilingual name pairs.

Thought we used IPA as a bridge language there are other viable options. For example, as shown in Khapra et al. (2010) we can use English as the bridge language. Since name transliteration problem is being studied for a considerable time, many resources already exist between English and other languages. So, one can argue the appropriateness of IPA as bridge language compared to, say, English. While this is an important question, in this paper, we are primarily interested in showing the importance of handling language specific phenomenon in the bridge language approaches. In future, we would like to study the appropriateness of IPA vs. English as the bridge language and also the generalizability of our technique to other scenarios.

## Abstract

This paper proposes a novel method for lexicon extraction that extracts translation pairs from comparable corpora by using graph-based label propagation. In previous work, it was established that performance drastically decreases when the coverage of a seed lexicon is small. We resolve this problem by utilizing indirect relations with the bilingual seeds together with direct relations, in which each word is represented by a distribution of translated seeds. The seed distributions are propagated over a graph representing relations among words, and translation pairs are extracted by identifying word pairs with a high similarity in the seed distributions. We propose two types of the graphs: a co-occurrence graph, representing co-occurrence relations between words, and a similarity graph, representing context similarities between words. Evaluations using English and Japanese patent comparable corpora show that our proposed graph propagation method outperforms conventional methods. Further, the similarity graph achieved improved performance by clustering synonyms into the same translation.

## 1 Introduction

Bilingual lexicons are important resources for bilingual tasks such as machine translation (MT) and cross-language information retrieval (CLIR). Therefore, the automatic building of bilingual lexicons from corpora is one of the issues that have attracted many researchers. As a solution, a number of previous works proposed extracting bilingual lexicons

from comparable corpora, in which documents were not direct translations but shared a topic or domain<sup>1</sup>. The use of comparable corpora is motivated by the fact that large parallel corpora are only available for a few language pairs and for limited domains.

Most of the previous methods are based on assumption (I), that a word and its translation tend to appear in similar contexts across languages (Rapp, 1999). Based on this assumption, many methods calculate word similarity using context and then extract word translation pairs with a high-context similarity. We call these methods context-similarity-based methods. The context similarities are usually computed using a seed bilingual lexicon (e.g. a general bilingual dictionary) by mapping contexts expressed in two different languages into the same space. In the mapping, information not represented by the seed lexicon is discarded. Therefore, the context-similarity-based methods could not find accurate translation pairs if using a small seed lexicon.

Some of the previous methods tried to alleviate the problem of the limited seed lexicon size (Koehn and Knight, 2002; Morin and Prochasson, 2011; Hazem et al., 2011), while others did not require any seed lexicon (Rapp, 1995; Fung, 1995; Haghghi et al., 2008; Ismail and Manandhar, 2010; Daumé III and Jagarlamudi, 2011). However, they suffer the problems of high computational cost (Rapp, 1995), sensitivity to parameters (Hazem et al., 2011), low accuracy (Fung, 1995; Ismail and Manandhar, 2010), and ineffectiveness for language pairs with

<sup>1</sup>Although Vulić et al. (2011) regarded document-aligned texts such as texts on Wikipedia as comparable corpora, we do not limit comparable corpora to these kinds of texts.

different types of characters (Koehn and Knight, 2002; Haghighi et al., 2008; Daumé III and Jagarlamudi, 2011).

In face of the above problems, we propose a novel method that uses a graph-based label propagation technique (Zhu and Ghahramani, 2002). The proposed method is based on assumption (II), which is derived by recursively applying assumption (I) to the “contexts”: a word and its translation tend to have similar co-occurrence (direct and indirect) relations with all bilingual seeds across languages.

Based on assumption (II), we propose a three-step approach: (1) constructing a graph for each language with each edge indicating a direct co-occurrence relation, (2) representing every word as a seed translation distribution by iteratively propagating translated seeds in each graph, (3) finding two words in different languages with a high similarity with respect to the seed distributions. By propagating all the seeds on the graph, indirect co-occurrence relations are also considered when computing bilingual relations, which have been neglected in previous methods. In addition to the co-occurrence-based graph construction, we propose a similarity graph, which also takes into account context similarities between words.

The main contributions of this paper are as follows:

- We propose a bilingual lexicon extraction method that captures co-occurrence relations with all the seeds, including indirect relations, using graph-based label propagation. In our experiments, we confirm that the proposed method outperforms conventional context-similarity-based methods (Rapp, 1999; Andrade et al., 2010), and works well even if the coverage of a seed lexicon is low.
- We propose a similarity graph which represents context similarities between words. In our experiments, we confirm that a similarity graph is more effective than a co-occurrence-based graph.

## 2 Context-Similarity-based Extraction Method

The bilingual lexicon extraction from comparable corpora was pioneered in (Rapp, 1995; Fung, 1995).

The popular similarity-based methods consist of the following steps: modeling contexts, calculating context similarities, and finding translation pairs.

**Step 1. Modeling contexts:** The context of each word is generally modeled by a vector where each dimension corresponds to a context word and each dimension has a value indicating occurrence correlation. Various definitions for the context have been used: distance-based context (e.g. in a sentence (Laroche and Langlais, 2010), in a paragraph (Fung and McKeown, 1997), in a predefined window (Rapp, 1999; Andrade et al., 2010)), and syntactic-based context (e.g. predecessors and successors in dependency trees (Garera et al., 2009), certain dependency position (Otero and Campos, 2008)). Some treated context words equally regardless of their positions (Fung and Yee, 1998), while others treated the words separately for each position (Rapp, 1999). Various correlation measures have been used: log-likelihood ratio (Rapp, 1999; Chiao and Zweigenbaum, 2002), tf-idf (Fung and Yee, 1998), pointwise mutual information (PMI) (Andrade et al., 2010), context heterogeneity (Fung, 1995), etc.

Shao and Ng (2004) represented contexts using language models. Andrade et al. (2010) used a set of words with a positive association as a context. Andrade et al. (2011a) used dependency relations instead of context words. Ismail and Manandhar (2010) used only in-domain words in contexts. Pekar et al. (2006) constructed smoothed context vectors for rare words. Laws et al. (2010) used graphs in which vertices correspond to words and edges indicate three types of syntactic relations such as adjectival modification.

**Step 2. Calculating context similarities:** The contexts which are expressed in two different languages are mapped into the same space. Previous methods generally use a seed bilingual lexicon for this mapping. After that, similarities are calculated based on the mapped context vectors using various measures: city-block metric (Rapp, 1999), cosine similarity (Fung and Yee, 1998), weighted jaccard index (Hazem et al., 2011), Jensen-Shannon divergence (Pekar et al., 2006), the number of overlapping context words (Andrade et al., 2010), Sim-Rank (Laws et al., 2010), euclidean distance (Fung, 1995), etc.

Figure 1: An Example of a Previous Method and our Proposed Method

Andrade et al. (2011b) performed a linear transformation of context vectors in accordance with the notion that importance varies by context positions. Gaussier et al. (2004) mapped context vectors via latent classes to capture synonymy and polysemy in a seed lexicon. Fišer et al. (2011) and Kaji (2005) calculated 2-way similarities.

**Step 3. Finding translation pairs:** A pair of words is treated as a translation pair when their context similarity is high. Various clues have been considered when computing the similarities: concept class information obtained from a multilingual thesaurus (Déjean et al., 2002), co-occurrence models generated from aligned documents (Prochasson and Fung, 2011), and transliteration information (Shao and Ng, 2004).

## 2.1 Problems from Previous Works

Most of previous methods used a seed bilingual lexicon for mapping modeled contexts in two different languages into the same space. The mapping heavily relies on the entries in a given bilingual lexicon. Therefore, if the coverage of the seed lexicon is low,

the context vectors become sparser and its discriminative capability becomes lower, leading to extraction of incorrect translation equivalents.

Consider the example in Figure 1, where a context-similarity-based method and our proposed method find translation equivalents of the Japanese word “ピラニア (piranha)”. There are three context words for the query. However, the information on co-occurrence with “淡水 (freshwater)” disappears after the context vector is mapped, because the seed lexicon does not include “淡水 (freshwater)”. The same thing happens with the English word “piranha”. As a result, the pair of “ピラニア (piranha)” and “anaconda” could be wrongly identified as a translation pair.

Some previous work focused on the problem of seed lexicon limitation. Morin and Prochasson (2011) complemented the seed lexicon with bilingual lexicon extracted from parallel sentences. Koehn and Knight (2002) used identically-spelled words in two languages as a seed lexicon. However, the method is not applicable for language pairs with different types of characters such as English and Japanese. Hazem et al. (2011) exploited  $k$ -nearest words for a query, which is very sensitive to the parameter  $k$ .

Some previous work did not require any seed lexicon. Rapp (1995) proposed a computationally demanding matrix permutation method which maximizes a similarity between co-occurrence matrices in two languages. Ismail and Manandhar (2010) introduced a similarity measure between two words in different languages without requiring any seed lexicon. Fung (1995) used context heterogeneity vectors where each dimension is independent on language types. However, their performances are worse than those of conventional methods using a small seed lexicon. Haghighi et al. (2008) and Daumé III and Jagarlamudi (2011) proposed a generative model based on probabilistic canonical correlation analysis, where words are represented by context features and orthographic features<sup>2</sup>. However, their experiments showed that orthographic features to be important for effectiveness, which means low per-

<sup>2</sup>In Haghighi et al. (2008) and Daumé III and Jagarlamudi (2011), indirect relations with seeds are considered topologically, but our method utilizes degrees of indirect correlations with seeds.

formance for language pairs with different character types.

### 3 Lexicon Extraction Based on Label Propagation

As described in Section 2, the performance of previous work is significantly degraded when used with a small seed lexicon. This problem could be resolved by incorporating indirect relations with all the seeds when identifying translation pairs. For example, in Figure 1, “ピラニア (piranha)” has some degree of association with the seed “魚 - fish” through “淡水 (freshwater)” in both the Japanese side and the English side, although “ピラニア (piranha)” and “魚 (fish)” do not co-occur in the same contexts. Moreover, “anaconda” has very little association with the seed “魚 - fish” in the English side. Therefore, the indirect relation with the seed “魚 - fish” helps to discriminate from between “piranha” and “anaconda” and could be an important clue for identifying a correct translation pair.

To utilize indirect relations, we introduce assumption (II): a word and its translation tend to have similar co-occurrence (direct and indirect) relations with all bilingual seeds across languages<sup>3</sup>. Based on assumption (II), we propose to identify a word pair as a translation pair when its co-occurrence (direct and indirect) relations with all the seeds are similar.

To obtain co-occurrence relations with all the seeds, including indirect relations, we focus on a graph-based label propagation (LP) technique (Zhu and Ghahramani, 2002). LP transfers labels from labeled data points to unlabeled data points. In the process, all vertices have soft labels that can be interpreted as label distributions. We apply LP to bilingual lexicon extraction by representing each word as a vertex in a graph with each edge encoding a direct co-occurrence relation. Translated seeds are propagated as labels, and seed distributions are obtained for each word. From the seed distributions, we identify translation pairs.

In summary, our proposed method consists of three steps (see Algorithm 1): (1) graph construc-

<sup>3</sup>Assumption (I) indicates direct co-occurrence relations between a word and its context words are preserved across different languages. Therefore, assumption (II) is derived by recursively applying assumption (I) to the “context words”.

---

tion for each language, (2) seed propagation in each graph, (3) translation pair extraction.

#### 3.1 Graph Construction

We construct a graph representing the association between words for each language. Each graph is an undirected graph because the association does not have direction. The graphs are constructed as follows:

**Step 1. Vertex assignment** extracts words from each corpus, and assigns a vertex to each of the extracted words. Let  $V = \{v_1, \dots, v_n\}$  be a set of vertices.

**Step 2. Edge weight calculation** calculates association strength between two words as the weights of edges. Let  $E$  and  $W$  be a set of edges and that of the weights respectively, and  $e_{ij} \in E$  links  $v_i$  and  $v_j$ , and  $w_{ij} \in W$  is the weight of  $e_{ij}$ . Note that  $|E| = |W|$ .

**Step 3. Edge pruning** excludes edges whose weights are lower than threshold, in order to reduce the computational cost during seed propagations.

We propose two types of graphs that differ in the association measure used in Step 2: a co-occurrence graph and a similarity graph<sup>4</sup>.

##### 3.1.1 Co-occurrence Graph

A co-occurrence graph directly encodes assumption (II). Each edge in the graph indicates correlation strength between occurrences of two linked words. An example is shown in Figure 1.

In **edge weight calculation**, the co-occurrence frequencies are first computed for each word pair in the same context, and then the correlation strength is estimated. There are various definitions of a context or correlation measures that can be used (e.g. the

<sup>4</sup>We can combine the association measures used in a co-occurrence graph and a similarity graph. We will leave this combination approach for future work.

approaches used for modeling contexts in context-similarity-based methods). In this paper, we use words in a predefined window (window size is 10 in our experiments) as the context and PMI as the correlation measure:

$$w_{ij} = PMI(v_i, v_j) = \log \frac{p(v_i, v_j)}{p(v_i) \cdot p(v_j)},$$

where  $p(v_i)$  (or  $p(v_j)$ ) is the probability that  $v_i$  (or  $v_j$ ) occurs in a context, and  $p(v_i, v_j)$  is the probability that  $v_i$  and  $v_j$  co-occur within the same context. We estimate  $PMI(v_i, v_j)$  by the Bayesian method proposed by Andrade et al.(2010). Then, edges with a negative association,  $PMI(v_i, v_j) \leq 0$ , are pruned in **edge pruning**.

### 3.1.2 Similarity Graph

Co-occurrence graphs are very sensitive to accidental relation caused by lower frequent co-occurrence. Thus, we propose a similarity graph where context similarities are employed as weights of edges instead of simple co-occurrence-based correlations. Since the context similarities are computed by the global correlation among words which co-occur, a similarity graph is less subject to accidental co-occurrence. The use of a similarity graph is inspired by assumption (III): a word and its translation tend to have similar context similarities with all bilingual seeds across languages<sup>5</sup>.

In **edge weight calculation**, we first construct a correlation vector representing co-occurrence relations for each word. The correlation vectors are constructed in the same way as the context vectors used in context-similarity-based methods (see Section 2), where context words are words in a predefined window (window size is 4 in our experiment), the association measure is PMI, and context words are treated separately for each position. A correlation vector for each position is computed separately, then concatenated into a single vector within the window. Secondly, we calculate similarities between correlation vectors. There are various similarity measures that can be used, and cosine similarity is used in this

<sup>5</sup>This assumption is justified because context similarities are based on co-occurrence relations that are preserved across different languages.

paper:

$$w_{ij} = Cos(\vec{f}_i, \vec{f}_j) = \frac{\vec{f}_i \cdot \vec{f}_j}{\|\vec{f}_i\| \|\vec{f}_j\|},$$

where  $\vec{f}_i$  (or  $\vec{f}_j$ ) is the correlation vector of  $v_i$  (or  $v_j$ ). Then, in **edge pruning**, we preserve the edges with top 100 weight for each vertex.

### 3.2 Seed Propagation

LP is a graph-based technique which transfers the labels from labeled data to unlabeled data in order to infer labels for unlabeled data. This is primarily used when there is scarce labeled data but abundant unlabeled data. LP has been successfully applied in common natural language processing tasks such as word sense disambiguation (Niu et al., 2005; Alexandrescu and Kirchhoff, 2007), multi-class lexicon acquisition (Alexandrescu and Kirchhoff, 2007), and part-of-speech tagging (Das and Petrov, 2011). LP iteratively propagates label information from any vertex to nearby vertices through weighted edges, and then a label distribution for each vertex is generated where the weights of all labels add up to 1.

We adopt LP to obtain relations with all bilingual seeds including indirect relations by treating each seed as a label. First, each translated seed is assigned to a label, and then the labels are propagated in the graph described in Section 3.1.

The seed distribution for each word is initialized as follows:

$$q_i^0(z) = \begin{cases} 1 & \text{if } v_i \in V_s \text{ and } z = v_i \\ 0 & \text{if } v_i \in V_s \text{ and } z \neq v_i \\ u(z) & \text{otherwise} \end{cases},$$

where  $V_s$  is the set of vertices corresponding to translated seeds,  $u$  is a uniform distribution,  $q_i^k$  ( $i = 1 \dots |V|$ ) is the seed distribution for  $v_i$  after  $k$  propagation, and  $q_i^k(z)$  is the weight of a label (i.e., a translated seed)  $z$  in  $q_i^k$ .

After initialization, we iteratively propagate the seeds through weighted edges. In each propagation, seeds are probabilistically propagated from linked vertices under the condition that larger edge weights allow seeds to travel through easier. Thus, the closer vertices are, the more likely they have similar seed distributions. In Figure 1, the balloons attached to

vertices in the graphs show examples of the seed distributions generated by propagations. For example, the English word “piranha” has the seed distribution where the weights of the seeds “Amazon”, “jungle”, and “fish” are 0.5, 0.3, and 0.2, respectively. Specifically, each of seed distributions is updated as follows:

$$q_i^m(z) = \begin{cases} q_i^0(z) & \text{if } v_i \in V_s \\ \frac{\sum_{v_j \in N(v_i)} w_{ij} \cdot q_j^{m-1}(z)}{\sum_{v_j \in N(v_i)} w_{ij}} & \text{otherwise} \end{cases},$$

where  $N(v_i)$  is the set of vertices linking to  $v_i$ . We ran this procedure for 10 iterations in our experiments.

### 3.3 Translation Pair Extraction

After label propagations, we treat a pair of words in different languages with similar seed distributions as a translation pair. Seed distribution can be regarded as a vector where each dimension corresponds to each translated seed and each dimension has updated weight through label propagations. A similarity between seed distributions can therefore be calculated in the same way as a context-similarity-based method. In this paper, we use the cosine similarity defined by the following:

$$\text{Cos}(q_x^f, q_y^e) = \frac{\sum_{s_i \in S} q_x^f(v_i^f) \cdot q_y^e(v_i^e)}{\sqrt{\sum_{s_i \in S} (q_x^f(v_i^f))^2} \sqrt{\sum_{s_i \in S} (q_y^e(v_i^e))^2}},$$

where  $q_x^f$  (or  $q_y^e$ ) is the seed distribution for a word  $x$  (or  $y$ ) in the source language (or target language),  $S$  is the seed lexicon whose  $i$ -th entry  $s_i$  is a pairing of a translated seed in the source language  $v_i^f$  and one in the target language  $v_i^e$ .

## 4 Experiment

### 4.1 Experiment Data

We used English and Japanese patent documents published between 1993 and 2005 by the US Patent & Trademark Office and the Japanese Patent Office respectively, which were a part of the data used in the NTCIR-8 patent translation task (Fujii et al., 2010). Note that these documents are not aligned.

There are over three million English-Japanese parallel sentences (e.g. training data, test data, and

	Pair	Japanese Word	English Word
$Lex_S$	2,742	2,566	2,326
$Lex_L$	28,053	18,587	12,893

Table 1: Size of Seed Lexicons

development data used in the NTCIR-8 patent translation task, which is called *NTCIR parallel data* hereafter) in the patent data. However, a preliminary examination showed that the NTCIR parallel data covers less than 3% of all words because there are a number of technical terms and neologisms. Therefore, the patent translation task is a task that requires bilingual lexicon extraction from non-parallel data.

We selected documents belonging to the *physics* domain from each monolingual corpus based on International Patent Classification (IPC) code<sup>6</sup>, and then used them as a comparable corpus in our experiments. As a result, we used 1,479,831 Japanese documents and 438,227 English documents. The reason for selecting the *physics* domain is that this domain contains the most documents of all the domains.

The Japanese texts were segmented and part-of-speech tagged by ChaSen<sup>7</sup>, and the English texts were tokenized and part-of-speech tagged by Tree-Tagger (Schmid, 1994). Next, function words were removed since function words with little semantic information spuriously co-occurred with many words. As a result, the number of distinct words in Japanese corpus and English corpus amounted to 1,111,302 and 4,099,825<sup>8</sup>, respectively.

We employed seed lexicons from two sources: (1) EDR bilingual dictionary (EDR, 1990), (2) automatic word alignments generated by running GIZA++ (Och and Ney, 2003) with the NTCIR parallel data consisting of 3,190,654 parallel sentences. From each source, we extracted pairs of nouns appearing in our corpus. From (2), we excluded word pairs where the average of 2-way translation proba-

<sup>6</sup>SECTION G of IPC code indicates the *physics* domain.

<sup>7</sup><http://chasen-legacy.sourceforge.jp/>

<sup>8</sup>The English words contain words in tables or mathematical formula but the Japanese words do not because the data format differs between English and Japanese. This is why the number of English words is larger than that of Japanese words, even though the number of English documents is smaller than that of Japanese documents.

bilities was lower than 0.5. The pairs from (1) and (2) amounted to 27,353 and 2,853 respectively, and the two sets were not exclusive. In order to measure the impact of seed lexicon size, we prepared two seed lexicons:  $Lex_L$ , a large seed lexicon that is a union of all the extracted word pairs, and  $Lex_S$ , a small seed lexicon that is a union of a random sampling one-tenth of the pairs from (1) and one-tenth of the pairs from (2). Table 1 shows the size of each seed lexicon. Note that our seed lexicons include one-to-many or many-to-one translation pairs.

We randomly selected 1,000 Japanese words as our test data which were identified as either a noun or an unknown by ChaSen and were not covered either by the EDR bilingual dictionary or by the NT-CIR parallel data. This is because the purpose of our method is to complement existing bilingual dictionaries or parallel data. Note that the Japanese words in our test data may not have translation equivalents in the English side.

## 4.2 Competing Methods

We evaluated two types of our label propagation based methods against two baselines. *Cooc* employs co-occurrence graphs and *Sim* uses similarity graphs when constructing graphs for label propagation as described in Section 3.

*Rapp* is a typical context-similarity-based method described in Section 2 (Rapp, 1999). Context words are words in a window (window size is 10) and are treated separately for each position. Associations with context words are computed using the log-likelihood ratio (Dunning, 1993). The similarity measure between context vectors is the city-block metric.

*Andrade* is a sophisticated method in context-similarity-based methods (Andrade et al., 2010). Context is a set of words with a positive association in a window (window size is 10). The association is calculated using the PMI estimated by a Bayesian method, and a similarity between contexts is estimated based on the number of overlapping words (see the original paper for details).

## 4.3 Experiment Results

Table 2 shows the performance of each method using  $Lex_S$  or  $Lex_L$ . Hereafter,  $Method(L)$  (or  $Method(S)$ ) denotes the  $Method$  using  $Lex_L$  (or

	$Lex_S$		$Lex_L$	
	$Acc_1$	$Acc_{20}$	$Acc_1$	$Acc_{20}$
<i>Rapp</i>	1.5%	3.8%	4.8%	17.6%
<i>Andrade</i>	1.9%	4.2%	5.6%	17.6%
<i>Cooc</i>	3.2%	8.6%	9.2%	28.3%
<i>Sim</i>	4.1%	11.5%	10.8%	30.6%

Table 2: Performance on Bilingual Lexicon Extraction

$Lex_S$ ). We measure the performance on bilingual lexicon extraction as Top N accuracy ( $Acc_N$ ), which is the number of test words whose top N translation candidates contain a correct translation equivalent over the total number of test words (=1,000). Table 2 shows Top 1 and Top 20 accuracy. We manually<sup>9</sup> evaluated whether translation candidates contained a correct translation equivalent. We did not use recall because we do not know if the translation equivalents of a test word appear in the corpus.

Table 2 shows that the proposed methods outperform the baselines both when using  $Lex_S$  and using  $Lex_L$ . The improvements are statistically significant in the sign-test with 1% significance-level. The results show that capturing the relations with all the seeds including indirect relations is effective.

The accuracies of the baselines in Table 2 are worse than the previous reports: 14%  $Acc_1$  and 46%  $Acc_{10}$  (Andrade et al., 2010), and 72%  $Acc_1$  (Rapp, 1999). This is because previous works evaluated only the queries whose translation equivalents existed in the experiment data, which is not always true in our experiments. Moreover, previous works evaluated only high-frequency words: common nouns (Rapp, 1999) and words with a document frequency of at least 50 (Andrade et al., 2010). Our test data, on the other hand, includes many low-frequency words. It is generally true that translation of high-frequency words is much easier than that of low frequency words. We discuss the impact of test word frequencies in detail in Section 5.3.

Table 2 also shows that *Sim* outperforms *Cooc* both when using  $Lex_S$  and using  $Lex_L$ . The improvements of  $Acc_{20}$  are statistically significant in the sign-test with 5% significance-level.

<sup>9</sup>We could not evaluate using existing dictionaries because most of the test data are technical terms and neologisms not included in the dictionaries.

	<i>Sim(L)</i> (2)	<i>Cooc(L)</i> (5)	<i>Andrade(L)</i> (181)

Table 4: Seeds with the Highest Weight

## 5 Discussion

### 5.1 Effect of Indirect Relations with Seeds

Table 3 shows a list of the top 5 translation candidates for the Japanese word “躁鬱病 (manic-depression)” for each method, where the ranks of the correct translations are shown in parentheses next to method names. Table 4 shows the top 5 translated seeds which characterize the query, where the values in parentheses indicate weight. Table 3 shows that *Cooc(L)* can find the correct translation equivalent but *Andrade(L)* cannot. Table 4 shows that *Cooc(L)* can utilize more seeds closely tied to the query (e.g. “神経症 (neurosis)”, “不眠症 (insomnia)”), which did not occur in the context of the query in the experiment data. The result shows that

indirectly-related seeds are also important clues, and our proposed method can utilize these.

### 5.2 Impact of Seed Lexicon Size

Table 2 shows that a reduction of seed lexicon size degrades performance. This is natural for the baseline methods because *Lex<sub>S</sub>* cannot translate most of context words, which are necessary for word characterization. Consider *Andrade(L)* and *Andrade(S)* in the example in Section 5.1. Table 4 shows that *Andrade(S)* uses less relevant seeds with the query, and has to express the query by seeds with less association. For example, “精神病 (psychosis)” cannot be used in *Andrade(S)* because *Lex<sub>S</sub>* does not have the seed. Therefore, it is more difficult for *Andrade(S)* to find correct translation pairs.

The proposed methods also share the same tendency, although each word is expressed by all the seeds in the seed lexicon. Consider *Cooc(L)* and *Cooc(S)* in the above example. Table 4 shows that *Cooc(S)* expresses the query by a smooth seed distribution, which is difficult to discriminate from others. This is because *Lex<sub>S</sub>* does not have relevant seeds for the query. This is why *Cooc(S)* cannot find the correct translation equivalent. On the other hand, *Cooc(L)* characterizes “躁鬱病” and “manic-depression” by strongly relevant seeds (e.g. “精神病 (psychosis)”, “神経症 (neurosis)”), and then finds the correct translation equivalent.

To examine the robustness-to-seed lexicon size, we calculated the reduction rate of *Acc<sub>20</sub>* with the following expression: (*Acc<sub>20</sub>* with *Lex<sub>L</sub>* - *Acc<sub>20</sub>* with *Lex<sub>S</sub>*) / *Acc<sub>20</sub>* with *Lex<sub>L</sub>*. The reduction rates of *Rapp*, *Andrade*, *Cooc*, and *Sim* are 78.4%, 76.1%, 69.6%, and 62.4% respectively. Moreover, the difference between degradation in *Cooc* and that in *Andrade* is statistically significant in the sign-test with 1% significance-level. These results indicate that the proposed methods are more robust to seed lexicon size than the baselines. This is because the proposed methods can utilize seeds with indirect relations while the baselines utilize only seeds in the context.

To verify our claim, we examined the number of test words which occurred with no seeds in the context. There were 570 such words in *Rapp(S)*, 387 in *Rapp(L)*, 572 in *Andrade(S)*, and 388 in *Andrade(L)*. The baselines cannot find their trans-

	Low Freq.		High Freq.	
	$Acc_1$	$Acc_{20}$	$Acc_1$	$Acc_{20}$
$Rapp(L)$	0.5%	2.4%	7.2%	25.6%
$Andrade(L)$	0.3%	1.8%	8.6%	26.3%
$Cooc(L)$	0.8%	4.3%	13.9%	40.7%
$Sim(L)$	2.2%	6.7%	15.0%	42.0%

Table 5: Comparison between Performance for High and Low Frequency Words

lation equivalents. Words such as this occur even if using  $Lex_L$ , and that number increases when  $Lex_S$  is used. On the other hand, the proposed methods are able to utilize all the seeds in order to find equivalents for words such as these. Therefore, the proposed methods work well even if the coverage of a seed lexicon is low.

### 5.3 Impact of Word Frequencies

Our test data includes many low-frequency words which are not covered by the EDR bilingual dictionary or the NTCIR parallel data. 624 words appear in the corpus less than 50 times. Table 5 shows  $Acc_N$  using  $Lex_L$  for 624 low-frequency words and 376 high-frequency words. Table 5 shows that performance for low-frequency words is much worse than that for high-frequency words. This is because translation of high-frequency words utilizes abundant and reliable context information, while the context information for low-frequency words is statistically unreliable. In the proposed methods, edges linking rare words are sometimes generated based on accidental co-occurrences, and then unrelated seed information is transferred through the edges. Therefore, even our label propagation based methods, especially for  $Cooc$ , could not identify the correct translation equivalents for rare words.  $Sim$  alleviated the problem by using a similarity graph in which edges are generated based on global correlation among words, as indicated by Table 5. Table 5 also suggests that top 20 translation candidates for high-frequency words have potential to contribute to bilingual tasks such as MT and CLIR although the overall performance is still low.

### 5.4 Effect of Similarity Graphs

We examined  $Acc_N$  for synonyms of translated seeds in Japanese. The  $Acc_1$  and  $Acc_{20}$  of  $Sim(L)$  are 15.6% and 56.3%, respectively, and those of  $Cooc(L)$  are 9.4% and 37.5%, respectively. The results show that similarity graphs are effective for clustering synonyms into the same translation equivalents. For example,  $Sim(L)$  extracted the correct translation pair of the English word “iodine” and the Japanese word “イオディン”, a synonym of the translated seed “ヨウ素 (iodine)” in Japanese. This is because synonyms tend to be linked in the similarity graph and have similar seed distributions. On the other hand, in the co-occurrence graph, synonyms tend to be indirectly linked through mutual context words, so the seed distributions of the two could be far away from each other.

There are in particular many loanwords in patent documents, which are spelled in different ways from person to person. For example, the loan word for the English word “user” is often written as “ユ-ザ”, but it is sometimes written as “ユ-ザー”, with an additional prolonged sound mark. Therefore,  $Sim$  is particularly effective for the experiment data.

### 5.5 Error Analysis

We discuss errors of the proposed methods except the errors for low-frequency words (see Section 5.3). Our test data includes words whose translation equivalents inherently cannot be found. The first of these types are words whose equivalent does not exist in the English corpus. This is an unavoidable problem for methods based on comparable corpora. The second one are words whose English equivalents are compound words. The Japanese morphological analyzer tends to group a compound word into a single word, while the English text analyzer does not perform a collocation of words divided by the delimiter *space*. For example, the single Japanese word “掌紋” is equivalent to “palm pattern” or “palm print”, which is composed of two words. This case was counted as an error even though the proposed methods found the word “palm” as a equivalent of “掌紋”.

A main reason of errors other than those above is word sense ambiguity, which is different in every language. For example, the Japanese word “右”

means “right” and “conservatism” in English. The proposed methods merge different senses by propagating seeds through these polysemous words in only one language side. This is why translation pairs could have wrong seed distributions and then the proposed methods could not identify correct translation pairs. We will leave this word sense disambiguation problem for future work.

## 6 Related Work

Besides the comparable corpora approach discussed in Section 2, many alternatives have been proposed for bilingual lexicon extraction. The first is a method that finds translation pairs in parallel corpora (Wu and Xia, 1994; Fung and Church, 1994; Och and Ney, 2003). However, large parallel corpora are only available for a few language pairs and for limited domains. Moreover, even the large parallel corpora are relatively smaller than comparable corpora.

The second is a method that exploits the Web. Lu et al. (2004) extracted translation pairs by mining web anchor texts and link structures. As an alternative, mixed-language web pages are exploited by first retrieving texts including both source and target languages from the web by using a search engine or simple rules, and then extracting translation pairs from the mixed-language texts utilizing various clues: Zhang and Vines (2004) used co-occurrence statistics, Cheng et al. (2004) used co-occurrences and context similarity information, and Huang et al. (2005) used phonetic, semantic and frequency-distance features. Lin et al. (2008) proposed a method for extracting parenthetically translated terms, where a word alignment algorithm is used for establishing the correspondences between in-parenthesis and pre-parenthesis words. However, those methods cannot find translation pairs when they are not connected with each other through link structures, or when they do not co-occur in the same text.

Transliteration is a completely different way for bilingual lexicon acquisition, in which a word in one language is converted into another language using phonetic equivalence (Knight and Graehl, 1998; Karimi et al., 2011). Although machine transliteration works particularly well for proper names and loan words, it cannot be employed for phonetically

dissimilar translations.

All the methods mentioned above may potentially extract translation pairs more precisely than our comparable corpora approach when their underlying assumptions are satisfied. We might improve the performance of our method by augmenting a seed lexicon with translation pairs extracted using the above methods, as experimented with in Section 4, in which additional lexical entries are included from parallel data.

## 7 Conclusion

We proposed a novel bilingual lexicon extraction method using label propagation for alleviating the limited seed lexicon size problem. The proposed method captures relations with all the seeds including indirect relations by propagating seed information. Moreover, we proposed using similarity graphs in propagation process in addition to co-occurrence graphs. Our experiments showed that the proposed method outperforms conventional context-similarity-based methods (Rapp, 1999; Andrade et al., 2010), and the similarity graphs improve the performance by clustering synonyms into the same translation.

We are planning to investigate the following open problems in future work: word sense disambiguation and translation of compound words as described in (Daille and Morin, 2005; Morin et al., 2007). In addition, indirect relations have also been used in other tasks, such as paraphrase acquisition from bilingual parallel corpora (Kok and Brockett, 2010). We will utilize their random walk approach or other graph-based techniques such as modified adsorption (Talukdar and Crammer, 2009) for generating seed distributions. We are also planning an end-to-end evaluation, for instance, by employing the extracted bilingual lexicon into an MT system.

<sup>3</sup>{parker}@sas.upenn.edu

## Abstract

We present a system for automatic identification of schizophrenic patients and healthy controls based on narratives the subjects recounted about emotional experiences in their own life. The focus of the study is to identify the lexical features that distinguish the two populations. We report the results of feature selection experiments that demonstrate that the classifier can achieve accuracy on patient level prediction as high as 76.9% with only a small set of features. We provide an in-depth discussion of the lexical features that distinguish the two groups and the unexpected relationship between emotion types of the narratives and the accuracy of patient status prediction.

lexical differences have not been investigated in detail.

In this paper we introduce a dataset of autobiographical narratives told by schizophrenic patients and by healthy controls. The narratives are related to emotional personal experiences of the subjects for five basic emotions: ANGER, SAD, HAPPY, DISGUST, FEAR. We train an SVM classifier to predict subject status. Our good results on the relatively small dataset indicate the potential of the approach. An automatic system for predicting patient status from autobiographical narratives can aid psychiatrists in tracking patients over time and can serve as an easy way to administer large scale screening. The detailed feature analysis we performed also pinpoints key differences between the two populations.

## 1 Introduction

Recent studies have shown that automatic language analysis can be successfully applied to detect cognitive impairment and language disorders. Our work further extends this line of investigation with analysis of the lexical differences between patients suffering from schizophrenia and healthy controls.

Prior work has reported on characteristic language peculiarities exhibited by schizophrenia patients. There are more repetitions in speech of patients compared to controls (Manschreck et al., 1985). Patients also tend to repeatedly refer back to themselves (Andreasen., 1986). Deviations from normal language use in patients on different levels, including phonetics and syntax, have been documented (Covington et al., 2005), however

We study a range of lexical features including individual words, repetitions as well as classes of words defined in specialized dictionaries compiled by psychologists (Section 4). We use several approaches for feature analysis to identify statistically significant differences in the two populations. There are 169 significant features among all of the 6057 features we examined. Through feature selection we are able to obtain a small set of 25 highly predictive features which lead to status classification accuracy significantly better than chance (Section 6.3). We also show that differences between patients and controls are revealed best in stories related to SAD and ANGRY narratives, they are decent in HAPPY stories, and that distinctions are poor for DISGUST and FEAR (Section 6.5).

## 2 Related Work

Research in psychometrics has studied patterns of lexical usage in a large variety of scenarios. A popular tool used for psychometric analysis is Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2007). One of the most interesting discoveries in that line of research is that people with physical or emotional pain are likely to use first-person singular pronouns more often than the general population (Rude et al., 2004). In the view of therapy, Pennebaker discovered that writing emotional experiences can be helpful in therapeutic process (Pennebaker, 1997). It has also been shown that the usage of pronouns and function words can be indicators of writing styles, physical health and other distinctions (Tausczik and Pennebaker, 2010).

The combination of natural language processing (NLP) and machine learning (ML) has been explored in many psychology related projects, and is gaining popularity. It has been shown that features from language models (LMs) can be used to detect impairment in monolingual and bilingual children (Gabani et al., 2009). Even better results are achieved when features derived from LMs are combined with other surface features to predict language impairment. Similarly, studies on child language development and autism have shown that  $n$ -gram cross-entropy from LMs representative of healthy and impaired subjects is a highly significant feature predictive of language impairment (Prud’hommeaux et al., 2011). The feasibility of making use of lexical features to analyze language dominance among bilingual children has also been confirmed (Solorio et al., 2011).

In non-medically related research, LIWC and lexical features have been used to recognize different personalities such as *introvert vs extrovert*, *openness vs experience*, *conscientiousness vs unconscientiousness*, etc. (Mairesse et al., 2007). Similar features have been applied to differentiate author personality of e-mails (Gill et al., 2006), blogs (Gill et al., 2009) and other documents.

Speech-related features and interactional aspects of dialog behavior such as pauses, fillers, etc, have also been found helpful in identifying autistic patients (Heeman et al., 2010).

Variables (# Subjects)	Schizophrenia (n=23)	Control (n=16)
Mean age (SD)	33.81 (9.65)	32.29 (6.59)
Mean number of words per story (SD)	192.22 (122.4)	180.79 (95.87)

Table 1: Basic demographic information

Syntax features have been used in approaches of automatic detection of neurological problems. Parsing texts produced by subjects and using bag of rules as features have been applied in analyzing language dominance (Solorio et al., 2011). Methods that quantify syntactic complexity like Yngve score and Fraizer score have been used to analyze autism (Prud’hommeaux et al., 2011). Moreover, there has been research on detecting mild cognitive impairment, which could be an earlier state of Alzheimer’s disease: five different ways of evaluating syntactic complexity measures were introduced in their paper (Roark et al., 2011).

In our own work, we focus our analysis exclusively on lexical features. Similarly to prior work, we present the most significant features related to differences between schizophrenic patients and healthy controls. Unlike prior work, instead of doing class ablation studies we perform feature selection from the full set of available features and identify a small set of highly predictive features which are sufficient to achieve the top performance we report. Such targeted analysis is more helpful for medical professionals as they search to develop new therapies and ways to track patient status between visits.

## 3 Data

For our experiments we collected autobiographical narratives from 39 speakers. The speakers are asked to tell their experience involving the following emotions: HAPPY, ANGER, SAD, FEAR and DISGUST, which comprise the set of the five basic emotions (Cowie, 2000). Most subjects told a single story for each of the emotions, some told two. The total number of stories in the dataset is 201.

The stories were narrated in the doctor’s office. The recordings of the narratives were manually transcribed in plain text format. We show age and length in words of the told stories for the two groups

in Table 1. There are 23 patients with schizophrenia and 16 healthy controls, telling 120 and 81 stories respectively.

## 4 Features

Here we introduce the large set of lexical features that we group in three classes: a large class of features computed for individual lexical items, basic features, features derived on the basis of pre-existing dictionaries and language model features. We also detail the way we performed feature normalization and feature selection.

### 4.1 Surface Features

#### 4.1.1 Basic Features

Basic features include token to type ratio to capture vocabulary diversity, letters per word, words per sentence, sentences per document and words per document. These features describe the general properties of the language used by the subject, without focus on specific words.

Repetitions, revisions, large amount of fillers or disfluencies can be indicators for language impairment. In our basic features we detect the number of repetitions in words, punctuations and sentences for each transcript. Then these three measures are normalized by total number of words or sentences.

We define repetitions as the occurrence of the same token in a sliding window of five items within the same sentence. We count repetitions of words and punctuation separately. The repetition of punctuation, mostly commas and full-stops, are indicative of phrasing in speech which has been indirectly captured in the transcript. Repetition of any word is counted, regardless of which specific word was repeated. For example, for the sentence *I am, am, afraid, that something bad would happen.* *am* is counted as repeated once, and comma is counted as repeated twice. Finally, sentence repetition captures the amount of overlapping at the beginning of two adjacent sentences, defined as the number of tokens from the beginning of the sentence until the first token where the two sentences differ.

#### 4.1.2 Lexical Features

For words in the vocabulary: we use a real value feature equal to the word frequency for each

document. Of particular interest we track the use of pronouns because early research has reported that people with cognitive impairment have a tendency to use subjective words or referring to themselves (Rude et al., 2004).

In addition, for each word in the vocabulary, we apply the presence of the repetition about one particular word.

### 4.1.3 Perplexity from Language Models

Inspired by the predictive power of language model reported in prior work, we also include several language model features. We build language models on words as well as part-of-speech (POS) tags from Stanford POS-tagger (Toutanova et al., 2003). We tried unigram, bigram and trigram language models by word and POS tag. Experiments showed that bigram performed better than random, and the other two performed below random. Thus in the experiments we report later we train one model for patients and one for controls and use the perplexity of a given text according to the bigram language models on word and POS as features in prediction.

### 4.2 Dictionaries: LIWC and Diction

Text analysis packages have been widely used in research related to personality analysis, sentimental analysis and psychometric studies. We use two dictionary-based systems, LIWC (Pennebaker et al., 2007)<sup>1</sup> and Diction<sup>2</sup>, which both give scores to transcripts based on broad categories.

#### 4.2.1 Linguistic Inquiry&Word Count(LIWC)

LIWC calculates the degree to which people use different categories of words. Several manually compiled dictionaries are at the heart of the application. Each word or word stem could be in one or more word categories or sub-dictionaries. For instance, the word “cried” is part of the following categories: *sadness*, *negative emotion*, *overall affect*, *verb*, and *past tense verb*. When a narrative contains the word “cried”, the scale scores corresponding to these five subcategories are incremented. The final output for each narrative is a real value score for each of the 69 categories.

<sup>1</sup>See <http://www.liwc.net>

<sup>2</sup>See <http://www.dictionsoftware.com>

Because of the elaborate development of dictionaries and categories, LIWC has been used for predicting emotional and cognitive problems from subject’s spoken and written samples. Representative applications include studying attention focus through personal pronouns, studying honesty and deception by emotion words and exclusive words and identifying thinking styles (Tausczik and Pennebaker, 2010). Thus it is reasonable to expect that LIWC derived features would be helpful in identifying schizophrenia patients. In Section 6.4 we discuss in more detail the features which turned out to be significantly different between patients and controls within LIWC.

#### 4.2.2 Diction

We also use Diction to analyze the lexical characteristics of the transcripts. Similar to LIWC, Diction scores are computed with reference to manually compiled dictionaries. The master variable scores in Diction include *activity*, *certainty*, *commonality*, *optimism* and *realism*. These five main scores are computed with 33 dictionaries that define pertinent subcategories. The master variable scores are constructed as follows:  $S_m = \sum_{i=1}^n a_i - \sum_{j=1}^m s_j$ , where  $a_i$  are additive traits,  $s_j$  are subtractive traits (giving positive/negative evidence for the presence of the feature, respectively). For example, Certainty and Realism scores are calculated as follows:

**Realism** = [*Familiarity* + *Spatial Awareness* + *Temporal Awareness* + *Present Concern* + *Human Interest* + *Concreteness*] - [*Past Concern* + *Complexity*]

**Certainty** = [*Tenacity* + *Leveling* + *Collectives* + *Insistence*] - [*Numerical Terms* + *Ambivalence* + *Self Reference* + *Variety*]

We also give definitions for some important categories. The complete description of categories is available in the *Diction* manual (Hart, 2000).

**Cognition:** *Words referring to cerebral processes, both functional and imaginative.*

**Satisfaction:** *Terms associated with positive affective states.*

**Insistence:** *A measure of code-restriction and contentedness, with the assumption that the repetition of key terms indicates a preference for a*

*limited, ordered world.*

**Diversity:** *Words describing individuals or groups of individuals differing from the norm.*

**Familiarity:** *Consisted of the most common words in English.*

**Certainty:** *Language indicating resoluteness, inflexibility, and completeness and a tendency to speak ex cathedra.*

**Realism:** *Language describing tangible, immediate, recognizable matters that affect people’s everyday lives.*

### 4.3 Feature normalization

We use two feature normalization approaches: projection normalization and binary normalization. Both of the two approaches are applied to basic features, dictionary features and word features. As for repetition, we don’t use normalization, because it is in itself binary. For transcript  $i$ , we denote the value of the  $j$ th feature as  $v_{ij}$ . We denote  $min_j$ ,  $max_j$ ,  $average_j$  as the minimum, maximum and average value for each feature in the training corpus, respectively. Thus for each feature  $j$ , we have:  $average_j = \frac{1}{n} \sum_{i=1}^n v_{ij}$   $min_j = \min_i \{v_{ij}\}$ ,  $max_j = \max_i \{v_{ij}\}$ .

#### 4.3.1 Projection Normalization

Here we simply normalize all feature values to a range of  $[0, 1]$ , where 0 corresponds to the smallest observed value and 1 to the largest observed value across all transcripts. Then we could have  $p_{ij} = \frac{v_{ij} - min_j}{max_j - min_j}$ , where  $p_{ij}$  is the feature value after normalization.

#### 4.3.2 Binary normalization

Here all features are converted to binary values, reflecting whether the value falls below or above the average value for that feature observed in training. The value  $p_{ij}$  of  $j$ -th feature for the  $i$ -th instance is as below:

$$p_{ij} = \begin{cases} 0 & v_{ij} < \frac{1}{n} \sum_{i=1}^n v_{ij} \\ 1 & \text{otherwise} \end{cases}$$

#### 4.3.3 Prediction on the Test Set

All of the previous values,  $average_j$ ,  $max_j$  and  $min_j$  are derived from the training set. While doing classification, for a new testing instance, we denote the feature vector as  $f = (f_1, f_2, \dots, f_n)$ .

$f_j$  is then compared with  $average_j$  to do binary normalization. We also use  $p_j = \frac{f_j - min_j}{max_j - min_j}$  to do projection normalization. If  $p_j < 0$ , we change  $p_j$  into 0; if  $p_j > 1$ , we change  $p_j$  into 1. For the words or features that are not seen in training, we just ignore this dimension.

#### 4.4 Feature selection

All lexically based analysis is plagued by data sparsity problems. In the medical domain this problem is even more acute because collecting patient data is difficult. The number of features we defined outnumbers our samples by orders of magnitude. Therefore, in our classification procedure, we perform feature selection by doing two-sided T-test to compare the values of features in the patient and control groups. The features with p-value  $\leq 0.05$  are considered as indicative and are selected for later machine learning experiments, in which 169 out of 6057 features have been selected. We discuss the significant features in the full set in Section 6.4.

Note however that we don't use the features selected on the full dataset for machine learning experiments because when T-tests are applied on the full dataset feature selection decisions would include information about the test set as well. Therefore, we adopt a leave-one-subject-out (LOSO) evaluation approach instead. In each iteration, we set aside one subject as test set. The data from the remaining subjects form the training set. Feature selection is done on the training set only and a model is trained. The predictions are tested on the held out subject. The procedure is repeated for every subject as test set.

The choice of p-value cut-off allows us to relax and tighten the requirement on significance of the features and thus the size of the feature set. We report results with different p-values in Table 3. We also explore alternative feature ranking and feature selection procedures in Section 6.3. In each fold different features may be selected. For ease of discussing feature differences we present a discussion of the 169 significant features on the entire dataset.

## 5 Our approach

The goal of our system is to classify the person who told a story in one of two categories: Schizophrenia group (SC) and Control group (CO). In order to do this, we give labels to the stories told by each subject. Therefore we could use our model to identify the status of the person who told each individual story, the task is to answer the question "Was the subject who told this story a patient or control?". Then we combine the predictions for stories to predict status of each subject, and the task becomes answering the question "Is this subject a patient or control given that they told these five stories?". Thus in story level prediction we use no information about the fact that subjects told more than one story, while in subject-level prediction we do use this information.

First we present an experiment that relies only on language models for the prediction. Then we present the complete learning-based system that uses the full set of features. Finally, we describe the decision making approach to combine the story level predictions to derive a subject-level prediction.

### 5.1 Language Model

Language models have been used previously for language impairment on children (Gabani et al., 2009) and language dominance prediction (Solorio et al., 2011). Patients with speaking disorder or cognitive impairment express themselves in atypical ways. Language models (LMs) give a straightforward way of estimating the probability of the productions of a given subject. We expect that the approach would be useful for the study of schizophrenia as well and so start with a description of the LM experiments.

We use LMs on words to recognize the difference between patients and controls in vocabulary use. We also trained a LM on POS tags because it could reduce sparsity and focus more on grammatical patterns. Two separate LMs are trained on transcripts of schizophrenia and controls respectively, using leave-one-subject-out protocol.

Story-level decisions are made by assigning the class whose language model yields lower perplexity:

$$s(t) = \begin{cases} SC & PER_{SC}(t) \leq PER_{CO}(t) \\ CO & \text{otherwise} \end{cases}$$

by Story (%)	SC-F	CO-F	Accuracy	Macro-F
Random	54.4	44.6	50.0	49.5
Majority	74.8	0.0	59.7	37.4
2-gram	62.5	44.4	55.2	53.5
2-gram-Pos	62.2	53.3	58.2	57.8

by Subject (%)	SC-F	CO-F	Accuracy	Macro-F
Random	54.1	45.1	50.0	49.6
Majority	74.2	0.0	59.1	37.1
2-gram	65.2	50.0	58.9	57.6
2-gram-Pos	66.7	54.5	61.5	60.6

Table 2: Language model performance

Here  $t$  means a transcript from a subject, while  $PER_{SC}$  and  $PER_{CO}$  are perplexities for patients and controls, respectively. We experimented with unigram, bigram and trigram LMs on words and POS tags. Laplace smoothing is used when generating word probabilities.

## 5.2 Classification Phase

Language models are convenient because they summarize information from patterns in lexical and POS use into a single number. However, most of the successful applications of LMs require large amount of training data while our dataset is relatively small. Moreover, we would like to analyze more specific differences between the patient and control group and this would be more appropriately done using a larger set of features.

We have described our features and feature selection process in Section 4. We use SVM-light (Joachims, 1999) for our machine learning algorithm, as its effectiveness has been proved in various learning-based clinical tasks compared to other classifiers (Gabani et al., 2009).

## 5.3 Status Decision

Story level predictions are made for each transcript either based on LM perplexity or SVM prediction. The most intuitive way to obtain a subject-level prediction is by voting from story-level predictions between the stories told by the particular subject. The subject-level prediction is simply set to equal the majority prediction from individual stories. On the few occasions where there are equal votes for schizophrenia and control, the system makes a preference towards schizophrenia, because it is more

P-value cut-off	by Story	by Subject	# Features
0.15	59.0	58.9	450
0.10	61.7	64.1	341
0.05	62.7	<b>64.1</b>	169
0.01	57.7	<b>65.4</b>	44
0.005	64.2	<b>71.6</b>	32
0.001	65.7	<b>75.6</b>	18
0.0005	61.7	66.7	14

Table 3: Performance by subject after T-test feature selection in different confidence levels.

dangerous to omit a potential patient.

## 6 Experiments and Results

We perform our experiments on the 201 transcripts of the 39 speakers. The two baselines we compare with are doing random assignments and majority class, which for our datasets correspond to predicting all subjects into the Schizophrenia group.

We report precision, recall and F-measure for both patient and control groups, as well as overall accuracy and Macro-F value. We get predictions in leave-one-subject-out fashion and compute the results over the complete set of predictions.

### 6.1 Language Model Performance

Our first experiment relies only on the perplexity from language models to make the prediction. We use the 1,2,3-gram models on word and POS sequences. From the result in Table 2 we can see bigram LM performed better than random baseline for both story and subject level prediction. 3-gram and 1-gram LM did not give a credible performance, with results worse than that of the baselines. Because of space constraints we do not report the specific numbers.

### 6.2 Classification Result after Feature Selection

Next we evaluate the performance of classification with different number of features from the classes we define in Section 4. As discussed above, we performed feature selection by choosing different levels of significance for the p-value cut-off. Feature selection is performed 39 times for each LOSO training fold. On the standard cut-off p-value  $\leq 0.05$ , our system could achieve 62.7% accuracy on story and 64.1% on patient level prediction. The best performance is achieved when the cut-off p-value is

		Schizophrenia			Control			General	
Measurement		P (%)	R (%)	F (%)	P (%)	R (%)	F (%)	Accuracy (%)	Macro-F (%)
Story	Random	59.7	50.0	54.4	40.5	50.0	44.6	50.0	49.5
	Majority	59.7	100.0	74.8	NA	0.0	0.0 (NA)	59.7	37.4
	25-Features	68.7	75.0	71.7	57.1	49.4	52.9	64.7	62.3
Subject	Random	59.0	50.0	54.1	41.0	50.0	45.0	50.0	49.6
	Majority	59.0	100.0	74.2	NA	0.0	0.0 (NA)	59.0	37.1
	25-Features	<b>75.0</b>	<b>91.3</b>	<b>82.4</b>	81.8	56.3	66.7	<b>76.9</b>	<b>74.6</b>

Table 4: Performance on best feature-set by feature ranking using signal to noise

stricter, 0.001, where an accuracy of 75.6% can be reached. In this case only about 18 features are used for the classification. Detailed results are shown in Table 3.

### 6.3 Performance with Different Feature Size

Next we investigate the relationship between feature set size and accuracy of prediction. We are interested in identifying the smallest possible set of features which gives performance close to the one reported on the full set of significant features. Narrowing the feature set as much as possible will be most useful for clinicians as they understand the differences between the groups and look for indicators of the illness they need to track during regular patient visits. Physicians and psychologists are also interested to know the most significant lexical differences revealed by the stories.

As an alternative to ranking features by p-value, we use the Challenge Learning Object Package (CLOP)<sup>3</sup> (Guyon et al., 2006). It is a toolkit with a combination of preprocessing and feature selection. We experiment with signal-to-noise (s2n), Gram-Schmidt orthogonalization and Recursive Feature Elimination for finding a subset of indicative features (Guyon and Elisseeff, 2003). The signal-to-noise method gives better results than the other two by at least 6% for the top performance feature set. Thus we pick the best  $k$  features according to the s2n result and use only those  $k$  features for classification.

Figure 1 shows how prediction accuracy changes with feature sets of different sizes. From the plot we clearly see that our top performance is achieved with 25 to 40 features, after which performance drops. The peak performance is achieved when

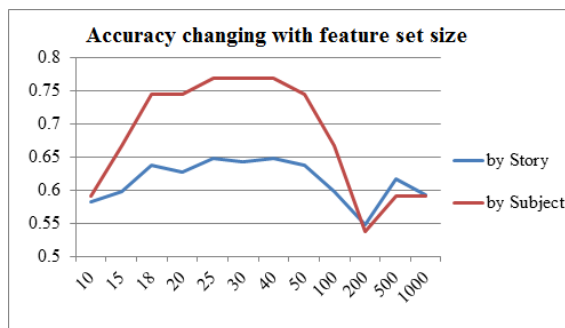

Figure 1: Story and Subject prediction accuracy

there are 25 features, where we could reach 75.0% precision, 91.3% recall, 82.4% F-measure for patient, and 76.9% accuracy for overall, as shown in Table 4. Detailed information about the top 30 features can be found in Table 5. ‘+’ and ‘-’ means more prevalent for patient and control, while ‘prj’ and ‘01’ correspond to the two normalization approaches in Section 4.3, projection and binary respectively.

### 6.4 Analysis of Significant Features

In this section we discuss the specific features that were revealed as most predictive by the feature selection methods that we employed. We have seen that it only requires about 25-40 features to obtain peak performance.

First we briefly review the features that turned out to be statistically significant (for 0.05 p-value cut-off). Table 7 provides a list of the features with higher values for Schizophrenia and Control respectively.<sup>4</sup> We group the significant features according to the feature classes we introduced in

<sup>3</sup>See <http://clopinet.com/CLOP/>

<sup>4</sup>LM1 is defined as the ratio of CO perplexity and SC perplexity from LMs, LM7 comes from projection normalization of LM1. If LM perplexity for CO is smaller than that of SC, then we set LM3 as 1; otherwise we set LM4 as 1.

Rank	Feature	Category	P-value

Table 5: Table of the top 30 features by signal-to-noise ranking

Section 4. Of the 169 significant features, 111 are more prevalent in patients, 58 are more prevalent among the controls. If a feature was significant with both normalizations we use, we list it only once in Table 7.

Among the words indicative of schizophrenia, subjective words such as *I* and LIWC category *self* are among the most significant. This finding conforms with prior research that patients with mental disorders refer to themselves more often than regular people. Patients produce more questions (as indicated by the significance of the question mark as a feature). It is possible that this indicates a disruption in their thought process and they forget what they are talking about. Further work will be needed to understand this difference better.

In terms of words, patients talked more about *money*, *trouble*, and used adverbs like *moderately* and *basically*. Repetition in language is also a revealing characteristic of the patient narratives. There is a substantial difference in the appearance of repetitions between the two groups, as well as repetition of specific words: *I*, *and*, and repetition of filled pauses *um*. As patients focus more on their own feelings, they talked a lot about their family, using words such as *son*, *grandfather* and even *dogs*.

Diction features revealed some unexpected differences. The schizophrenia group scores higher in the *Self*, *Cognition*, *Past*, *Insistence* and *Satisfaction* categories. This indicates that they are more likely to talk about past experience, using cognitive terms and having a repetition of key

terms. We were particularly curious to understand why patients score higher on *Satisfaction* ratings. On closer inspection we discovered that patients' stories were rated higher in *Satisfaction* when they were telling SAD stories. This finding has important clinical implications because one of the diagnostic elements for the disease is inappropriate emotion expression. Our study is the first to apply an automatic measure to detect such anomaly in patients' emotional narratives. Prompted by this discovery, we take a closer look at the interaction between the emotion expressed in a story and the accuracy of status prediction in the next section.

The control group exhibited more word complexity, sentence complexity and thoughtfulness in their stories. They use more adverbs and exclusive words (e.g. *but*, *without*, *exclude*) on general trend. They use the word *sorry* significantly more often than patients.

## 6.5 Status Prediction by Emotion

We also investigate if classification accuracy differs depending on the type of conveyed emotion. Accuracy per emotion with three feature selection methods is shown in Table 6. When using signal-to-noise, we can see that on SAD stories the two groups can be distinguished better. Story-level accuracies on HAPPY stories reach 72.5%, and that the accuracy on HAPPY stories is the next highest one. When applying the 0.05 p-value cut-off to select significant features, ANGER stories become the ones for which the status of a subject

Accuracy (%)	s2n (25)	T-test (0.05)	T-test (0.001)
Happy	66.7	59.0	<b>71.8</b>
Disgust	63.4	61.0	51.2
Anger	61.0	<b>70.7</b>	<b>70.7</b>
Fear	60.0	55.0	67.5
Sad	<b>72.5</b>	60.0	67.5
Story	64.7	62.9	65.7
Patient	76.9	64.1	74.4
Majority	59.0	59.0	59.0

Table 6: Accuracy per emotion by different feature-sets

can be predicted most accurately. Using the threshold of 0.001 for selection gives the best overall prediction. In that case, HAPPY and ANGER are the emotions for which recognition is best. The changes in the recognition accuracy depending on feature selection suggests that in future studies it may be more beneficial to perform feature selection only on stories from a given type because obviously indicative features exist at least for the SAD, ANGER and HAPPY stories.

Regardless of the feature selection approach, it is more difficult to tell the two groups apart when they tell DISGUST and FEAR stories. These results seem to indicate that when talking about certain emotions patients and controls look much more alike than when other emotions are concerned. Future data acquisition efforts can focus only on collecting autobiographical narratives relevant to the emotions for which patients and controls differ most.

Number of significant features changing with p-value per emotion

Figure 2: Number of significant features by P-value selection on different thresholds (per emotion)

In future work we would like to use only stories from a given emotion to classify between patients

Types	Significant features more common in SCH
Basic	repeat-word, sentence/document
LIWC	I, insight, personal-pronoun
Diction	self, cognition, past, insistence, satisfaction
Lexical	?, ain't, alone, at, aw, become, before, behind care, chance, confused, couldn't, December, dog dogs, extreme, extremely, feeling, forty, friends god, got, grandfather, guess, guy, hand, hanging hearing, hundred, increased, looking, loved mental, met, mild, mildly, moderate, moderately money, my, myself, outside, paper, passed, piece remember, sister, son, stand, step, story, take taken, throwing, took, trouble, use, wake wanna, way
Repeat	a, and, I, um, was
LM	LM1, LM4, LM7

Types	Significant features more common in CO
Basic	length/word, words/sentence
LIWC	≥6-letters, adverb, exclusive words, inhibitive
Diction	certainty, cooperation, diversity familiarity, realism
Lexical	”,”, able, actually, are, basically, be, being, get's in, late, not, really, relationship, result, she's sleep, sorry, tell, their, there's, very, weeks
Repeat	very, ”,”
LM	LM3

Table 7: Significant features (p-value ≤ 0.05)

and controls. Doing this with our current dataset is not feasible because there are only about 40 transcripts per emotion. Therefore, we use our data to identify significant features that distinguish patients from controls only on narratives from a particular emotion. For example, we compare the differences of SAD stories told by patients and controls. We count the number of significant features between patients and controls with 11 different p-value cut-offs, and provide a plot that visualizes the results in Figure 2. From the graph, it is clear that there are many more differences between the two groups in ANGER and SAD narratives. HAPPY comes next, then DISGUST and FEAR. However, at lower confidence levels, HAPPY has equal number of significant features as ANGER and SAD, which is in line with the result in Table 6.

The feature analysis performed by emotion reveals more differences between patients and controls, beyond common features such as *self*, *I*, etc. For HAPPY stories, patients talk more about their *friends* and *relatives*; they also have a

higher tendency of being *ambivalent*. For DISGUST stories, patients are more disgusted with *dogs*, and they talk more about *health*. The control group shows a higher *communication* score, referring to a better social interaction. ANGER is one of the emotions that best reveals the differences between groups, and schizophrenia patients show more *aggression* and *cognition* while talking, according to features derived from Diction. The control group sometimes talks more about *praise*. In FEAR stories patients talk about *money* more often than controls. Meanwhile, the control group uses more *inhibition* words, for instance: block, constrain and stop. An interesting phenomenon happens in SAD narratives. When talking about sad experiences, patients sometimes show *satisfaction* and *insistence*, while the controls talked more about *working* experiences.

## 7 Conclusion

In this paper, we analyzed the predictive power of different kinds of features for distinguishing schizophrenia patients from healthy controls. We provided an in-depth analysis of features that distinguish patients from controls and showed that the type of emotion conveyed by the personal narratives is important for the distinction and that stories for different emotions give different sets indicators for subject status. We report classification results as high as 76.9% on the subject level, with 75.0% precision and 91.3% on recall for schizophrenia patients.

We consider the results presented here to be a pilot study. We are currently collecting and transcribing additional stories from the two groups which we would like to use as a definitive test set to verify the stability of our findings. We plan to explore syntactic and coherence models to analyze the stories, as well as emotion analysis of the narratives.

# Streaming Analysis of Discourse Participants

Benjamin Van Durme

Human Language Technology Center of Excellence  
Johns Hopkins University

## Abstract

Inferring attributes of discourse participants has been treated as a *batch*-processing task: data such as all tweets from a given author are gathered in bulk, processed, analyzed for a particular feature, then reported as a result of academic interest. Given the sources and scale of material used in these efforts, along with potential use cases of such analytic tools, discourse analysis should be reconsidered as a *streaming* challenge. We show that under certain common formulations, the batch-processing analytic framework can be decomposed into a sequential series of updates, using as an example the task of gender classification. Once in a streaming framework, and motivated by large data sets generated by social media services, we present novel results in approximate counting, showing its applicability to space efficient streaming classification.

## 1 Introduction

The rapid growth in social media has led to an equally rapid growth in the desire to mine it for useful information: the content of public discussions, such as found in tweets, or in posts to online forums, can support a variety of data mining tasks. Inferring the underlying properties of those that engage with these platforms, the *discourse participants*, has become an active topic of research: predicting individual attributes such as age, gender, and political preferences (Rao et al., 2010), or relationships *between* communicants, such as organizational dominance (Diehl et al., 2007). This research can benefit areas such as: (A) commercial applications, e.g.,

improved models for advertising placement, or detecting fraudulent or otherwise unhelpful product reviews (Jindal and Liu, 2008; Ott et al., 2011); and (B) in enhanced models of civic discourse, e.g., inexpensive, large-scale, *passive polling* of popular opinion (O’Connor et al., 2010).

Classification with streaming data has usually been taken in the computational linguistics community to mean individual decisions made on items that are presented over time. For example: assigning a label to each newly posted product review as to whether it contains positive or negative sentiment, or whether the latest tweet signals a novel topic that should be tagged for tracking (Petrovic et al., 2010).

Here we consider a distinct form of stream-based classification: we wish to assign, then *dynamically update*, labels on discourse participants based on their associated streaming communications. For instance, rather than classifying individual reviews as to their sentiment polarity, we might wish to classify the underlying author as to whether they are genuine or paid-advertising, and then update that decision as they continue to post new reviews. As the scale of social media continues to grow, we desire that our model be aggressively space efficient, which precludes a naive solution of storing the full communication history for all users.

In this paper we make two contributions: (1) we make explicit that a standard bag-of-words classification model for predicting latent author attributes can be simply decomposed into a series of streaming updates; then (2) show how the randomized algorithm, *Reservoir Counting* (Van Durme and Lall, 2011), can be extended to maintain approximate av-

erages, allowing for significant space savings in our classification model. Our running example task is gender prediction, based on spoken communication and microblogs/Twitter feeds.

## 2 Model

Assume that each discourse participant (e.g., speaker, author)  $a$  has an associated stream of communications (e.g., tweets, utterances, emails, etc.):  $(c_i) = C$ . Then let  $C_t = (c_1, \dots, c_t)$  represent the first  $t$  elements of  $C$ .

Assume access to a pretrained classifier  $\Phi$ :<sup>1</sup>

$$\Phi(a) = \begin{cases} 1 & \text{if } w \cdot f(C) \geq 0, \\ 0 & \text{otherwise,} \end{cases}$$

which we initially take to be linear: author labels are determined by computing the sign of the dot product between a weight vector  $w$ , and feature vector  $f(C)$ , each of dimension  $d$ . Note that  $f(C)$  is a feature vector over the entire set of communications from a given author.

For example,  $\Phi$  might be trained to classify author gender:

$$\text{Gender}(a) = \begin{cases} \text{Male} & \text{if } w \cdot f(C) \geq 0, \\ \text{Female} & \text{otherwise.} \end{cases}$$

We now make explicit how under certain common restrictions on the feature space, the classification decision can be decomposed into a series of decision *updates* over the elements of  $C$ .

Define  $\hat{f}(c_i)$  to be the vector containing the local, count-based feature values of communication  $c_j$ .<sup>2</sup> For convenience let us assume that  $\hat{f}(c_i) \in \mathbb{N}^d$ . Where  $|v|_1 = \sum_i |v_i|$  is the L1-norm of vector  $v$ , let  $z_t$  be the *normalizing constant* at  $t$ :

$$z_t = \sum_{i=1}^t |\hat{f}(c_i)|_1$$

Now define  $f_j(C)$ , the  $j$ -th entry of  $f(C)$ , as:

$$f_j(C) = \frac{\sum_{i=1}^n \hat{f}_j(c_i)}{z_n}$$

Thus  $f(C)$  represents the global relative frequency of each local, count-based feature. This allows us to rearrange terms:

<sup>1</sup>While here we assume binary decision tasks, dynamic classification in a multiclass, or regression, setting is an interesting avenue of exploration, for which these definitions generalize.

<sup>2</sup>As seen later in Table 1, we have in mind features such as the frequency of the  $n$ -gram *my wife*.

$$\begin{aligned} w \cdot f(C) &= \sum_{j=1}^d w_j f_j(C) \\ &= \frac{1}{z_n} \sum_{j=1}^d w_k \left( \sum_{i=1}^n \hat{f}_j(c_i) \right) \\ &= \frac{1}{z_n} \sum_{i=1}^n \left( \sum_{j=1}^d w_k \hat{f}_j(c_i) \right) \end{aligned}$$

Let  $(s_t, z_t)$  be the current *state* of the classifier:

$$(s_t, z_t) \doteq \left( \sum_{i=1}^t \sum_{k=1}^d w_k \hat{f}_k(c_j), z_t \right)$$

which pairs the observed *rolling sum*,  $s_t$  with the feature stream length  $z_t$ .

The classifier decision after seeing everything up to and including communication  $c_t$  is thus a simple average:

$$\Phi_t(a) = \begin{cases} 1 & \text{if } \frac{s_t}{z_t} \geq 0, \\ 0 & \text{otherwise.} \end{cases}$$

Finally we reach the observation that:

$$\begin{aligned} s_t &= s_{t-1} + w \cdot \hat{f}(c_t) \\ z_t &= z_{t-1} + |\hat{f}(c_t)|_1 \end{aligned}$$

which means that from an engineering standpoint we can process a stream of communication one element at a time, without the need to preserve the history explicitly. That is: for each author, for each attribute being analyzed, an online system only need maintain a state pair  $(s_t, z_t)$  by extracting and weighting features locally for each new communication. Beyond the computational savings of not needing to store communications nor explicit feature vectors in memory, there are potential privacy benefits as well: analytic systems need not have a lasting record of discourse, they can instead glean whatever signal is required locally in the stream, and then discard the actual communications.

**Log-linear** Rather than a strictly linear  $\Phi$ , such as instantiated via perceptron or SVM with linear kernel, many prefer log-linear models as their classification framework:

$$\Phi(a) = \begin{cases} 1 & \text{if } \frac{1}{1 + \exp(-w \cdot f(C))} \geq 0.5, \\ 0 & \text{otherwise.} \end{cases}$$

Figure 1: A streaming analytic model should update its decision with each new communication, becoming more stable in its prediction as evidence is acquired.

In either setting, the state of the classifier is sufficiently captured by the pair  $(s_t, z_t)$ , under the restrictions on  $f$ .<sup>3</sup>

## 2.1 Validation

As an example of a model decomposed into a stream, we revisit the task of gender classification based on speech transcripts, as explored by Boulis and Ostendorf (2005) and later Garera and Yarowsky (2009). In the original problem definition, one would collect all transcribed utterances from a given speaker in a corpus such as Fisher (Cieri et al., 2004) or Switchboard (Godfrey et al., 1992), known as a *side* of the conversation. Then by collapsing these utterances into a single document, one could classify it as to whether it was generated by a male or female. Here we define the task as: starting from scratch, report the classifier probability of the speaker being male, as each utterance is presented.

Intuitively we would expect that as more utterances are observed, the better our classification accuracy. Researchers such as Burger et al. (2011) have considered this point, but by comparing the classification accuracy based on the volume of batch data available per author (in that case, tweets): the more prolific the author had been, the better able they were to correctly classify their gender. We confirm here this can be reframed: as a speaker (author) continues to emit a stream of communication, a dynamic model tends to improve its online prediction.

Our collection based on Switchboard consisted of 520 unique speakers (240 female, 280 male), with a total of roughly 400k utterances. Similar to Boulis and Ostendorf, we extracted unigram and bigram counts as features, but without further

<sup>3</sup>Note that some non-linear kernels can be maintained online in a similar fashion. For instance, a polynomial kernel of degree  $p$  decomposes as:  $(f(C_n) \cdot w)^p = (\frac{s_n}{z_n})^p$ .

Figure 2: Accuracy on Switchboard gender classification, reported at every fifth utterance, using a dynamic log-linear model with 10-fold cross validation.

TFIDF reweighting. Ngrams were required to occur at least 10 times in the training set, recomputed for each split of 10-fold cross validation. Weights were computed under a log-linear model using `LibLinear` (Fan et al., 2008), with 5% of training held out for tuning an L2 regularizing term. Feature extraction and dynamic aspects were handled through additions to the `Jerboa` package (Van Durme, 2012). Similar to previous work, we found intuitive features such as *my husband* to be weighted heavily (see Table 1), along with certain non-lexical vocalizations such as transcribed laughter.

Table 1: Top ten features by gender.

<b>Male</b>	a, wife, is, my wife, right, of, the, uh, actually, [vocalized-noise]
<b>Female</b>	have, and, [laughter], my husband, really, husband, children, are, would

Figure 3: Streaming analysis of eight randomly sampled speakers, four per gender (red-solid: female, blue-dashed: male). Being a log-linear model, the decision boundary is marked at  $y = 0.5$ .

As seen in Figure 2, accuracy indeed improves as more content is emitted. Figure 3 highlights the streaming perspective: individual speakers can be viewed as distinct trajectories through  $[0, 1]$ , based on features of their utterances.

### 3 Randomized Model

Now situated within a streaming context we exact space savings through approximation, extending the approach of Van Durme and Lall (2011), there concerned with online Locality Sensitive Hashing, here initially concerned with taking averages.

When calculating the average over a sequence of values,  $X_n = (x_1, \dots, x_n)$ , we divide the sum of the sequence,  $\text{sum}(X_n) = \sum_{i=1}^n x_i$ , by its length,  $\text{length}(X_n) = |X_n|$ :

$$\text{avg}(X_n) = \frac{\text{sum}(X_n)}{\text{length}(X_n)}$$

Our goal in this section is to maintain a space efficient approximation of  $\text{avg}(X_t)$ , as  $t$  increases, by using a bit-saving approximation of both the sum, and the length of the sequence.

We begin by reviewing the method of Reservoir Counting, then extend it to a new notion we refer to as Reservoir Averaging. This will allow in the subsequent section to map our analytic model to a form

Figure 4: Social media platforms such as Facebook or Twitter deal with a very large number of individuals, each with a variety of implicit attributes (such as gender). This motivates a desire for online space efficiency.

explicitly amenable to keeping an online average.

#### 3.1 Reservoir Counting

Reservoir Counting plays on the folklore algorithm of reservoir sampling, first described in the literature by Vitter (1985). As applied to a stream of arbitrary elements, reservoir sampling maintains a list (reservoir) of length  $k$ , where the contents of the reservoir represents a uniform random sample over all elements  $1 \dots t$  observed thus far in the stream.

When the stream is a sequence of positive and negative integers, reservoir counting implicitly views each value as being unrolled into a sequence made up of either 1 or -1. For instance, the sequence: (3, -2, 1) would be viewed as:

$$(1, 1, 1, -1, -1, 1)$$

Since there are only two distinct values in this stream, the contents of the reservoir can be characterized by knowing the fixed value  $k$ , and then  $s$ : how many elements in the reservoir are 1.<sup>4</sup> This led to Van Durme and Lall defining a method, `ReservoirUpdate`, here abbreviated to `ResUp`, that allows for maintaining an approximate sum, defined as  $t(\frac{2s}{k} - 1)$ , through updating these two parameters  $t$  and  $s$  with each newly observed element. Expected accuracy of the approximation varies with the size of the sample,  $k$ . Reservoir Counting exploits the fact that the reservoir need only be considered implicitly, where  $s$  represented as a  $b$ -bit unsigned integer can be used to characterize a reservoir of size  $k = 2^b - 1$ . This allowed those authors to show a 50% space reduction in the task of online

<sup>4</sup>As the number of -1 values is simply:  $k - s$ .

Locality Sensitive Hashing, at similar levels of accuracy, by replacing explicit 32-bit counting variables with approximate counters of smaller size. See (Van Durme and Lall, 2011) for further details.

### 3.2 Reservoir Averaging

For a given integer  $x$ , let  $m = |x|$  be the magnitude of  $x$ , and  $\sigma = \text{sign}(x)$ . For a given sequence, let  $m^*$  be the largest such value of  $m$ .

Modifying the earlier implicit construction, consider the sequence (3, -2, 1), with  $m^* = 3$ , mapped to the sequence:

(1, 1, 1, 1, 1, 1, -1, -1, -1, -1, -1, 1, 1, 1, 1, 1, -1, -1)

where each value  $x$  is replaced with  $m^* + m$  elements of  $\sigma$ , and  $m^* - m$  elements of  $-\sigma$ . This views  $x$  as a sequence of length  $2m^*$ , made up of 1s and -1s, where each  $x$  in the discrete range  $[-m^*, m^*]$  has a unique number of 1s.

Now recognize that the average over the original sequence, here  $\frac{3-2+1}{3} = \frac{2}{3}$ , is proportional to the average over the implicit sequence,  $\frac{1+1+\dots-1-1}{18} = \frac{4}{18} = \frac{2}{9}(\frac{1}{m^*})$ .

Generally for a sequence  $(x_1, \dots, x_n)$ , with  $m^*$  as defined, the average times  $\frac{1}{m^*}$  is equal to:

$$\begin{aligned} \frac{\sum_{i=1}^n x_i}{n} \left(\frac{1}{m^*}\right) &= \frac{1}{n2m^*} \sum_{i=1}^n \left( \sum_{l=1}^{m^*+m_i} \sigma_i + \sum_{l=1}^{m^*-m_i} -\sigma_i \right) \\ &= \frac{\sum_{i=1}^n m_i \sigma}{nm^*} \end{aligned}$$

where  $n2m^*$  is the total number of 1s and -1s observed in the implicit stream, up to and including the mapping of element  $x_n$ . If applying Reservoir Counting,  $s$  would then record the sampled number of 1s, as per norm, where  $t$  maintained as the implicit stream length can also be viewed as storing  $t = n2m^*$ . At any point in the stream, the average over the original value sequence can then be approximated as: (1) the approximate sum of the implicit stream; divided by (2) the implicit stream length; times (3)  $m^*$  to cancel the  $\frac{1}{m^*}$  term:

$$\left(t \left(\frac{2s}{k} - 1\right)\right)_1 \left(\frac{1}{t}\right)_2 (m^*)_3 = \left(\frac{2s}{k} - 1\right) m^*$$

**Granularity** As defined this scheme operates on streams of integers. We extend the definition to work

with a stream of fixed precision floating point variables. Let  $g$  be a positive integer that we refer to as the *granularity*. Modify the mapping of value  $x$  from a sequence of length  $2m^*$ , to a sequence of length  $g$ , comprised of  $\frac{m^*+m}{2m^*}g$  instances of  $\sigma$ , and  $(1 - \frac{m^*-m}{2m^*})g$  instances of  $-\sigma$ . As seen in line 4 of Algorithm 1, a random coin flip determines placement of the remainder.

For example, the value 1.3, with  $m^* = 3$ , and  $g = 10$ , would now be represented as a sequence of  $\frac{3+1.3}{6}g = 7.16 \in (7, 8)$  instances of 1, followed by however many instances of -1 that lead to a sequence of length  $g$ , after probabilistic rounding. The possible sequences are thus:

(1, 1, 1, 1, 1, 1, 1, -1, -1, -1)  
(1, 1, 1, 1, 1, 1, 1, 1, -1, -1)

with the former more likely.

At this point we have described the framework captured by Algorithm 1, where Van Durme and Lall (2011) defined ResUp.

---

**Algorithm 1** UPDATEAVERAGE( $n, k, m, m^*, \sigma, g, s$ )

**Parameters:**

$n$  : size of stream  
 $k$  : size of reservoir, also maximum value of  $s$   
 $m$  : magnitude of update  
 $m^*$  : maximum magnitude of all updates  
 $\sigma$  : sign of update  
 $g$  : granularity  
 $s$  : current value of reservoir

- 1: **if**  $m = 0$  or  $\sigma = 0$  **then**
  - 2:   Return without doing anything
  - 3:  $v := \frac{m+m^*}{2m^*}g$
  - 4:  $v := \lceil v \rceil$  with probability  $v - \lfloor v \rfloor$ ,  $\lfloor v \rfloor$  otherwise
  - 5:  $s' := \text{ResUp}(ng, k, v, \sigma, s)$
  - 6:  $s' := \text{ResUp}((ng + v), k, g - v, -\sigma, s')$
  - 7: Return  $s'$
- 

**Log-scale Counting** For additional space savings we might approximate the length parameter  $t$  with a small bit representation, using the approximate counting scheme of Morris (1978). The method enables counting in log-scale by probabilistically incrementing a counter, where it becomes less and less likely to update the counter after each increment. This scheme is popularly known and used in a variety of contexts, recently in the community by Talbot (2009) and Van Durme and Lall (2009)

Figure 5: Results on averaging randomly generated sequences, with  $m^* = 100, g = 100$ , and using an 8 bit Morris-style counter of base 2. Larger reservoir sizes lead to better approximation, at higher cost in bits.

to provide a streaming extension to the Bloom-filter based count-storage mechanism of Talbot and Osborne (2007a) and Talbot and Osborne (2007b). See (Flajolet, 1985) for a detailed analysis of Morris-style counting.

### 3.3 Experiment

We show through experimentation on synthetic data that this approach gives reasonable levels of accuracy at space efficient sizes of the length and sum parameter. Random sequences of 1,000 values were generated by: (1) fix a value for  $m^*$ ; (2) draw a polarity bias term  $\mu$  uniformly from the range  $[0,1]$ ; then (3) for each value,  $x$ : (a)  $\sigma$  was positive with probability  $\mu$ ; (b)  $m$  was drawn from  $[0, m^*]$ . Figure 5 shows results for varying reservoir sizes (using 4, 8 or 12 bits) when  $g = 100, m^* = 100$ , and the length parameter was represented with an 8 bit Morris-style counter of base 2.

### 3.4 Justification

Before we close this section, one might ask why this extension is needed in the first place. As Reservoir Counting already allows for keeping an online sum, and pairs it with a length parameter, then this would presumably be what is needed to get the average we

are focussed on. Unfortunately that is not the case: the parameter recording the current stream length, here called  $t$ , tracks the length of the implicit stream of 1s and -1s, it does not track the length of the original stream of values that gave rise to the mapped version. As an example, consider again the sequence:  $(3, -2, 1)$ , as compared to:  $(2, 1, -1, 1)$ . Both have the same sum, and would therefore be viewed the same under the pre-existing Reservoir Counting algorithm, giving rise to implicit streams of the same length. But critically the sequences have different averages:  $\frac{2}{3} \neq \frac{2}{5}$ , which we cannot detect based on the original counting algorithm.

Finally, we restate the constraint: for the sequence to averaged, one must know  $m^*$  ahead of time.

## 4 Application to Classification

Going back to our streaming analysis model, we have a situation that can be viewed as a sequence of values, such that we do know  $m^*$ . First reinterpret the fraction  $\frac{s_t}{z_t}$  equivalently as the normalized sum of a stream of elements sampled from  $w$ :

$$\frac{s_t}{z_t} = \frac{1}{z_t} \sum_{i=1}^t \sum_{j=1}^d \sum_{l=1}^{\hat{f}_j(c_i)} w_j$$

The value  $m^*$  is then:  $m^* = \max_j |w_j|$ , over a sequence of length  $z_t$ . Rather than updating  $s_t$  and  $z_t$  through basic addition, we can now use a smaller bit-wise representation for each variable, and update via Reservoir Averaging.

### 4.1 Problems in Practice

Reconsidering the earlier classification experiment, we found this approximation method led to terrible results: while our experiments on synthetic data worked well, those sequences were sampled somewhat uniformly over the range of possible values. As seen in Figure 6, sequences arising from observed feature weights in a practical setting may not be so broadly distributed. In brief: the more the maximum possible update,  $m^*$ , can be viewed as an outlier, then the more the resulting implicit encoding of  $g$  elements per observed weight becomes dominated by “filler”. As few observed elements will in that case require the provided range, then the implicit representation will be a mostly balanced set of

Figure 6: Frequency of individual feature weights observed over a full set of communications by a single example speaker. Most observed features have relatively small magnitude weight. The mean value is 1.3, with  $\frac{1}{1+e^{-1.3}} = 0.79 > 0.5$ , which properly classifies the speaker as MALE.

1 and -1 values. These mostly balanced encodings make it difficult to maintain an adequate approximation of the true average, when reliant on a small, implicit uniform sample. Here we leave further analysis aside, focusing instead on a modified solution for the classification model under consideration.

## 4.2 Rewriting History

Practically we would like to restrict our range to the dense region of weight updates, while at the same time not throwing away or truncating larger weights that appear outside a reduced window. We do this by fitting a replacement to  $m^*$ :  $m' \leq m^*$ , based on the classifier’s training data, such that too-large elements will be *accommodated* into the stream by implicitly assuming that the portion of a value that falls outside the restricted window is “spread out” over the previously observed values. That is, we modify the contents of the implicit reservoir by *rewriting history*: pretending that earlier elements were larger than they were, but still within the reduced window. As long as we don’t see too many values that are overly large, then there will be room to accommodate the overflow without any theoretical damage to the implicit stream: all count mass may still be ac-

counted for. If a moderately high number of overly large elements are observed, then we expect in practice for this to have a negligible impact on downstream performance. If an exceptional number of elements are overly large, then the training data was not representative of the test set.

The newly introduced parameter  $m'$  is used in MODIFIEDUPDATEAVERAGE (MUA), which relies on REWRITEHISTORY. Note that MUA uses the same value of  $n$  when calling REWRITEHISTORY as it does in the subsequent line calling UPDATEAVERAGE: we modify the state of the reservoir without incrementing the stream length, taking the current overflow and pretending we saw it earlier, spread out across previous elements. This happens by first estimating the number of 1 values seen thus far in the stream:  $\frac{s}{k}n$ , then adding in twice the overflow value, which represents removing  $o$  instances of  $-\sigma$  from the stream, and then adding  $o$  instances of  $\sigma$ . We probabilistically round the resultant fraction to achieve a modified version of  $s$ , which is returned.

---

### Algorithm 2 MUA( $n, k, m, m', \sigma, g, s$ )

---

- 1: **if**  $m < m'$  **then**
  - 2:     Return UPDATEAVERAGE( $n, k, m, m', \sigma, g, s$ )
  - 3:  $s' :=$  REWRITEHISTORY( $n, k, m, m', \sigma, g, s$ )
  - 4: Return UPDATEAVERAGE( $n, k, m', m', \sigma, g, s'$ )
- 

---

### Algorithm 3 REWRITEHISTORY( $n, k, m, m', \sigma, g, s$ )

---

**Parameters:**

$o$ : overflow to be accommodated

- 1:  $o := \frac{m-m'}{2m'}g$
  - 2: **if**  $\sigma > 0$  **then**
  - 3:     **if**  $s = k$  **then**
  - 4:         Return  $s$
  - 5:      $p := \min(1.0, \frac{s}{k} + \frac{2o}{n})$
  - 6:     **else**
  - 7:         **if**  $s = 0$  **then**
  - 8:             Return  $s$
  - 9:      $p := \max(0.0, \frac{s}{k} - \frac{2o}{n})$
  - 10: Return  $\lceil pk \rceil$  with prob.  $pk - \lfloor pk \rfloor, \lfloor pk \rfloor$  otherwise
- 

## 4.3 Experiment

Figure 7 compares the results seen in Figure 2 to a version of the experiment when using approximation. Parameters were:  $g = 100$ ;  $k = 255$ ; and a Morris-style counter for stream length using 8 bits

Figure 7: Comparison between using explicit counting and approximation on the Switchboard dataset, with bands reflecting 95% confidence.

and a base of 1.3. The value  $m'$  was fit independently for each split of 10-fold cross validation, by finding through simple line search that which minimized the number of prediction errors on the original training data (see Figure 8). This result shows our ability to replace 2 variables of 32 bits (sum and length) with 2 approximation variables of 8 bits (reservoir status  $s$ , and stream length  $n$ ), leading to a 75% reduction in the cost of maintaining online classifier state, with no significant cost in accuracy.

## 5 Real World Stream: Twitter

### 5.1 Setup

Based on the tweet IDs from the data used by Burger et al. (2011), we recovered 2,958,107 of their roughly 4 million original tweets.<sup>5</sup> These tweets were then matched against the gender labels established in that prior work. As reported by Burger et al., the dominant language in the collection is English (66.7% reported), followed by Portuguese (14.4%) then Spanish (6.0%), with a large variety of other languages with small numbers of examples.

<sup>5</sup>Standard practice in Twitter data exchanges is to share only the unique tweet identifications and then query the content from Twitter, thus allowing, e.g., the individual authors the ability to delete previous posts and have that reflected in future data collects. While respectful of author privacy, it does pose a challenge for scientific reproducibility.

Figure 8: Summed 0/1 loss over all utterances by each speaker in the Switchboard training set, across 10 splits. A value of  $m' = 5$  was on average that which minimized the number of mistakes made.

Content was lowercased, then processed by regular expression to collapse the following into respective single symbols: emoticons; URLs; usernames (@mentions); and hashtags. Any content deemed to be a retweet (following the characters *RT*) was removed. Text was then tokenized according to a modified version of the Penn TreeBank tokenization standard<sup>6</sup> that was less English-centric.

### 5.2 Experiment

A log-linear classifier was built using all those authors in the training set<sup>7</sup> with at least 10 tweets. Similar to the previous experiment, unigrams and bigrams features were used exclusively, with the parameter  $m'$  fit on the training data.

As seen in Figure 9, results were as in Switchboard: accuracy improves as more data streams in per author, and our approximate model sacrifices perhaps a point of accuracy in return for a 75% reduction in memory requirements per author.

Table 2 gives the top features per gender. We see similarities to Switchboard in terms such as *my*

<sup>6</sup>Such as codified in <http://www.cis.upenn.edu/~treebank/tokenizer.sed>

<sup>7</sup>The same training, development and test set partitions were used as by Burger et al. (2011), minus those tweets we were unable to retrieve (as previously discussed).

Figure 9: Comparison between using explicit counting and approximation, on the Twitter dataset, with bands reflecting 95% confidence.

wife, along with terms suggesting a more youthful population. Foreign terms are recognized by their parenthetical translation and 1st- or 2nd-person + Male/Female gender marking. For example, the Portuguese *obrigado* can be taken to be literally saying: *I'm obliged (thank you), and I'm male*.

## 6 Related Work

Streaming algorithms have been developed within the applied communities of networking, and (very large) databases, as well as being a popular topic in the theoretical computer science literature. A sum-

Table 2: Top thirty-five features by gender in Twitter.

<b>Male</b>	obrigado ( <i>thank you</i> [1M]), wife, my wife, bro, cansado ( <i>tired</i> [1M]), gay, mate, dude, [@username] why, buddy, windows, album, dope, beer, [@username] yo, sir, ps3, comics, galera ( <i>folks/people</i> ), amigo ( <i>friend</i> [2M]), man !, fuckin, omg omg, cheers, ai n't
<b>Female</b>	obrigada ( <i>thank you</i> [1F]), hubby, husband, cute, my husband, ?, cansada ( <i>tired</i> [1F]), hair, dress, soooo, lovely, etsy, boyfriend, jonas, loved, book, sooo, girl, sé ( <i>I</i> ), lindo ( <i>cute</i> ), shopping, amiga ( <i>friend</i> [2F]), yummy, ppl, cupcakes

mary of the streaming algorithms community is beyond the scope of this work: interested readers are directed to Muthukrishnan (2005) as a starting point.

Within computational linguistics interest in streaming approaches is a more recent development; we provide here examples of representative work, beyond those described in previous sections. Levenberg and Osborne (2009) gave a streaming variant of the earlier perfect hashing language model of Talbot and Brants (2008), which operated in batch-mode. Using a similar decomposition to that here, Van Durme and Lall (2010) showed that Locality Sensitive Hash (LSH) signatures (Indyk and Motwani, 1998; Charikar, 2002) built using count-based feature vectors can be maintained online, as compared to their earlier uses in the community (Ravichandran et al., 2005; Bhagat and Ravichandran, 2008). Finally, Goyal et al. (2009) applied the frequent items<sup>8</sup> algorithm of Manku and Motwani (2002) to language modeling.

For further background in predicting author attributes such as gender, see (Garera and Yarowsky, 2009) for an overview of previous work and (non-streaming) methodology.

## 7 Conclusions and Future Work

We have taken the predominately batch-oriented process of analyzing communication data and shown it to be fertile territory for research in large-scale streaming algorithms. Using the example task of automatic gender detection, on both spoken transcripts and microblogs, we showed that classification can be thought of as a continuously running process, becoming more robust as further communications become available. Once positioned within a streaming framework, we presented a novel approximation technique for compressing the streaming memory requirements of the classifier (per author) by 75%.

There are a number of avenues to explore based on this framework. For instance, while here we assumed a static, pre-built classifier which was then applied to streaming data, future work may consider the interplay with online learning, based on methods such as by Crammer et al. (2006). In the appli-

<sup>8</sup>See the survey by Cormode and Hadjieleftheriou (2009) for approaches to the *frequent items* problem, otherwise known as finding *heavy hitters*.

cations arena, one might take the savings provided here to run multiple models in parallel, either for more robust predictions (perhaps “triangulating” on language ID and/or domain over the stream), or predicting additional properties, such as age, nationality, political orientation, and so forth. Finally, we assumed here strictly count-based features; streaming log-counting methods, tailored Bloom-filters for binary feature storage, and other related topics are assuredly applicable, and should give rise to many interesting new results.

## Abstract

A mixture of positive (friendly) and negative (antagonistic) relations exist among users in most social media applications. However, many such applications do not allow users to explicitly express the polarity of their interactions. As a result most research has either ignored negative links or was limited to the few domains where such relations are explicitly expressed (e.g. Epinions trust/distrust). We study text exchanged between users in online communities. We find that the polarity of the links between users can be predicted with high accuracy given the text they exchange. This allows us to build a signed network representation of discussions; where every edge has a sign: positive to denote a friendly relation, or negative to denote an antagonistic relation. We also connect our analysis to social psychology theories of balance. We show that the automatically predicted networks are consistent with those theories. Inspired by that, we present a technique for identifying subgroups in discussions by partitioning signed networks representing them.

## 1 Introduction

Most online communities involve a mixture of positive and negative relations between users. Positive relations may indicate friendship, agreement, or approval. Negative relations usually indicate antagonism, opposition, or disagreement.

Most of the research on relations in social media applications has almost exclusively focused on positive links between individuals (e.g. friends, fans, followers, etc.). We think that one of the main reasons, of why the interplay of positive and negative links did not receive enough attention, is the lack of a notion for explicitly expressing negative interactions. Recently, this problem has received increasing attention. However, all studies have been limited to a handful of datasets from applications that allow users to explicitly label relations as either positive or

negative (e.g. trust/distrust on Epinion (Leskovec et al., 2010b) and friends/foes on Slashdot (Kunegis et al., 2009)).

Predicting positive/negative relations between discussants is related to another well studied problem, namely debate stance recognition. The objective of this problem is to identify which participants are supporting and which are opposing the topic being discussed. This line of work does not pay enough attention to the relations between participants, rather it focuses on participant's stance toward the topic. It also assumes that every participant either supports or opposes the topic being discussed. This is a simplistic view that ignore the nature of complex topics that has many aspects involved which may result in more than two subgroups with different opinions.

In this work, we apply Natural Language Processing techniques to text correspondences exchanged between individuals to identify the underlying signed social structure in online communities. We present a method for identifying user attitude and for automatically constructing a signed social network representation of discussions. We apply the proposed methods to a large set of discussion posts. We evaluate the performance using a manually labeled dataset. We also conduct a large scale evaluation by showing that predicted links are consistent with the principals of social psychology theories, namely the Structural Balance Theory (Heider, 1946). The balance theory has been shown to hold both theoretically (Heider, 1946) and empirically (Leskovec et al., 2010c) for a variety of social community settings. Finally, we present a method for identifying subgroups in online discussions by identifying groups with high density of intra-group positive relations and high density of inter-group negative relations. This method is capable of identifying subgroups even if the community splits into more than two subgroups which is more general than stance recognition which assumes that only two groups exist.

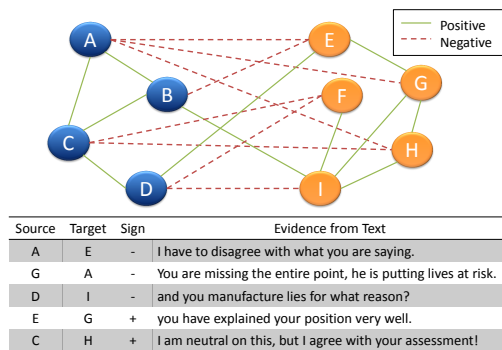

Figure 1: An example showing a signed social network along with evidence from text that justifies edge signs.

The input to our algorithm is a set of text correspondences exchanged between users (e.g. posts or comments). The output is a *signed network* where edges signify the existence of an interaction between two users. The resulting network has polarity associated with every edge. Edge polarity is a means for indicating positive or negative affinity between two individuals.

Figure 1 shows a signed network representation for a subset of posts from a long discussion thread. The thread discussed the November 2010 Wikileaks cable release. We notice that participants split into two groups, one supporting and one opposing the leak. We also notice that most negative edges are between groups, and most positive edges are within groups. It is worth mentioning that networks generated from larger datasets (i.e. with thousands of posts) have much more noise compared to this example.

The rest of the paper is structured as follows. In section 2, we review some of the related prior work on mining sentiment from text, mining online discussions, extracting social networks from text, and analyzing signed social networks. We define our problem and explain our approach in Section 3. Section 4 describes our dataset. Results and discussion are presented in Section 5. We present a method for identifying subgroups in online discussions in Section 3.3. We conclude in Section 6.

## 2 Related Work

In this section, we survey several lines of research that are related to our work.

### 2.1 Mining Sentiment from Text

Our general goal of mining attitude from one individual toward another makes our work related to a huge body of work on sentiment analysis. One such line of research is the well-studied problem of identifying the polarity of individual words (Hatzivassiloglou and McKeown, 1997; Turney and Littman, 2003; Kim and Hovy, 2004; Takamura et al., 2005). Subjectivity analysis is yet another research line that is closely related to our general goal of mining attitude. The objective of subjectivity analysis is to identify text that presents opinion as opposed to objective text that presents factual information (Wiebe, 2000; Hatzivassiloglou and Wiebe, 2000; Banea et al., 2008; Riloff and Wiebe, 2003). Our work is different from subjectivity analysis because we are not only interested in discriminating between opinions and facts. Rather, we are interested in identifying the polarity of interactions between individuals. Our method is not restricted to phrases or words, rather it generalizes this to identifying the polarity of an interaction between two individuals based on several posts they exchange.

### 2.2 Stance Classification

Perhaps the closest work to this paper is the work on stance classification. We notice that most of these methods focus on the polarity of the written text assuming that anyone using positive text belongs to one group and anyone using negative text belongs to another. This works well for single-aspect topics or entities like the ones used in (Tan et al., 2011) (e.g. Obama, Sara Palin, Lakers, etc.). In this simple notion of topics, it is safe to assume that text polarity is a good enough discriminator. This unfortunately is not the case in online discussions about complex topics having many aspects (e.g. abortion, health care, etc.). In such complex topics, people use positive and negative text targeting different aspects of the topic, for example in the health care bill topic, discussants expressed their opinion regarding many aspects including: the enlarged coverage, the insurance premiums, Obama, socialism, etc. This shows that simply looking at text polarity is not enough to identify groups.

Tan et al. (2011) studied how twitter following relations can be used to improve stance classification. Their main hypothesis is that connected users are more likely to hold similar opinions. This may be correct for the twitter following relations, but it is not necessarily correct for open discussions where

no such relations exist. The only criterion that can be used to connect discussants is how often they reply to each other's posts. We will show later that while many people reply to people with similar opinions, many others reply to people with different opinions as well.

Thomas et al. (2006) address the same problem of determining support and opposition as applied to congressional floor-debates. They assess the agreement/disagreement between different speakers by training a text classifier and applying it to a window surrounding the names of other speakers. They construct their training data by assuming that if two speakers have the same vote, then every reference connecting them is an agreement and vice versa. We believe this will result in a very noisy training/testing set and hence we decided to recruit human annotators to create a training set. We found out that many instances with references to other discussants were labeled as neither agreement nor disagreement regardless of whether the discussants have similar or opposing positions. We will use this system as a baseline and will show that the existence of positive/negative words close to a person name does not necessarily show agreement or disagreement with that person.

Hassan et al. (2010) use a language model based approach for identifying agreement and disagreement sentences in discussions. This work is limited to sentences. It does not consider the overall relation between participants. It also does not consider subgroup detection. We will use this method as a baseline for one of our components and will show that the proposed method outperforms it.

Murakami and Raymond (2010) present another method for stance recognition. They use a small number of hand crafted rules to identify agreement and disagreement interactions. Hand crafted rules usually result in systems with very low recall causing them to miss many agreement/disagreement instances (they report 0.26 recall at the 0.56 precision level). We present a machine learning system to solve this problem and achieve much better performance. Park et al. (2011) propose a method for finding news articles with different views on contentious issues. Mohit et al. (2008) present a set of heuristics for including disagreement information in a minimum cut stance classification framework. Galley et al. (2004) show the value of using durational and structural features for identifying agreement and disagreement in spoken conver-

sational speech. They use features like duration of spurts, speech rate, speaker overlap, etc. which are not applicable to written language.

Our approach is different from agreement/disagreement identification because we not only study sentiment at the local sentiment level but also at the global level that takes into consideration many posts exchanged between participants to build a signed network representation of the discussion. Research on debate stance recognition attempts to perform classification under the "supporting vs. opposing" paradigm. However such simple view might not always be accurate for discussions on more complex topics with many aspects. After building the signed network representation of discussions, we present a method that can detect how the large group could split into many subgroups (not necessarily two) with coherent opinions.

### 2.3 Extracting Social Networks from Text

Little work has been done on the front of extracting social relations between individuals from text. Elson et al. (2010) present a method for extracting social networks from nineteenth-century British novels and serials. They link two characters based on whether they are in conversation or not. McCallum et al. (2007) explored the use of structured data such as email headers for social network construction. Gruzd and Hyrthonthwaite (2008) explored the use of post text in discussions to study interaction patterns in e-learning communities. Extracting social power relations from natural language (i.e. who influences whom) has been studied in (Bramsen et al., 2011; Danescu-Niculescu-Mizil et al., 2011).

Our work is related to this line of research because we employ natural language processing techniques to reveal embedded social structures. Despite similarities, our work is uniquely characterized by the fact that we extract signed social networks with both positive and negative links from text.

### 2.4 Signed Social Networks

Most of the work on social networks analysis has only focused on positive interactions. A few recent papers have taken the signs of edges into account.

Brzozowski et al. (2008) study the positive and negative relationships between users of Essembly. Essembly is an ideological social network that distinguishes between ideological allies and nemeses. Kunegis et al. (2009) analyze user relationships in

the Slashdot technology news site. Slashdot allows users of the website to tag other users as friends or foes, providing positive and negative endorsements. Leskovec et al. (2010b) study signed social networks generated from Slashdot, Epinions, and Wikipedia. They also connect their analysis to theories of signed networks from social psychology. A similar study used the same datasets for predicting positive and negative links given their context (Leskovec et al., 2010a).

All this work has been limited to analyzing a handful of datasets for which an explicit notion of both positive and negative relations exists. Our work goes beyond this limitation by leveraging the power of natural language processing to automate the discovery of signed social networks using the text embedded in the network.

The research presented in this paper extends this previous work in a number of ways: (i) we present a method based on linguistic analysis that finds instances of showing positive or negative attitude between participants (ii) we propose a technique for representing discussions as signed networks where a sign is associated with every edge to denote whether the relation is friendly or antagonistic (iii) we evaluate the proposed methods using human annotated data and also conduct a large scale evaluation based on social psychology theories; (iv) finally we present a method for identifying subgroups that globally splits the community involved in the discussion by utilizing the dynamics of the local interactions between participants.

### 3 Approach

#### 3.1 Identifying Attitude from Text

To build a signed network representation of discussants, we start by trying to identify sentences that show positive or negative attitude from the writer to the addressee. The first step toward identifying attitude is to identify words with positive/negative semantic orientation. The semantic orientation or polarity of a word indicates the direction the word deviates from the norm (Lehrer, 1974). We use Opinion-Finder (Wilson et al., 2005a) to identify words with positive or negative semantic orientation. The polarity of a word is also affected by the context where the word appears. For example, a positive word that appears in a negated context should have a negative polarity. Other polarized words sometimes appear as neutral words in some contexts. To identify contex-

tual polarity of words, a large set of features is used including words, sentences, structure, and other features similar to the method described in (Wilson et al., 2005b).

Our overall objective is to find the direct attitude between participants. Hence after identifying the semantic orientation of individual words, we move on to predicting which polarized expressions target the addressee and which do not.

Text polarity alone cannot be used to identify attitude between participants. Sentences that show an attitude are different from subjective sentences. Subjective sentences are sentences used to express opinions, evaluations, and speculations (Riloff and Wiebe, 2003). While every sentence that shows an attitude is a subjective sentence, not every subjective sentence shows an attitude toward the recipient.

In this method, we address the problem of identifying sentences with attitude as a relation detection problem in a supervised learning setting. We study sentences that has mentions to the addressee and polarized expressions (negative/positive words or phrases). Mentions could either be names of other participants or second person pronouns (you, your, yours) used in text posted as a reply to another participant. Reply structure (i.e. who replies to whom) is readily available in many discussion forums. In cases where reply structure is not available, we can use a method like the one in (Lin et al., 2009) to recover it.

We predict whether the mention is related to the polarized expression or not. We regard the mention and the polarized expression as two entities and try to learn a classifier that predicts whether the two entities are related or not.

The text connecting the two entities offers a very condensed representation of the information needed to assess whether they are related or not. For example the two sentences “*you are completely unqualified*” and “*you know what, he is unqualified ...*” show two different ways the words “*you*”, and “*unqualified*” could appear in a sentence. In the first case the polarized word “*unqualified*” refers to the word “*you*”. In the second case, the two words are not related. The information in the shortest path between two entities in a dependency tree can be used to assert whether a relationship exists between them (Bunescu and Mooney, 2005).

The sequence of words connecting the two entities is a very good predictor of whether they are related or not. However, these paths are completely

lexicalized and consequently their performance will be limited by data sparseness. To alleviate this problem, we use higher levels of generalization to represent the path connecting the two tokens. These representations are the part-of-speech tags, and the shortest path in a dependency graph connecting the two tokens. We represent every sentence with several representations at different levels of generalization. For example, the sentence “*your ideas are very inspiring*” will be represented using lexical, polarity, part-of-speech, and dependency information as follows:

LEX: “*YOUR ideas are very POS*”  
 POS: “*YOUR NNS VBP RB JJ\_POS*”  
 DEP: “*YOUR poss nsubj POS*”

The set of features we use are the set of unigrams, and bigrams representing the words, part-of-speech tags, and dependency relations connecting the two entities. For example the following features will be set for the previous example:

YOUR\_ideas, YOUR\_NNS, YOUR\_poss,  
 poss\_nsubj, ....., etc.

We use Support Vector Machines (SVM) as a learning system because it is good with handling high dimensional feature spaces.

### 3.2 Extracting the Signed Network

In this subsection, we describe the procedure we used to build the signed network given the component we described in the previous subsection. This procedure consists of two main steps. The first is building the network without signs, and the second is assigning signs to different edges.

To build the network, we parse our data to identify different threads, posts and senders. Every sender is represented with a node in the network. An edge connects two nodes if there exists an interaction between the corresponding participants. We add a directed edge  $A \rightarrow B$ , if  $A$  replies to  $B$ ’s posts at least  $n$  times in  $m$  different threads. We set  $m$ , and  $n$  to 2 in all of our experiments. The interaction information (i.e. who replies to whom) can be extracted directly from the thread structure. Alternatively, as mentioned earlier, we can use a method similar to the one presented in (Lin et al., 2009) to recover the reply structure if it is not readily available.

Once we build the network, we move to the more challenging task in which we associate a sign with

Participant Features
Number of posts per month for A (B)
Percentage of positive posts per month for A (B)
Percentage of negative posts per month for A (B)
gender
Interaction Features
Percentage/number of positive (negative) sentences per post
Percentage/number of positive (negative) posts per thread
Discussion Domain (e.g. politics, science, etc.)

Table 1: Features used by the Interaction Sign Classifier.

every edge. We have shown in the previous section how sentences with positive and negative attitude can be extracted from text. Unfortunately the sign of an interaction cannot be trivially inferred from the polarity of sentences. For example, a single negative sentence written by  $A$  and directed to  $B$  does not mean that the interaction between  $A$  and  $B$  is negative. One way to solve this problem would be to compare the number of negative sentences to positive sentences in all posts between  $A$  and  $B$  and classify the interaction according to the plurality value. We will show later, in our experiments section, that such a simplistic method does not perform well in predicting the sign of an interaction.

As a result, we decided to pose the problem as a classical supervised learning problem. We came up with a set of features that we think are good predictors of the interaction sign, and we trained a classifier using those features on a labeled dataset. Our features include numbers and percentages of positive/negative sentences per post, posts per thread, and so on. A sentence is labeled as positive/negative if a relation has been detected in this sentence between a mention referring to the addressee and a positive/negative expression. A post is considered positive/negative based on the majority of relations detected in it. We use two sets of features. The first set is related to  $A$  only or  $B$  only. The second set is related to the interactions between  $A$  and  $B$ . The features are summarized in Table 1.

### 3.3 Sub-Group Detection

In any discussion, different subgroups may emerge. Members of every subgroup usually have a common focus (positive or negative) toward the topic being discussed. Each member of a group is more likely to show positive attitude to members of the same group, and negative attitude to members of opposing groups. The signed network representation could prove to be very useful for identifying those subgroups. To detect subgroups in a discussion thread,

we would like to partition the corresponding signed network such that positive intra-group links and negative inter-group links are dense.

This problem is related to the constrained clustering (Wagstaff et al., 2001) and the correlation clustering problem (Bansal et al., 2004). In constrained clustering, a pairwise similarity metric (which is not available in our domain), and a set of must-link/cannot-link constraints are used with a standard data clustering algorithm. Correlation clustering operates in a scenario where given a signed graph  $G = (V, E)$  where the edge label indicates whether two nodes are similar (+) or different (-), the task is to cluster the vertices so that similar objects are grouped together. Bansal et. al (2004) proved NP-hardness and gave constant-factor approximation algorithms for the special case in which the graph is complete (full information) and every edge has weight +1 or -1 which is not the case in our network. Alternatively, we can use a greedy optimization algorithm to find partitions. A criterion function for a local optimization partitioning procedure is constructed such that positive links are dense within groups and negative links are dense between groups.

For any potential partition  $C$ , we seek to optimize the following function:  $P(C) = \alpha \sum_n + (1-\alpha) \sum_p$  where  $\sum_n$  is the number of negative links between nodes in the same subgroup,  $\sum_p$  is the number of positive links between nodes in different subgroups, and  $\alpha$  is a trade factor that represents the importance of the two terms. We set  $\alpha$  to 0.5 in all our experiments.

Clusters are selected such that:  $C^* = \arg \min P(C)$ . A greedy optimization framework is used to minimize  $P(C)$ . Initially, nodes are randomly partitioned into  $t$  different clusters and the criterion function  $P$  is evaluated for that cluster. Every cluster has a set of neighbors in the cluster space. A neighbor cluster is obtained by moving one node from one cluster to another, or by exchanging two nodes in two different clusters. Neighbor partitions are evaluated, and if one with a lower value for the criterion function is found, it is set as the current partition. This greedy procedure is repeated with random restarts until a minimal solution is found. To determine the number of subgroups  $t$ , we select  $t$  that minimizes the optimization function  $P(C)$ . In all experiments we used an upper limit of  $t = 5$ . This technique was able to identify the correct number of subgroups in 77% of the times. In the rest of the cases, the number was different from the correct

number by at most 1 except for a single case where it was 2.

## 4 Data

### 4.1 Signed Network Extraction

Our data consists of a large amount of discussion threads collected from online discussion forums. We collected around 41,000 topics (threads) and 1.2M posts from the period between the end of 2008 and the end of 2010. All threads were in English and had 5 posts or more. They covered 11 different domains including: politics, religion, science, etc. The average number of participants per domain is 1320 and per topic is 52. The data was tokenized, sentence-split, and part-of-speech tagged with the OpenNLP toolkit. It was parsed with the Stanford parser (Klein and Manning, 2003).

We randomly selected around 5300 posts (1000 interactions), and asked human annotators to label them. Our annotators were instructed to read all the posts exchanged between two participants and decide whether the interaction between them is positive or negative. We used Amazon Mechanical Turk for annotations. Following previous work (Callison-Burch, 2009; Akkaya et al., 2010), we took several precautions to maintain data integrity. We restricted annotators to those based in the US to maintain an acceptable level of English fluency. We also restricted annotators to those who have more than 95% approval rate for all previous work. Moreover, we asked three different annotators to label every interaction. The label was computed by taking the majority vote among the three annotators. We refer to this data as the *Interactions Dataset*.

We ran a different annotation task where we selected sentences including mentions referring to discussants (names or pronouns) and polarized expressions. Annotators were asked to select sentences where the polarized attribute is referring to the mention and hence show a positive or negative attitude toward other discussion participants. This resulted in a set of 5000 manually annotated sentences. We refer to this data as the *Sentences Dataset*.

We asked three different annotators to label every instance. The kappa measure between the three groups of annotations was 0.62 for the *Interactions Dataset* and 0.64 for the *Sentences Dataset*. To better assess the quality of the annotations, we asked a trained annotator to label 10% of the data. We measured the agreement between the expert annotator

	Class	Pos.	Neg.	Weigh. Avg.
Logistic Reg.	Precision	0.848	0.724	0.809
	Recall	0.884	0.657	0.812
	F-Measure	0.866	0.689	0.81
	Accuracy	-	-	<b>0.812</b>
SVM	Precision	0.906	0.71	0.844
	Recall	0.847	0.809	0.835
	F-Measure	0.875	0.756	0.838
	Accuracy	-	-	<b>0.835</b>

Table 3: A comparison of different sign interaction classifiers.

and the majority label from Mechanical Turk. The kappa measure was 0.69 for the *Interactions Dataset* and 0.67 for the *Sentences Dataset*.

## 4.2 Sub-group Detection

We used a dataset of more than 42 topics and approximately 9000 posts collected from two political forums (Createdebate<sup>1</sup> and Politicalforum<sup>2</sup>). The forum administrators ran a poll asking participants to select their stance from a set of possible answers and hence the dataset was self-labeled with respect to groups. We also used a set of discussions from the Wikipedia discussion section. When a topic on Wikipedia is disputed, the editors of that topic start a discussion about it. We collected 117 Wikipedia discussion threads. The threads contain a total of 1,867 posts. The discussions were annotated by an expert annotator (a professor in sociolinguistics, not an author of the paper) who was instructed to read each of the Wikipedia discussion threads in its entirety and determine whether the discussants split into subgroups, in which case he was asked to identify the subgroup membership for each discussant. In total, we had 159 topics with an average of approximately 500 posts, 60 participants and 2.7 subgroups per topic. Examples of the topics include: Arizona immigration law, airport security, oil spill, evolution, Ireland partitions, abortion and many others.

## 5 Results and Discussion

We performed experiments on the data described in the previous section. We trained and tested the sentence with the attitude detection classifiers described in Section 3.1 using the *Sentences Dataset*.

<sup>1</sup>www.createdebate.com

<sup>2</sup>www.politicalforum.com

We also trained and tested the interaction sign classifier described in Section 3.2 using the *Interactions Dataset*. We built one signed social network for every domain (e.g. politics, economics, etc.). We decided to build a network for every domain as opposed to one single network because the relation between any two individuals may vary across domains (e.g. politics vs. science). In the rest of this section, we will describe the experiments we did to assess the performance of the sentences with attitude detection and interaction sign prediction steps.

In addition to classical evaluation, we evaluate our results using the structural balance theory which has been shown to hold both theoretically (Heider, 1946) and empirically (Leskovec et al., 2010c). We validate our results by showing that the *automatically* extracted networks mostly agree with the theory. We evaluated the approach using the structural balance theory because it presents a global (pertaining to relations between multiple edges) and large-scale (used millions of posts and thousands of users) evaluation of the results as opposed to traditional evaluation which is local in nature (only considers one edge at a time) and smaller in scale (used thousands of posts).

### 5.1 Identifying Sentences with Attitude

We compare the proposed methods to two baselines. The first baseline is based on the work of (Thomas et al., 2006). We used the speaker agreement component presented in (Thomas et al., 2006) as a baseline. The speaker agreement component is one step in their approach. In this component, they used an SVM classifier trained using a window of text surrounding references to other speakers to predict agreement/disagreement between speakers.

We build an SVM text classifier trained on the sentence at which the mention referring to the other participant occurred. We refer to this baseline as the *Text Classification* approach. The second baseline adopts the language model approach presented in (Hassan et al., 2010). Two language models are trained using a stream of words, part-of-speech tags, and dependency relations, one for sentences that show an attitude and one for sentences that do not. New sentences are classified based on generation likelihoods. We refer to this baseline as the *Language Models* approach.

We tested this component using the *Sentences Dataset* described in Section 4. We compared the performance of the proposed method and the two

Domain	Extracted Networks				Random Networks			
	(+++)	(++-)	(+--)	(---)	(+++)	(++-)	(+--)	(---)
abortion	51.67	26.31	18.92	0.48	35.39	43.92	18.16	2.52

terrorism	64.96	23.36	9.46	0.73	41.54	42.42	14.36	1.68

Table 4: Percentage of different types of triangles in the extracted networks vs. the random networks.

Method	Accuracy	Precision	Recall	F1
Text Classification	60.4	61.1	60.2	60.6
Language Models	80.3	81.0	79.4	80.2
Relation Extraction	82.3	82.3	82.3	82.3

Table 5: Comparison of attitude identification methods.

baselines. Table 5 compares the precision, recall, F1, and accuracy for the three methods. The text classification based approach does much worse than others. The reason is that it ignores the structure and uses much less information (part-of-speech tags and dependency trees are not used) compared to the other methods. Additionally, the short length of the sentences compared to what is typical in text classification may have had a bad effect on the performance. Both other models try to learn the characteristics of the path connecting the mention and the polarized expression. We notice that optimizing the weights for unigram and bigram features using SVM results in a better performance compared to language models because it does not have the constraints imposed by the former model on the learned weights.

We evaluated the importance of the feature types (i.e. dependency vs. pos tags vs words) by measuring the chi-squared statistic for every feature with respect to the class. Dependency features were most helpful, but other types of features helped improve the performance as well.

## 5.2 Interaction Sign Classifier

We used the relation detection classifier described in Section 3.1 to find sentences with positive and negative attitude. The output of this classifier was used to compute the features described in Section 3.2, which were used to train a classifier that predicts the sign of an interaction between any two individuals.

We used both Support Vector Machines (SVM) and logistic regression to train the sign interaction

classifier. We report several performance metrics for them in Table 2. We notice that the SVM classifier performs better with an accuracy of 83.5% and an F-measure of 81%. All results were computed using 10 fold cross validation on the labeled data. To better assess the performance of the proposed classifier, we compare it to a baseline that labels the relation as negative if the percentage of negative sentences exceeds a particular threshold, otherwise it is labeled as positive. The thresholds were empirically estimated using a separate development set. The accuracy of this baseline is only 71%.

To better assess the performance of the proposed classifier, we compare it to three baselines. The first is a random baseline that predicts an interaction as positive with probability  $p$  that equals the proportion of positive instances to all instances in the training set. The second classifier (Thresh-Num) labels the edge as negative if the number of negative instances exceeds a threshold  $T_n$ . The third classifier (Thresh-Perc) labels the edge as negative if the percentage of negative instances to all instances exceeds a threshold  $T_p$ . The cutoff thresholds were estimated using a separate development set.

The 3 baselines were tested using the entire labeled dataset. The SVM classifier was tested using 10 fold cross validation. The accuracy of the random classifier, the two based on a cut off number and percentage, and the SVM classifier are shown in Table 3. We notice that the random classifier performs worst, and the classifier based on percentage cutoff outperforms the one based on number cutoff. The SVM classifier significantly outperforms all other classifiers. We tried to train a classifier using both the number and percentage of negative and positive posts. The improvement over using the baseline using the percentage of negative posts was not statistically significant.

We evaluated the importance of the features listed

in Table 1 by measuring the chi-squared statistic for every feature with respect to the class. We found out that the features describing the interaction between the two participants are more informative than the ones describing individuals characteristics. The later features are still helpful though and they improve the performance by a statistically significant amount. We also noticed that all features based on percentages are more informative than those based on counts. The most informative features are: percentage of negative posts per tread, percentage of negative sentences per post, percentage of positive posts per thread, number of negative posts, and discussion domain.

### 5.3 Structural Balance Theory

The structural balance theory is a psychological theory that tries to explain the dynamics of signed social interactions. It has been shown to hold both theoretically (Heider, 1946) and empirically (Leskovec et al., 2010c). In this section, we study the agreement between the theory and our *automatically* extracted networks. The theory has its origins in the work of Heider (1946). It was then formalized in a graph theoretic form by (Cartwright and Harary, 1956). The theory is based on the principles that “the friend of my friend is my friend”, “the enemy of my friend is my enemy”, “the friend of my enemy is my enemy”, and variations on these. The structural balance theory states that triangles that have an odd number of positive signs (+ + + and + - -) are balanced, while triangles that have an even number of positive signs (- - - and + + -) are not.

In this section, we compare the predictions of edge signs made by our system to the structural balance theory by counting the frequencies of different types of triangles in the predicted network. Table 4 shows the frequency of every type of triangle for 10 different domains. To better understand these numbers, we compare them to the frequencies of triangles in a set of random networks. We shuffle the signs for all edges on every network keeping the fractions of positive and negative edges constant. We repeat shuffling for 1000 times and report the average.

We find that the all-positive triangle (+ + +) is overrepresented in the generated network compared to chance across all domains. We also see that the triangle with two positive edges (+ + -), and the all-negative triangle (- - -) are underrepresented compared to chance across all domains. The tri-

angle with a single positive edge is slightly overrepresented in most but not all of the topics compared to chance. This shows that the predicted networks mostly agree with the structural balance theory. The slightly non standard behavior of the triangle with one positive edge could be explained in light of the weak balance theory. In this theory, Davis (1967) states that this triangle, which corresponds to the “enemy of enemy is my friend” proposition, holds only if the network can be partitioned into exactly two subsets, but not when there are more than two. In general, the percentage of balanced triangles in the predicted networks is higher than in the shuffled networks, and hence the balanced triangles are significantly overrepresented compared to chance showing that our *automatically* constructed network is similar to explicit signed networks in that they both mostly agree with the balance theory.

### 5.4 Sub-Group Detection

We compare the performance of the sub-group detection method to three baselines. The first baseline uses graph clustering (GC) to partition a network based on the frequency of interaction between participants. We build a graph where each node represents a participant. Edges link participants if they exchange posts, and edge weights are based on the number of posts exchanged. The second baseline (TC) is based on the premise that participants with similar text are more likely to belong to the same subgroup. We measure text similarity by computing the cosine similarity between the tf-idf representations of the text in a high dimensional vector space. We tried two methods for partitioning those graphs: spectral partitioning (Luxburg, 2007) and a hierarchical agglomeration algorithm which works by greedily optimizing the modularity for graphs (Clauset et al., 2004). The third baseline is based on stance classification approaches (e.g. (Tan et al., 2011)). In this baseline we put all the participants who use more positive text in one subgroup and the participants who use more negative text in another subgroup. Text polarity is identified using the method described in Section 3.1.

Table 6 shows the average purity (*Purity*), entropy (*Entropy*), Normalizes Mutual Information (*NMI*), and Rand Index (*RandIndex*) values of the method based on signed networks and the baselines using different partitioning algorithms. The differences in the results shown in the table are statistically significant at the 0.05 level (as indicated by a 2-tailed

Figure 2: A signed network representing participants in a discussion about the “Health Care Reform Bill”. Blue (dark) nodes represent participants with the bill, Yellow (light) nodes represent participants against the bill, red (solid) edges represent negative attitude, while green (dashed) edges represent positive attitude.

Method	Createdebate				Politicalforum				Wikipedia			
	Purity	Entropy	NMI	RandIndex	Purity	Entropy	NMI	RandIndex	Purity	Entropy	NMI	RandIndex
GC - Spectral	0.50	0.85	0.28	0.40	0.50	0.88	0.27	0.39	0.49	0.89	0.33	0.35
GC - Hierarchical	0.48	0.86	0.30	0.41	0.47	0.89	0.31	0.40	0.49	0.87	0.38	0.39
TC - Spectral	0.50	0.85	0.31	0.43	0.48	0.90	0.30	0.45	0.51	0.87	0.40	0.46
TC - Hierarchical	0.49	0.90	0.35	0.46	0.48	0.91	0.33	0.49	0.53	0.80	0.40	0.49
Text Polarity	0.55	0.80	0.38	0.49	0.54	0.91	0.31	0.38	0.34	0.95	0.30	0.40
Signed Networks	<b>0.64</b>	<b>0.74</b>	<b>0.46</b>	<b>0.59</b>	<b>0.58</b>	<b>0.80</b>	<b>0.43</b>	<b>0.55</b>	<b>0.65</b>	<b>0.54</b>	<b>0.51</b>	<b>0.60</b>

Table 6: Comparison of the sub-group detection method to baseline systems

paired t-test).

We notice that partitioning the signed network that was automatically extracted from text results in significantly better partitions on the three datasets as indicated by the higher Purity, NMI, and RandIndex and the lower Entropy values it achieves. We believe that the first two baselines performed poorly because the interaction frequency and the text similarity are not key factors in identifying subgroup structures. Many people would respond to people they disagree with more, while others would mainly respond to people they agree with most of the time. Also, people in opposing subgroups tend to use very similar text when discussing the same topic and hence text clustering does not work as well. The baseline that classifies the stance of discussants based on the polarity of their text performed bad too because it overlooks the fact that most of the discussed topics in our datasets have multiple aspects and a discussant may use both positive and negative text targeting different aspects of the topic. An example of a signed network and the corresponding subgroups as extracted from real data is shown in Figure 2.

## 6 Conclusions

In this paper, we have shown that natural language processing techniques can be reliably used to extract signed social networks from text correspondences. We believe that this work brings us closer to understanding the relation between language use and social interactions and opens the door to further research efforts that go beyond standard social network analysis by studying the interplay of positive and negative connections. We rigorously evaluated the proposed methods on labeled data and connected our analysis to social psychology theories to show that our predictions mostly agree with them. Finally, we presented potential applications that benefit from the automatically extracted signed network.

## Abstract

User simulation is frequently used to train statistical dialog managers for task-oriented domains. At present, goal-driven simulators (those that have a persistent notion of what they wish to achieve in the dialog) require some task-specific engineering, making them impossible to evaluate intrinsically. Instead, they have been evaluated extrinsically by means of the dialog managers they are intended to train, leading to circularity of argument. In this paper, we propose the first fully generative goal-driven simulator that is fully induced from data, without hand-crafting or goal annotation. Our goals are latent, and take the form of topics in a topic model, clustering together semantically equivalent and phonetically confusable strings, implicitly modelling synonymy and speech recognition noise. We evaluate on two standard dialog resources, the Communicator and Let's Go datasets, and demonstrate that our model has substantially better fit to held out data than competing approaches. We also show that features derived from our model allow significantly greater improvement over a baseline at distinguishing real from randomly permuted dialogs.

## 1 Introduction

Automatically simulating user behaviour in human-machine dialogs has become vital for training statistical dialog managers in task-oriented domains. These managers are often trained with some variant of reinforcement learning (Sutton and Barto, 1998), where optimal behaviour is sought or learnt through the exploration of the space of possible dialogs. Although learning by interacting with human

subjects is a possibility (Gašić et al., 2011), it has been argued that user simulation avoids the expensive, labour intensive, and error-prone experience of exposing real humans to fledgling dialog systems (Eckert et al., 1997).

Training effective dialog managers should benefit from exposure to properties exhibited by real users. Table 1 shows an example dialog in a domain such as we consider, where the objective is to simulate at the semantic level. In such task oriented domains, the user has a *goal* (in this case, to book a flight from New York to Osaka), and the machine is tasked with fulfilling it. Notice that the user is consistent with this goal throughout the dialog, in that they do not provide contradictory information (although an ASR error is present), but that every mention of their destination city uses a different string. This motivates our first desideratum: that simulation be consistent over the course of a dialog. Furthermore, one can imagine users not always responding identically in identical situations: we thus additionally require *variability*. In this paper we demonstrate a fully generative, latent variable probability model exhibiting both of these properties.

Thus far, consistent simulators have been partially deterministic and have required some hand-engineering. As a result, it has only been possible to evaluate them extrinsically using dialog managers. This is circular because we need simulators to train managers, but need managers to evaluate simulators. The issue is that judgements of quality of each depend on the specifics of the other and that a proper evaluation of one depends on the correct functioning of the other. Furthermore, there is little reason to assume that because a simulator performs well with a certain dialog manager, it would perform similarly

Speech	Semantic Representation
M: Hello, How Can I help?	M: GREETING M: META_REQUEST_INFO
U: A trip from New York City to Osaka, please.	U: PROVIDE <i>orig_city</i> <b>New York City</b> U: PROVIDE <i>dest_city</i> <b>Salt Lake City</b>
M: Leaving from New York City to Salt Lake City. What day would you like to travel?	M: IMPLICIT_CONFIRM <i>orig_dest_city</i> M: REQUEST <i>depart_date</i>
U: No, no. Leaving from New York to Osaka in Japan.	U: NO_ANSWER <i>null</i> <b>no</b> U: PROVIDE <i>orig_city</i> <b>New York</b> U: PROVIDE <i>dest_city</i> <b>Osaka Japan</b>
M: Leaving from New York to Osaka Japan, correct?	M: EXPLICIT_CONFIRM <i>orig_city</i> M: EXPLICIT_CONFIRM <i>dest_city</i>
U: Yes.	U: YES_ANSWER <i>null</i> <b>yes</b>

Table 1: An example of a dialog in speech and its semantic equivalent. M and U denote machine and user utterances respectively. Note how a single speech utterance is split by the semantic parser into multiple logical utterances, each of which is broken down to an ACT, *slot*, and **value**. We consider resources where gold standard transcriptions are not available; thus there will be speech recognition noise, e.g. **Osaka** rendered as **Salt Lake City**, something our model is able to capture.

well with other managers. In contrast, a probabilistic formulation such as we propose allows us to evaluate our models intrinsically using standard machine learning metrics, and without reference to a *specific* manager, thus breaking the circularity, and guarding against such experimental biases.

We demonstrate the efficacy of our model on two tasks, and compare it to two other approaches. Firstly we use a standard bigram model as conceived by Eckert et al. (1997) and Levin and Pieraccini (2000); secondly we compare to a probabilistic goal-based simulator where the goals are string literals, as envisaged by Scheffler and Young (2002) and Schatzmann et al. (2007b). We demonstrate substantial improvement over these models in terms of predicting heldout data on two standard dialog resources: DARPA Communicator (Levin et al., 2000; Georgila et al., 2005b) and Let’s Go (Black and Eskenazi, 2009).

## 2 Related Work

### 2.1 Related Work on User Simulation

User simulation as a stochastic process was first envisioned by Eckert et al. (1997): their *Bigram* model conditions user utterances exclusively on the preceding machine utterance. This was extended by Levin and Pieraccini (2000), who manually restrict

the model to estimating “sensible” pairs of user and machine utterances by assigning all others probability zero.

Bigram models ensure that a locally sensible response to a machine utterance is provided by the simulator; however, they do not ensure that it provides responses consistent with one another throughout the dialog. Several approaches have attempted to overcome this problem. Pietquin (2004), for example, explicitly models a user goal as a set of slot-value pairs randomly generated once per dialog. He then hand selects parameters to ensure that the user’s actions are in accordance with their goal.

Jung et al. (2009) use large amounts of dialog state annotations (e.g. what information has been provided so far) to learn Conditional Random Fields over the user utterances, and assume that those features ensure user consistency. Georgila et al. (2005a) instead consider only act-slot pairs, and thus inconsistency is not a factor.

Scheffler and Young (2002) simulate user behaviour by introducing rules for actions that depend on the user goal, and probabilistic modelling for actions that are not goal-dependent. They then map out a decision network that determines user actions at every node prior to the start of the dialog. Agenda-based user simulation, another approach from the literature, assumes a probability distribution over the

user goal which is either induced from data (Schatzmann et al., 2007b), or is manually set when no data is available (Schatzmann et al., 2007a). An agenda, which is a stack-like structure of utterances to be produced given the goal, is then devised deterministically. Keizer et al. (2010) combine the decision network with the agenda and goal to allow for some variability for some actions. These models ensure consistency but restrict the variability in user behaviour that can be accommodated. Furthermore, because these approaches do not define a complete probability distribution over user behaviour, they restrict possibilities for their evaluation, a point to which we now turn.

## 2.2 Related Work on Simulator Evaluation

No standardised metric of evaluation has been established for user simulators largely because they have been so inextricably linked to dialog managers. The most popular method of evaluation relies on generating synthetic dialogs through the interaction of the user simulator with some dialog manager. Schatzmann et al. (2005) hand-craft a simple deterministic dialog manager based on finite automata, and compute similarity measures between these synthetically produced dialogs and real dialogs. Georgila et al. (2006) use a scoring function to evaluate synthetic dialogs using accuracy, precision, recall, and perplexity, while Schatzmann et al. (2007b) rely on dialog completion rates. Williams (2008) use a Cramer–von Mises test, a hypothesis test to determine whether simulated and real dialogs are significantly different, while Janarthanam and Lemon (2009) use Kullback Leibler Divergence between the empirical distributions over acts in real and simulated dialogs. Singh et al. (2000) and Ai and Litman (2008) judge the consistency of human quality ranked synthetic dialogs generated by different simulators interacting with the IT-SPOKE dialog system.

Schatzmann et al. (2007b) use a simulator to train a statistical dialog manager and then evaluate the learned policy. Because this only indirectly evaluates the simulator, it is inappropriate as a sole measure of quality.

There has been far less evaluation of simulators without a dialog manager. The main approach is to compute precision and recall on an utterance ba-

sis, which is intended to measure the similarity between real user responses in the corpora and simulated user responses produced under similar circumstances (Schatzmann et al., 2005; Georgila et al., 2006). However, this is a harsh evaluation as it assumes a correct or “best” answer, and penalises valid variability in user behaviour.

## 3 Dialog as a Statistical Process

We consider a dialog to be a series of *turns*, comprised of multiple *utterances*. Each Utterance consists of an ACT, a *slot*, and a **value**, as shown in Table 1. Dialogs proceed by the user and the machine alternating turns. Because the dialogs are of mixed initiative, there is no restriction on the number of contiguous machine or user utterances.

Our aim is to model the user, and are interested in the conditional distribution of the user utterances given the dialog up to that point. In other words, we are interested in the distribution  $p(u_i | d_1 \dots d_{i-1})$ , where  $d_n$  is either a machine utterance  $m_n$  or a user utterance  $u_n$ .

## 4 Models of Users in Dialogs

This section describes several models of increasing complexity: a Bigram model, which serves as a baseline; an upper-bound on String-Goal models, which we design to mimic the behaviour of previous goal-based approaches, but with a probabilistic formulation; and finally our approach, the Topic-Goal model.

### 4.1 Bigram Model

The simplest model we define over dialogs is the bigram model of Eckert et al. (1997):

$$p(u_i | \mathbf{m}) = p(u_i | m_{i-1}) \quad (1)$$

$$p(\mathbf{u} | \mathbf{m}) = \prod_i p(u_i | \mathbf{m}) \quad (2)$$

The probability of each user utterance  $u_i$  (the complete {ACT, *slot*, **value**} triple) is dependent only on the machine utterance immediately preceding it (the slight abuse of notation  $m_{i-1}$  here does not mean the utterance at  $i-1$  in the machine utterance list, but the utterance immediately preceding the  $i$ -th), and utterances in the dialog are conditionally independent of

one another. (Georgila et al. (2006) found no benefit from increasing the Markov horizon). Since each utterance is generated independently of others in the dialog with the same context, there is no enforced consistency between utterances.

Since we require a distribution over all possible utterances, assigning non-zero probability to cases outside of the training data, our bigram model is interpolated with a unigram model, which itself is interpolated with a smoothing model which assumes independence between the act, slot, and value elements of the utterance. Interpolation weights are set to maximise probability of a development set of dialogs. Each sub-model uses the maximum likelihood estimator (the relative frequency of the utterance), and unseen machine utterances place full weight on the unigram/smoothed model (ignoring the bigram probability since it has no meaning if  $m_{i-1}$  is unobserved). We label this model the Bigram model in subsequent experiments.

## 4.2 Goal-Based Models

One way to ensure consistency and more realistic behaviour is to have a *goal* for the user in the dialog, which corresponds to values for slots required in the problem. For instance, they might be the origin and destination cities in a flight booking domain. In standard machine learning terms, the goal becomes a latent variable  $g$  in a probability model. We can then define a distribution over utterances as:

$$p(u_i | \mathbf{m}, g) = p(u_i | m_{i-1}, g) \quad (3)$$

$$p(\mathbf{u} | \mathbf{m}) = \sum_g p(g) \prod_i p(u_i | m_{i-1}, g) \quad (4)$$

## 4.3 An Upper-Bound on String-Goal Models

The simplest variant of  $g$  has string values for each of the slots the user is required to provide in order for the dialog to succeed. Thus we may have:

$$g = [\text{orig\_city: New York; dest\_city: Osaka}]$$

as presented in Schatzmann et al. (2005) and Schatzmann et al. (2007b). However, in these simulators, while the goal is probabilistic, there is no distribution over utterances given the goal because utterances are assembled deterministically from a series of rule applications. There is also no marginalisation over the goal as in (4) above.

The issue with a model of user goals as strings in this fashion is that users describe the same values in multiple ways (**Osaka Japan, Osaka**), and speech recognition errors corrupt consistent user input (**Osaka** mis-recognised as **Salt Lake City**). Users also might legitimately switch their goals mid-dialog. Inference in the model would have to allow for these possibilities: we would have to marginalise over all possible goal switches.

For the sake of comparison, we compute an upper-bound on string-goal models, which gives a flavour for how such models would perform *optimistically*. The upper-bound assigns probability to dialogs as follows: for each utterance  $u_i$  if the corresponding value  $v_i$  has been seen before in the dialog, the probability used for that utterance is just  $p(a_i, s_i | m_{i-1})$ , that is, the probability of the act  $a_i$  and slot  $s_i$  only; there is no penalty for repetition of the value. If the value is unseen in the dialog, we use the full probability of the utterance from the bigram model as described above. This is optimistic because there is no penalty for repeated goal changes besides that imposed by the bigram model itself, and no penalty is imposed for choosing between previously sampled goals as would be necessary in a probability model.

Any string-based model necessarily assigns lower probabilities to data than the upper bound, because it would penalise goal changes (in a probabilistic sense; that is, there would be a term to reflect the probability of some new goal given the old) to allow for the discrepancy in values present in dialogs. In contrast, our upper bound does not include such a term. Furthermore, once multiple goal values had been uttered in the dialog, we would have to sample one to use for the next utterance, which would again incur some cost: again, we do not have such a cost in our upper bound.

We could in theory use an external model of noise to account for these value discrepancies (and the ASR errors we model in the next section). However, this would further decrease the probability, as some probability mass currently assigned to the heldout data would have to be reserved for the possibility of string renderings other than those we observe.

It bears reiterating that our upper bound on string-goals is not a generative model: however, it allows us to assign probabilities to unseen data (albeit optimistically), and thus provides us with a point of

comparison. Although not technically a model, we refer to this as the String-Goal model for the remainder of the paper.

#### 4.4 Topic-Goal Model

To motivate our proposal, consider that over the course of a dialog one could look at the set of all values used for some slot, for example the destination city, as a count vector:

$$v_{\text{dest.city}} = \mathbf{Salt\ Lake:1; Osaka:2; Osaka\ Japan:1}$$

The above vector may arise because the user actually wants to go to **Osaka**, but the destination is initially mis-recognised as **Salt Lake**, and the user finally disambiguates with the addition of the country. Such situations are common in the noisy dialog resources from which simulators are induced—however, any string-based goal will necessarily consider these different renderings to be different goals, and will require resampling or smoothing terms to deal with them.

Our approach instead treats the count vector as samples from a topic model; that is, a mixture over multinomial distributions. Whilst by far the most popular topic model is LDA (Blei et al., 2003), it provides too flexible a distribution over count vectors to be used with such small samples (we confirmed the poor suitability of this model in preliminary experiments). Instead we use the simpler Mixture-of-Multinomials model, where the latent topic is sampled once per dialog instead of once per value uttered. We describe below how parameters to this model are estimated, and focus for now on how the resulting model assigns probability to dialogs.

In this formulation, the latent goal for each slot, which was previously a string, now becomes an indicator for a topic in a topic model. Each topic can in theory generate any string (so the model is inherently smoothed), but most strings in most topics will have only the smoothing weight and most probability mass will be on a small number of highly correlated strings. We treat the slots as being independent of one another in the goal, and thus:

$$p(g) = \prod_s p(z_s) \quad (5)$$

Where  $z_s$  is the topic indicator for some slot  $s$ . If slot  $s$  has associated with it a count vector of values  $\mathbf{v}_s$ ,

each looking like the example above, then the distribution over the values used for each slot becomes:

$$p(v_s) = \sum_{z_s} p(z_s) p(v_s|z_s) \quad (6)$$

We then define a bigram-based Act model to describe the probabilities of the  $\{\text{ACT}, \text{slot}\}$  pairs to which these values belong, so that:

$$p(\mathbf{u}|\mathbf{m}) = \prod_s p(z_s) \cdot \prod_i p(a_i, s_i | m_{i-1}) p(v_i | z_{s_i}) \quad (7)$$

In reality, some slots will not have corresponding values, or will be slots whose values are not appropriate to model in the above way. Dates and times, for example, have ordinal and structural relations between them, and a model which treats them as disconnected entities is inappropriate. For utterances defined over such slots we use a standard bigram model as in (1), and for appropriate utterances we use a topic-goal model as in (7). This constitutes the only domain knowledge necessary to adapt the model for a new resource. We refer to this model as the Topic-Goal model.

##### 4.4.1 Topic Model Parameter Estimation

Our topic model is a Bayesian version of the Mixture-of-Multinomials model. Under this model, each dialog has associated with it a latent variable  $z_s$  for each slot  $s$  in the goal, which indicates which topic is used to draw the values for that slot. Conditioned on  $z$ , independent samples are drawn from the distribution over words to which that value of  $z$  corresponds—however, the effect in the marginal distribution over words is to strongly prefer sets which have co-occurred in training as these are assigned to the same topic.

Bayesian inference in mixture models has been described in detail in Neal (1991) and Griffiths and Steyvers (2004), so we give only a brief account here for our particular model. We take  $r$  appropriately-spaced samples from a Gibbs' sampler over the posterior mixture parameters  $\theta, \phi$ :  $\theta$  are the word-topic parameters and  $\phi$  are the mixture proportions. We assume a uniform Dirichlet prior on  $\theta$  and  $\phi$ , leading to Dirichlet posteriors which we integrate out in the predictive distribution over  $v$  using the standard Dirichlet integral. For each of our  $r$  samples we have

components  $z$  parameterised by  $\gamma_{rz}$  (the Dirichlet parameter for the  $z$ -th mixture component in the  $r$ -th sample) and  $\alpha_{rzj}$  for each word  $j$  in the  $z$ -th topic for the  $r$ -th sample. The  $\bullet$  notation indicates a sum over the corresponding index, i.e.  $\gamma_{r\bullet} = \sum_z \gamma_{rz}$ . Then:

$$p(v) = \frac{1}{|r|} \sum_r \sum_z \frac{\gamma_{rz}}{\gamma_{r\bullet}} p(v|\alpha_{rz}) \quad (8)$$

$$p(v|\alpha) = \frac{\Gamma(\alpha_\bullet)}{\Gamma(\alpha_\bullet + v_\bullet)} \prod_j \frac{\Gamma(v_j + \alpha_j)}{\Gamma(\alpha_j)} \quad (9)$$

This states that each of the  $r$  samples has topics  $z$  which are multinomial distributions with posteriors governed by parameters  $\alpha_{rz}$ . For any of these topics, the distribution over  $v$  is as given in Equation (9) (we suppress the subscripting of  $\alpha$  here for the different samples and topics, since this holds whatever its value). The final predictive probability given in Equation (8) averages over the samples  $r$  and the topics  $z$  (with topics weighted by their parameters  $\gamma_{rz}$ ).

## 5 Experimental Setup

Our experiments use two standard corpora, the first of which is DARPA Communicator (DC), a flight booking domain collected between 2000-2001 through the interaction of real users with 10 different systems (Levin et al., 2000). It was later automatically annotated by Georgila et al. (2005b) to include semantic information. The second corpora is Let’s Go (LG), years 2007, 2008, and 2009, distributed as part of the Spoken Dialog Challenge (Black and Eskenazi, 2009). Let’s Go is a bus routing domain in Pittsburgh collected by having the general public interact with the CMU dialog system to find their way through the city. The dialogs in both corpora are of mixed-initiative, having a free number of contiguous system and user responses.

We preprocessed the corpora, converting Communicator XML-tagged files and Let’s Go system log files into sequences of ACT, *slot*, and **value** utterances. Table 2 gives examples. We then divided the corpora into training, development and test sets as follows: Communicator contains 2285 dialogs in total, and Let’s Go contains 17992, and in each case we selected 80% of dialogs at random for training, 10% for development, and 10% for testing.

DC:	PROVIDE_INFO <i>orig_city</i> <b>Boston</b>
LG:	INFORM <i>place</i> [departure_place <b>CMU</b> , arrival_place <b>airport</b> ]

Table 2: Example utterances from the two corpora. Note how in addition to the value, the Let’s Go utterances contain properties (departure\_place and arrival\_place).

Let’s Go is a noisy corpus that contains far more speech recognition errors than Communicator. In addition, users tend to be more flexible with their bus routes than they are with their flight destinations, and so values are a lot more varied throughout the course of Let’s Go dialogs than Communicator ones. Furthermore, Let’s Go semantic parses contain ambiguity not present in Communicator; the parser fails to distinguish departure from arrival places over 90% of the time, and instead assigns them a generic Single\_Place property. Our current model assumes the decisions made by the semantic parser are correct. In reality however, a better model would incorporate potential noise in the semantic parse in a joint model. We defer this more complex treatment for future work.

Free model parameters are set by a simple search on the development set, where the objective is likelihood—for the bigram model the parameters are the interpolation weights, and for the topic model we search for the number of topics and smoothing constant for the topic distributions. For Let’s Go, since we can have multiple places provided in a single act, we treat each utterance as containing a set of values and build the count vector for the topic model as the union of these sets over the whole dialog. The slots over which the topic model is defined for Communicator are *dest\_city* and *orig\_city* (this takes into account PROVIDE and REPROVIDE acts). For Let’s Go we derive the model over the three properties: single\_place, arrival\_place and departure\_place, as opposed to the less informative slot *place*.

## 6 Evaluating the Simulators

We evaluate each of the models in terms of the probability they assign to the test data. This metric is more suitable than the precision and recall metrics which have been previously used, because it acknowledges that, rather than each user response being “correct” at the point which it is observed, there

Model	DC(A)	DC(P)	LG(A)	LG(P)
Topic	<b>252.78</b>	<b>860.2</b>	<b>113.45</b>	<b>1417.06</b>
String	270.09	1286.03	169.87	4578.23
Bigram	347.88	5979.53	223.23	10125.87
Act	9.56	5.2	2.77	2.34

Table 3: The mean per-utterance perplexity on heldout data. DC-A is all acts for Communicator, while DC-P is the calculated on PROVIDE acts alone (the acts on which our model is designed to improve prediction). LG-A and LG-P have the same meaning for Let’s Go.

is a distribution over possible responses. Because the models we define are full probability models, we are able to compute this metric and do not need to use an arbitrarily selected dialog manager for evaluation.

The heldout probability metric should be understood as a means of comparing the relative viability of different models of the same data. Note that we are reporting the probability of unobserved data, rather than data from which the models were induced, and are thus measuring the generalisability of the models (in contrast, maximising the probability of the training data would simply encourage overfitting). The absolute numbers are hard to interpret, as there is no hard upper bound; while it may be appealing to think of an upper bound of 1, this is incorrect as it would imply that there was no variability in the data. However, it should be understood that assigning particular behaviour higher probability means that the model is more likely to exhibit it when run in simulation mode—and since the user behaviour in question has not been seen at training time, this measures the extent to which the models have generalised beyond the training data relative to one another.

We report the mean per-utterance log probability of unseen data, that is, the probability of the whole heldout corpus divided by the number of user utterances.

## 6.1 Results

Figure 1 shows the results of our evaluation. We see that the Bigram model is weak on both resources. The results of the String Goal model suggest that, even using the generous evaluation we do here, there

Figure 1: Heldout probability of the two resources for varying percentages of training dialogs. Note that while the percentages match across resources, Let’s Go is much larger and thus the absolute numbers of dialogs are different, which explains the better performance on Let’s Go.

is much variability due to synonymy and recognition errors which string goals are unable to capture (in contrast to our Topic Goal model). The Topic Goal model explains this much more easily by grouping commonly co-occurring values into the same topic. Table 3 shows the perplexities corresponding to the performances with 100% training data for all acts and just PROVIDE acts (perplexity is  $2^{-lp}$  where  $lp$  is the log probability). Improvements are more apparent when we compute the probability over PROVIDE acts alone, which the models are designed to handle. And since perplexity is not on a log scale, the differences are more pronounced. The Act model, which is a bigram model over  $\{\text{ACT}, \text{slot}\}$  pairs alone excluding the values, demonstrates the vast discrepancy in uncertainty between the full problem and the valueless prediction problem. We note that the perplexity of our Act model on Communicator is comparable to that of Georgila et al. (2006).

## 6.2 Example Simulator Behaviour

In this section we give examples of our Topic Goal model simulator in generation mode, which corresponds to sampling from the induced model.

$d$	$z_{dest\_city}$ [probability]	proportion of samples	user utterance given topic $z_{dest\_city}$ and machine utterance REQUEST_INFO $dest\_city$
1	<b>Norfolk Virginia</b> [0.562]	0.264	PROVIDE_INFO $dest\_city$ <b>Norfolk Virginia</b>
	<b>Norfolk</b> [0.234]	0.111	PROVIDE_INFO $dest\_city$ <b>Norfolk</b>
	<b>Newark Virginia</b> [0.088]	0.039	PROVIDE_INFO $dest\_city$ <b>Newark Virginia</b>
	<b>Virginia Beach</b> [0.0412]	0.028	PROVIDE_INFO $orig\_city$ <b>Las Vegas Nevada</b>
	<b>Newark</b> [0.040]	0.028	NO_ANSWER <i>null no</i>
		0.025	COMMAND <i>start_over start over</i>
2	<b>Chicago</b> [0.350]	0.164	PROVIDE_INFO $dest\_city$ <b>Chicago</b>
	<b>Chicago Illinois</b> [0.182]	0.082	PROVIDE_INFO $dest\_city$ <b>Chicago Illinois</b>
	<b>Duluth Minnesota</b> [0.124]	0.057	PROVIDE_INFO $dest\_city$ <b>New Orleans</b>
	<b>New Orleans</b> [0.122]	0.055	PROVIDE_INFO $dest\_city$ <b>Duluth Minnesota</b>
	<b>New Orleans Louisiana</b> [0.085]	0.039	PROVIDE_INFO $dest\_city$ <b>New Orleans Louisiana</b>
		0.028	NO_ANSWER <i>null no</i>
3	<b>Anchorage</b> [0.539]	0.252	PROVIDE_INFO $dest\_city$ <b>Anchorage</b>
	<b>Anchorage Alaska</b> [0.148]	0.072	PROVIDE_INFO $dest\_city$ <b>Anchorage Alaska</b>
	<b>Jacksonville Florida</b> [0.124]	0.056	PROVIDE_INFO $dest\_city$ <b>Jacksonville Florida</b>
	<b>Great Anchorage Alaska</b> [0.098]	0.048	PROVIDE_INFO $dest\_city$ <b>Great Anchorage Alaska</b>
	<b>Duluth Minnesota</b> [0.057]	0.047	PROVIDE_INFO $orig\_city$ <b>Hartford Connecticut</b>
		0.026	PROVIDE_INFO $dest\_city$ <b>Duluth Minnesota</b>

Table 4: Examples of sampling from the topic goal model. Left: top 5 strings (with probabilities) sampled from topics for three different dialogs  $d$ . Right: top 6 utterances (plus fraction of samples in 10,000) generated in response to the machine utterance “REQUEST\_INFO  $dest\_city$ ” and conditioned on the topic  $z_{dest\_city}$ .

Our examples are drawn from the model induced for the Communicator data. Sampling from standard distributions can be implemented following the algorithms in Bishop (2006) and other statistical resources. Utterances are sampled by sampling ACT, *slot* pairs from the distribution  $p(a_i, s_i | m_{i-1})$  (drawing a value from a multinomial distribution). If we sample a PROVIDE\_INFO act, we check whether we have sampled a topic for the corresponding slot thus far in the dialog. If not, we sample one by drawing a topic indicator from  $p(z_s) = \frac{\gamma_{rz}}{\gamma_{\bullet\bullet}}$  and then drawing a multinomial distribution over strings from the Dirichlet posterior corresponding to  $z$ . Once the topic for the slot is set, we sample **values** as draws from the fixed multinomial and add these to the ACT, *slot* pair.

Table 4 shows some examples drawn from the model. For each row in the table (corresponding to a new dialog  $d$ ), we sample a topic for the *dest\_city* and *orig\_city* as needed, and sample 10000 utterances given that topic. The left hand side of the table shows the top five strings in the sampled topic,

while the right hand side shows the top six utterances in response to REQUEST\_INFO  $dest\_city$ . Note that the proportion of utterances on the right does not match the probability of the values on the left because of the presence of other user acts besides PROVIDE  $dest\_city$ .

## 7 Evaluating Model Consistency

Having shown in the previous section that our Topic Goal model is a much better predictor of heldout data than the String Goal model or Bigram model, we now turn to a demonstration of the model’s capturing of consistency.

In the face of value synonymy and ASR errors, we define *inconsistent* dialogs to be ones that are locally coherent but lack the structure of a real dialog from one turn to the next. We then suggest that an appropriate task for consistent models is distinguishing between consistent and inconsistent dialogs.

To test this hypothesis, we devise the following classification problem: can we discriminate between

Baseline	Dialog length (turns)
	Mean, standard deviation, min and max acts per turn
	Presence of special machine acts (flight offer and confirm)
	Presence of user acts (provide a dest city and arrival city)
String Consistency	Proportion of acts which were provides
	Did the user provide inconsistent information about dest city?
	Did the user provide inconsistent information about orig city?
Topic Model	Ranked list of posterior probabilities of top 50 topics
	Normalised probability of dialog for topic model

Table 5: Feature sets for consistency experiments

real dialogs and those generated by randomly sampling turns from different dialogs? In this section we induce classifiers over various feature sets to demonstrate that we can, and that the Topic Goal model contains far more useful information in this regard than string-based consistency features. (The bigram model by definition provides no help here, since the units of which dialogs consist contain the entire window of context used for the bigram model).

We take our training and development data from the Communicator corpus in the previous section, and create a classification problem as follows: real dialogs form positive examples in the classification problem. To create negative examples, we sample {machine, user} turns at random from the appropriate resource. We keep a histogram over real dialog lengths, and sample a number of turns for our “fake” dialogs proportional to this histogram. We then sample this many turns from the frequency distribution over turns in the real data, and create exactly as many dialogs in this fashion as real dialogs in the data. The result is an equal number of dialogs comprised of real turns, of (expected) real length, but where the sequence of turns is highly unlikely to be coherent given the random sampling. The classification problem is thus far from trivial. We do this from our training data to produce data with which to train the classifier, and from our development data to provide test instances. This gives rise to 2500 training instances, and 500 test instances.

We learn linear SVMs with various features described in Table 6. These feature sets are designed to capture different aspects of consistency: the baseline features are intended to capture surface level features of the dialogs, inspired by (Schatzmann et

al., 2005) where they provide trivial separation of real from simulated dialogs. However, our setting is different: we do not seek to tell real dialogs from fully simulated ones, but real dialogs from scrambled versions of real dialogs. In addition to length-based features, we add binary presence indicator for several user and machine acts highly correlated with the completion of dialogs, as well as for acts which indicate the provision of information and the proportion of all acts occupied by these. The table gives a complete list of these Baseline (B) features.

We derive a second set of features intended to replicate the utility of string-based goals: we set up binary features to fire if contradictory information is provided for the slots over the course of the dialog. These are our String Consistency (SC) features.

Finally, we use our topic-model simulator to derive consistency features. Our features are the posterior distribution over topics for each slot given that dialog. Our topics are induced from the real training dialogs, and their posterior probabilities computed for all dialogs relative to this model. We take posterior probabilities of the fifty most probable topics for each of the *dest\_city* and *orig\_city* slots as features, as well as the normalised log probability of the dialog (the log probability divided by the number of user utterances). These form our Topic Model (TM) features.

Our classifiers are linear SVMs, and we use libsvm (Chang and Lin, 2011), scaling features to the range  $[0 - 1]$ . All other parameters are left at their defaults.

Feature Set	Accuracy
Baseline (B)	74.34 $\pm$ 3.77
String Consistency (SC)	63.60 $\pm$ 4.27
B + SC	77.63 $\pm$ 3.58
Topic Model (TM)	79.61 $\pm$ 3.44
B + SC + TM	85.96 $\pm$ 2.89

Table 6: Performances for the classifiers. Errors are 95% intervals to the accuracies assuming they are parameters to a binomial distribution

## 7.1 Results

The results of the classifiers are shown in Table 5. Since we have an equally balanced binary classification task, accuracy is the most appropriate metric. Here we see that the baseline and string consistency features have roughly the same discriminatory potential, and their union produces a slight improvement. The topic model features are far superior to this, and the union of all three sets gives a further improvement.

These results demonstrate that our model encodes notions of consistency which go substantially beyond those defined at the level of strings. Features defined over the latent topic goal space substantially improve performance in a difficult discrimination task, demonstrating that our model captures an important notion of how real dialogs appear that is not shared by the other models we consider.

## 8 Concluding Remarks and Future Work

This paper presents a fully generative goal driven user simulator, the first to merge both consistency and variability within a fully probabilistic framework. We evaluate our model on two task-based dialog domains, Let’s Go and Communicator, and find it to outperform both a simple bigram model and an upper bound on probability models where the strings are represented as goals, in terms of the probability the model assigns to heldout dialogs.

We then move on to show that features derived from the model lead to substantial improvement in detecting real dialogs from those where the turns have been selected at random from all turns in the training data: this is a fairly difficult task, but our model allows significant improvement over strong and sensible baselines.

Our model could be extended in a number of ways. It could be improved to incorporate noise resulting from the decisions made by the semantic parser. Another possible improvement is to explore the effects of introducing dependency between the slots in the user goal, which would enforce more plausible values pairings and would potentially improve the simulator’s performance. The effects of a dependence assumption between the different utterances occurring in a single user turn under the act model can also be explored. We would also like to use our simulator to train a POMDP-based dialog manager using a form of reinforcement learning.

## Abstract

Incremental processing allows system designers to address several discourse phenomena that have previously been somewhat neglected in interactive systems, such as backchannels or barge-ins, but that can enhance the responsiveness and naturalness of systems. Unfortunately, prior work has focused largely on deterministic incremental decision making, rendering system behaviour less flexible and adaptive than is desirable. We present a novel approach to incremental decision making that is based on *Hierarchical Reinforcement Learning* to achieve an interactive optimisation of Information Presentation (IP) strategies, allowing the system to generate and comprehend backchannels and barge-ins, by employing the recent psycholinguistic hypothesis of *information density (ID)* (Jaeger, 2010). Results in terms of average rewards and a human rating study show that our learnt strategy outperforms several baselines that are not sensitive to ID by more than 23%.

## 1 Introduction

Recent work on incremental systems has shown that adapting a system's turn-taking behaviour to be more human-like can improve the user's experience significantly, based on incremental models of automatic speech recognition (ASR) (Baumann et al., 2011), dialogue management (Buss et al., 2010), and speech generation (Skantze and Hjalmarsson, 2010). All of these approaches are based on the same general abstract architecture of incremental processing (Schlangen and Skantze, 2011). While this architecture offers inherently incremental mechanisms to

update and revise input hypotheses, it is affected by a number of drawbacks, shared by deterministic models of decision making in general: they rely on hand-crafted rules which can be time-consuming and expensive to produce, they do not provide a mechanism to deal with uncertainty introduced by varying user behaviour, they are unable to generalise and adapt flexibly to unseen situations, and they do not use automatic optimisation. Statistical approaches to incremental processing that address some of these problems have been suggested by Raux and Eskenazi (2009), who use a cost matrix and decision theoretic principles to optimise turn-taking in a dialogue system under the constraint that users prefer no gaps and no overlap at turn boundaries. Also, DeVault et al. (2009) use maximum entropy classification to support responsive overlap in an incremental system by predicting the completions of user utterances. Selfridge et al. (2011) use logistic regression models to predict the stability and accuracy of incremental speech recognition results to enhance performance without causing delay. For related work on (deterministic) incremental language generation, please see (Kilger and Finkler, 1995; Purver and Otsuka, 2003).

Recent years have seen a number of data-driven approaches to interactive systems that automatically adapt their decisions to the dialogue context using Reinforcement Learning (Levin et al., 2000; Walker, 2000; Young, 2000; Singh et al., 2002; Pietquin and Dutoit, 2006; Henderson et al., 2008; Cuayáhuitl et al., 2010; Thomson, 2009; Young et al., 2010; Lemon, 2011; Janarthnam and Lemon, 2010; Rieser et al., 2010; Cuayáhuitl and Dethlefs,

2011; Dethlefs and Cuayáhuitl, 2011). While these approaches have been shown to enhance the performance and adaptivity of interactive systems, unfortunately none of them has yet been combined with incremental processing.

In this paper, we present a novel approach to incremental decision making for output planning that is based on Hierarchical Reinforcement Learning (HRL). In particular, we address the problem of optimising IP strategies while allowing the system to generate and comprehend backchannels and barge-ins based on a partially data-driven reward function. Generating backchannels can be beneficial for grounding in interaction. Similarly, barge-ins can lead to more efficient interactions, e.g. when a system can clarify a bad recognition result immediately before acting based on a misrecognition.

A central concept to our approach is Information Density (ID) (Jaeger, 2010), a psycholinguistic hypothesis that human utterance production is sensitive to a uniform distribution of information across the utterance. This hypothesis has also been adopted for low level output planning recently, see e.g. Rajkumar and White (2011). Our results in terms of average rewards and a human rating study show that a learning agent that is sensitive to ID can learn when it is most beneficial to generate feedback to a user, and outperforms several other agents that are not sensitive to ID.

## 2 Incremental Information Presentation

### 2.1 Information Presentation Strategies

Our example domain of application is the Information Presentation phase in an interactive system for restaurant recommendations, extending previous work by Rieser et al. (2010). This previous work incrementally constructs IP strategies according to the predicted user reaction, whereas our approach focuses on whether and when to generate backchannels and barge-ins and how to react to user barge-ins in the context of dynamically changing input hypotheses. We therefore implement a simplified version of Rieser et al.'s model. Their system distinguished two steps: the selection of an IP strategy and the selection of attributes to present to the user. We assume here that the choice of attributes is determined by matching the types specified in the user in-

put, so that our system only needs to choose a strategy for presenting its results. Attributes include *cuisine*, *food quality*, *location*, *price range* and *service quality* of a restaurant. The system then performs a database lookup and chooses among three main IP strategies *summary*, *comparison*, *recommendation* and several ordered combinations of these. Please see Rieser et al. (2010) for details. Table 1 shows examples of the main types of IP strategies that we generate.

### 2.2 Backchannels and Barge-ins

An important advantage of incremental processing can be the increased reactivity of systems. In this paper, we focus on the phenomena of backchannels and barge-ins that can act as feedback in an interaction for both user and system. Figure 1 shows some examples. *Backchannels* can often be interpreted as signals of grounding. Coming from the user, the system may infer that the user is following the presentation of information or is confirming a piece of information without trying to take the turn. Similarly, we can allow a system to generate backchannels to the user to confirm that it understands the user's preferences, i.e. receives high confidence scores from the ASR module. An important decision for a dialogue system is then *when to generate a backchannel?*

*Barge-ins* typically occur in different situations. The user may barge-in on the system to correct an ASR error (such as 'Italian' instead of 'Indian' in Figure 1) or the system may want to barge-in on the user to confirm a low-confidence ASR hypothesis so as to be able to start an immediate database look up for results. In the former case, the user barging-in on the system, we assume that the system has two choices: *yielding the turn* to the user, or *trying to keep* the turn. In the latter case, the system barging-in on the user, the system would have to decide *if and when it would be beneficial to barge-in* on a user utterance. In the following sections, we will develop a model of dialogue optimisation that can address these question based on Hierarchical RL that optimises system behaviour based on trade-offs defined in terms of ID.

Type	Example
<b>Comparison</b>	The restaurant <i>Roma</i> is in the medium price range, but does not serve excellent food. The restaurants <i>Firenze</i> and <i>Verona</i> both have great food but are more expensive. The restaurant <i>Verona</i> has good service, too.
<b>Recommendation</b>	Restaurant <i>Verona</i> has the best overall match with your query. It is a bit more expensive, but has great food and service.
<b>Summary</b>	I found 24 Italian restaurants in the city centre that match your query. 11 of them are in the medium price range, 5 are cheap and 8 are expensive.

Table 1: Examples of IP as a *comparison*, *recommendation* and *summary* for a user looking for Italian restaurants in the city centre that have a good price for value.

### Backchannel 1 (the system backchannels)

**USR** I want Italian food [500 ms] in the city centre...

**SYS** uh-huh

**SYS** OK. I found 24 Italian restaurants in the city centre. The restaurant *Roma* is in the medium price range, but does not have great food. The restaurants *Firenze* and *Verona* ...

### Backchannel 2 (the user backchannels)

**USR** I want Italian food in the centre of town ...

**SYS** OK. I found 35 central Italian restaurants ...

**USR** OK.

**SYS** The restaurant *Verona* has great food but is also a bit expensive. The *Roma* is cheaper, but not as central as *Verona* ...

### Barge-ins 1 (the user barges-in on system)

**USR** I want Italian food in the centre of town ...

**SYS** I found 35 Indian ...

**USR** Not Indian, I want Italian.

**SYS** OK, Italian ...

**SYS** I have 24 Italian restaurants ...

### Barge-ins 2 (the system barges-in on user)

**USR** I need an Italian restaurant that is located ...

**SYS** I'm sorry. Did you say

Indian or Italian?

**USR** I said Italian. And in the centre of town please.

**SYS** OK, let me see. I have 24 Italian restaurants ...

Figure 1: Example phenomena generated with the learnt policy. The agent has learnt to produce backchannels and barge-ins at the appropriate moment and alternative strategies to deal with user barge-ins.

## 3 Information Theory

Information Theory as introduced by Shannon (1948) is based on two main concepts: a *communication channel* through which information is transferred in bits and the *information gain*, i.e. the information load that each bit carries. For natural language, the assumption is that people aim to com-

municate according to the channel's capacity, which corresponds to the hearer's capacity in terms of cognitive load. If they go beyond that, the cognitive load of the listener gets too high. If they stay (far) below, too little information is transferred per bit (i.e., the utterance is inefficient or uninformative). The information gain of each word, which is indicative of how close we are to the channel's capacity, can be computed using entropy measures.

### 3.1 Information Density

Psycholinguistic research has presented evidence for users distributing information across utterances uniformly, so that each word is carrying roughly the same amount of information. This has been observed for phonetic phenomena based on words (Bell et al., 2003) and syllables (Aylett and Turk, 2004), and for syntactic phenomena (Levy and Jaeger, 2007; Jaeger, 2010). Relating ID to likelihood, we can say that the less frequent a word is, the more information it is likely to carry (Jaeger, 2010). For example the word '*the*' often has a high corpus frequency but a low ID.

The ID is defined as the log-probability of an event (i.e. a word) (Shannon, 1948; Levy and Jaeger, 2007), so that for an utterance  $u$  consisting of the word sequence  $w_1 \dots w_{i-1}$ , we can compute the ID at each point during the utterance as:

$$\log \frac{1}{P(u)} = \sum_{i=1}^n \log \frac{1}{P(w_i | w_1 \dots w_{i-1})} \quad (1)$$

While typically the context of a word is given by all preceding words of the utterance, we follow Genzel and Charniak (2002) in restricting our computation to tri-grams for computability reasons. Given a

language model of the domain, we can therefore optimise ID in system-generated discourse, where we treat ID as “an optimal solution to the problem of *rapid yet error-free communication* in a noisy environment” (Levy and Jaeger (2007), p.2). We will now transfer the notion of ID to IP and investigate the distribution of information over user restaurant queries.

### 3.2 Information Density in User Utterances

We aim to use ID for incremental IP in two ways: (1) to estimate the best moment for generating backchannels or barge-ins to the user, and (2) to decide whether to yield or keep the current system turn in case of a user barge-in. While we do not have specific data on human barge-in behaviour, we know from the work of (Jaeger, 2010), e.g., that ID influences human language production. We therefore hypothesise a relationship between ID and incremental phenomena. A human-human data collection is planned for the near future.

To compute the ID of user and system utterances at each time step, we estimated an  $n$ -gram language model (using Kneser-Ney smoothing) based on a transcribed corpus of human subjects interacting with a system for restaurant recommendations of Rieser et al. (2011).<sup>1</sup> The corpus contained user utterances as exemplified in Figure 1 and allowed us to compute the ID at any point during a user utterance.<sup>2</sup> In this way, we can estimate points of low density which may be eligible for a barge-in or a backchannel. Figure 2 shows some example utterances drawn from the corpus and their ID including the first sentence from Figure 1. These examples were typical for what could generally be observed from the corpus. We see that while information is transmitted with varying amounts of density, the main bits of information are transmitted at a scale between 2 and 7.

Due to a lack of human data for the system utterances, we use the same corpus data to compute the ID of system utterances.<sup>3</sup> The learning agent can use

<sup>1</sup>Available at <http://www.macs.hw.ac.uk/ilabarchive/classicproject/data/login.php>.

<sup>2</sup>Note that our model does not currently handle out-of-domain words. In future work, we will learn when to seek clarification.

<sup>3</sup>We plan a data collection of such utterances for the future,

Figure 2: Information Density for example utterances, where peaks indicate places of high density.

this information to consider the trade-off of yielding a current turn to the user or trying to keep it, e.g., in case of a user barge-in given the ID of its own turn and of the user’s incoming turn. Such decisions will be made incrementally in our domain given dynamically changing hypotheses of user input.

## 4 Incremental Utterance Optimisation

To optimise incremental decision making for an interactive system given the optimisation measure of ID, we formalise the dialogue module as a Hierarchical Reinforcement Learning agent and learn an optimal action policy by mapping states to actions and optimising a long-term reward signal. The dialogue states can be seen as representing the system’s knowledge about the task, the user and the environment. The dialogue actions correspond to the system’s capabilities, such as *present the results* or *barge-in on the user*. They also handle incremental updates in the system. In addition, we need a transition function that specifies the way that actions change the environment (as expressed in the state representation) and a reward function which specifies a numeric value for each action taken. In this way, decision making can be seen as a finite sequence of states, actions and rewards  $\{s_0, a_0, r_1, s_1, a_1, \dots, r_{t-1}, s_t\}$ , where the goal is to induce an optimal strategy automatically using Reinforcement Learning (RL) (Sutton and Barto, 1998).

We used Hierarchical RL, rather than flat RL, because the latter is affected by the *curse of dimensionality*, the fact that the state space grows exponentially according to the state variables taken into account. This affects the scalability of flat RL agents

but for now make the assumption that using the corpus data is informative since they are from the same domain.

and limits their application to small-scale problems. Since timing is crucial for incremental approaches, where processing needs to be fast, we choose a hierarchical setting for better scalability. We denote the hierarchy of RL agents as  $M_j^i$  where the indexes  $i$  and  $j$  only identify an agent in a unique way, they do not specify the execution sequence of subtasks, which is subject to optimisation. Each agent of the hierarchy is defined as a Semi-Markov Decision Process (SMDP) consisting of a 4-tuple  $\langle S_j^i, A_j^i, T_j^i, R_j^i \rangle$ . Here,  $S_j^i$  denotes the set of states,  $A_j^i$  denotes the set of actions, and  $T_j^i$  is a probabilistic state transition function that determines the next state  $s'$  from the current state  $s$  and the performed action  $a$ .  $R_j^i(s', \tau | s, a)$  is a reward function that specifies the reward that an agent receives for taking an action  $a$  in state  $s$  lasting  $\tau$  time steps (Dietterich, 1999). Since actions in SMDPs may take a variable number of time steps to complete, the variable  $\tau$  represents this number of time steps. The organisation of the learning process into discrete time steps allows us to define incremental hypothesis updates as state updates and transitions in an SMDP. Whenever conditions in the learning environment change, such as the recogniser’s best hypothesis of the user input, we represent them as transitions from one state to another. At each time step, the agent checks for changes in its state representation and takes the currently best action according to the new state. The best action in an incremental framework can also include generating a *backchannel* to the user to indicate the status of grounding or *barging-in* to confirm an uncertain piece of information. Once information has been presented to the user, it is *committed* or *realised*. Realised information is represented in the agent’s state, so that it can monitor its own output.

Actions in a Hierarchical Reinforcement learner can be either primitive or composite. The former are single-step actions that yield single rewards, and the latter are multi-step actions that correspond to SMDPs and yield cumulative rewards. Decision making occurs at any time step of an SMDP: after each single-step action, we check for any updates of the environment that require a system reaction or change of strategy. If no system action is required (e.g. because the user is speaking), the system can

decide to do nothing. The goal of each SMDP is to find an optimal policy  $\pi^*$  that maximises the reward for each visited state, according to

$$\pi_j^{*i}(s) = \arg \max_{a \in A} Q_j^{*i}(s, a), \quad (2)$$

where  $Q_j^i(s, a)$  specifies the expected cumulative reward for executing action  $a$  in state  $s$  and then following  $\pi^*$ . We use HSMQ-Learning to induce dialogue policies, see (Cuayáhuitl, 2009), p. 92.

## 5 Experimental Setting

### 5.1 Hierarchy of Learning Agents

The HRL agent in Figure 3 shows how the tasks of (1) dealing with incrementally changing input hypotheses, (2) choosing a suitable IP strategy and (3) presenting information, are connected. Note that we focus on a detailed description of models  $M_{0...3}^1$  here, which deal with barge-ins and backchannels and are the core of this paper. Please see Dethlefs et al. (2012) for details of an RL model that deals with the remaining decisions.

Briefly, model  $M_0^0$  deals with dynamic input hypotheses. It chooses when to listen to an incoming user utterance ( $M_3^1$ ) and when and how to present information ( $M_{0...2}^1$ ) by calling and passing control to a child subtask. The variable ‘incrementalStatus’ characterises situations in which a particular (incremental) action is triggered, such as a floor holder ‘*let me see*’, a correction or self-correction. The variable ‘presStrategy’ indicates whether a strategy for IP has been chosen or not, and the variable ‘userReaction’ shows the user’s reaction to an IP episode. The ‘userSilence’ variable indicates whether the user is speaking or not. The detailed state and action space of the agents is given in Figure 4. We distinguish actions for Information Presentation (IP), actions for attribute presentation and ordering (Slot-ordering), and incremental actions (Incremental).

Models  $M_{0...2}^1$  correspond to different ways of presenting information to the user. They perform attribute selection and ordering and then call the child agents  $M_{0...4}^2$  for attribute realisation. Whenever a user barges in over the system, these agents will decide to either yield the turn to the user or to try and keep the turn based on information density. The variables representing the status of the cuisine,

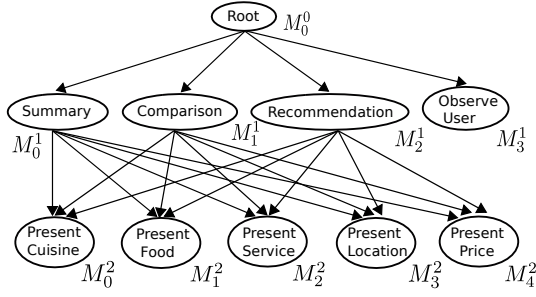

Figure 3: Hierarchy of learning agent for incremental Information Presentation and Slot Ordering.

food, location, price and service of restaurants indicate whether the slot is of interest to the user (we assume that 0 means that the user does not care about this slot), and what input confidence score is currently associated with the value of the slot. For example, if our current best hypothesis is that the user is interested in Indian restaurants, the variable 'statusCuisine' will have a value between 1-3 indicating the strength of this hypothesis. Once slots have been presented to the user, they are *realised* and can only be changed through a correction or self-correction.

Model  $M_3^1$  is called whenever the user is speaking. The system's main choice here is to remain silent and listen to the user or barge-in to request the desired cuisine, location, or price range of a restaurant. This can be beneficial in certain situations, such as when the system is able to increase its confidence for a slot from 'low' to 'high' through barging-in with a direct clarification request, e.g. 'Did you say Indian?' (and thereby saving several turns that may be based on a wrong hypothesis). This can also be harmful in certain situations, though, assuming that users have a general preference for not being barged-in on. The learning agent will need to learn to distinguish these situations. This agent is also responsible for generating backchannels and will over time learn the best moments to do this.

Models  $M_{0..4}^2$  choose surface forms for presentation to the user from hand-crafted templates. They are not the focus of this paper, however, and therefore not presented in detail. The state-action space size of this agent is roughly 1.5 million.<sup>4</sup> The agent

<sup>4</sup>Note that a flat RL agent, in contrast, would need  $8 \times 10^{25}$  million state-actions to represent this problem.

reaches its goal state (defined w.r.t. the state vari-

ables in Fig. 4) when an IP strategy has been chosen and all information has been presented.

## 5.2 The Simulated Environment

For a policy to converge, a learning agent typically needs several thousand interactions in which it is exposed to a multitude of different circumstances. For our domain, we designed a simulated environment with three main components addressing IP, incremental input hypotheses and ID. Using this simulation, we trained the agent for 10 thousand episodes, where one episode corresponds to one recommendation dialogue.

### 5.2.1 Information Presentation

To learn a good IP strategy, we use a user simulation<sup>5</sup> by Rieser et al. (2010) which was estimated from human data and uses bi-grams of the form  $P(a_{u,t}|IP_{s,t})$ , where  $a_{u,t}$  is the predicted user reaction at time  $t$  to the system’s IP strategy  $IP_{s,t}$  in state  $s$  at time  $t$ . We distinguish the user reactions of *select* a restaurant, *addMoreInfo* to the current query to constrain the search, and *other*. The last category is usually considered an undesirable user reaction that the system should learn to avoid. The simulation uses linear smoothing to account for unseen situations. In this way, we can predict the most likely user reaction to each system action. Even though previous work has shown that  $n$ -gram-based simulations can lead to dialogue inconsistencies, we assume that for the present study this does not present a problem, since we focus on generating single utterances and on obtaining user judgements for single, independent utterances.

### 5.2.2 Input Hypothesis Updates

While the IP strategies can be used for incremental and non-incremental dialogue, the second part of the simulation deals explicitly with the dynamic environment updates that the system will need to be sensitive to in an incremental setting. We assume that for each restaurant recommendation, the user has the option of filling any or all of the attributes *cuisine*, *food quality*, *location*, *price range* and *service quality*. The possible values of each attribute and possible confidence scores for each value are

<sup>5</sup>The simulation data are available from [www.classic-project.org](http://www.classic-project.org).

shown in Table 2. A score of 0 means that the user does not care about the attribute, 1 means that the system’s confidence in the attribute’s value is low, 2 that the confidence is medium, and 3 means that the confidence is high. A value of 4 means that the attribute has already been *realised*, i.e. communicated to the user. At the beginning of a learning episode, we assign each attribute a possible value and confidence score with equal probability. For food and service quality, we assume that the user is never interested in bad food or service. Subsequently, confidence scores can change at each time step. In future work these transition probabilities will be estimated from a data collection, though the following assumptions are realistic based on our experience. We assume that a confidence score of 0 changes to any other value with a likelihood of 0.05. A confidence score of 1 changes with a probability of 0.3, a confidence score of 2 with a probability of 0.1 and a confidence score of 3 with a probability of 0.03. Once slots have been realised, their value is set to 4. They cannot be changed then without an explicit correction. We also assume that realised slots change with a probability of 0.1. If they change, we assume that half of the time, the user is the origin of the change (because they changed their mind) and half of the time the system is the origin of the change (because of an ASR or interpretation error). Each time a confidence score is changed, it has a probability of 0.5 for also changing its value. The resulting input to the system are data structures of the form *present(cuisine=Indian), confidence=low*. The probability of observing this data structure in our simulation is  $0.1$  (for Indian)  $\times$   $0.2$  (for low confidence) =  $0.02$ . Its probability of changing to *present(cuisine=italian), confidence=high* is  $0.1$  (for changing from low to medium)  $\times$   $0.05$  (for changing from Indian to Italian) =  $0.005$ .

### 5.2.3 Information Density Updates

We simulate ID of user utterances based on probabilistic context-free grammars (PCFG) that were automatically induced from the corpus data in Section 3.2 using the ABL algorithm (van Zaanen, 2000). This algorithm takes a set of strings as input and computes a context-free grammar as output by aligning strings based on Minimum Edit Distance. We use the  $n$ -gram language models trained earlier to

Attribute	Values	Confidence
<b>Cuisine</b>	Chinese, French, German, Indian, Italian, Japanese, Mexican, Scottish, Spanish, Thai	0, 1, 2, 3, 4
<b>Quality</b>	bad, adequate, good, very good	0, 1, 2, 3, 4
<b>Location</b>	7 distinct areas of the city	0, 1, 2, 3, 4
<b>Price</b>	cheap, good-price-for-value, expensive, very expensive	0, 1, 2, 3, 4
<b>Service</b>	bad, adequate, good, very good	0, 1, 2, 3, 4

Table 2: User goal slots for restaurant queries with possible values and confidence scores.

add probabilities to grammar rules. We use these PCFGs to simulate user utterances to which the system has to react. They can be meaningful utterances such as ‘*Show me restaurants nearby*’ or less meaningful fragments such as ‘*um let me see, do you...hm*’. The former type is more frequent in the data, but both types can be simulated along with their ID (clearly, the first type is more dense than the second).

In addition to simulating user utterances, we hand-crafted context-free grammars of system utterances and augmented them with probabilities estimated using the same user corpus data as above (where again, we make the assumption that this is to some extent feasible given the shared domain). We use the simulated system utterances to compute varying degrees of ID for the system.

Both measures, the ID of user and system utterances, can inform the system during learning to balance the trade-off between them for generating and receiving backchannels and barge-ins.

### 5.3 A Reward Function for Incremental Dialogue Based on Information Density

To train the HRL agent, we use a partially data-driven reward function. For incremental IP, we use rewards that are based on human intuition. The

agent receives

$$R = \begin{cases} +100 & \text{if the user selects an item,} \\ 0 & \text{if the user adds further constraints to the search,} \\ -100 & \text{if the user does something else or a self-correction,} \\ -0.5 & \text{for the system holding a turn,} \\ -1 & \text{otherwise.} \end{cases}$$

The agent is encouraged to choose those sequences of actions that lead to the user selecting a restaurant as quickly as possible. If the agent is not sure what to say (because planning has not finished), it can generate a floor holding marker, but should in any case avoid a self-correction due to having started speaking too early.

The remaining rewards are based on ID scores computed incrementally during an interaction. The agent receives the following rewards, where  $\text{infoDensity}(\text{Usr})$  and  $\text{infoDensity}(\text{Sys})$  refer to the ID of the current user and system utterance, respectively, as defined in Equation 1.

$$R = \begin{cases} -\text{infoDensity}(\text{Usr}) & \text{for keeping a turn,} \\ & \text{barging-in or} \\ & \text{a backchannel,} \\ -\text{infoDensity}(\text{Sys}) & \text{for yielding a turn.} \end{cases}$$

These two measures encourage the agent to consider the trade-offs between its own ID and the one transmitted by an incoming user utterance. Barging-in on a user utterance at a low ID point then yields a small negative reward, whereas barging-in on a user utterance at a high ID point yields a high negative reward. Both rewards are negative because barging-in on the user always contains some risk. Similarly, keeping a turn over a non-dense user utterance receives a smaller negative reward than keeping it over a dense user utterance. A reward of  $-2$  is assigned for barging-in over a user utterance fragment with a falling ID to reflect results from a qualitative study of our corpus data: humans tend to barge-in *between* information peaks, so that a barge-in to clarify a low-confidence slot appears immediately before the ID is rising again for a new slot. The exact best moment for barge-ins and backchannels to occur will be subject to optimisation.

## 6 Experimental Results

The agent learns to barge-in or generate backchannels to users at points where the ID is low but rising. In particular, the agent learns to barge-in *right before* information density peaks in an incoming user utterance to clarify or request slots that are still open from the previous information density peak. If a user has specified their desired cuisine type but the system has received a low ASR confidence score for it, it may barge-in to clarify the slot. This case was illustrated in the last example in Figure 1, where the system clarified the previous (cuisine) slot (which is associated with a high ID) just before the user specifies the location slot (which again would have a high ID). The main benefit the system can gain through clarification barge-ins is to avoid self-corrections when having acted based on a low ASR confidence, leading to more efficient interactions.

The system learns to generate backchannels *after* information peaks to confirm newly acquired slots that have a high confidence. An example is shown in the first dialogue fragment in Figure 1.

In addition, the system learns to yield its current turn to a user that is barging-in if its own ID is low, falling or rising, or if the ID of the incoming user utterance is high. If the system’s own ID is high, but the user’s is not, it will try to keep the turn.<sup>6</sup> This is exemplified in the third dialogue fragment in Figure 1.

We compare our learnt policy against two baselines. **Baseline 1** was designed to always generate barge-ins *after* an information peak in a user utterance, i.e. when ID has just switched from *high* to *falling*. We chose this baseline to confirm that users indeed prefer barge-ins before information peaks rather than at any point of low ID. Baseline 1 yields a turn to a user barge-in if its own ID is low and tries to keep it otherwise. **Baseline 2** generates barge-ins and backchannels randomly and at any point during a user utterance. The decision of yielding or keeping a turn in case of a user barge-in is also random. Both baselines also use HRL to optimise their IP strategy. We do not compare different IP strategies, which has been done in detail by Rieser et al. (2010). All re-

<sup>6</sup>Incidentally, this also helps to prevent the system yielding its turn to a user backchannel; cf. Example 2 in Fig. 1.

Figure 5: Performance in terms of rewards (averaged over 10 runs) for the HRL agent and its baselines.

sults are summarised in Table 3.

### 6.1 Average Rewards over Time

Figure 5 shows the performance of all systems in terms of average rewards in simulation. The learnt policy outperforms both baselines. While the learnt policy and Baseline 1 appear to achieve similar performance, an absolute comparison of the last 1000 episodes of each behaviour shows that the improvement of the HRL agent over Baseline 1 corresponds to 23.42%. The difference between the learnt policy and its baselines is significant at  $p < 0.0001$  according to a paired t-test and has a high effect size of  $r = 0.85$ .

The main reason for these different performances is the moment each system will barge-in. Since Baseline 1 barges-in on users after an information peak, when ID may still be high, it continuously receives a negative reward reflecting the user preference for late barge-ins. As a result of this continuous negative reward, the agent will then learn to avoid barge-ins altogether, which may in turn lead to less efficient interactions because low confidence ASR scores are clarified only late in the interaction.

The main problem of the random barge-ins of Baseline 2 is that users may often have to restart a turn because the system barged-in too early or in the middle of an information peak. In addition, Baseline 2 needs to occasionally self-correct its own utterances because it started to present information too early, when input hypotheses were not yet stable enough to act upon them.

Policy	Average Reward	User Rating (%)
Learnt	55.54 <sup>***</sup>	43% <sup>**</sup>
Baseline 1	45.0 <sup>**</sup>	26%
Baseline 2	1.47	31%

Table 3: Comparison of policies in terms of average rewards and user ratings. \* indicates a significant improvement over Baseline 1 and \*\* over Baseline 2.

## 6.2 Human Rating Study

To confirm our simulation-based results, we conducted a user rating study on the CrowdFlower crowd sourcing platform.<sup>7</sup> Participants were shown user utterances along with three options of barging-in over them. For example: | I want [OPTION 1] Italian food [OPTION 2] in the city [OPTION 3] centre|, where OPTION 1 corresponds to the learnt policy, OPTION 2 to Baseline 2 and OPTION 3 to Baseline 1.

Users were asked to choose one option which they considered the best moment for a barge-in. Participants in the study rated altogether 144 utterances. They preferred the *learnt* system 63 times (43%), Baseline 1 37 times (26%) and Baseline 2 44 times (31%). This is statistically significant at  $p < 0.02$  according to a Chi-Square test ( $\chi^2 = 7.542$ ,  $df = 2$ ). In a separate test, directly comparing the *learnt* policy and Baseline 1, *learnt* was chosen significantly more often than Baseline 1; i.e. 79% of the time (for 127 utterances, using a 1-tailed Sign test,  $p < 0.0001$ ). Finally, *learnt* was directly compared to Baseline 2 and shown to be significantly more often chosen; i.e. 59% of the time (138 utterances, 1-tailed Sign test,  $p < 0.025$ ). These results provide evidence that an optimisation of the timing of generating barge-ins and backchannels in incremental dialogue can be sensitive to fine-grained cues in evolving ID and therefore achieve a high level of adaptivity. Such sensitivity is difficult to hand-craft as can be concluded w.r.t. the performance of Baseline 1, which received similar rewards to *learnt* in simulation, but is surprisingly beaten by the random Baseline 2 here. This indicates a strong human dislike for late barge-ins. The bad performance of Baseline 2 in terms of average rewards was due to the random barge-ins leading to less efficient dialogues.

<sup>7</sup>[www.crowdflower.com](http://www.crowdflower.com)

Regarding user ratings however, Baseline 2 was preferred over Baseline 1. This is most likely due to the timing of barge-ins: since Baseline 2 has a chance of barging-in at earlier occasions than Baseline 1, it may have received better ratings. The evaluation shows that humans care about timing of a barge-in regarding the density of information that is currently conveyed and dislike late barge-ins. ID is then useful in determining when to barge-in. We can therefore further conclude that ID can be a feasible optimisation criterion for incremental decision making.

## 7 Conclusion and Future Work

We have presented a novel approach to incremental dialogue decision making based on *Hierarchical RL* combined with the notion of *information density*. We presented a learning agent in the domain of IP for restaurant recommendations that was able to generate backchannels and barge-ins for higher responsiveness in interaction. Results in terms of average rewards and a human rating study have shown that a learning agent that is optimised based on a partially *data-driven reward function* that addresses information density can learn to decide when and if it is beneficial to barge-in or backchannel on user utterances and to deal with backchannels and barge-ins from the user. Future work can take several directions. Given that ID is a measure influencing human language production, we could replace our template-based surface realiser by an agent that optimises the information density of its output. Currently we learn the agent’s behaviour offline, before the interaction, and then execute it statistically. More adaptivity towards individual users and situations could be achieved if the agent was able to learn from ongoing interactions. Finally, we can confirm the human results obtained from an overhearer-style evaluation in a real interactive setting and explicitly extend our language model to discourse phenomena such as pauses or hesitations to take them into account in measuring ID.

# Mixed Membership Markov Models for Unsupervised Conversation Modeling

Michael J. Paul

Center for Language and Speech Processing

Johns Hopkins University

Baltimore, MD 21218, USA

mpaul@cs.jhu.edu

## Abstract

Recent work has explored the use of hidden Markov models for unsupervised discourse and conversation modeling, where each segment or block of text such as a message in a conversation is associated with a hidden state in a sequence. We extend this approach to allow each block of text to be a mixture of multiple classes. Under our model, the probability of a class in a text block is a log-linear function of the classes in the previous block. We show that this model performs well at predictive tasks on two conversation data sets, improving thread reconstruction accuracy by up to 15 percentage points over a standard HMM. Additionally, we show quantitatively that the induced word clusters correspond to speech acts more closely than baseline models.

## 1 Introduction

The proliferation of social media in recent years has lead to an increased use of informal Web data in the language processing community. With this rising interest in social domains, it is natural to consider models which explicitly incorporate the conversational patterns of social text. Compared to the naive approach of treating conversations as flat documents, models which include conversation structure have been shown to improve tasks such as forum search (Elsas and Carbonell, 2009; Seo et al., 2009), question answering and expert finding (Xu et al., 2008; Wang et al., 2011a), and interpersonal relationship identification (Diehl et al., 2007).

While conversational features may be important, Web-derived corpora are not always annotated with

this information, and the nature of conversations on the Web can vary wildly across domains and venues. Addressing these concerns, there has been recent work with *unsupervised* models of Web conversations based on hidden Markov models (Ritter et al., 2010), where each state corresponds to a conversational class or “act.” Unlike more traditional uses of HMMs in which a single token is emitted per time step, HMM emissions in conversations correspond to entire blocks of text, such that an entire message is generated at each step. Because each time step is associated with a block of variables, we refer to this type of HMM as a *block HMM* (Fig. 1a).

While block HMMs offer a concise model of inter-message structure, they have the limitation that each text block (message) belongs to exactly one class. Many modern generative models of text, in contrast, allow documents to contain many latent classes. For example, topic models such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) assume each document has its own distribution over multiple classes (often called “topics”). For many predictive tasks, topic models outperform single-class generative models such as Naive Bayes. These properties could similarly be desirable in conversation modeling. An email might contain a request, a question, and an answer to a previous question – three distinct dialog acts within a single message. This motivates the desire to allow a message to be a *mixture* of classes.

In this paper, we introduce a new type of model which combines the functionality of topic models, which posit latent class assignments to each individual token, with Markovian sequence models, which

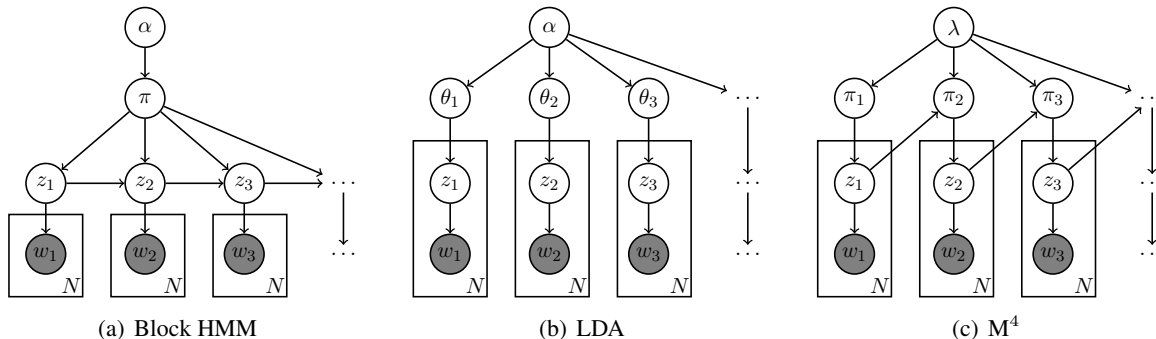

Figure 1: The graphical models for the block HMM (left) where each block of tokens depends on exactly one latent class, LDA (center) where each token individually depends on a latent class, and  $M^4$  (right) where the class distributions are dependent across blocks. Some parameters are omitted for simplicity. This figure depicts the Bayesian variant of the block HMM (Ritter et al., 2010) where the transition distributions  $\pi$  depend on a Dirichlet( $\alpha$ ) prior.

govern the transitions between text blocks in a sequence. We generalize the block HMM approach so that there is no longer a one-to-one correspondence between states in the Markov chain and latent discourse classes. Instead, we allow a state in the HMM to correspond to a mixture of many classes: we refer to this family of models as **mixed membership Markov models** ( $M^4$ ). Instead of defining explicit transition probabilities from one class to another as in a traditional HMM, we define the distribution over classes as a function of the entire histogram of class assignments of the previous text segment. We define our model using the same number of parameters as a standard HMM (§2), and we present a straightforward approximate inference algorithm (§3).

While we introduce a general model, we will focus on the task of unsupervised conversation modeling. Specifically, we build off the Bayesian block HMMs used by Ritter et al. (2010) for modeling Twitter conversations, which will be our primary baseline. After discussing related work (§4), we present experimental results on a set of Twitter conversations as well as a set of threads from CNET discussion forums (§5). We show that  $M^4$  increases thread reconstruction accuracy by up to 15% compared to the HMM of Ritter et al. (2010), and we reduce variation of information against speech act annotations by an average of 18% from HMM and LDA baselines. To the best of our knowledge, this work is the first attempt to quantitatively compare unsupervised models against gold standard speech act annotations.

## 2 $M^4$ : Mixed Membership Markov Models

In this section, we extend the block HMM by introducing mixed membership Markov models ( $M^4$ ).

Under the block HMM, as utilized by Ritter et al. (2010), messages in a conversation flow according to a Markov process, where the words of messages are generated according to language models associated with a state in a hidden Markov model. The intuition is that HMM states should correspond to some notion of a conversation “act” such as QUESTION or ANSWER. The intuition is the same under  $M^4$ , but now each token in a message is given its own class assignment, according to a class distribution for that particular message. A message’s class distribution depends on the class assignments of the previous message, yielding a model that retains sequential dependencies between messages, while allowing for finer grained class allocation than the block HMM. Modeling messages (or more generally, text blocks) as a mixture of multiple classes rather than a single class gives rise to the “mixed membership” property.

In the subsections below, we formalize and analyze this new model.

### 2.1 Structure Assumptions

We first define the discourse structure and terminology we will be assuming. The discourse structure is a directed graph, where nodes correspond to segments of a document (which we will refer to as “blocks” of text), and the edges define the dependencies between them.

Thus, a text *block* is a set of tokens, while a *document* consists of the discourse graph and all blocks associated with it. In the context of modeling conversation threads, which will be the focus of our experiments later, we will assume a block corresponds to a single message in a thread. The parent of a message  $m$  is the message to which it is a response; if a message is not in response to anything in particular, then it has no parent. Any replies to the message  $m$  are the children of  $m$ . The thread as a whole is called a document.

The discourse graph should be acyclic. A directed acyclic graph (DAG) offers a flexible representation of discourse (Rosé et al., 1995), but for simplicity, we will restrict this and assume that each subgraph is a tree; i.e. no message has multiple parents. The graph as a whole may be a forest: for example, someone could write a new message in a conversation that is not directly in reply to any previous message, so this message would not have any parents, and would form the root of a new tree in the forest.

## 2.2 Generative Story

Extending the block HMM, latent classes in  $M^4$  are now associated with each individual token, rather than one class for an entire block. The key difference between the generative process behind  $M^4$  and the block HMM is that the transition distributions are defined with a log-linear model, which uses class assignments in a block as features to define the distribution over classes for the children of that block. Put another way, a state in  $M^4$  corresponds to a class histogram, and transitions between states are functions of the log-linear parameters.

Given a block  $b$ , we will use the notation  $\mathbf{b}$  to denote the block’s feature vector, which consists of the histogram of latent class assignments for the tokens of  $b$ .<sup>1</sup> There are  $K$  classes. Additionally, we assume each feature vector has an extra cell containing an indicator denoting whether the block has no parent – this allows us to learn transitions from a “start” state. We also include a bias feature that is always 1, to learn a default weight for each class. There

<sup>1</sup>One could also use other functions of the class histograms rather than the raw counts themselves. For example, we experimented with binary indicator features (i.e. “does class  $k$  appear anywhere in block  $b$ ?”), but this performed consistently worse in early experiments, and we do not consider this further.

are thus  $K + 2$  features which are used to predict the probability of each of the  $K$  classes. The features are weighted by transition parameters, denoted  $\lambda$ . The random variable  $z$  denotes a latent class, and  $\phi_z$  is a discrete distribution over word types – that is, each class is associated with a unigram language model. The transition distribution over classes is denoted  $\pi$ , which is given in terms of  $\lambda$  and the feature vector of the parent block.

Under this model, a corpus  $\mathcal{D}$  is generated by:

1. For each  $(j, k)$  in the transition matrix  $\Lambda_{K \times K+2}$ :
  - (a) Draw transition weight  $\lambda_{jk} \sim \mathcal{N}(0, \sigma^2)$ .
2. For each class  $j$ :
  - (a) Draw word distribution  $\phi_j \sim \text{Dirichlet}(\omega)$ .
3. For each block  $b$  of each document  $d$  in  $\mathcal{D}$ :
  - (a) Set class probability  $\pi_{bj} = \frac{\exp(\lambda_j^T \mathbf{a})}{\sum_{j'} \exp(\lambda_{j'}^T \mathbf{a})}$  for all classes  $j$ , where  $\mathbf{a}$  is the feature vector for block  $a$ , the parent of  $b$ .
  - (b) For each token  $n$  in block  $b$ :
    - i. Sample class  $z_{(b,n)} \sim \pi_b$ .
    - ii. Sample word  $w_{(b,n)} \sim \phi_z$ .

For each block of text in a document (e.g. each message in a conversation), the distribution over classes  $\pi$  is computed as a function of the feature vector of the block’s parent and the transition parameters (feature weights)  $\Lambda$ . Each  $\lambda_{jk}$  has an intuitive interpretation: a positive value means that the occurrence of class  $k$  in a parent block increases the probability that  $j$  will appear in the next block, while a negative value reduces this probability.

The observed words of each block are generated by repeatedly sampling classes from the block’s distribution  $\pi$ , and for each sampled class  $z$ , a single word is sampled from the class-specific distribution over words  $\phi_z$ . In contrast, under the block HMM, a class  $z$  is sampled once from the transition distribution, and words are repeatedly sampled from  $\phi_z$ .

We place a symmetric Dirichlet prior on each  $\phi$  with concentration parameter  $\omega$ , which smoothes the word distributions, and we place a 0-mean Gaussian prior on each  $\lambda$  parameter, which acts as a regularizer. The graphical diagram is shown in Figure 1 along with the block HMM and LDA. This figure

shows how  $M^4$  combines the sequential dependencies of the block HMM with the token-specific class assignments of LDA.

### 2.3 Discussion

Like the block HMM,  $M^4$  is a type of HMM. A latent sequence under  $M^4$  forms a Markov chain in which a state corresponds to a histogram of classes. (For simplicity, we are ignoring the extra features of the start state indicator and bias in this discussion.) If we assume *a priori* that the length of a block is unbounded, then this state space is  $\mathbb{N}^K$  where  $0 \in \mathbb{N}$ . The probability of transitioning from a state  $\mathbf{b}$  to another state  $\tilde{\mathbf{b}} \in \mathbb{N}^K$  is:

$$P(\mathbf{b} \rightarrow \tilde{\mathbf{b}}) \propto \zeta_N \text{Multinomial}(\tilde{\mathbf{b}}|\pi(\mathbf{b}), N) \quad (1)$$

where  $N = \sum_k \tilde{\mathbf{b}}_k$ ,  $\zeta_N$  is the probability that a block has  $N$  tokens,<sup>2</sup> and  $\pi(\mathbf{b})$  is the transition distribution given a vector  $\mathbf{b}$ . This follows from the generative story defined above, with an additional step of generating the number of tokens  $N$  from the distribution  $\zeta$ .

We currently define a block  $b$ 's distribution  $\pi_b$  in terms of the discrete feature vector  $\mathbf{a}$  given by its parent  $a$ . We could have instead made  $\pi_b$  a function of the parent's distribution  $\pi_a$  – this would lead to a model that assumes a dynamical system over a continuous space rather than a Markov chain. However, as a generative story we believe it makes more sense for a block's distribution to depend on the actual class values which are emitted by the parent. Similar arguments are made by Blei and McAuliffe (2007) when designing supervised topic models.

Under a block HMM with one class per block, there are  $K$  states corresponding to the  $K$  classes, requiring  $K \times K$  parameters to define the transition matrix. Under  $M^4$ , there is a countably infinite number of states, but the transitions are still defined by  $K \times K$  parameters (ignoring extra features).  $M^4$  thus utilizes a larger state space without increasing the number of free parameters.

### 3 Inference and Parameter Estimation

We must infer the values of the hidden variables  $\mathbf{z}$  as well as the parameters for the word distributions

<sup>2</sup>The distribution over the number of tokens can be arbitrary, as this is observed and does not affect inference. In topic models, this is sometimes assumed to be Poisson (Blei et al., 2003).

$\Phi$  and transition weights  $\Lambda$ . Standard HMM dynamic programming algorithms cannot straightforwardly be used for  $M^4$  because of the unboundedly large state space. We instead turn to Markov chain Monte Carlo (MCMC) methods as a tool for approximate inference. We derive a stochastic EM algorithm in which we alternate between sampling class assignments for the word tokens and optimizing the transition parameters, outlined in the following two subsections.

#### 3.1 Latent Class Sampling

To explore the posterior distribution over latent classes, we use a collapsed Gibbs sampler such that we marginalize out each word multinomial  $\phi$  and only need to sample the token assignments  $\mathbf{z}$  conditioned on each other. Given the current state of the sampler, we sample a token's class according to:

$$P(z_{(b,n)} = k | \mathbf{z}_{-(b,n)}, \mathbf{w}, \lambda, \omega) \propto \quad (2)$$

$$\frac{\exp(\lambda_k^T \mathbf{a})}{\sum_{k'} \exp(\lambda_{k'}^T \mathbf{a})} \frac{n_k^w + \omega}{n_k + W\omega} \prod_{c \in \mathcal{C}} \prod_j \left( \frac{\exp(\lambda_j^T \mathbf{b})}{\sum_{j'} \exp(\lambda_{j'}^T \mathbf{b})} \right)^{n_c^j}$$

The notation  $n_k^w$  indicates the number of tokens with word type  $w$  that have been assigned to topic  $k$ .  $W$  is the vocabulary size.  $a$  is the parent block of  $b$ , and  $\mathcal{C}$  is the set of  $b$ 's children.  $\mathbf{b}$  is the feature vector corresponding to block  $b$  (i.e. the class histogram plus the bias feature), where the histogram includes the incremented count of the candidate class  $k$ .

This sampling distribution is very similar to that of LDA (Griffiths and Steyvers, 2004), but the distribution over “topics” is now a function of the previous block, which gives the leftmost term. The rightmost term is a result of the dependency of the child blocks ( $\mathcal{C}$ ) on the class assignments of  $b$ .

Due to the rightmost term, the complexity of computing the sampling distribution is quadratic in the number of classes, rather than the linear complexity of a single-class HMM. Our assumption is that the number of sequence-dependent classes (e.g. speech acts or discourse states) will be reasonably small. If it is desired to have a large number of latent topics as is common in LDA, this model could be combined with a standard topic model without sequential dependencies, as explored by Ritter et al. (2010).

### 3.2 Transition Parameter Optimization

Differentiating the corpus likelihood with respect to  $\Lambda$  yields the standard equation for log-linear models:

$$\frac{\partial \ell}{\partial \lambda_{zk}} = \sum_b \mathbf{a}_k \left( n_b^z - n_b \frac{\exp(\lambda_z^T \mathbf{a})}{\sum_{z'} \exp(\lambda_{z'}^T \mathbf{a})} \right) - \frac{\lambda_{zk}}{\sigma^2} \quad (3)$$

where  $a$  is the parent of block  $b$ ,  $\mathbf{a}$  is the feature vector associated with  $a$ ,  $n_b^z$  is the number of times class  $z$  occurs in block  $b$  and  $n_b$  is the total number of tokens in block  $b$ .

Standard optimization methods can be used to learn these parameters. In our experiments, we find that we obtain good results by simply performing a single iteration of gradient ascent after each sampling iteration  $t$ ,<sup>3</sup> with the following update:

$$\lambda_{zk}^{(t+1)} = \lambda_{zk}^{(t)} + \eta(t) \frac{\partial \ell}{\partial \lambda_{zk}} \quad (4)$$

where  $\eta$  is a step size function.

## 4 Related Work

Hidden Markov models have a recent history as simple models of document structure. Stolcke et al. (2000) used HMMs as a general model of discourse with an application to speech acts (or dialog acts) in conversations. Barzilay and Lee (2004) applied HMMs as an *unsupervised* model of discourse. This work used HMMs to model the progression of sentences in articles, and was shown to be useful for ordering sentences and generating summaries of news articles. More recently, Wang et al. (2011b) experimented with similar tasks using a related HMM-based model called the Structural Topic Model.

Unsupervised HMMs were applied to conversational data by Ritter et al. (2010) who experimented with Twitter conversations. The authors also experimented with incorporating a topic model on top of the HMM to distinguish speech acts from topical clusters, with mixed results. Joty et al. (2011) extended this work by enriching the emission distributions and using additional features such as speaker and position information. An approach to unsupervised discourse modeling that does not use HMMs is

<sup>3</sup>Incremental updates are justified under the generalized EM algorithm (Dempster et al., 1977). Each gradient step with respect to  $\lambda$  corresponds to a generalized M-step, while each sampling iteration corresponds to a stochastic E-step.

the latent permutation model of Chen et al. (2009). This model assumes each segment (e.g. paragraph) in a document is associated with a latent class or topic, and the ordering of topics within a document is modeled as a deviation from some canonical ordering.

Extensions to the block HMM have incorporated mixed membership properties within blocks, notably the Markov Clustering Topic Model (Hospedales et al., 2009), which allows each HMM state to be associated with its own distribution over topics in a topic model. Like the block HMM, this still assumes a relatively small number of HMM states, but with an extra layer of latent variables before the observations are emitted. This is more restrictive than the unbounded state space of  $M^4$ .

Decoupling HMM states from latent classes was considered by Beal et al. (1997) with the Factorial HMM, which uses factorized state representations. The Factorial HMM is most often used to model independent Markov chains, whereas  $M^4$  has a dense graphical model topology: the probability of each of the latent classes depends on the counts of all of the classes in the previous block. The trick in  $M^4$  is to define the transition matrix via a function of a limited number of parameters, allowing tractable inference in a model with arbitrarily many states.

In topic models, log-linear formulations of latent class distributions<sup>4</sup> are utilized in correlated topic models (Blei and Lafferty, 2007) as a means of incorporating covariance structure among topic probabilities. Applying log-linear regression to potentially many features was combined with LDA by Mimno and McCallum (2008), who model the Dirichlet prior over topics as a function of document features. In  $M^4$ , such features would correspond to the class histograms of previous blocks, introducing additional dependencies between documents.

One topic model that imposes sequential dependencies between documents is Sequential LDA (Du et al., 2010), which models a document as a sequence of segments (such as paragraphs) governed by a Pitman-Yor process, in which the latent topic distribution of one segment serves as the base distribution for the next segment. This is in the spirit

<sup>4</sup>This formulation corresponds to the *natural* parameterization of the multinomial distribution.

of our work, where the latent classes in a segment depend on the class distribution of the previous segment. By using the Pitman-Yor process, however, this work assumes topics are positively correlated, i.e. the occurrence of a topic in one segment makes it likely to appear in the next. In contrast, we wish to learn arbitrary transitions, both positive and negative, between the latent classes.

## 5 Experiments with Conversation Data

We experiment with two corpora of text-based asynchronous conversations on the Web. One of these is annotated with speech act labels, against which we compare our unsupervised clusters. We measure the predictive capabilities of the model via perplexity experiments and the task of thread reconstruction.

### 5.1 Data Sets

First, we use a corpus of discussion threads from CNET forums (Kim et al., 2010), which are mostly technical discussion and support. This corpus includes 321 threads and a total of 1309 messages, with an average message length of 78 tokens after preprocessing.<sup>5</sup> Second, we use the Twitter data set created by Ritter et al. (2010). We consider 36K conversation threads for a total of 100K messages with average length 13.4 tokens.

Both data sets are already annotated with the reply structure, so the discourse graph is given. We preprocess the data by treating contiguous blocks of punctuation as tokens, and we remove infrequent words. The Twitter corpus has some additional preprocessing, such as converting URLs to a single word type.

### 5.2 Baseline Models

Our work is motivated by the Bayesian HMM approach of Ritter et al. (2010) – the model we refer to as the block HMM (BHMM) – and we consider this our primary baseline. (See also (Goldwater and Griffiths, 2007) for more details on Bayesian HMMs with Dirichlet priors.) We also compare against LDA, which makes latent assignments at the token-level, but blocks of text are independent of

<sup>5</sup>Three messages in this corpus have multiple parents. For the sake of conciseness, we simply remove these threads rather than introducing a method to model multiple parents.

each other. In other words, BHMM models sequential dependencies but allows only single-class membership, whereas LDA uses no sequence information but has a mixed membership property.  $M^4$  combines these two properties.

We use standard Gibbs samplers for both baseline models, and we optimize the Dirichlet hyperparameters (for the transition and topic distributions) using Minka’s fixed-point iterations (2003).

### 5.3 Incorporating Background Distributions

In our experiments, we find that the intrusion of common stop words can make the results difficult to interpret, but we do not want to perform simple stop word removal because common function words often play important roles in the latent classes (i.e. speech acts) of the conversation data we consider here. We instead handle this by extending our model to include a “background” distribution over words which is independent of the latent classes in a document; this was also done by Wang et al. (2011b).

The idea is to introduce a binary switching variable  $x$  into the model which determines whether a word is generated from the general background distribution or from the distribution specific to a latent class  $z$ . Loosely, if the marginal probability of a word was given by  $p(w) = \sum_z p(w|z)p(z)$ , the introduction of a background distribution gives the marginal probability  $p(w) = p(x = 0)p(w|B) + p(x = 1)\sum_z p(w|z)$ . This is common practice and we will not go into detail; see (Chemudugunta et al., 2006) for a general example on sampling switching variables. We augment all three models with a background distribution in exactly the same way, so that the comparison is fair. We use a Beta(10.0, 10.0) prior over the switching distribution.

### 5.4 Experimental Setup

All of our results are averaged across four randomly initialized chains which are run for 5000 iterations, with five samples collected during the final 500 iterations. We take small gradient steps of decreasing size with  $\eta(t) = 0.1/(1000 + t)$ .

We set  $\sigma^2 = 10.0$  as the variance of the  $\lambda$  weights. We use optimized asymmetric priors as described in §5.2, and we use a symmetric Dirichlet for the word distributions, following Wallach et al. (2009). We sample the scaling hyperparameter  $\omega$  via

	5	10	15	20	25
CNET					
Unigram	63.07	63.07	63.07	63.07	63.07
LDA	57.16	54.35	52.88	51.63	50.50
BHMM	61.26	61.06	60.92	60.86	60.85
M <sup>4</sup>	60.38	59.58	59.26	59.21	59.25
Twitter					
Unigram	93.00	93.00	93.00	93.00	93.00
LDA	83.70	78.40	74.01	70.91	70.16
BHMM	90.51	89.94	89.68	89.59	89.38
M <sup>4</sup>	88.44	86.17	85.50	85.55	86.31

Table 1: Average perplexity of held-out data for various numbers of latent classes.

Metropolis-Hastings proposals: we add Gaussian-distributed noise to the log of the current  $\omega$ , then exponentiate this to yield the proposed  $\omega^{(\text{new})}$ . This log-space proposal ensures that  $\omega$  is always positive.

When computing the transition distributions for M<sup>4</sup>, we normalize the class histograms so that the counts to sum to 1. This helps with numeric stability because the input vectors stay within a small bounded range.<sup>6</sup>

## 5.5 Experimental Results

### 5.5.1 Perplexity

We begin with standard measures of the perplexity of held-out data. For these experiments, we train on 75% of the data, and test on the remaining 25%. We run the sampler for 500 iterations using the word distributions and transition parameters learned during training; we compute the average perplexity from the final ten sampling iterations.

Results for different numbers of classes are shown in Table 1. These results demonstrate the advantage of models with the mixed membership property. Although LDA outperforms both sequence models, this is to be expected. Each block’s topic distribution is stochastically generated with LDA, whereas in the two sequence models, the distribution over classes is simply a deterministic function of the previous block. This allows LDA to infer parameters that fit the data more tightly. Comparing only the two sequence models, we find that M<sup>4</sup> does significantly better than BHMM in all cases with  $p < 0.05$ .

<sup>6</sup>Implementations of both M<sup>4</sup> and the block HMM will be available at <http://cs.jhu.edu/~mpaul>

Figure 2: Accuracy at the task of thread reconstruction. The horizontal bar indicates a random baseline.

If capturing sequence information is not important, then LDA may provide a better fit to a corpus than sequence models. In the next two subsections, we will consider tasks where the sequential structure is important, thus LDA is not an appropriate choice.

### 5.5.2 Thread Reconstruction

A natural predictive task of the sequence models is to reconstruct the discourse graph of a document where the structure is unknown. In the conversation domain, this corresponds to the task of *thread reconstruction* (Yeh and Harnly, 2006; Wang et al., 2011c). Given only a flat structure, can we recover the reply structure of messages in the conversation?

Previous work with BHMM found the optimal structure by computing the likelihood of all permutations of a thread or sequence (Ritter et al., 2010; Wang et al., 2011b). We take a more practical approach and find the optimal structure as part of our inference procedure. We do this by treating the parent of each block as a hidden variable to be inferred. The parent of block  $b$  is the random variable  $r_b$ , and we alternate between sampling values of the latent classes  $\mathbf{z}$  and the parents  $\mathbf{r}$ . The sampling distributions are annealed, as a search technique to find the best configuration of assignments (Finkel et al., 2005). At temperature  $\tau$ , we sample a block’s parent according to:

$$P(r_b = a | \mathbf{z}, \lambda) \propto \prod_j \left( \frac{\exp(\lambda_j^T \mathbf{a})}{\sum_{j'} \exp(\lambda_{j'}^T \mathbf{a})} \right)^{n_b^j / \tau} \quad (5)$$

For each conversation thread, any message is a candidate for the parent of block  $b$  (except  $b$  itself) including the dummy “start” block.

As before, we train on 75% of the data, and run this experiment on the remaining 25%. We run the sampler for 500 iterations, cooling  $\tau$  by 1% after each iteration, where  $\tau^{(0)} = 1$ . We measure accuracy as the percentage of blocks whose assignment for  $r_b$  matches the true parent. For each fold, we run this estimation procedure from five random initializations and average the results. Like Ritter et al. (2010), we do not enforce temporal constraints in the thread structure for this experiment. We are purely evaluating the predictive abilities of the model rather than its performance in a full-fledged reconstruction setup, which would require richer features beyond the scope of this paper.

Figure 2 shows results comparing  $M^4$  against BHMM. Because all blocks are independent under LDA, it cannot be used in this experiment; using LDA would amount to a random baseline.

We plot the distribution of results from various samples and various numbers of classes in  $\{5, \dots, 25\}$ . Most of the variance is across folds and samples; we find that there is not a strong trend in accuracy as a function of the number of classes. This suggests that most of the sequence predictions are carried by a small subset of the classes.

On average,  $M^4$  outperforms BHMM by more than 15 points on the CNET corpus.  $M^4$  is also better on the Twitter corpus, but the difference is not so stark. This seems to confirm our intuition that the advantage of  $M^4$  over BHMM is greater when the blocks are longer; tweets may be short enough that the single-class assumption is not as limiting.

### 5.5.3 Speech Act Discovery

Thus far, we have investigated the predictive power of the model, but we would also like to determine if the inferred clusters correspond to human-interpretable classes. In the case of conversation data, our hope is that some of the latent classes represent *speech acts* or dialog acts (Searle, 1975). While there is a body of work in supervised speech act classification (Cohen et al., 2004; Bangalore et al., 2006; Surendran and Levow, 2006; Qadir and Riloff, 2011), the variety of conversation domains on the Web motivates the use of unsupervised ap-

Figure 3: The variation of information between the human-created speech act annotations of the CNET corpus and the latent class assignments by various models.

proaches.

The CNET corpus is annotated with twelve speech act classes: QUESTION and ANSWER, which are both broken down into multiple sub-classes, as well as RESOLUTION, REPRODUCTION, and OTHER (Kim et al., 2010). We would like to quantitatively measure how closely the latent states induced by our model match these annotations.<sup>7</sup>

We can measure this with *variation of information* (Meila, 2003), which has been used in recent years for unsupervised evaluation, e.g. in part-of-speech clustering (Goldwater and Griffiths, 2007). Given two sets of variable assignments  $\mathbf{z}$  and  $\mathbf{z}'$ , the variation of information is defined as  $H(Z|Z') + H(Z'|Z)$ . In other words, given one clustering, how much uncertainty do we have about the other? Results are shown in Figure 3: a lower value corresponds to higher similarity.

On the CNET corpus,  $M^4$  outperforms both baselines in all cases by a very significant margin. Qualitatively, we see clusters and transition parameters that make sense. For example, the class with top words  $\{i, my, have, computer, am, ?, tried, help\}$  is most likely to begin a thread (with  $\lambda = +1.94$ ) and appears to describe questions or requests for

<sup>7</sup>Some messages have multiple labels. Since messages are not annotated at finer granularities, we handle this by simply duplicating such messages, once per label, and measuring clustering performance on this expanded set of labeled data which now has one label per token.

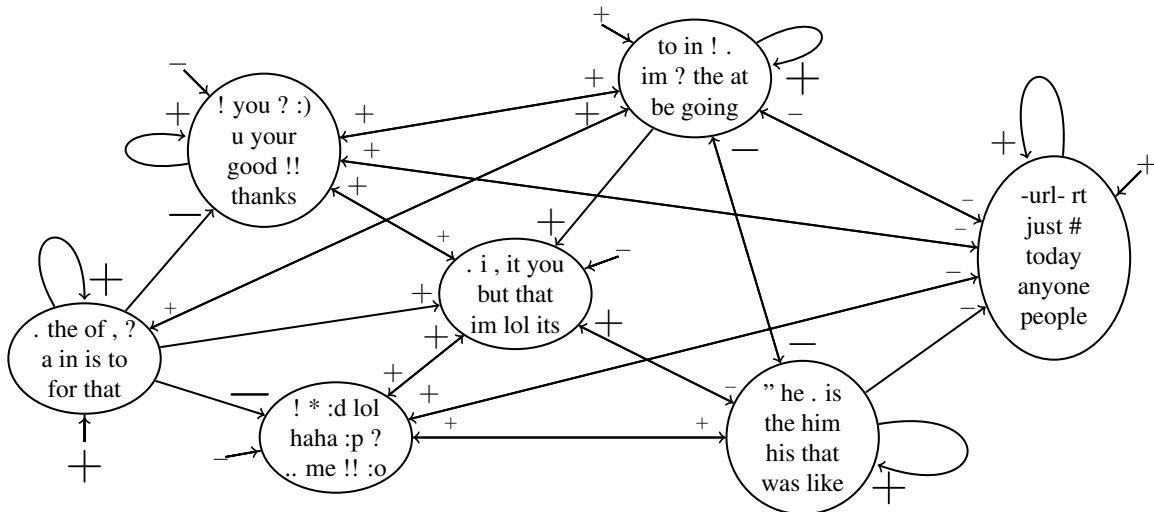

Figure 4: Example output from a model trained on the Twitter corpus with 15 classes (7 shown). Each node corresponds to a class learned by the model, and the most probable words are shown for each class. The symbols + and - on the directed edges denote the sign of the  $\lambda$  associated with transitioning from one class to another, and the size of the symbols is scaled by the magnitude of  $\lambda$ . Non-edge arrows going into a node represent the weight of starting a conversation with that class. Low-magnitude weights are not shown, and some edges are omitted to avoid clutter.

help. The class is not likely to be followed by itself ( $\lambda = -0.32$ ) but is likely to be followed by the class with words  $\{you, your, /, com, ., http, windows\}$  (with  $\lambda = +1.38$ ).

The Twitter corpus does not have speech act annotations, so we offer example output in Figure 4. We again see patterns that we might expect to find in social media conversations, and some classes appear to correspond to speech acts such as declarations, personal questions, and replies. For example, the class in the center of the figure has words like *you* and *but* which suggests it is used in reply to other messages, and indeed we see that it has a positive weight of following almost every class, but a negative weight for actually starting a thread. Conversely, the class containing URLs (which corresponds to the act of sharing news or media) is likely to begin a thread, but is not likely to follow other classes except itself.

How well unsupervised models can truly capture speech acts is an open question. Much as LDA “topics” do not always correspond to what humans would judge to be semantic classes (Chang et al., 2009), the conversation classes inferred by unsupervised sequence models are similarly unlikely to be a perfect fit to human-assigned classes. Nevertheless, these results suggest  $M^4$  is a step forward.

Our model provides a framework for defining inter-message transitions as functions of multiple classes, which will be a desirable property for many corpora.

## 6 Conclusion

We have presented mixed membership Markov models ( $M^4$ ), which extend the simple HMM approach to discourse modeling by positing class assignments at the level of individual tokens. This allows blocks of text to belong to potentially multiple classes, a property that relates  $M^4$  to topic models. This type of model can be viewed as an HMM with an expanded state space, but because the transition probabilities are a function of a small number of parameters, the output remains human-interpretable.

$M^4$  can be taken as a general family of models and can be readily extended. In this work, we focused on introducing a model of *inter*-message structure, but certainly more sophisticated models of *intra*-message structure beyond unigram language models could be incorporated into  $M^4$ . Standard topic model extensions such as  $n$ -gram models (Wallach, 2006) can straightforwardly be applied here, and indeed we already applied such an extension by incorporating background distributions in §5.3. For conversational data, it could make sense to segment

messages (e.g. into sentences) and constraint each segment to belong to one class or speech act; modifications along these lines have been applied to topic models as well (Gruber et al., 2007). While we have focused on conversation modeling,  $M^4$  is a general probabilistic model that could be applied to other discourse applications, for example modeling sentences or paragraphs in articles rather than messages in conversations; it could also be applied to data beyond text.

Compared to a Bayesian block HMM,  $M^4$  performs much better at a variety of tasks. A drawback is that the time complexity of inference as presented here is quadratic in the number of classes rather than linear. Improving this may be the subject of future research. Another potential avenue of future work is to model transitions such that a Dirichlet prior for the class distribution of a block, rather than the class distribution itself, depends on the previous class assignments. This would yield a model that more closely resembles LDA, but with topic priors that encode sequence information.

# An Entity-Topic Model for Entity Linking

Xianpei Han    Le Sun

Institute of Software, Chinese Academy of Sciences  
HaiDian District, Beijing, China.

{xianpei, sunle}@nfs.iscas.ac.cn

## Abstract

*Entity Linking (EL)* has received considerable attention in recent years. Given many name mentions in a document, the goal of EL is to predict their referent entities in a knowledge base. Traditionally, there have been two distinct directions of EL research: one focusing on the effects of mention’s *context compatibility*, assuming that “*the referent entity of a mention is reflected by its context*”; the other dealing with the effects of document’s *topic coherence*, assuming that “*a mention’s referent entity should be coherent with the document’s main topics*”. In this paper, we propose a generative model – called *entity-topic model*, to effectively join the above two complementary directions together. By jointly modeling and exploiting the context compatibility, the topic coherence and the correlation between them, our model can accurately link all mentions in a document using both the local information (including the *words* and the *mentions* in a document) and the global knowledge (including *the topic knowledge*, *the entity context knowledge* and *the entity name knowledge*). Experimental results demonstrate the effectiveness of the proposed model.

## 1 Introduction

Entity Linking (EL) has received considerable research attention in recent years (McNamee & Dang, 2009; Ji et al., 2010). Given many name mentions in a document, the goal of EL is to predict their referent entities in a given knowledge base (KB), such as the *Wikipedia*<sup>1</sup>. For example, as

shown in Figure 1, an EL system should identify the referent entities of the three mentions *WWDC*, *Apple* and *Lion* correspondingly are the entities *Apple Worldwide Developers Conference*, *Apple Inc.* and *Mac OS X Lion* in KB. The EL problem appears in many different guises throughout the areas of natural language processing, information retrieval and text mining. For instance, in many applications we need to collect all appearances of a specific entity in different documents, EL is an effective way to resolve such an information integration problem. Furthermore, EL can bridge the mentions in documents with the semantic information in knowledge bases (e.g., *Wikipedia* and *Freebase*<sup>2</sup>), thus can provide a solid foundation for knowledge-rich methods.

Figure 1. A Demo of Entity Linking

Unfortunately, the accurate EL is often hindered by the *name ambiguity* problem, i.e., a name may refer to different entities in different contexts. For example, the name *Apple* may refer to more than 20 entities in Wikipedia, such as *Apple Inc.*, *Apple (band)* and *Apple Bank*. Traditionally, there have been two distinct directions in EL to resolve the *name ambiguity* problem: one focusing on the effects of mention’s *context compatibility* and the other dealing with the effects of document’s *topic coherence*. EL methods based on context

<sup>1</sup> www.wikipedia.org

<sup>2</sup> www.freebase.com

compatibility assume that “*the referent entity of a mention is reflected by its context*”(Mihalcea & Cosomai, 2007; Zhang et al., 2010; Zheng et al., 2010; Han & Sun, 2011; Kataria et al., 2011; Sen 2012). For example, the context compatibility based methods will identify the referent entity of the mention *Lion* in Figure 1 is the entity *Mac OS X Lion*, since this entity is more compatible with its context words *operating system* and *release* than other candidates such as *Lion(big cats)* or *Lion(band)*. EL methods based on topic coherence assume that “*a mention’s referent entity should be coherent with document’s main topics*” (Medelyan et al., 2008; Milne & Witten, 2008; Kulkarni et al., 2009; Han et al., 2011). For example, the topic coherence based methods will link the mention *Apple* in Figure 1 to the entity *Apple Inc.*, since it is more coherent with the document’s topic *MAC OS X Lion Release* than other referent candidates such as *Apple (band)* or *Apple Bank*.

In recent years, both of the above two EL directions have shown their effectiveness to some extent, and obviously they are *complementary* to each other. Therefore we believe that bring the above two directions together will enhance the EL performance. Traditionally, the above two directions are usually be brought together using a hybrid method (Zhang and Sim, 2011; Ratinov et al., 2011; Han et al., 2011), i.e., the context compatibility and the topic coherence are first *separately* modeled, then their EL evidence are combined through an additional model. For example, Zhang and Sim (2011) first models the context compatibility as a context similarity and the topic coherence as a similarity between the underlying topics of documents and KB entries, then these two similarities are combined through an additional SVM classifier for the final EL decision.

The main drawback of these hybrid methods, however, is that they model the context compatibility and the topic coherence *separately*, which makes it difficult to capture the *mutual reinforcement* effect between the above two directions. That is, the topic coherence and the context compatibility are highly correlated and their evidence can be used to reinforce each other in EL decisions. For example, in Figure 1, if the context compatibility gives a high likelihood the mention *Apple* refers to the entity *Apple Inc.*, then this likelihood will give more evidence for this

document’s topic is about *MAC OS X Lion*, and it in turn will reinforce the topic coherence between the entity *MAC OS X Lion* and the document. In reverse, once we known the topic of this document is about *MAC OS X Lion*, the context compatibility between the mention *Apple* and the entity *Apple Inc.* can be improved as the importance of the context words *operating system* and *release* will be increased using the topic knowledge. In this way, we believe that modeling the above two directions *jointly*, rather than *separately*, will further improve the EL performance by capturing the *mutual reinforcement* effect between the context compatibility and the topic coherence.

In this paper, we propose a method to *jointly* model and exploit the context compatibility, the topic coherence and the correlation between them for better EL performance. Specifically, we propose a generative probabilistic model – called *entity-topic model*, which can uniformly model the text compatibility and the topic coherence as the *statistical dependencies* between the *mentions*, the *words*, the underlying *entities* and the underlying *topics* of a document by assuming that each document is generated according to the following two assumptions:

1) **Topic coherence assumption:** *All entities in a document should be centered around the main topics of the document.* For example, the entity *Apple Inc.* tends to occur in documents about *IT*, but the entity *Apple Bank* will more likely to occur in documents about *bank* or *investment*.

2) **Context compatibility assumption:** *The context words of a mention should be centered on its referent entity.* For example, the words *computer*, *phone* and *music* tends to occur in the context of the entity *Apple Inc.*, meanwhile the words *loan*, *invest* and *deposit* will more likely to occur in the context of the entity *Apple Bank*.

In this way, the entity-topic model uniformly models the context compatibility, the topic coherence and the correlation between them as the dependencies between the observed information (the *mentions* and the *words*) in a document and the hidden information we want to know (the underlying *topics* and *entities*) through the global knowledge (including *the topic knowledge*, *the entity name knowledge* and *the entity context knowledge*). And the EL problem can now be decomposed into the following two inference tasks:

- 1) *Predicting the underlying topics and the underlying entities of a document* based on the observed information and the global knowledge. We call such a task the **prediction task**;
- 2) *Estimating the global knowledge from data*. Notice that the topic knowledge, the entity name knowledge and the entity context knowledge are all not previously given, thus we need to estimate them from data. We call such a task the **knowledge discovery task**.

Because the accurate inference of the above two tasks is intractable in our entity-topic model, this paper also develops an approximate inference algorithm – the Gibbs sampling algorithm to solve them.

**Contributions.** The main contributions of this paper are summarized below:

- We propose a generative probabilistic model, the *entity-topic model*, which can *jointly* model and exploit the context compatibility, the topic coherence and the correlation between them for better EL performance;
- We develop a *Gibbs sampling algorithm* to solve the two inference tasks of our model: 1) Discovering the global knowledge from data; and 2) Collectively making accurate EL decisions.

This paper is organized as follows. Section 2 describes the proposed entity-topic model. Section 3 demonstrates the Gibbs sampling algorithm. The experimental results are presented and discussed in Section 4. The related work is reviewed in Section 5. Finally we conclude this paper in Section 6.

## 2 The Entity-Topic Model for Entity Linking

In this section, we describe the proposed entity-topic model. In following we first demonstrate how to capture the context compatibility, the topic coherence and the correlation between them in the document generative process, then we incorporate the global knowledge generation into our model for knowledge estimation from data.

### 2.1 Document Generative Process

As shown in Section 1, we jointly model the context compatibility and the topic coherence as the statistical dependencies in the entity-topic model by assuming that all documents are generated in a topical coherent and context

compatible way. In following we describe the document generative process.

In our model, each document  $d$  is assumed composed of two types of information, i.e., the *mentions* and the *words*. Formally, we represent a document as:

*A document is a collection of  $M$  mentions and  $N$  words, denoted as  $\mathbf{d} = \{m_1, \dots, m_M; w_1, \dots, w_N\}$ , with  $m_i$  the  $i^{\text{th}}$  mention and  $w_j$  the  $j^{\text{th}}$  word.*

For example, the document in Figure 1 is represented as  $\mathbf{d} = \{WWDC, \mathbf{Apple}, \mathbf{Lion}; \text{at, the, conference, ...}\}$ , where *WWDC, Apple, Lion* are the three mentions and the other are the words.

To generate a document, our model relies on three types of global knowledge, including:

- **Topic Knowledge**  $\phi$  (*The entity distribution of topics*): In our model, all entities in a document are generated based on its underlying topics, with each topic is a group of semantically related entities. Statistically, we model each topic as a multinomial distribution of entities, with the probability indicating the likelihood an entity to be extracted from this topic. For example, we may have a topic  $\phi_{Apple\ Inc.} = \{Steve\ Jobs^{0.12}, iPhone^{0.07}, iPod^{0.08}, \dots\}$ , indicating the likelihood of the entity *Steve Jobs* be extracted from this topic is *0.12*, etc.
- **Entity Name Knowledge**  $\psi$  (*The name distribution of entities*): In our model, all name mentions are generated using the name knowledge of its referent entity. Specifically, we model the name knowledge of an entity as a multinomial distribution of its names, with the probability indicating the likelihood this entity is mentioned by the name. For example, the name knowledge of the entity *Apple Inc.* may be  $\psi_{Apple\ Inc.} = \{Apple^{0.51}, Apple\ Computer\ Inc.^{0.10}, Apple\ Inc.^{0.07}, \dots\}$ , indicating that the entity *Apple Inc.* is mentioned by the name *Apple* with probability *0.51*, etc.
- **Entity Context Knowledge**  $\xi$  (*The context word distribution of entities*): In our model, all context words of an entity’s mention are generated using its context knowledge. Concretely, we model the context knowledge of an entity as a multinomial distribution of words, with the probability indicating the likelihood a word appearing in this entity’s context. For example, we may have  $\xi_{Apple\ Inc.} = \{phone^{0.07}, computer^{0.10}, IT^{0.06}, phone^{0.002}, \dots\}$ , indicating that the word *computer* appearing in the context of the entity *Apple Inc.* with probability *0.1*, etc.

Given the topic knowledge  $\phi$ , the entity name knowledge  $\psi$  and the entity context knowledge  $\xi$ :

1. For each doc  $d$  in  $\mathbf{D}$ , sample its topic distribution  $\theta_d \sim \text{Dir}(\alpha)$ ;
2. For each of the  $M_d$  mentions  $m_i$  in doc  $d$ :
  - a) Sample a topic assignment  $z_i \sim \text{Mult}(\theta_d)$ ;
  - b) Sample an entity assignment  $e_i \sim \text{Mult}(\phi_{z_i})$ ;
  - c) Sample a mention  $m_i \sim \text{Mult}(\psi_{e_i})$ ;
3. For each of the  $N_d$  words  $w_i$  in doc  $d$ :
  - a) Sample a target entity it describes from  $d$ 's referent entities  $a_i \sim \text{Unif}(e_{m_1}, e_{m_2}, \dots, e_{m_d})$ ;
  - b) Sample a describing word using  $a_i$ 's context word distribution  $w_i \sim \text{Mult}(\xi_{a_i})$ .

Figure 2. The document generative process, with  $\text{Dir}(\cdot)$ ,  $\text{Mult}(\cdot)$  and  $\text{Unif}(\cdot)$  correspondingly *Dirichlet*, *Multinomial* and *Uniform distribution*

Given the entity list  $\mathbf{E} = \{e_1, e_2, \dots, e_E\}$  in the knowledge base, the word list  $\mathbf{V} = \{w_1, w_2, \dots, w_V\}$ , the entity name list  $\mathbf{K} = \{n_1, n_2, \dots, n_K\}$  and the global knowledge described in above, the generation process of a document collection (corpus)  $\mathbf{D} = \{d_1, d_2, \dots, d_D\}$  is shown in Figure 2. To demonstrate the generation process, we also demonstrate how the document in Figure 1 can be generated using our model in following steps:

**Step 1:** The model generates the topic distribution of the document as  $\theta_d = \{Apple\ Inc.^{0.45}, Operating\ System(OS)^{0.55}\}$ ;

**Step 2:** For the three mentions in the document:

i. According to the topic distribution  $\theta_d$ , the model generates their topic assignments as  $z_1=Apple\ Inc.$ ,  $z_2 = Apple\ Inc.$ ,  $z_3 = OS$ ;

ii. According to the topic knowledge  $\phi_{Apple\ Inc.}$ ,  $\phi_{OS}$  and the topic assignments  $z_1, z_2, z_3$ , the model generates their entity assignments as  $e_1 = Apple\ Worldwide\ Developers\ Conference$ ,  $e_2 = Apple\ Inc.$ ,  $e_3 = Mac\ OS\ X\ Lion$ ;

iii. According to the name knowledge of the entities *Apple Worldwide Developers Conference*, *Apple Inc.* and *Mac OS X Lion*, our model generates the three mentions as  $m_1=WWDC$ ,  $m_2 = Apple$ ,  $m_3 = Lion$ ;

**Step 3:** For all words in the document:

i. According to the referent entity set in document  $\mathbf{e}_d = \{Apple\ Worldwide\ Developers\ Conference, Apple\ Inc., Mac\ OS\ X\ Lion\}$ , the model generates the target entity it describes as

$a_3=Apple\ Worldwide\ Developers\ Conference$  and  $a_4=Apple\ Inc.$ ;

ii. According to their target entity and the context knowledge of these entities, the model generates the context words in the document. For example, according to the context knowledge of the entities *Apple Worldwide Developers Conference*, the model generates its context word  $w_3 = conference$ , and according to the context knowledge of the entity *Apple Inc.*, the model generates its context word  $w_4 = introduces$ .

Through the above generative process, we can see that all entities in a document are extracted from the document's underlying topics, ensuring the topic coherence; and all words in a document are extracted from the context word distributions of its referent entities, resulting in the context compatibility. Furthermore, the generation of topics, entities, mentions and words are highly correlated, thus our model can capture the correlation between the topic coherence and the context compatibility.

## 2.2 Global Knowledge Generative Process

The entity-topic model relies on three types of global knowledge (including the topic knowledge, the entity name knowledge and the entity context knowledge) to generate a document. Unfortunately, all three types of global knowledge are unknown and thus need to be estimated from data. In this paper we estimate the global knowledge through Bayesian inference by also incorporating the knowledge generation process into our model.

Specifically, given the topic number  $T$ , the entity number  $E$ , the name number  $K$  and the word number  $V$ , the entity-topic model generates the global knowledge as follows:

$$1) \phi|\beta \sim \text{Dir}(\beta)$$

For each topic  $z$ , our model samples its entity distribution  $\phi_z$  from an  $E$ -dimensional Dirichlet distribution with hyperparameter  $\beta$ .

$$2) \psi|\gamma \sim \text{Dir}(\gamma)$$

For each entity  $e$ , our model samples its name distribution  $\psi_e$  from a  $K$ -dimensional Dirichlet distribution with hyperparameter  $\gamma$ .

$$3) \xi|\delta \sim \text{Dir}(\delta)$$

For each entity  $e$ , our model samples its context word distribution  $\xi_e$  from a  $V$ -dimensional Dirichlet distribution with hyperparameter  $\delta$ .

Finally, the full entity-topic model is shown in Figure 3 using the plate representation.

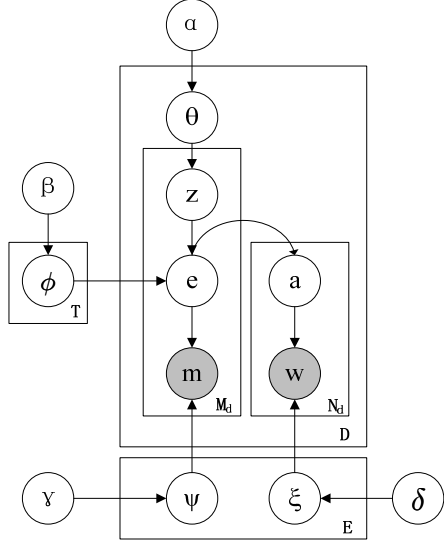

Figure 3. The plate representation of the entity-topic model

### 2.3 The Probability of a Corpus

Using the entity-topic model, the probability of generating a corpus  $\mathbf{D}=\{d_1, d_2, \dots, d_D\}$  given hyperparameters  $\alpha, \beta, \gamma$  and  $\delta$  can be expressed as:

$$\begin{aligned}
P(\mathbf{D}; \alpha, \beta, \gamma, \delta) &= \prod_d P(\mathbf{m}_d, \mathbf{w}_d; \alpha, \beta, \gamma, \delta) \\
&= \prod_d \sum_{\mathbf{e}_d} P(\mathbf{e}_d | \alpha, \beta) P(\mathbf{m}_d | \mathbf{e}_d, \gamma) P(\mathbf{w}_d | \mathbf{e}_d, \delta) \\
&= \int_{\phi} P(\phi | \beta) \int_{\psi} P(\psi | \gamma) \prod_d \sum_{\mathbf{e}_d} P(\mathbf{m}_d | \mathbf{e}_d, \psi) \\
&\times \int_{\xi} P(\xi | \delta) \sum_{\mathbf{a}_d} P(\mathbf{a}_d | \mathbf{e}_d) P(\mathbf{w}_d | \mathbf{a}_d, \xi) \\
&\times \int_{\theta} P(\theta | \alpha) P(\mathbf{e}_d | \theta, \phi) d\theta d\xi d\psi d\phi \quad (2.1)
\end{aligned}$$

where  $\mathbf{m}_d$  and  $\mathbf{e}_d$  correspondingly the set of mentions and their entity assignments in document  $d$ ,  $\mathbf{w}_d$  and  $\mathbf{a}_d$  correspondingly the set of words and their entity assignments in document  $d$ .

### 3 Inference using Gibbs Sampling

In this section, we describe how to resolve the entity linking problem using the entity-topic model. Overall, there were two inference tasks for EL:

1) **The prediction task.** Given a document  $d$ , predicting its *entity assignments* ( $\mathbf{e}_d$  for mentions and  $\mathbf{a}_d$  for words) and *topic assignments* ( $\mathbf{z}_d$ ). Notice that here the EL decisions are just the prediction of per-mention entity assignments ( $\mathbf{e}_d$ ).

2) **The knowledge discovery task.** Given a corpus  $\mathbf{D}=\{d_1, d_2, \dots, d_D\}$ , estimating the global knowledge (including *the entity distribution of topics*  $\phi$ , *the name distribution*  $\psi$  and *the context word distribution*  $\xi$  of entities) from data.

Unfortunately, due to the heaven correlation between *topics, entities, mentions* and *words* (the correlation is also demonstrated in Eq. (2.1), where the integral is intractable due to the coupling between  $\theta, \phi, \psi$  and  $\xi$ ), the accurate inference of the above two tasks is intractable. For this reason, we propose an approximate inference algorithm – the *Gibbs sampling algorithm* for the entity-topic model by extending the well-known Gibbs sampling algorithm for LDA (Griffiths & Steyvers, 2004). In Gibbs sampling, we first construct the posterior distribution  $P(\mathbf{z}, \mathbf{e}, \mathbf{a} | \mathbf{D})$ , then this posterior distribution is used to: 1) estimate  $\theta, \phi, \psi$  and  $\xi$ ; and 2) predict the entities and the topics of all documents in  $D$ . Specifically, we first derive the joint posterior distribution from Eq. (2.1) as:

$$P(\mathbf{z}, \mathbf{e}, \mathbf{a} | \mathbf{D}) \propto P(\mathbf{z}) P(\mathbf{e} | \mathbf{z}) P(\mathbf{m} | \mathbf{e}) P(\mathbf{a} | \mathbf{e}) P(\mathbf{w} | \mathbf{a})$$

where

$$P(\mathbf{z}) = \left( \frac{\Gamma(T\alpha)}{\Gamma(\alpha)^T} \right)^D \prod_{d=1}^D \prod_t \frac{\Gamma(\alpha + C_{dt}^{DT})}{\Gamma(T\alpha + C_{d*}^{DT})} \quad (3.1)$$

is the probability of the joint topic assignment  $\mathbf{z}$  to all mentions  $\mathbf{m}$  in corpus  $D$ , and

$$P(\mathbf{e} | \mathbf{z}) = \left( \frac{\Gamma(E\beta)}{\Gamma(\beta)^E} \right)^T \prod_{t=1}^T \prod_e \frac{\Gamma(\beta + C_{te}^{TE})}{\Gamma(E\beta + C_{t*}^{TE})} \quad (3.2)$$

is the conditional probability of the joint entity assignments  $\mathbf{e}$  to all mentions  $\mathbf{m}$  in corpus  $D$  given all topic assignments  $\mathbf{z}$ , and

$$P(\mathbf{m} | \mathbf{e}) = \left( \frac{\Gamma(K\gamma)}{\Gamma(\gamma)^K} \right)^E \prod_{e=1}^E \prod_m \frac{\Gamma(\gamma + C_{em}^{EM})}{\Gamma(K\gamma + C_{e*}^{EM})} \quad (3.3)$$

is the conditional probability of all mentions  $\mathbf{m}$  given all per-mention entity assignments  $\mathbf{e}$ , and

$$P(\mathbf{a} | \mathbf{e}) = \prod_{d=1}^D \prod_{e \in \mathbf{e}_d} \left( \frac{C_{de}^{DE}}{C_{d*}^{DE}} \right)^{C_{de}^{DA}} \quad (3.4)$$

is the conditional probability of the joint entity assignments  $\mathbf{a}$  to all words  $\mathbf{w}$  in corpus  $D$  given all per-mention entity assignments  $\mathbf{e}$ , and

$$P(\mathbf{w}|\mathbf{a}) = \left(\frac{\Gamma(V\delta)}{\Gamma(\delta)^V}\right)^E \prod_{e=1}^E \frac{\prod_w \Gamma(\delta + C_{ew}^{EW})}{\Gamma(V\delta + C_{e*}^{EW})} \quad (3.5)$$

is the conditional probability of all words  $\mathbf{w}$  given all per-word entity assignments  $\mathbf{a}$ . In all above formulas,  $\Gamma(\cdot)$  is the Gamma function,  $C_{dt}^{DT}$  is the times topic  $t$  has been assigned for all mentions in document  $d$ ,  $C_{d*}^{DT} = \sum_t C_{dt}^{DT}$  is the topic number in document  $d$ , and  $C_{te}^{TE}$ ,  $C_{em}^{EM}$ ,  $C_{de}^{DE}$ ,  $C_{de}^{DA}$ ,  $C_{ew}^{EW}$  have similar explanation.

Based on the above joint probability, we construct a Markov chain that converges to the posterior distribution  $P(\mathbf{z}, \mathbf{e}, \mathbf{a}|\mathbf{D})$  and then draw samples from this Markov chain for inference. For entity-topic model, each state in the Markov chain is an assignment (including *topic assignment to a mention*, *entity assignment to a mention* and *entity assignment to a word*). In Gibbs sampling, all assignments are sequentially sampled conditioned on all the current other assignments. So here we only need to derive the following three fully conditional assignment distributions:

- 1)  $P(z_i = t|\mathbf{z}_{-i}, \mathbf{e}, \mathbf{a}, \mathbf{D})$ : the topic assignment distribution to a mention given the current other topic assignments  $\mathbf{z}_{-i}$ , the current entity assignments  $\mathbf{e}$  and  $\mathbf{a}$ ;
- 2)  $P(e_i = e|\mathbf{z}, \mathbf{e}_{-i}, \mathbf{a}, \mathbf{D})$  : the entity assignment distribution to a mention given the current entity assignments of all other mentions  $\mathbf{e}_{-i}$ , the current topic assignments  $\mathbf{z}$  and the current entity assignments of context words  $\mathbf{a}$ ;
- 3)  $P(a_i = e|\mathbf{z}, \mathbf{e}, \mathbf{a}_{-i}, \mathbf{D})$  : the entity assignment distribution to a context word given the current entity assignments of all other context words  $\mathbf{a}_{-i}$ , the current topic assignments  $\mathbf{z}$  and the current entity assignments  $\mathbf{e}$  of mentions.

Using the Formula 3.1-3.5, we can derive the above three conditional distributions as (where  $m_i$  is contained in doc  $d$ ):

$$P(z_i = t|\mathbf{z}_{-i}, \mathbf{e}, \mathbf{a}, \mathbf{D}) \propto \frac{C_{(-i)dt}^{DT} + \alpha}{C_{(-i)d*}^{DT} + T\alpha} \times \frac{C_{(-i)te}^{TE} + \beta}{C_{(-i)t*}^{TE} + E\beta}$$

where the topic assignment to a mention is determined by the probability this topic appearing in doc  $d$  (the 1<sup>st</sup> term) and the probability the referent entity appearing in this topic (the 2<sup>nd</sup> term);

$$P(e_i = e|\mathbf{z}, \mathbf{e}_{-i}, \mathbf{a}, \mathbf{D}) \propto \frac{C_{(-i)te}^{TE} + \beta}{C_{(-i)t*}^{TE} + E\beta} \times \frac{C_{(-i)em}^{EM} + \gamma}{C_{(-i)e*}^{EM} + K\gamma} \times \left(\frac{C_{(-i)de}^{DE} + 1}{C_{(-i)de}^{DE}}\right)^{C_{de}^{DA}}$$

where the entity assignment to a mention is determined by the probability this entity extracted from the assigned topic (the 1<sup>st</sup> term), the probability this entity is referred by the name  $m$  (the 2<sup>nd</sup> term) and the contextual words describing this entity in doc  $d$  (the 3<sup>rd</sup> term);

$$P(a_i = e|\mathbf{z}, \mathbf{e}, \mathbf{a}_{-i}, \mathbf{D}) \propto \frac{C_{de}^{DE}}{C_{d*}^{DE}} \times \frac{C_{(-i)ew}^{EW} + \delta}{C_{(-i)e*}^{EW} + V\delta}$$

where the entity assignment to a word is determined by the number of times this entity has been assigned to mentions in doc  $d$  (the 1<sup>st</sup> term) and the probability the word appearing in the context of this entity (the 2<sup>nd</sup> term).

Finally, using the above three conditional distributions, we iteratively update all assignments of corpus  $\mathbf{D}$  until coverage, then the global knowledge is estimated using the final assignments, and the final entity assignments are used as the referents of their corresponding mentions.

**Inference on Unseen Documents.** When unseen documents are given, we predict its entities and topics using the incremental Gibbs sampling algorithm described in (Kataria et al., 2011), i.e., we iteratively update the entity assignments and the topic assignments of an unseen document as the same as the above inference process, but with the previously learned global knowledge fixed.

**Hyperparameter setting.** One still problem here is the setting of the hyperparameters  $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\delta$ . For  $\alpha$  and  $\beta$ , this paper empirically set the value of them to  $\alpha = 50/T$  and  $\beta = 0.1$  as in Griffiths & Steyvers(2004). For  $\gamma$ , we notice that  $K\gamma$  is the number of pseudo names added to each entity, when  $\gamma = 0$  our model only mentions an entity using its previously used names. Observed that an entity typically has a fixed set of names, we set  $\gamma$  to a small value by setting  $K\gamma = 1.0$ . For  $\delta$ , we notice that  $V\delta$  is the number of pseudo words added to each entity, playing the role of smoothing its context word distribution. As there is typically a relatively loose correlation between an entity and its context words, we set  $\delta$  to a relatively large value by fixing the total smoothing words added to each entity, a typical value is  $V\delta = 2000$ .

## 4 Experiments

In this section, we evaluate our method and compare it with the traditional EL methods. We first explain the experimental settings in Section 4.1-4.4, then discuss the results in Section 4.5.

### 4.1 Knowledge Base

In our experiments, we use the Jan. 30, 2010 English version of Wikipedia as the knowledge base, which contains over 3 million entities. Notice that we also take the general concepts in Wikipedia (such as *Apple*, *Video*, *Computer*, etc.) as entities, so the entity in this paper may not strictly follow its definition.

### 4.2 Data Sets

There are two standard data sets for EL: IITB<sup>3</sup> and TAC 2009 EL data set (McNamee & Dang, 2009), where IITB focuses on *aggressive recall* EL and TAC 2009 focuses on EL on *salient mentions*. Due to the collective nature of our method, we mainly used the **IITB** as the primary data set as the same as Kulkarni et al.(2009) and Han et al.(2011). But we also give the EL accuracies on the TAC 2009 in Sect. 4.5.4 as auxiliary results.

Overall, the IITB data set contains 107 web documents. For each document, the name mentions' referent entities in Wikipedia are manually annotated to be as exhaustive as possible. In total, 17,200 name mentions are annotated, with 161 name mentions per document on average. In our experiments, we use only the name mentions whose referent entities are contained in Wikipedia.

### 4.3 Evaluation Criteria

This paper adopted the same performance metrics used in the Kulkarni et al. (2009), which includes *Recall*, *Precision* and *F1*. Let  $M^*$  be the golden standard set of the EL results (each EL result is a pair  $(m, e)$ , with  $m$  the mention and  $e$  its referent entity),  $M$  be the set of EL results outputted by an EL system, then these metrics are computed as:

$$Precision = \frac{|M \cap M^*|}{|M|}$$

$$Recall = \frac{|M \cap M^*|}{|M^*|}$$

where two EL results are considered equal if and only if both their mentions and referent entities are equal. As the same as Kulkarni et al.(2009),

*Precision* and *Recall* are averaged across documents and overall *F1* is used as the primary performance metric by computing from average *Precision* and *Recall*.

### 4.4 Baselines

We compare our method with five baselines which are described as follows:

**Wikify!**. This is a context compatibility based EL method using vector space model (Mihalcea & Csomai, 2007). *Wikify!* computes the context compatibility using the word overlap between the mention's context and the entity's Wikipedia entry.

**EM-Model**. This is a statistical context compatibility based EL method described in Han & Sun(2011), which computes the compatibility by integrating the evidence from the entity popularity, the entity name knowledge and the context word distribution of entities.

**M&W**. This is a relational topic coherence based EL method described in Milne & Witten(2008). *M&W* measures an entity's topic coherence to a document as its average semantic relatedness to the *unambiguous* entities in the document.

**CSAW**. This is an EL method which combines context compatibility and topic coherence using a hybrid method (Kulkarni et al., 2009), where context compatibility and topic coherence are first separated modeled as context similarity and the sum of all *pair-wise* semantic relatedness between the entities in the document, then the entities which can maximize the weighted sum of the context compatibility and the topic coherence are identified as the referent entities of the document.

**EL-Graph**. This is a graph based hybrid EL method described in Han et al. (2011), which first models the context compatibility as text similarity and the topic coherence of an entity as its node importance in a referent graph which captures all mention-entity and entity-entity relations in a document, then a random walk algorithm is used to collectively find all referent entities of a document.

Except for *CSAW* and *EL-Graph*, all other baselines are designed only to link the salient name mentions (i.e., key phrases) in a document. In our experiment, in order to compare the EL performances on also the non-salient name mentions, we push these systems' recall by reducing their respective importance thresholds of linked mentions.

<sup>3</sup> <http://www.cse.iitb.ac.in/~soumen/doc/QCQ/>

## 4.5 Experimental Results

### 4.5.1 Overall Performance

We compared our method with all the above five baselines. For our method, we estimate the global knowledge using all the articles in the Jan. 30, 2010 English version of Wikipedia, and totally there were 3,083,158 articles. For each article, the mentions within it are detected using the methods described in Medelyan et al.(2008) and all terms in an article are used as context words, so a term may both be a mention and a context word. The topic number of our model is  $T = 300$  (will be empirically set in Sect 4.5.2). To train the entity-topic model, we run 500 iterations of our Gibbs sampling algorithm to converge. The training time of our model is nearly one week on our server using 20 GB RAM and one core of 3.2 GHz CPU. Since the training can be done offline, we believe that the training time is not critical to the real-world usage as the online inference on new document is very quick. Using the above settings, the overall results are shown in Table 1.

	<b>Precision</b>	<b>Recall</b>	<b>F1</b>
<i>Wikify!</i>	0.55	0.28	0.37
<i>EM-Model</i>	0.82	0.48	0.61
<i>M&amp;W</i>	0.80	0.38	0.52
<i>CSAW</i>	0.65	0.73	0.69
<i>EL-Graph</i>	0.69	0.76	0.73
<b>Our Method</b>	<b>0.81</b>	<b>0.80</b>	<b>0.80</b>

Table 1. The overall results on IITB data set

From the overall results in Table 1, we can see that:

1) By *jointly* modeling and exploiting the context compatibility and the topic coherence, our method can achieve competitive performance: ① compared with the context compatibility baselines *Wikify!* and *EM-Model*, our method correspondingly gets 43% and 19% F1 improvement; ② compared with the topic coherence baselines *M&W*, our method achieves 28% F1 improvement; ③ compared with the hybrid baselines *CSAW* and *EL-Graph*, our method correspondingly achieves 11% and 7% F1 improvement.

2) Compared with the *context compatibility only* and the *topic coherence only* methods, the main advantage of our method is that, rather than only achieved high entity linking precision on *salient* mentions, it can also effectively link the

*non-salient* mentions in a document: this is demonstrated in our method’s significant *Recall* improvement: a 32~52% Recall improvement over baselines *Wikify!*, *EM-Model* and *M&W*. We believe this is because a document usually contains little evidence for EL decisions on non-salient mentions, so with either only context compatibility or only topic coherence the evidence is not enough for EL decisions on these non-salient mentions, and bring these two directions together is critical for the accurate EL on these mentions.

3) Compared with the *hybrid* methods, the main advantage of our method is the improvement of EL precision (a 11~16% improvement over baselines *CSAW* and *EL-Graph*), we believe this is because: ① Our method can further capture the mutual reinforcement effect between the context compatibility and the topic coherence; ② The traditional hybrid methods usually determine the topic coherence of an entity to a document using *all entities* in the document, in comparison our method uses only *the entities in the same topic*, we believe this is more reasonable for EL decisions.

### 4.5.2 Parameter Tuning

One still parameter of our method is the topic number  $T$ . An appropriate  $T$  will distribute entities into well-organized topics, in turn it will capture the co-occurrence information of entities. Figure 4 plots the *F1* at different  $T$  values. We can see that the *F1* is not very sensitive to the topic number and with  $T = 300$  our method achieves its best *F1* performance.

Figure 4. The *F1* vs. the topic number  $T$

### 4.5.3 Detailed Analysis

In this section we analyze why and how our method works well in detail. Generally, we believe the main advantages of our method are:

1) **The effects of topic knowledge.** One main advantage of our model is that the topic knowledge

can provide a *document-specific entity prior* for EL. Concretely, using the topic knowledge and the topic distribution of documents, the prior for an entity appearing in a document  $d$  is highly related to the document’s topics:

$$P(e|d) = \sum_z P(z|d)P(e|z)$$

This prior is obviously more reasonable than the “information less prior” (i.e., all entities have equal prior) or “a global entity popularity prior” (Han & Sun, 2011). To demonstrate, Table 2-3 show the 3 topics where the *Apple Inc.* and the fruit *Apple* have the largest generation probability  $P(e|z)$  from these topics. We can see that the topic knowledge can provide a reasonable prior for entities appearing in a document: the *Apple Inc.* has a large prior in documents about *Computer*, *Video* and *Software*, and the fruit *Apple* has a large prior in documents about *Wine*, *Food* and *Plant*.

Topic( <b>Computer</b> )	Topic( <b>Video</b> )	Topic( <b>Software</b> )
<i>Computer</i>	<i>Video</i>	<i>Computer software</i>
<i>CPU</i>	<i>Mobile phone</i>	<i>Microsoft Windows</i>
<i>Hardware</i>	<i>Mass media</i>	<i>Linux</i>
<i>Personal computer</i>	<i>Music</i>	<i>Web browser</i>
<i>Computer memory</i>	<i>Television</i>	<i>Operating system</i>

Table 2. The 3 topics where the *Apple Inc.* has the largest  $P(e|z)$

Topic( <b>Wine</b> )	Topic( <b>Food</b> )	Topic( <b>Plant</b> )
<i>Wine</i>	<i>Food</i>	<i>Plant</i>
<i>Grape</i>	<i>Restaurant</i>	<i>Flower</i>
<i>Vineyard</i>	<i>Meat</i>	<i>Leaf</i>
<i>Winery</i>	<i>Cheese</i>	<i>Tree</i>
<i>Apple</i>	<i>Vegetable</i>	<i>Fruit</i>

Table 3. The 3 topics where the fruit *Apple* has the largest  $P(e|z)$

## 2) The effects of a fine-tuned context model.

The second advantage of our model is that it provides a statistical framework for fine-tuning the context model from data. To demonstrate such an effect, Table 4 compares the EL performance of ① the entity-topic model with no context model is used (*No Context*), i.e., we determine the referent entity of a mention by deleting the 3rd term of the formula  $P(e_i = e|z, \mathbf{e}_{-i}, \mathbf{a}, \mathbf{D})$  in Section 3; ② with the context model estimated using the entity’s Wikipedia page (*Article Content*), ③ with the context model estimated using the 50 word window of all its mentions in Wikipedia (*Mention Context*) and; ④ with the context model in the original entity-topic model (*Entity-Topic Model*). From Table 4 we can see that a fine-tuned context model will result in a 2~7% F1 improvement.

Context Model	F1
<i>No Context</i>	0.73
<i>Article Content</i>	0.75
<i>Mention Context</i>	0.78
<b><i>Entity-Topic Model</i></b>	<b>0.80</b>

Table 4. The *F1* using different context models

3) **The effects of joint model.** The third advantage of our model is that it *jointly* model the context compatibility and the topic coherence, which bring two benefits: ① the mutual reinforcement between the two directions can be captured in our model; ② the context compatibility and the topic coherence are uniformly modeled and jointly estimated, which makes the model more accurate for EL.

## 4.5.4 EL Accuracies on TAC 2009 dataset

We also compare our method with the top 5 EL systems in TAC 2009 and the two state-of-the-art systems (*EM-Model* and *EL-Graph*) on TAC 2009 data set in Figure 5 (For *EL-Graph* and our method, a NIL threshold is used to detect whether the referent entity is contained in the knowledge base, if the knowledge base not contains the referent entity, we assign the mention to a NIL entity). From Figure 5, we can see that our method is competitive: 1) Our method can achieve a 3.4% accuracy improvement over the best system in TAC 2009; 2) *Our method*, *EM-Model* and *EL-Graph* get very close accuracies (0.854, 0.86 and 0.838 correspondingly), we believe this is because: ① The mentions to be linked in TAC data set are mostly salient mentions; ② The influence of the NIL referent entity problem, i.e., the referent entity is not contained in the given knowledge base: Most referent entities (67.5%) on TAC 2009 are NIL entity and our method has no special handling on this problem, rather than other methods such as the *EM-Model*, which affects the overall performance of our method.

Figure 5. The EL accuracies on TAC 2009 dataset

## 5 Related Work

In this section, we briefly review the related work of EL. Traditionally, the *context compatibility* based methods link a mention to the entity which has the largest compatibility with it. Cucerzan (2007) modeled the compatibility as the cosine similarity between the vector space representation of mention's context and of entity's Wikipedia entry. Mihalcea & Csomai (2007), Bunescu & Pasca (2006), Fader et al. (2009), Gottipati et al.(2011) and Zhang et al.(2011) extended the vector space model with more information such as the entity category and the acronym expansion, etc. Han & Sun (2011) proposed a generative model which computes the compatibility using the evidences from entity's popularity, name distribution and context word distribution. Kataria et al.(2011) and Sen (2012) used a latent topic model to learn the context model of entities. Zheng et al. (2010), Dredze et al. (2010), Zhang et al. (2010), Zhou et al. (2010) and Ji & Chen(2011) employed the ranking techniques to further take relations between candidate entities into account.

On the other side, the *topic coherence* based methods link a mention to the entity which are most coherent to the document containing it. Medelyan et al. (2008) measured the topic coherence of an entity to a document as the weighted average of its relatedness to the unambiguous entities in the document. Milne and Witten (2008) extended Medelyan et al. (2008)'s coherence by incorporating commonness and context quality. Bhattacharya and Getoor (2006) modeled the topic coherence as the likelihood an entity is generated from the latent topics of a document. Sen (2012) modeled the topic coherence as the groups of co-occurring entities. Kulkarni et al. (2009) modeled the topic coherence as the sum of all pair-wise relatedness between the referent entities of a document. Han et al.(2011) and Hoffart et al.(2011) modeled the topic coherence of an entity as its node importance in a graph which captures all mention-entity and entity-entity relations in a document.

## 6 Conclusions and Future Work

This paper proposes a generative model, the entity-topic model, for entity linking. By uniformly modeling context compatibility, topic coherence and the correlation between them as statistical

dependencies, our model provides an effective way to jointly exploit them for better EL performance.

In this paper, the entity-topic model can only link mentions to the previously given entities in a knowledge base. For future work, we want to overcome this limit by incorporating an *entity discovery* ability into our model, so that it can also discover and learn the knowledge of previously unseen entities from a corpus for linking name mentions to these entities.

## Abstract

Existing techniques for disambiguating named entities in text mostly focus on Wikipedia as a target catalog of entities. Yet for many types of entities, such as restaurants and cult movies, relational databases exist that contain far more extensive information than Wikipedia. This paper introduces a new task, called Open-Database Named-Entity Disambiguation (Open-DB NED), in which a system must be able to resolve named entities to symbols in an arbitrary database, without requiring labeled data for each new database. We introduce two techniques for Open-DB NED, one based on distant supervision and the other based on domain adaptation. In experiments on two domains, one with poor coverage by Wikipedia and the other with near-perfect coverage, our Open-DB NED strategies outperform a state-of-the-art Wikipedia NED system by over 25% in accuracy.

## 1 Introduction

Named-entity disambiguation (NED) is the task of linking names mentioned in text with an established catalog of entities (Bunescu and Pasca, 2006; Ratnikov et al., 2011). It is a vital first step for semantic understanding of text, such as in grounded semantic parsing (Kwiatkowski et al., 2011), as well as for information retrieval tasks like person name search (Chen and Martin, 2007; Mann and Yarowsky, 2003).

NED requires a catalog of symbols, called referents, to which named-entities will be resolved. Most NED systems today use Wikipedia as the catalog of

referents, but exclusive focus on Wikipedia as a target for NED systems has significant drawbacks: despite its breadth, Wikipedia still does not contain all or even most real-world entities mentioned in text. As one example, it has poor coverage of entities that are mostly important in a small geographical region, such as hotels and restaurants, which are widely discussed on the Web. 57% of the named-entities in the Text Analysis Conference's (TAC) 2009 entity linking task refer to an entity that does not appear in Wikipedia (McNamee et al., 2009). Wikipedia is clearly a highly valuable resource, but it should not be thought of as the only one.

Instead of relying solely on Wikipedia, we propose a novel approach to NED, which we refer to as *Open-DB NED*: the task is to resolve an entity to Wikipedia or to *any* relational database that meets mild conditions about the format of the data, described below. Leveraging structured, relational data should allow systems to achieve strong accuracy, as with domain-specific or database-specific NED techniques like Hoffart *et al.*'s NED system for YAGO (Hoffart et al., 2011). And because of the availability of huge numbers of databases on the Web, many for specialized domains, a successful system for this task will cover entities that a Wikipedia NED or database-specific system cannot.

We investigate two complementary learning strategies for Open-DB NED, both of which significantly relax the assumptions of traditional NED systems. The first strategy, a distant supervision approach, uses the relational information in a given database and a large corpus of unlabeled text to learn a database-specific model. The second strat-

egy, a domain adaptation approach, assumes a single source database that has accompanying labeled data. Classifiers in this setting must learn a model that transfers from the source database to any new database, without requiring new training data for the new database. Experiments show that both strategies outperform a state-of-the-art Wikipedia NED system by wide margins without requiring any labeled data from the test domain, highlighting the significant advantage of having domain-specific relational data.

The next section contrasts Open-DB NED with previous work. Section 3 formalizes the task. Sections 4 and 5 present our distant supervision strategy and domain-adaptation strategy, respectively. Section 6 introduces a technique that is a hybrid of the two learning strategies. Section 7 describes our experiments, and Section 8 concludes.

## 2 Previous Work

As mentioned above, restricting the catalog of referents to Wikipedia, as most recent NED systems do (Bunescu and Pasca, 2006; Mihalcea and Csomai, 2007; Fader et al., 2009; Han and Zhao, 2009; Kulkarni et al., 2009; Ratinov et al., 2011), can restrict the coverage of the system. Zhou *et al.* (2010) estimate that 23% of names in Yahoo! news articles have no referent in Wikipedia, and Cucerzan (2007) estimates the rate at 16% in MSNBC news articles. There is reason to suspect that these estimates are on the low side, however, as news tends to cover popular entities, which are most likely to appear in Wikipedia; the mentions in TAC’s 2009 entity linking task are drawn from both newswire and blogs, and have a far higher rate (57%) of missing Wikipedia entries. Lin *et al.* (2012) find that 33% of mentions in a corpus of 500 million Web documents cannot be linked to Wikipedia.

NED systems that are focused on specific domains (or verticals) greatly benefit from repositories of domain-specific knowledge, only a subset of which may be found in Wikipedia. For example, Pantel and Fuxman (2011) use a query-click graph to resolve names in search engine queries to a large product catalog from a commercial search engine, while Dalvi *et al.* (2009; 2012) focus on movie and restaurant databases. Bellare and McCallum

(2009) use the sequence information available in citation text to link author, title, and venue names to a publication database. Open-DB NED systems work on any database, so they can serve as baselines for domain-specific NED tasks, as well as provide disambiguation for domains where no domain-specific NED system exists.

Numerous previous studies have considered distant or weak supervision from a single relational database as an alternative to manual supervision for information extraction (Hoffmann et al., 2011; Weld et al., 2009; Bellare and McCallum, 2007; Bunescu and Mooney, 2007; Mintz et al., 2009; Riedel et al., 2010; Yao et al., 2010). In contrast to these systems, our distant supervision NED system provides a meta-algorithm for generating an NED system for *any* database and any entity type.

Existing domain adaptation or transfer learning approaches are inappropriate for the Open-DB NED task, either because they require labeled data in both the source and target domains (Daumé III et al., 2010; Ben-David et al., 2010), or because they leverage some notion of distributional similarity between words in the source and target domains (Blitzer et al., 2006; Huang and Yates, 2009), which does not apply to the database symbols across the two domains. Instead, our domain adaptation technique uses *domain-independent* features of relational data, which apply regardless of the actual contents of the database, as explained further below.

## 3 The Open-DB NED Problem and Assumptions

### 3.1 Problem Formulation

A *mention* is an occurrence of a named-entity in a document. Formally, a mention  $m = (d, start, end)$  is a triple consisting of a document  $d$ , as well as a start and end position for the mention within the document. We say that  $d$  is the *context* of  $m$ . A *relational database* is a 2-tuple  $(S, R)$ . Here,  $S$  is a set of symbols for constants, attributes, and relations in the database, and  $R = \{r_1, \dots, r_n\}$  is a set of relation instances of the form  $r_i = \{(c_{1,1}, \dots, c_{1,k_i}), \dots, (c_{n_i,1}, \dots, c_{n_i,k_i})\}$ , where each  $c_j$  is taken from  $S$ ,  $k_i$  is the *arity* of relation  $r_i$  and  $n_i$  is the number of known instances of  $r_i$ . We will write example database symbols in

movie			actor		acted_in		
id	title	year	id	name	movie_id	actor_id	role
1	Next Door	1975	1	Nicole Kreuz	5	1	Evelyn
2	Next Door	2005	2	Richard Ryan	5	2	Bruce
3	Next Door	2008	3	Kristoffer Joner	2	3	John

1	Carlos Lee	6'2"	LF	1	San Diego Padres	4	3
2	Rob Bironas	6'0"	K	2	Houston Texans	5	2
3	Chris Johnson	6'3"	3B	3	Tennessee Titans	3	5
4	Chris Johnson	5'11"	RB	4	Oakland Raiders	1	5
5	Chris Johnson	6'1"	DB	5	Houston Astros	2	3
...	...	...	...	...	...	...	...

Figure 1: Example movie database (above) and sports database (below) in BCNF.

teletype, and mentions in “quotations.” For a particular database  $DB$ , we refer to its components as  $DB.S$  and  $DB.R$ . For a set of databases  $D$ , define the set of referents as  $S_D = (\bigcup_{DB \in D} DB.S) \cup \{OOD\}$ , where  $OOD$  is a special symbol indicating something that is “out of database”, or not found in any of the databases in  $D$ .

Given a corpus  $C$ , a set of mentions  $M$  that occur in  $C$ , and a set of databases  $D$ , the Open-DB NED task is to produce a function  $f : M \rightarrow S_D$ , which identifies an appropriate target symbol from one of the databases in  $D$ , or determines that the mention is  $OOD$ . Note that this problem formulation assumes no labeled data. This is significantly more challenging than traditional NED settings, but allows the system to generalize easily to any new database. In the domain adaptation section below, we relax this condition somewhat, to allow labeled data for a small number of initial databases; the system must then transfer what it learns from the labeled domains to any new database. Also note that the focus for this paper is disambiguation; we assume that the set of mentions are correctly demarcated in the input text. Previous systems, such as Lex (Downey et al., 2007), have investigated the task of finding correct named-entity boundaries in text.

### 3.2 Assumptions

To allow our systems to handle arbitrary databases, we need to make some assumptions about a standard format for the data. We will assume that databases are provided in a particular form, called *Boyce-Codd*

*Normal Form* (BCNF) (Silberschatz et al., 2010). A relational schema is said to be in BCNF when all redundancy based on functional dependency has been removed, although other types of redundancy may still exist. Formally, a schema  $R$  is said to be in BCNF with respect to a set of functional dependencies  $\mathcal{F}$  if for every one of the dependencies  $(X \rightarrow Y) \in \mathcal{F}$ , either

1.  $Y \subset X$ , meaning this is a trivial functional dependency, or
2.  $X$  is a *superkey*, meaning that  $X$  is a set of attributes that together define a unique ID for the relation.

In practice, this is a relatively safe assumption as database designers often aim for even stricter normal forms. For databases not in BCNF, such as tables extracted from Web pages, standard algorithms exist for converting them into BCNF, given appropriate functional dependencies, although there are sets of functional dependencies for which BCNF is not achievable. Figure 1 shows two example databases in BCNF. We use these tables as examples throughout the paper.

We will additionally assume that all attributes, including names and nicknames, of entities that are covered by the database are treated as functional dependencies of the entity. Again, in practice, this is a fairly safe assumption as this is part of good database design, but if a database does not conform to this, then there will be some entities in the database that our algorithms cannot resolve to. This assumption implies that it is enough to use the set of superkeys for relations as the set of possible referents; our algorithms make use of this fact.

Finally, we will assume the existence of a function  $\mu(s, t)$  which indicates whether the text  $t$  is a valid surface form of database symbol  $s$ . Our experiments in Section 7.3 explore several possible simple definitions for this function.

## 4 A Distant Supervision Strategy for Open-DB NED

Our first approach to the Open-DB NED problem relies on the fact that, while many mentions are indeed ambiguous and difficult to resolve correctly, most

mentions have only a very small number of possible referents in a given database. “Chris Johnson” is the name of doubtless thousands of people, but for articles that are reasonably well-aligned with our sports database, most of the time the name will refer to just three different people. Most sports names are in fact less ambiguous still. Thus, taking a corpus of unlabeled sports articles, we use the information in the database to provide (uncertain) labels, and then train a log-linear model from this probabilistically-labeled data.

This strategy requires a set of features for the model. Traditionally, such features would be hand-crafted for a particular domain and database. As a first step towards our Open-DB system, we present a log-linear model for disambiguation, as well as a simple feature-generation algorithm that produces a large set of useful features from a BCNF database. We then present a distant-supervision learning procedure for this model.

#### 4.1 Disambiguation Model

Let  $S_D$  be the set of possible referents. We construct a vector of feature functions  $\mathbf{f}(m, s)$  describing the degree to which  $m$  and  $s \in S_D$  appear to match one another. The feature functions are described below. The model includes a vector of weights  $\mathbf{w}$ , one weight per feature function, and sets the probability of entity  $s$  given  $m$  and  $\mathbf{w}$  as:

$$P(s|m, \mathbf{w}) = \frac{\exp(\mathbf{w} \cdot \mathbf{f}(m, s))}{\sum_{s' \in S_D} \exp(\mathbf{w} \cdot \mathbf{f}(m, s'))} \quad (1)$$

#### 4.2 Database-driven Feature Generation

Figure 2 shows our algorithm for automatically generating feature functions  $f_i(m, s)$  from a BCNF database. As mentioned above, we only need to consider resolving to database symbols  $s$  that are keys, or unique IDs, for some tuple in a database. For an entity in the database with key  $id$ , the feature generation algorithm generates two types of feature functions: attribute counts and similar entity counts. Each of these features measures the similarity between the information stored in the database about the entity  $id$ , and the information in the text in  $d$  surrounding mention  $m$ .

An *attribute count* feature function  $f_{i,j}^{att}(m, id)$  for the  $j$ th attribute of relation  $r_i$  counts how many

---

#### Algorithm: Feature Generation

---

Input:  $DB$ , a database in BCNF

Output:  $\mathbf{F}$ , a set of feature functions

Initialization:  $\mathbf{F} \leftarrow \emptyset$

#### Attribute Count Feature Functions:

For each relation  $r_i \in DB.R$

For each  $j$  in  $\{1, \dots, k_i\}$

Define function  $f_{i,j}^{att}(m, id)$ :

$count \leftarrow 0$

Identify the tuple  $t \in r_i$  containing  $id$

$val \leftarrow t_j$

$count \leftarrow count +$

$ContextMatches(val, m)$

return  $count$

$\mathbf{F} \leftarrow \mathbf{F} \cup \{f_{i,j}^{att}\}$

#### Similar-Entity Count Feature Functions:

For each relation  $r_i \in DB.R$

For each  $j$  in  $\{1, \dots, k_i\}$

Define function  $f_{i,j}^{sim}(m, id)$ :

$count \leftarrow 0$

Identify the tuple  $t \in r_i$  containing  $id$

$val \leftarrow t_j$

Identify the set of similar tuples  $T'$ :

$T' = \{t' | t' \in r_i, t'_j = val\}$

For each tuple  $t' \in T'$

For each  $j' \in \{1, \dots, k_i\}$

$val' \leftarrow t'_{j'}$

$count \leftarrow count +$

$ContextMatches(val', m)$

return  $count$

$\mathbf{F} \leftarrow \mathbf{F} \cup \{f_{i,j}^{sim}\}$

---

Figure 2: Feature generation algorithm. The  $ContextMatches(s, m)$  function counts how many times a string that matches database symbol  $s$  appears in the context of  $m$ . In our implementation, we use all of  $d(m)$  as the context. Matching between strings and database symbols is discussed in Sec. 7.3.

attributes of the entity  $id$  appear near  $m$ . For example, if  $id$  is 5 in the `movie` relation in Figure 1, the feature function for attribute `year` would count how often 2010 matches the text surrounding mention  $m$ . Defining precisely whether a database symbol “matches” a word or phrase is a subtle issue; we explore several possibilities in Section 7.3. In addition

to attribute counts for attributes within a single relation, we also use attributes from relations that have been inner-joined on primary key and foreign key pairs. For example, for movies, we include attributes such as director name, genre, and actor name. High values for these attribute count features indicate that the text around  $m$  closely matches the information in the database about entity  $id$ , and therefore  $id$  is a strong candidate for the referent of  $m$ . We use the whole document as the context for finding matches, although other variants are worth future investigation.

A *similar entity count* feature function  $f_{i,j}^{sim}(m, id)$  for the  $j$ th attribute in relation  $r_i$  counts how many entities similar to  $id$  are mentioned in the neighborhood of  $m$ . As an example, consider a mention of “Chris Johnson”,  $id = 3$ , and the similar entity feature for the `position` attribute of the `players` relation in the sports database. The feature function would first identify that 3B is the position of the player with  $id = 3$ . It would then identify all players that had the same position. Finally, it would count how often any attributes of this set of players appear near “Chris Johnson”. Likewise, the similar entity feature for the `team id` attribute would count how many teammates of the player with  $id = 3$  appear near “Chris Johnson”. A high count for this teammate feature is a strong clue that  $id$  is the correct referent for  $m$ , while a high count for players of the same position is a weak but still valuable clue.

### 4.3 Parameter Estimation via Distant Supervision

Using string similarity, we can heuristically determine that three IDs with `name` attribute `Chris Johnson` are highly likely to be the correct target for a mention of “Chris Johnson”. Our distant supervision parameter estimation strategy is to move as much probability mass as possible onto the set of realistic referents obtained via string similarity. Since our features rely on finding attributes and similar entities, the side effect of this strategy is that most of the probability mass for a particular mention is moved onto the one target ID with high attribute count and similar entity count features, thus disambiguating the entity. Although the string-similarity heuristic is typically noisy, the strong information in

the database and the fact that many entity mentions are typically not ambiguous allows the technique to learn effectively from unlabeled text.

Let  $\phi(m, DB)$  be a heuristic string-matching function that returns a set of plausible ID values in database  $DB$  for mention  $m$ . The objective function for this training procedure is a modified marginal log likelihood (MLL) function that encourages probability mass to be placed on the heuristically-matched targets:

$$MLL(M, \mathbf{w}) = \sum_{m \in M} \log \sum_{id \in \phi(m, DB)} P(id|m, \mathbf{w})$$

This objective is smooth but non-convex. We use a gradient-based optimization procedure that finds a local maximum. Our implementation uses an open-source version of the LBFSG-S optimization technique (Liu and Nocedal, 1989). The gradient of our objective is given by

$$\frac{\partial LL(M, \mathbf{w})}{\partial w_i} = \sum_{m \in M} \mathbf{E}_{id \in \phi(m, DB)} [f_i(m, id)] - \mathbf{E}_{id \in DB.S} [f_i(m, id)]$$

where the expectations are taken according to  $P(id|m, \mathbf{w})$ .

## 5 A Domain-Adaptation Strategy for Open-DB NED

Our domain-adaptation strategy builds an Open-DB NED system by training it on labeled examples from an initial database or small set of initial databases. Unlike traditional NED, however, the purpose in Open-DB NED is to resolve to any database. Thus the strategy must take care to build a model that can transfer what it has learned to a new database, without requiring additional labeled data for the new database.

At first, the problem seems intractable — just because a system can disambiguate between “Next Door”, the 2005 Norwegian film, and “Next Door”, the 1975 short film by director Andrew Silver, that seems to provide little benefit for disambiguating between different athletes named “Andre Smith.” The crux of the problem lies in the fact that database-driven features are domain-specific. Counting how many times the director of a movie appears is highly

useful in the movie domain, but worthless in the sports domain.

Our solution works by re-defining the problem in such a way that we can define domain-independent and database-independent features. For example, rather than counting how often the director of a movie appears in the context around a movie mention, we create a domain-independent Count Att( $m, s$ ) feature function that counts how often *any* attribute of  $s$  appears in the context of  $m$ . For movies, Count Att will add together counts for appearances of a movie’s production year and IMDB rating, among other attributes. In the sports domain, Count Att will add together counts for appearances of a player’s height, position, salary, *etc.*. But in either domain, the feature is well-defined, and in either domain, larger values of the feature indicate a better match between  $m$  and  $s$ . Thus there is a hope for training a model with domain-independent features like Count Att on labeled data from one domain, say movies, and producing a model that has high accuracy on the sports domain.

We first formalize the notion of a domain adaptation NED model, and then describe our algorithm for producing such a model. We say that a *domain* consists of a database  $DB$  as well as a distribution  $\mathcal{D}(\mathcal{M})$ , where  $\mathcal{M}$  is the space of mentions. For instance, the movie domain might consist of the Internet Movie Database (IMDB) and a distribution that places most probability mass on documents about movies and Hollywood stars. In *domain adaptation*, a system observes a set of training examples  $(m, s, g(m, s))$ , where instances  $m \in \mathcal{M}$  are drawn from a *source* domain’s distribution  $\mathcal{D}_S$  and referents  $s$  are drawn from the source domain’s database  $DB_S$ . The labels  $g(m, s)$  are boolean values indicating a correct or incorrect match between the mention and referent. The system must then learn a hypothesis for classifying examples  $(m, s)$  drawn from a *target* domain’s distribution  $\mathcal{D}_T$  and database  $DB_T$ . Note that for domain adaptation, we cannot use the more traditional problem formulation in which the referent  $s$  is a label (*i.e.*,  $s = g(m)$ ) for the mention, since the set of possible referents changes from domain to domain, and therefore the output of  $g$  would be completely different from one domain to the next.

Table 1 lists the domain-independent features

---

### Domain-Independent Feature Functions

---

Count Att:	$\sum_{i,j} f_{i,j}^{att}(m, s)$
Count Sim:	$\sum_{i,j} f_{i,j}^{sim}(m, s)$
Count All:	Count Att + Count Sim
Count Unique:	$\sum_{i,j} \begin{cases} 0 & \text{if } f_{i,j}^{att}(m, s) = 0, \\ 1 & \text{if } f_{i,j}^{att}(m, s) > 0. \end{cases}$
Count Num:	$\sum_{i,j   j \text{ is a numeric att.}} f_{i,j}^{att}(m, s)$

---

Table 1: Primary feature functions for a domain adaptation approach to NED. These features made the biggest difference in our experiments, but we also tested variations such as counting unique numeric attribute appearances, counting unique similar entities, counting relation name appearances, counting extended attributed appearances, and others.

used in our domain adaptation model. These features use the attribute counts and similar entity counts from the distant supervision model as subroutines. By aggregating over those domain-dependent feature functions, the domain adaptation system arrives at feature functions that can be defined for *any* database, rather than for a specific database.

Note that there is a tradeoff between the domain adaptation technique and the distant supervision technique. The domain adaptation model has access to labeled data, unlike the distant supervision model. In addition, the domain adaptation model requires no text whatsoever from the target domain, not even an unlabeled corpus, to set weights for the target domain. Once trained, it is ready for NED over any database that meets our assumptions, out of the box. However, because the model needs to be able to transfer to arbitrary new domains, the domain adaptation model is restricted to domain-independent features, which are “coarser-grained.” That is, the distant supervision model has the ability to place more weight on attributes like director rather than genre, or team rather than position, if those attributes are more discriminative. The domain adaptation model cannot place different weights on the different attributes, since those weights would not transfer across databases.

As with distant supervision, the domain adaptation strategy uses a log-linear model over these feature functions. We use standard techniques for training the model using labeled data from the source do-

main: conditional log likelihood (CLL) as the objective function, and LBFG-S for convex optimization.

$$CLL(L, \mathbf{w}) = \sum_{(m, id, label) \in L} \log P(label|m, id, \mathbf{w})$$

The training algorithm is guaranteed to converge to the globally optimal parameter setting for this objective function over the training data. The manually annotated data contains only positive examples; to generate negative examples, we use the same name-matching heuristic  $\phi(m, DB)$  to identify a set of potentially confusing bad matches. On test data, we use the trained model to choose the  $id$  for a given  $m$  with the highest probability of being correct.

## 6 A Hybrid Model

The distant supervision and domain adaptation strategies use two very different sources of evidence for training a disambiguation classifier: the string-matching heuristic and unlabeled text from the target domain for the distant supervision model, and aggregate features over labeled text from a separate domain for domain adaptation. This begs the question, do these sources of evidence complement one another? To address this question, we design a Hybrid model with features and training strategies from both distant supervision and domain adaptation.

The training data consists of a set  $L_S$  of labeled mentions from a source domain, a source database  $DB_S$ , a set of unlabeled mentions  $M_T$  from the target domain, and the target-domain database  $DB_T$ . The full feature set of the Hybrid model is the union of the distant supervision feature functions for the target domain and the domain-independent domain adaptation feature functions. Note that the distant supervision feature functions are domain-specific, so they almost always will be uniformly zero on  $L_S$ , but the domain adaptation feature functions will be activated on both  $L_S$  and  $M_T$ . The combined training objective for the Hybrid model is:

$$LL(L_S, M_T, \mathbf{w}) = CLL(L_S, \mathbf{w}) + MLL(M_T, \mathbf{w})$$

## 7 Experiments

Our experiments compare our strategies for OpenDB NED against one another, as well as against a Wikipedia NED system from previous work, on two domains: sports and movies.

### 7.1 Data

For the movie domain, we collected a set of 156 cult movie titles from an online movie site ([www.olivefilms.com](http://www.olivefilms.com)). For each movie title, we executed a Web search using a commercial search engine, and collected the top five documents for each title from the search engine’s results. Nearly all top-five results included at least one mention of an entity not found in Wikipedia; overall, only 16% of the mentions could be linked to Wikipedia. After stripping javascript and html annotations, we removed documents with fewer than 50 words, leaving a total of 770 documents. We select one occurrence of any of the 156 movie titles from each document as our set of mentions. Many titles are ambiguous not just among different movies with the same name, but also among novels, plays, geographical entities, and assorted other types of entities. To provide labels for these mentions, we use both a movie database and Wikipedia. We downloaded the complete data dump from the online Internet Movie Database (IMDB, [www.imdb.com](http://www.imdb.com)). For our set of possible referents, we use the set of all key values in IMDB, and the set of all Wikipedia articles. Annotators manually labeled each mention using this set of referents. Table 2 shows summary statistics about this labeled data.

For the sports domain, we downloaded all player data from Yahoo!, Inc.’s sports database for the years 2011-2012 and two American sports leagues, the National Football League (NFL) and Major League Baseball (MLB). From the database, we extracted ambiguous player names and team names, including names like “Philadelphia” which may refer to Philadelphia Eagles in the NFL data, Philadelphia Phillies in the MLB data, or the city of Philadelphia itself (in both types of data). We then collected 1300 Yahoo! news articles which include a mention that partially matches at least one of these database symbols. We manually labeled a random sample of 564 mentions from this data, including 279 player name mentions and 285 city name mentions. Many player name and place name mentions are ambiguous between the two sports leagues, as well as with teams or players from other leagues. In order to focus on the hardest cases, we specifically exclude mentions like “Philadelphia” from the labeled data if any of their

domain	$ M $	$E \phi(m, DB) $	<i>OOD</i>	Wiki
movies	770	2.6	13%	16%
sports	549	4.5	0%	100%

Table 2: Number of mentions, average number of referents per mention, % of mentions that are *OOD*, and % of mentions that are in Wikipedia in our movie and sports data.

unambiguous completions appears in the same article (that is, if either of the team names “Philadelphia Eagles” or “Philadelphia Phillies” appears in the same article, we exclude the “Philadelphia” mention). As before, the set of possible referents includes the symbol *OOD*, key values from the sports database, and Wikipedia articles, and a given mention may be labeled with both a sports entity and a Wikipedia article, if appropriate. All of our data is available from the last author’s website.

## 7.2 Evaluation Metric

We report on a version of exact-match accuracy. The system chooses the most likely label  $\hat{s}$  for each  $m$ . This is judged correct if  $\hat{s}$  matches the correct label  $s$  exactly, or (in cases where both a Wikipedia and a database entity are considered correct) if one of the labels matches  $\hat{s}$  exactly. This metric allows systems to resolve against either reference, Wikipedia or another database, without requiring it to match both if the same entity appears in both references.

## 7.3 Exact or Partial Matching?

One important question in the design of our systems is how to determine the “match” between database symbols and text. This question comes into play in two components of our systems: it affects the computation of feature functions that count how often a match of some attribute is found in text, and it affects which set of heuristically-determined database entities are considered to be possible matches for a given mention.

We experiment with two different matching strategies between a symbol  $s$  and text  $t$ , exact matching and partial matching. Exact matching  $\mu_{exact}(s, t)$  requires the sequence of characters in  $s$  to appear exactly (modulo character encoding) in  $t$ . For instance, the database value `Chris Johnson`

System	Accuracy
No-Wikipedia Domain Adapt.	0.61
DocSim-Wikipedia Domain Adapt.	<b>0.69</b>

Table 3: Including a simple document-similarity feature for comparing a mention’s context with a Wikipedia page provides an 8% improvement over ignoring Wikipedia information.

would match “Chris Johnson”, but not “C. Johnson” or “Johnson” in text. For partial matching, we used different tests for numeric and textual entities. For numeric entities,  $\mu_{partial}$  matched  $s$  and  $t$  if the numeric value of one was within 10% of the other, so that 5312 would match “5,000.” We made no attempt to convert numeric phrases, such as “3.6 million”, into numeric values. For textual entities,  $\mu_{partial}$  matched  $s$  and  $t$  if at least one token from each matched exactly. Thus `Chris Johnson` matches both “Chris” and “C. Johnson”.

We found  $\mu_{partial}$  to be consistently superior for computing  $\phi(m, DB)$ , since it has much better recall for mentions like “Philadelphia”. On the other hand, if we use  $\mu_{partial}$  for computing our models’ feature functions, like the Count Att( $m, s$ ) in the domain adaptation model, counts varied widely across domains. A simple version of the domain adaptation classifier (only the Count All and Count Unique features) trained on sports data and tested on movies achieved an accuracy of 24% using  $\mu_{partial}$ , compared with 61% using  $\mu_{exact}$ . For all remaining tests, we used  $\mu_{exact}$  for computing features, and  $\mu_{partial}$  for computing  $\phi(m, DB)$ .

## 7.4 Incorporating Wikipedia referents

Thus far, all of our features work on relational data, not Wikipedia. In order to allow our systems to link to Wikipedia, we create a single “document similarity” feature describing the similarity between the text around a mention and the text appearing on a Wikipedia page. We build a vector space model of both the document containing the mention and the Wikipedia page, remove stopwords, and use cosine similarity to compute this feature.

To evaluate the effectiveness of this Wikipedia feature, we tested two versions of our domain adaptation system, both trained on sports data and tested

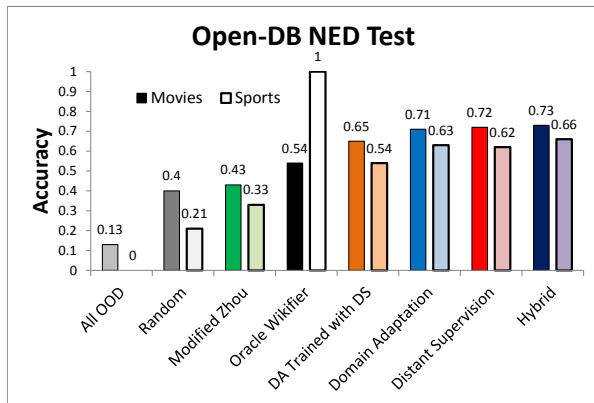

Figure 3: **All three Open-DB NED strategies outperform a state-of-the-art Wikipedia NED system by 25% or more on sports and movies, and outperform a Wikipedia NED system with oracle information by 14% or more on the movie data.** Differences between the Modified Zhou Wikifier and the Open-DB strategies are statistically significant ( $p < 0.01$ , Fisher’s exact test) on both domains.

on the movies domain. The first version involves no Wikipedia information whatsoever, thus it has no reason to select a Wikipedia article over *OOD*. The second system includes the document similarity feature. Table 3 shows the results of these systems. Encouragingly, our single document similarity feature produces a significant improvement over the model without Wikipedia information, so we use this feature in all of our systems tested below. More sophisticated use of Wikipedia is certainly possible, and an important question for future work is how to combine Open-DB NED more seamlessly with Wikipedia NED.

### 7.5 Comparing Open-DB NED Strategies

For each domain, we compare our domain-adaptation strategy, distant supervision, and hybrid strategies. The domain-adaptation model is trained on the labeled data for sports when testing on movies, and *vice versa*. We use a movies test set of 180 mentions that is separate from the development data used for the above tests. For the distant supervision strategy, we use the entire collection of texts from each domain as input (1300 articles for sports, 770 articles for movies), with the labels removed during training.

We compare against a state-of-the-art Wikipedia

NED system used in production by a major Web company. This system is a modified version of the system described by Zhou et al. (2010), where certain features have been removed for efficiency. We refer to this as the Modified-Zhou Wikifier. This system uses a gradient-boosted decision tree and multiple local and global features for computing the similarity between a mention’s context and a Wikipedia article. We also test a hypothetical system, Oracle Wikifier, which is given no information about entities in IMDB, but is assumed to be able to correctly resolve any mention that refers to an entity found in Wikipedia. Thus, this system has perfect accuracy on mentions that can be found in Wikipedia, and accuracy similar to a baseline that predicts randomly on all mentions that fall outside of Wikipedia<sup>1</sup>. Oracle-Wikifier serves as an upper bound on systems that have no access to a domain-specific database. In addition, we compare against two standard baselines: a classifier that always predicts *OOD*, and a classifier that chooses randomly. Finally, we compare against a system that trains the domain adaptation model using distant supervision (“DA Trained with DS”).

Figure 3 shows our results. All three Open-DB approaches outperform the baseline techniques on this test by wide margins, with the Hybrid model increasing by 30% or more over the random baseline. On the movie domain, the Hybrid model outperforms the Oracle Wikifier by nearly 20%. Encouragingly, the Hybrid model consistently outperforms both distant supervision and domain adaptation, suggesting that the two sources of evidence are partially complementary. Distant supervision performs better on the movies test, whereas domain adaptation has the advantage on sports. The differences among all three Open-DB approaches is relatively small, compared with the difference between these approaches and Oracle Wikifier on the movie data.

The domain adaptation system outperforms DA Trained with DS on both domains, suggesting that labeled data from a separate domain is better evidence for parameter estimates than unlabeled data from the same domain. The distant supervision system also outperforms DA Trained with

<sup>1</sup>Alternatively, one could make the oracle system predict *OOD* on all mentions that fall outside of Wikipedia. Random predictions perform better on our data.

DS on both domains, suggesting that the fine-grained, domain-specific features do in fact provide more helpful information than the coarser-grained, domain-independent features of the domain adaptation model.

All of the Open-DB NED systems outperform the Modified Zhou Wikifier on both data sets by a wide margin. In fact the Modified Zhou Wikifier has similar results on both domains, despite the fact that Wikipedia has far greater coverage on sports than movies. In part, the poor performance of the Modified Zhou Wikifier reflects the difficult nature of the task. In previous experiments on an MSNBC news test set it reached 85% accuracy, but a random classifier there achieved 60% accuracy compared with 21% on our sports data. Another difficulty with the Modified Zhou Wikifier is its strong preference for globally common entities. It consistently classifies mentions that are ambiguous between a city and a team (like “Chicago” in “Chicago sweeps the Red Sox”) as cities when they should be resolved to teams, in large part because `Chicago` is a more common referent in general text than either of the baseball teams that play in that city. In sports articles, however, both meanings are common, and only the surrounding context can help determine the correct referent.

Besides wikifiers, NED systems may also be compared with dictionary-based word sense disambiguation techniques like the Lesk algorithm<sup>2</sup> (Lesk, 1986). The Lesk algorithm is “open” in the sense that it works for arbitrary dictionaries, and it defines a vector space model of the dictionary definitions that may be likened to the attribute-value model in our representation of entities in the database. Our approach, however, estimates parameters for a statistical model from data, whereas the Lesk algorithm uses an equal weight for all attributes. To make an empirical comparison, we created a variant of the Lesk algorithm for relational data: we took the disambiguation model from Eqn. 1, supplied all of the features from the distant supervision model, and manually set  $\mathbf{w} = \mathbf{1}$ . This “relational Lesk” model achieves an accuracy of 0.11 on movies, and 0.15 on sports, significantly below the random baseline. Giving equal weight to noisy attributes like `genre`

---

<sup>2</sup>We thank the reviewers for making this connection.

and more discriminative attributes like `director` significantly hurts the performance.

For both the movie and sports domain, approximately 80% of the Hybrid model’s errors are because of predicting database symbols, when the correct referent is a Wikipedia page or *OOD*. This nearly always occurs because some words in the context of a mention match an attribute of an incorrect database referent. For instance, the `crime` genre is an attribute for several movies, but it also matches in contexts surrounding book titles and numerous other entities. In the movie domain, most of the remaining errors are incorrect *OOD* predictions for mentions that should resolve to the database, but the article contains no attributes or similar entities to the database entity. In the sports domain, many of the remaining errors were due to predicting incorrect player referents. Quite often, this was because the document discusses a fantasy sports league or team, where players from different professional sports teams are mixed together on a “fantasy team” belonging to a fan of the sport. Since players in the fantasy leagues have different teammates than they do in the database, these articles consistently confuse our methods.

## 8 Conclusion and Future Work

This paper introduces the task of Open-DB Named Entity Disambiguation, and presents two distinct strategies for solving this task. Experiments indicate that a mixture of the two strategies significantly outperforms a state-of-the-art Wikipedia NED system, on a dataset where Wikipedia has good coverage and on another dataset where Wikipedia has poor coverage. The results indicate that there is a significant benefit to leveraging other sources of knowledge in addition to Wikipedia, and that it is possible to leverage this knowledge without requiring labeled data for each new source. The initial success of these Open-DB NED approaches indicates that this task is a promising area for future research, including exciting extensions that link large numbers of domain-specific databases to text.

## Abstract

Generic rule-based systems for Information Extraction (IE) have been shown to work reasonably well out-of-the-box, and achieve state-of-the-art accuracy with further domain customization. However, it is generally recognized that manually building and customizing rules is a complex and labor intensive process. In this paper, we discuss an approach that facilitates the process of building customizable rules for Named-Entity Recognition (NER) tasks via rule induction, in the Annotation Query Language (AQL). Given a set of basic features and an annotated document collection, our goal is to generate an initial set of rules with reasonable accuracy, that are interpretable and thus can be easily refined by a human developer. We present an efficient rule induction process, modeled on a four-stage manual rule development process and present initial promising results with our system. We also propose a simple notion of extractor complexity as a first step to quantify the interpretability of an extractor, and study the effect of induction bias and customization of basic features on the accuracy and complexity of induced rules. We demonstrate through experiments that the induced rules have good accuracy and low complexity according to our complexity measure.

## 1 Introduction

Named-entity recognition (NER) is the task of identifying mentions of rigid designators from text belonging to named-entity types such as persons, organizations and locations (Nadeau and Sekine, 2007). Generic NER rules have been shown to work reasonably well-out-of-the-box, and with further domain customization (Chiticariu et al., 2010b), achieve quality surpassing state-of-the-art results. Table 1

System	Dataset	$F_{\beta=1}$	
		Generic	Customized
GATE	ACE2002	57.8	82.2
	ACE 2005	57.32	88.95
SystemT	CoNLL 2003	64.15	91.77
	Enron	76.53	85.29

Table 1: Quality of generic vs. customized rules.

summarizes the quality of NER rules out-of-the-box and after domain customization in the GATE (Cunningham et al., 2011) and SystemT (Chiticariu et al., 2010a) systems, as reported in (Maynard et al., 2003) and (Chiticariu et al., 2010b) respectively.

Rule-based systems are widely used in enterprise settings due to their *explainability*. Rules are transparent, which leads to better explainability of errors. One can easily identify the cause of a false positive or negative, and refine the rules without affecting other correct results identified by the system. Furthermore, rules are typically easier to understand by an IE developer and can be customized for a new domain without requiring additional labeled data.

Typically, a rule-based NER system consists of a combination of four categories of rules (Chiticariu et al., 2010b): (1) *Basic Feature (BF)* rules to identify components of an entity such as first name and last name. (2) *Candidate definition (CD)* rules to identify complete occurrences of an entity by combining the output of multiple BF rules, e.g., first name followed by last name is a person candidate. (3) *Candidate refinement (CR)* rules to refine candidates generated by CD rules. E.g., discard candidate persons contained within organizations. (4) *Consolidation rules (CO)* to resolve overlapping candidates generated by multiple CD and CR rules.

A well-known drawback that influences the adoptability of rule-based NER systems is the man-

ual effort required to build the rules. A common approach to address this problem is to build a generic NER extractor and then customize it for specific domains. While this approach partially alleviates the problem, substantial manual effort (in the order of several person weeks) is still required for the two stages as reported in (Maynard et al., 2003; Chiticariu et al., 2010b). In this paper, we present initial work towards facilitating the process of building a generic NER extractor using induction techniques.

Specifically, given as input an annotated document corpus, a set of BF rules, and a default CO rule for each entity type, our goal is to generate a set of CD and CR rules such that the resulting extractor constitutes a good starting point for further refinement by a developer. Since the generic NER extractor has to be manually customized, a major challenge is to ensure that the generated rules have good accuracy, and, at the same time, that they are *not too complex*, and consequently *interpretable*.

The main contributions in this paper are

1. An *efficient* system for NER rule induction, using a highly expressive rule language (AQL) as the target language. The first phase of rule induction uses a combination of *clustering* and *relative least general generalization (RLGG)* techniques to learn CD rules. The second phase identifies CR rules using a propositional rule learner like *JRIP* to learn accurate compositions of CD rules.
2. Usage of induction biases to enhance the interpretability of rules. These biases capture the expertise gleaned from manual rule development and constrain the search space in our induction system.
3. Definition of an initial notion of extractor complexity to quantify the interpretability of an extractor and to guide the process of adding induction biases to favor learning *less complex* extractors. This is to ensure that the rules are easily customizable by the developer.
4. Scalable induction process through usage of SystemT, a state-of-the-art IE system which serves as a highly efficient theorem prover for AQL, and performance optimizations such as clustering of examples and parallelizing various modules (E.g.: propositional rule learning).

**Roadmap** We first describe preliminaries on SystemT and AQL (Section 3) and define the target language for our induction algorithm and the notion of rule complexity (Section 4). We then present our approach for inducing CD and CR rules, and discuss induction biases that would favor interpretability (Section 5), and discuss the results of an empirical evaluation (Section 6). We conclude with avenues for improvement in the future (Section 7).

## 2 Related Work

Existing approaches to rule induction for IE focus on rule-based systems based on the cascading grammar formalism exemplified by the Common Pattern Specification Language (CPSL) (Appelt and Onyshkevych, 1998), where rules are specified as a sequence of basic features that describe an entity, with limited predicates in the context of an entity mention. Patel et al. (2009) and Soderland (1999) elaborate on top-down techniques for induction of IE rules, whereas (Califf and Mooney, 1997; Califf and Mooney, 1999) discuss a bottom-up IE rule induction system that uses the *relative least general generalization (RLGG)* of examples<sup>1</sup>. However, in all these systems, the expressivity of the rule-representation language is restricted to that of capturing sequence information. As discussed in Section 3, contextual clues and higher level rule interactions such as *filtering* and *join* are very difficult, if not impossible to express in such representations without resorting to custom code. Learning higher level interactions between rules has received little attention. Our technique for learning higher level interactions is similar to the induction of *ripple down rules* (Gaines and Compton, 1995), which, to the best of our knowledge, has not been previously applied to IE. A framework for refining AQL extractors based on an annotated document corpus described in (Liu et al., 2010). We present complementary techniques for inducing an initial extractor that can be automatically refined in this framework.

## 3 Preliminaries

SystemT is a declarative IE system based on an algebraic framework. In SystemT, developers write rules in AQL. To represent annotations in a docu-

<sup>1</sup>Our work also makes use of RLGGs but computes these generalizations for clusters of examples, instead of pairs.

```

Figure 1: Example *Person* extractor in AQL

ment, AQL uses a simple relational data model with three types: a *span* is a region of text within a document identified by its “begin” and “end” positions; a *tuple* is a fixed-size list of spans; a *relation*, or *view*, is a multi-set of tuples, where every tuple in the view must be of the same size.

Figure 1 shows a portion of a *Person* extractor written in AQL. The basic building block of AQL is a *view*. A *view* is a logical description of a set of tuples in terms of (i) the document text (denoted as a special view called *Document*), and (ii) the contents of other views, as specified in the *from* clauses of each statement. Figure 1 also illustrates five of the basic constructs that can be used to define a view, and which we explain next. The complete specification can be found in the AQL manual (IBM, 2012). In the paper, we will use ‘rules’ and ‘views’ interchangeably.

**The *extract* statement** specifies basic character-level extraction primitives such as regular expression and dictionary matching over text, creating a tuple for each match. As an example, rule  $R_1$  uses the *extract* statement to identify matches (*Caps* spans) of a

regular expression for capitalized words.

**The *select* statement** is similar to the SQL *select* statement but it contains an additional *consolidate on* clause (explained further), along with an extensive collection of text-specific predicates. Rule  $R_5$  illustrates a complex example: it selects *First* spans immediately followed within zero tokens by a *Last* span, where the latter is also a *Caps* span. The two conditions are specified using two join predicates: *FollowsTok* and *Equals* respectively. For each triplet of *First*, *Last* and *Caps* spans satisfying the two predicates, the *CombineSpans* built-in scalar function in the *select* clause constructs larger *PersonFirstLast* spans that begin at the begin position of the *First* span, and end at the end position of the *Last* (also *Caps*) span.

**The *union all* statement** merges the outputs of two or more statements. For example, rule  $R_6$  unions person candidates identified by rules  $R_4$  and  $R_5$ .

**The *minus* statement** subtracts the output of one statement from the output of another. For example, rule  $R_8$  defines a view *PersonAll* by filtering out *PersonInvalid* tuples from the set of *PersonCandidate* tuples. Notice that rule  $R_7$  used to define the view *PersonInvalid* illustrates another join predicate of AQL called *Overlaps*, which returns true if its two argument spans overlap in the input text. Therefore, at a high level, rule  $R_8$  removes person candidates that overlap with an *Organization* span. (The *Organization* extractor is not depicted in the figure.)

**The *consolidate* clause** of a *select* statement removes selected overlapping spans from the indicated column of the input tuples, according to the specified policy (for instance, ‘ContainedWithin’). For example, rule  $R_9$  retains *PersonAll* spans that are not contained in other *PersonAll* spans.

Internally, SystemT compiles an AQL extractor into an executable plan in the form of a graph of *operators*. The formal definition of these operators takes the form of an algebra (Reiss et al., 2008), similar to relational algebra, but with extensions for text processing. The decoupling between AQL and the operator algebra allows for greater rule expressivity because the rule language is not constrained by the need to compile to a finite state transducer, as in grammar systems based on the CPSL standard. In fact, join predicates such as *Overlaps*, as well as filter operations (*minus*) are extremely difficult to ex-

press in CPSL systems such as GATE without an escape to custom code (Chiticariu et al., 2010b). In addition, the decoupling between the AQL specification of “*what*” to extract from “*how*” to extract it, allows greater flexibility in choosing an efficient execution strategy among the many possible operator graphs that may exist for the same AQL extractor. Therefore, extractors written in AQL achieve orders of magnitude higher throughput (Chiticariu et al., 2010a).

#### 4 Induction Target Language

Our goal is to automatically generate NER extractors with good quality, and at the same time, manageable complexity, so that the extractors can be further refined and customized by the developer. To this end, we focus on inducing extractors using the subset of AQL constructs described in Section 3. We note that we have chosen a small subset of AQL constructs that are sufficient to implement several common operations required for NER. However, AQL is a much more expressive language, and incorporating additional constructs is subject to our future work.

In this section we describe the building blocks of our target language, and propose a simple definition for measuring the complexity of an extractor.

**Target Language.** The components of the target language are as follows, and summarized in Table 2. *Basic features (BF)*: *BF views* are specified using the *extract* statement, such as rules  $R_1$  to  $R_3$  in Figure 1. In this paper, we assume as input a set of *basic features*, consisting of dictionaries and regular expressions.

*Candidate definition (CD)*: *CD views* are expressed using the *select* statement to combine BF views with join predicates (e.g., *Equals*, *FollowsTok* or *Overlaps*), and the *CombineSpans* scalar function to construct larger candidate spans from input spans. Rules  $R_4$  and  $R_5$  in Figure 1 are example CD rules. In general, a CD view is defined as: “*Select all spans constructed from  $view_1, view_2, \dots, view_n$ , such that all join predicates are satisfied*”.

*Candidate refinement (CR)*: *CR views* are used to discard spans output by the CD views that may be incorrect. In general, a CR view is defined as: “*From the list of spans of  $view_{valid}$  subtract all those spans that belong to  $view_{invalid}$* ”.  $view_{valid}$  is obtained by joining all the positive CD clues on the *Equals* predicate

and  $view_{invalid}$  is obtained by joining all the negative overlapping clues with the *Overlaps* predicate and subsequently ‘union’ing all the negative clues. (e.g., similar in spirit to rules  $R_6, R_7$  and  $R_8$  in Figure 1, except that the subtraction is done from a single view and not the *union* of multiple views).

*Consolidation (CO)*: Finally, a *select* statement with a fixed *consolidate* clause is used for each entity type to remove overlapping spans from CR views. An example CO view is defined by rule  $R_9$  in Figure 1.

**Extractor Complexity.** Since our goal is to generate extractors with manageable complexity, we must introduce a quantitative measure of extractor complexity, in order to (1) judge the complexity of the extractors generated by our system, and (2) reduce the search space considered by the induction system.

To this end, we define a simple complexity score that is a function of the number of rules, and the number of input views to each rule of the extractor. In particular, we define the *length of rule  $R$* , denoted as  $L(R)$ , as the number of input views in the *from* clause(s) of the view. For example, in Figure 1, we have  $L(R_4) = 2$  and  $L(R_5) = 3$ , since  $R_4$  and  $R_5$  have two, and respectively three views in the *from* clause. Furthermore,  $L(R_8) = 2$  since each of the two inner statements of  $R_8$  has one *from* clause with a single input view. The complexity of BF rules (e.g.,  $R_1$  to  $R_3$ ) and CO rules (e.g.,  $R_9$ ) is always 1, since these types of rules have a single input view. We define the *complexity of extractor  $E$* , denoted as  $C(E)$  as the sum of lengths of all rules of  $E$ . For example, the complexity of the *Person* extractor from Figure 1 is 15, plus the length of all rules involved in defining *Organization*, which are omitted from the figure.

Our simple notion of rule length is motivated by existing literature in the area of database systems (Abiteboul et al., 1995), where the *size* of a conjunctive query is determined only by the number of atoms in the body of the query (e.g., items in the FROM clause), and it is independent on the number of join variables (i.e., items in the WHERE clause), or the size of the head of the query (e.g., items in the SELECT clause). As such, our notion of complexity is rather coarse, and we shall discuss its shortcomings in detail in Section 6.2. However, we shall show that the complexity score significantly reduces the search space of our induction techniques leading to

Phase name	AQL statements	Prescription	Rule Type
Basic Features	<b>extract</b>	Off-the-shelf, Learning using prior work (Riloff, 1993; Li et al., 2008)	Basic Features Definition
Phase 1 (Clustering and RLGG)	<b>select</b>	Bottom-up learning (LGG), Top-down refinement	Development of Candidate Rules
Phase 2 (Propositional Rule Learning)	<b>select, union all, minus</b>	RIPPER, Lightweight Rule Induction	Candidate Rules Filtering
Consolidation	<b>consolidate, union all</b>	Manually identified consolidation rules, based on domain knowledge	Consolidation rules

Table 2: Phases in induction, the language constructs invoked in each phase, the prescriptions for inducing rules in the phase and the corresponding type of rule in manual rule development.

simpler and smaller extractors, and therefore constitutes a good basis for more comprehensive measures of interpretability in the future.

## 5 Induction of Rules

Since the goal is to generate rules that can be customized by humans, the overall structure of the induced rules must be similar in spirit to what a developer following best practices would write. Hence, the induction process is divided into multiple phases. Figure 2 shows the correspondence between the phases of induction and the types of rules. In Table 2, we summarize the phases of our induction algorithm, along with the subset of AQL constructs that comprise the language of the rules learnt in that phase, the possible methods prescribed for inducing the rules and their correspondence with the stages in the manual rule development.

Our induction system generates rules for two of the four categories, namely CD and CR rules as highlighted in Figure 2. We assume that we are given the BFs in the form of dictionaries and regular expressions. Prior work on learning dictionaries (Riloff, 1993) and regular expressions (Li et al., 2008) could be leveraged to semi-automate the process of defining the basic features.

We represent each example, in conjunction with relevant background knowledge in the form *first order horn clauses*. This background knowledge will serve as input to our induction system. The first phase of induction uses a combination of *clustering* and *relative least general generalization (RLGG)* (Nienhuys-Cheng and Wolf, 1997; Muggleton and Feng, 1992) techniques. At the end of this phase, we have a number of CD rules. In the second phase, we begin by forming a structure called the *span-view table*. Broadly speaking, this is an

attribute-value table formed by all the views induced in the first phase along with the textual spans generated by them. The attribute-value table is used as input to a propositional rule learner such as *JRIP* to learn accurate compositions of a useful (as determined by the learning algorithm) subset of the CD rules. This forms the second phase of our system. The rules learnt from this phase are the CR rules. At various phases, several induction biases are introduced to enhance the interpretability of rules. These biases capture the expertise gleaned from manual rule development and constrain the search space in our induction system.

The *hypothesis language* of our induction system is *Annotation Query Language (AQL)* and we use *SystemT* as the *theorem prover*. SystemT provides a very fast rule execution engine and is crucial in our induction system as we test multiple hypotheses in the search for the more promising ones. AQL provides a very expressive rule representation language that is proven to be capable of encoding all the paradigms that any rule-based representation can encode. The dual advantages of *rich rule-representation* and *execution efficiency* are the main motivation behind our choice.

We discuss our induction procedure in detail next.

### 5.1 Basic Features and Background Knowledge

We assume that we are provided with a set of dictionaries and regular expressions for defining all our basic *create view* statements.  $R_1$ ,  $R_2$  and  $R_3$  in Figure 1 are such basic view definitions. The basic views are compiled and executed in SystemT over the training document collection and the resulting spans are represented by equivalent predicates in first order logic. Essentially, each training example is represented as a definite clause,

Figure 2: Correspondence between Manual Rule development and Rule Induction.

that includes in its body, the basic view-types encoded as background knowledge predicates. To establish relationships between different background knowledge predicates for each training example, we define some additional “glue predicates” such as `contains` and `before`.

## 5.2 Induction of Candidate Definition Rules

**Clustering Module.** We obtain non-overlapping clusters of examples within each type, by computing similarities between their representations as definite clauses. We present the intuition behind this approach in Figure 3 which illustrates the process of taking two examples and finding their generalization. It is worthwhile to look at generalizations of instances that are similar. For instance, two token person names such as *Mark Waugh* and *Mark Twain* are part of a single cluster. However, we would not be able to generalize a two-token name (e.g., *Mark Waugh*) with another name consisting of initials followed by a token (e.g., *M. Waugh*). Using a wrapper around the hierarchical agglomerative clustering implemented in LingPipe<sup>2</sup>, we cluster examples and look at generalizations only within each cluster. Clustering also helps improve efficiency by reducing the computational overhead, since otherwise, we would have to consider generalizations of all pairs of examples (Muggleton and Feng, 1992).

**RLGG computation.** We compute our CD rules as the *relative least general generalization* (RLGG) (Nienhuys-Cheng and Wolf, 1997; Muggleton and Feng, 1992) of examples in each cluster. Given a set of clauses in first order logic, their RLGG is the least generalized clause in the

<sup>2</sup><http://alias-i.com/lingpipe/demos/tutorial/cluster/readme.html>

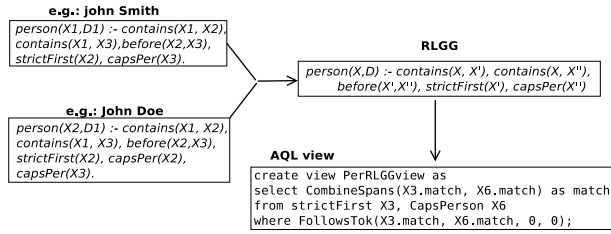

Figure 3: Relative Least General Generalization

subsumption lattice of the clauses relative to the background knowledge (Nienhuys-Cheng and Wolf, 1997). RLGG is associative, and we use this fact to compute RLGGs of sets of examples in a cluster. The RLGG of two bottom clauses as computed in our system and its translation to an AQL view is illustrated in Figure 3. We filter out noisy RLGGs and convert the selected RLGGs into the equivalent AQL views. Each such AQL view is treated as a CD rule. We next discuss the process of filtering-out noisy RLGGs. We interchangeably refer to the RLGGs and the clusters they represent.

**Iterative Clustering and RLGG filtering.** Since clustering is sub-optimal, we expected some clusters in a single run of clustering to have poor RLGGs, either in terms of complexity or precision. We therefore use an iterative clustering approach, based on the *separate-and-conquer* (Fürnkranz, 1999) strategy. In each iteration, we pick the clusters with the best RLGGs and remove all examples covered by those RLGGs. The best RLGGs must have precision and number of examples covered above a pre-specified threshold.

## 5.3 Induction of Candidate Refinement Rules

**Span-View Table.** The CD views from phase 1 along with the textual spans they generate, yield the *span-view table*. The rows of the table correspond to the *set of spans* returned by all the CD views. The columns correspond to the set of CD view names. Each span either belongs to one of the named entity types (PER, ORG or LOC) or is none of them (NONE); the type information constitutes its class label (see Figure 4 for an illustrated example). The cells in the table correspond to either a match (M) or a no-match (N) or partial/overlapping match (O) of a span generated by a CD view. This attribute-value table is used as input to a propositional learner

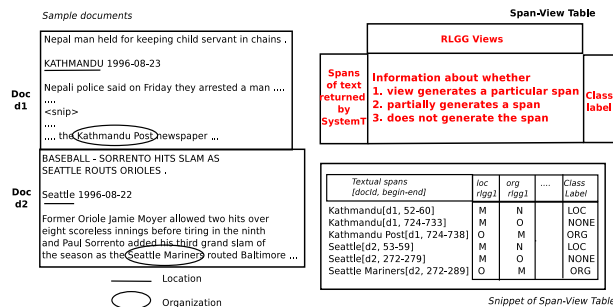

Figure 4: Span-View Table

like *JRIP* to learn compositions of CD views.

**Propositional Rule Learning.** Based on our study of different propositional rule learners, we decided to use *RIPPER* (Fürnkranz and Widmer, 1994) implemented as the *JRIP* classifier in weka (Witten et al., 2011). Some considerations that favor *JRIP* are (i) absence of rule ordering, (ii) ease of conversion to AQL and (iii) amenability to add induction biases in the implementation.

A number of syntactic biases were introduced in *JRIP* to aid in the interpretability of the induced rules. We observed in our manually developed rules that CR rules for a type involve interaction between CDs for the same type and negations (not-overlaps, not matches) of CDs of the other types. This bias was incorporated by constraining a *JRIP* rule to contain only positive features (CDs) of the same type (say *PER*) and negative features (CDs) of only other types (*ORG* and *LOC*, in this case).

The output of the *JRIP* algorithm is a set of rules, one set for each of *PER*, *ORG* and *LOC*. Here is an example rule: **PER-CR-Rule**  $\Leftarrow$  (**PerCD** = **m**) **AND** (**LocCD**  $\neq$  **o**) which is read as : “If a span matches *PerCD* and does not overlap with *LocCD*, then that span denotes a *PER* named entity”. Here **PerCD** is  $\{[\text{FirstName} \wedge \text{CapsPerson}][\text{LastName} \wedge \text{CapsPerson}]\}^3$  and **LocCD** is  $\{[\text{CapsPlace} \wedge \text{CitiesDict}]\}$ . This rule filters out wrong person annotations like “*Prince William*” in *Prince William Sound*. (This is the name of a location but has overlapped with a person named entity.) In AQL, this effect can be achieved most elegantly by the **minus** (filter) construct. Such an AQL rule will filter all those occurrences of *Prince William* from the list of

<sup>3</sup>Two consecutive spans where the 1st is *FirstName* and *CapsPerson* and the 2nd is *LastName* and *CapsPerson*.

persons that overlap with a city name.

Steps such as clustering, computation of RLGGs, *JRIP*, and theorem proving using *SystemT* were parallelized. Once the CR views for each type of named entity are learnt, many forms of consolidations (COs) are possible, both within and across types. A simple consolidation policy that we have incorporated in the system is as follows: union all the rules of a particular type, then perform a *contained within* consolidation, resulting in the final set of consolidated views for each named entity type.

## 6 Experiments

We evaluate our system on CoNLL03 (Tjong Kim Sang and De Meulder, 2003), a collection of Reuters news stories. We used the CoNLL03 training set for induction and report results on the CoNLL03 test collection.

The basic features (BFs) form the primary input to our induction system. We experimented with three sets of BFs:

**Initial set (E1):** The goal in this setup is to induce an initial set of rules based on a small set of reasonable BFs. We use a conservative initial set consisting of 15 BFs (5 regular expressions and 10 dictionaries).

**Enhanced set (E2):** Based on the results of E1, we identify a set of additional domain independent BFs<sup>4</sup>. Five views were added to the existing set in E1 (1 regular expression and 4 dictionaries). The goal is to observe whether our approach yields reasonable accuracies compared to generic rules developed manually.

**Domain customized set (E3):** Based on the knowledge of the domain of the training dataset (CoNLL03), we introduced a set of features specific to this dataset. These included sports-related person, organization and location dictionaries<sup>5</sup>. These views were added to the existing set in E2. The intended goal is to observe what are the best possible accuracies that could be achieved with BFs customized to a particular domain.

The set of parameters for iterative clustering on which the accuracies reported are : the precision threshold for the RLGGs of the clusters was 70%

<sup>4</sup>E.g., the feature *preposition dictionary* was added in E2 to help identify organization names such as *Bank of England*.

<sup>5</sup>Half of the documents in CoNLL03 are sports-related.

Type	Train			Test			C(E)
	P	R	F	P	R	F	
<b>E1 (Initial set)</b>							
PER	88.5	41.4	56.4	92.5	39.4	55.3	144
ORG	89.1	7.3	13.4	85.9	5.2	9.7	22

Table 3: Results on CoNLL03 dataset with different basic feature sets

and the number of examples covered by each RLGG was 5. We selected the top 5 clusters from each iteration whose RLGGs crossed this threshold. If there were no such clusters then we would lower the precision threshold to 35% (half of the threshold). When no new clusters were formed, we ended the iterations.

## 6.1 Experiments and Results

**Effect of Augmenting Basic Features.** Table 3 shows the accuracy and complexity of rules induced with the three basic feature sets E1, E2 and E3, respectively<sup>6</sup>. The overall F-measure on the test dataset is 48.5% with E1, it increases to around 53.3% with E2 and is highest at 68.9% with E3. As we increase the number of BFs, the accuracies of the induced extractors increases, at the cost of an increase in complexity. In particular, the recall increases significantly across the board, and is more prominent between E2 and E3, where the additional domain specific features result in recall increase from 5.9% to 47.5% for ORG. The precision increases slightly for PER, but decreases slightly for LOC and ORG with the addition of domain specific features.

**Comparison with manually developed rules.** We compared the induced extractors with the manually developed extractors of (Chiticariu et al., 2010b), heretofore referred to as *manual extractors*. (For a detailed analysis, we obtained the extractors from

<sup>6</sup>These are the results for the configuration with bias.

the authors). Table 4 shows the accuracy and complexity of the induced rules with E2 and E3 and the manual extractors for the generic domain and, respectively, customized for the CoNLL03 domain. (In the table, ignore the column *Induced (without bias)*, which is discussed later). Our technique compares reasonably with the manually constructed generic extractor for two of the three entity types; and on precision for all entity types, especially since our system generated the rules in 1 hour, whereas the development of manual rules took much longer<sup>7</sup>. Additional work is required to match the manual customized extractor’s performance, primarily due to shortcomings in our current target language. Recall that our framework is limited to a small subset of AQL constructs for expressing CD and CR rules, and there is a single consolidation rule. In particular, advanced constructs such as dynamic dictionaries are not supported, and the set of predicates to the Filter construct supported in our system is restricted to predicates over other concepts, which is only a subset of those used in (Chiticariu et al., 2010b). The manual extractors also contain a larger number of rules covering many different cases, improving the accuracy, but also leading to a higher complexity score. To better analyze the complexity, we also computed the average rule length for each extractor by dividing the complexity score by the number of AQL views of the extractor. The average rule length is 1.78 and 1.87 for the induced extractors with E2 and E3, respectively, and 1.9 and 2.1 for the generic and customized extractors of (Chiticariu et al., 2010b), respectively. The average rule length increases from the generic extractor to the customized extractor in both cases. On average, however, an individual induced rule is slightly smaller than a manually developed rule.

**Effect of Bias.** The goal of this experiment is to demonstrate the importance of biases in the induction process. The biases added to the system are broadly of two types: (i) Partition of basic features based on types (ii) Restriction on the type of CD views that can appear in a CR view.<sup>8</sup> Without

<sup>7</sup>(Chiticariu et al., 2010b) mentions that customization for 3 domains required 8 person weeks. It is reasonable to infer that developing the generic rules took comparable effort.

<sup>8</sup>For e.g., person CR view can contain only person CD views as positive clues and CD views of other types as negative clues.

(i) many semantically similar basic features (especially, regular expressions) would match a given token, leading to an increase in the length of a CD a rule. For example, in the CD rule  $[FirstNameDict][CapsPerson \wedge CapsOrg]$  (“A *FirstNameDict* span followed by a *CapsPerson* span that is also a *CapsOrg* span”), *CapsPerson* and *CapsOrg* are two very similar regular expressions identifying capitalized phrases that look like person, and respectively, organization names, with small variations (e.g., the former may allow special characters such as ‘-’). Including both BFs in a CD rule leads to a larger rule that is unintuitive for a developer. The former bias excludes such CD rules from consideration.

The latter type of bias prevents CD rules of one type to appear as positive clues for a CR rule of a different type. For instance, without this bias, one of the CR rules obtained was  $Per \Leftarrow (OrgCD = m) \text{ AND } (LocCD \neq o)$  (“If a span matches *OrgCD* and does not overlap with *LocCD*, then that span denotes a *PER* named entity”). Here *OrgCD* was  $\{[CapsOrg][CapsOrg]\}$  and *LocCD* was  $\{[CapsLoc \wedge CitiesDict]\}$ . The inclusion of an Organization CD rule as a positive clue for a Person CR rule is unintuitive for a developer.

Table 4, shows the effect (for E2 and E3) on the test dataset of disabling and enabling bias during the induction of CR rules using JRIP. Adding bias improves the precision of the induced rules. Without bias, however, the system is less constrained in its search for high recall rules, leading to slightly higher overall F measure. This comes at the cost of an increase in extractor complexity and average rule length. For example, for E2, the average rule length decreases from 2.17 to 1.78 after adding the bias. Overall, our results show that biases lead to less complex extractors with only a very minor effect on accuracy, thus biases are important factors contributing to inducing rules that are understandable and may be refined by humans.

**Comparison with other induction systems.** We also experimented with two other induction systems, Aleph<sup>9</sup> and ALP<sup>10</sup>, a package that implements one of the reportedly good information extraction algorithms (Ciravegna, 2001). While induction in Aleph

<sup>9</sup>A system for inductive logic programming. See <http://www.cs.ox.ac.uk/activities/machlearn/Aleph/aleph.html>

<sup>10</sup><http://code.google.com/p/alpie/>

was performed with the same target language as in our approach, the target language of ALP is JAPE, which has been shown (Chiticariu et al., 2010b) to lack in some of the constructs (such as minus) that AQL provides and which form a part of our target language (especially the rule refinement phase). However, despite experimenting with all possible parameter configurations for each of these (in each of E1, E2 and E3 settings), the accuracies obtained were substantially (30-50%) worse and the extractor complexity was much (around 60%) higher when compared to our system (with or without bias). Additionally, Aleph takes close to three days for induction, whereas both ALP and our system require less than an hour.

## 6.2 Discussion

**Weak and Strong CDs reflected in CRs.** In our experiments, we found that varying the precision and complexity thresholds while inducing the CDs (c.f Section 5) affected the F1 of the final extractor only minimally. But reducing the precision threshold generally improved the precision of the final extractor, which seemed counter-intuitive at first. We found that CR rules learned by JRIP consist of a strong CD rule (high precision, typically involving a dictionary) and a weak CD rule (low precision, typically involving only regular expressions). The strong CD rule always corresponded to a positive clue (match) and the weak CD rule corresponded to the negative clue (overlaps or not-matches). This is illustrated in the following CR rule:  $PER \Leftarrow (PerCD = m) \text{ AND } (OrgCD \neq o)$  where *(PerCD* is  $\{[CapsPersonR][CapsPersonR \wedge LastNameDict]\}$  and *(OrgCD* is  $\{[CapsOrgR][CapsOrgR][CapsOrgR]\}$ ). This is posited to be the way the CR rule learner operates – it tries to learn conjunctions of weak and strong clues so as to filter one from the other. Therefore, setting a precision threshold too high limited the number of such weak clues and the ability of the CR rule learner to find such rules.

**Interpretability.** Measuring interpretability of rules is a difficult problem. In this work, we have taken a first step towards measuring interpretability using a coarse grain measure in the form of a simple notion of complexity score. The complexity is very helpful in comparing alternative rule sets based on

		Chiticariu et al. 2010b				Induced (With Bias)				Induced (Without Bias)

Table 4: Comparison of induced rules (with and without bias) and manually developed rules. (CoNLL03 test dataset)

the number of rules, and the size of each rule, but exhibits a number of shortcomings described next. First, it disregards other components of a rule besides its from clause, for example, the number of items in the select clause, or the where clause. Second, rule developers use semantically meaningful view names such as those shown in Figure 1 to help them recall the semantics of a rule at a high-level, an aspect that is not captured by the complexity measure. Automatic generation of meaningful names for induced views is an interesting direction for future work. Finally, the overall structure of an extractor is not considered. In simple terms, an extractor consisting of 5 rules of size 1 is indistinguishable from an extractor consisting of a single rule of size 5, and it is arguable which of these extractors is more interpretable. More generally, the extent of this shortcoming is best explained using an example. When informally examining the rules induced by our system, we found that CD rules are similar in spirit to those written by rule developers. On the other hand, the induced CR rules are too fine-grained. In general, rule developers group CD rules with similar semantics, then write refinement rules at the higher level of the group, as opposed to the lower level of individual CD views. For example, one may write multiple CD rules for candidate person names of the form  $\langle First \rangle \langle Last \rangle$ , and multiple CD rules of the form  $\langle Last \rangle, \langle First \rangle$ . One would then union together the candidates from each of the two groups into two different views, e.g., *PerFirstLast* and *PerLastCommaFirst*, and write filter rules at the higher level of these two views, e.g., “Remove *PerLastCommaFirst* spans that overlap with a *PerFirstLast* span”. In contrast, our induction algorithm considers CR rules consisting of combinations of CD rules directly, leading to many semantically

similar CR rules, each operating over small parts of a larger semantic group (see rule in Section 6.1). This results in repetition, and qualitatively less interpretable rules, since humans prefer higher levels of abstraction and generalization. This nuance is not captured by the complexity score which may deem an extractor consisting of many rules, where many of the rules operate at higher levels of groups of candidates to be more complex than a smaller extractor with many fine-grained rules. Indeed, as shown before, the complexity of the induced extractors is much smaller compared to that of manual extractors, although the latter follow the semantic grouping principle and are considered more interpretable.

## 7 Conclusion

We presented a system for efficiently inducing named entity annotation rules in the AQL language. The design of our approach is aimed at producing accurate rules that can be understood and refined by humans, by placing special emphasis on low complexity and efficient computation of the induced rules, while mimicking a four stage approach used for manually constructing rules. The induced rules have good accuracy and low complexity according to our complexity measure. While our complexity measure informs the biases in our system and leads to simpler, smaller extractors, it captures extractor interpretability only to a certain extent. Therefore, we believe more work is required to devise a more comprehensive quantitative measure for interpretability, and refine our techniques in order to increase the interpretability of induced rules. Other interesting directions for future work are introducing more constructs in our framework, and applying our techniques to other languages.

## Abstract

Active learning is a promising way for sentiment classification to reduce the annotation cost. In this paper, we focus on the imbalanced class distribution scenario for sentiment classification, wherein the number of positive samples is quite different from that of negative samples. This scenario posits new challenges to active learning. To address these challenges, we propose a novel active learning approach, named co-selecting, by taking both the imbalanced class distribution issue and uncertainty into account. Specifically, our co-selecting approach employs two feature subspace classifiers to collectively select most informative minority-class samples for manual annotation by leveraging a certainty measurement and an uncertainty measurement, and in the meanwhile, automatically label most informative majority-class samples, to reduce human-annotation efforts. Extensive experiments across four domains demonstrate great potential and effectiveness of our proposed co-selecting approach to active learning for imbalanced sentiment classification.

## 1 Introduction

Sentiment classification is the task of identifying the sentiment polarity (e.g., positive or negative) of

a natural language text towards a given topic (Pang et al., 2002; Turney, 2002) and has become the core component of many important applications in opinion analysis (Cui et al., 2006; Li et al., 2009; Lloret et al., 2009; Zhang and Ye, 2008).

Most of previous studies in sentiment classification focus on learning models from a large number of labeled data. However, in many real-world applications, manual annotation is expensive and time-consuming. In these situations, active learning approaches could be helpful by actively selecting most informative samples for manual annotation. Compared to traditional active learning for sentiment classification, active learning for imbalanced sentiment classification faces some unique challenges.

As a specific type of sentiment classification, imbalanced sentiment classification deals with the situation in which there are many more samples of one class (called *majority class*) than the other class (called *minority class*), and has attracted much attention due to its high realistic value in real-world applications (Li et al., 2011a). In imbalanced sentiment classification, since the minority-class samples (denoted as *MI* samples) are normally much sparse and thus more precious and informative for learning compared to the majority-class ones (denoted as *MA* samples), it is worthwhile to spend more on manually annotating *MI* samples to guarantee both the quality and quantity of *MI* samples. Traditionally, uncertainty has been popularly used as a basic measurement in active learning (Lewis and Gale, 2004). Therefore, how to select most informative *MI* samples for manual annotation without violating the basic

---

\* Corresponding author

uncertainty requirement in active learning is challenging in imbalanced sentiment classification.

In this paper, we address above challenges in active learning for imbalanced sentiment classification. The basic idea of our active learning approach is to use two complementary classifiers for collectively selecting most informative *MI* samples: one to adopt a certainty measurement for selecting most possible *MI* samples and the other to adopt an uncertainty measurement for selecting most uncertain *MI* samples from the most possible *MI* samples returned from the first classifier. Specifically, the two classifiers are trained with two disjoint feature subspaces to guarantee their complementariness. This also applies to selecting most informative *MA* samples. We call our novel active learning approach co-selecting due to its collectively selecting informative samples through two disjoint feature subspace classifiers. To further reduce the annotation efforts, we only manually annotate those most informative *MI* samples while those most informative *MA* samples are automatically labeled using the predicted labels provided by the first classifier.

In principle, our active learning approach differs from existing ones in two main aspects. First, a certainty measurement and an uncertainty measurement are employed in two complementary subspace classifiers respectively to collectively select most informative *MI* samples for manual annotation. Second, most informative *MA* samples are automatically labeled to further reduce the annotation cost. Evaluation across four domains shows that our active learning approach is effective for imbalanced sentiment classification and significantly outperforms the state-of-the-art active learning alternatives, such as uncertainty sampling (Lewis and Gale, 2004) and co-testing (Muslea et al., 2006).

The remainder of this paper is organized as follows. Section 2 overviews the related work on sentiment classification and active learning. Section 3 proposes our active learning approach for imbalanced sentiment classification. Section 4 reports the experimental results. Finally, Section 5 draws the conclusion and outlines the future work.

## 2 Related Work

In this section, we give a brief overview on sentiment classification and active learning.

### 2.1 Sentiment Classification

Sentiment classification has become a hot research topic in NLP community and various kinds of classification methods have been proposed, such as unsupervised learning methods (Turney, 2002), supervised learning methods (Pang et al., 2002), semi-supervised learning methods (Wan, 2009; Li et al., 2010), and cross-domain classification methods (Blitzer et al., 2007; Li and Zong, 2008; He et al., 2011). However, imbalanced sentiment classification is relatively new and there are only a few studies in the literature.

Li et al. (2011a) pioneer the research in imbalanced sentiment classification and propose a co-training algorithm to perform semi-supervised learning for imbalanced sentiment classification with the help of a great amount of unlabeled samples. However, their semi-supervised approach to imbalanced sentiment classification suffers from the problem that their balanced selection strategy in co-training would generate many errors in late iterations due to the imbalanced nature of the unbalanced data. In comparison, our proposed active learning approach can effectively avoid this problem. By the way, it is worth to note that the experiments therein show the superiority of under-sampling over other alternatives such as cost-sensitive and one-class classification for imbalanced sentiment classification.

Li et al. (2011b) focus on supervised learning for imbalanced sentiment classification and propose a clustering-based approach to improve traditional under-sampling approaches. However, the improvement of the proposed clustering-based approach over under-sampling is very limited.

Unlike all the studies mentioned above, our study pioneers active learning on imbalanced sentiment classification.

### 2.2 Active Learning

Active learning, as a standard machine learning problem, has been extensively studied in many research communities and several approaches have been proposed to address this problem (Settles, 2009). Based on different sample selection strategies, they can be grouped into two main categories: (1) uncertainty sampling (Lewis and Gale, 2004) where the active learner iteratively select most uncertain unlabeled samples for manual annotation; and (2) committee-based

sampling where the active learner selects those unlabeled samples which have the largest disagreement among several committee classifiers. Besides query by committee (QBC) as the first of such type (Freund et al., 1997), co-testing learns a committee of member classifiers from different views and selects those contention points (i.e., unlabeled examples on which the views predict different labels) for manual annotation (Muslea et al., 2006).

However, most previous studies focus on the scenario of balanced class distribution and only a few recent studies address the active learning issue on imbalanced classification problems including Yang and Ma (2010), Zhu and Hovy (2007), Ertekin et al. (2007a) and Ertekin et al. (2007b)<sup>2</sup>. Unfortunately, they straightly adopt the uncertainty sampling as the active selection strategy to address active learning in imbalanced classification, which completely ignores the class imbalance problem in the selected samples.

Attenberg and Provost (2010) highlights the importance of selecting samples by considering the proportion of the classes. Their simulation experiment on text categorization confirms that selecting class-balanced samples is more important than traditional active selection strategies like uncertainty. However, the proposed experiment is simulated and non real strategy is proposed to balance the class distribution of the selected samples.

Doyle et al. (2011) propose a real strategy to select balanced samples. They first select a set of uncertainty samples and then randomly select balanced samples from the uncertainty-sample set. However, the classifier used for selecting balanced samples is the same as the one for supervising uncertainty, which makes the balance control unreliable (the selected uncertainty samples take very low confidences which are unreliable to correctly predict the class label for controlling the balance). Different from their study, our approach possesses two merits: First, two feature subspace classifiers are trained to finely integrate the certainty and uncertainty measurements. Second, the *MA* samples are automatically annotated,

<sup>2</sup> Ertekin et al. (2007a) and Ertekin et al. (2007b) select samples closest to the hyperplane provided by the SVM classifier (within the margin). Their strategy can be seen as a special case of uncertainty sampling.

which reduces the annotation cost in a further effort.

### 3 Active Learning for Imbalanced Sentiment Classification

Generally, active learning can be either stream-based or pool-based (Sassano, 2002). The main difference between the two is that the former scans through the data sequentially and selects informative samples individually, whereas the latter evaluates and ranks the entire collection before selecting most informative samples at batch. As a large collection of samples can easily gathered once in sentiment classification, pool-based active learning is adopted in this study.

Figure 1 illustrates a standard pool-based active learning approach, where the most important issue is the sampling strategy, which evaluates the informativeness of one sample.

---

**Input:**

Labeled data  $L$ ;  
Unlabeled pool  $U$ ;

**Output:**

New Labeled data  $L$

**Procedure:**

Loop for  $N$  iterations:

- (1). Learn a classifier using current  $L$
  - (2). Use current classifier to label all unlabeled samples
  - (3). Use the sampling strategy to select  $n$  most informative samples for manual annotation
  - (4). Move newly-labeled samples from  $U$  to  $L$
- 

Figure 1: Pool-based active learning

#### 3.1 Sampling Strategy: Uncertainty vs. Certainty

As one of the most popular selection strategies in active learning, uncertainty sampling depends on an uncertainty measurement to select informative samples. Since sentiment classification is a binary classification problem, the uncertainty measurement of a document  $d$  can be simply defined as follows:

$$Uncer(d) = \min_{y \in \{pos, neg\}} P(y|d)$$

Where  $P(y|d)$  denotes the posterior probability of the document  $d$  belonging to the class  $y$  and  $\{pos,$

neg} denotes the class labels of positive and negative.

In imbalanced sentiment classification, *MI* samples are much sparse yet precious for learning and thus are believed to be more valuable for manual annotation. The key in active learning for imbalanced sentiment classification is to guarantee both the quality and quantity of newly-added *MI* samples. To guarantee the selection of *MI* samples, a certainty measurement is necessary. In this study, the certainty measurement is defined as follows:

$$Cer(d) = \max_{y \in \{pos, neg\}} P(y|d)$$

Meanwhile, in order to balance the samples in the two classes, once an informative *MI* sample is manually annotated, an informative *MA* sample is automatically labeled. In this way, the annotated data become more balanced than a random selection strategy.

However, the two sampling strategies discussed above are apparently contradicted: while the uncertainty measurement is prone to selecting the samples whose posterior probabilities are nearest to 0.5, the certainty measurement is prone to selecting the samples whose posterior probabilities are nearest to 1. Therefore, it is essential to find a solution to balance uncertainty sampling and certainty sampling in imbalanced sentiment classification,

### 3.2 Co-selecting with Feature Subspace Classifiers

In sentiment classification, a document is represented as a feature vector generated from the feature set  $F = \{f_1, \dots, f_m\}$ . When a feature subset, i.e.,  $F^S = \{f_1^S, \dots, f_r^S\}$  ( $r < m$ ), is used, the original  $m$ -dimensional feature space becomes an  $r$ -dimensional feature subspace. In this study, we call a classifier trained with a feature subspace a feature subspace classifier.

Our basic idea of balancing both the uncertainty measurement and the certainty measurement is to train two subspace classifiers to adopt them respectively. In our implementation, we randomly select two disjoint feature subspaces, each of which is used to train a subspace classifier. On one side, one subspace classifier is employed to select some certain samples; on the other side, the other classifier is employed to select the most uncertain sample from those certain samples for manual

annotation. In this way, the selected samples are certain in terms of one feature subspace for selecting more possible *MI* samples. Meanwhile, the selected sample remains uncertain in terms of the other feature subspace to introduce uncertain knowledge into current learning model. We name this approach as co-selecting because it collectively selects informative samples by two separate classifiers. Figure 2 illustrates the co-selecting algorithm. In our algorithm, we strictly constrain the balance of the samples between the two classes, i.e., positive and negative. Therefore, once two samples are annotated with the same class label, they will not be added to the labeled data, as shown in step (7) in Figure 2.

---

#### Input:

Labeled data  $L$  with balanced samples over the two classes

Unlabeled pool  $U$

#### Output:

New Labeled data  $L$

#### Procedure:

Loop for  $N$  iterations:

- (1). Randomly select a feature subset  $F^S$  with size  $r$  (with the proportion  $\theta = r/m$ ) from  $F$
  - (2). Generate a feature subspace from  $F^S$  and train a corresponding feature subspace classifier  $C_{Cer}$  with  $L$
  - (3). Generate another feature subspace from the complement set of  $F^S$ , i.e.,  $F - F^S$  and train a corresponding feature subspace classifier  $C_{Uncer}$  with  $L$
  - (4). Use  $C_{Cer}$  to select top certain  $k$  positive and  $k$  negative samples, denoted as a sample set  $CER_1$
  - (5). Use  $C_{Uncer}$  to select the most uncertain positive sample and negative sample from  $CER_1$
  - (6). Manually annotate the two selected samples
  - (7). If the annotated labels of the two selected samples are different from each other:  
Add the two newly-annotated samples into  $L$
- 

Figure 2: The co-selecting algorithm

There are two parameters in the algorithm: the size of the feature subspace for training the first subspace classifier, i.e.,  $\theta$  and the number of

selected certain samples, i.e.,  $k$ . Both of the two parameters will be empirically studied in our experiments.

### 3.3 Co-selecting with Selected *MA* Samples Automatically Labeled

---

**Input:**

Labeled data  $L$  with balanced samples over the two classes

Unlabeled pool  $U$

*MA* and *MI* Label (positive or negative)

**Output:**

New Labeled data  $L$

**Procedure:**

Loop for  $N$  iterations:

- (1). Randomly select a proportion of features (with the proportion  $\theta$ ) from  $F$  to get a feature subset  $F^S$
  - (2). Generate a feature subspace from  $F^S$  and train a corresponding subspace classifier  $C_{Cer}$  with  $L$
  - (3). Generate another feature subspace from the complement set of  $F^S$ , i.e.,  $F - F^S$  and train a corresponding subspace classifier  $C_{Uncer}$  with  $L$
  - (4). Use  $C_{Cer}$  to select top certain  $k$  positive and  $k$  negative samples, denoted as a sample set  $CER_1$
  - (5). Use  $C_{Uncer}$  to select the most uncertain positive sample and negative sample from  $CER_1$
  - (6). Manually annotate the sample that is predicted as a *MI* sample by  $C_{Cer}$  and automatically annotate the sample that is predicted as *majority class*
  - (7). If the annotated labels of the two selected samples are different from each other:  
Add the two newly-annotated samples into  $L$
- 

Figure 3: The co-selecting algorithm with selected *MA* samples automatically labeled

To minimize manual annotation, it is a good choice to automatically label those selected *MA* samples. In our co-selecting approach, automatically labeling those selected *MA* samples is easy and

straightforward: the subspace classifier for monitoring the certainty measurement provides an ideal solution to annotate the samples that have been predicted as *majority class*. Figure 3 shows the co-selecting algorithm with those selected *MA* samples automatically labeled. The main difference from the original co-selecting is shown in Step (6) in Figure 3. Another difference is the input where a prior knowledge of which class is *majority class* or *minority class* should be known. In real applications, it is not difficult to know this. We first use a classifier trained with the initial labeled data to test all unlabeled data. If the predicted labels in the classification results are greatly imbalanced, we can assume that the unlabeled data is imbalanced, and consider the dominated class as *majority class*.

## 4 Experimentation

In this section, we will systematically evaluate our active learning approach for imbalanced sentiment classification and compare it with the state-of-the-art active learning alternatives.

### 4.1 Experimental Setting

**Dataset**

We use the same data as used by Li et al. (2011a). The data collection consists of four domains: Book, DVD, Electronic, and Kitchen (Blitzer et al., 2007). For each domain, we randomly select an initial balanced labeled data with 50 negative samples and 50 positive samples. For the unlabeled data, we randomly select 2000 negative samples, and 14580/12160/7140/7560 positive samples from the four domains respectively, keeping the same imbalanced ratio as the whole data. For the test data in each domain, we randomly extract 800 negative samples and 800 positive samples.

**Classification algorithm**

The Maximum Entropy (ME) classifier implemented with the Mallet<sup>3</sup> tool is mainly adopted, except that in the margin-based active learning approach (Ertekin et al., 2007a) where SVM is implemented with light-SVM<sup>4</sup>. The features for classification are unigram words with Boolean weights.

---

<sup>3</sup> <http://mallet.cs.umass.edu/>

<sup>4</sup> [http://www.cs.cornell.edu/people/tj/svm\\_light/](http://www.cs.cornell.edu/people/tj/svm_light/)

Figure 4: Performance comparison of different active learning approaches on imbalanced sentiment classification

### Evaluation metrics

The popular geometric mean  $G-mean = \sqrt{TP_{rate} \times TN_{rate}}$  is adopted, where  $TP_{rate}$  is the true positive rate (also called positive recall or sensitivity) and  $TN_{rate}$  is the true negative rate (also called negative recall or specificity) (Kubat and Matwin, 1997).

### 4.2 Experimental Results

For thorough comparison, various kinds of active learning approaches are implemented including:

- **Random:** randomly select the samples from the unlabeled data for manual annotation;
- **Margin-based:** iteratively select samples closest to the hyperplane provided by the SVM classifier, which is suggested by Ertekin et al. (2007a) and Ertekin et al. (2007b). One sample is selected in each iteration;
- **Uncertainty:** iteratively select samples using the uncertainty measurement according to the output of ME classifier. One sample is selected in each iteration;
- **Certainty:** iteratively select class-balanced samples using the certainty measurement according to the output of ME classifier. One positive and negative sample (the positive and negative label is provided by the ME classifier) are selected in each iteration;
- **Co-testing:** first get contention samples (i.e., unlabeled examples on which the member

classifiers predict different labels) and then select the least confidence one among the hypotheses of different member classifiers, i.e., the aggressive strategy as described Muslea et al. (2006). Specifically, the member classifiers are two subspace classifiers trained by splitting the whole feature space into two disjoint subspaces of same size;

- **Self-selecting:** first select  $k$  uncertainty samples and then randomly select a positive and negative sample from the uncertainty-sample set, which is suggested by Doyle et al. (2011). We call it self-selecting since only one classifier is involved to measure uncertainty and predict class labels.

For those approaches involving random selection of features, we run 5 times for them and report the average results. Note that the samples selected by these approaches are imbalanced. To address the problem of classification on imbalanced data, we adopt the under-sampling strategy which has been shown effective for supervised imbalanced sentiment classification (Li et al., 2011a). Our active learning approach includes two versions: the co-selecting algorithm as described in Section 3.2 and the co-selecting with selected  $MA$  samples automatically labeled as described in Section 3.3. For clarity, we refer the former as **co-selecting-basic** and the latter as **co-selecting-plus** in the following.

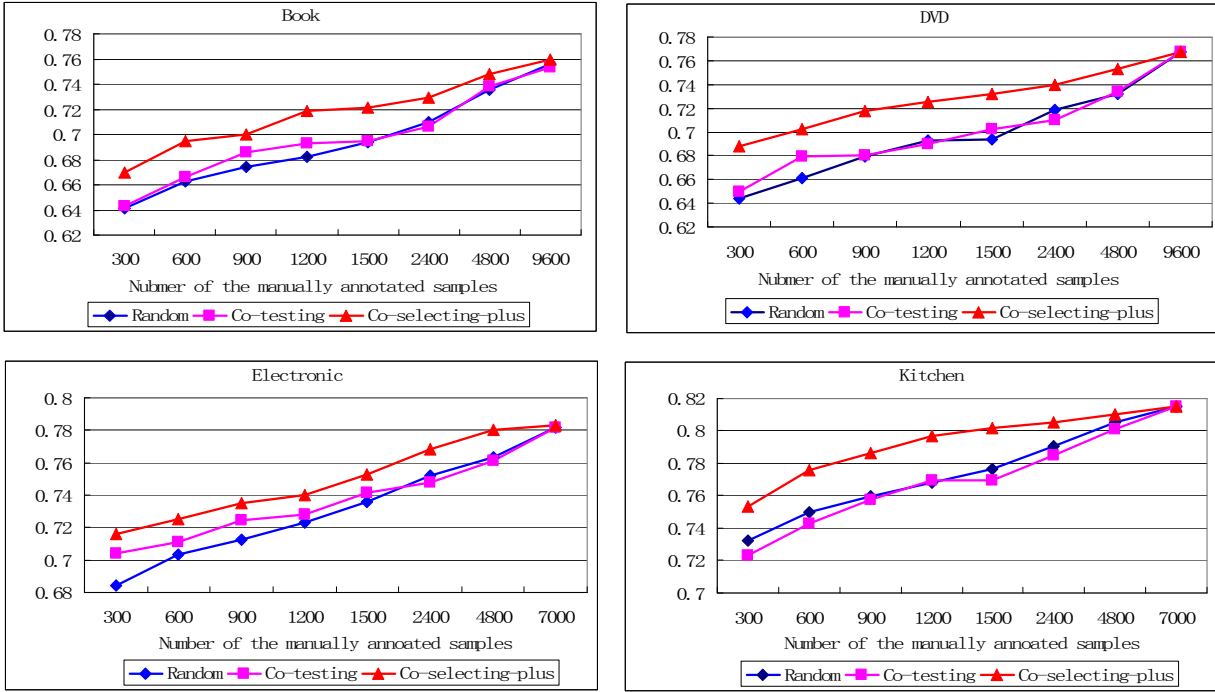

Figure 5: Performance comparison of three active learning approaches: random selection, co-testing and co-selecting-plus, by varying the number of the selected samples for manually annotation

### Comparison with other active learning approaches

Figure 4 compares different active learning approaches to imbalanced sentiment classification when 600 unlabeled samples are selected for annotation. Specifically, the parameters  $\theta$  and  $k$  is set to be 1/16 and 50 respectively. Figure 4 justifies that it is challenging to perform active learning in imbalanced sentiment classification: the approaches of **margin-based**, **uncertainty-based** and **self-selecting** perform no better than random selection while **co-testing** only outperforms random selection in two domains: DVD and Electronic with only a small improvement (about 1%). In comparison, our approaches, both **co-selecting-basic** and **co-selecting-plus** significantly outperform the random selection approach on all the four domains. It also shows that **co-selecting-plus** is preferable over **co-selecting-basic**. This verifies the effectiveness of automatically labeling those selected *MA* samples in imbalanced sentiment classification.

Specifically, we notice that only using the certainty measurement (i.e., **certainty**) performs worst, which reflects that only considering sample

balance factor in imbalanced sentiment classification is not helpful.

Figure 5 compares our approach to other active learning approaches by varying the number of the selected samples for manually annotation. For clarity, we only include random selection and **co-testing** in comparison and do not show the performances of the other active learning approaches due to their similar behavior to random selection. From this figure, we can see that **co-testing** is effective on Book and Electronic when less than 1500 samples are selected for manual annotation but it fails to outperform random selection in the other two domains. In contrast, our **co-selecting-plus** approach is apparently more advantageous and significantly outperforms random selection across all domains ( $p$ -value<0.05) when less than 4800 samples are selected for manual annotation.

### Sensitiveness of the parameters $\theta$

The size of the feature subspace is an important parameter in our approach. Figure 6 shows the performance of **co-selecting-plus** with varying sizes of the feature subspaces for the first subspace

classifier  $C_{Cer}$ . From Figure 6, we can see that a choice of the proportion  $\theta$  between 1/8 and 1/32 is recommended. This result also shows that the size of the feature subspace for selecting certain samples should be much less than that for selecting uncertain samples, which indicates the more important role of the uncertainty measurement in active learning.

Figure 6: Performance of **co-selecting-plus** over varying sizes of feature subspaces ( $\theta$ )

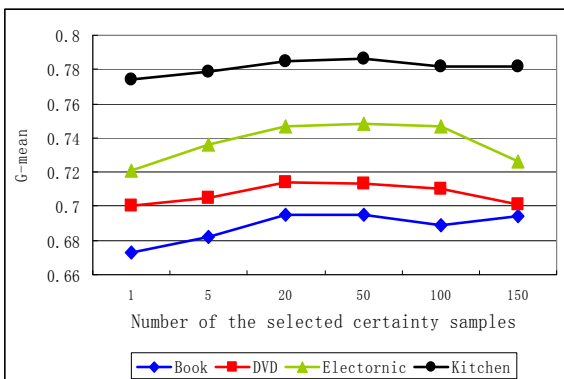

Figure 7: Performance of **co-selecting-plus** over varying numbers of the selected certain samples ( $k$ )

### Sensitiveness of parameter $k$

Figure 7 presents the performance of **co-selecting-plus** with different numbers of the selected certain samples in each iteration, i.e., parameter  $k$ . Empirical studies suggest that setting  $k$  between 20 and 100 could get a stable performance. Also, this figure demonstrates that using certainty as the only query strategy is much less effective (see the result when  $k=1$ ). This once again verifies the importance of the uncertainty strategy in active learning.

### Number of $MI$ samples selected for manual annotation

In Table 1, we investigate the number of the  $MI$  samples selected for manual annotation using different active learning approaches when a total of 600 unlabeled samples are selected for annotation. From this table, we can see that almost all the existing active learning approaches can only select a small amount of  $MI$  samples, taking similar imbalanced ratios as the whole unlabeled data. Although the **certainty** approach could select many  $MI$  samples for annotation, this approach performs worst due to its totally ignoring the uncertainty factor. When our approach is applied, especially **co-selecting-plus**, more  $MI$  samples are selected for manual annotation and finally included to learn the models. This greatly improves the effectiveness of our active learning approach.

Table 1: The number of  $MI$  samples selected for manual annotation when 600 samples are annotated on the whole.

	Book	DVD	Electronic	Kitchen
Random	71	82	131	123
SVM-based	65	72	135	106
Uncertainty	78	93	137	136
Certainty	160	200	236	227
Co-testing	89	84	136	109
Self-selecting	87	95	141	126
Co-selecting-basic	101	112	179	174
Co-selecting-plus	161	156	250	272

### Precision of automatically labeled $MA$ samples

In **co-selecting-plus**, all the added  $MA$  samples are automatically labeled by the first subspace classifier. It is encouraging to observe that 92.5%, 91.25%, 92%, and 93.5% of automatically labeled  $MA$  samples are correctly annotated in Book, DVD, Electronic, and Kitchen respectively. This suggests that the subspace classifiers are able to predict the  $MA$  samples with a high precision. This indicates the rationality of automatically annotating  $MA$  samples.

## 5 Conclusion

In this paper, we propose a novel active learning approach, named **co-selecting**, to reduce the annotation cost for imbalanced sentiment classification. It first trains two complementary

classifiers with two disjoint feature subspaces and then uses them to collectively select most informative *MI* samples for manual annotation, leaving most informative *MA* samples for automatic annotation. Empirical studies show that our co-selecting approach is capable of greatly reducing the annotation cost and in the meanwhile, significantly outperforms several active learning alternatives

For the future work, we are interested in applying our co-selecting approach to active learning for other imbalanced classification tasks, especially those with much higher imbalanced ratio.

## Acknowledgments

The research work described in this paper has been partially supported by three NSFC grants, No.61003155, No.60873150 and No.90920004, one National High-tech Research and Development Program of China No.2012AA011102, Open Projects Program of National Laboratory of Pattern Recognition, and the NSF grant of Zhejiang Province No.Z1110551. # A Weakly Supervised Model for Sentence-Level Semantic Orientation Analysis with Multiple Experts

Lizhen Qu and Rainer Gemulla and Gerhard Weikum

Max Planck Institute for Informatics

Saarbrücken, Germany

{lqu, rgemulla, weikum}@mpi-inf.mpg.de

## Abstract

We propose the weakly supervised *Multi-Experts Model* (MEM) for analyzing the semantic orientation of opinions expressed in natural language reviews. In contrast to most prior work, MEM predicts both opinion polarity and opinion strength at the level of individual sentences; such fine-grained analysis helps to understand better why users like or dislike the entity under review. A key challenge in this setting is that it is hard to obtain sentence-level training data for both polarity and strength. For this reason, MEM is weakly supervised: It starts with potentially noisy indicators obtained from coarse-grained training data (i.e., document-level ratings), a small set of diverse base predictors, and, if available, small amounts of fine-grained training data. We integrate these noisy indicators into a unified probabilistic framework using ideas from ensemble learning and graph-based semi-supervised learning. Our experiments indicate that MEM outperforms state-of-the-art methods by a significant margin.

## 1 Introduction

Opinion mining is concerned with analyzing opinions expressed in natural language text. For example, many internet websites allow their users to provide both natural language reviews and numerical ratings to items of interest (such as products or movies). In this context, opinion mining aims to uncover the relationship between users and (features of) items. Preferences of users to items can be well understood by coarse-grained methods of opinion mining, which

focus on analyzing the semantic orientation of documents as a whole. To understand *why* users like or dislike certain items, however, we need to perform more fine-grained analysis of the review text itself.

In this paper, we focus on sentence-level analysis of semantic orientation (SO) in online reviews. The SO consists of *polarity* (positive, negative, or other<sup>1</sup>) and *strength* (degree to which a sentence is positive or negative). Both quantities can be analyzed jointly by mapping them to numerical ratings: Large negative/positive ratings indicate a strong negative/positive orientation. A key challenge in fine-grained rating prediction is that fine-grained training data for both polarity and strength is hard to obtain. We thus focus on a weakly supervised setting in which only coarse-level training data (such as document ratings and subjectivity lexicons) and, optionally, a small amount of fine-grained training data (such as sentence polarities) is available.

A number of lexicon-based approaches for phrase-level rating prediction has been proposed in the literature (Taboada et al., 2011; Qu et al., 2010). These methods utilize a subjectivity lexicon of words along with information about their semantic orientation; they focus on phrases that contain words from the lexicon. A key advantage of sentence-level methods is that they are able to cover all sentences in a review and that phrase identification is avoided. To the best of our knowledge, the problem of rating prediction at the sentence level has not been addressed in the literature. A naive approach would be to simply average phrase-level ratings. Such an approach performs

<sup>1</sup>We assign polarity *other* to text fragments that are off-topic or not directly related to the entity under review.

poorly, however, since (1) phrases are analyzed out of context (e.g., modal verbs or conditional clauses), (2) domain-dependent information about semantic orientation is not captured in the lexicons, (3) only phrases that contain lexicon words are covered. Here (1) and (2) lead to low precision, (3) to low recall.

To address the challenges outlined above, we propose the weakly supervised *Multi-Experts Model* (MEM) for sentence-level rating prediction. MEM starts with a set of potentially noisy indicators of SO including phrase-level predictions, language heuristics, and co-occurrence counts. We refer to these indicators as *base predictors*; they constitute the set of experts used in our model. MEM is designed such that new base predictors can be easily integrated. Since the information provided by the base predictors can be contradicting, we use ideas from ensemble learning (Dietterich, 2002) to learn the most confident indicators and to exploit domain-dependent information revealed by document ratings. Thus, instead of averaging base predictors, MEM integrates their features along with the available coarse-grained training data into a unified probabilistic model.

The integrated model can be regarded as a Gaussian process (GP) model (Rasmussen, 2004) with a novel *multi-expert prior*. The multi-expert prior decomposes into two component distributions. The first component distribution integrates sentence-local information obtained from the base predictors. It forms a special realization of stacking (Dzeroski and Zenko, 2004) but uses the features from the base predictors instead of the actual predictions. The second component distribution propagates SO information across similar sentences using techniques from graph-based semi-supervised learning (GSSL) (Zhu et al., 2003; Belkin et al., 2006). It aims to improve the predictions on sentences that are not covered well enough by our base predictors. Traditional GSSL algorithms support either discrete labels (classification) or numerical labels (regression); we extend these techniques to support both types of labels simultaneously. We use a novel variant of word sequence kernels (Cancedda et al., 2003) to measure sentence similarity. Our kernel takes the relative positions of words but also their SO and synonymity into account.

Our experiments indicate that MEM significantly outperforms prior work in both sentence-level rating prediction and sentence-level polarity classification.

## 2 Related Work

There exists a large body of work on analyzing the semantic orientation of natural language text. Our approach is unique in that it is weakly supervised, predicts both polarity and strength, and operates on the sentence level.

Supervised approaches for sentiment analysis focus mainly on opinion mining at the document level (Pang and Lee, 2004; Pang et al., 2002; Pang and Lee, 2005; Goldberg and Zhu, 2006), but have also been applied to sentence-level polarity classification in specific domains (Mao and Lebanon, 2006; Pang and Lee, 2004; McDonald et al., 2007). In these settings, a sufficient amount of training data is available. In contrast, we focus on opinion mining tasks with little or no fine-grained training data.

The weakly supervised HCRF model (Täckström and McDonald, 2011b; Täckström and McDonald, 2011a) for sentence-level polarity classification is perhaps closest to our work in spirit. Similar to MEM, HCRF uses coarse-grained training data and, when available, a small amount of fine-grained sentence polarities. In contrast to MEM, HCRF does not predict the strength of semantic orientation and ignores the order of words within sentences.

There exists a large number of lexicon-based methods for polarity classification (Ding et al., 2008; Choi and Cardie, 2009; Hu and Liu, 2004; Zhuang et al., 2006; Fu and Wang, 2010; Ku et al., 2008). The lexicon-based methods of (Taboada et al., 2011; Qu et al., 2010) also predict ratings at the phrase level; these methods are used as experts in our model.

MEM leverages ideas from ensemble learning (Dietterich, 2002; Bishop, 2006) and GSSL methods (Zhu et al., 2003; Zhu and Ghahramani, 2002; Chapelle et al., 2006; Belkin et al., 2006). We extend GSSL with support for multiple, heterogenous labels. This allows us to integrate our base predictors as well as the available training data into a unified model that exploits that strengths of algorithms from both families.

## 3 Base Predictors

Each of our *base predictors* predicts the polarity or the rating of a single phrase. As indicated above, we do not use these predictions directly in MEM but instead integrate the features of the base predictors

(see Sec. 4.4). MEM is designed such that new base predictors can be integrated easily.

Our base predictors use a diverse set of available web and linguistic resources. The hope is that this diversity increases overall prediction performance (Dietterich, 2002): The *statistical polarity predictor* focuses on local syntactic patterns; it is based on corpus statistics for SO-carrying words and opinion topic words. The *heuristic polarity predictor* uses manually constructed rules to achieve high precision but low recall. Both the *bag-of-opinions rating predictor* and the *SO-CAL rating predictor* are based on lexicons. The BoO predictor uses a lexicon trained from a large generic-domain corpus and is recall-oriented; the SO-CAL predictor uses a different lexicon with manually assigned weights and is precision-oriented.

### 3.1 Statistical Polarity Predictor

The polarity of an SO-carrying word strongly depends on its target word. For example, consider the phrase “I began this novel with the *greatest of hopes* [...]”. Here, “greatest” has a positive semantic orientation in all subjectivity lexicons, but the combination “greatest of hopes” often indicates a negative sentiment. We refer to a pair of SO-carrying word (“greatest”) and a target word (“hopes”) as an *opinion-target pair*. Our statistical polarity predictor learns the polarity of opinions and targets jointly, which increases the robustness of its predictions.

Syntactic dependency relations of the form  $A \xrightarrow{R} B$  are a strong indicator for opinion-target pairs (Qiu et al., 2009; Zhuang et al., 2006); e.g., “great”  $\xrightarrow{\text{nmod}}$  “product”. To achieve high precision, we only consider pairs connected by the following predefined set of shortest dependency paths: verb  $\xleftarrow{\text{subj}}$  noun, verb  $\xleftarrow{\text{obj}}$  noun, adj  $\xrightarrow{\text{nmod}}$  noun, adj  $\xrightarrow{\text{prd}}$  verb  $\xleftarrow{\text{subj}}$  noun. We only retain opinion-target pairs that are sufficiently frequent.

For each extracted pair  $z$ , we count how often it co-occurs with each document polarity  $y \in \mathcal{Y}$ , where  $\mathcal{Y} = \{\text{positive}, \text{negative}, \text{other}\}$  denotes the set of polarities. If  $z$  occurs in a document but is preceded by a negator, we treat it as a co-occurrence of opposite document polarity. If  $z$  occurs in a document with polarity *other*, we count the occurrence with only half weight, i.e., we increase both  $\#z$  and  $\#(\text{other}, z)$  by 0.5. These documents are typically a mixture of

positive and negative opinions so that we want to reduce their impact. The marginal distribution of polarity label  $y$  given that  $z$  occurs in a sentence is estimated as  $P(y | z) = \#(y, z) / \#z$ . The predictor is trained using the text and ratings of the reviews in the training data, i.e., without relying on fine-grained annotations.

The statistical polarity predictor can be used to predict sentence-level polarities by averaging the phrase-level predictions. As discussed previously, such an approach is problematic; we use it as a baseline approach in our experimental study. We also employ phrase-level averaging to estimate the variance of base predictors; see Sec. 4.3. Denote by  $Z(\mathbf{x})$  the set of opinion-target pairs in sentence  $\mathbf{x}$ . To predict the sentence polarity  $y \in \mathcal{Y}$ , we take the Bayesian average of the phrase-level predictors:  $P(y | Z(\mathbf{x})) = \sum_{z \in Z(\mathbf{x})} P(y | z) P(z) = \sum_{z \in Z(\mathbf{x})} P(y, z)$ . Thus the most likely polarity is the one with the highest co-occurrence count.

### 3.2 Heuristic Polarity Predictor

Heuristic patterns can also serve as base predictors. In particular, we found that some authors list positive and negative aspects separately after keywords such as “pros” and “cons”. A heuristic that exploits such patterns achieved a high precision ( $> 90\%$ ) but low recall ( $< 5\%$ ) in our experiments.

### 3.3 Bag-of-Opinions Rating Predictor

We leverage the bag-of-opinion (BoO) model of Qu et al. (2010) as a base predictor for phrase-level ratings. The BoO model was trained from a large generic corpus without fine-grained annotations.

In BoO, an opinion consists of three components: an SO-carrying word (e.g., “good”), a set of intensifiers (e.g., “very”) and a set of negators (e.g., “not”). Each opinion is scored based on these words (represented as a boolean vector  $\mathbf{b}$ ) and the polarity of the SO-carrying word (represented as  $\text{sgn}(r) \in \{-1, 1\}$ ) as indicated by the MPQA lexicon of Wilson et al. (2005). In particular, the score is computed as  $\text{sgn}(r)\omega^T \mathbf{b}$ , where  $\omega$  is the learned weight vector. The sign function  $\text{sgn}(r)$  ensures consistent weight assignment for intensifiers and negators. For example, an intensifier like “very” can obtain a large positive or a large negative weight depending on whether it is used with a positive or negative SO-carrying

word, respectively.

### 3.4 SO-CAL Rating Predictor

The Semantic Orientation Calculator (SO-CAL) of Taboada et al. (2011) also predicts phrase-level ratings via a scoring function similar to the one of BoO. The SO-CAL predictor uses a manually created lexicon, in which each word is classified as either an SO-carrying word (associated with a numerical score), an intensifier (associated with a modifier on the numerical score), or a negator. SO-CAL employs various heuristics to detect irrealis and to correct for the positive bias inherent in most lexicon-based classifiers. Compared to BoO, SO-CAL has lower recall but higher precision.

## 4 Multi-Experts Model

Our multi-experts model incorporates features from the individual base predictors, coarse-grained labels (i.e., document ratings or polarities), similarities between sentences, and optionally a small amount of sentence polarity labels into an unified probabilistic model. We first give an overview of MEM, and then describe its components in detail.

### 4.1 Model Overview

Denote by  $\mathbf{X} = \{\mathbf{x}_1, \dots, \mathbf{x}_N\}$  a set of sentences. We associate each sentence  $\mathbf{x}_i$  with a set of *initial labels*  $\hat{\mathbf{y}}_i$ , which are strong indicators of semantic orientation: the coarse-grained rating of the corresponding document, the polarity label of our heuristic polarity predictor, the phrase-level ratings from the SO-CAL predictor, and optionally a manual polarity label. Note that the number of initial labels may vary from sentence to sentence and that initial labels are heterogeneous in that they refer to either polarities or ratings. Let  $\hat{\mathbf{Y}} = \{\hat{\mathbf{y}}_1, \dots, \hat{\mathbf{y}}_N\}$ . Our goal is to predict the unobserved ratings  $\mathbf{r} = \{r_1, \dots, r_N\}$  of each sentence.

Our multi-expert model is a probabilistic model for  $\mathbf{X}$ ,  $\hat{\mathbf{Y}}$ , and  $\mathbf{r}$ . In particular, we model the rating vector  $\mathbf{r}$  via a multi-expert prior  $P_E(\mathbf{r} | \mathbf{X}, \beta)$  with parameter  $\beta$  (Sec. 4.2).  $P_E$  integrates both features from the base predictors and sentence similarities. We correlate ratings to initial labels via a set of conditional distributions  $P_b(\hat{\mathbf{y}}^b | \mathbf{r})$ , where  $b$  denotes the type of initial label (Sec. 4.3). The posterior of  $\mathbf{r}$  is

then given by

$$P(\mathbf{r} | \mathbf{X}, \hat{\mathbf{Y}}, \beta) \propto \prod_b P_b(\hat{\mathbf{y}}^b | \mathbf{r}) P_E(\mathbf{r} | \mathbf{X}, \beta).$$

Note that the posterior is influenced by both the multi-expert prior and the set of initial labels.

We use MAP inference to obtain the most likely rating of each sentence, i.e., we solve

$$\operatorname{argmin}_{\mathbf{r}, \beta} - \sum_b \log(P_b(\hat{\mathbf{y}}^b | \mathbf{r})) - \log(P_E(\mathbf{r} | \mathbf{X}, \beta)),$$

where as before  $\beta$  denotes the model parameters. We solve the above optimization problem using cyclic coordinate descent (Friedman et al., 2008).

### 4.2 Multi-Expert Prior

The multi-expert prior  $P_E(\mathbf{r} | \mathbf{X}, \beta)$  consists of two component distributions  $\mathcal{N}_1$  and  $\mathcal{N}_2$ . Distribution  $\mathcal{N}_1$  integrates features from the base predictors,  $\mathcal{N}_2$  incorporates sentence similarities to propagate information across sentences.

In a slight abuse of notation, denote by  $\mathbf{x}_i$  the set of features for the  $i$ -th sentence. Vector  $\mathbf{x}_i$  contains the features of all the base predictors but also includes bigram features for increased coverage of syntactic patterns; see Sec. 4.4 for details about the feature design. Let  $m(\mathbf{x}_i) = \beta^T \mathbf{x}_i$  be a linear predictor for  $r_i$ , where  $\beta$  is a real weight vector. Assuming Gaussian noise,  $r_i$  follows a Gaussian distribution  $\mathcal{N}_1(r_i | m_i, \sigma^2)$  with mean  $m_i = m(\mathbf{x}_i)$  and variance  $\sigma^2$ . Note that predictor  $m$  can be regarded as a linear combination of base predictors because both  $m$  and each of the base predictors are linear functions. By integrating all features into a single function, the base predictors are trained jointly so that weight vector  $\beta$  automatically adapts to domain-dependent properties of the data. This integrated approach significantly outperformed the alternative approach of using a weighted vote of the individual predictions made by the base predictors. We regularize the weight vector  $\beta$  using a Laplace prior  $P(\beta | \alpha)$  with parameter  $\alpha$  to encourage sparsity.

Note that the bigram features in  $\mathbf{x}_i$  partially capture sentence similarity. However, such features cannot be extended to longer subsequences such as trigrams due to data sparsity: useful features become as infrequent as noisy terms. Moreover, we would

like to capture sentence similarity using gapped (i.e., non-consecutive) subsequences. For example, the sentences “The book is an easy read.” and “It is easy to read.” are similar but do not share any consecutive bigrams. They do share the subsequence “easy read”, however. To capture this similarity, we make use of a novel sentiment-augmented variant of word sequence kernels (Cancedda et al., 2003). Our kernel is used to construct a similarity matrix  $\mathbf{W}$  among sentences and the corresponding regularized Laplacian  $\tilde{\mathbf{L}}$ . To capture the intuition that similar sentences should have similar ratings, we introduce a Gaussian prior  $\mathcal{N}_2(\mathbf{r} \mid 0, \tilde{\mathbf{L}}^{-1})$  as a component into our multi-expert prior; see Sec. 4.5 for details and a discussion of why this prior encourages similar ratings for similar sentences.

Since the two component distributions feature different expertise, we take their product and obtain the multi-expert prior

$$P_E(\mathbf{r} \mid \mathbf{X}, \boldsymbol{\beta}) \propto \mathcal{N}_1(\mathbf{r} \mid \mathbf{m}, \mathbf{I}\sigma^2)\mathcal{N}_2(\mathbf{r} \mid 0, \tilde{\mathbf{L}}^{-1})P(\boldsymbol{\beta} \mid \alpha),$$

where  $\mathbf{m} = (m_1, \dots, m_N)$ . Note that the normalizing constant of  $P_E$  can be ignored during MAP inference since it does not depend on  $\boldsymbol{\beta}$ .

### 4.3 Incorporating Initial Labels

Recall that the initial labels  $\hat{\mathbf{Y}}$  are strong indicators of semantic orientation associated with each sentence; they correspond to either discrete polarity labels or to continuous rating labels. This heterogeneity constitutes the main difficulty for incorporating the initial labels via the conditional distributions  $P_b(\hat{\mathbf{y}}^b \mid \mathbf{r})$ . We assume independence throughout so that  $P_b(\hat{\mathbf{y}}^b \mid \mathbf{r}) = \prod_i P_b(\hat{y}_i^b \mid r_i)$ .

**Rating Labels** For continuous labels, we assume Gaussian noise and set  $P_b(\hat{y}_i^b \mid r_i) = \mathcal{N}(\hat{y}_i^b \mid r_i, \eta_i^b)$ , where variance  $\eta_i^b$  is a type- and sentence-dependent.

For SO-CAL labels, we simply set  $\eta_i^{\text{SO-CAL}} = \eta^{\text{SO-CAL}}$ , where  $\eta^{\text{SO-CAL}}$  is a hyperparameter. The SO-CAL scores have limited influence in our overall model; we found that more complex designs lead to little improvement. We proceed differently for document ratings. Our experiment suggests that document ratings constitute the most important indicator of the SO of a sentence. Thus sentence ratings should be close to document ratings unless strong evidence to

the contrary exists. In other words, we want variance  $\eta_i^{\text{Doc}}$  to be small.

When no manually created sentence-level polarity labels are available, we set the value of  $\eta_i^{\text{Doc}}$  depending on the polarity class. In particular, we set  $\eta_i^{\text{Doc}} = 1$  for both positive and negative documents, and  $\eta_i^{\text{Doc}} = 2$  for neutral documents. The reasoning behind this choice is that sentence ratings in neutral documents express higher variance because these documents often contain a mixture of positive and negative sentences.

When a small set of manually created sentence polarity labels is available, we train a classifier that predicts whether the sentence polarity coincides with the document polarity. If so, we set the corresponding variance  $\eta_i^{\text{Doc}}$  to a small value; otherwise, we choose a larger value. In particular, we train a logistic regression classifier (Bishop, 2006) using the following binary features: (1) an indicator variable for each document polarity, and (2) an indicator variable for each triple of base predictor, predicted polarity, and document polarity (set to 1 if the polarities match). We then set  $\eta_i^{\text{Doc}} = (\tau p_i)^{-1}$ , where  $p_i$  is the probability of matching polarities obtained from the classifier and  $\tau$  is a hyperparameter that ensures correct scaling.

**Polarity Labels** We now describe how to model the correlation between the polarity of a sentence and its rating. A simple and effective approach is to partition the range of ratings into three consecutive partitions, one for each polarity class. We thus consider the polarity classes  $\{\text{positive}, \text{other}, \text{negative}\}$  as ordered and formulate polarity classification as an ordinal regression problem (Chu and Ghahramani, 2006). We immediately obtain the distribution

$$\begin{aligned} P_b(\hat{y}_i^b = \text{pos} \mid r_i) &= \Phi\left(\frac{r_i - b^+}{\sqrt{\eta^b}}\right) \\ P_b(\hat{y}_i^b = \text{oth} \mid r_i) &= \Phi\left(\frac{b^+ - r_i}{\sqrt{\eta^b}}\right) - \Phi\left(\frac{b^- - r_i}{\sqrt{\eta^b}}\right) \\ P_b(\hat{y}_i^b = \text{neg} \mid r_i) &= \Phi\left(\frac{b^- - r_i}{\sqrt{\eta^b}}\right), \end{aligned}$$

where  $b^+$  and  $b^-$  are the partition boundaries between *positive/other* and *other/negative*, respectively,<sup>2</sup>  $\Phi(x)$  denotes the cumulative distribution function of the

<sup>2</sup>We set  $b^+ = 0.3$  and  $b^- = -0.3$  to calibrate to SO-CAL, which treats ratings in  $[-0.3, 0.3]$  as polarity *other*.

Figure 1: Distribution of polarity given rating.

Gaussian distribution, and variance  $\eta^b$  is a hyperparameter. It is easy to verify that  $\sum_{\hat{y}_i^b \in \mathcal{Y}} p(\hat{y}_i^b | r_i) = 1$ . The resulting distribution is shown in Fig. 1. We can use the same distribution to use MEM for sentence-level polarity classification; in this case, we pick the polarity with the highest probability.

#### 4.4 Incorporating Base Predictors

Base predictors are integrated into MEM via component  $\mathcal{N}_1(r_i | m_i, \sigma^2)$  of the multi-expert prior (see Sec. 4.2). Recall that  $m_i$  is a linear function of the features  $\mathbf{x}_i$  of each sentence. In this section, we discuss how  $\mathbf{x}_i$  is constructed from the features of the base predictors. New base predictors can be integrated easily by exposing their features to MEM.

Most base predictors operate on the phrase level; our goal is to construct features for the entire sentence. Denote by  $n_i^b$  the number of phrases in the  $i$ -th sentence covered by base predictor  $b$ , and let  $\mathbf{o}_{ij}^b$  denote a set of associated features. Features  $\mathbf{o}_{ij}^b$  may or may not correspond directly to the features of base predictor  $b$ ; see the discussion below. A straightforward strategy is to set  $\mathbf{x}_i^b = (n_i^b)^{-1} \sum_j \mathbf{o}_{ij}^b$ . We proceed slightly differently and average the features associated with phrases of positive prior polarity separately from those of phrases with negative prior polarity (Taboada et al., 2011). We then concatenate the averaged feature vectors, i.e., we set  $\mathbf{x}_i^b = (\bar{\mathbf{o}}_{ij}^{b,pos} \quad \bar{\mathbf{o}}_{ij}^{b,neg})$ , where  $\bar{\mathbf{o}}_{ij}^{b,p}$  denotes the average of the feature vectors  $\mathbf{o}_{ij}^b$  associated with phrases of prior polarity  $p$ . This procedure allows us to learn a different weight for each feature depending on its

context (e.g., the weight of intensifier “very” may differ for positive and negative phrases). We construct  $\mathbf{x}_i$  by concatenating the sentence-level features  $\mathbf{x}_i^b$  of each base predictor and a feature vector of bigrams.

To integrate a base predictor, we only need to specify the relevant features and, if applicable, prior phrase polarities. For our choice of base predictors, we use the following features:

**SO-CAL predictor.** The prior polarity of a SO-CAL phrase is given by the polarity of its SO-carrying word in the SO-CAL lexicon. The feature vector  $\mathbf{o}_{ij}^{\text{SO-CAL}}$  consists of the weight of the SO-carrying word from the lexicon as well the set of negator words, irrealis marker words, and intensifier words in the phrase. Moreover, we add the first two words preceding the SO-carrying word as context features (skipping nouns, negators, irrealis markers, and intensifiers, and stopping at clause boundaries). All words are encoded as binary indicator features.

**BoO predictor.** Similar to SO-CAL, we determine the prior polarity of a phrase based on the BoO dictionary. In contrast to SO-CAL, we directly use the BoO score as a feature because the BoO predictor weights have been trained on a very large corpus and are thus reliable. We also add irrealis marker words in the form of indicator features.

**Statistical polarity predictor.** Recall that the statistical polarity predictor is based on co-occurrence counts of opinion-topic pairs and document polarities. We treat each opinion-topic pair as a phrase and use the most frequently co-occurring polarity as the phrase’s prior polarity. We use the logarithm of the co-occurrence counts with positive, negative, and other polarity as features; this set of features performed better than using the co-occurrence counts or estimated class probabilities directly. We also add the same type of context features as for SO-CAL, but rescale each binary feature by the logarithm of the occurrence count  $\#z$  of the opinion-topic pair (i.e., the features take values in  $\{0, \log \#z\}$ ).

#### 4.5 Incorporating Sentence Similarities

The component distribution  $\mathcal{N}_2(\mathbf{r} | 0, \tilde{\mathbf{L}}^{-1})$  in the multi-expert prior encourages similar sentences to have similar ratings. The main purpose of  $\mathcal{N}_2$  is to propagate information from sentences on which the base predictors perform well to sentences for which base prediction is unreliable or unavailable (e.g., be-

cause they do not contain SO-carrying words). To obtain this distribution, we first construct an  $N \times N$  sentence similarity matrix  $\mathbf{W}$  using a sentiment-augmented word sequence kernel (see below). We then compute the regularized graph Laplacian  $\tilde{\mathbf{L}} = \mathbf{L} + \mathbf{I}/\lambda^2$  based on the unnormalized graph Laplacian  $\mathbf{L} = \mathbf{D} - \mathbf{W}$  (Chapelle et al., 2006), where  $\mathbf{D}$  be a diagonal matrix with  $d_{ii} = \sum_j w_{ij}$  and hyperparameter  $\lambda^2$  controls the scale of sentence ratings.

To gain insight into distribution  $\mathcal{N}_2$ , observe that

$$\mathcal{N}_2(\mathbf{r} \mid 0, \tilde{\mathbf{L}}^{-1}) \propto \exp\left(-\frac{1}{2} \sum_{i,j} w_{ij} (r_i - r_j)^2 - \|\mathbf{r}\|_2^2 / \lambda^2\right).$$

The left term in the exponent forces the ratings of similar sentences to be similar: the larger the sentence similarity  $w_{ij}$ , the more penalty is paid for dissimilar ratings. For this reason,  $\mathcal{N}_2$  has a smoothing effect. The right term is an L2 regularizer and encourages small ratings; it is controlled by hyperparameter  $\lambda^2$ .

The entries  $w_{ij}$  in the sentence similarity matrix determine the degree of smoothing for each pair of sentence ratings. We compute these values by a novel sentiment-augmented word sequence kernel, which extends the well-known word sequence kernel of Cancedda et al. (2003) by (1) BoO weights to strengthen the correlation of sentence similarity and rating similarity and (2) synonym resolution based on WordNet (Miller, 1995).

In general, a word sequence kernel computes a similarity score of two sequences based on their shared subsequences. In more detail, we first define a score function for a pair of shared subsequences, and then sum up these scores to obtain the overall similarity score. Consider for example the two sentences “The book is an easy read.” ( $s_1$ ) and “It is easy to read.” ( $s_2$ ) along with the shared subsequence “is easy read” ( $u$ ). Observe that the words “an” and “to” serve as gaps as they are not part of the subsequence. We represent subsequence  $u$  in sentence  $s$  via a real-valued projection function  $\phi_u(s)$ . In our example,  $\phi_u(s_1) = v_{is}v_{an}^g v_{easy}v_{read}$  and  $\phi_u(s_2) = v_{is}v_{easy}v_{to}^g v_{read}$ . The decay factors  $v_w \in (0, 1]$  for matching words characterize the importance of a word (large values for significant words). On the contrary, decay factors  $v_w^g \in (0, 1]$

for gap words are penalty terms for mismatches (small values for significant words). The score of subsequence  $u$  is defined as  $\phi_u(s_1)\phi_u(s_2)$ . Thus two shared subsequences have high similarity if they share significant words and few gaps. Following Cancedda et al. (2003), we define the similarity between two sequences as

$$k_n(s_i, s_j) = \sum_{u \in \Omega^n} \phi_u(s_i)\phi_u(s_j),$$

where  $\Omega$  is a finite set of words and  $n$  denotes the length of the considered subsequences. This similarity function can be computed efficiently using dynamic programming.

To apply the word sequence kernel, we need to specify the decay factors. A traditional choice is  $v_w = \log(\frac{N}{N_w}) / \log(N)$ , where  $N_w$  is the document frequency of the word  $w$  and  $N$  is the total number of documents. This IDF decay factor is not well-suited to our setting: Important opinion words such as “great” have a low IDF value due to their high document frequency. To overcome this problem, we incorporate additional weights for SO-carrying words using the BoO lexicon. To do so, we first rescale the BoO weights into  $[0, 1]$  using the sigmoid  $g(w) = (1 + \exp(-a\omega_w + b))^{-1}$ , where  $\omega_w$  denotes the BoO weight of word  $w$ .<sup>3</sup> We then set  $v_w = \min(\log(\frac{N}{N_w}) / \log(N) + g(w), 0.9)$ . The decay factor for gaps is given by  $v_w^g = 1 - v_w$ . Thus we strongly penalize gaps that consist of infrequent words or opinion words.

To address data sparsity, we incorporate synonyms and hypernyms from WordNet into our kernel. In particular, we represent words found in WordNet by their first two synset names (for verbs, adjectives, nouns) and their direct hypernym (nouns only). Two words are considered the same when their synsets overlap. Thus, for example, “writer” has the same representation as “author”.

To build the similarity matrix  $\mathbf{W}$ , we construct a  $k$ -nearest-neighbor graph for all sentences.<sup>4</sup> We consider subsequences consisting of three words (i.e.,  $w_{ij} = k_3(s_i, s_j)$ ); longer subsequences are overly sparse, shorter subsequences are covered by the bigrams features in  $\mathcal{N}_1$ .

<sup>3</sup>We set  $a = 2$  and  $b = 1$  in our experiments.

<sup>4</sup>We use  $k = 15$  and only consider neighbors with a similarity above 0.001.

## 5 Experiments

We evaluated both MEM and a number of alternative approaches for both sentence-level polarity classification and sentence-level strength prediction across a number of domains. We found that MEM outperforms state-of-the-art approaches by a significant margin.

### 5.1 Experimental Setup

We implemented MEM as well as the HCRF classifier of (Täckström and McDonald, 2011a; Täckström and McDonald, 2011b), which is the best-performing estimator of sentence-level polarity in the weakly-supervised setting reported in the literature. We train both methods using (1) only coarse labels (MEM-Coarse, HCRF-Coarse) and (2) additionally a small number of sentence polarities (MEM-Fine, HCRF-Fine<sup>5</sup>). We also implemented a number of baselines for both polarity classification and strength prediction: a document oracle (DocOracle) that simply uses the document label for each sentence, the BoO rating predictor (Base<sub>BoO</sub>), and the SO-CAL rating predictor (Base<sub>SO-CAL</sub>). For polarity classification, we compare our methods also to the statistical polarity predictor (Base<sub>polarity</sub>). To judge on the effectiveness of our multi-expert prior for combining base predictors, we take the majority vote of all base predictors and document polarity as an additional baseline (Majority-Vote). Similarly, for strength prediction, we take the arithmetic mean of the document rating and the phrase-level predictions of Base<sub>BoO</sub> and Base<sub>SO-CAL</sub> as a baseline (Mean-Rating). We use the same hyperparameter setting for MEM across all our experiments.

We evaluated all methods on Amazon reviews from different domains using the corpus of Ding et al. (2008) and the test set of Täckström and McDonald (2011a). For each domain, we constructed a large balanced dataset by randomly sampling 33,000 reviews from the corpus of Ding et al. (2008). We chose the books, electronics, and music domains for our experiments; the dvd domain was used for development. For sentence polarity classification, we use the test set of Täckström and McDonald (2011a), which

<sup>5</sup>We used the best-performing model that fuses HCRF-Coarse and the supervised model (McDonald et al., 2007) by interpolation.

contains roughly 60 reviews per domain (20 for each polarity). For strength evaluation, we created a test set of 300 pairs of sentences per domain from the polarity test set. Each pair consisted of two sentences of the same polarity; we manually determined which of the sentences is more positive. We chose this pairwise approach because (1) we wanted the evaluation to be invariant to the scale of the predicted ratings, and (2) it much easier for human annotators to rank a pair of sentences than to rank a large collection of sentences.

We followed Täckström and McDonald (2011b) and used 3-fold cross-validation, where each fold consisted of a set of roughly 20 documents from the test set. In each fold, we merged the test set with the reviews from the corresponding domain. For MEM-Fine and HCRF-Fine, we use the data from the other two folds as fine-grained polarity annotations. For our experiments on polarity classification, we converted the predicted ratings of MEM, Base<sub>BoO</sub>, and Base<sub>SO-CAL</sub> into polarities by the method described in Sec. 4.3. We compare the performance of each method in terms of accuracy, which is defined as the fraction of correct predictions on the test set (correct label for polarity / correct ranking for strength). All reported numbers are averages over the three folds. In our tables, boldface numbers are statistically significant against all other methods (t-test, p-value 0.05).

### 5.2 Results for Polarity Classification

Table 1 summarizes the results of our experiments for sentence polarity classification. The base predictors perform poorly across all domains, mainly due to the aforementioned problems associated with averaging phrase-level predictions. In fact, DocOracle performs almost always better than any of the base predictors. However, accuracy increases when we combine base predictors and DocOracle using majority voting, which indicates that ensemble methods work well.

When no fine-grained annotations are available (HCRF-Coarse, MEM-Coarse), both MEM-Coarse and Majority-Vote outperformed HCRF-Coarse, which in turn has been shown to outperform a number of lexicon-based methods as well as classifiers trained on document labels (Täckström and McDonald, 2011a). MEM-Coarse also performs better than Majority-Vote. This is because MEM propagates

	Book	Electronics	Music	Avg
Base <sub>polarity</sub>	43.7	40.3	43.8	42.6
Base <sub>BoO</sub>	50.9	48.9	52.6	50.8
Base <sub>SO-CAL</sub>	44.6	50.2	45.0	46.6
DocOracle	51.9	49.6	59.3	53.6
Majority-Vote	53.7	53.4	58.7	55.2
HCRF-Coarse	52.2	53.4	57.2	54.3
MEM-Coarse	54.4	54.9	<b>64.5</b>	57.9
HCRF-Fine	55.9	<b>61.0</b>	58.7	58.5
MEM-Fine	<b>59.7</b>	59.6	63.8	<b>61.0</b>

Table 1: Accuracy of polarity classification per domain and averaged across domains.

evidence across similar sentences, which is especially useful when no explicit SO-carrying words exist. Also, MEM learns weights of features of base predictors, which leads to a more adaptive integration, and our ordinal regression formulation for polarity prediction allows direct competition among positive and negative evidence for improved accuracy.

When we incorporate a small amount of sentence polarity labels (HCRF-Fine, MEM-Fine), the accuracy of all models greatly improves. HCRF-Fine has been shown to outperform the strongest supervised method on the same dataset (McDonald et al., 2007; Täckström and McDonald, 2011b). MEM-Fine falls short of HCRF-Fine only in the electronics domain but performs better on all other domains. In the book and music domains, where MEM-Fine is particularly effective, many sentences feature complex syntactic structure and SO-carrying words are often used without reference to the quality of the product (but to describe contents, e.g., “a love story” or “a horrible accident”).

Our models perform especially well when they are applied to sentences containing no or few opinion words from lexicons. Table 2 reports the evaluation results for both sentences containing SO-carrying words from either MPQA or SO-CAL lexicons and for sentences containing no such words. The results explain why our model falls short of HCRF-Fine in the electronics domain: reviews of electronic products contain many SO-carrying words, which almost always express opinions. Nevertheless, MEM-Fine handles sentences without explicit SO-carrying words well across all domains; here the propagation of information across sentences helps to learn the SO

	Book		Electronics		Music	
	op	fact	op	fact	op	fact
HCRF-Fine	55.7	55.9	<b>63.3</b>	54.6	59.0	57.4
MEM-Fine	<b>58.9</b>	<b>62.4</b>	60.7	<b>56.7</b>	<b>64.5</b>	<b>60.8</b>

Table 2: Accuracy of polarity classification for sentences with opinion words (op) and without opinion words (fact).

of facts (such as “short battery life”).

We found that for all methods, most of the errors are caused by misclassifying positive/negative sentences as *other* and vice versa. Moreover, sentences with polarity opposite to the document polarity are hard cases if they do not feature frequent strong patterns. Another difficulty lies in off-topic sentences, which may contain explicit SO-carrying words but are not related to the item under review. This is one of the main reasons for the poor performance of the lexicon-based methods.

Overall, we found that MEM-Fine is the method of choice. Thus our multi-expert model can indeed balance the strength of the individual experts to obtain better estimation accuracy.

### 5.3 Results for Strength Prediction

Table 3 shows the accuracy results for strength prediction. Here our models outperformed all baselines by a large margin. Although document ratings are strong indicators in the polarity classification task, they lead to worse performance than lexicon-based methods. The main reason for this drop in accuracy is that the document oracle assigns the same rating to all sentences within a review. Thus DocOracle cannot rank sentences from the same review, which is a severe limitation. This shortage can be partly compensated by averaging the base predictions and document rating (Mean-Rating). Note that it is non-trivial to apply existing ensemble methods for the weights of individual base predictors because of the absence of the sentence ratings as training labels. In contrast, our MEM models use indirect supervision to adaptively assign weights to the features from base predictors. Similar to polarity classification, a small amount of sentence polarity labels often improved the performance of MEM.

	Book	Electronics	Music	Avg
Base <sub>BoO</sub>	58.3	51.6	53.5	54.5
Base <sub>SO-CAL</sub>	60.6	57.1	47.6	55.1

Mean-Rating	70.3	57.0	60.8	62.7
MEM-Coarse	68.7	60.5	<b>69.5</b>	66.2
MEM-Fine	<b>72.4</b>	<b>63.3</b>	67.2	<b>67.6</b>

Table 3: Accuracy of strength prediction.

## 6 Conclusion

We proposed the Multi-Experts Model for analyzing both opinion polarity and opinion strength at the sentence level. MEM is weakly supervised; it can run without any fine-grained annotations but is also able to leverage such annotations when available. MEM is driven by a novel multi-expert prior, which integrates a number of diverse base predictors and propagates information across sentences using a sentiment-augmented word sequence kernel. Our experiments indicate that MEM achieves better overall accuracy than alternative methods.

# Collocation Polarity Disambiguation Using Web-based Pseudo Contexts

Yanyan Zhao, Bing Qin and Ting Liu\*

Harbin Institute of Technology, Harbin, China

{yyzhao, bqin, tliu}@ir.hit.edu.cn

## Abstract

This paper focuses on the task of collocation polarity disambiguation. The *collocation* refers to a binary tuple of a polarity word and a target (such as ⟨long, battery life⟩ or ⟨long, startup⟩), in which the sentiment orientation of the polarity word (“long”) changes along with different targets (“battery life” or “startup”). To disambiguate a collocation’s polarity, previous work always turned to investigate the polarities of its surrounding contexts, and then assigned the majority polarity to the collocation. However, these contexts are limited, thus the resulting polarity is insufficient to be reliable. We therefore propose an unsupervised three-component framework to expand some pseudo contexts from web, to help disambiguate a collocation’s polarity. Without using any additional labeled data, experiments show that our method is effective.

## 1 Introduction

In recent years, more attention has been paid to sentiment analysis as it has been widely used in various natural language processing applications, such as question answering (Wiebe et al., 2003; Yu and Hatzivassiloglou, 2003), information extraction (Riloff et al., 2005) and opinion-oriented summarization (Hu and Liu, 2004; Liu et al., 2005). Meanwhile, it also brings us lots of interesting and challenging research topics, such as subjectivity analysis (Riloff and Wiebe, 2003), sentiment classification (Pang et al., 2002; Kim and Hovy, 2005;

Wilson et al., 2009; He et al., 2011), opinion retrieval (Zhang et al., 2007; Zhang and Ye, 2008; Li et al., 2010) and so on.

One fundamental task for sentiment analysis is to determine the semantic orientations of words. For example, the word “beautiful” is positive, while “ugly” is negative. Many researchers have developed several algorithms for this purpose and generated large *static* lexicons of words marked with prior polarities (Hatzivassiloglou and McKeown, 1997; Turney et al., 2003; Esuli, 2008; Mohammad et al., 2009; Velikovich et al., 2010). However, there exist some polarity-ambiguous words, which can *dynamically* reflect different polarities along with different contexts. A typical polarity-ambiguous word “长” (“long” in English) is shown with two example sentences as follows.

1. 该相机的[电池寿命]<sup>t</sup>很[长]<sup>p</sup>。(Positive)

Translated as: The [battery life]<sup>t</sup> of this camera is [long]<sup>p</sup>. (Positive)

2. 该相机的[启动时间]<sup>t</sup>很[长]<sup>p</sup>。(Negative)

Translated as: This camera has [long]<sup>p</sup> [startup]<sup>t</sup>. (Negative)

The phrases marked with *p* superscript are the polarity-ambiguous words, and the phrases marked with *t* superscript are targets modified by the polarity words. In the above two sentences, the sentiment orientation of the polarity word “长” (“long” in English) changes along with different targets. When modifying the target “电池寿命” (“battery life” in English), its polarity is positive; and when modifying “启动时间” (“startup” in English), its polarity is

\*Correspondence author: tliu@ir.hit.edu.cn

negative. In this paper, we especially *define the collocation* as a binary tuple of the polarity-ambiguous word and its modified target, such as ⟨长, 电池寿命⟩ (⟨long, battery life⟩ in English) or ⟨长, 启动时间⟩ (⟨long, startup⟩ in English). This paper concentrates on the task of **collocation polarity disambiguation**.

This is an important task as the problem of polarity-ambiguity is frequent. We analyze 4,861 common binary tuples of polarity words and their modified targets from 478 reviews<sup>1</sup>, and find that over 20% of them are the collocations defined in this paper. Therefore, the task of collocation polarity disambiguation is worthy of study.

For a sentence  $s$  containing such a collocation  $c$ , since the in-sentence features are always ambiguous, it is difficult to disambiguate the polarity of  $c$  by using them. Thus some previous work turned to investigate its surrounding contexts' polarities (such as the sentences before or after  $s$ ), and then assigned the majority polarity to the collocation  $c$  (Hatzivassiloglou and McKeown, 1997; Hu and Liu, 2004; Kanayama and Nasukawa, 2006). However, since the amount of contexts from the original review is very limited, the final resulting polarity for the collocation  $c$  is insufficient to be reliable.

Fortunately, most collocations may appear multiple times, in different forms, both within the same review and within topically-related reviews. Thus for a collocation, we can collect large amounts of contexts from other reviews to improve its polarity disambiguation. These expanded contexts are called *pseudo contexts* in this paper. Some previous work used the similar methods. For example, Ding (Ding et al., 2008) expanded some pseudo contexts from a topically-related review set. But since the review set is limited, the expanded contexts are still limited and unreliable. In order to overcome this problem, we propose an unsupervised three-component framework to expand more pseudo contexts from web for the collocation polarity disambiguation.

Without using any labeled data, experiments on a Chinese data set from four product domains show that the three-component framework is feasible and the web-based pseudo contexts are useful for the collocation polarity disambiguation. Compared to other previous work, our method achieves an *F1*

score of 72.02%, which is about 15% higher.

The remainder of this paper is organized as follows. Section 2 introduces the related work. Section 3 shows the proposed approach including three independent components. Section 4 and 5 presents the experiments and results. Finally we conclude this paper in Section 6.

## 2 Related Work

The key of the collocation polarity disambiguation task is to recognize the polarity word's sentiment orientation of a collocation. There are basically two types of approaches for word polarity recognition: corpus-based and dictionary-based approaches. Corpus-based approaches find co-occurrence patterns of words in the large corpora to determine the word sentiments, such as the work in (Hatzivassiloglou and McKeown, 1997; Wiebe, 2000; Riloff and Wiebe, 2003; Turney et al., 2003; Kaji and Kitsuregawa, 2007; Velikovich et al., 2010). On the other hand, dictionary-based approaches use synonyms and antonyms in WordNet to determine word sentiments based on a set of seed polarity words. Such approaches are studied in (Kim and Hovy, 2006; Esuli and Sebastiani, 2005; Kamps et al., 2004). Overall, most of the above approaches aim to generate a large *static* polarity word lexicon marked with prior polarities.

However, it is not sensible to predict a word's sentiment orientation without considering its context. In fact, even in the same domain, a word may indicate different polarities depending on what targets it is applied to, especially for the polarity-ambiguous words, such as “长” (“long” in English) shown in Section 1. Based on these, we need to consider both the polarity words and their modified targets, i.e., the collocations mentioned in this paper, rather than only the polarity words.

To date, the task in this paper is similar with much previous work. Some researchers exploited the features of the sentences containing collocations to help disambiguate the polarity of the polarity-ambiguous word. For example, Hatzivassiloglou (Hatzivassiloglou and McKeown, 1997) and Kanayama (Kanayama and Nasukawa, 2006) used conjunction rules to solve this problem from large domain corpora. Suzuki (Suzuki et al., 2006)

<sup>1</sup>The dataset will be introduced in Section 4.1 in detail.

took into account many contextual information of the word within the sentence, such as exclamation words, emoticons and so on. However, the experimental results show that these in-sentence features are not rich enough.

Instead of considering the current sentence alone, some researchers exploited external information and evidences in other sentences or other reviews to infer the collocation’s polarity. For a collocation, Hu (Hu and Liu, 2004) analyzed its surrounding sentences’ polarities to disambiguate its polarity. Ding (Ding et al., 2008) proposed a holistic lexicon-based approach of using global information to solve this problem. However, the contexts or evidences from these two methods are limited and unreliable. Except for the above unsupervised methods, some researchers (Wilson et al., 2005; Wilson et al., 2009) proposed supervised methods for this task, which need large annotated corpora.

In addition, many related works tried to learn word polarity in a specific domain, but ignored the problem that even the same word in the same domain may indicate different polarities (Jijkoun et al., 2010; Bollegala et al., 2011). And some work (Lu et al., 2011) combined difference sources of information, especially the lexicons and heuristic rules for this task, but ignored the important role of the context. Besides, there exists some research focusing on word sense subjectivity disambiguation, which aims to classify a word sense into subjective or objective (Wiebe and Mihalcea, 2006; Su and Markert, 2009). Obviously, this task is different from ours.

### 3 The Proposed Approach

#### 3.1 Overview

The motivation of our approach is to make full use of web sources to collect more useful pseudo contexts for a collocation, whose original contexts are limited or unreliable. The framework of our approach is illustrated in Figure 1.

In order to disambiguate a collocation’s polarity, three components are carried out:

**1. Query Expansion and Pseudo Context Acquisition:** This paper uses the collocation as query. For a collocation, three heuristic query expansion strategies are used to generate more flexible queries, which have the same or completely opposite polar-

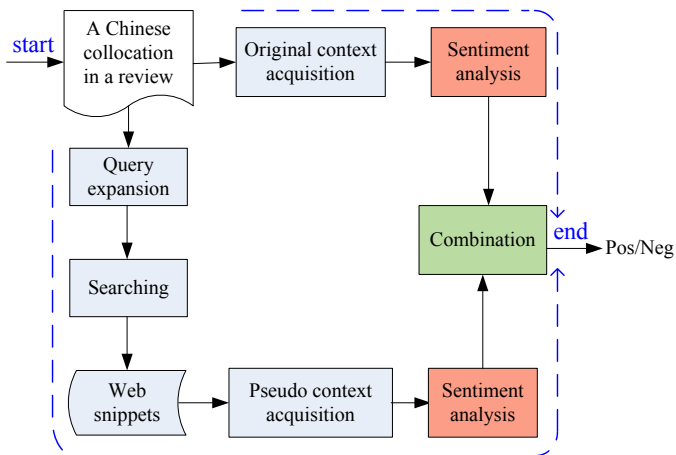

Figure 1: The framework of our approach.

ity with this collocation. Searching these queries in the domain-related websites, lots of snippets can be acquired. Then we can extract the pseudo contexts from these snippets.

**2. Sentiment Analysis:** For both original contexts and the expanded pseudo contexts from web, a simple lexicon-based sentiment computing method is used to recognize each context’s polarity.

**3. Combination:** Two strategies are designed to integrate the polarities of the original and pseudo contexts, under the assumption that these two kinds of contexts can be complementary to each other.

**It is worth noting** that this three-component framework is flexible and we can try to design different strategies for each component. Next sections will give a simple example strategy for each component to show its feasibility and effectiveness.

#### 3.2 Query Expansion and Pseudo Context Acquisition

##### 3.2.1 Why Expanding Queries

For a collocation, such as  $\langle \text{长, 电池寿命} \rangle$  ( $\langle \text{long, battery life} \rangle$  in English), the most intuitive query used for searching is constructed by the form of “target + polarity word”, i.e., 电池寿命长 (battery life long in English). Even if we search this query alone, a great many web snippets covering the polarity word and target will be retrieved. But why do we still need to expand the queries?

In fact, for a collocation, though the amount of the retrieved snippets is large, lots of them cannot provide accurate pseudo contexts. The reason is that the

polarity words in some snippets do not really modify the targets, such as in the sentence “The *battery life* is short, and finds few buyers for a *long* time.” There exist no modifying relation between “*battery life*” and “*long*”.

In order to filter these meaningless snippets, we can simply search with a new query “电池寿命长” by *surrounding it with quotes* (noted as **Strategy0**). However, this can drastically decline the amount of snippets. In addition, as the new query is short, in many retrieved snippets, there also exist no modifying relations between the polarity words and targets. As a result, if we just use this query strategy, the expanded pseudo contexts are limited and cannot yield ideal performance.

Therefore, we need to design some effective query expansion strategies to ensure that (1) the polarity words do modify the targets in the retrieved web snippets, and (2) the snippets are more enough.

### 3.2.2 Query Expansion Strategy

We first investigate the modifying relations between polarity words and the targets, and then construct effective queries.

Observed from previous work (Bloom et al., 2007; Kobayashi et al., 2004; Popescu and Etzioni, 2005), there are two kinds of common relations between the polarity words and their targets. One is the “subject-copula-predicate” relation, such as the relationship between “long” and “battery life” in the sentence “The *battery life* of this camera is *long*”. The other is the “attribute-head” relation, such as the relationship between them in the sentence “This camera has *long battery life*”.

As a result, three heuristic query expansion strategies are adopted to construct efficient queries for searching. Take the collocation ⟨长, 电池寿命⟩ (⟨long, battery life⟩ in English) as an example, the strategies are described as follows.

**Strategy1:** target + *modifier* + polarity word: Such as the query “电池寿命很长” or “电池寿命非常长” (“the battery life is *very* long” in English). Different from Strategy0, this strategy adds a *modifier* element. It refers to the words that are used to change the degree of a polarity word, such as “很” or “非常” (“very” in English). Due to the usage of the modifiers, the queries from this strategy can satisfy the “subject-copula-predicate” relation.

**Strategy2:** *modifier* + polarity word + 的+ target: Such as the query “很长的电池寿命” or “非常长的电池寿命” (“*very* long battery life” in English). This strategy also uses *modifiers* to modify polarity words, and the generated queries can satisfy the “attribute-head” relation.

**Strategy3:** *negation word* + polarity word + 的+ target: Such as the query “不长的电池寿命” or “没有长的电池寿命” (“*not* long battery life” in English). This strategy uses *negation words* to modify the polarity words. And the queries from this strategy can satisfy the “attribute-head” relation. The only difference is that the polarity of this kind of queries is opposite to that of the collocation.

Similar to the queries from Strategy0, the queries generated by Strategy1~3 are all searched with quotes. In addition, note that the *modifier* and the *negation word* are taken from *Modifier Lexicon* and *Negation Lexicon* introduced in Table 2.

### 3.2.3 Pseudo Context Acquisition

For each query from Strategy0~3, we search it in some websites to acquire the related snippets. If we directly search it using Google without site restrictions, it does return all the snippets containing the query, but lots of them are non-reviews. Further, the pseudo contexts generated by these non-reviews are useless or even harmful. To overcome this problem, the *advanced search* of Google is used to search the query within the *forum sites* of the product domain. We can flexibly choose several popular forum sites for each domain. The URLs of the forum sites used in this paper are listed in Table 1.

Formally, given a collocation  $c$ , the expanded pseudo contexts  $Conx(c)$  can be obtained using the following function:

$$\begin{aligned} Conx(c) &= \bigcup_{i=0}^3 f(Query_i) \\ &= \bigcup_{i=0}^3 \bigcup_{j=1}^n f(query_{ij}) \end{aligned} \quad (1)$$

Here,  $Query_i$  is the query set generated by the  $i$ th query expansion strategy;  $query_{ij}$  is the  $j$ th query generated by the  $i$ th strategy. And the parameter  $n$  is the total number of queries from the  $i$ th query expansion strategy. From this function, we can collect the contexts of  $c$  by summing up all the pseudo contexts from every  $query_{ij}$ .

Table 1: The URLs used in context expansion for different domains.

In detail, the pseudo context acquisition algorithm for a collocation  $c$  is illustrated in Figure 2. Note that, the original context acquisition of  $c$  can be considered as a simplified version of the pseudo context acquisition. That’s because the current review containing  $c$  can be considered as only one snippet in pseudo context acquisition. Thus, we can just carry out the two steps in (2) of Figure 2 to obtain the original contexts.

Analyzing either the pseudo contexts or the original contexts, we can find that not all of them are useful contexts. Thus we will simply filter the noisy ones by context sentiment computation, and choose the contexts showing sentiment orientations as the useful contexts.

### 3.3 Sentiment Analysis

For both the original and expanded pseudo contexts, we employ the lexicon-based sentiment computing method (Hu and Liu, 2004) to compute the polarity value for each context. This unsupervised approach is quite straightforward and makes use of the sentiment lexicons in Table 2.

The polarity value  $Polarity(con)$  for a context  $con$

#### Algorithm: Pseudo Context Expansion Algorithm

---

**Input:** A collocation  $c$  and the URL list

**Output:** The pseudo context set  $Conx(c)$

1. Use Strategy0~3 to expand  $c$  and the expanded queries are saved as a set  $Query(c)$ .
  2. For any query  $q \in Query(c)$ , acquire its pseudo contexts  $Conx(q)$  as follows:
    - (1) search  $q$  in the domain-related URL list, the top 100 retrieved snippets for each URL are collected as  $Snip(q)$
    - (2) for each snippet  $sp \in Snip(q)$ 
      - find the sentence  $s$  containing  $q$
      - obtain the two sentences before and after  $s$  as the contexts of  $q$  in this  $sp$ , noted as  $Conx(q, sp)$
$$Conx(q) = \bigcup_{sp \in Snip(q)} Conx(q, sp)$$
  3.  $Conx(c) = \bigcup_{q \in Query(c)} Conx(q) = \bigcup_{q \in Query(c)} \bigcup_{sp \in Snip(q)} Conx(q, sp)$
-

Modifier Lexicon	很, 比较, 非常, 十分, 太, 特别, 挺, 相当, 格外, 分外 (“very” or “quite” in English)
Negation Lexicon	没有, 不, 不是 (“no” or “not” in English)
Positive Lexicon	There are 3,730 Chinese words are collected from HOWNET!
Negative Lexicon	There are 3,116 Chinese words are collected from HOWNET.

<sup>1</sup> [http://www.keenage.com/html/e\\_index.html](http://www.keenage.com/html/e_index.html).

Table 2: The lexicons used in this paper.

is computed by summing up the polarity values of all words in  $con$ , making use of both the word polarity defined in the positive and negative lexicons and the contextual shifters defined in the negation lexicon. The algorithm is illustrated in Figure 3.

In this algorithm,  $n$  is the parameter controlling the window size within which the negation words have influence on the polarity words, and here  $n$  is set to 3.

Normally, if the polarity value  $Polarity(con)$  is more than 0, the context  $con$  is labeled as positive; if less than 0, the context is negative. We also consider the transitional words, such as “但是” (“but” in English). Finally, the contexts with positive/negative polarities are used as the useful contexts.

Domain	# of reviews	# of $c$ (All)	# of single $c$ (Sig)	Sig / All (%)	# of multiple $c$ / kinds of multiple $c$

**Algorithm:** Sentiment Analysis

---

**Input:** a context  $con$ , and three lexicons:  $Positive\_Dic$ ,  $Negative\_Dic$ ,  $Negation\_Dic$

**Output:** Polarity value  $Polarity(con)$

1. Segment  $con$  into word set  $W(con)$
2. For each word  $w \in W(con)$ , compute its polarity value  $Polarity(w)$  as follows:
  - (1) if  $w \in Positive\_Dic$ ,  $Polarity(w) = 1$ ;
  - (2) if  $w \in Negative\_Dic$ ,  $Polarity(w) = -1$ ;
  - (3) otherwise,  $Polarity(w) = 0$ ;
  - (4) Within the window of  $n$  words previous to  $w$ , if there is a word  $w' \in Negation\_Dic$ ,  $Polarity(w) = -Polarity(w')$
3.  $Polarity(con) = \sum_{w \in W(con)} Polarity(w)$

---

Figure 3: The algorithm for context polarity computation.

### 3.4 Combination

After the pseudo context acquisition and polarity computation, two kinds of effective contexts: *original contexts* and *pseudo contexts*, and their corresponding polarities can be obtained.

In order to yield a relatively accurate polarity  $Polarity(c)$  for a collocation  $c$ , we exploit the following combination methods:

1. **Majority Voting:** Rather than considering the difference between the two kinds of contexts, this combination method relies on the polarity tag of each context. Suppose  $c$  has  $n$  effective contexts (including original and pseudo contexts), it can obtain  $n$  polarity tags based on the individual sentiment analysis algorithm. The polarity tag receiving more votes is chosen as the final polarity of  $c$ .

2. **Complementation:** For a collocation  $c$ , we first employ “Majority Voting” method just on the expanded pseudo contexts to obtain the polarity tag.

If the polarity of  $c$  cannot be recognized<sup>2</sup>, the majority polarity tag voted on the original contexts is chosen as the final polarity tag.

## 4 Experimental Setup

### 4.1 Dataset and Evaluation Metrics

We conduct the experiments on a Chinese collocation corpus of four product domains, which is from the Task3 of the Chinese Opinion Analysis Evaluation (COAE)<sup>3</sup> (Zhao et al., 2008). Table 3 describes the corpus in detail.

From 478 reviews, 1,001 collocations (454 positive and 547 negative) with polarity-ambiguous words are found and manually annotated by two annotators. Cohen’s kappa (Cohen, 1960), a measure of inter-annotator agreement ranging from zero to one, is 0.83, indicating a good strength of agreement<sup>4</sup>. In Table 3, *Sig* of the fourth column denotes the collocations that appear once in all the domain-related reviews. And *multiple* in the last column denotes the collocations that appear several times. From Table 3, we can find that among all the reviews, nearly 60% collocations only appear once. Even for the *multiple* collocations, they averagely appear less than 4 times. Therefore, for a collocation, if we only consider its original contexts alone or the expanded pseudo contexts from the domain-related review set alone, the contexts are obviously limited and unreliable.

Instead of using accuracy, we use precision ( $P$ ), recall ( $R$ ) and F-measure ( $FI$ ) to measure the performance of this task. That’s because two kinds of collocations’ polarities cannot be disambiguated. One

<sup>2</sup>The reason will be explained in the last paragraph of Section 4.1.

<sup>3</sup><http://www.ir-china.org.cn/coae2008.html>

<sup>4</sup>A small number of collocations are still difficult to be disambiguated from contexts.

is the sparse collocations, which obtain no effective contexts. The other is the collocations that acquire the same amount of positive and negative contexts. The metrics are defined as follows.

$$P = \frac{\text{correctly disambiguated collocations}}{\text{disambiguated collocations}} \quad (2)$$

$$R = \frac{\text{correctly disambiguated collocations}}{\text{all collocations}} \quad (3)$$

$$F1 = \frac{2PR}{P + R} \quad (4)$$

## 4.2 System Description

In order to compare our method with previous work, we build several systems as follows:

*NoExp*: Following the method proposed by Hu (Hu and Liu, 2004), without using the expanded pseudo contexts, we only consider the two original contexts  $Sen_{bef}$  and  $Sen_{aft}$  of a collocation  $c$  in the current review. **If**  $Sen_{bef}$  expresses the polarity  $polar$ , then  $Polarity(ac) = polar$ . **Else if**  $Sen_{aft}$  expresses the polarity  $polar'$ , then  $Polarity(ac) = polar'$ . **Else**, this method cannot disambiguate the polarity of  $c$ . In this method, the transitional words, such as “但是” (“but” in English) are considered.

*Exp<sub>dataset</sub>*: Following the method proposed by Ding (Ding et al., 2008), we solve this task with the help of the pseudo contexts in the domain-related review dataset. For a collocation  $c$  appearing in many domain-related reviews, this method refers to the polarities of the same  $c$  in other reviews. The majority polarity is chosen as final polarity.

*Exp<sub>web+sig</sub>*: This method is the same as our method in this paper, except for (1) not combining the original contexts, and (2) not using all the three query expansion strategies, but just using the *single* (abbr. *sig*) Strategy0. This method expands the pseudo contexts from the *web*. The majority polarity is chosen as the final polarity.

*Exp<sub>web+exp</sub>*: This method is the same as our proposed method in this paper, except for not combining the original contexts. It expands the pseudo contexts from the *web*. And the “*exp*” in the subscript means that this method uses all the query expansion strategies. The majority polarity of all the pseudo contexts is chosen as the final polarity.

*Exp<sub>web+exp+com</sub><sup>mv/c</sup>*: This is the method proposed in this paper, which combines the original and expanded pseudo contexts. The superscript “*mv/c*” is short for the two combination methods: Majority Voting and Complementation.

## 5 Results

### 5.1 Comparisons among All the Systems

In fact, all the systems shown in Section 4.2 can be considered as *context* based methods. The essential difference among them lies in the contexts they used. For a collocation, the contexts for *NoExp* are two original contexts from the current review. Breaking down the boundary of the current review, *Exp<sub>dataset</sub>* explores the pseudo contexts from other domain-related reviews. Further, *Exp<sub>web+sig</sub>*, *Exp<sub>web+exp</sub>* and *Exp<sub>web+exp+com</sub><sup>mv/c</sup>* expand the pseudo contexts from *web*, which can be considered as a large corpus and can provide more evidences for the collocation polarity disambiguation.

System	P(%)	R(%)	F1(%)
<i>NoExp</i>	67.32	41.16	51.08
<i>Exp<sub>dataset</sub></i>	68.14	47.85	56.22
<i>Exp<sub>web+sig</sub></i>	70.00	53.85	60.87
<i>Exp<sub>web+exp</sub></i>	74.97	63.14	68.55
<i>Exp<sub>web+exp+com</sub><sup>mv</sup></i>	75.53	67.83	71.47
<i>Exp<sub>web+exp+com</sub><sup>c</sup></i>	74.36	69.83	72.02

Table 4: Comparative results for the collocation polarity disambiguation task.

Table 4 illustrates the comparative results of all systems for collocation polarity disambiguation. It can be observed that our system *Exp<sub>web+exp+com</sub><sup>mv</sup>* and *Exp<sub>web+exp+com</sub><sup>c</sup>* outperform all the other systems. We discuss the experimental results as follows:

*NoExp* yields the worst performance, especially on the recall. The reason is that the original contexts used in this system are limited, and some of them are even noisy. In comparison, *Exp<sub>dataset</sub>* adds a post-processing step of expanding pseudo contexts from the topically-related review dataset, which achieves a better result with an absolute improvement of 5.14% (*F1*). This suggests that the contexts expanded from other reviews are helpful in disambiguating the collocation’s polarity.

However,  $Exp_{dataset}$  is just effective in disambiguating the polarity of such a collocation  $c$ , which appears many times in the domain-related reviews. From Table 3, we can notice that this kind of collocations only accounts for 40% in all the collocations, and further they appear less than 4 times on average. Thus, for such a collocation  $c$ , the pseudo contexts expanded from other reviews that contain the same  $c$  are still far from enough, since the review set size in this system is not very large.

In order to avoid the context limitation problem, we expand more pseudo contexts from web for each collocation. We first try to use a simple query form (Strategy0) for web mining. Table 4 illustrates that the corresponding system  $Exp_{web+sig}$  outperforms the system  $Exp_{dataset}$ . It can demonstrate that our web mining based pseudo context expansion is useful for disambiguating the collocation’s polarity, since this system can explore more contexts. However, we can find that the performance is not very ideal. This system can generate some harmful contexts for the reason of the wrong modifying relations between polarity words and targets in the retrieved snippets.

Thus this paper adds three query expansion strategies to generate more and accurate pseudo contexts. Table 4 shows that the corresponding system  $Exp_{web+exp}$  can achieve a better result with  $F1 = 68.55\%$ , which is significantly ( $\chi^2$  test with  $p < 0.01$ ) outperforms  $Exp_{web+sig}$ . It demonstrates that the query expansion strategies are useful.

Finally, Table 4 gives the results of our method in this paper,  $Exp_{web+exp+com}^{mv}$  and  $Exp_{web+exp+com}^c$ , which combines the original and expanded pseudo contexts to yield a final polarity. We can observe that both of these systems outperform the system  $NoExp$  of just using the original contexts and the system  $Exp_{web+exp}$  of just using the expanded pseudo contexts. This can illustrate that the two kinds of contexts are complementary to each other. In addition, we can also find that the two combination methods produce similar results. In detail,  $Exp_{web+exp+com}^{mv}$  disambiguates 899 collocations, 679 of them are correct;  $Exp_{web+exp+com}^c$  disambiguates 940 collocations, 699 of them are correct.

We can further find that, although the amount of original contexts is small, it also plays an important role in disambiguating the polarities of the collo-

cations that cannot be recognized by the expanded pseudo contexts.

## 5.2 The Contributions of the Query Expansion Strategies

The expanded pseudo contexts from our method can be partly credited to the query expansion strategies. Based on this, this section aims to analyze the different contributions of the query expansion strategies in our method.

Strategy	$P(\%)$	$R(\%)$	$F1(\%)$	Avg(#)
Strategy0	70.00	53.85	60.87	71
Strategy1	74.14	55.84	63.70	112
Strategy2	61.84	37.56	46.74	26
Strategy3	64.34	33.17	43.77	20
$Exp_{web+exp}$	74.97	63.14	<b>68.55</b>	229

Table 5: The performance of our method based on each query expansion strategy for collocation polarity disambiguation.

Table 5 provides the performance of our method based on each query expansion strategy for collocation polarity disambiguation. For each strategy, “Avg” in Table 5 denotes the average number of the expanded pseudo contexts for each collocation. From this table, we can find that the larger the “Avg” is, the better ( $F1$ ) the strategy is. In detail, Strategy1 with the largest “Avg” has the best performance; and Strategy3 with the fewest “Avg” has the worst performance. This can further demonstrate our idea that more and effective pseudo contexts can improve the performance of the collocation polarity disambiguation task.  $Exp_{web+exp}$  integrates all the query expansion strategies and obtains much more “Avg”. Therefore, this can significantly increase the recall value, and further produce a better result. On the other hand, the results in Table 5 show that these heuristic query expansion strategies are effective.

## 5.3 Deep Experiments in the Three-Component Framework

In order to do a detailed analysis into our three-component framework, some deep experiments are made:

**Query Expansion** The aim of query expansion is to retrieve lots of relative snippets, from which we can extract the useful pseudo contexts. For each

	Strategy0 (%)	Strategy1 (%)	Strategy2 (%)	Strategy3 (%)
Query Expansion	76.75	94.50	85.50	85.25
Pseudo Context	71.25	73.50	67.50	74.50
Sentiment Analysis	63.00	68.25	59.00	69.75

Table 6: The accuracies of the query expansion, pseudo context and sentiment analysis for each strategy.

snippet, if the polarity word of the collocation does modify the target, we consider this snippet as a correct query expansion result.

**Pseudo Context** For each expanded pseudo context from web, if it shows the same sentiment orientation with the collocation (or opposite with the collocation’s polarity because of the usage of transitional words), we consider this context as a correct pseudo context.

**Sentiment Analysis** For each expanded pseudo context, if its polarity can be correctly recognized by the polarity computation method in Figure 3, and meanwhile it shows the same sentiment orientation with the collocation, we consider this context as a correct one.

Table 6 illustrates the accuracy of each experiment for each strategy in detail, where 400 web retrieved snippets for *Query Expansion* and 400 expanded pseudo contexts for *Pseudo Context* and *Sentiment Analysis* are randomly selected and manually evaluated for each strategy.

Seen from Table 6, we can find that:

1. For *Query Expansion*, all strategies yield good accuracies except for Strategy0. This can draw a same conclusion with our analysis in Section 3.2.1. The queries from Strategy0 are short, thus in many retrieved snippets, there exist no modifying relations between the polarity words and targets. Accordingly, the pseudo contexts from these snippets are incorrect. This can result in the low accuracy of Strategy0. On the other hand, we can find that the other three query expansion strategies perform well.

2. Although the final result of our three-component framework is good, the accuracies of *Pseudo Context* and *Sentiment Analysis* for each strategy is not very high. This is perhaps caused by unrefined work on the specific sub-stages. For example, we get all the pseudo contexts using the algorithm in Figure 2. However, in some reviews, the two sentences before and after the target sentence

have no polarity relation with the target sentence itself. This can bring in some noises. On the other hand, the context polarity computation algorithm in Figure 3 is just a simple attempt, which is not the best way to compute the context’s polarity.

**In fact**, this paper aims to try some simple algorithms for each component to validate the effectiveness of the three-component framework. We will polish every component of our framework in future.

## 6 Conclusion and Future Work

This paper proposes a web-based context expansion framework for collocation polarity disambiguation. The basic assumption of this framework is that, if a collocation appears in different forms, both within the same review and within topically-related reviews, then the large amounts of pseudo contexts from these reviews can help to disambiguate such a collocation’s polarity. Based on this assumption, this framework includes three independent components. First, the heuristic query expansion strategies are adopted to expand pseudo contexts from web; then a simple but effective polarity computation method is used to recognize the polarities for both the original contexts and the expanded pseudo contexts; and finally, we integrate the polarities from the original and pseudo contexts as the collocation’s polarity. Without using any additional labeled data, experiments on a Chinese data set from four product domains show that the proposed framework outperforms other previous work.

This paper can be concluded as follows:

1. A framework including three independent components is proposed for collocation polarity disambiguation. We can try other different algorithms for each component.
2. Web-based pseudo contexts are effective for disambiguating a collocation’s polarity.

3. The query expansion strategies are promising, which can generate more useful and correct contexts.
4. The initial contexts from current reviews and the expanded contexts from web are complementary to each other.

The immediate extension of our work is to polish each component of this framework, such as improving the accuracy of query expansion and pseudo context acquisition, using other effective polarity computing methods for each context and so on. In addition, we will explore other query expansion strategies to generate more effective contexts.

# Aligning Predicates across Monolingual Comparable Texts using Graph-based Clustering

Michael Roth and Anette Frank

Department of Computational Linguistics

Heidelberg University

Germany

{mroth, frank}@cl.uni-heidelberg.de

## Abstract

Generating coherent discourse is an important aspect in natural language generation. Our aim is to learn factors that constitute coherent discourse from data, with a focus on how to realize predicate-argument structures in a model that exceeds the sentence level. We present an important subtask for this overall goal, in which we align predicates across comparable texts, admitting partial argument structure correspondence. The contribution of this work is two-fold: We first construct a large corpus resource of comparable texts, including an evaluation set with manual predicate alignments. Secondly, we present a novel approach for aligning predicates across comparable texts using graph-based clustering with Mincuts. Our method significantly outperforms other alignment techniques when applied to this novel alignment task, by a margin of at least 6.5 percentage points in  $F_1$ -score.

## 1 Introduction

Discourse coherence is an important aspect in natural language generation (NLG) applications. A number of theories have investigated coherence inducing factors. A prominent example is *Centering Theory* (Grosz et al., 1995), which models local coherence by relating the choice of referring expressions to the importance of an entity at a certain stage of a discourse. A data-driven model based on this theory is the *entity-based approach* by Barzilay and Lapata (2008), which models coherence phenomena by observing sentence-to-sentence transitions of entity occurrences.

Barzilay and Lapata show that their approach can discriminate between a coherent and a non-coherent set of ordered sentences. However, their model is not able to generate alternative entity realizations by itself. Furthermore, the entity-based approach only investigates realization patterns for individual entities in discourse in terms of core grammatical functions. It does not investigate the interplay between entity transitions and realization patterns for full-fledged semantic structures. This interplay, however, is an important factor for a semantics-based, generative model of discourse coherence.

The main hypothesis of our work is that we can automatically learn context-specific realization patterns for predicate argument structures (PAS) from a semantically parsed corpus of comparable text pairs. Our assumption builds on the success of previous research, where comparable and parallel texts have been exploited for a range of related learning tasks, e.g., unsupervised discourse segmentation (Barzilay and Lee, 2004) and bootstrapping semantic analyzers (Titov and Kozhevnikov, 2010).

For our purposes, we are interested in finding corresponding PAS across comparable texts that are known to talk about the same events, and hence involve the same set of underlying event participants. By aligning predicates in such texts, we can investigate the factors that determine discourse coherence in the realization patterns for the involved arguments. These include the specific forms of argument realization, as a pronoun or a specific type of referential expression, as studied in prior work in NLG (Belz et al., 2009, inter alia). The specific set-up we examine, however, allows us to further investi-

gate the factors that govern the *non-realization* of an argument position, as a special form of coherence inducing element in discourse. Example (1), extracted from our corpus of aligned texts, illustrates this point: Both texts report on the same event of locating victims in an avalanche. While (1.a) explicitly talks about the location of this event, the role remains implicit in the second sentence of (1.b), given that it can be recovered from the preceding sentence. In fact, realization of this argument role would impede the fluency of discourse by being overly repetitive.

- (1) a. ...The official said that [no bodies]<sub>Arg1</sub> had been recovered [from the avalanches]<sub>Arg2</sub> which occurred late Friday in the Central Asian country near the Afghan border some 300 kilometers (185 miles) southeast of the capital Dushanbe.
- b. Three other victims were trapped *in an avalanche* in the village of Khichikh. [None of the victims bodies]<sub>Arg1</sub> have been found [<sub>Argm-loc</sub>.

This phenomenon clearly relates to the problem of discourse-linking of implicit roles, a very challenging task in discourse processing.<sup>1</sup> In our work, we consider this problem from a content-based generation perspective, concentrating on the discourse factors that allow for the omission of a role.

Thus, our aim is to identify comparable predications across aligned texts, and to study the discourse coherence factors that determine the realization patterns of arguments in the respective discourses. This can be achieved by considering the full set of arguments that can be recovered from the aligned predications. This paper focuses on the first of these tasks, henceforth called *predicate alignment*.<sup>2</sup>

In line with data-driven approaches in NLP, we automatically align predicates in a suitable corpus of paired texts. The induced alignments will (i) serve to identify events described in both comparable texts, and (ii) provide information about the underlying argument structures and how they are realized in each context to establish a coherent discourse. We investigate a graph-based clustering method for induc-

<sup>1</sup>See the recent SemEval 2010 task: *Linking Events and their Participants in Discourse*, (Ruppenhofer et al., 2010).

<sup>2</sup>Note that we provide details regarding the construction of a suitable data set and further examples involving non-realized arguments in a complementary paper (Roth and Frank, 2012).

ing such alignments as clustering provides a suitable framework to implicitly relate alignment decisions to one another, by exploiting global information encoded in a graph.

The remainder of this paper is structured as follows: In Section 2, we discuss previous work in related tasks. Section 3 describes our task and a suitable data set. Section 4 introduces a graph-based clustering model using Mincuts for the alignment of predicates. Section 5 outlines the experiments and presents evaluation results. Finally, we conclude in Section 6 and discuss future work.

## 2 Related Work

The task of aligning words in general has been studied extensively in previous work, for example as part of research in statistical machine translation (SMT). Typically, alignment models in SMT are trained by observing and (re-)estimating co-occurrence counts of word pairs in parallel sentences (Brown et al., 1993). The same methods have also been applied in monolingual settings, for example to align words in paraphrases (Cohn et al., 2008). In contrast to traditional word alignment tasks, our focus is not on pairs of isolated sentences but on aligning predicates within the discourse contexts in which they are situated. Furthermore, text pairs for our task should not be strictly parallel as we are specifically interested in the impact of different discourse contexts. In Section 5, we will show that this particular setting indeed constitutes a more challenging task compared to traditional word alignment in parallel or paraphrasing sentences.

Another set of related tasks is found in the area of textual inference. Since 2006, there have been regular challenges on the task of Recognizing Textual Entailment (RTE). In the original task description, Dagan et al. (2006) define *textual entailment* “as a directional relationship between pairs of text expressions, denoted by  $T$  - the entailing ‘Text’ -, and  $H$  - the entailed ‘Hypothesis’. (...)  $T$  entails  $H$  if the meaning of  $H$  can be inferred from the meaning of  $T$ , as would typically be interpreted by people.” Although this relation does not necessarily require the presence of corresponding predicates, previous work by MacCartney et al. (2008) shows that word alignments can serve as a good indicator of entailment.

As a matter of fact, the same holds true for the task of detecting paraphrases. In contrast to RTE, this latter task requires bi-directional entailments, i.e., each of the two phrases must entail the other. Wan et al. (2006) show that a simple approach solely based on word (and lemmatized n-gram) overlap can already achieve an  $F_1$ -score of up to 83% for detecting paraphrases in the Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005, MSRPC). In fact, this is just 0.6% points below the state-of-the-art results recently reported by Socher et al. (2011).

The MSRPC and data sets from the first RTE challenges only consisted of isolated pairs of sentences. The Fifth PASCAL Recognizing Textual Entailment Challenge (Bentivogli et al., 2009) introduced a “Search Task”, where entailing sentences for a hypothesis have to be found in a set of full documents. This new task first opened the doors for assessing the role of discourse (Mirkin et al., 2010a; Mirkin et al., 2010b) in RTE. However, this setting is still limited as discourse contexts are only provided for the entailing part ( $T$ ) of each text pair but not for the hypothesis  $H$ .

A further task related to ours is the detection of event coreference. The goal of this task is to identify all mentions of the same event within a document and, in some settings, also across documents. However, the task setting is typically more restricted than ours in that its focus lies on identical events/references (cf. Walker et al. (2006), Weischedel et al. (2011), *inter alia*). In particular, verbalizations of different aspects of an event (e.g., ‘buy’–‘sell’, ‘kill’–‘die’, ‘recover’–‘find’) are generally not linked in this paradigm. In contrast to coreference methods that identify chains of events, we are interested in pairs of corresponding predicates (and their argument structure), for which we can observe alternative realizations in discourse.

### 3 Aligning Predicates Across Texts

This section summarizes how we built a large corpus of comparable texts, as a basis for the *predicate alignment* task. We motivate the choice of the corpus and present a strategy for extracting comparable text pairs. Subsequently, we report on the preparation of an evaluation data set with manual predicate alignments across the paired texts. We conclude this

section with an example that showcases the potential of using aligned predicates for the study of coherence phenomena. More detailed information regarding corpus creation, annotation guidelines and additional examples illustrating the potential of this corpus can be found in Roth and Frank (2012).

#### 3.1 Corpus Creation

The goal of our work is to investigate coherence factors for argument structure realization, using comparable texts that describe the same events, but that include variation in textual presentation. This requirement fits well with the news domain, for which we can trace varying textual sources that describe the same underlying events. The English Gigaword Fifth Edition (Parker et al., 2011) corpus (henceforth just *Gigaword*) is one of the largest corpus collections for English. It comprises a total of 9.8 million newswire articles from seven distinct sources.

In previous work (Roth and Frank, 2012), we introduced *GigaPairs*, a sub-corpus extracted from Gigaword that includes over 160,000 pairs of newswire articles from distinct sources. *GigaPairs* has been derived from Gigaword using the pairwise similarity method on headlines presented by Wubben et al. (2009). In addition to calculating the similarity of news titles, we impose an additional date constraint to further increase the precision of extracted pairs of texts. Random inspection of about 100 documents revealed only two texts describing different events. Overall, we extracted 167,728 document pairs containing a total of 50 million word tokens. Each document in this corpus consists of up to 7,564 words with a mean and median of 301 and 213 words, respectively. All texts have been pre-processed using MATE tools (Björkelund et al., 2010; Bohnet, 2010), a pipeline of NLP modules including a state-of-the-art semantic role labeler that computes PropBank/NomBank annotations (Palmer et al., 2005; Meyers et al., 2008).

#### 3.2 Gold Standard Annotation

We selected 70 text pairs from the *GigaPairs* corpus for manual predicate alignment. All document pairs were randomly chosen with the constraint that each text consists of 100 to 300 words.<sup>3</sup> Predi-

<sup>3</sup>This constraint is satisfied by 75.3% of all documents in *GigaPairs*.

cates identified by the semantic parser are provided as pre-labeled annotations for alignment. We asked two students<sup>4</sup> to tag corresponding predicates across each text pair. Following standard practice in word alignment tasks (cf. Cohn et al. (2008)) the annotators were instructed to distinguish between *sure* and *possible* alignments, depending on how certainly, in their opinion, two predicates describe verbalizations of the same event. The following examples show predicate pairings marked as sure (2) and as possible alignments (3).

- (2) a. The regulator ruled on September 27 that Nasdaq too was qualified to bid for OMX [...]  
 b. The authority [...] had already approved a similar application by Nasdaq.
- (3) a. Myanmar’s military government said earlier this year it has released some 220 political prisoners [...]  
 b. The government has been regularly releasing members of Suu Kyi’s National League for Democracy party [...]

In total, the annotators (A/B) aligned 487/451 sure and 221/180 possible alignments with a Kappa score (Cohen, 1960) of 0.86.<sup>5</sup> For the construction of a gold standard, we merged the alignments from both annotators by taking the union of all possible alignments and the intersection of all sure alignments. Cases which involved a sure alignment on which the annotators disagreed were resolved in a group discussion with the first author.

We split the final corpus into a development set of 10 document pairs and a test set of 60 document pairs. The test set contains a total of 3,453 predicates (1,531 nouns and 1,922 verbs). Its gold standard annotation consists of 446 sure and 361 possible alignments, which corresponds to an average of 7.4 sure (6.0 possible) alignments per document pair. Most of the gold alignments (82.4%) are between predicates of the same part-of-speech (242 noun and 423 verb pairs). A total of 383 gold alignments (47.5%) have been annotated between predicates with identical lemma form. Diverging numbers of realized arguments can be observed in 320 pairs (39.7%).

<sup>4</sup>Both annotators are students in computational linguistics, one undergraduate (A) and one postgraduate (B) student.

<sup>5</sup>Following Brockett (2007), we computed agreement on labeled annotations, including unaligned predicate pairs as an additional *null* category.

### 3.3 Potential for Discourse Coherence

This section presents an example of an aligned predicate pair from our development set that illustrates the potential of aggregating corresponding PAS across comparable texts. The example represents one of eleven cases involving unrealized arguments that can be found in our development set of only ten document pairs.

- (4) a. The Chadians said they<sub>Arg0</sub> had fled in fear of their lives.  
 b. The United Nations says some 20,000 refugees<sub>Arg0</sub> have fled into Cameroon<sub>Arg1</sub>.

In both sentences, the Arg0 role of the predicate flee is filled, but Arg1 (here: the goal) has not been realized in (4.a). However, sentence (4.a) is still part of a coherent discourse, as a role filler for the omitted argument can be inferred from the preceding context. For the goal of our work, we are interested in factors that license such omissions of an argument. Potential factors on the discourse level include the information status of the entity filling an argument position, and its salience at the corresponding point in discourse. Roth and Frank (2012) discuss additional examples that demonstrate the importance of factors on further linguistic levels, e.g., lexical choice of predicates and their syntactic realization.

In the example above, the aggregation of aligned PAS presents an effective means to identify appropriate fillers for unrealized roles. Hence, we can utilize each such pair as one positive and one negative training instance for a model of discourse coherence that controls the omissibility of arguments. In what follows, we introduce an alignment approach that can be used to automatically acquire more training data using the entire GigaPairs corpus.

## 4 Model

For the automatic induction of predicate alignments across texts, we opt for an unsupervised graph-based clustering method. In this section, we first define a graph representation for pairs of documents. In particular, predicates are represented as nodes in such a graph and similarities between predicates as edges. We then proceed to describe various similarity measures that can be used to identify similar predicate instances. Finally, we introduce the clustering algorithm that we apply to graphs (representing pairs of

documents) in order to induce alignments between corresponding predicates.

#### 4.1 Graph representation

We build a bipartite graph representation for each pair of texts, using as vertices the predicate argument structures assigned in pre-processing (cf. Section 3.1). We represent each predicate as a node and integrate information about arguments only implicitly. Given the sets of predicates  $P_1$  and  $P_2$  of two comparable texts  $T_1$  and  $T_2$ , respectively, we formally define an undirected graph  $G_{P_1, P_2}$  as follows:

$$G_{P_1, P_2} = \langle V, E \rangle \quad \text{where} \quad \begin{aligned} V &= P_1 \cup P_2 \\ E &= P_1 \times P_2 \end{aligned} \quad (1)$$

**Edge weights.** We specify the edge weight between two nodes representing predicates  $p_1 \in P_1$  and  $p_2 \in P_2$  as a weighted linear combination of four similarity measures described in the next section: *WordNet* and *VerbNet* similarity, *Distributional* similarity and *Argument* similarity.

$$\begin{aligned} w_{p_1 p_2} &= \lambda_1 * \text{sim}_{\text{WN}}(p_1, p_2) \\ &+ \lambda_2 * \text{sim}_{\text{VN}}(p_1, p_2) \\ &+ \lambda_3 * \text{sim}_{\text{Dist}}(p_1, p_2) \\ &+ \lambda_4 * \text{sim}_{\text{Arg}}(p_1, p_2) \end{aligned} \quad (2)$$

Initially we set all weighting parameters  $\lambda_1 \dots \lambda_4$  to have uniform weights by default. In Section 5, we define an optimized weighting setting for the individual similarity measures.

#### 4.2 Similarity Measures

We employ a number of similarity measures that make use of complementary information that is type-based ( $\text{sim}_{\text{WN}/\text{VN}/\text{Dist}}$ ) or token-based ( $\text{sim}_{\text{Arg}}$ ).<sup>6</sup> Given two lemmatized predicates  $p_1, p_2$  and their set of arguments  $A_1 = \text{args}(p_1)$ ,  $A_2 = \text{args}(p_2)$ , we define the following measures.

**WordNet similarity.** Given all pairs of synsets  $s_1, s_2$  that contain the predicates  $p_1, p_2$ , respectively, we compute the maximal similarity using the information theoretic measure described in Lin (1998). Our implementation exploits the WordNet hierarchy

<sup>6</sup>All token-based frequency counts (i.e.,  $\text{freq}()$  and  $\text{idf}()$ ) are computed over all documents from the AFP and APW parts of the English Gigaword Fifth Edition.

(Fellbaum, 1998) to find the synset of the least common subsumer (lcs) and uses the pre-computed Information Content (IC) files from Pedersen et al. (2004) to compute Lin’s measure:

$$\text{sim}_{\text{WN}}(p_1, p_2) = \frac{IC(\text{lcs}(s_1, s_2))}{IC(s_1) * IC(s_2)} \quad (3)$$

In order to compute similarities between verbal and nominal predicates, we further use derivation information from NomBank (Meyers et al., 2008): if a noun represents a nominalization of a verbal predicate, we resort to the corresponding verb synset. If no relation can be found between two predicates, we set a default value of  $\text{sim}_{\text{WN}} = 0$ . This applies in particular to all cases that involve a predicate not present in WordNet.

**VerbNet similarity.** To overcome systematic problems with the WordNet verb hierarchy (cf. Richens (2008)), we further compute similarity between verbal predicates using VerbNet (Kipper et al., 2008). Verbs in VerbNet are categorized into semantic classes according to their syntactic behavior. A class  $C$  can recursively embed sub-classes  $C_s \in \text{sub}(C)$  that represent finer semantic and syntactic distinctions. We define a simple similarity function that defines fixed similarity scores between 0 and 1 for pairs of predicates  $p_1, p_2$  depending on their relatedness within the VerbNet class hierarchy:

$$\text{sim}_{\text{VN}}(p_1, p_2) = \begin{cases} 1.0 & \text{if } \exists C : p_1, p_2 \in C \\ 0.8 & \text{if } \exists C, C_s : C_s \in \text{sub}(C) \\ & \wedge p_1, p_2 \in C \cup C_s \\ 0.0 & \text{else} \end{cases} \quad (4)$$

**Distributional similarity.** As some predicates may not be covered by the WordNet and VerbNet hierarchies, we additionally calculate similarity based on distributional meaning in a semantic space (Laudauer and Dumais, 1997). Following the traditional bag-of-words approach that has been applied in related tasks (Guo and Diab, 2011; Mitchell and Lapata, 2010), we consider the 2,000 most frequent context words  $c_1, \dots, c_{2000} \in C$  as dimensions of a vector space and define predicates as vectors using their Pointwise Mutual Information (PMI):

$$\vec{p} = (\text{PMI}(p, c_1), \dots, \text{PMI}(p, c_{2000})) \quad (5)$$

$$\text{with } \text{PMI}(x, y) = \frac{\text{freq}(x, y)}{\text{freq}(x) * \text{freq}(y)}$$

Given the vector representations of two predicates, we calculate their similarity as the cosine of the angle between the two vectors:

$$\text{sim}_{\text{Dist}}(p_1, p_2) = \frac{\vec{p}_1 \cdot \vec{p}_2}{|\vec{p}_1| * |\vec{p}_2|} \quad (6)$$

**Argument similarity.** While the previous similarity measures are purely type-based, *argument similarity* integrates token-based, i.e., discourse-specific, similarity information about predications by taking into account the similarity of their arguments. This measure calculates the association between the arguments  $A_1$  of the first and the arguments  $A_2$  of the second predicate by determining the ratio of overlapping words in both argument sets.

$$\text{sim}_{\text{Arg}}(p_1, p_2) = \frac{\sum_{w \in A_1 \cap A_2} \text{idf}(w)}{\sum_{w \in A_1} \text{idf}(w) + \sum_{w \in A_2} \text{idf}(w)} \quad (7)$$

In order to give higher weight to (rare) content words, we weight each word by its Inverse Document Frequency (IDF), which we calculate over all documents  $d$  from the AFP and APW sections of the Gigaword corpus:

$$\text{idf}(w) = \log \frac{|D|}{|\{d : w \in D\}|} \quad (8)$$

**Normalization.** In order to make the outputs of all similarity measures comparable, we normalize their value ranges on the development set to have a mean and standard deviation of 1.0.

### 4.3 Mincut-based Clustering

Our graph clustering method uses minimum cuts (or *Mincut*) in order to partition the bipartite text graph into clusters of aligned predicates. A Mincut operation divides a given graph into two disjoint sub-graphs. Each minimum cut is performed as a cut between some source node  $s$  and some target node  $t$ , such that (i) each of the two nodes will be in a different sub-graph and (ii) the sum of weights of all removed edges will be as small as possible. Our system determines each Mincut using an implementation of the method by Goldberg and Tarjan (1986).<sup>7</sup>

<sup>7</sup>Basic graph operations are performed using the freely available Java library JGraph, cf. <http://jgraph.org/>.

    end if
  end for
  return  $clusters$ ;
end function

```

---

Figure 2: Pseudo code of our clustering algorithm

As our goal is to induce clusters that correspond to pairs of similar predicates, we set a maximum number of two nodes per cluster as stopping criterion. Given an input graph  $G$ , our algorithm recursively applies Mincuts in three steps as described in Figure 2. Step 1 identifies the edge  $e$  with lowest weight in the given graph  $G$ . Step 2 performs the actual Mincut operation on  $G$ . Finally, the stopping criterion and recursion are applied in Step 3. An example of a clustered graph is illustrated in Figure 1.

The advantage of our method compared to off-the-shelf clustering techniques is two-fold: On the one hand, the clustering algorithm is free of any parameters, such as the number of clusters or a clustering threshold, that require fine-tuning. On the other hand, the approach makes use of a termination criterion that very well represents the nature of the goal of our task, namely to align pairs of predicates across comparable texts. The next section provides empirical evidence for the advantage of this approach.

## 5 Experiments

This section evaluates our graph-clustering model on the task of aligning predicates across comparable texts. For comparison to related tasks and methods, we describe different evaluation settings, vari-

Figure 1: The predicates of two sentences (white: “The company has said it plans to restate its earnings for 2000 through 2002.”; grey: “The company had announced in January that it would have to restate earnings (...)”) from the Microsoft Research Paragraph Corpus are aligned by computing clusters with minimum cuts.

ous baselines, as well as results for these baselines and the model presented above.

## 5.1 Settings

In order to benchmark our model against traditional methods for word alignment, we first apply our graph-based alignment model (**Full**) on three sentence-based paraphrase corpora. This model uses the similarity measures defined in Section 4.2 and the clustering algorithm introduced in Section 4.3.

In a second experiment, we evaluate **Full** on our novel task of inducing predicate alignments across comparable monolingual texts, using the **GigaPairs** data set described in Section 3. We evaluate against the manually annotated gold alignments in the test data set described in Section 3.2. To gain more insight into the performance of the various similarity measures included in the **Full** model, we evaluate simplified versions that omit individual similarity measures (**Full**–[measure name]).

The relative differences in performance against various baselines will help us quantify the differences and difficulties between a traditional sentence-based word alignment setting and our novel alignment task that operates on full texts.

### 5.1.1 Sentence-level Alignment Setting

For sentence-based predicate alignment we make use of the following three corpora that are word-aligned subsets of the paraphrase collections described in (Cohn et al., 2008): **MTC** consists of 100

sentence pairs from the Multiple-Translation Chinese Corpus (Huang et al., 2002), **Leagues** contains 100 sentential paraphrases from two translations of Jules Verne’s “Twenty Thousand Leagues Under the Sea”, and **MSR** is a sub-set of the Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005), consisting of 130 sentence pairs. All three paraphrase collections are in English.

Results for these experiments are reported in Section 5.3.1. Note that in order to determine alignment candidates, we apply the same pre-processing steps as used for the annotation of our corpus. The semantic parser identified an average number of 3.8, 5.1 and 4.7 predicates per text (i.e., per paraphrase sentence) in **MTC**, **Leagues** and **MSR**, respectively. All models are evaluated against the subset of gold standard alignments (cf. Cohn et al. (2008)) between pairs of words marked as predicates.

### 5.1.2 Text-level Alignment Setting

Results for our own data set, **GigaPairs**, are reported in Section 5.3.2. In this setting, models are evaluated against the annotated gold standard alignments between predicates as described in Section 3.2. Since all text pairs in **GigaPairs** comprise multiple sentences each, the average number of predicates per text to consider (27.5) is much higher than in the paraphrase settings. As the full graph representation becomes rather inefficient to handle (by default, edges are inserted between all predicate pairs), we use the development set of 10 text pairs to estimate

	<b>MTC</b>			<b>Leagues</b>			<b>MSR</b>		
	Precision	Recall	F1	Precision	Recall	F1	Precision	Recall	F1
<b>LemmaId</b>	25.1**	74.9	37.6**	31.5**	67.2	42.9**	42.3**	90.8	57.7**
<b>Greedy</b>	74.8**	<b>88.3**</b>	81.0	75.0**	<b>86.0**</b>	80.1	80.7**	<b>97.0**</b>	88.1
<b>WordAlign</b>	<b>99.3</b>	86.6	<b>92.5</b>	<b>98.7</b>	78.5	<b>87.4</b>	<b>99.5</b>	96.0*	<b>97.7*</b>
<b>Full</b>	92.3	72.2	81.1	92.7	69.4	79.4	94.5	88.3	91.3

Table 1: Results for sentence-based predicate alignment in the three benchmark settings **MTC**, **Leagues** and **MSR** (all numbers in %); results that significantly differ from **Full** are marked with asterisks (\*  $p < 0.05$ ; \*\*  $p < 0.01$ ).

a threshold on predicate similarity for adding edges. We tested all thresholds from 1.5 to 4.0 with a step-size of 0.25 and found 2.5 to perform best. This threshold is applied in the evaluation of all graph-based models.

## 5.2 Baselines

A simple baseline for both settings is to align all predicates whose lemmas are identical. This baseline, henceforth called **LemmaId**, is computed as a lower bound for all settings. In order to assess the benefits of the clustering step, we propose a second baseline that uses the same similarity measures and thresholds as our **Full** model, but omits the clustering step described in Section 4.3. Instead, it greedily computes as many 1-to-1 alignments as possible, starting from the highest similarity to the learned threshold (**Greedy**).

As a more sophisticated baseline, we make use of alignment tools commonly used in statistical machine translation (SMT). For the three sentence-based paraphrase settings **MTC**, **Leagues** and **MSR**, Cohn et al. (2008) readily provide GIZA++ (Och and Ney, 2003) alignments as part of their word-aligned paraphrase corpus. For the experiments in the **GigaPairs** setting, we train our own word alignment model using the state-of-the-art word alignment tool Berkeley Aligner (Liang et al., 2006). As word alignment tools require pairs of sentences as input, we first extract paraphrases in the latter setting using a re-implementation of the paraphrase detection system by Wan et al. (2006).<sup>8</sup> In the following section, we abbreviate both baselines using SMT alignment tools as **WordAlign**.

<sup>8</sup>Note that the performance of this system lies slightly below the state-of-the-art results reported by Socher et al. (2011). However, we were not able to reproduce the results of Socher et al. using the publicly available release of their software.

## 5.3 Results

We measure precision as the number of predicted alignments that are annotated in the gold standard divided by the total number of predictions. Recall is measured as the number of correctly predicted *sure* alignments divided by the total number of *sure* alignments in the gold standard. This conforms to evaluation measures used for word alignment models in SMT (Och and Ney, 2003). Following Cohn et al. (2008), we subsequently compute the  $F_1$ -score as the harmonic mean between precision and recall.

We compute statistical significance of result differences with a paired t-test (Cohen, 1995) over the affected test set documents and provide corresponding significance levels where appropriate.

### 5.3.1 Sentence-level Predicate Alignment

The results for **MTC**, **Leagues** and **MSR** are presented in Table 1. The numbers indicate that **WordAlign** consistently outperforms all other models on the three data sets in terms of  $F_1$ -score. Statistical significance of result differences between **WordAlign** and **Full** can only be observed for recall and  $F_1$ -score on the **MSR** data set ( $p < 0.05$ ). Other differences are not significant due to high variance of results compared to data set sizes.

The overall performance of **WordAlign** does not come much as a surprise, seeing that all three data sets consist of highly parallel sentence pairs. In fact, the results for **LemmaId** show that by aligning all predicates with identical lemmas, most of the *sure* alignments in the three settings are already covered. The reason for the low precision lies in the fact that the same lemma can occur multiple times in the same paraphrase, a phenomenon that is better handled by **WordAlign**, **Greedy** and **Full**. Interestingly, the **Greedy** model achieves the highest recall in all settings but it performs below our **Full**

model in terms of precision and  $F_1$ -score. The performance differences between **Greedy** and **Full** are statistically significant ( $p < 0.01$ ) regarding precision and recall.

### 5.3.2 Text-level Predicate Alignment

We now turn to the experiments on our own data set, **GigaPairs**, which comprises full documents of unequal lengths instead of pairs of single sentences. Table 2 presents the results for our full model and the three baselines. From all four approaches, **WordAlign** yields lowest performance. We observe two main reasons for this: On the one hand, sentence paraphrase detection does not perform perfectly. Hence, the extracted sentence pairs do not always contain gold alignments. On the other hand, even sentence pairs that contain gold alignments are generally less parallel than in the previous settings, which make them harder to align. The increased difficulty can also be seen in the results for the **Greedy** baseline, which only achieves an  $F_1$ -score of 20.1% in this setting. In contrast, we observe that the majority of all sure alignments (60.3%) can be retrieved by applying the **LemmaId** model.

The **Full** model achieves a recall of 46.6%, but it significantly outperforms **LemmaId** ( $p < 0.01$ ) in terms of precision (58.7%, +18.4 percentage points). This is an important factor for us, as we plan to use the alignments in subsequent tasks. With 52.0%, **Full** achieves the best overall  $F_1$ -score.

**Ablating similarity measures.** All aforementioned results were conducted in experiments with a uniform weighting scheme of similarity measures as introduced in Section 4.3. Table 3 shows the performance impact of individual similarity measures by removing them completely (i.e., setting their weight to 0.0). The numbers indicate that not all measures contribute positively to the overall performance when using equal weights. However, a significant difference can only be observed when removing the argument similarity measure, which drastically reduces the results. This clearly highlights the importance of incorporating the context of individual predications in this task.

**Tuning weights.** Subsequently, we tested various combinations of weights on our development set in order to estimate a good overall weighting scheme.

	Precision	Recall	F1
<b>LemmaId</b>	40.3**	<b>60.3**</b>	48.3
<b>Greedy</b>	19.6**	20.6**	20.1**
<b>WordAlign</b>	19.7**	15.2**	17.2**
<b>Full</b>	<b>58.7</b>	46.6	<b>52.0</b>

Table 2: Results for **GigaPairs** (all numbers in %); results that significantly differ from **Full** are marked with asterisks (\*  $p < 0.05$ ; \*\*  $p < 0.01$ ).

	Precision	Recall	F1
<b>Full-WN</b>	58.9	48.0	52.9
<b>Full-VN</b>	57.3	48.7	52.6
<b>Full-Dist</b>	54.3	42.8	47.9
<b>Full-Args</b>	40.1**	24.0**	30.0**
<b>Full</b>	58.7	46.6	52.0
<b>Full+tuned</b>	<b>59.7**</b>	<b>50.7**</b>	<b>54.8**</b>

Table 3: Impact of removing individual measures and using a tuned weighting scheme (all numbers in %); results that significantly differ from **Full** are marked with asterisks (\*  $p < 0.05$ ; \*\*  $p < 0.01$ ).

This tuning procedure is implemented as a brute-force technique, in which we fix the weight of one similarity measure and allow all other measures to receive a weight assignment between 0.25 to 5.0 times the fixed weight. Finally, the resulting weights are normalized to sum to 1.0. We found the best performing weighting scheme to be 0.09, 0.48, 0.24 and 0.19 for  $\lambda_1, \dots, \lambda_4$ , respectively (cf. Eq. (2), Section 4). The performance gains of the resulting model (**Full+tuned**) can be seen in Table 3. Computing statistical significance of the result differences between **Full+tuned** and all baseline models confirmed significant improvements ( $p < 0.01$ ) for both precision and  $F_1$ -score.

### 5.4 Error Analysis

We perform an error analysis on the output of **Full+tuned** on the development set of **GigaPairs** in order to determine re-occurring problems. In total, the model missed 13 out of 35 sure alignments (Type I errors) and predicted 23 alignments not annotated in the gold standard (Type II errors).

Six Type I errors (46%) occurred when the lemma of an affected predicate occurred more than once in a text and the model missed a correct link. Vice versa, identical predicates that refer to different events have

been the source of 8 Type II errors (35%). We observe that these errors are frequently related to predicates, such as “say” and “appear”, that often occur in news texts. Altogether, we find 15 Type II errors (65%) that are due to high predicate similarity despite low argument overlap (cf. Example (5)).

- (5) a. The US alert (...) followed intelligence reports that ...  
 b. The Foreign Ministry announcement called on Japanese citizens to be cautious ...

We observe that argument overlap itself can be low even for correct alignments. This clearly indicates that a better integration of context is needed. Example (6.a) illustrates a case in which the agent of a warning event is not realized. Here, contextual information is required to correctly align it to the first warning event in (6.b). This involves inference beyond the local PAS.

- (6) a. The US alert (...) is one step down from a full [travel]<sub>Arg1</sub> warning [ ]<sub>Arg0</sub>.  
 b. Japan has issued a travel alert ... (which) follows similar warnings [from American and British authorities]<sub>Arg0</sub>. (...) An official said it was highly unusual for [Tokyo]<sub>Arg0</sub> to issue such a warning ...

## 6 Conclusion

We presented a novel task for *predicate alignment* across comparable monolingual texts, which we address using graph-based clustering with Mincuts. The motivation for this task is to acquire empirical data for studying discourse coherence factors related to argument structure realization.

As a first step, we constructed a data set of comparable texts that provide full discourse contexts for alternative verbalizations of the same underlying events. The data set is derived from all newswire pairs found in the English Gigaword Fifth Edition and contains a total of more than 160,000 paired documents.

A subset of these pairs forms an evaluation set, annotated with gold alignments that relate predications, which exhibit a (possibly partial) corresponding argument structure. We established that the annotation task, while difficult, can be performed with good inter-annotator agreement ( $\kappa$  at 0.86).

Our main contribution is a novel clustering approach using Mincuts for aligning predications across comparable texts. Our experiments established that recursive clustering improves on greedy selection methods by profiting from global information encoded in the graph representation. While the Mincut-based method is in itself unsupervised, a small amount of development data is needed to tune parameters for the construction of particularly suitable input graphs.

We tested our full model against two additional baselines: simple heuristic alignment based on identical lemma forms and a combination of techniques from SMT and paraphrase detection. The evaluation for our novel task was complemented by a traditional word alignment task using established paraphrase data sets. We determined clear differences in performance for all models for the two types of task settings. While word alignment methods from SMT outperform the competing models in the sentence-based alignment tasks, they perform poorly in the discourse setting.

In future work, we will enhance our model by incorporating more refined similarity measures including discourse-based criteria. We will further explore tuning techniques, e.g., a more suitable pre-selection method for edges in graph construction, in order to increase either precision or recall. The decision of optimizing towards one measure or another is clearly task-dependent. In our case, high precision is favorable as we plan to learn accurate discourse model parameters from the computed alignments. Even though such an optimization will result in an overall lower recall, application of the alignment model on the entire GigaPairs corpus can still provide us with a large amount of precise predicate alignments. Using this set of alignments, we will then proceed to exploit contextual information in order to learn a semantic model for discourse coherence in argument structure realization.

## Abstract

Computational approaches to metonymy resolution have focused almost exclusively on the local context, especially the constraints placed on a potentially metonymic word by its grammatical collocates. We expand such approaches by taking into account the larger context. Our algorithm is tested on the data from the metonymy resolution task (Task 8) at SemEval 2007. The results show that incorporation of the global context can improve over the use of the local context alone, depending on the types of metonymies addressed. As a second contribution, we move towards unsupervised resolution of metonymies, made feasible by considering ontological relations as possible readings. We show that such an unsupervised approach delivers promising results: it beats the supervised most frequent sense baseline and performs close to a supervised approach using only standard lexico-syntactic features.

## 1 Introduction

With the exception of explicit tasks in metonymy and metaphor analysis, computational treatment of language relies on the assumption that the texts to be processed have a literal interpretation. This contrasts with the fact that figurative expressions are common in language, as exemplified by the metonymy in the excerpt from a Wikipedia article in Example 1 and another in Example 2 from the SemEval 2007 metonymy resolution task (Markert and Nisim, 2009).

- (1) In the gold medal game, *Canada* defeated the American team 2-0 to win their third consecutive gold.
- (2) This keyword is only required when your relational database is *Oracle*.

The *defeating* in Example 1 will not be done by the country as such, but by a team representing the country in a sporting event. Hence, in a metonymy a potentially metonymic expression or word (here *Canada*) stands for a conceptually related entity (here, people of Canada). In the second Example, a company name (*Oracle*) stands for a product (database) developed by the company.

Metonymy resolution can be important for a variety of tasks. Textual entailment may need metonymy resolution (Bentivogli et al., 2007): for example, we would like to be able to induce from Example 1 the hypothesis

*The Canadian team won . . . .*

Leveling and Hartrumpf (2008) show that metonymy recognition on location proper names helps geographical information retrieval by excluding metonymically used place names from consideration (such as Example 1 or the use of *Vietnam* for the *Vietnam war*). Metonymies also frequently interact with anaphora resolution (Nunberg, 1995; Markert and Hahn, 2002), as in Example 1 where the metonymic use of *Canada* is referred to by a plural pronoun afterward (*their*).

Metonymies can be quite regular: company names can be used for their management or their products, country names can be used for associated sports teams. Following from this, the currently

prevalent set-up for metonymy resolution — as in the SemEval 2007 task — provides a manually compiled list of frequent readings or metonymic patterns such as *organization-for-product* for pre-specified semantic classes (such as organizations) as well as annotated examples for these patterns so that systems can then treat metonymy resolution as a (supervised) word sense disambiguation task. However, this approach needs novel, manual provision of readings as well as annotated examples for each new semantic class.

In contrast, we will see readings as relations between the potentially metonymic word (PMW) and other concepts in a large concept network, a priori allowing all possible relations as readings. We base this approach on the observation that metonymic words stand in for concepts that they are related with – e.g. the part for the whole, the company for the product. These readings are obtained on the fly and are therefore independent of manually provided, preclassified interpretations or semantic classes, leading eventually to the possibility of unsupervised metonymy resolution. We achieve this by first linking a PMW to an article in Wikipedia. Then we extract from a large concept network derived from Wikipedia the relations surrounding the PMW.

As there will be (many) more than one such relation, these need to be ranked or scored. We achieve this in a probabilistic framework where we condition the probability of a relation on the context of the PMW. This ranking showcases our second major innovation in that the flexibility of our framework allows us to incorporate a wider context than in most prior approaches. Let us consider the indications for metonymic readings and its interpretation in Example 1, on the one hand, and Example 2, on the other hand. In Example 1, the grammatical relation to the verb *defeat* and the verb’s selectional preferences indicate the metonymy. We will call all such grammatically related words and the grammatical relations *the local context* of the PMW. Such types of local context have been used by most prior approaches (Pustejovsky, 1991; Hobbs et al., 1993; Fass, 1991; Nastase and Strube, 2009, among others). However, Example 2 shows that the local context can be ambiguous or often weak, such as the verb *to be*. In these examples, the wider context (*database, key-*

*word*) is a better indication for a metonymy but has not been satisfactorily integrated in prior approaches (see Section 2). We here call all words surrounding the PMW but not grammatically related to it *the global context*.

In our approach we integrate both the local and the global context in our probabilistic framework. For the local context, we compute the selectional preferences for the words related to the PMW from a corpus of English Wikipedia articles and generalize them in the Wikipedia concept network, thus (automatically) providing a set of *abstractions* – general concepts in the network that capture the semantic classes required by the local context. In the next step we compute probabilities of the global context surrounding the PMWs under each (locally required) abstraction, and combine this with the selectional preferences of the grammatically related words. That we can integrate local and global context in one probabilistic but also knowledge-based framework is possible because we combine two descriptions of meaning – ontological and distributional – by exploiting different sources of information in Wikipedia (category-article hierarchy and article texts).

We compute the probabilities of the relations (= readings) between the concept corresponding to the PMW and its directly related concepts. These can be used either (i) as additional features in a supervised approach or (ii) directly for unsupervised resolution. We do both in this paper and show that (i) the supervised approach using both local and global context can outperform one using just local context, dependent on the semantic class studied and (ii) that an unsupervised approach — although lower than the supervised one — outperforms the supervised most frequent reading baseline and performs close to a standard supervised model with the basic set of lexico-syntactic features (Nissim and Markert, 2005).

## 2 Related Work

The word sense disambiguation setting for metonymy resolution as developed by Nissim and Markert (2005) and used for the SemEval 2007 task (Markert and Nissim, 2009) uses a small, pre-specified number of frequently occurring readings.

The approaches building on this work (Farkas et al., 2007; Nicolae et al., 2007, among others) are supervised, mostly using shallow surface features as well as grammatical relations.<sup>1</sup> Most effective in the SemEval task as summarized in Markert and Nissim (2009) has been the local, grammatical context, with the two systems relying on the global context or the local/global context in a BOW model (Leveling, 2007; Poibeau, 2007) not outperforming the most frequent reading baseline. We believe that might be due to the lack of a link between the local and global context in these approaches — in our work, we condition the global context on the abstractions and selectional preferences yielded by the local context and achieve better results.

Lapata (2003), Shutova (2009) as well as Roberts and Harabagiu (2011) deal with the issue of logical metonymy, where the participant stands in for the full event: e.g. *Mary enjoyed the book.*, where *book* stands in for *reading the book*, and this missing event (*reading*) can be inferred from a corpus. Utiyama et al. (2000), Lapata (2003) propose a probabilistic model for finding the correct interpretation of such metonymies in an unsupervised manner. However, these event type metonymies differ from the problem dealt with in our paper and the SemEval 2007 task in that their recognition (i.e. their distinction from literal occurrences) is achieved simply by grammatical patterns (a noun instead of a gerund or to-infinitive following the verb) and the problem is limited to interpretation.

Our view of relations in a concept network being the interpretations of metonymies is strongly reminiscent of older work in metonymy resolution such as Hobbs et al. (1993), Fass (1991), Markert and Hahn (2002) or the use of a generative lexicon and its relations in Pustejovsky (1991), which also are unsupervised. However, these approaches lacked scalability due to the use of small hand-modeled knowledge bases which our use of a very large Wikipedia-derived ontology overcomes. In addition, most of these approaches (Fass, 1991; Hobbs et al., 1993; Pustejovsky, 1991; Harabagiu, 1998) rely on the view that metonymies violate selectional restrictions in their immediate, local context, usually those

<sup>1</sup>Brun et al. (2007) is semi-supervised but again relies on the local grammatical context.

imposed by the verbs on their arguments. As can be seen in the Example 2, this misses metonymies which do not violate selectional restrictions. Nastase and Strube (2009) use more flexible probabilistic selectional preferences instead of strict constraint violations as well as WordNet as a larger taxonomy but are also restricted to the local context. Markert and Hahn (2002) do propose a treatment of metonymies that takes into account the larger discourse in the form of anaphoric relations between a metonymy and the prior context. However, they constrain discourse integration to potential PMWs that are definite NPs and the context to few previous noun phrases. In addition, their framework uses a strict rule-based ranking of competing readings that cannot be easily extended.

The work presented here also relies on a concept network, built automatically from Wikipedia. This resource provides us with links between entities in the text, and also a variety of ontological relations for the PMW, that will allow us to identify a wide variety of metonymic interpretations. Our approach combines information from the concept network with automatically acquired selectional preferences as well as a possibility to combine in a probabilistic framework the influence of the local and global context on the interpretation of a potentially metonymic word.

### 3 The Approach

The approach we present takes into account both the local, grammatical, context and the larger textual context of a potentially metonymic word. Figure 1 presents a graphical representation of our approach.

On the one hand, the word/term to be interpreted (the potentially metonymic word/term – PMW) is mapped onto a concept in the concept network (Section 3.3), which gives us access to the conceptual relations ( $\mathcal{R}_i$ ) between the PMW and other concepts ( $c_x \in C_{\mathcal{R}_i}$ ). On the other hand, any word  $w$  grammatically related to the PMW via a grammatical relation  $r$  provides us with semantic restrictions on the interpretation of the PMW, namely preferred semantic classes  $A_j$  (we call them *abstractions*) and a selectional preference score.<sup>2</sup> These are automatically

<sup>2</sup>We restrict the grammatical context that provides selectional preferences to verbs or adjectives grammatically related

Figure 1: Metonymy resolution using selectional preferences  $A_j$  derived from local context  $w$  and  $r$ , semantic relations  $\mathcal{R}_i$  to the PMW from a concept network, and the global context surrounding a term to be interpreted

acquired by using a corpus of Wikipedia articles and a repository of encyclopedic knowledge (presented in Section 3.1), as described in detail in 3.2. Because the abstractions  $A_j$  and the PMW’s related concepts ( $c_x$ ) come from the same structured resource, we can compute the probabilities for each  $\mathcal{R}_i$  given the grammatically related word  $w$  and the grammatical relation  $r$ . The global context can also easily be added to the computation, as the probability of each word in the context relative to an abstraction  $A_j$  can be computed through the resource’s *is\_a* hierarchy and its link to Wikipedia articles. This is detailed in Section 3.4.

### 3.1 A concept network obtained from Wikipedia

We use a Wikipedia article dump (January 2011) which provided over 3.5 million English articles, interconnected through a hierarchy of categories and hyperlinks. This partly structured repository is transformed into a large-scale multilingual concept network, whose nodes are concepts corresponding to articles or categories in Wikipedia (Nastase et al., 2010). Concepts in this network are connected through a variety of semantic relations (e.g. *is a*, *member of*, *nationality*) derived from category names and infoboxes. The version of WikiNet used

had 3,707,718 nodes and 49,931,266 relation instances of 494 types, and is freely available<sup>3</sup>.

WikiNet is used here as a concept inventory, and its links and structure to generalize more specific concepts identified in texts to general concepts. The fact that nodes in WikiNet correspond to articles/categories in Wikipedia is used to link article texts in Wikipedia to general concepts, for the purpose of computing various probability scores (detailed in Section 3.4).

### 3.2 Selectional preferences and abstractions

To compute selectional preferences we use the set of English Wikipedia articles, which describe specific concepts. Wikipedia contributors are encouraged to insert hyperlinks, which link important terms in an article to the corresponding articles. A hyperlink consists of two parts, the actual link (i.e. a URL) and a phrase to appear in the text. Hyperlinks then constitute a bridge from the textual level to the conceptual level without the need for word sense disambiguation. We exploit these links to gather concept arguments for verbs and adjectives, and generalize these using the concept network built from Wikipedia.

The corpus of Wikipedia articles was first enriched with hyperlinks, making the “one sense per

to the PMW.

**Algorithm 2** MDL( $\Gamma, S$ )

---

**Input:**  $\Gamma = \{(c, f)\}$  – a scored list of concepts  
 $S$  – the set of observations (concept collocates)

**Output:** MDL( $\Gamma, S$ )

```
 $\hat{\theta} = \langle f_1, \dots, f_n \rangle; (c_i, f_i) \in \Gamma$ 
remove  $\{(c, f) \in \Gamma | f = 1\}$  // parameter description length :
 $L(\hat{\theta} | \Gamma) = \frac{|\Gamma|-1}{2} * \log(|S|)$  // data description length :
for all  $(c, f) \in \Gamma$  do
   $L(S | \Gamma, \hat{\theta}) = L(S | \Gamma, \hat{\theta}) + f * \log(\frac{f}{hyponyms(c)*|\Gamma|})$ 
return  $L(\hat{\theta} | \Gamma) - L(S | \Gamma, \hat{\theta})$ 
```

---

---

**Algorithm 3** abstract( $S, WkN$ )

---

**Input:**  $S = \{(c, f) | (w, \mathcal{R}, c) \in G\}$   
WkN – WikiNet

**Output:**  $S'$

```
 $S' = \{\}$ 
for  $c | (c, \_) \in S$  do
  while  $c$  has only one is_a link do
     $c = c', (c, is\_a, c') \in WkN$ 
     $C = \{(c', c) | (c, is\_a, c') \in WkN\}$ 
    for  $(c', c) \in C$  do
      if  $(c', f') \in S'$  then
        replace  $(c', f')$  with  $(c', f' + \frac{f}{|C|})$ ,  $(c, f) \in S$ 
        in  $S'$ 
      else
         $S' \cup = \{(c', f)\}, (c, f) \in S$ 
// Remove hyponyms.
for all  $\{(c, c') \in S' | (c', is\_a, c) \in WkN\}$  do
  // update frequency  $f$  of  $c$ 
   $f_c = f_c + f_{c'}, f \in S$ 
  delete  $c'$ 
return  $S'$ 
```

---

discourse” assumption – a phrase that appears associated with a hyperlink once in the article body will be associated with the same hyperlink throughout the article (this applies to the article title as well, which is not hyperlinked in the article itself). This new version of the corpus was then split into sentences, and those without hyperlinks were removed. The remaining 18 million sentences were parsed with a parallelized version of Ensemble<sup>4</sup> (Surdeanu and Manning, 2010), and we extracted  $G$ , the set of all grammatical relations of the type (*verb, dependency, hyperlink*) and (*adjective, dependency, hyperlink*), with the hyperlinks resolved to their corresponding node (concept) in the network ( $|G| = 1,578,413$  triples). For each verb and adjective in the extracted collocations, and for each of their dependency relations, their collocates were generalized in the network defined by the hypernym/hyponym relations in WikiNet following a method similar to the Minimum Description Length principle (Li and Abe, 1998).

Essentially, we aimed to determine a small set of (more general) concepts that describe the set of collocates for a word  $w$  and grammatical relation  $r$ . Starting from the concept collocates gathered, we go upwards following WikiNet’s *is\_a* links, and for each node found that covers at least  $N$  concept collocates ( $N$  is a parameter,  $N=2$  in the experiments presented here), the MDL score of the node is computed (Algorithm 2). We place a limit  $M$  on the number of upward steps in the hierarchy ( $M=3$  in our experiments). The disjoint set of nodes that has the lowest overall MDL score is chosen ( $\Gamma$ ), and for each node in this cut (which we call *abstraction*), we compute the selectional preference score, based on the number of concepts it dominates.

As an example, for the verb *defeat*, the corpus leads to collocations such as<sup>5</sup>:

**defeat**

*nsubj*

Earle Page (10357) – 8, Manuela Maleeva (1092361) – 7, New York Yankees (10128601) – 5, Tommy Haas (1118005) – 5, ...

*obj*

---

<sup>4</sup><http://www.surdeanu.name/mihai/ensemble/>

<sup>5</sup>The format is:  
Article name (Article Id) – frequency.

New York Yankees (10128601) – 9, Oakland Athletics (11641124) – 6, Phoenix Suns (11309373) – 4, Jason Suttie (10080653) – 3, Ravana (100234) – 3, ...

Determining abstractions and selectional preferences leads to the following information<sup>6</sup>:

**defeat**

*nsubj*  
 Martial artists (118977183) – 0.5, Person (219599) – 0.3518, Interest (146738) – 0.037, ...

*obj*  
 Video games (9570081) – 0.25, British games (24489088) – 0.25, Person (219599) – 0.1445, Interest (146738) – 0.1341, ...

**3.3 Linking the PMW to the concept network**

In our environment, linking the PMW to the concept network is equivalent to finding its corresponding concept in our ontology, WikiNet. We see this corresponding concept as the literal reading of the PMW. Doing so is a non-trivial task (see the Cross-Lingual Link Discovery task at NTCIR-9 (Tang et al., 2011) and the Cross-Lingual Entity Linking task – part of the Knowledge Base Population track – at TAC 2011<sup>7</sup>). In our particular setting, where we use the metonymy data from SemEval 2007, the domain of the PMW is well defined: locations and companies, respectively. Using these constraints, finding the corresponding Wikipedia articles is much simplified, by using the category hierarchy and constraining the concepts to fall under the *Geography* and *Companies* categories respectively. When multiple options are present, we find instead a matching disambiguation page. In this case we pick the article that is listed first on this disambiguation page. On a manually checked random sample, the accuracy of the approach was 100% (on a sample of 100 PMWs).

**3.4 Scoring conceptual relations with local and global context**

We work under the assumption that the concept corresponding to the PMW is related to the possible interpretations through a semantic relation, in particular one that is captured in the concept network. After

<sup>6</sup>The format is:

Concept name (Concept Id) – selectional preference score.

<sup>7</sup><http://nlp.cs.gc.cuny.edu/kbp/2011/>

countries	: Administrator_of,	Architect_of,
	Based_in,	Built_in,
	Continent,	...
companies	: Association,	Brand,
	Company,	Distributed_by,
	Executive_of,	...

Table 1: Example conceptual relations

establishing the connection to the resource by linking the PMW to the concept  $c_{PMW}$  corresponding to its literal interpretation (see Section 3.3), we extract the relations in which it is involved ( $\mathcal{R}_i, i = 1, k$ ), and the concepts it is connected to through these relations ( $\mathcal{C}_{\mathcal{R}_i} = \{c_x | (c_{PMW} \mathcal{R}_i c_x)\}$ ). Table 1 shows examples of conceptual relations extracted for companies and countries.

We are interested in computing the likelihood of a conceptual relation being the correct interpretation of a PMW, given its local and global context  $p(\mathcal{R}_i | Cont, w, r)$ .

**3.4.1 The local context**

The local context considered in this work are all grammatically related verbs and adjectives  $w$  and their associated grammatical relation  $r$ . The grammatical analysis (see Section 3.2) provides the set of abstractions corresponding to the grammatically related word  $w$  and grammatical relation  $r$ :  $A_j, j = 1, n$ . Remember that these are local context constraints on the interpretation of the PMW.

Through the knowledge resource used we can establish and quantify connections between each  $c_x$  and  $A_j$ , and thus between each  $\mathcal{R}_i$  and  $A_j$ :

$$(3) \quad p(\mathcal{R}_i | A_j) = \sum_{x \in \mathcal{C}_{\mathcal{R}_i}} p(c_x | A_j)$$

where  $p(c_x | A_j)$  is the probability of concept  $c_x$  under abstraction  $A_j$ , which is computed based on the semantic relations in WikiNet:

$$p(c_x | A_j) = \sum_H \prod_{h_i \in H} p(h_i | h_{i+1})$$

where  $H$  is in turn each path from  $c_x$  to  $A_j$  following *is-a* links in WikiNet, starting with  $c_x$  (i.e.  $h_0 = c_x$ ) and ending in  $A_j$ .  $p(h_i | h_{i+1})$  is the probability of the child node  $h_i$  given its ancestor  $h_{i+1}$ . Within this work we assume a uniform probability distribution in each node:

$$p(h_i|h_{i+1}) = \frac{1}{|\text{descendants}(h_{i+1})|}$$

Through this, it is straightforward that  $\sum_{c_x} p(c_x|A_j) = 1$  when  $c_x$  ranges over all concepts subsumed by  $A_j$ , and is thus a valid probability distribution.

### 3.4.2 The global context

The abstractions obtained before are concepts. We extract all nodes in the network subsumed by these concepts, and their corresponding articles in Wikipedia (if they have one). This produces “abstraction-specific” article sets, based on which we compute the probability of the global context of a PMW for each abstraction. We are interested in the probability of an abstraction, given the context and the word  $w$  and grammatical relation  $r$ , which we compute as:

$$p(A_j|Cont, w, r) = \frac{p(Cont|A_j, w, r) * p(A_j, w, r)}{p(Cont, w, r)}$$

which, considering that  $p(Cont, w, r)$  is the same for a given context, we approximate as

$$p(A_j|Cont) \approx p(Cont|A_j) * p(A_j, w, r)$$

$p(A_j, w, r) = p(A_j|w, r) * p(w, r)$ , and we approximate it through the computed selectional preference  $p(A_j|w, r)$ , since  $p(w, r)$  is constant for a given example to analyze.

$$\begin{aligned} p(Cont|A_j, w, r) &= \sum_{j=1}^n p(Cont|A_j) p(A_j|w, r) \\ &= \sum_{j=1}^n \left( \prod_{l=1}^m p(w_l|A_j) \right) p(A_j|w, r) \end{aligned}$$

where  $Cont$  is the global context consisting of  $m$  words  $w_l, l = 1, m$ .<sup>8</sup>

<sup>8</sup>The global context therefore could be all words in a text or all words in a sentence or any other token-based definition in our framework. As the SemEval 2007 data gives metonymic examples in a three-sentence context we use all the words in the 3 sentences as our global context.

$$p(w_l|A_j) = \frac{\text{count}(w_l, A_j)}{|A_j|}$$

where  $A_j$  is the set of articles subsumed by abstraction  $A_j$ , and  $\text{count}(w_l, A_j)$  is the number of times word  $w_l$  appears in the article collection  $A_j$ .

### 3.4.3 Putting it all together

This enables us now to compute  $p(\mathcal{R}_i|Cont, w, r)$  based on the formulas 3, 4:

$$p(\mathcal{R}_i|Cont, w, r) = \sum_{j=1}^n (p(\mathcal{R}_i|A_j) * p(A_j|Cont, w, r))$$

## 4 Experiments

The computed probabilities for each conceptual relation (= potential readings) of the PMW in the concept network can be used as features in a supervised framework or directly as an unsupervised prediction, returning the most likely conceptual relation given the context as the required reading.

Although the latter is our ultimate goal, to allow comparison with related work from the metonymy resolution task (Task 8) at SemEval 2007, we first investigate the supervised set-up. We then simulate the unsupervised setting in Section 4.3.

### 4.1 Data

We use the data from the metonymy resolution task (Task 8) at SemEval 2007. It consists of training and test data for country and company names which are potentially metonymic. Table 2 shows the statistics of the data, and the possible interpretations for the PMWs. The training-test division was achieved randomly so that the test data can have metonymic readings for which no training data exists, showing again the limitations of a supervised approach of prespecified readings.

**Grammatical features** The features used by Nissim and Markert (2005), and commonly used for the supervised classification of metonymy readings (Markert and Nissim, 2009):

- grammatical role of PMW (subj, obj, ...);
- lemmatized head/modifier of PMW (announce, say, ...);

reading	train	test
locations	925	908
literal	737	721
mixed	15	20
othermet	9	11
obj-for-name	0	4
obj-for-representation	0	0
place-for-people	161	141
place-for-event	3	10
place-for-product	0	1
organizations	1090	842
literal	690	520
mixed	59	60
othermet	14	8
obj-for-name	8	6
obj-for-representation	1	0
org-for-members	220	161
org-for-event	2	1
org-for-product	74	67
org-for-facility	15	16
org-for-index	7	3

Table 2: Statistics for the Task 8 data

- determiner of PMW (def, indef, bare, demonst, other, ...);
- grammatical number of PMW (sg, pl);
- number of grammatical roles in which the PMW appears in its current context;
- number of words in PMW.

All these features can be extracted from the grammatically annotated and POS tagged data provided by the organizers.

The annotations provided are dependency relations, many of which contain a preposition as an argument (e.g. (to, *pp*, UK) from the example ... *the visit to the UK of ...*). Such relations are not informative, but together with the head that dominates the prepositional complement (e.g. *visit to*) they may be. Because of this, we process the provided annotations and add wherever possible to the simple prepositions the head of their subsuming constituent. This would change the above mentioned dependency to (visit, *prep-to*, UK).

**Semantic relations as features** To evaluate the proposed approach we use the PMW’s conceptual relations as features. The feature values are the  $p(\mathcal{R}_i|Cont, w, r)$  scores.

For the “countries” portion of the data this adds 109 semantic relation features, and for companies 29 features. Table 1 showed examples of these new features.

## 4.2 Supervised learning

We use the SMO classifier in the WEKA machine learning toolkit (Witten and Frank, 2000) with its standard settings, training on the SemEval 2007 (Task 8) training set.

Table 3 shows the results of various configurations on the test data, in comparison with a most frequent reading baseline (assigning literal to all PMWs) as well as a system M&N that shows the results computed using only the features proposed by Nissim and Markert (2005). In addition, we compare to the best results<sup>9</sup> at SemEval 2007 ( $SE_{max}$ ) and Nastase and Strube (2009) (N09). Nastase and Strube (2009) added WordNet supersenses as features, and their values are selectional preferences computed with reference to WordNet. These are similar to our abstractions, which in our approach serve to link the local and the global context to the ontological relations, but do not appear as features.

Our system  $SP$  shows the results obtained using the M&N features plus the conceptual relation features conditioned on both local and global context whereas  $SP_{local}$  and  $SP_{global}$  use conceptual relations conditioned on local ( $p(A_j|Cont, w, r) \approx p(A_j|w, r)$ ) or global context ( $p(A_j|Cont, w, r) \approx p(A_j|Cont) = \sum_{j=1}^n (\prod_{l=1}^m p(w_l|A_j))$ ) only.

While the differences in overall accuracies are small, there are significant differences in classifying individual classes, as shown in Tables 4 – 5<sup>10</sup>, where the *distrib.* column shows the class distribution in the test data. It is interesting to note that, in our setting, the global context is more useful than the local

<sup>9</sup>We show the best result for each category, not necessarily from the overall best performing system. This holds for Tables 4 and 5 as well.

<sup>10</sup>The detailed results for previous approaches are reproduced from (Nastase and Strube, 2009). We include only the classes that have a non-zero F-score for at least one of the presented approaches.

Table 4: Fine-grained results for each classification task for countries (F-scores)

Table 5: Fine-grained results for each classification task for companies (F-scores)

one for resolving metonymies. Combining local and global evidence improves over both, indicating that the information they provide is not redundant.

For companies the difference is small in terms of accuracy, but in classification of individual classes the difference in performance is higher, but because of the small data size not statistically significant.

Countries in WikiNet have a high number of surrounding relations, because they are used as categorization criteria for professionals, for example, which generates fine-grained relations such as *Administrator\_of*, *Ambassador\_of*, *Chemist\_of*.... Such a fine grained distinction between different professions for people in a country is not necessary, or indeed, desirable, for the metonymy resolution task. The results show that despite this shortcoming, the results are on par with the state-of-the-art, but in future work we plan to explore the task of relation generalization and its impact on the current task.

### 4.3 Simulating unsupervised metonymy resolution

In an unsupervised metonymy resolution approach, we would assign as interpretation the conceptual relation whose probability given the PMW, global and local contexts is highest. To simulate then the unsupervised metonymy resolution task, we make the relation features (used in the supervised approach) binary, where for each instance the relation that has highest probability has the value 1, the others 0.

Using only the relation features simulates an unsupervised approach – this set-up learns a mapping between the relations used as features and the metonymy classes in the data used. Column  $SP_{Unsup}$  in Table 3 shows the results obtained in this configuration. As expected the results are lower, but still close to the supervised method when using only grammatical features (M&N) for the location

setting. The results also significantly beat the baseline (apart from the Location-Fine setting). One feature that contributes greatly to the results, especially for the company semantic class, is the grammatical role of the PMW, but we could not incorporate this in the unsupervised setting.

The results in the simulated unsupervised setting indicate that relations are a viable substitute for manually provided classes in an unsupervised framework, while leaving space for improvement.

## 5 Conclusion

We have explored the usage of local and global context for the task of metonymy resolution in a probabilistic framework. The global context has been rarely used for the task of determining the intended reading of a potentially metonymic word (PMW) in context. We rely on automatically computed selectional preferences, extracted from a corpus of Wikipedia articles, and generalized based on a concept network also extracted from Wikipedia. Despite relying on automatically derived resources, the presented approach produces results on-a-par with current state-of-the-art systems. The method described here is also a step towards the unsupervised resolution of metonymic words in context, by taking into account knowledge about the concept corresponding to the literal interpretation of the PMW, and its relations to other concepts. This framework would also allow for exploring the metonymy resolution phenomena in various languages (since Wikipedia and WikiNet are multilingual), and investigate whether the same relations apply or different languages have different metonymic patterns.

## Abstract

Learning inference relations between verbs is at the heart of many semantic applications. However, most prior work on learning such rules focused on a rather narrow set of information sources: mainly distributional similarity, and to a lesser extent manually constructed verb co-occurrence patterns. In this paper, we claim that it is imperative to utilize information from various textual scopes: verb co-occurrence within a sentence, verb co-occurrence within a document, as well as overall corpus statistics. To this end, we propose a much richer novel set of linguistically motivated cues for detecting entailment between verbs and combine them as features in a supervised classification framework. We empirically demonstrate that our model significantly outperforms previous methods and that information from each textual scope contributes to the verb entailment learning task.

## 1 Introduction

Inference rules are an important building block of many semantic applications, such as Question Answering (Ravichandran and Hovy, 2002) and Information Extraction (Shinyama and Sekine, 2006). For example, given the sentence “*Churros are coated with sugar*”, one can use the rule ‘coat → cover’ to answer the question “*What are Churros covered with?*”. Inference rules specify a directional inference relation between two text fragments, and we follow the *Textual Entailment* modeling of inference (Dagan et al., 2006), which refers to such rules as *entailment rules*. In this work we focus on one

of the most important rule types, namely, lexical entailment rules between verbs (*verb entailment*), e.g., ‘whisper → talk’, ‘win → play’ and ‘buy → own’. The significance of such rules has led to active research in automatic learning of entailment rules between verbs or verb-like structures (Zanzotto et al., 2006; Abe et al., 2008; Schoenmackers et al., 2010).

Most prior efforts to learn verb entailment rules from large corpora employed distributional similarity methods, assuming that verbs are semantically similar if they occur in similar contexts (Lin, 1998; Berant et al., 2012). This led to the automatic acquisition of large scale knowledge bases, but with limited precision. Fewer works, such as *VerbOcean* (Chklovski and Pantel, 2004), focused on identifying verb entailment through verb instantiation of manually constructed patterns. For example, the sentence “*he scared and even startled me*” implies that ‘startle → scare’. This led to more precise rule extraction, but with poor coverage since contrary to nouns, in which patterns are common (Hearst, 1992), verbs do not co-occur often within rigid patterns. However, verbs do tend to co-occur in the same document, and also in different clauses of the same sentence.

In this paper, we claim that on top of standard pattern-based and distributional similarity methods, corpus-based learning of verb entailment can greatly benefit from exploiting additional linguistically-motivated cues that are specific to verbs. For instance, when verbs co-occur in different clauses of the same sentence, the syntactic relation between the clauses can be viewed as a proxy for the semantic relation between the verbs. Moreover, we claim that to

improve performance it is crucial to combine information sources from different textual scopes: verb co-occurrence within a sentence and within a document, distributional similarity over the entire corpus, etc.

Our contribution in this paper is two-fold. First, we suggest a novel set of entailment *indicators* that help to detect the likelihood of verb entailment. Our novel indicators are specific to verbs and are linguistically-motivated. Second, we encode our novel indicators as features within a supervised classification framework and integrate them with other standard features adapted from prior work. This results in a supervised corpus-based learning method that combines verb entailment information at the sentence, document and corpus levels.

We test our model on a manually labeled data set, and show that it outperforms the best performing previous work by 24%. In addition, we examine the effectiveness of indicators that operate at the sentence-level, document-level and corpus-level. This analysis reveals that using a rich and diverse set of indicators that capture sentence-level interactions between verbs substantially improves verb entailment detection.

## 2 Background

The main approach for learning entailment rules between verbs and verb-like structures has employed the *distributional hypothesis*, which assumes that words with similar meanings appear in similar contexts. For example, we expect the words *‘buy’* and *‘purchase’* to occur with similar subjects and objects in a large corpus. This observation has led to ample work on developing both symmetric and directional similarity measures that attempt to capture semantic relations between lexical items by comparing their neighborhood context (Lin, 1998; Weeds and Weir, 2003; Geffet and Dagan, 2005; Szpektor and Dagan, 2008; Kotlerman et al., 2010).

A far less explored direction for learning verb entailment involves exploiting verb co-occurrence in a sentence or a document. One prominent work is Chklovsky and Pantel’s VerbOcean (2004). In VerbOcean, the authors manually constructed 33 patterns and divided them into five pattern groups, where each group signals one of the following five

semantic relations: *similarity*, *strength*, *antonymy*, *enablement* and *happens-before*. For example, the pattern *‘Xed and later Yed’* signals the *happens-before* relation between the verbs *‘X’* and *‘Y’*. Starting with candidate verb pairs based on a distributional similarity measure, the patterns are used to choose a semantic relation per verb pair based on the different patterns this pair instantiates. This method is more precise than distributional similarity approaches, but it is highly susceptible to sparseness issues, since verbs do not typically co-occur within rigid patterns. Utilizing verb co-occurrence at the document level, Chambers and Jurafsky (2008) estimate whether a pair of verbs is narratively related by counting the number of times the verbs share an argument in the same document. In a similar manner, Pekar (2008) detects entailment rules between templates from shared arguments within discourse-related clauses in the same document.

Recently, supervised classification has become standard in performing various semantic tasks. Mirkin et al. (2006) introduced a system for learning entailment rules between nouns (*e.g.*, *‘novel → book’*) that combines distributional similarity and Hearst patterns as features in a supervised classifier. Pennacchiotti and Pantel (2009) augment Mirkin et al’s features with web-based features for the task of entity extraction. Hagiwara et al. (2009) perform synonym identification based on both distributional and contextual features. Tremper (2010) extract “loose” sentence-level features in order to identify the *presupposition* relation (*e.g.*, the verb *‘win’* presupposes the verb *‘play’*). Last, Berant et al. (2012) utilized various distributional similarity features to identify entailment between lexical-syntactic predicates.

In this paper, we follow the supervised approach for semantic relation detection in order to identify verb entailment. While we utilize and adapt useful features from prior work, we introduce a diverse set of novel features for the task, effectively combining verb co-occurrence information at the sentence, document, and corpus levels.

## 3 Linguistically-Motivated Indicators

As mentioned in Section 1, verbs behave quite differently from nouns in corpora. In this section, we

introduce linguistically motivated indicators that are specific to verbs and may signal the semantic relation between verb pairs. Then, in Section 4 we describe how these indicators are exactly encoded as features within a supervised classification framework.

**Verb co-occurrence** When (non-auxiliary) verbs co-occur in a sentence, they are often the main verbs of different clauses. We thus aim to use information about the relation between clauses to learn about the relation between the clauses' main verbs. *Discourse markers* (Hobbs, 1979; Schiffrin, 1988) are lexical terms such as *'because'* and *'however'* that indicate a semantic relation between discourse fragments (i.e., propositions or speech acts). We suggest that these markers can indicate semantic relations between the main verbs of the connected clauses. For example, in the sentence *"He always snores while he sleeps"*, the marker *'while'* indicates a temporal relation between the clauses, indicating that *'snoring'* occurs while *'sleeping'* (and so *'snore* → *'sleep'*).

Often the relation between clauses is not expressed explicitly with an overt discourse marker, but is still implied by the syntactic structure of the sentence. For example, in dependency parsing the relation can be captured by labeled dependency edges expressing that one clause is an adverbial adjunct of the other, or that two clauses are coordinated. This can indicate the existence (or lack) of entailment between verbs. For instance, in the sentence *"When I walked into the room, he was working out"*, the verb *'walk'* is an adverbial adjunct of the verb *'work out'*. Such co-occurrence structure does not indicate a deep semantic relation, such as entailment, between the two verbs.

**Verb classes** Verb classes are sets of semantically-related verbs sharing some linguistic properties (Levin, 1993). One of the most general verb classes are stative vs. event verbs (Jackendoff, 1983). Stative verb, such as *'love'* and *'think'*, usually describe a state that lasts some time. On the other hand, event verbs, such as *'run'* and *'kiss'*, describe an action. We hypothesize that verb classes are relevant for determining entailment, for example, that stative verbs are not likely to entail event verbs.

**Verb generality** Verb-particle constructions are multi-word expressions consisting of a head verb and a particle, e.g., *switch off* (Baldwin and Villavicencio, 2002). We conjecture that the more general a verb is, the more likely it is to appear with many different particles. Detecting verb generality can help us tackle an infamous property of distributional similarity methods, namely, the difficulty in detecting the direction of entailment (Berant et al., 2012). For example, the verb *'cover'* appears with many different particles such as *'up'* and *'for'*, while the verb *'coat'* does not. Thus, assuming we have evidence for an entailment relation between the two verbs, this indicator can help us discern the direction of entailment and determine that *'coat* → *'cover'*.

**Typed Distributional Similarity** As discussed in section 2, distributional similarity is the most common source of information for learning semantic relations between verbs. Yet, we suggest that on top of standard distributional similarity measures, which take several verbal arguments into account (such as subject, object, etc.) simultaneously, we should also focus on each type of argument independently. In particular, we apply this approach to compute similarity between verbs based on the set of adverbs that modify them. Our hypothesis is that adverbs may contain relevant information for capturing the direction of entailment. If a verb appears with a small set of adverbs, it is more likely to be a specific verb that already conveys a specific action or state, making an additional adverb redundant. For example, the verb *'whisper'* conveys a specific manner of talking and will probably not appear with the adverb *'loudly'*, while the verb *'talk'* is more likely to appear with such an adverb. Thus, measuring similarity based solely on adverb modifiers could reveal this phenomenon.

## 4 Supervised Entailment Detection

In the previous section, we discussed linguistic observations regarding novel indicators that may help in detecting entailment relations between verbs. We next describe how to incorporate these indicators as features within a supervised framework for learning lexical entailment rules between verbs. We follow prior work on supervised lexical semantics (Mirkin et al., 2006; Hagiwara et al., 2009; Tremper, 2010)

and address the rule learning task as a classification task. Specifically, given an ordered verb pair  $(v_1, v_2)$  as input, we learn a classifier that detects whether the entailment relation ' $v_1 \rightarrow v_2$ ' holds for this pair.

We next detail how our novel indicators, as well as other diverse sources of information found useful in prior work, are encoded as features. Then, we describe the learning model and our feature analysis procedure.

#### 4.1 Entailment features

Most of our features are based on information extracted from the target verb pair co-occurring within varying textual scopes (sentence, document, corpus). Hence, we group the features according to their related scope. Naturally, when the scope is small, *i.e.*, at a sentence level, the semantic relation between the verbs is easier to discern but the information may be sparse. Conversely, when co-occurrence is loose the relation is harder to discern but coverage is increased.

##### 4.1.1 Sentence-level co-occurrence

We next detail features that address co-occurrence of the target verb pair within a sentence. These include our novel linguistically-motivated indicators, as well as features that were adapted from prior work.

**Discourse markers** As discussed in Section 3, discourse markers may signal relations between the main verbs of adjacent clauses. The literature is abundant with taxonomies that classify markers to various discourse relations (Mann and Thompson, 1988; Hovy and Maier, 1993; Knott and Sanders, 1998). Inspired by Marcu and Echihiabi (2002), we employ markers that are mapped to four discourse relations '*Contrast*', '*Cause*', '*Condition*' and '*Temporal*', as specified in Table 1. This definition can be viewed as a relaxed version of VerbOcean's (Chklovski and Pantel, 2004) patterns, although the underlying intuition is different (see Section 3).

For a target verb pair  $(v_1, v_2)$  and each discourse relation  $r$ , we count the number of times that  $v_1$  is the main verb in the main clause,  $v_2$  is the main verb in the subordinate clause, and the clauses are connected via a marker mapped to  $r$ . For example, given the sentence "*You must enroll in the competition be-*

*fore you can participate in it*", the verb pair ('*enroll*', '*participate*') appears in the '*Temporal*' relation, indicated by the marker '*before*', where '*enroll*' is in the main clause. Each count is then normalized by the total number of times  $(v_1, v_2)$  appear with any marker. The same procedure is done when  $v_1$  is in the subordinate clause and  $v_2$  in the main clause. We term the features by the relevant discourse relation, *e.g.*, '*v1-contrast-v2*' refers to  $v_1$  being in the main clause and connected to the subordinate clause via a *contrast* marker.

**Dependency relations between clauses** As noted in Section 3, the syntactic structure of verb co-occurrence can indicate the existence or lack of entailment. In dependency parsing this may be expressed via the label of the dependency relation connecting the main and subordinate clauses. In our experiments we used the ukWaC corpus<sup>1</sup> (Baroni et al., 2009) which was parsed by the MALT parser (Nivre et al., 2006). Hence, we identified three MALT dependency relations that connect a main clause with its subordinate clause. The first relation is the object complement relation '*obj*'. In this case the subordinate clause is an object complement of the main clause. For example, in "*it surprised me that the lizard could talk*" the verb pair ('*surprise*', '*talk*') is connected by the '*obj*' relation. The second relation is the adverbial adjunct relation '*adv*', in which the subordinate clause is adverbial and describes the time, place, manner, etc. of the main clause, *e.g.*, "*he gave his consent without thinking about the repercussions*". The last relation is the coordination relation '*coord*', *e.g.*, "*every night my dog Lucky sleeps on the bed and my cat Flippers naps in the bathtub*".

Similar to discourse markers, we compute for each verb pair  $(v_1, v_2)$  and each dependency label  $d$  the proportion of times that  $v_1$  is the main verb of the main clause,  $v_2$  is the main verb of the subordinate clause, and the clauses are connected by dependency relation  $d$ , out of all the times they are connected by any dependency relation. We term the features by the dependency label, *e.g.*, '*v1-adv-v2*' refers to  $v_1$  being in the main clause and connected to the subordinate clause via an *adverbial* adjunct.

Discourse Rel.	Discourse Markers
Contrast	although , despite , but , whereas , notwithstanding , though
Cause	because , therefore , thus
Condition	if , unless
Temporal	whenever , after , before , until , when , finally , during , afterwards , meanwhile

Table 1: Discourse relations and their mapped markers.

**Pattern-based** We follow Chklovski and Pantel (2004) and extract occurrences of *VerbOcean* patterns that are instantiated by the target verb pair. As mentioned in Section 2, VerbOcean patterns were originally grouped into five semantic classes. Based on a preliminary study we conducted, we decided to utilize only four *strength*-class patterns as positive indicators for entailment, *e.g.*, “he *scared and even startled* me”, and three *antonym*-class patterns as negative indicators for entailment, *e.g.*, “you can *either open or close* the door”. We note that these patterns are also commonly used by RTE systems<sup>2</sup>.

Since the corpus pattern counts were very sparse, we defined for a target verb pair  $(v_1, v_2)$  two binary features: the first denotes whether the verb pair instantiates at least one positive pattern, and the second denotes whether the verb pair instantiates at least one negative pattern. For example, given the aforementioned sentences, the value of the positive feature for the verb pair (*startle*, *scare*) is ‘1’. Patterns are directional, and so the value of (*scare*, *startle*) is ‘0’.

**Polarity** We compute the proportion of times that the two verbs appear in different polarity. For example, in “he *didn’t say why he left*”, the verb *say* appears in negative polarity and the verb *leave* in positive polarity. Such change in polarity is usually an indicator of non-entailment between the two verbs.

**Tense ordering** The temporal relation between verbs may provide information about their semantic relation. For each verb pair co-occurrence, we extract the verbs’ tenses and order them as follows: *past* < *present* < *future*. We then add the features *tense-v1* < *tense-v2*, *tense-v1* = *tense-v2*, and *tense-v1* > *tense-v2*, corresponding to the propor-

tion of times the tense of  $v_1$  is smaller, equal to, or bigger than the tense of  $v_2$ . This indicates the prevalent temporal relation between the verbs in the corpus and may assist in detecting the direction of entailment. *e.g.*, if *tense-v1* > *tense-v2*, the verb pair is less likely to entail.

**Co-reference** Following Tremper (2010), in every co-occurrence of  $(v_1, v_2)$  we extract for each verb the set of arguments at either the subject or object positions, denoted  $A_1$  and  $A_2$  (for  $v_1$  and  $v_2$ , respectively). We then compute the proportion of co-occurrences in which  $v_1$  and  $v_2$  share an argument, *i.e.*,  $A_1 \cap A_2 \neq \phi$ , out of all the co-occurrences in which both  $A_1$  and  $A_2$  are non-empty. The intuition, which is similar to distributional similarity, is that semantically related verbs tend to share arguments.

**Syntactic and lexical distance** Following Tremper (2010) again, we compute the average distance  $d$  in dependency edges between the co-occurring verbs. We compute three features corresponding to three bins indicating if  $d < 3$ ,  $3 \leq d \leq 7$ , or  $d > 7$ . Similar features are computed for the distance in words (bins are  $0 < d < 5$ ,  $5 \leq d \leq 10$ ,  $d > 10$ ). This feature provides insight into the syntactic relatedness of the verbs.

**Sentence-level pmi** Pointwise mutual information (pmi) between  $v_1$  and  $v_2$  is computed, where the co-occurrence scope is a sentence. Higher pmi should hint at semantically related verbs.

#### 4.1.2 Document-level co-occurrence

This group of features addresses co-occurrence of a target verb pair within the same document. These features are less sparse, but tend to capture coarser semantic relations between the target verbs.

**Narrative score** Chambers and Jurafsky (2008) suggested a method for learning sequences of actions or events (expressed by verbs) in which a sin-

<sup>2</sup>[http://aclweb.org/aclwiki/index.php?title=RTE\\_Knowledge\\_Resources#Ablation\\_Tests](http://aclweb.org/aclwiki/index.php?title=RTE_Knowledge_Resources#Ablation_Tests)

gle entity is involved. They proposed a pmi-like *narrative score* (see Eq. (1) in their paper) that estimates whether a pair consisting of a verb and one of its dependency relations  $(v_1, r_1)$  is narratively-related to another such pair  $(v_2, r_2)$ . Their estimation is based on quantifying the likelihood that two verbs will share an argument that instantiates both the dependency position  $(v_1, r_1)$  and  $(v_2, r_2)$  within documents in which the two verbs co-occur. For example, given the document “*Lindsay was prosecuted for DUI. Lindsay was convicted of DUI.*” the pairs (*prosecute*, *subj*) and (*convict*, *subj*) share the argument *Lindsay* and are part of a narrative chain. Such narrative relations may provide cues to the semantic relatedness of the verb pair.

We compute for every target verb pair nine features using their narrative score. In four features,  $r_1 = r_2$  and the common dependency is either a subject, an object, a preposition complement (e.g., “we meet at the *station*.”), or an adverb (termed *chamb-subj*, *chamb-obj*, and so on). In the next three features,  $r_1 \neq r_2$  and  $r_1, r_2$  denote either a subject, object, or preposition complement<sup>3</sup> (termed *chamb-subj-obj* and so on). Last, we add as features the average of the four features where  $r_1 = r_2$  (termed *chamb-same*), and the average of the three features where  $r_1 \neq r_2$  (termed *chamb-diff*).

**Document-level pmi** Similar to sentence-level pmi, we compute the pmi between  $v_1$  and  $v_2$ , but this time the co-occurrence scope is a document.

#### 4.1.3 Corpus-level statistics

The final group of features ignores sentence or document boundaries and is based on overall corpus statistics.

**Distributional similarity** Following our hypothesis regarding typed distributional similarity (Section 3), we first compute for each verb and each argument (subject, object, preposition complement and adverb) a separate vector that counts the number of times each word in the corpus instantiates the argument of that verb. In addition, we also compute a vector that is the concatenation of the previous separate vectors, which captures the standard distributional similarity statistics. We then

<sup>3</sup>adverbs never instantiate the subject, object or preposition complement positions.

apply three state-of-the-art distributional similarity measures, *Lin* (Lin, 1998), *Weeds precision* (Weeds and Weir, 2003) and *Blnc* (Szpektor and Dagan, 2008), to compute for every verb pair a similarity score between each of the five count vectors<sup>4</sup>. We term each feature by the method and argument, e.g., *weeds-prep* and *lin-all* represent the Weeds measure over prepositional complements and the Lin measure over all arguments.

**Verb classes** Following our discussion in Section 3, we first measure for each target verb  $v$  a “stative” feature  $f$  by computing the proportion of times it appears in progressive tense, since stative verbs usually do not appear in the progressive tense (e.g., *knowing*). Then, given a verb pair  $(v_1, v_2)$  and their corresponding stative features  $f_1$  and  $f_2$ , we add two features  $f_1 \cdot f_2$  and  $\frac{f_1}{f_2}$ , which capture the interaction between the verb classes of the two verbs.

**Verb generality** For each verb, we add as a feature the number of different particles it appears with in the corpus, following the hypothesis that this is a cue to its generality. Then, given a verb pair  $(v_1, v_2)$  and their corresponding features  $f_1$  and  $f_2$ , we add the feature  $\frac{f_1}{f_2}$ . We expect that when  $\frac{f_1}{f_2}$  is high,  $v_1$  is more general than  $v_2$ , which is a negative entailment indicator.

## 4.2 Learning model and feature analysis

The total number of features in our model as described above is 63. We combine the features in a supervised classification framework with a linear SVM. Since our model contains many novel features, it is important to investigate their utility for detecting verb entailment. To that end, we employ feature ranking methods as suggested by Guyon et al. (2003). In feature ranking methods, features are ranked by some score computed for each feature independently. In this paper we use Pearson correlation between the feature values and the corresponding labels as the ranking criterion.

<sup>4</sup>We employ the common practice of using the pmi between a verb and an argument rather than the argument count as the argument’s weight.

## 5 Evaluation and Analysis

### 5.1 Experimental Setting

To evaluate our proposed supervised model, we constructed a dataset containing labeled verb pairs. We started by randomly sampling 50 verbs out of the common verbs in the RCV1 corpus<sup>5</sup>, which we denote here as *seed verbs*. Next, we extracted the 20 most similar verbs to each seed verb according to the Lin similarity measure (Lin, 1998), which was computed on the RCV1 corpus. Then, for each seed verb  $v_s$  and one of its extracted similar verbs  $v_s^i$  we generated the two directed pairs  $(v_s, v_s^i)$  and  $(v_s^i, v_s)$ , which represent the candidate rules ' $v_s \rightarrow v_s^i$ ' and ' $v_s^i \rightarrow v_s$ ' respectively. To reduce noise, we filtered out verb pairs where one of the verbs is an auxiliary or a light verb such as 'do', 'get' and 'have'. This step resulted in 812 verb pairs as our dataset<sup>6</sup>, which were manually annotated by the authors as representing a valid entailment rule or not. To annotate these pairs, we generally followed the rule-based approach for entailment rule annotation, where a rule ' $v_1 \rightarrow v_2$ ' is considered as correct if the annotator could think of reasonable contexts under which the rule holds (Dekang and Pantel, 2001; Szpektor et al., 2004). In total 225 verb pairs were labeled as entailing (the rule ' $v_1 \rightarrow v_2$ ' was judged as correct) and 587 verb pairs were labeled as non-entailing (the rule ' $v_1 \rightarrow v_2$ ' was judged as incorrect). The Inter-Annotator Agreement (IAA) for a random sample of 100 pairs was moderate (0.47), as expected from the rule-based approach (Szpektor et al., 2007).

For each verb pair, all 63 features within our model (Section 4) were computed using the ukWaC corpus (Baroni et al., 2009), which contains 2 billion words. For classification, we utilized SVM-perf's (Joachims, 2005) linear SVM implementation with default parameters, and evaluated our model by performing 10-fold cross validation (CV) over the labeled dataset.

### 5.2 Feature selection and analysis

As discussed in Section 4.2, we followed the feature ranking method proposed by Guyon et al. (2003) to investigate the utility of our proposed features. Table 2 depicts the 10 most positively and negatively correlated features with entailment according to the Pearson correlation measure

From Table 2, it is clear that distributional similarity features are amongst the most positively correlated with entailment, which is in line with prior work (Geffet and Dagan, 2005; Kotlerman et al., 2010). Looking more closely, our suggestion for typed distributional similarity proved to be useful, and indeed most of the highly correlated distributional similarity features are typed measures. Standing out are the adverb-typed measures, with two features in the top 10, including the highest, '*Weeds-adverb*', and '*BInc-adverb*'. We also note that the highly correlated distributional similarity measures are directional, *Weeds* and *BInc*.

The table also indicates that document-level co-occurrence contributes positively to entailment detection. This includes both the Chambers narrative measure, with the typed feature *Chambers-obj*, and document-level PMI, which captures a more loose co-occurrence relationship between verbs. Again, we point at the significant correlation of our novel typed measures with verb entailment, in this case the typed narrative measure.

Last, our feature analysis shows that many of our novel co-occurrence features at the sentence level contribute useful negative information. For example, verbs connected via an adverbial adjunct ('*v2-adverb-v1*') or an object complement ('*v1-obj-v2*') are negatively correlated with entailment. In addition, the novel '*verb generality*' feature as well as the tense difference feature ('*tense-v1 > tense-v2*') are also strong negative indicators. On the other hand, '*v2-coord-v1*' is positively correlated with entailment. This shows that encoding various aspects of verb co-occurrence at the sentence level can lead to better prediction of verb entailment. Finally, we note that PMI at the sentence level is highly correlated with entailment even more than at the document level, since the local textual scope is more indicative, though sparser.

To conclude, our feature analysis shows that fea-

Rank	Top Positive	Top Negative
1	Weeds-adverb	tense-v1 > tense-v2
2	Sentence-level PMI	v2-adverb-v1 co-occurrence
3	Weeds-subj	v2-obj-v1 co-occurrence
4	Weeds-prep	v1-obj-v2 co-occurrence
5	Weeds-all	v1-adverb-v2 co-occurrence
6	Chambers-obj	verb generality $\frac{f_1}{f_2}$
7	v2-coord-v1 co-occurrence	v1-contrast-v2
8	BInc-adverb	tense-v1 < tense-v2
9	Document-level PMI	lexical-distance 0-5
10	Chambers-same	Lin-subj

Table 2: Top 10 positive and negative features according to the Pearson correlation score.

tures at all levels: sentence, document and corpus, contain useful information for entailment detection, both positive and negative, and should be combined together. Moreover, many of our novel features are among the highly correlated features, showing that devising a rich set of verb-specific and linguistically-motivated features provides better discriminative evidence for entailment detection.

### 5.3 Results and Analysis

We compared our method to the following baselines which were mostly taken from or inspired by prior work:

**Random:** A simple decision rule: for any pair  $(v_1, v_2)$ , randomly classify as “yes” with a probability equal to the number of entailing verb pairs out of all verb pairs in the labeled dataset (*i.e.*,  $\frac{225}{812} = 0.277$ ).

**VO-KB:** A simple unsupervised rule: for any pair  $(v_1, v_2)$ , classify as “yes” if the pair appears in the *strength* relation (corresponding to entailment) in the VerbOcean knowledge-base, which was computed over Web counts.

**VO-ukWaC:** A simple unsupervised rule: for any pair  $(v_1, v_2)$ , classify as “yes” if the value of the positive VerbOcean feature is ‘1’ (Section 4.1, computed over ukWaC).

**TDS:** Include only the 15 distributional similarity features in our supervised model. This baseline extends Berant et al. (2012), who trained an entailment

Method	P%	R%	AUC	F <sub>1</sub>
All	<b>40.2</b>	<b>71.0</b>	<b>0.65</b>	<b>0.51</b>
TDS+VO	36.8	53.2	0.58	0.41
TDS	34.6	44.8	0.56	0.37
Random	27.9	28.8	0.51	0.28
VO-KB	33.1	14.8	0.53	0.2
VO-ukWaC	23.3	4.7	0.29	0.08

Table 3: Average precision, recall, AUC and F<sub>1</sub> for our method and the baselines.

classifier over several distributional similarity features, and provides an evaluation of the discriminative power of distributional similarity alone, without co-occurrence features.

**TDS+VO:** Include only the 15 typed distributional similarity features and the two VerbOcean features in our supervised model. This baseline is inspired by Mirkin et al. (2006), who combined distributional similarity features and Hearst patterns (Hearst, 1992) for learning entailment between nouns.

**All:** Our full-blown model, including all features described in Section 4.1.

For all tested methods, we performed 10-fold cross validation and averaged Precision, Recall, Area under the ROC curve (AUC) and F<sub>1</sub> over the 10 folds. Table 3 presents the results of our full-blown model as well as the baselines.

First, we note that, as expected, the VerbOcean baselines *VO-KB* and *VO-ukWaC* provide low recall,

Method	P%	R%	AUC	F <sub>1</sub>
All	40.2	71.0	0.65	0.51
Sent+Corpus-level	39.7	70.4	0.64	0.50
Sent+Doc-level	39.0	70.0	0.63	0.50
Doc+Corpus-level	37.7	64.0	0.62	0.47
Sent-level	35.8	63.8	0.59	0.46
Doc-level	30.0	45.4	0.52	0.35
Corpus-level	35.4	58.1	0.58	0.44

Table 4: Average precision, recall, AUC and F<sub>1</sub> for each subset of the feature groups.

due to the sparseness of rigid pattern instantiation for verbs both in the ukWaC corpus and on the web. Yet, VerbOcean positive and negative patterns do add some discriminative power over only distributional similarity measures, as seen by the improvement of *TDS+VO* over *TDS* in all criteria. But, it is the combination of all types of information sources that yields the best performance. Our complete model, employing the full set of features, outperforms all other models in terms of both precision and recall. Its improvement in terms of F<sub>1</sub> over the second best model (*TDS+VO*), which includes all distributional similarity features as well as pattern-based features, is by 24%. This result shows the benefits of integrating linguistically motivated co-occurrence features with traditional pattern-based and distributional similarity information.

To further investigate the contribution of features at various co-occurrence levels, we trained and tested our model with all possible combinations of feature groups corresponding to a certain co-occurrence scope (sentence, document and corpus). Table 4 presents the results of these tests.

The most notable result of this analysis is that sentence-level features play an important role within our model. Indeed, removing either the document-level features (*Sent+Corpus-level*) or the corpus-level features (*Sent+Doc-level*) results in only a slight decline in performance. Yet, removing the sentence-level features (*Doc+Corpus-level*), ends in a more substantial decline of 8.5% in F<sub>1</sub>. In addition, sentence-level features alone (*Sent-level*) provide the best discriminative power for verb entailment, compared to document and corpus levels, which include distributional similarity features. Yet,

we note that sentence-level features alone do not capture all the information within our model, and they should be combined with one of the other feature groups to reach performance close to the complete model. This shows again the importance of combining co-occurrence indicators at different levels.

As an additional insight from Table 4, we point out that document-level features are not good entailment indicators by themselves (*Doc-level* in Table 4), and they perform worse than the distributional similarity baseline (*TDS* at Table 3). Still, they do complement each of the other feature groups. In particular, since the *Sent+Doc-level* model performs almost as good as the full model, this subset may be a good substitute to the full model, since its features are easier to extract from large corpora, as they may be extracted in an on-line fashion, processing one document at a time (contrary to corpus-level features).

As a final analysis, we randomly sampled correct entailment rules learned by our model but missed by the typed distributional similarity classifier (*TDS*). Our overall impression is that employing co-occurrence information helps to better capture entailment relations other than synonymy and troponymy. For example, our model learns that *acquire* → *own*, corresponding to the *cause-effect* entailment relation, and that *patent* → *invent*, corresponding to the *presupposition* entailment relation.

## 6 Conclusions and Future Work

We presented a supervised classification model for detecting lexical entailment between verbs. At the heart of our model stand novel linguistically motivated indicators that capture positive and negative entailment information. These indicators encompass co-occurrence relationships between verbs at the sentence, document and corpus level, as well as more fine-grained typed distributional similarity measures. Our model incorporates these novel indicators together with useful features from prior work, combining co-occurrence and distributional similarity information about verb pairs.

Our experiment over a manually labeled dataset showed that our model significantly outperforms several state-of-the-art models both in terms of Pre-

cision and Recall. Further feature analysis indicated that our novel indicators contribute greatly to the performance of the model, and that co-occurrence at multiple levels, combined with distributional similarity features, is necessary to achieve the model's best performance.

In future work we'd like to investigate which indicators may contribute to learning different fine-grained types of entailment, such as presupposition and cause-effect, and attempt to perform a more fine-grained classification to subtypes of entailment.

## Abstract

Recently there has been substantial interest in using spectral methods to learn generative sequence models like HMMs. Spectral methods are attractive as they provide globally consistent estimates of the model parameters and are very fast and scalable, unlike EM methods, which can get stuck in local minima. In this paper, we present a novel extension of this class of spectral methods to learn dependency tree structures. We propose a simple yet powerful latent variable generative model for dependency parsing, and a spectral learning method to efficiently estimate it. As a pilot experimental evaluation, we use the spectral tree probabilities estimated by our model to re-rank the outputs of a near state-of-the-art parser. Our approach gives us a moderate reduction in error of up to 4.6% over the baseline re-ranker.

## 1 Introduction

Markov models have been for two decades a workhorse of statistical pattern recognition with applications ranging from speech to vision to language. Adding latent variables to these models gives us additional modeling power and have shown success in applications like POS tagging (Merialdo, 1994), speech recognition (Rabiner, 1989) and object recognition (Quattoni et al., 2004). However, this comes at the cost that the resulting parameter estimation problem becomes non-convex and techniques like EM (Dempster et al., 1977) which are used to estimate the parameters can only lead to locally optimal solutions.

Recent work by Hsu et al. (2008) has shown that globally consistent estimates of the parameters of HMMs can be found by using spectral methods, particularly by singular value decomposition (SVD) of appropriately defined linear systems. They avoid the NP Hard problem of the global optimization problem of the HMM parameters (Terwijn, 2002), by putting restrictions on the smallest singular value of the HMM parameters. The main intuition behind the model is that, although the observed data (i.e. words) seem to live in a very high dimensional space, but in reality they live in a very low dimensional space (size  $k \sim 30 - 50$ ) and an appropriate eigen decomposition of the observed data will reveal the underlying low dimensional dynamics and thereby revealing the parameters of the model. Besides ducking the NP hard problem, the spectral methods are very fast and scalable to train compared to EM methods.

In this paper we generalize the approach of Hsu et al. (2008) to learn dependency tree structures with latent variables.<sup>1</sup> Petrov et al. (2006) and Musillo and Merlo (2008) have shown that learning PCFGs and dependency grammars respectively with latent variables can produce parsers with very good generalization performance. However, both these approaches rely on EM for parameter estimation and can benefit from using spectral methods.

We propose a simple yet powerful latent variable generative model for use with dependency pars-

<sup>1</sup>Actually, instead of using the model by Hsu et al. (2008) we work with a related model proposed by Foster et al. (2012) which addresses some of the shortcomings of the earlier model which we detail below.

ing which has one hidden node for each word in the sentence, like the one shown in Figure 1 and work out the details for the parameter estimation of the corresponding spectral learning model. At a very high level, the parameter estimation of our model involves collecting unigram, bigram and trigram counts sensitive to the underlying dependency structure of the given sentence.

Recently, Luque et al. (2012) have also proposed a spectral method for dependency parsing, however they deal with *horizontal markovization* and use hidden states to model sequential dependencies within a word’s sequence of children. In contrast with that, in this paper, we propose a spectral learning algorithm where latent states are not restricted to HMM-like distributions of modifier sequences for a particular head, but instead allow information to be propagated through the entire tree.

More recently, Cohen et al. (2012) have proposed a spectral method for learning PCFGs.

Its worth noting that recent work by Parikh et al. (2011) also extends Hsu et al. (2008) to latent variable dependency trees like us but under the restrictive conditions that model parameters are trained for a specified, albeit arbitrary, tree topology.<sup>2</sup> In other words, all training sentences and test sentences must have identical tree topologies. By doing this they allow for node-specific model parameters, but must re-train the model entirely when a different tree topology is encountered. Our model on the other hand allows the flexibility and efficiency of processing sentences with a variety of tree topologies from a single training run.

Most of the current state-of-the-art dependency parsers are discriminative parsers (Koo et al., 2008; McDonald, 2006) due to the flexibility of representations which can be used as features leading to better accuracies and the ease of reproducibility of results. However, unlike discriminative models, generative models can exploit unlabeled data. Also, as is common in statistical parsing, re-ranking the outputs of a parser leads to significant reductions in error (Collins and Koo, 2005).

Since our spectral learning algorithm uses a gen-

<sup>2</sup>This can be useful in modeling phylogeny trees for instance, but precludes most NLP applications, since there is a need to model the full set of different tree topologies possible in parsing.

Figure 1: Sample dependency parsing tree for “Kilroy was here”

erative model of words given a tree structure, it can score a tree structure i.e. its probability of generation. Thus, it can be used to re-rank the n-best outputs of a given parser.

The remainder of the paper is organized as follows. In the next section we introduce the notation and give a brief overview of the spectral algorithm for learning HMMs (Hsu et al., 2008; Foster et al., 2012). In Section 3 we describe our proposed model for dependency parsing in detail and work out the theory behind it. Section 4 provides experimental evaluation of our model on Penn Treebank data. We conclude with a brief summary and future avenues for research.

## 2 Spectral Algorithm For Learning HMMs

In this section we describe the spectral algorithm for learning HMMs.<sup>3</sup>

### 2.1 Notation

The HMM that we consider in this section is a sequence of hidden states  $h \in \{1, \dots, k\}$  that follow the Markov property:

$$p(h_t|h_1, \dots, h_{t-1}) = p(h_t|h_{t-1})$$

and a sequence of observations  $x \in \{1, \dots, n\}$  such that

$$p(x_t|x_1, \dots, x_{t-1}, h_1, \dots, h_t) = p(x_t|h_t)$$

<sup>3</sup>As mentioned earlier, we use the model by Foster et al. (2012) which is conceptually similar to the one by Hsu et al. (2008), but does further dimensionality reduction and thus has lower sample complexity. Also, critically, the fully reduced dimension model that we use generalizes much more cleanly to trees.

The parameters of this HMM are:

- A vector  $\pi$  of length  $k$  where  $\pi_i = p(h_1 = i)$ : The probability of the start state in the sequence being  $i$ .
- A matrix  $T$  of size  $k \times k$  where  $T_{i,j} = p(h_{t+1} = i | h_t = j)$ : The probability of transitioning to state  $i$ , given that the previous state was  $j$ .
- A matrix  $O$  of size  $n \times k$  where  $O_{i,j} = p(x = i | h = j)$ : The probability of state  $h$  emitting observation  $x$ .

Define  $\delta_j$  to be the vector of length  $n$  with a 1 in the  $j^{\text{th}}$  entry and 0 everywhere else, and  $\text{diag}(v)$  to be the matrix with the entries of  $v$  on the diagonal and 0 everywhere else.

The joint distribution of a sequence of observations  $x_1, \dots, x_m$  and a sequence of hidden states  $h_1, \dots, h_m$  is:

$$\begin{aligned} p(x_1, \dots, x_m, h_1, \dots, h_m) \\ = \pi_{h_1} \prod_{j=2}^{m-1} T_{h_j, h_{j-1}} \prod_{j=1}^m O_{x_j, h_j} \end{aligned}$$

Now, we can write the marginal probability of a sequence of observations as

$$\begin{aligned} p(x_1, \dots, x_m) \\ = \sum_{h_1, \dots, h_m} p(x_1, \dots, x_m, h_1, \dots, h_m) \end{aligned}$$

which can be expressed in matrix form<sup>4</sup> as:

$$p(x_1, \dots, x_m) = \mathbf{1}^\top A_{x_m} A_{x_{m-1}} \cdots A_{x_1} \pi$$

where  $A_{x_m} \equiv T \text{diag}(O^\top \delta_{x_m})$ , and  $\mathbf{1}$  is a  $k$ -dimensional vector with every entry equal to 1.

$A$  is called an ‘‘observation operator’’, and is effectively a third order tensor, and  $A_{x_m}$  which is a matrix, gives the distribution vector over states at time  $m+1$  as a function of the state distribution vector at the current time  $m$  and the current observation  $\delta_{x_m}$ . Since  $A_{x_m}$  depends on the hidden state, it is not observable, and hence cannot be directly estimated.

<sup>4</sup>This is essentially the matrix form of the standard dynamic program (forward algorithm) used to estimate HMMs.

However, Hsu et al. (2008) and Foster et al. (2012) showed that under certain conditions there exists a fully observable representation of the observable operator model.

## 2.2 Fully observable representation

Before presenting the model, we need to address a few more points. First, let  $U$  be a ‘‘representation matrix’’ (eigenfeature dictionary) which maps each observation to a reduced dimension space ( $n \rightarrow k$ ) that satisfies the conditions:

- $U^\top O$  is invertible
- $|U_{ij}| < 1$ .

Hsu et al. (2008); Foster et al. (2012) discuss  $U$  in more detail, but  $U$  can, for example, be obtained by the SVD of the bigram probability matrix (where  $P_{ij} = p(x_{t+1} = i | x_t = j)$ ) or by doing CCA on neighboring  $n$ -grams (Dhillon et al., 2011).

Letting  $y_i = U^\top \delta_{x_i}$ , we have

$$\begin{aligned} p(x_1, \dots, x_m) \\ = c_\infty^\top C(y_m) C(y_{m-1}) \cdots C(y_1) c_1 \end{aligned} \quad (1)$$

where

$$\begin{aligned} c_1 &= \mu \\ c_\infty &= \mu^\top \Sigma^{-1} \\ C(y) &= K(y) \Sigma^{-1} \end{aligned}$$

and  $\mu$ ,  $\Sigma$  and  $K$ , described in more detail below, are quantities estimated by frequencies of unigrams, bigrams, and trigrams in the observed (training) data.

Under the assumption that data is generated by an HMM, the distribution  $\hat{p}$  obtained by substituting the estimated values  $\hat{c}_1$ ,  $\hat{c}_\infty$ , and  $\hat{C}(y)$  into equation (1) converges to  $p$  sufficiently fast as the amount of training data increases, giving us consistent parameter estimates. For details of the convergence proof, please see Hsu et al. (2008) and Foster et al. (2012).

## 3 Spectral Algorithm For Learning Dependency Trees

In this section, we first describe a simple latent variable generative model for dependency parsing. We then define some extra notation and finally present

the details of the corresponding spectral learning algorithm for dependency parsing, and prove that our learning algorithm provides a consistent estimation of the marginal probabilities.

It is worth mentioning that an alternate way of approaching the spectral estimation of latent states for dependency parsing is by converting the dependency trees into linear sequences from root-to-leaf and doing a spectral estimation of latent states using Hsu et al. (2008). However, this approach would not give us the correct probability distribution over trees as the probability calculations for different paths through the trees are not independent. Thus, although one could calculate the probability of a path from the root to a leaf, one cannot generalize from this probability to say anything about the neighboring nodes or words. Put another way, when a parent has more than the one descendant, one has to be careful to take into account that the hidden variables at each child node are all conditioned on the hidden variable of the parent.

### 3.1 A latent variable generative model for dependency parsing

In the standard setting, we are given training examples where each training example consists of a sequence of words  $x_1, \dots, x_m$  together with a dependency structure over those words, and we want to estimate the probability of the observed structure. This marginal probability estimates can then be used to build an actual generative dependency parser or, since the marginal probability is conditioned on the tree structure, it can be used re-rank the outputs of a parser.

As in the conventional HMM described in the previous section, we can define a simple latent variable first order dependency parsing model by introducing a hidden variable  $h_i$  for each word  $x_i$ . The joint probability of a sequence of observed nodes  $x_1, \dots, x_m$  together with hidden nodes  $h_1, \dots, h_m$  can be written as

$$\begin{aligned}
 & p(x_1, \dots, x_m, h_1, \dots, h_m) \\
 &= \pi_{h_1} \prod_{j=2}^m t_{d(j)}(h_j | h_{pa(j)}) \prod_{j=1}^m o(x_j | h_j)
 \end{aligned} \tag{2}$$

Figure 2: Dependency parsing tree with observed variables  $y_1$ ,  $y_2$ , and  $y_3$ .

where  $pa(j)$  is the parent of node  $j$  and  $d(j) \in \{L, R\}$  indicates whether  $h_j$  is a left or a right node of  $h_{pa(j)}$ . For simplicity, the number of hidden and observed nodes in our tree are the same, however they are not required to be so.

As is the case with the conventional HMM, the parameters used to calculate this joint probability are unobservable, but it turns out that under suitable conditions a fully observable model is also possible for the dependency tree case with the parameterization as described below.

### 3.2 Model parameters

We will define both the theoretical representations of our observable parameters, and the sampling versions of these parameters. Note that in all the cases, the estimated versions are unbiased estimates of the theoretical quantities.

Define  $T_d$  and  $T_d^u$  where  $d \in \{L, R\}$  to be the hidden state transition matrices from parent to left or right child, and from left or right child to parent (hence the  $u$  for ‘up’), respectively. In other words (referring to Figure 2)

$$\begin{aligned}
 T_R &= t(h_3 | h_1) \\
 T_L &= t(h_2 | h_1) \\
 T_R^u &= t(h_1 | h_3) \\
 T_L^u &= t(h_1 | h_2)
 \end{aligned}$$

Let  $U_{x(i)}$  be the  $i^{\text{th}}$  entry of vector  $U^\top \delta_x$  and  $G = U^\top O$ . Further, recall the notation  $\text{diag}(v)$ , which is a matrix with elements of  $v$  on its diagonal, then:

- Define the  $k$ -dimensional vector  $\mu$  (unigram

counts):

$$\begin{aligned}\mu &= G\pi \\ [\hat{\mu}]_i &= \sum_{u=1}^n \bar{c}(u)U_{u(i)}\end{aligned}$$

where  $\bar{c}(u) = \frac{c(u)}{N_1}$ ,  $c(u)$  is the count of observation  $u$  in the training sample, and  $N_1 = \sum_{u \in n} c(u)$ .

- Define the  $k \times k$  matrices  $\Sigma_L$  and  $\Sigma_R$  (left child-parent and right child-parent bigram counts):

$$\begin{aligned}[\hat{\Sigma}_L]_{i,j} &= \sum_{u=1}^n \sum_{v=1}^n \bar{c}_L(u,v)U_{u(j)}U_{v(i)} \\ \Sigma_L &= GT_L^u \text{diag}(\pi)G^\top \\ [\hat{\Sigma}_R]_{i,j} &= \sum_{u=1}^n \sum_{v=1}^n \bar{c}_R(u,v)U_{u(j)}U_{v(i)} \\ \Sigma_R &= GT_R^u \text{diag}(\pi)G^\top\end{aligned}$$

where  $\bar{c}_L(u,v) = \frac{c_L(u,v)}{N_{2L}}$ ,  $c_L(u,v)$  is the count of bigram  $(u,v)$  where  $u$  is the left child and  $v$  is the parent in the training sample, and  $N_{2L} = \sum_{(u,v) \in n \times n} c_L(u,v)$ . Define  $\bar{c}_R(u,v)$  similarly.

- Define  $k \times k \times k$  tensor  $K$  (left child-parent-right child trigram counts):

$$\begin{aligned}\hat{K}_{i,j,l} &= \sum_{u=1}^n \sum_{v=1}^n \sum_{w=1}^n \bar{c}(u,v,w)U_{w(i)}U_{u(j)}U_{v(l)} \\ K(y) &= GT_L \text{diag}(G^\top y)T_R^u \text{diag}(\pi)G^\top\end{aligned}$$

where  $\bar{c}(w,u,v) = \frac{c(w,u,v)}{N_3}$ ,  $c(w,u,v)$  is the count of bigram  $(w,u,v)$  where  $w$  is the left child,  $u$  is the parent and  $v$  is the right child in the training sample, and  $N_3 = \sum_{(w,u,v) \in n \times n \times n} c(w,u,v)$ .

- Define  $k \times k$  matrices  $\Omega_L$  and  $\Omega_R$  (skip-bigram counts (left child-right child) and (right child-

left child))<sup>5</sup>:

$$\begin{aligned}[\hat{\Omega}_L]_{i,j} &= \sum_{u=1}^n \sum_{v=1}^n \sum_{w=1}^n \bar{c}(u,v,w)U_{w(i)}U_{u(j)} \\ \Omega_L &= GT_L T_R^u \text{diag}(\pi)G^\top \\ [\hat{\Omega}_R]_{i,j} &= \sum_{u=1}^n \sum_{v=1}^n \sum_{w=1}^n \bar{c}(u,v,w)U_{w(j)}U_{u(i)} \\ \Omega_R &= GT_R T_L^u \text{diag}(\pi)G^\top\end{aligned}$$

### 3.3 Parameter estimation

Using the above definitions, we can estimate the parameters of the model, namely  $\mu, \Sigma_L, \Sigma_R, \Omega_L, \Omega_R$  and  $K$ , from the training data and define observables useful for the dependency model as<sup>6</sup>

$$\begin{aligned}c_1 &= \mu \\ c_\infty^T &= \mu^T \Sigma_R^{-1} \\ E_L &= \Omega_L \Sigma_R^{-1} \\ E_R &= \Omega_R \Sigma_L^{-1} \\ D(y) &= E_L^{-1} K(y) \Sigma_R^{-1}\end{aligned}$$

As we will see, these quantities allow us to recursively compute the marginal probability of the dependency tree,  $\hat{p}(x_1, \dots, x_m)$ , in a bottom up manner by using belief propagation.

To see this, let  $hch(i)$  be the set of hidden children of hidden node  $i$  (in Figure 2 for instance,  $hch(1) = \{2, 3\}$ ) and let  $och(i)$  be the set of observed children of hidden node  $i$  (in the same figure  $och(i) = \{1\}$ ). Then compute the marginal probability  $p(x_1, \dots, x_m)$  from Equation 2 as

$$r_i(h) = \prod_{j \in hch(i)} \alpha_j(h) \prod_{j \in och(i)} o(x_j|h) \quad (3)$$

where  $\alpha_i(h)$  is defined by summing over all the hidden random variables i.e.,  $\alpha_i(h) = \sum_{h'} p(h'|h)r_i(h')$ .

This can be written in a compact matrix form as

$$\begin{aligned}\vec{r}_i^\top &= 1^\top \prod_{j \in hch(i)} \text{diag}(T_{d_j}^\top \vec{r}_j) \\ &\cdot \prod_{j \in och(i)} \text{diag}(O^\top \delta_{x_j})\end{aligned} \quad (4)$$

<sup>5</sup>Note that  $\Omega_R = \Omega_L^T$ , which is not immediately obvious from the matrix representations.

<sup>6</sup>The details of the derivation follow directly from the matrix versions of the variables.

where  $\vec{r}_i$  is a vector of size  $k$  (the dimensionality of the hidden space) of values  $r_i(h)$ . Note that since in Equation 2 we condition on whether  $x_j$  is the left or right child of its parent, we have separate transition matrices for left and right transitions from a given hidden node  $d_j \in \{L, R\}$ .

The recursive computation can be written in terms of observables as:

$$\begin{aligned} \vec{r}_i^\top &= c_\infty^\top \prod_{j \in hch(i)} D(E_{d_j}^\top \vec{r}_j) \\ &\cdot \prod_{j \in och(i)} D((U^\top U)^{-1} U^\top \delta_{x_j}) \end{aligned}$$

The final calculation for the marginal probability of a given sequence is

$$\hat{p}(x_1, \dots, x_m) = \vec{r}_1^\top c_1 \quad (5)$$

The spectral estimation procedure is described below in Algorithm 1.

---

**Algorithm 1** Spectral dependency parsing (Computing marginal probability of a tree.)

---

- 1: **Input:** Training examples-  $x^{(i)}$  for  $i \in \{1, \dots, M\}$  along with dependency structures where each sequence  $x^{(i)} = x_1^{(i)}, \dots, x_{m_i}^{(i)}$ .
- 2: Compute the spectral parameters  $\hat{\mu}, \hat{\Sigma}_R, \hat{\Sigma}_L, \hat{\Omega}_R, \hat{\Omega}_L$ , and  $\hat{K}$   
#Now, for a given sentence, we can recursively compute the following:
- 3: **for**  $x_j^{(i)}$  for  $j \in \{m_i, \dots, 1\}$  **do**
- 4:   Compute:

$$\begin{aligned} \vec{r}_i^\top &= c_\infty^\top \prod_{j \in hch(i)} D(E_{d_j}^\top \vec{r}_j) \\ &\cdot \prod_{j \in och(i)} D((U^\top U)^{-1} U^\top \delta_{x_j}) \end{aligned}$$

- 5: **end for**
- 6: Finally compute

$$\hat{p}(x_1, \dots, x_{m_i}) = \vec{r}_1^\top c_1$$

#The marginal probability of an entire tree.

---

### 3.4 Sample complexity

Our main theoretical result states that the above scheme for spectral estimation of marginal probabilities provides a guaranteed consistent estimation scheme for the marginal probabilities:

**Theorem 3.1.** *Let the sequence  $\{x_1, \dots, x_m\}$  be generated by an  $k \geq 2$  state HMM. Suppose we are given a  $U$  which has the property that  $U^\top O$  is invertible, and  $|U_{ij}| \leq 1$ . Suppose we use equation (5) to estimate the probability based on  $N$  independent triples. Then*

$$N \geq C_m \frac{k^2}{\epsilon^2} \log \left( \frac{k}{\delta} \right) \quad (6)$$

where  $C_m$  is specified in the appendix, implies that

$$1 - \epsilon \leq \left| \frac{\hat{p}(x_1, \dots, x_m)}{p(x_1, \dots, x_m)} \right| \leq 1 + \epsilon$$

holds with probability at least  $1 - \delta$ .

*Proof.* A sketch of the proof, in the case without directional transition parameters, can be found in the appendix. The proof with directional transition parameters is almost identical.  $\square$

## 4 Experimental Evaluation

Since our algorithm can score any given tree structure by computing its marginal probability, a natural way to benchmark our parser is to generate n-best dependency trees using some standard parser and then use our algorithm to re-rank the candidate dependency trees, e.g. using the log spectral probability as described in Algorithm 1 as a feature in a discriminative re-ranker.

### 4.1 Experimental Setup

Our base parser was the discriminatively trained MSTParser (McDonald, 2006), which implements both first and second order parsers and is trained using MIRA (Crammer et al., 2006) and used the standard baseline features as described in McDonald (2006).

We tested our methods on the English Penn Treebank (Marcus et al., 1993). We use the standard splits of Penn Treebank; i.e., we used sections 2-21 for training, section 22 for development and section 23 for testing. We used the PennConverter<sup>7</sup> tool to convert Penn Treebank from constituent to dependency format. Following (McDonald, 2006; Koo

<sup>7</sup>[http://nlp.cs.lth.se/software/treebank\\_converter/](http://nlp.cs.lth.se/software/treebank_converter/)

et al., 2008), we used the POS tagger by Ratnaparkhi (1996) trained on the full training data to provide POS tags for development and test sets and used 10-way jackknifing to generate tags for the training set. As is common practice we stripped our sentences of all the punctuation. We evaluated our approach on sentences of all lengths.

## 4.2 Details of spectral learning

For the spectral learning phase, we need to just collect word counts from the training data as described above, so there are no tunable parameters as such. However, we need to have access to an attribute dictionary  $U$  which contains a  $k$  dimensional representation for each word in the corpus. A possible way of generating  $U$  as suggested by Hsu et al. (2008) is by performing SVD on bigrams  $P_{21}$  and using the left eigenvectors as  $U$ . We instead used the eigenfeature dictionary proposed by Dhillon et al. (2011) (LR-MVL) which is obtained by performing CCA on neighboring words and has provably better sample complexity for rare words compared to the SVD alternative.

We induced the LR-MVL embeddings for words using the Reuters RCV1 corpus which contains about 63 million tokens in 3.3 million sentences and used their context oblivious embeddings as our estimate of  $U$ . We experimented with different choices of  $k$  (the size of the low dimensional projection) on the development set and found  $k = 10$  to work reasonably well and fast. Using  $k = 10$  we were able to estimate our spectral learning parameters  $\mu, \Sigma_{L,R}, \Omega_{L,R}, K$  from the entire training data in under 2 minutes on a 64 bit Intel 2.4 Ghz processor.

## 4.3 Re-ranking the outputs of MST parser

We could not find any previous work which describes features for discriminative re-ranking for dependency parsing, which is due to the fact that unlike constituency parsing, the base parsers for dependency parsing are discriminative (e.g. MST parser) which obviates the need for re-ranking as one could add a variety of features to the baseline parser itself. However, parse re-ranking is a good testbed for our spectral dependency parser which can score a given tree. So, we came up with a baseline set of features to use in an averaged perceptron re-ranker (Collins, 2002). Our baseline features comprised of two main

Method	Accuracy	Complete
I Order		
MST Parser (No RR)	90.8	37.2
RR w. Base. Features	91.3	37.5
RR w. Base. Features + $\log \hat{p}$	<b>91.7</b>	<b>37.8</b>
II Order		
MST Parser (No RR)	91.8	40.6
RR w. Base. Features	92.4	41.0
RR w. Base. Features + $\log \hat{p}$	<b>92.7</b>	<b>41.3</b>

Table 1: (Unlabeled) Dependency Parse re-ranking results for English test set (Section 23). **Note:** 1). RR = Re-ranking 2). *Accuracy* is the number of words which correctly identified their parent and *Complete* is the number of sentences for which the entire dependency tree was correct. 3). Base. Features are the two re-ranking features described in Section 4.3. 4).  $\log \hat{p}$  is the spectral log probability feature.

features which capture information that varies across the different n-best parses and moreover were not used as features by the baseline MST parser,  $\langle \text{POS-left-modifier} \wedge \text{POS-head} \wedge \text{POS-right-modifier} \rangle$  and  $\langle \text{POS-left/right-modifier} \wedge \text{POS-head} \wedge \text{POS-grandparent} \rangle$ <sup>8</sup>. In addition to that we used the log of spectral probability ( $\hat{p}(x_1, \dots, x_m)$ ) - as calculated using Algorithm 1) as a feature.

We used the MST parser trained on entire training data to generate a list of n-best parses for the development and test sets. The n-best parses for the training set were generated by 3-fold cross validation, where we train on 2 folds to get the parses for the third fold. In all our experiments we used  $n = 50$ . The results are shown in Table 1. As can be seen, the best results give up to 4.6% reduction in error over the re-ranker which uses just the baseline set of features.

## 5 Discussion and Future Work

Spectral learning of structured latent variable models in general is a promising direction as has been shown by the recent interest in this area. It allows us to circumvent the ubiquitous problem of getting stuck in local minima when estimating the latent variable models via EM. In this paper we ex-

<sup>8</sup>One might be able to come up with better features for dependency parse re-ranking. Our goal in this paper was just to get a reasonable baseline.

tended the spectral learning ideas to learn a simple yet powerful dependency parser. As future work, we are working on building an end-to-end parser which would involve coming up with a spectral version of the inside-outside algorithm for our setting. We are also working on extending it to learn more powerful grammars e.g. split head-automata grammars (SHAG) (Eisner and Satta, 1999).

## 6 Conclusion

In this paper we proposed a novel spectral method for dependency parsing. Unlike EM trained generative latent variable models, our method does not get stuck in local optima, it gives consistent parameter estimates, and it is extremely fast to train. We worked out the theory of a simple yet powerful generative model and showed how it can be learned using a spectral method. As a pilot experimental evaluation we showed the efficacy of our approach by using the spectral probabilities output by our model for re-ranking the outputs of MST parser. Our method reduced the error of the baseline re-ranker by up to a moderate 4.6%.

## 7 Appendix

This appendix offers a sketch of the proof of Theorem 1. The proof uses the following definitions, which are slightly modified from those of Foster et al. (2012).

**Definition 1.** Define  $\Lambda$  as the smallest element of  $\mu$ ,  $\Sigma^{-1}$ ,  $\Omega^{-1}$ , and  $K()$ . In other words,

$$\Lambda \equiv \min\left\{\min_i |\mu_i|, \min_{i,j} |\Sigma_{ij}^{-1}|, \min_{i,j} |\Omega_{ij}^{-1}|, \min_{i,j,k} |K_{ijk}|, \min_{i,j} |\Sigma_{ij}|, \min_{i,j} |\Omega_{ij}|, \right\}$$

where  $K_{ijk} = K(\delta_j)_{ik}$  are the elements of the tensor  $K()$ .

**Definition 2.** Define  $\sigma_k$  as the smallest singular value of  $\Sigma$  and  $\Omega$ .

The proof relies on the fact that a row vector multiplied by a series of matrices, and finally multiplied by a column vector amounts to a sum over all possible products of individual entries in the vectors and matrices. With this in mind, if we bound the largest relative error of any particular entry in the matrix by, say,  $\omega$ , and there are, say,  $s$  parameters (vectors and

matrices) being multiplied together, then by simple algebra the total relative error of the sum over the products is bounded by  $\omega^s$ .

The proof then follows from two basic steps. First, one must bound the maximal relative error,  $\omega$  for any particular entry in the parameters, which can be done using central limit-type theorems and the quantity  $\Lambda$  described above. Then, to calculate the exponent  $s$  one simply counts the number of parameters multiplied together when calculating the probability of a particular sequence of observations.

Since each hidden node is associated with exactly one observed node, it follows that  $s = 12m + 2L$ , where  $L$  is the number of levels (for instance in our example “Kilroy was here” there are two levels).  $s$  can be easily computed for arbitrary tree topologies.

It follows from Foster et al. (2012) that we achieve a sample complexity

$$N \geq \frac{128k^2s^2}{\epsilon^2 \Lambda^2 \sigma_k^4} \log \left( \frac{2k}{\delta} \right) \cdot \underbrace{\frac{\approx 1}{\epsilon^2/s^2}}_{(\sqrt{s} + \epsilon - 1)^2} \quad (7)$$

leading to the theorem stated above.

Lastly, note that in reality one does not see  $\Lambda$  and  $\sigma_k$  but instead estimates of these quantities; Foster et al. (2012) shows how to incorporate the accuracy of the estimates into the sample complexity.

**Acknowledgement:** We would like to thank Emily Pitler for valuable feedback on the paper.

## Abstract

Topic models traditionally rely on the bag-of-words assumption. In data mining applications, this often results in end-users being presented with inscrutable lists of *topical unigrams*, single words inferred as representative of their topics. In this article, we present a hierarchical generative probabilistic model of *topical phrases*. The model simultaneously infers the location, length, and topic of phrases within a corpus and relaxes the bag-of-words assumption within phrases by using a hierarchy of Pitman-Yor processes. We use Markov chain Monte Carlo techniques for approximate inference in the model and perform slice sampling to learn its hyperparameters. We show via an experiment on human subjects that our model finds substantially better, more interpretable topical phrases than do competing models.

## 1 Introduction

Probabilistic topic models have been the focus of intense study in recent years. The archetypal topic model, Latent Dirichlet Allocation (LDA), posits that words within a document are conditionally independent given their topic (Blei et al., 2003). This “bag-of-words” assumption is a common simplification in which word order is ignored, but one which introduces undesirable properties into a model meant to serve as an unsupervised exploratory tool for data analysis.

When an end-user runs a topic model, the output he or she is often interested in is a list of topical

unigrams, words probable in a topic (hence, representative of it). In many situations, such as during the use of the topic model for the analysis of a new or ill-understood corpus, these lists can be insufficiently informative. For instance, if a layperson ran LDA on the NIPS corpus, he would likely get a topic whose most prominent words include *policy*, *value*, and *reward*. Seeing these words isolated from their context in a list would not be particularly insightful to the layperson unfamiliar with computer science research. An alternative to LDA which produced richer output like *policy iteration algorithm*, *value function*, and *model-based reinforcement learning* alongside the unigrams would be much more enlightening. Most situations where a topic model is actually useful for data exploration require a model whose output is rich enough to dispel the need for the user’s extensive prior knowledge of the data.

Furthermore, lists of topical unigrams are often made only marginally interpretable by virtue of their non-compositionality, the principle that a collocation’s meaning typically is not derivable from its constituent words (Schone and Jurafsky, 2001). For example, the meaning of *compact disc* as a music medium comes from neither the unigram *compact* nor the unigram *disc*, but emerges from the bigram as a whole. Moreover, non-compositionality is topic dependent; *compact disc* should be interpreted as a music medium in a music topic, and as a small region bounded by a circle in a mathematical topic. LDA is prone to decompose collocations into different topics and violate the principle of non-compositionality, and its unigram lists are harder to interpret as a result.

We present an extension of LDA called Phrase-Discovering LDA (PDLDA) that satisfies two desiderata: providing rich, interpretable output and honoring the non-compositionality of collocations. PDLDA is built in the tradition of the ‘‘Topical N-Gram’’ (TNG) model of Wang et al. (2007). TNG is a topic model which satisfies the first desideratum by producing lists of representative, topically cohesive  $n$ -grams of the form shown in Figure 1. We diverge from TNG by our addressing the second desideratum, and we do so through a more straightforward and intuitive definition of what constitutes a phrase and its topic. In the furtherance of our goals, we employ a hierarchical method of modeling phrases that uses dependent Pitman-Yor processes to ameliorate overfitting. Pitman-Yor processes have been successfully used in the past in  $n$ -gram (Teh, 2006) and LDA-based models (Wallach, 2006) for creating Bayesian language models which exploit word order, and they prove equally useful in this scenario of exploiting both word order and topics.

This article is organized as follows: after describing TNG, we discuss PDLDA and how PDLDA addresses the limitations of TNG. We then provide details of our inference procedures and evaluate our model against competing models on a subset of the TREC AP corpus (Harman, 1992) in an experiment on human subjects which assesses the interpretability of topical  $n$ -gram lists. The experiment is premised on the notion that topic models should be evaluated through a real-world task instead of through information-theoretic measures which often negatively correlate with topic quality (Chang et al., 2009).

## 2 Background: LDA and TNG

LDA represents documents as probabilistic mixtures of latent topics. Each word  $w$  in a corpus  $\mathbf{w}$  is drawn from a distribution  $\phi$  indexed by a topic  $z$ , where  $z$  is drawn from a distribution  $\theta$  indexed by its document  $d$ . The formal definition of LDA is

$$\begin{aligned} \theta_d &\sim \text{Dirichlet}(\alpha) & z_i | d, \theta &\sim \text{Discrete}(\theta_d) \\ \phi_z &\sim \text{Dirichlet}(\beta) & w_i | z_i, \phi &\sim \text{Discrete}(\phi_{z_i}) \end{aligned}$$

where  $\theta_d$  is document  $d$ ’s topic distribution,  $\phi_z$  is topic  $z$ ’s distribution over words,  $z_i$  is the topic assignment of the  $i$ th token, and  $w_i$  is the  $i$ th word.  $\alpha$  and  $\beta$  are hyperparameters to the Dirichlet priors.

Here and throughout the article, we use a bold font for vector notation: for example,  $\mathbf{z}$  is the vector of all topic assignments, and its  $i$ th entry,  $z_i$ , corresponds to the topic assignment of the  $i$ th token in the corpus.

TNG extends LDA to model  $n$ -grams of arbitrary length in order to create the kind of rich output for text mining discussed in the introduction. It does this by representing a joint distribution  $P(\mathbf{z}, \mathbf{c} | \mathbf{w})$  where each  $c_i$  is a Boolean variable that signals the start of a new  $n$ -gram beginning at the  $i$ th token.  $\mathbf{c}$  partitions a corpus into consecutive non-overlapping  $n$ -grams of various lengths. Formally, TNG differs from LDA by the distributional assumptions

$$\begin{aligned} w_i | w_{i-1}, z_i, c_i = 1, \phi &\sim \text{Discrete}(\phi_{z_i}) \\ w_i | w_{i-1}, z_i, c_i = 0, \sigma &\sim \text{Discrete}(\sigma_{z_i w_{i-1}}) \\ c_i | w_{i-1}, z_{i-1}, \pi &\sim \text{Bernoulli}(\pi_{z_{i-1} w_{i-1}}) \end{aligned}$$

where the new distributions  $\pi_{zw}$  and  $\sigma_{zw}$  are endowed with conjugate prior distributions:  $\pi_{zw} \sim \text{Beta}(\lambda)$  and  $\sigma_{zw} \sim \text{Dirichlet}(\delta)$ . When  $c_i = 0$ , word  $w_i$  is joined into a topic-specific bigram with  $w_{i-1}$ . When  $c_i = 1$ ,  $w_i$  is drawn from a topic-specific unigram distribution and is the start of a new  $n$ -gram.

An unusual feature of TNG is that words within a *topical  $n$ -gram*, a sequence of words delineated by  $\mathbf{c}$ , do not share the same topic. To compensate for this after running a Gibbs sampler, Wang et al. (2007) analyze each topical  $n$ -gram post hoc as if the topic of the final word in the  $n$ -gram was the topic assignment of the entire  $n$ -gram. Though this design simplifies inference, we perceive it as a shortcoming since the aforementioned principle of non-compositionality supports the intuitive idea that each collocation ought to be drawn from a single topic. Another potential drawback of TNG is that the topic-specific bigram distributions  $\sigma_{zw}$  share no probability mass between each other or with the unigram distributions  $\phi_z$ . Hence, observing a bigram under one topic does not make it more likely under another topic or make its constituent unigrams more probable. To be more concrete, in TNG, observing *space shuttle* under a topic  $z$  (or under two topics, one for each word) regrettably does not make *space shuttle* more likely under a topic  $z' \neq z$ , nor does it make observing *shuttle* more likely under any topic. Smoothing, the sharing of probability mass between

Figure 1: Six out of one hundred topics found by our model, PDLDA, on the Touchstone Applied Science Associates (TASA) corpus (Landauer and Dumais, 1997). Each column within a box shows the top fifteen phrases for a topic and is restricted to phrases of a minimum length of one, two, or three words, respectively. The rows are ordered by likelihood.

Figure 2: PDLDA drawn in plate notation.

contexts, is desirable so that a model like this does not need to independently infer the probability of every bigram under every topic. The advantages of smoothing are especially pronounced for small corpora or for a large number of topics. In these situations, the observed number of bigrams in a given topic will necessarily be very small and thus not support strong inferences.

### 3 PDLDA

A more natural definition of a topical phrase, one which meets our second desideratum, is to have each phrase possess a single topic. We adopt this intuitive idea in PDLDA. It can also be understood through the lens of Bayesian changepoint detection. Changepoint detection is used in time series models in which the generative parameters periodically change abruptly (Adams and MacKay, 2007). Viewing a sentence as a time series of words, we posit that the generative parameter, the topic, changes period-

ically in accordance with the changepoint indicators  $\mathbf{c}$ . Because there is no restriction on the number of words between changepoints, topical phrases can be arbitrarily long but will always have a single topic drawn from  $\theta_d$ .

The full definition of PDLDA is given by

$$\begin{aligned}
 w_i \mid \mathbf{u} &\sim \text{Discrete}(G_{\mathbf{u}}) \\
 G_{\mathbf{u}} &\sim \text{PYP}(a_{|\mathbf{u}|}, b_{|\mathbf{u}|}, G_{\pi(\mathbf{u})}) \\
 G_{\emptyset} &\sim \text{PYP}(a_0, b_0, H) \\
 z_i \mid d, z_{i-1}, \theta_d, c_i &\sim \begin{cases} \delta_{z_{i-1}} & \text{if } c_i = 0 \\ \text{Discrete}(\theta_d) & \text{if } c_i = 1 \end{cases} \\
 c_i \mid w_{i-1}, z_{i-1}, \pi &\sim \text{Bernoulli}(\pi_{w_{i-1}z_{i-1}})
 \end{aligned}$$

with the prior distributions over the parameters as

$$\begin{aligned}
 \theta_d &\sim \text{Dirichlet}(\alpha) & \pi_{zw} &\sim \text{Beta}(\lambda) \\
 a_{|\mathbf{u}|} &\sim \text{Beta}(\rho) & b_{|\mathbf{u}|} &\sim \text{Gamma}(\epsilon)
 \end{aligned}$$

Like TNG, PDLDA assumes that the probability of a changepoint  $c_{i+1}$  after the  $i$ th token depends on the current topic  $z_i$  and word  $w_i$ . This causes the length of a phrase to depend on its topic and constituent words. The changepoints explicitly model which words tend to start and end phrases in each document. Depending on  $c_i$ ,  $z_i$  is either set deterministically to the preceding topic (when  $c_i = 0$ ) or is drawn anew from  $\theta_d$  (when  $c_i = 1$ ). In this way, each topical phrase has a single topic drawn from its document's topic distribution. As in TNG, the parameters  $\pi_{zw}$  and  $\theta_d$  are given conjugate priors parameterized by  $\lambda$  and  $\alpha$ .

Let  $\mathbf{u}$  be a *context vector* consisting of the phrase topic and the past  $m$  words:  $\mathbf{u} \triangleq \langle z_i, w_{i-1}, w_{i-2}, \dots, w_{i-m} \rangle$ . The operator  $\pi(\mathbf{u})$  denotes the prefix of  $\mathbf{u}$ , the vector with the rightmost element of  $\mathbf{u}$  removed.  $|\mathbf{u}|$  denotes the length of  $\mathbf{u}$ , and  $\emptyset$  represents an empty context. For practical reasons, we pad  $\mathbf{u}$  with a special start symbol when the context overlaps a phrase boundary. For example, the first word  $w_i$  of a phrase beginning at a position  $i$  necessarily has  $c_i = 1$ ; consequently, all the preceding words  $w_{i-j}$  in the context vector are treated as start symbols so that  $w_i$  is effectively drawn from a topic-specific unigram distribution.

In PDLDA, each token is drawn from a distribution conditioned on its context  $\mathbf{u}$ . When  $m = 1$ , this conditioning is analogous to TNG's word distribution. However, in contrast with TNG, the word

Figure 3: Illustration of the hierarchical Pitman-Yor process for a toy two-word vocabulary  $V = \{honda, civic\}$  and two-topic ( $T = 2$ ) model with  $m = 1$ . Each node  $G$  in the tree is a Pitman-Yor process whose base distribution is its parent node, and  $H$  is a uniform distribution over  $V$ . When, for example, the context is  $\mathbf{u} = z_1 : honda$ , the darkened path is followed and the probability of the next word is calculated from the shaded node using Equation 1, which combines predictions from all the nodes along the darkened path.

distributions used are Pitman-Yor processes (PYPs) linked together into a tree structure. This hierarchical construction creates the desired smoothing among different contexts. The next section explains this hierarchical distribution in more detail.

### 3.1 Hierarchical Pitman-Yor process

Words in PDLDA are emitted from  $G_{\mathbf{u}}$ , which has a PYP prior (Pitman and Yor, 1997). PYPs are a generalization of the Dirichlet Process, with the addition of a discount parameter  $0 \leq a \leq 1$ . When considering the distribution of a sequence of words  $\mathbf{w}$  drawn *iid* from a PYP-distributed  $G$ , one can analytically marginalize  $G$  and consider the resulting conditional distribution of  $\mathbf{w}$  given its parameters  $a$ ,  $b$ , and base distribution  $\phi$ . This marginal can best be understood by considering the distribution of any  $w_i | w_1, \dots, w_{i-1}, a, b, \phi$ , which is characterized by a generative process known as the generalized *Chinese Restaurant Process* (CRP) (Pitman, 2002). In the CRP metaphor, one imagines a restaurant with an unbounded number of tables, where each table has one shared dish (a draw from  $\phi$ ) and can seat an unlimited number of customers. The CRP specifies a

process by which customers entering the restaurant choose a table to sit at and, consequently, the dish they eat. The first customer to arrive always sits at the first table. Subsequent customers sit at an occupied table  $k$  with probability proportional to  $c_k - a$  and choose a new unoccupied table with probability proportional to  $b + ta$ , where  $c_k$  is the number of customers seated at table  $k$  and  $t$  is the number of occupied tables in  $G$ . For our language modeling purposes, “customers” are word tokens and “dishes” are word types.

The hierarchical PYP (HPYP) is an intuitive recursive formulation of the PYP in which the base distribution  $\phi$  is itself PYP-distributed. Figure 3 demonstrates this principle as applied to PDLDA. The hierarchy forms a tree structure, where leaves are restaurants corresponding to full contexts and internal nodes correspond to partial contexts. An edge between a parent and child node represents a dependency of the child on the parent, where the base distribution of the child node is its parent. This smooths each context’s distribution like the Bayesian  $n$ -gram model of Teh (2006), which is a Bayesian version of interpolated Kneser-Ney smoothing (Chen and Goodman, 1998). One ramification of this setup is that if a word occurs in a context  $\mathbf{u}$ , the sharing makes it more likely in other contexts that have something in common with  $\mathbf{u}$ , such as a shared topic or word.

The HPYP gives the following probability for a word following the context  $\mathbf{u}$  being  $w$ :

$$P_{\mathbf{u}}(w | \tau, \mathbf{a}, \mathbf{b}) = \frac{c_{\mathbf{u}w} - a_{|\mathbf{u}|} t_{\mathbf{u}w}}{b_{|\mathbf{u}|} + c_{\mathbf{u}\cdot}} + \frac{b_{|\mathbf{u}|} + a_{|\mathbf{u}|} t_{\mathbf{u}\cdot}}{b_{|\mathbf{u}|} + c_{\mathbf{u}\cdot}} P_{\pi(\mathbf{u})}(w | \tau, \mathbf{a}, \mathbf{b}) \quad (1)$$

where  $P_{\pi(\emptyset)}(w | \tau, \mathbf{a}, \mathbf{b}) = G_{\emptyset}(w)$ ,  $c_{\mathbf{u}w}$  is the number of customers eating dish  $w$  in restaurant  $\mathbf{u}$ , and  $t_{\mathbf{u}w}$  is the number of tables serving  $w$  in restaurant  $\mathbf{u}$ , and  $\tau$  represents the current seating arrangement. Here and throughout the rest of the paper, we use a dot to indicate marginal counts: e.g.,  $c_{\mathbf{u}\cdot} = \sum_k c_{\mathbf{u}wk}$  where  $c_{\mathbf{u}wk}$  is the number of customers eating  $w$  in  $\mathbf{u}$  at table  $k$ . The base distribution of  $G_{\emptyset}$  was chosen to be uniform:  $H(w) = 1/V$  with  $V$  being the vocabulary size. The above equation an interpolation between distributions of context lengths

$|\mathbf{u}|, |\mathbf{u}| - 1, \dots, 0$  and realizes the sharing of statistical strength between different contexts.

### 3.2 Inference

In this section, we describe Markov chain Monte Carlo procedures to sample from  $P(\mathbf{z}, \mathbf{c}, \tau | \mathbf{w}, U)$ , the posterior distribution over topic assignments  $\mathbf{z}$ , phrase boundaries  $\mathbf{c}$ , and seating arrangements  $\tau$  given an observed corpus  $\mathbf{w}$ . Let  $U$  be shorthand for  $\alpha, \lambda, \mathbf{a}, \mathbf{b}$ . In order to draw samples from  $P(\mathbf{z}, \mathbf{c}, \tau | \mathbf{w}, U)$ , we employ a Metropolis-Hastings sampler for approximate inference. The sampler we use is a *collapsed* sampler (Griffiths and Steyvers, 2004), wherein  $\theta, \phi$ , and  $\mathbf{G}$  are analytically marginalized. Because we marginalize each  $G$ , we use the Chinese Restaurant Franchise representation of the hierarchical PYPs (Teh, 2006). However, rather than onerously storing the table assignment of every token in  $\mathbf{w}$ , we store only the counts of how many tables there are in a restaurant and how many customers are sitting at each table in that restaurant. We refer the inquisitive reader to the appendix of Teh (2006) for further details of this procedure.

Our sampling strategy for a given token  $i$  in document  $d$  is to jointly propose changes to the changepoint  $c_i$  and topic assignment  $z_i$ , and then to the seating arrangement  $\tau$ . Recall that according to the model, if  $c_i = 0$ ,  $z_i = z_{i-1}$ ; otherwise  $z_i$  is generated from the topic distribution for document  $d$ . Since the topic assignment remains the same until a new changepoint at a position  $i'$  is reached, each token  $w_j$  for  $j$  from position  $i$  until  $i' - 1$  will depend on  $z_i$  because for these  $j$ ,  $z_j = z_i$ . We call this set of tokens the *phrase suffix* of the  $i$ th token and denote it  $s(i)$ . More formally, let  $s(i)$  be the maximal set of continuous indices  $j \geq i$  including  $i$  such that, if  $j \neq i$ ,  $c_j = 0$ . That is,  $s(i)$  are the indices comprising the remainder of the phrase beginning at position  $i$ . In addition, let  $x(i)$  indicate the *extended suffix* version of  $s(i)$  which includes one additional index:  $x(i) \triangleq \{s(i) \cup \{\max(s(i)) + 1\}\}$ . In addition to the words in the suffix  $s(i)$ , the changepoint indicator variables  $c_j$  for  $j$  in  $x(i)$  are also conditioned on  $z_i$ . To make these dependencies more explicit, we refer to  $\mathbf{z}_{s(i)} \triangleq z_j \forall j \in s(i)$ , which are constrained by the model to share a topic.

The variables that depend directly on  $z_i, c_i$  are  $\mathbf{z}_{s(i)}, \mathbf{w}_{s(i)}, \mathbf{c}_{x(i)}$ . The proposal distribution first

draws from a multinomial over  $T + 1$  options: one option for  $c_i = 0, z_i = z_{i-1}$ ; and one for  $c_i = 1$  paired with each possible  $z_i = z \in 1 \dots T$ . This is given by

$$P(\mathbf{z}_{s(i)}, c_i | \mathbf{z}_{\neg s(i)}, \mathbf{c}_{\neg i}, \tau_{\neg s(i)}, \mathbf{w}, U) \propto \prod_{j \in x(i)} \frac{n_{z_{j-1} w_{j-1} c_j} + \lambda_{c_j}}{n_{z_{j-1} w_{j-1} \cdot} + \lambda_0 + \lambda_1} \prod_{j \in s(i)} P(z_j | \mathbf{c}, \mathbf{z}_{\neg s(j)}, U) P_{\mathbf{u}_j}(\mathbf{w}_j | \tau_{\neg s(i)}, U)$$

with

$$P(z_j | \mathbf{c}, \mathbf{z}_{\neg s(j)}, U) = \begin{cases} \frac{n_{dz_j}^{\neg s(j)} + \alpha}{n_d^{\neg s(j)} + T\alpha} & \text{if } c_j = 1 \\ \delta_{z_j, z_{j-1}} & \text{if } c_j = 0 \end{cases}$$

where  $P_{\mathbf{u}_j}(\mathbf{w}_j | \tau_{\neg s(i)}, U)$  is given by Equation 1,  $T$  is the number of topics,  $n_{dz}^{\neg s(j)}$  is the number of phrases in document  $d$  that have topic  $z$  when  $s(j)$ 's assignment is excluded, and  $n_{zwc}^{\neg s(j)}$  is the number of times a changepoint  $c$  has followed a word  $w$  with topic  $z$  when  $s(j)$ 's assignments are excluded.

After drawing a proposal for  $c_i, \mathbf{z}_{s(i)}$  for token  $i$ , the sampler adds a customer eating  $w_i$  to a table serving  $w_i$  in restaurant  $\mathbf{u}_i$ . An old table  $k$  is selected with probability  $\propto \max(0, c_{\mathbf{u}wk} - a_{|\mathbf{u}|})$  and a new table is selected with probability  $\propto (b_{|\mathbf{u}_i|} + a_{|\mathbf{u}_i|} t_{\mathbf{u}_i \cdot}) P_{\pi(\mathbf{u})}(w_i)$ .

Let  $\mathbf{z}'_{s(i)}, c'_i, \tau'_{s(i)}$  denote the proposed change to  $\mathbf{z}_{s(i)}, c_i, \tau_{s(i)}$ . We accept the proposal with probability  $\min(A, 1)$  where

$$A = \frac{\hat{P}(\mathbf{z}'_{s(i)}, c'_i, \tau'_{s(i)}) Q(\mathbf{z}_{s(i)}, c_i, \tau_{s(i)})}{\hat{P}(\mathbf{z}_{s(i)}, c_i, \tau_{s(i)}) Q(\mathbf{z}'_{s(i)}, c'_i, \tau'_{s(i)})}$$

where  $Q$  is the proposal distribution and  $\hat{P}$  is the true unnormalized distribution.  $\hat{P}$  differs from  $Q$  in that the probability of each word  $w_j$  and the seating arrangement depends only on  $\neg s(j)$ , as opposed to the simplification of using  $\neg s(i)$ . Almost all proposals are accepted; hence, this theoretically motivated Metropolis Hastings correction step makes little difference in practice.

Because the parameters  $\mathbf{a}$  and  $\mathbf{b}$  have no intuitive interpretation and we lack any strong belief about what they should be, we give them vague priors where  $\rho_1 = \rho_2 = 1$  and  $\epsilon_1 = 10, \epsilon_2 = .1$ . We then

interleave a slice sampling algorithm (Neal, 2000) between sweeps of the Metropolis-Hastings sampler to learn these parameters. We chose not to do inference on  $\alpha$  in order to make the tests of our model against TNG more equitable.

## 4 Related Work

An integral part of modeling topical phrases is the relaxation of the bag-of-words assumption in LDA. There are many models that make this relaxation. Among them, Griffiths and Steyvers (2005) present a model in which words are generated either conditioned on a topic or conditioned on the previous word in a bigram, but not both. They use this to model human performance on a word-association task. Wallach (2006) experiments with incorporating LDA into a bigram language model. Her model uses a hierarchical Dirichlet to share parameters across bigrams in a topic in a manner similar to our use of PYPs, but it lacks a notion of the topic being shared between the words in an  $n$ -gram. The Hidden Topic Markov Model (HTMM) (Gruber et al., 2007) assumes that all words in a sentence have the same topic, and consecutive sentences are likely to have the same topic. By dropping the independence assumption among topics, HTMM is able to achieve lower perplexity scores than LDA at minimal additional computational costs. These models are unconcerned with topical  $n$ -grams and thus do not model phrases.

Johnson (2010) presents an Adaptor Grammar model of topical phrases. Adaptor Grammars are a framework for specifying nonparametric Bayesian models over context-free grammars in which certain subtrees are “memoized” or remembered for reuse. In Johnson’s model, subtrees corresponding to common phrases for a topic are memoized, resulting in a model in which each topic is associated with a distribution over whole phrases. While it is a theoretically elegant method for finding topical phrases, for large corpora we found inference to be impractically slow.

## 5 Phrase Intrusion Experiment

Perplexity is the typical information theoretic measure of language model quality used in lieu of extrinsic measures, which are more difficult and costly to run. However, it is well known that perplexity

scores may negatively correlate with actual quality as assessed by humans (Chang et al., 2009). With that fact in mind, we expanded the methodology of Chang et al. (2009) to create a “phrase intrusion” task that quantitatively compares the quality of the topical  $n$ -gram lists produced by our model against those of other models.

Each of 48 subjects underwent 80 trials of a web-based experiment on Amazon Mechanical Turk, a reliable (Paolacci et al., 2010) and increasingly common venue for conducting online experiments. In each trial, a subject is presented with a randomly ordered list of four  $n$ -grams (cf. Figure 4). Each subject’s task is to select the *intruder phrase*, a spurious  $n$ -gram not belonging with the others in the list. If, other than the intruder, the items in the list are all on the same topic, then subjects can easily identify the intruder because the list is semantically cohesive and makes sense. If the list is incohesive and has no discernible topic, subjects must guess arbitrarily and performance is at random.

To construct each trial’s list, we chose two topics  $z$  and  $z'$  ( $z \neq z'$ ), then selected the three most probable  $n$ -grams from  $z$  and the intruder phrase, an  $n$ -gram probable in  $z'$  and improbable in  $z$ . This design ensures that the intruder is not identifiable due solely to its being rare. Interspersed among the phrase intrusion trials were several simple screening trials intended to affirm that subjects possessed a minimal level of attentiveness and reading comprehension. For example, one such screening trial presented subjects with the list *banana, apple, television, orange*. Subjects who got any of these trials

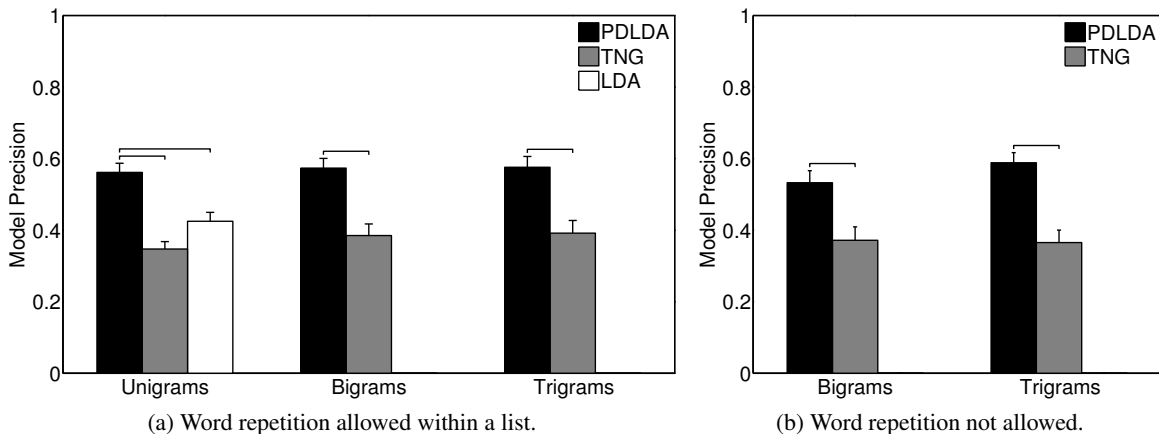

Figure 5: An across-subject measure of the ability to detect intruders as a function of  $n$ -gram size and model. Excluding trials with repeated words does not qualitatively affect the results.

wrong were excluded from our analyses.

Each subject was presented with trials constructed from the output of PDLDA and TNG for unigrams, bigrams, and trigrams. For unigrams, we also tested the output of the original smoothed LDA (Blei et al., 2003). The experiment was conducted twice for a 2,246-document subset of the TREC AP corpus (Blei et al., 2003; Harman, 1992): the first time proceeded as described above, but the second time did not allow word repetition within a topic’s list. The topical phrases found by TNG and PDLDA often revolve around a central  $n$ -gram, with other words pre- or post- appended to it. In this intrusion experiment, any  $n$ -gram not containing the central word or phrase may be trivially identifiable, regardless of its relevance to the topic. For example, the intruder in Trial 4 of Figure 4 is easily identifiable even if a subject does not understand English. This second experiment was designed to test whether our conclusions hinge on word repetition.

We used the MALLET toolbox (McCallum, 2002) for the implementations of LDA and TNG. Each model was run with 100 topics for 5,000 iterations. We set  $m = 2$ ,  $\alpha = .01$ ,  $\beta = .01$ ,  $\lambda = 1$ ,  $\pi_1 = \pi_2 = 1$ ,  $\rho_1 = 10$ , and  $\rho_2 = .1$ . For all models, we treated certain punctuation as the start of a phrase by setting  $c_j = 1$  for all tokens  $j$  immediately following periods, commas, semicolons, and exclamation and question marks. To reduce runtime, we removed stopwords occurring in the MALLET tool-

box’s stopwords list. Because TNG and LDA had trouble with single character words not in the stoplist, we manually removed them before the experiment. Any token immediately following a removed word was treated as if it were the start of a phrase.

As in Chang et al. (2009), performance is measured via model precision, the fraction of subjects agreeing with the model. It is defined as  $MP_k^{m,n} = \sum_s \mathbb{1}(i_{k,s}^{m,n} = \omega_{k,s}^{m,n}) / S$  where  $\omega_{k,s}^{m,n}$  is the index of the intruding  $n$ -gram for subject  $s$  among the words generated from the  $k$ th topic of model  $m$ ,  $i_{k,s}^{m,n}$  is the intruder selected by  $s$ , and  $S$  is the number of subjects. The model precisions are shown in Figure 5. PDLDA achieves the highest precision in all conditions. Model precision is low in all models, which is a reflection of how challenging the task is on a small corpus laden with proper nouns and low-frequency words. Figure 5b demonstrates that the outcome of the experiment does not depend strongly on whether the topical  $n$ -gram lists have repeated words.

## 6 Conclusion

We presented a topic model which simultaneously segments a corpus into phrases of varying lengths and assigns topics to them. The topical phrases found by PDLDA are much richer sources of information than the topical unigrams typically produced in topic modeling. As evidenced by the phrase-intrusion experiment, the topical  $n$ -gram lists that PDLDA finds are much more interpretable than

those found by TNG.

The formalism of Bayesian changepoint detection arose naturally from the intuitive assumption that the topic of a sequence of tokens changes periodically, and that the tokens in between changepoints comprise a phrase. This formalism provides a principled way to discover phrases within the LDA framework. We presented a model embodying these principles and showed how to incorporate dependent Pitman-Yor processes into it.

## Abstract

We describe a nonparametric model and corresponding inference algorithm for learning Synchronous Context Free Grammar derivations for parallel text. The model employs a Pitman-Yor Process prior which uses a novel base distribution over synchronous grammar rules. Through both synthetic grammar induction and statistical machine translation experiments, we show that our model learns complex translational correspondences— including discontiguous, many-to-many alignments—and produces competitive translation results. Further, inference is efficient and we present results on significantly larger corpora than prior work.

## 1 Introduction

In the twenty years since Brown et al. (1992) pioneered the first word-based statistical machine translation (SMT) models substantially more expressive models of translational equivalence have been developed. The prevalence of complex phrasal, discontiguous, and non-monotonic translation phenomena in real-world applications of machine translation has driven the development of hierarchical and syntactic models based on synchronous context-free grammars (SCFGs). Such models are now widely used in translation and represent the state-of-the-art in most language pairs (Galley et al., 2004; Chiang, 2007). However, while the models used for translation have evolved, the way in which they are learnt has not: naïve word-based models are still used to infer translational correspondences from parallel corpora.

In this work we bring the learning of the minimal units of translation in step with the representational power of modern translation models. We present a nonparametric Bayesian model of translation based on SCFGs, and we use its posterior distribution to infer synchronous derivations for a parallel corpus using a novel Gibbs sampler. Our model is able to: 1) directly model many-to-many alignments, thereby capturing non-compositional and idiomatic translations; 2) align discontiguous phrases in both the source and target languages; 3) have no restrictions on the length of a rule, the number of non-terminal symbols per rule, or their configuration.

Learning synchronous grammars is hard due to the high polynomial complexity of dynamic programming and the exponential space of possible rules. As such most prior work for learning SCFGs has relied on inference algorithms that were heuristically constrained or biased by word-based alignment models and small experiments (Wu, 1997; Zhang et al., 2008; Blunsom et al., 2009; Neubig et al., 2011). In contrast to these previous attempts, our SCFG model scales to large datasets (over 1.3M sentence pairs) without imposing restrictions on the form of the grammar rules or otherwise constraining the set of learnable rules (e.g., with a word alignment).

We validate our sampler by demonstrating its ability to recover grammars used to generate synthetic datasets. We then evaluate our model by inducing word alignments for SMT experiments in several typologically diverse language pairs and across a range of corpora sizes. Our results attest to our model’s ability to learn synchronous grammars encoding complex translation phenomena.

## 2 Prior Work

The goal of directly inducing phrasal translation models from parallel corpora has received a lot of attention in the NLP and SMT literature. Marcu and Wong (2002) presented an ambitious maximum likelihood model and EM inference algorithm for learning phrasal translation representations. The first issue this model faced was a massive parameter space and intractable inference. However a more subtle issue is that likelihood based models of this form suffer from a degenerate solution, resulting in the model learning whole sentences as phrases rather than minimal units of translation. DeNero et al. (2008) recognised this problem and proposed a nonparametric Bayesian prior for contiguous phrases. This had the dual benefits of biasing the model towards learning minimal translation units, and integrating out the parameters such that a much smaller set of statistics would suffice for inference with a Gibbs sampler. However this work fell short by not evaluating the model independently, instead only presenting results in which it was combined with a standard word-alignment initialisation, thus leaving open the question of its efficacy.

The fact that flat phrasal models lack a structured approach to reordering has led many researchers to pursue SCFG induction instead (Wu, 1997; Cherry and Lin, 2007; Zhang et al., 2008; Blunsom et al., 2009). The asymptotic time complexity of the inside algorithm for even the simplest SCFG models is  $O(|s|^3|t|^3)$ , too high to be practical for most real translation data. A popular solution to this problem is to heuristically restrict inference to derivations which agree with an independent alignment model (Cherry and Lin, 2007; Zhang et al., 2008). However this may have the unintended effect of biasing the model back towards the initial alignments that they attempt to improve upon. More recently Neubig et al. (2011) reported a novel Bayesian model for phrasal alignment and extraction that was able to model phrases of multiple granularities via a synchronous Adaptor Grammar. However this model suffered from the common problem of intractable inference and results were presented for a very small number of samples from a heuristically pruned beam, making interpreting the results difficult.

Blunsom et al. (2009) presented an approach similar to ours that implemented a Gibbs sampler for a nonparametric Bayesian model of ITG. While that work managed to scale to a non-trivially sized corpus, like other works it relied on a state-of-the-art word alignment model for initialisation. Our model goes further by allowing discontinuous phrasal translation units. Surprisingly, the freedom that this extra power affords allows the Gibbs sampler we propose to mix more quickly, allowing state-of-the-art results from a simple initialiser.

## 3 Model

We use a nonparametric generative model based on the 2-parameter Pitman-Yor process (PYP) (Pitman and Yor, 1997), a generalisation of the Dirichlet Process, which has been used for various NLP modeling tasks with state-of-the-art results such as language modeling, word segmentation, text compression and part of speech induction (Teh, 2006; Goldwater et al., 2006; Wood et al., 2011; Blunsom and Cohn, 2011). In this section we first provide a brief definition of the SCFG formalism and then describe our PYP prior for them.

### 3.1 Synchronous Context-Free Grammar

An synchronous context-free grammar (SCFG) is a 5-tuple  $\langle \Sigma, \Delta, V, S, R \rangle$  that generalises context-free grammar to generate strings concurrently in two languages (Lewis and Stearns, 1968).  $\Sigma$  is a finite set of source language terminal symbols,  $\Delta$  is a finite set of target language terminal symbols,  $V$  is a set of nonterminal symbols, with a designated start symbol  $S$ , and  $R$  is a set of synchronous rewrite rules. A string pair is generated by starting with the pair  $\langle S_1 \mid S_1 \rangle$  and recursively applying rewrite rules of the form  $X \rightarrow \langle \mathbf{s}, \mathbf{t}, \mathbf{a} \rangle$  where the left hand side (LHS)  $X$  is a nonterminal in  $V$ ,  $\mathbf{s}$  is a string in  $(\Sigma \cup V)^*$ ,  $\mathbf{t}$  is a string in  $(\Delta \cup V)^*$  and  $\mathbf{a}$  specifies a one-to-one mapping (bijection) between nonterminal symbols in  $\mathbf{s}$  and  $\mathbf{t}$ . The following are examples:<sup>1</sup>

$VP \rightarrow \langle \textit{schlage NP}_1 \textit{ NP}_2 \textit{ vor} \mid \textit{suggest NP}_2 \textit{ to NP}_1 \rangle$   
 $NP \rightarrow \langle \textit{die Kommission} \mid \textit{the commission} \rangle$

<sup>1</sup>The nonterminal alignment  $\mathbf{a}$  is indicated through subscripts on the nonterminals.

In a probabilistic SCFG, rules are associated with probabilities such that the probabilities of all rewrites of a particular LHS category sum to 1.

Translation with SCFGs is carried out by parsing the source language with the monolingual source language projection of the grammar (using standard monolingual parsing algorithms), which induces a parallel tree structure and translation in the target language (Chiang, 2007). Alignment or synchronous parsing is the process of concurrently parsing both the source and target sentences, uncovering the derivation or derivations that give rise to a string pair (Wu, 1997; Dyer, 2010).

Our goal is to infer the most probable SCFG derivations that explain a corpus of parallel sentences, given a nonparametric prior over probabilistic SCFGs. In this work we will consider grammars with a single nonterminal category  $X$ .

### 3.2 Pitman-Yor Process SCFG

Before training we have no way of knowing how many rules will be needed in our grammar to adequately represent the data. By using the Pitman-Yor process as a prior on the parameters of a synchronous grammar we can formulate a model which prefers smaller numbers of rules that are reused often, thereby avoiding degenerate grammars consisting of large, overly specific rules. However, as the data being fit grows, the model can become more complex. The PYP is parameterised by a *discount* parameter  $d$ , a *strength* parameter  $\theta$ , and the base distribution  $\mathcal{G}_0$ , which gives the prior probability of an event (in our case, events are rules) before any observations have occurred. The discount is subtracted from each positive rule count and dampens the rich get richer effect where frequent rules are given higher probability compared to infrequent ones. The strength parameter controls the variance, or concentration, about the base distribution.

In our model, a draw from a PYP is a distribution over SCFG rules with a particular LHS (in fact, it is a distribution over all well-formed rules). From this distribution we can in turn draw individual rules:

$$\begin{aligned} \mathcal{G}_X &\sim \text{PY}(d, \theta, \mathcal{G}_0), \\ X \rightarrow \langle \mathbf{s}, \mathbf{t}, \mathbf{a} \rangle &\sim \mathcal{G}_X. \end{aligned}$$

Although the PYP has no known analytical form, we can marginalise out the  $\mathcal{G}_X$ 's and reason about

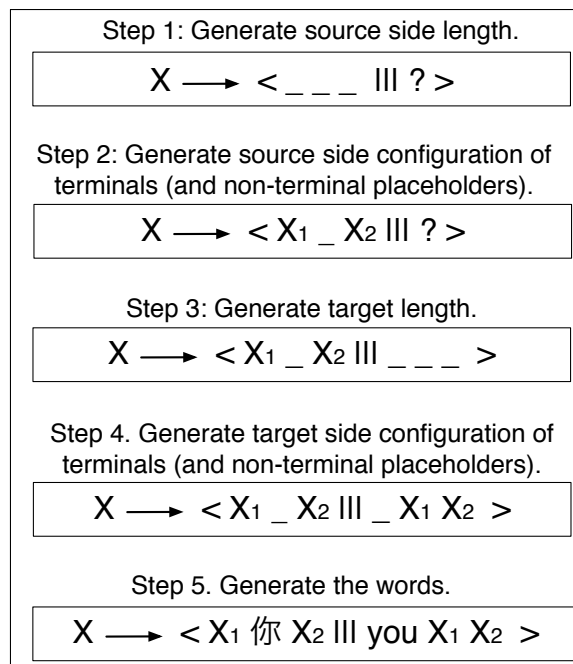

Figure 1: Example generation of a synchronous grammar rule in our  $\mathcal{G}_0$ .

individual rules directly using the process described by Teh (2006). In this process, at time  $n$  a rule  $r_n$  is generated by stochastically deciding whether to make another copy of a previously generated rule or to draw a new one from the base distribution,  $\mathcal{G}_0$ . Let  $\varphi = (\varphi_1, \varphi_2, \dots)$  be the sequence of draws from  $\mathcal{G}_0$ ; thus  $|\varphi|$  is the total number of draws from  $\mathcal{G}_0$ . A rule  $r_n$  corresponds to a selection of a  $\varphi_k$ . Let  $c_k$  be a counter indicating the number of times  $\varphi_k$  has been selected. In particular, we set  $r_n$  to  $\varphi_k$  with probability

$$\frac{c_k - d}{\theta + n},$$

and increment  $c_k$ , or with probability

$$\frac{\theta + d \cdot |\varphi|}{\theta + n},$$

we draw a new rule from  $\mathcal{G}_0$ , append it to  $\varphi$ , and use it for  $r_n$ .

### 3.3 Base Distribution

The base distribution  $\mathcal{G}_0$  for the PYP assigns probability to a rule based our belief about what constitutes a good rule independent of observing any of

the data. We describe a novel generative process for all rules  $X \rightarrow \langle \mathbf{s}, \mathbf{t}, \mathbf{a} \rangle$  that encodes these beliefs.

We describe the generative process generally here in text, and readers may refer to the example in Figure 1. The process begins by generating the source length (total number of terminal and nonterminal symbols, written  $|\mathbf{s}|$ ) by drawing from a Poisson distribution with mean 1:

$$|\mathbf{s}| \sim \text{Poisson}(1) .$$

This assigns high probability to shorter rules, but arbitrarily long rules are possible with a low probability. Then, for every position in  $\mathbf{s}$ , we decide whether it will contain a terminal or nonterminal symbol by repeated, independent draws from a Bernoulli distribution. Since we believe that shorter rules should be relatively more likely to contain terminal symbols than longer rules, we define the probability of a terminal symbol to be  $\phi^{|\mathbf{s}|}$  where  $0 < \phi < 1$  is a hyperparameter.

$$s_i \sim \text{Bernoulli}(\phi^{|\mathbf{s}|}) \quad \forall i \in [1, |\mathbf{s}|] .$$

We next generate the length of the target side of the rule. Let  $\#_{\text{NT}}(\mathbf{s})$  denote the number of nonterminal symbols we generated in  $\mathbf{s}$ , i.e., the arity of the rule. Our intuition here is that source and target lengths should be similar. However, to ensure that the rule is well-formed,  $\mathbf{t}$  must contain exactly as many nonterminal symbols as the source does. We therefore draw the number of target terminal symbols from a Poisson whose mean is the number of terminal symbols in the source, plus a small constant  $\lambda_0$  to ensure that it is greater than zero:

$$|\mathbf{t}| - \#_{\text{NT}}(\mathbf{s}) \sim \text{Poisson}(|\mathbf{s}| - \#_{\text{NT}}(\mathbf{s}) + \lambda_0) .$$

We then determine whether each position in  $\mathbf{t}$  is a terminal or nonterminal symbol by drawing uniformly from the bag of  $\#_{\text{NT}}(\mathbf{s})$  source nonterminals and  $|\mathbf{t}| - \#_{\text{NT}}(\mathbf{s})$  terminal indicators, without replacement. At this point we have created a rule template which indicates how large the rule is, whether each position contains a terminal or nonterminal symbol, and the reordering of the source nonterminals  $\mathbf{a}$ . To conclude the process we must select the terminal types from the source and target

vocabularies. To do so, we use the following distribution:

$$P_{\text{terminals}}(\mathbf{s}, \mathbf{t}) = \frac{P_{M1 \leftarrow}(\mathbf{s}, \mathbf{t}) + P_{M1 \rightarrow}(\mathbf{s}, \mathbf{t})}{2}$$

where  $P_{M1 \leftarrow}(\mathbf{s}, \mathbf{t})$  ( $P_{M1 \rightarrow}(\mathbf{s}, \mathbf{t})$ ) first generates the source (target) terminals from uniform draws from the vocabulary, then generates the string in the other language according to IBM MODEL 1, marginalizing over the alignments (Brown et al., 1993).

## 4 Gibbs Sampler

In this section we introduce a Gibbs sampler that enables us to perform posterior inference given a corpus of sentence pairs. Our innovation is to represent the synchronous derivation of a sentence pair in a hierarchical 4-dimensional binary alignment grid, with elements  $z_{[s,t,u,v]} \in \{0, 1\}$ .

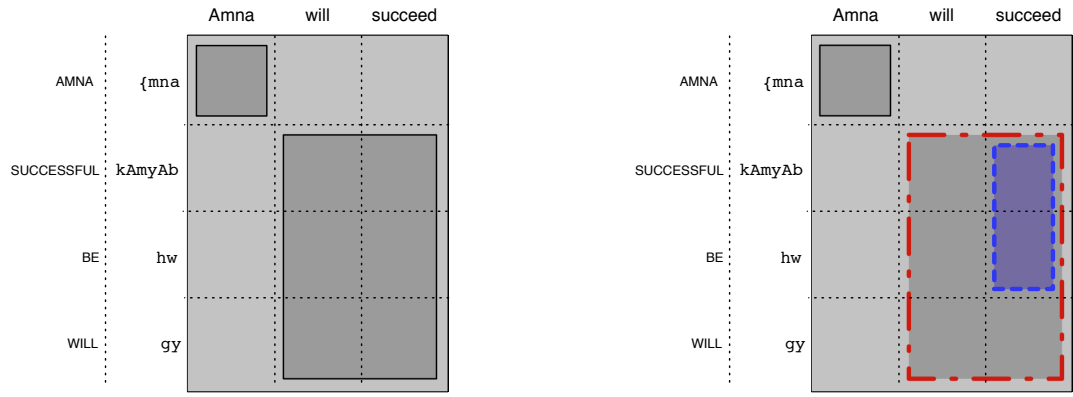

The settings of the grid variables completely determine the SCFG rules in the current derivation. A setting of a binary variable  $z_{[s,t,u,v]} = 1$  represents a constituent linking the source span  $[s, t]$  and the target span  $[u, v]$  in the current derivation; variables with a value of 0 indicate no link between spans  $[s, t]$  and  $[u, v]$ .<sup>2</sup> This relationship from our grid representation is illustrated in Figure 2a.

Our Gibbs sampler operates over the space of all the random variables  $z_{[s,t,u,v]}$ , resampling one at a time. Changes to a single variable imply that at most *two* additional rules must be generated, as illustrated in Figure 2b. The probability of choosing a binary setting of 0 or 1 for a variable is proportional to the probability of generating the two derivations under the model described in the previous section. Note that for a given sentence, most of the bispan variables must be set to 0 otherwise they would violate the *strict nesting constraint* required for valid SCFG derivations. We discuss below how to exploit this fact to limit the number of binary variables that must be resampled for each sentence.

To be valid, a Gibbs sampler must be *ergodic* and satisfy *detailed balance*. Ergodicity requires that there is non-zero probability that any state in the sampler be reachable from any other state. Clearly

<sup>2</sup>Our grid representation is the synchronous generalisation of the well-known correspondence between CFG derivations and Boolean matrices; see Lee (2002) for an overview.

(a) An example grid representation of a synchronous derivation. The SCFG rules (annotated with their bispans) that correspond to this setting of the grid are:

$$\begin{aligned}
 X_{[0,4,0,3]} &\rightarrow \langle X_{[0,1,0,1]} X_{[1,4,1,3]} \mid X_{[0,1,0,1]} X_{[1,4,1,3]} \rangle \\
 X_{[0,1,0,1]} &\rightarrow \langle \{mna \mid Amna \} \\
 X_{[1,4,1,3]} &\rightarrow \langle kAmyAb \quad hw \quad gy \mid will \quad succeed \rangle
 \end{aligned}$$

(b) The toggle operator resamples a bispan variable (here,  $z_{[1,3,2,3]}$ , shown in blue) to determine whether it should be subtracted from the immediately dominating rule (bispan in red) and made into a child rule in the derivation. This would require the addition of the following two rules:

$$\begin{aligned}
 X_{[1,4,1,3]} &\rightarrow \langle X_{[1,3,2,3]} \varrho Y \mid will \quad X_{[1,3,2,3]} \rangle \\
 X_{[1,3,2,3]} &\rightarrow \langle kAmyAb \quad hw \mid succeed \rangle
 \end{aligned}$$

Alternatively, the active bispan variable can be set so it is *not* a constituent, which would require the single rule:

$$X_{[1,4,1,3]} \rightarrow \langle kAmyAb \quad hw \quad gy \mid will \quad succeed \rangle$$

Figure 2: A single operation of the Gibbs sampler for a binary alignment grid.

our operator satisfies this since given any configuration of the alignment grid we can use the toggle operator to flatten the derivation to a single rule and then break it back down to reach any derivation.

Detailed balance requires that the probability of transitioning between two possible adjacent sampler states respects their joint probabilities in the stationary distribution. One way to ensure this is to make the order in which bispan variables are visited deterministic and independent of the variables' current settings. Then, the probability of the sampler targeting any bispan in the grid is equal regardless of the current configuration of the alignment grid.

A naive instantiation of this strategy is to visit all  $|s|^2|t|^2$  bispans in some order. However, since we wish to be able to draw many samples, this is not computationally feasible. A much more efficient approach avoids resampling variables that would result in violations without visiting each of them individually. However, to ensure detailed balance is maintained, the order that we resample bispans has to match the order we would sample them using

any exhaustive approach. We achieve this by always checking a derivation top-down, from largest to smallest bispan. Under this ordering, whether or not a smaller bispan is visited will be independent of how the larger ones were resampled. Furthermore, the set of variables that may be resampled is fixed given this ordering. Therefore, the probability of sampling any possible bispan in the sentence pair is still uniform (ensuring detailed balance), while our sampler remains fast.

## 5 Evaluation

The preceding sections have introduced a model, and accompanying inference technique, designed to induce a posterior distribution over SCFG derivations containing discontinuous and phrasal translation rules. The evaluation that follows aims to determine our models ability to meet these design goals, and to do so in a range of translation scenarios.

In order to validate both the model and the sampler's ability to learn an SCFG we first conduct a synthetic experiment in which the true grammar is

known. Subsequently we conduct a series of experiments on real parallel corpora of increasing sizes to explore the empirical properties of our model.

## 5.1 Synthetic Data Experiments

Prior work on SCFG induction for SMT has validated modeling claims by reporting BLEU scores on real translation tasks. However, the combination of noisy data and the complexity of SMT pipelines conspire to obscure whether models actually achieve their design goals, normally stated in terms of an ability to induce SCFGs with particular properties.

Here we include a small synthetic data experiment to clearly validate our models ability to learn an SCFG that includes discontinuous and phrasal translation rules with non-monotonic word order.

Using the probabilistic SCFG shown in the top half of Table 1 we stochastically generated three thousand parallel sentence pairs as training data for our model. We then ran the Gibbs sampler for fifty iterations through the data.

The bottom half of Table 1 lists the five rules with the highest marginal probability estimated by the sampler. Encouragingly our model was able to recover a grammar very close to the original. Even for such a small grammar the space of derivations is enormous and the task of recovering it from a data sample is non-trivial. The divergence from the true probabilities is due to the effect of the prior assigning shorter rules higher probability. With a larger data sample we would expect the influence of the prior in the posterior to diminish.

## 5.2 Machine Translation Evaluation

Ultimately the efficacy of a model for SCFG induction will be judged on its ability to underpin a state-of-the-art SMT system. Here we evaluate our model by applying it to learning word alignments for parallel corpora from which SMT systems are induced. We train models across a range of corpora sizes and for language pairs that exhibit the type of complex alignment phenomena that we are interested in modeling: Chinese  $\rightarrow$  English (ZH-EN), Urdu  $\rightarrow$  English (UR-EN) and German  $\rightarrow$  English (DE-EN).

### Data and Baselines

The UR-EN corpus is the smallest of those used in our experiments and is taken from the NIST 2009

GRAMMAR RULE	TRUE PROBABILITY
$X \rightarrow \langle X_1 a X_2 \mid X_1 X_2 1 \rangle$	0.2
$X \rightarrow \langle b c d \mid 3 2 \rangle$	0.2
$X \rightarrow \langle b d \mid 3 \rangle$	0.2
$X \rightarrow \langle d \mid 3 \rangle$	0.2
$X \rightarrow \langle c d \mid 3 1 \rangle$	0.2
SAMPLED RULE	SAMPLED PROBABILITY
$X \rightarrow \langle d \mid 3 \rangle$	0.25
$X \rightarrow \langle b d \mid 3 \rangle$	0.24
$X \rightarrow \langle c d \mid 3 1 \rangle$	0.24
$X \rightarrow \langle b c d \mid 3 2 \rangle$	0.211
$X \rightarrow \langle X_1 a X_2 \mid X_1 X_2 1 \rangle$	0.012

Table 1: Manually created SCFG used to generate synthetic data, and the five most probable inferred rules by our model.

	ZH-EN NIST	UR-EN NIST	DE-EN EUROPARL

TRAIN (TRG)	9.5M	1.0M	36M
DEV (SRC)	22K	18K	26K
DEV (TRG)	27K	16K	28K

Table 2: Corpora statistics (in words).

translation evaluation.<sup>3</sup> The ZH-EN data is of a medium scale and comes from the FBIS corpus. The DE-EN pair constitutes the largest corpus and is taken from Europarl, the proceedings of the European Parliament (Koehn, 2003). Statistics for the data are shown in Table 2. We measure translation quality via the BLEU score (Papineni et al., 2001).

All translation systems employ a Hiero translation model during decoding. Baseline word alignments were obtained by running GIZA++ in both directions and symmetrizing using the `grow-diag-final-and` heuristic (Och and Ney, 2003; Koehn et al., 2003). Decoding was performed with the `cdec` decoder (Dyer et al., 2010) with the synchronous grammar extracted using the techniques developed by Lopez (2008). All translation systems include a 5-gram language model built from a five hundred million token subset

<sup>3</sup><http://www.itl.nist.gov/iad/mig/tests/mt/2009/>

LANGUAGE PAIR	TEST SET	MODEL 4	MODEL 1	PYP-SCFG

Table 3: Results for the SMT experiments in BLEU . The baseline is produced using a full GIZA++ run. The MODEL 1 INITIALISATION column is from the initialisation alignments using MODEL 1 and no sampling. The PYP-SCFG columns show results for the 500th sample for both MODEL 1 and HMM initialisations.

of all the English data made available for the NIST 2009 shared task (Graff, 2003).

### Experimental Setup

To obtain the PYP-SCFG word alignments we ran the sampler for five hundred iterations for each of the language pairs and experimental conditions described below. We used the approach of Newman et al. (2007) to distribute the sampler across multiple threads. The strength  $\theta$  and discount  $d$  hyperparameters of the Pitman-Yor Processes, and the terminal penalty  $\phi$  (Section 3.3), were inferred using slice sampling (Neal, 2000).

The Gibbs sampler requires an initial set of derivations from which to commence sampling. In our experiments we investigated both *weak* and a *strong* initialisations, the former based on word alignments from IBM Model 1 and the latter on alignments from an HMM model (Vogel et al., 1996). For decoding we used the word alignments implied by the derivations in the final sample to extract a Hiero grammar with the same standard set of relative frequency, length, and language model features used for the baseline.

### Weak Initialisation

Our first translation experiments ascertain the degree to which our proposed Gibbs sampling inference algorithm is able to learn good synchronous derivations for the PYP-SCFG model. A number of prior works on alignment with Gibbs samplers have only evaluated models initialised with the more complex GIZA++ alignment models (Blunsom et al., 2009; DeNero et al., 2008), as a result it can be difficult to separate the performance of the sampler from that of the initialisation. In order to do this, we initialise the sampler

LANGUAGE PAIR	PYP-SCFG	
	MODEL 1 INIT.	HMM INIT.
UR-EN	1.93/2.08	1.45/1.58
ZH-EN	3.47/4.28	1.69/2.37
DE-EN	4.05/4.77	1.50/2.04

Table 4: Average source/target rule lengths in the PYP-SCFG models after the 500th sample for the different initialisations.

using just the MODEL 1 distribution used in the PYP-SCFG model’s base distribution. We denote this a weak initialisation as no alignment models outside of those included in the PYP-SCFG model influence the resulting word alignments. The BLEU scores for translation systems built from the five hundredth sample are show in the WEAK M1 INIT. column of Table 3. Additionally we build a translation system from the MODEL 1 alignment used to initialise the sampler without using our PYP-SCFG model or sampling. BLEU scores are shown in the MODEL 1 INITIALISATION column of Table 3. Firstly it is clear MODEL 1 is indeed a weak initialiser as the resulting translation systems achieve uniformly low BLEU scores. In contrast, the models built from the output of the Gibbs sampler for the PYP-SCFG model achieve BLEU scores comparable to those of the MODEL 4 BASELINE. Thus the sampler has moved a good distance from its initialisation, and done so in a direction that results in better synchronous derivations.

### Strong Initialisation

Given we have established that the sampler can produce state-of-the-art translation results from a

weak initialisation, it is instructive to investigate whether initialising the model with a strong alignment system, the GIZA++ HMM (Vogel et al., 1996), leads to further improvements. Column HMM INIT. of Table 3 shows the results for initialising with the HMM word alignments and sampling for 500 iterations. Starting with a stronger initial sample results in both quicker mixing and better translation quality for the same number of sampling iterations.

Table 4 compares the average lengths of the rules produced by the sampler with both the strong and weak initialisers. As the size of the training corpora increases (UR-EN  $\rightarrow$  ZH-EN  $\rightarrow$  DE-EN) we see that the average size of the rules produced by the weakly initialised sampler also increases, while that of the strongly initialised model stays relatively uniform. Initially both samplers start out with a large number of long rules and as the sampling progresses the rules are broken down into smaller, more generalisable, pieces. As such we conclude from these metrics that after five hundred samples the strongly initialised model has converged to sampling from a mode of the distribution while the weakly initialised model converges more slowly and on the longer corpora is still travelling towards a mode. This suggests that longer sampling runs, and Gibbs operators that make simultaneous updates to multiple parts of a derivation, would enable the weakly initialised model to obtain better translation results.

### Grammar Analysis

The BLEU scores are informative as a measure of translation quality but we also explored some of the differences in the grammars obtained from the PYP-SCFG model compared to the standard approach. In Figures 3 and 4 we show some basic statistics of the grammars our model produces. From Figure 3 we see that the number of unique rules in the PYP-SCFG grammar decreases steadily as the sampler iterates through the data, so the model is finding an increasingly sparser distribution with fewer but better quality rules as sampling progresses. Note that the gradient of the curves appears to be a function of the size of the corpus and suggests that the model built from the large DE-EN corpus would benefit from a longer sampling run. Figure 4 shows the distribution of rules with a given arity as a percentage

Figure 3: Unique grammar rules for each language pair as a function of the number of samples. The number of rule types decreases monotonically as sampling continues. Rule counts are displayed by normalised corpus size (see Table 2).

the PYP-SCFG grammar that are not in the heuristically extracted grammar are correct and minimal phrasal units of translation, whereas only two of the top probability rules in the GIZA++ grammar are of good translation quality.

## 6 Conclusion and Further Work

In this paper we have presented a nonparametric Bayesian model for learning SCFGs directly from parallel corpora. We have also introduced a novel Gibbs sampler that allows for efficient posterior inference. We show state-of-the-art results and learn complex translation phenomena, including discontinuous and many-to-many

phrasal alignments, without applying any heuristic restrictions on the model to make learning tractable. Our evaluation shows that we can use a principled approach to induce SCFGs designed specifically to utilize the full power of grammar based SMT instead of relying on complex word alignment heuristics with inherent bias.

Future work includes the obvious extension to learning SCFGs that contain multiple nonterminals instead of a single nonterminal grammar. We also expect that expanding our sampler beyond strict binary sampling may allow us to explore the space of hierarchical word alignments more quickly allowing for faster mixing. We expect with these extensions our model of grammar induction may further improve translation output.

## Abstract

Multi-document summarization involves many aspects of content selection and surface realization. The summaries must be informative, succinct, grammatical, and obey stylistic writing conventions. We present a method where such individual aspects are learned separately from data (without any hand-engineering) but optimized jointly using an integer linear programme. The ILP framework allows us to combine the decisions of the expert learners and to select and rewrite source content through a mixture of objective setting, soft and hard constraints. Experimental results on the TAC-08 data set show that our model achieves state-of-the-art performance using ROUGE and significantly improves the informativeness of the summaries.

## 1 Introduction

Automatic summarization has enjoyed wide popularity in natural language processing (see the proceedings of the Document Understanding and Text Analysis conferences) due to its potential for practical applications but also because it incorporates many important aspects of both natural language understanding and generation. Of the many summarization paradigms that have been identified over the years (see Sparck Jones (1999) and Mani (2001) for comprehensive overviews), multi-document summarization — the task of producing summaries from clusters of thematically related documents — has consistently attracted attention.

Despite considerable research effort, the automatic generation of multi-document summaries that resemble those written by humans remains challenging. This is primarily due to the task itself which is complex and subject to several constraints: the summary must be maximally informative and minimally redundant, grammatical, coherent, adhere to a pre-specified length and stylistic conventions. An ideal model would learn to output summaries that simultaneously meet all these constraints from data (i.e., document clusters and their corresponding summaries). This *global inference problem* is, however, hard — the solution space is large and the lack of easily accessible datasets an obstacle to joint learning. It is thus no surprise that previous work has focused on specific aspects of joint learning.

Initial global formulations of the multi-document summarization task focused on extractive summarization and used approximate greedy algorithms for finding the sentences of the summary. Goldstein et al. (2000) search for the set of sentences that are both relevant and non-redundant, whereas Filatova and Hatzivassiloglou (2004) model multi-document summarization as an instance of the maximum coverage set problem.<sup>1</sup> More recent work improves on the search problem by considering exact solutions and permits a limited amount of rewriting. McDonald (2007) proposes an integer linear programming formulation that maximizes the sum of relevance scores of the selected sentences penalized by the

---

<sup>1</sup>Given  $C$ , a finite set of weighted elements, a collection  $T$  of subsets of  $C$ , and an integer  $k$ , find those  $k$  sets that maximize the total number of elements in the union of  $T$ 's members (Hochba, 1997).

sum of redundancy scores of all pairs of selected sentences. Gillick et al. (2008) develop an exact solution for a model similar to Filatova and Hatzivassiloglou (2004) under the assumption that the value of a summary is the sum of values of the unique concepts (approximated by bigrams) it contains. Subsequent work (Gillick et al., 2009; Berg-Kirkpatrick et al., 2011) extends this model to allow sentence compression in the form of word or constituent deletion.

In this paper we propose a model for multi-document summarization that attempts to cover many different aspects of the task such as content selection, surface realization, paraphrasing, and stylistic conventions. These aspects are learned separately using specific “expert” predictors, but are optimized jointly using an integer linear programming model (ILP) to generate the output summary.<sup>2</sup> All experts are learned from data without requiring additional annotation over and above the summaries written for each document cluster. Our predictors include the use of unique bigram information to model content and avoid redundancy, positional information to model important and poor locations of content, and language modeling to capture stylistic conventions. Learning each predictor separately gives better generalization, while the ILP framework allows us to combine the decisions of the expert learners through the use of objectives, hard and soft constraints.

The experts work collaboratively to rewrite the content using rules extracted from document clusters and model summaries. We adopt the synchronous tree substitution grammar (STSG) formalism (Eisner, 2003) which can model non-isomorphic tree structures (the grammar rules can comprise trees of arbitrary depth) and is thus suited to text-rewriting tasks which typically involve a number of local modifications to the input text. Specifically, we propose quasi-synchronous tree substitution grammar (QTSG) as a flexible formalism to learn general tree-edits from *loosely-aligned* phrase structure trees.

We evaluate our model on the 100-word “non-

---

<sup>2</sup>Our task is standard multi-document summarization and should not be confused with “guided” summarization where system and human summarizers are given a list of important aspects to cover in the summary. Our usage of the term aspects broadly refers to the different types of constraints (e.g., relating to content or style) a summary must meet, but these are learned rather than specified in advance.

update” summarization task as defined in the the Text Analysis Conference (TAC 2008). Experimental results show that our method obtains performance comparable and in some cases superior to state-of-the-art, in terms of ROUGE and human ratings of summary grammaticality and informativeness. Importantly, there is nothing inherent in our model that is specific to this particular summarization task. As all of the different experts are learned from data, it could easily adapt to other summarization styles or conventions as needed.

## 2 Related work

Recent years have seen increased interest in global inference methods for summarization. ILP-based models have been developed for several subtasks ranging from sentence compression (Clarke and Lapata, 2008), to single- and multi-document summarization (McDonald, 2007; Martins and Smith, 2009; Gillick and Favre, 2009; Woodsend and Lapata, 2010; Berg-Kirkpatrick et al., 2011), and headline generation (Deshpande et al., 2007; Woodsend et al., 2010). Most of these approaches are either purely extractive or implement a single rewrite operation, namely word deletion. Although it is well-known that hand-written summaries often exhibit additional edits and sentence recombinations (Jing, 2002), the challenges involved in acquiring the rewrite rules, interfacing them with inference, and ensuring grammatical output make the development of abstractive models non-trivial.

Our work is closest to Gillick et al. (2008) who also develop an ILP model for multi-document summarization. A key assumption in their model which we also follow is that input documents contain a variety of concepts, each of which are allocated a value, and the goal of a good summary is to maximize the sum of these values subject to the length constraint. The authors use bigrams as concepts and their frequency in the input documents as a proxy for their value. This model can also perform sentence compression (see also Gillick et al. (2009)), however, the deletion rules are hand-coded. Berg-Kirkpatrick et al. (2011) build on this work by recasting it as a structured prediction problem. They essentially combine the same bigram content scoring system with features relating to the parse tree

which they learn using a maximum-margin SVM trained on annotated gold-standard compressions.

Our multi-document summarization model jointly optimizes different aspects of the task involving both content selection and surface realization. Each individual aspect has its own dedicated expert, which we argue is advantageous as it renders inference simpler and affords flexibility (e.g., additional aspects can be incorporated into the model or trained separately on different datasets). Our work differs from Gillick et al. (2009) and Berg-Kirkpatrick et al. (2011) in three important respects. Firstly, we develop a genuinely abstractive model that is not limited to deletion. Our rewrite rules are encoded in quasi-synchronous tree substitution grammar and learned automatically from source documents and their summaries. Unlike previous applications of STSG to sentence compression (Cohn and Lapata, 2009; Cohn and Lapata, 2008) our quasi-synchronous TSG does not attempt to learn the complete translation from source to target sentence; it only loosely links the syntactic structure of the two (Smith and Eisner, 2006), and is therefore well suited to describing the relationship between documents and their abstracts. Secondly, our content selection component extends to features beyond the bigram horizon, as we learn to identify important concepts based on syntactic and positional information. We also learn which words are unlikely to appear in a summary. Thirdly, unlike Berg-Kirkpatrick et al. (2011) our model does not try to learn all the parameters (e.g., content, rewrite rules, style) of the summarization problem jointly; although decoupling learning from inference is perhaps less elegant from a modeling perspective, the learning process is more robust and reliable.

### 3 Modeling

There are many aspects to producing a good summary of multiple documents. The important content needs to be captured, typically key facts in each individual document, and information seen across the cluster. Stylistic features may be different in the summary from original documents. For instance, summaries tend to use more concise language, sources are not attributed as they are in news articles, and relative dates are not included. In addition, the summary must be fluent, coherent, and re-

spect a pre-specified maximum length requirement.

We present an approach where elements of all the above considerations are learned from training data by separate dedicated components, and then combined in an integer linear programme. Content selection is performed partly through identifying the most salient topics (bigrams); an additional component learns to identify which information from the source documents should be in the summary based on positional information. Meanwhile, in terms of surface realization, a language model identifies the words that *should not* be in the output summaries, whereas a separate component learns to exclude sentences that are poor candidates for summaries. QTSG rules, learned from the training corpus, are used to generate alternative compressions and paraphrases of the source sentences, in the style suitable for the summaries. Finally, an ILP model combines the output of these components into a summary, jointly optimizing content selection and surface realization preferences, and providing the flexibility to treat some components as soft while others as hard constraints.

#### 3.1 Document Representation

Given an input sentence, our approach deconstructs it into component phrases and clauses, typical of a phrase structure parser. In our experiments, we obtain this representation from the output of the Stanford parser (Klein and Manning, 2003) but any other broadly similar parser could be used instead. Nodes in the parse tree represent points where QTSG rules can be applied (and paraphrases generated), and they also represent decision points for the ILP. In the following, we will refer to these decision nodes as the set  $\mathcal{N}$ , and decisions for each node using the binary variable  $z_i$ ,  $i \in \mathcal{N}$ .

#### 3.2 Content Selection Using Bigrams

We follow Gillick et al. (2008) in modeling the information content of the summary as the weighted sum of the individual information units it contains. We represent information units as the set of bigrams  $\mathcal{B}$  seen in the source documents. The weight  $w$  of each bigram is calculated from the number of source documents where the bigram was seen. The summary is thus given the score  $f_{\mathcal{B}}(z)$ , i.e., the weighted sum of

its information units:

$$f_{\mathcal{B}}(z) = \sum_{j \in \mathcal{B}} w_j b_j \quad (1)$$

where  $w_j$  is the weight of concept  $j$ ,  $b_j$  a binary variable to indicate if concept  $j$  is present in the summary, and  $j \in \mathcal{B}$ .

Importantly, each information unit is counted only once; this encourages wide coverage of the source documents, and removes any drive towards redundant information without actively discouraging it, contrary to other global formulations where redundancy measures form part of the objective (McDonald, 2007). The counting mechanism is achieved by linking the variables  $z$  indicating nodes in the parse tree and  $b$  indicating bigrams:

$$b_j \leq \sum_{i \in \mathcal{N}: j \in \mathcal{B}_i} z_i \quad \forall j \in \mathcal{B} \quad (2)$$

where  $\mathcal{B}_i \subset \mathcal{B}$  is the subset of bigrams that are contained in node  $i$ . A drawback of the global nature of this counting mechanism, however, is that it cannot be integrated with local features such as those described below; our approach takes local features into account but these are weighted by other components.

### 3.3 Content Selection Using Saliency

The bigram approach is a powerful method for identifying important concepts within the document cluster. It works particularly well in the sentence extraction paradigm. However, additional elements are known to be good predictors of important information. Examples include the position of a sentence in the document (e.g., first sentences often contain salient information), whether it contains proper nouns, numbers, pronouns, mentions of money, and so on. We decided to learn which of these elements (represented as nodes in the parse tree) are informative from training data. Specifically, sentences in the cluster documents were aligned to sentences from corresponding human summaries. Alignment was based rather simply on identifying the sentence pairs with the highest number of overlapping bigrams, without compensating for sentence length, or matching the sequence of information in the summaries and source documents (Nelken and Schieber,

Weight	Feature
1.21	From first sentence in document
0.73	Contains proper nouns
0.68	Contains nouns
0.57	From first paragraph
0.53	From first three sentences
0.51	Contains numbers
-0.50	Contains pronouns
0.32	Contains money

Table 1: Weights and features of SVM that predicts the saliency of summary content. Negative weights indicate information that should not be included in the summary.

2006). Matched sentences in the source documents were given positive labels, while unaligned sentences were given negative labels. These labels were then propagated to phrase structure nodes.

We trained an SVM on this data (tree nodes and their labels) using surface features that do not overlap with bigram information: sentence and paragraph position, POS-tag information. Table 1 shows the most important features learned by the model as predictors of salient content.

The summary can be given a saliency score  $f_S(z)$  using the raw SVM prediction scores of the individual parse tree nodes:

$$f_S(z) = \sum_{i \in \mathcal{N}} (\Phi(i) \cdot \theta) z_i \quad (3)$$

where  $\Phi(i)$  is the feature vector for node  $i$ , and  $\theta$  the weights learned by the SVM.

### 3.4 Surface Realization Using Style

Some sentences in the source documents will make poor summary sentences, despite the information they contain, and therefore contrary to the predictions of the content selection indicators described above. This may be because the source sentence is very short, or is expressed as a quotation, or contains many pronouns that will not be resolved when the sentence is extracted.

Our idea is to learn which sentences are poor from a stylistic perspective using again aligned training data. We train a second SVM on the aligned sentences and their labels using surface features at the sentence level, such as sentence length and POS-tag information. The most important features learned by

Weight	Feature
-1.04	Word count less than 10
-0.83	Word count less than 20
-0.30	Question
-0.30	Quotation
-0.14	Personal pronouns

Table 2: Weights and features of SVM that predicts poor candidate sentences.

the model as predictors of poor sentences, and the weights assigned to them, are shown in Table 2.

The predictions of the SVM are incorporated into the ILP as a hard constraint, by forcing all parse tree nodes within those sentences predicted as poor (the set  $\mathcal{N}^-$ ) to be zero:

$$z_i = 0 \quad \forall i \in \mathcal{N}^-. \quad (4)$$

### 3.5 Surface Realization Using Lexical Preferences

Human-written summaries differ from the source news articles in a number of ways. They delete extraneous information, merge material from several sentences, employ paraphrases and syntactic transformations, change the order of the source sentences and replace phrases or clauses with more general or specific descriptions. We could attempt to learn the “language of summaries” with a language model which we could then use to guide the generation process (e.g., by producing maximally probable output). Aside from the logistics of gathering training data large enough to provide robust estimates, we believe that a more compelling approach is to focus on the words that are *unlikely* to appear in the summary despite appearing in the source documents.

A comparison of the language models generated from the source documents and model summaries, even at the unigram level, is revealing. Table 3 shows lexemes that appear in both source and summary documents, but where the likelihood of the lexeme appearing in the summary is much less than that of it appearing the document, taking into account that the summary is much shorter anyway. The final column shows the  $\log_{10}$ -ratio ( $L(w)$ ) between the two probabilities. We can see that least probable words are those that correspond to attributing information sources (e.g., *said, told, according*

Lexeme $w$	Source count	Summary count	$L(w)$
say	5670	88	-1.63
go	638	11	-1.52
last	616	9	-1.69
get	543	15	-1.05
tell	512	8	-1.62
come	488	12	-1.17
know	404	9	-1.27
monday	391	8	-1.35
think	382	7	-1.46
next	239	7	-0.99
spokesman	197	4	-1.36

Table 3: Counts of lexemes in the source news articles and summaries, and measure of the ratio of their probabilities (for most common lexemes with ratio  $< -0.95$ ).

*to, spokesman*), dates described relatively (e.g., *last Monday*), and events that are in the process of happening (e.g., *coming, going*).

As the amount of training data tends to be limited — there are usually only a few human-written summaries available per document cluster — we use a unigram language model, but conceivably a longer-range  $n$ -gram could be employed in the same vein. We incorporate preferences about summary language into the model as a soft constraint. The log-ratio values  $f_{\mathcal{L}\mathcal{R}}(z)$  are included in the objective and defined at the tree node level:

$$f_{\mathcal{L}\mathcal{R}}(z) = \sum_{i \in \mathcal{R}} \sum_{w \in \mathcal{W}_i} L(w) z_i \quad (5)$$

where  $L(w)$ ,  $w \in \mathcal{W}_i$  is the log-ratio value for an individual word  $w$ :

$$L(w) = \log_{10} \frac{P_{\text{src}}(w)}{P_{\text{sum}}(w)},$$

$P_{\text{src}}(w)$  and  $P_{\text{sum}}(w)$  are the probabilities of word  $w$  appearing in the source and summary documents respectively, and  $\mathcal{W}_i$  is the set of words at parse tree node  $i$ . Importantly, we include only those those lexemes with negative  $L(w)$  values. This guides the model *away from* the kind of phrases described above, but not towards any particular language preferences.

### 3.6 Quasi-synchronous Tree Substitution Grammar

Rewrite rules involving substitutions, deletions and reorderings are captured in our model using a quasi-synchronous tree substitution grammar. Given an input (source) sentence  $S1$  or its parse tree  $T1$ , the QTSG contains rules for generating possible translation trees  $T2$ . A grammar node in the target tree  $T2$  is modeled on a subset of nodes in the source tree, with a rather loose alignment between the trees.

We extract QTSG rules from aligned source and summary sentence pairs represented by their phrase structure trees. Our algorithm builds up a list of leaf node alignments based on lexical identity. Direct parent nodes are aligned where more than one child node aligns. This quasi-synchronous “bottom-up” process gives us better ability to match non-isomorphic structures. We do not assume an alignment between source and target root nodes, nor do we require a surjective alignment of all target nodes to the source tree. QTSG rules are then created from aligned nodes above the leaf node level if all the nodes in the target tree can be explained using nodes from the source. Individual rewrite rules describe the mapping of source tree fragments into target tree fragments, and so the grammar represents the space of valid target trees that can be produced from a given source tree (Eisner, 2003; Cohn and Lapata, 2009).

Examples of the most frequent QTSG rules learned by the above process are shown in Figure 1. Many of the rules relate to the compression of noun phrases through deletion, and examples are shown in the upper box. Others capture the compression of verb phrases (middle box). An important rewrite operation is the abstraction of a sentence from a more complex source sentence, adding final punctuation if necessary (lower box).

At generation, paraphrases are created from source sentence parse trees by identifying and applying QTSG rules with matching structure. The transduction process starts at the root node of the parse tree, applying QTSG rules to sub-trees until leaf nodes are reached. Note that we do not use the Bayesian probability model normally associated with quasi-synchronous grammars (Smith and Eisner, 2006); instead, we ask the QTSG to provide

$\langle \text{NP}, \text{NP} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}} \text{PP}], [\text{NP}_{\boxed{1}}] \rangle$
$\langle \text{NP}, \text{NP} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}} \text{VP}], [\text{NP}_{\boxed{1}}] \rangle$
$\langle \text{NP}, \text{NP} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}} \text{SBAR}], [\text{NP}_{\boxed{1}}] \rangle$
$\langle \text{NP}, \text{NP} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}} , \text{NP}_{\boxed{2}}], [\text{NP}_{\boxed{1}}] \rangle$
$\langle \text{NP}, \text{NP} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}} \text{CC NP}], [\text{NP}_{\boxed{1}}] \rangle$
$\langle \text{NP}, \text{NP} \rangle \rightarrow \langle [\text{NNP} \text{NNP}_{\boxed{1}}], [\text{NNP}_{\boxed{1}}] \rangle$
$\langle \text{NP}, \text{NP} \rangle \rightarrow \langle [\text{DT}_{\boxed{1}} \text{JJ} \text{NN}_{\boxed{2}}], [\text{DT}_{\boxed{1}} \text{NN}_{\boxed{2}}] \rangle$
$\langle \text{VP}, \text{VP} \rangle \rightarrow \langle [\text{VP}_{\boxed{1}} \text{CC VP}], [\text{VP}_{\boxed{1}}] \rangle$
$\langle \text{VP}, \text{VP} \rangle \rightarrow \langle [\text{VP} \text{CC VP}_{\boxed{1}}], [\text{VP}_{\boxed{1}}] \rangle$
$\langle \text{VP}, \text{VP} \rangle \rightarrow \langle [\text{VP}_{\boxed{1}} , \text{CC VP}], [\text{VP}_{\boxed{1}}] \rangle$
$\langle \text{S}, \text{S} \rangle \rightarrow \langle [\text{NP}_{\boxed{1}} \text{VP}_{\boxed{2}}], [\text{NP}_{\boxed{1}} \text{VP}_{\boxed{2}} .] \rangle$
$\langle \text{S}, \text{S} \rangle \rightarrow \langle [\text{ADVP} , \text{NP}_{\boxed{1}} \text{VP}_{\boxed{2}} .], [\text{NP}_{\boxed{1}} \text{VP}_{\boxed{2}} .] \rangle$

Figure 1: Examples of most frequently learned QTSG rules. Boxed subscripts show aligned nodes.

paraphrases that are *acceptable* rather than *probable*, and generate all paraphrases licensed by the QTSG.

The alternative paraphrases are incorporated into the target phrase structure tree as choices that the ILP can make. We use the set  $\mathcal{C} \subset \mathcal{N}$  to be the set of nodes where a choice of paraphrases is available, and  $\mathcal{C}_i \subset \mathcal{N}, i \in \mathcal{C}$  to be the actual paraphrases of  $i$ . Where there are alternatives, it makes sense of course to select only one, which we implement using the constraint:

$$\sum_{j \in \mathcal{C}_i} z_j = z_i \quad \forall i \in \mathcal{C}, j \in \mathcal{C}_i \quad (6)$$

More generally, we need to constrain the output to ensure that a parse tree structure is maintained. For each node  $i \in \mathcal{N}$ , the set  $\mathcal{D}_i \subset \mathcal{N}$  contains the list of dependent nodes (both ancestors and descendants) of node  $i$ , so that each set  $\mathcal{D}_i$  contains the nodes that depend on the presence of  $i$ . We introduce a constraint to force node  $i$  to be present if any of its dependent nodes are chosen:

$$z_j \rightarrow z_i \quad \forall i \in \mathcal{N}, j \in \mathcal{D}_i \quad (7)$$

### 3.7 The ILP Objective

The model we propose for generating a multi-document summary is expressed as an integer linear programme and incorporates the content selection and surface realization preferences, as well as the

soft and hard constraints described in the preceding sections. The objective of the optimization problem is to maximize the score contributed by the various elements of content selection ( $f_B(z)$  and  $f_S(z)$ ) and soft surface realization constraints ( $f_{LR}(z)$ ):

$$\max_z f_B(z) + f_S(z) + f_{LR}(z) \quad (8)$$

This objective is subject to the constraints (2), (4), (6), and (7) that represent hard constraint decisions, or maintain the logical integrity of the model. An overall length constraint completes the model:

$$\sum_{i \in \mathcal{N}} l_i z_i \leq l_{\max} \quad (9)$$

where  $l_i$  is the number of words generated by choosing node  $i$ , and  $l_{\max}$  is the global word length limit.

Note that the scores in the objective are for each tree node and not each sentence. This affords the model flexibility: the content selection elements are generally not competing with each other to give a decision on a sentence (see McDonald (2007)). Instead, components are marking positive and negative nodes. The ILP is implicitly searching the grammar rules for ways to rewrite the sentence, with the aim of including the salient nodes while removing negative-scoring nodes (deleting them increases the score of the node to zero). Figure 2 shows an example of a source sentence where the bigram, salience and language preference components of the ILP work together to score nodes in the parse tree. The nodes  $NP_{\square}$ ,  $VP_{\square}$  and  $VP_{\square}$  all have positive scores, while “said Tuesday” is negative. As a rewrite possibility, the rewrite rule shown bottom left is available, which will remove the negative node. Further rewrite rules allow  $VP_{\square}$  to be compressed. The output actually generated by the model used sub-trees (b) and (d) — the final text is included in Table 6.

## 4 Experimental Set-up

**Data** Our model was evaluated on the TAC non-update multi-document summarization task which involves generating a 100-word-limited summary from a cluster of 10 related input documents; additionally, TAC provides a set of four model summaries for each cluster, written by human experts. We used the 44 document clusters from TAC-2009 as training data, to learn the different elements of

the model. The 48 document clusters of TAC-2008 were reserved for the generation of test summaries.<sup>3</sup>

**Training** The two components described in Sections 3.3 and 3.4 were trained using binary SVM classifiers, with labels inferred automatically via alignment. The salience classifier was trained on 102,754 node instances (16,042 positive and 86,712 negative). The style classifier was trained on 20,443 sentence instances (2,083 positive and 18,360 negative). We learned the feature weights with a linear SVM, using the software SVM-OOPS (Woodsend and Gondzio, 2009). Because of the high compression rate in this task, sentence alignment leads to an unbalanced data set. We compensated for this by using different SVM hyper-parameters  $C^+$  and  $C^-$  as the loss multiplier for misclassification of positive and negative training samples respectively. SVM hyper-parameters were chosen that gave the highest F1 values using 10-fold cross-validation. The salience SVM obtained a precision of 0.28 and recall of 0.43. Precision for the style SVM was 0.20 and recall 0.63, respectively. The classifiers on their own would thus not be great predictors of salience or style, but in practice they were useful for breaking ties in bigram scores.

Aligned sentences from the training data were also used to learn the quasi-synchronous tree substitution grammar, using the process described in Section 3.6. Rules seen fewer than 3 times were removed, resulting in a total of 339 QTSG rules. Two unigram language models (see Section 3.5) were trained on the source articles and summaries, respectively. Their probabilities were compared to give the word list shown in Table 3. We removed words with a source count less than 50, providing a list of 60 lexemes. The resulting integer linear programmes were solved using SCIP,<sup>4</sup> and it took 55 seconds on average to read in and solve a document cluster problem.

**Evaluation** We compared our model against two systems. As a baseline, we used the ICSI-1 extractive system (Gillick et al., 2008) which is also based on ILP and was highly ranked in the TAC-2008 evaluation. We also compared against the “learned phrase compression” system of Berg-Kirkpatrick et

<sup>3</sup>This split follows Berg-Kirkpatrick et al. (2011).

<sup>4</sup><http://scip.zib.de/>

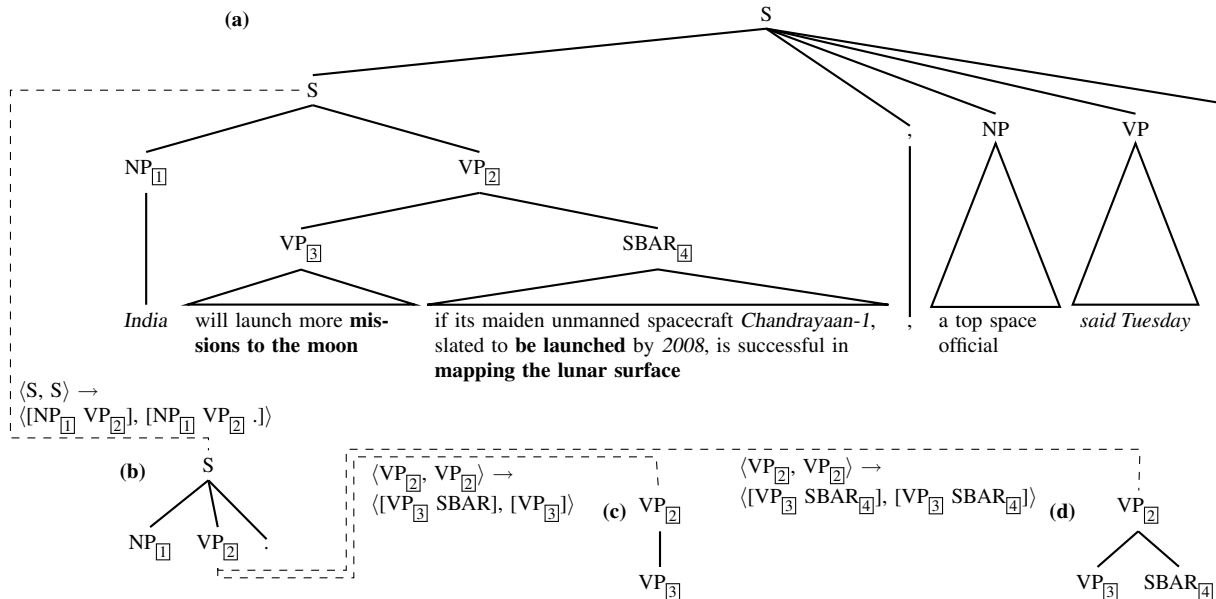

Figure 2: Sentence representation provided to the ILP. (a) The source sentence representation (child nodes condensed for space reasons). **Bigrams** are shown in bold, slanted text indicates *phrases with high salience scores*  $f_S$ , while *said Tuesday* is penalized by  $f_{LR}$ . Alternative sub-trees (b), (c) and (d) are created using QTSG rules (dashed lines). The output sentence (see Table 6) was generated from sub-trees (b) and (d).

al. (2011) (henceforth B-K), which has the highest reported ROUGE scores that we are aware of.<sup>5</sup> In addition to the full model described in Section 3, we also produced outputs where each of the five components described in Sections 3.2–3.6 were removed, to assess their individual contribution.

We evaluated the output summaries in two ways, using automatic measures and human judgements. Automatic evaluation was performed with ROUGE (Lin and Hovy, 2003) using TAC-2008 parameter settings. We report bigram overlap (ROUGE-2) and skip-bigram (ROUGE-SU4) recall values. We also used Translation Edit Rate (TER, Snover et al. (2006)) to examine the systems’ rewrite potential. TER is defined as the minimum number of edits (insertions, deletions, substitutions, and shifts) required to change the system output so that it exactly matches a reference (here, the reference is the most closely aligning source sentence). The perfect TER score is 0, however note that it can be higher than 1 due to insertions.

Our judgement elicitation study was conducted as follows. We randomly selected ten document

<sup>5</sup>We are grateful to Taylor Berg-Kirkpatrick for making his system output available to us.

clusters from the test set and generated summaries with our model (and its lesser variations). We also included the corresponding ICSI-1 and B-K summaries, and one randomly-selected model summary. The study was conducted over the Internet using Mechanical Turk and was completed by 54 volunteers, all self reported native English speakers. Participants were first asked to read the documents in each cluster. Next, they were asked a few comprehension questions to ensure they had understood and processed the documents. Finally, they were presented with a summary and asked to rate it along two dimensions: grammaticality (is the summary fluent and grammatical?), and informativeness (are the main topics captured in the summary?). The subjects used a 1–5 rating scale, with half-points allowed. Participants who declared themselves as non-native English speakers, did not answer the comprehension questions correctly or took only a few minutes to complete the task were eliminated.

## 5 Results

Our results are summarized in Table 4. Let us first discuss those obtained using ROUGE-2 (2-R) and ROUGE-SU4 (SU4-R) recall values. As can be seen

Models	ROUGE		TER (%)				Sentences		
	2-R	SU4-R	Ins	Del	Sub	Shift	Count	CR (%)	Mod (%)
ICSI-1	11.03	13.96	—	—	—	—	200	—	—
B-K	<b>11.71</b>	<b>14.47</b>	0.2	26.2	2.3	0.4	216	74.0	63.9
MA-ILP	11.37	<b>14.47</b>	0.7	11.6	5.3	0.6	191	89.1	61.8
ILP w/o bigrams	9.24	12.66	0.8	15.4	11.8	1.2	205	85.4	80.0
ILP w/o salience	11.38	14.71	1.1	19.1	12.0	1.3	233	82.1	92.3
ILP w/o style	<b>11.83</b>	<b>15.09</b>	1.4	17.4	18.9	1.7	271	84.1	86.3
ILP w/o log-ratio	11.41	14.70	1.2	16.9	12.5	1.5	223	84.3	90.1
ILP w/o QTSG	10.32	13.68	0	0	0	0	163	100.0	0

Table 4: Performance of the multiple-aspect ILP model against comparison systems using ROUGE and the four components of TER (insertion, deletion, substitution, shifts). In the lower section, performance of our model without (w/o) each component in turn. The final columns show the number of source sentences, the average compression ratio, and the proportion of sentences modified.

from the upper section of Table 4, the systems incorporating some form of rewriting gain slightly higher ROUGE scores than ICSI-1. The multiple aspects ILP system (MA-ILP) yields ROUGE scores similar to B-K, despite performing rewriting operations which increase the scope for error and without requiring any hand-crafted compression rules or manually annotated training data. Indeed, the outputs of the two systems are not significantly different under ROUGE (using a paired  $t$ -test,  $p > 0.5$ ).

In the lower section of Table 4, we show the performance of our model when each of the contributing components described in Section 3 are removed. Clearly the bigram content indicators are an important element for the ROUGE scores, as their removal yields a reduction of 2.46 points (see the row ILP w/o bigrams in Table 4). The model without QTSG rules (ILP w/o QTSG) is effectively limited to sentence extraction, and removing rewrite rules also lowers ROUGE scores to levels similar to ICSI-1. ROUGE scores are increased by allowing the model to select “poor quality” sentences (ILP w/o style), higher indeed than those of the B-K system. The inclusion of non-summary language (ILP w/o log-ratio) does not affect ROUGE scores to the same extent that bigrams and QTSG do.

Table 4 includes a break-down of the systems’ rewrite operations as measured by TER. We also show the number of source sentences (Count), the average compression ratio (CR %) and the proportion of sentences modified (Mod %) by each system. As can be seen, MA-ILP draws on fewer sentences,

Models	Grammar	Inform
ICSI-1	<b>4.68</b>	2.55
B-K	4.40	2.70
MA-ILP	<b>4.68</b>	<b>3.90</b>
ILP w/o style	3.30	2.67
Gold	4.90	4.75

Table 5: Mean ratings on system output output.

performs less deletion and more rewriting than B-K. The number of deletions increases when individual ILP components are removed and so does the number of substitutions. All the subsystems are more aggressive in their rewriting than when used in combination (higher TER, higher compression rate and a larger number of sentences are modified). Expectedly, when removing the QTSG rules, the ILP is limited to a pure extractive system (last row in Table 4).

The results of our human evaluation study are shown in Table 5. We elicited grammaticality and informativeness ratings for a randomly selected model summary, ICSI-1, B-K, the multiple aspect ILP (MA-ILP), and the ILP w/o style which we included in this study as it performed best under ROUGE. ICSI-1, B-K, and MA-ILP are rated highly on the grammaticality dimension. MA-ILP is indistinguishable from the sentence extraction system (ICSI-1). Both systems are significantly more grammatical than B-K ( $\alpha < 0.05$ , using a Post-hoc Tukey test). Notice that summaries created by the ILP w/o style are rated poorly by humans, contrary to ROUGE. The style component stops very short

Florida's Governor Jeb Bush asked the US Supreme Court to intervene to keep a comatose woman alive, over the wishes of her husband, who wants to disconnect the feeding tube that has sustained her for 14 years. Her husband, Michael Schiavo, and her parents, Robert and Mary Schindler, have conflicts of interest that prevent them from fairly deciding whether to keep her alive. Some doctors have testified that Terri Schiavo is in a persistent vegetative state with no hope for recovery. The state House in Florida passed a bill Thursday to extend life support for a brain-damaged woman.

The space agencies of India and France signed an agreement to cooperate in launching a satellite in four years that will help make climate predictions more accurate. The Indian Space Research Organization (ISRO) has short-listed experiments from five nations including the United States, Britain and Germany, for a slot on India's unmanned moon mission Chandrayaan-1 to be undertaken by 2006-2007, the Press Trust of India (PTI) reported Monday. India will launch more missions to the moon if its maiden unmanned spacecraft Chandrayaan-1, slated to be launched by 2008, is successful in mapping the lunar surface.

Table 6: Example summaries generated by the multiple aspects model (MA-ILP).

sentences and quotations from being included in the summary even if they have quite high bigram or content scores. Without it, the model tends to generate summaries that are fragmentary and lacking proper context, resulting in lower grammaticality (and informativeness) when judged by humans. The MA-ILP system obtains the highest rating with respect to information content. It is significantly better ( $\alpha < 0.05$ ) than ICSI-1 and B-K. This is not entirely surprising as our model includes additional content selection elements over and above the bigram units. There is still a significant gap from all systems to the gold-standard human-authored summaries. Example output summaries of the full ILP model are shown in Table 6.

Overall, we obtain best results when considering

the contributions from the individual model experts collectively. This suggests that additional improvements could be obtained with more experts. It is also possible that optimizing the relative weightings of experts in the ILP objective would improve output. The TER analysis shows that the experts have a tempering effect on each other, resulting in less aggressive, but qualitatively better, rewriting than when used individually. Generally, experts work together to shape an output sentence, but they can also compete. In the future, we also plan to test the ability of the model to adapt to other multi-document summarization tasks, where the location of summary information is not as regular as it is in news articles. We would also like to interface our model with sentence ordering and more generally with some notion of the coherence of the generated summary.

**Acknowledgments** We are grateful to Micha Elsner for his input on earlier versions of this work. We would also like to thank members of the ILCC at the School of Informatics for valuable discussions and comments. We acknowledge the support of EPSRC through project grants EP/I032916/1 and EP/I017127/1.

# Minimal Dependency Length in Realization Ranking

Michael White and Rajakrishnan Rajkumar

Department of Linguistics

{mwhite, raja}@ling.osu.edu

## Abstract

Comprehension and corpus studies have found that the tendency to minimize dependency length has a strong influence on constituent ordering choices. In this paper, we investigate dependency length minimization in the context of discriminative realization ranking, focusing on its potential to eliminate egregious ordering errors as well as better match the distributional characteristics of sentence orderings in news text. We find that with a state-of-the-art, comprehensive realization ranking model, dependency length minimization yields statistically significant improvements in BLEU scores and significantly reduces the number of heavy/light ordering errors. Through distributional analyses, we also show that with simpler ranking models, dependency length minimization can go overboard, too often sacrificing canonical word order to shorten dependencies, while richer models manage to better counterbalance the dependency length minimization preference against (sometimes) competing canonical word order preferences.

## 1 Introduction

In this paper, we show that for the constituent ordering problem in surface realization, incorporating insights from the minimal dependency length theory of language production (Temperley, 2007) into a discriminative realization ranking model yields significant improvements upon a state-of-the-art baseline. We demonstrate empirically using OpenCCG, our CCG-based (Steedman, 2000) surface realization system, the utility of a global feature encoding

the total dependency length of a given derivation. Although other works in the realization literature have used phrase length or head-dependent distances in their models (Filippova and Strube, 2009; Velldal and Oepen, 2005; White and Rajkumar, 2009, i.a.), to the best of our knowledge, this paper is the first to use insights from the minimal dependency length theory directly and study their effects, both qualitatively and quantitatively.

The impetus for this paper was the discovery that despite incorporating a sophisticated syntactic model borrowed from the parsing literature—including features with head-dependent distances at various scales—White & Rajkumar’s (2009) realization ranking model still often performed poorly on weight-related decisions such as when to employ heavy-NP shift. Table 1 illustrates this point. In wsj\_0034.9, the full model (incorporating numerous syntactic features) succeeds in reproducing the reference sentence, which is clearly preferable to the rather awkward variant selected by the baseline model (using various  $n$ -gram models). However, in wsj\_0013.16, the full model fails to shift the temporal modifier *for now* next to the phrasal verb *turned down*, leaving it at the end of its very long verb phrase where it is highly ambiguous (with multiple intervening attachment sites). Conversely, in wsj\_0044.3, the full model shifts *before* next to the verb, despite the NP *cheating* being very light, yielding a very confusing ordering given that *before* is meant to be intransitive.

The syntactic features in White & Rajkumar’s (2009) realization ranking model are taken from Clark & Curran’s (2007) normal form model

Table 1: Examples of OpenCCG output with White & Rajkumar’s (2009) models—the first represents a successful case, the latter two egregious ordering errors

(Table 3; see Section 3). In this model, head-dependent distances are considered in conjunction with lexicalized and unlexicalized CCG derivation steps, thereby appearing in numerous features. As such, the model takes into account the interaction of dependency length with derivation steps, but in essence **does not consider the main effect of dependency length** itself. In this light, our investigation of dependency length minimization can be viewed as examining the question of whether realization ranking models can be made more accurate—and in particular, avoid egregious ordering errors—by incorporating a feature to account for the main effect of dependency length.

It is important to observe at this point that dependency length minimization is more of a preference than an optimization objective, which must be balanced against other order preferences at times. A closer reading of Temperley’s (2007) study reveals that dependency length can sometimes run counter to many canonical word order choices. A case in point is the class of examples involving pre-modifying adjunct sequences that precede both the subject and the verb. Assuming that their parent head is the main verb of the sentence, a long-short sequence would minimize overall dependency length. However, in 613 examples found in the Penn Treebank, the average length of the first adjunct was 3.15 words while the second adjunct was 3.48 words long, thus reflecting a short-long pattern, as illustrated in the Temperley p.c. example in Table 2. Apart from these, Hawkins (2001) shows that arguments are generally located closer to the verb than adjuncts. Gildea and Temperley (2007) also suggest

that adverb placement might involve cases which go against dependency length minimization. An examination of 295 legitimate long-short post-verbal constituent orders (counter to dependency length) from Section 00 of the Penn Treebank revealed that temporal adverb phrases are often involved in long-short orders, as shown in wsj\_0075.13 in Table 2. In our setup, the preference to minimize dependency length can be balanced by features capturing preferences for alternate choices (e.g. the argument-ad adjunct distinction in our dependency ordering model, Table 4). Via distributional analyses, we show that while simpler realization ranking models can go overboard in minimizing dependency length, richer models largely succeed in overcoming this issue, while still taking advantage of dependency length minimization to avoid egregious ordering errors.

## 2 Background

### 2.1 Minimal Dependency Length

Comprehension and corpus studies (Gibson, 1998; Gibson, 2000; Temperley, 2007) point to the tendency of production and comprehension systems to adhere to principles of dependency length minimization. The idea of dependency length minimization is based on Gibson’s (1998) Dependency Locality Theory (DLT) of comprehension, which predicts that longer dependencies are more difficult to process. DLT predictions have been further validated using comprehension studies involving eye-tracking corpora (Demberg and Keller, 2008). DLT metrics also correlate reasonably well with activation decay over time expressed in computational models of

Temperley (p.c.)	[In 1976], [as a film student at the Purchase campus of the State University of New York], Mr. Lane, shot ...

Table 2: Counter-examples to dependency length minimization

comprehension (Lewis et al., 2006; Lewis and Vasishth, 2005).

Extending these ideas from comprehension, Temperley (2007) poses the question: Does language production reflect a preference for shorter dependencies as well so as to facilitate comprehension? By means of a study of Penn Treebank data, Temperley shows that English sentences do display a tendency to minimize the sum of all their head-dependent distances as illustrated by a variety of constructions. Further, Gildea and Temperley (2007) report that random linearizations have higher dependency lengths compared to actual English, while an “optimal” algorithm (from the perspective of dependency length minimization), which places dependents on either sides of a head in order of increasing length, is closer to actual English. Tily (2010) also applies insights from the above cited papers to show that dependency length constitutes a significant pressure towards language change. For head-final languages (e.g., Japanese), dependency length minimization results in the “long-short” constituent ordering in language production (Yamashita and Chang, 2001). More generally, Hawkins’s (1994; 2000) processing domains, dependency length minimization and end-weight effects in constituent ordering (Wasow and Arnold, 2003) are all very closely related. The dependency length hypothesis goes beyond the predictions made by Hawkins’ *Minimize Domains* principle in the case of English clauses with three post-verbal adjuncts: Gibson’s DLT correctly predicts that the first constituent tends to be shorter than the second, while Hawkins’ approach does not make predictions about the relative orders of the first two constituents.

However, it would be very reductive to consider dependency length minimization as the sole factor in language production. In fact, a large body of prior work discusses a variety of other factors involved in language production. These other prefer-

ences are either correlated with dependency length or can override the minimal dependency length preference. Complexity (Wasow, 2002; Wasow and Arnold, 2003), animacy (Snider and Zaenen, 2006; Branigan et al., 2008), information status considerations (Wasow and Arnold, 2003; Arnold et al., 2000), the argument-adjunct distinction (Hawkins, 2001) and lexical bias (Wasow and Arnold, 2003; Bresnan et al., 2007) are a few prominent factors. More recently, Anttila et al. (2010) argued that the principle of end weight can be revised by calculating weight in prosodic terms to provide more explanatory power. As Temperley (2007) suggests, a satisfactory model should combine insights from multiple approaches, a theme which we investigate in this work by means of a rich feature set adapted from the parsing and realization literature. Our feature design has been inspired by the conclusions of the above-cited works pertaining to the role of dependency length minimization in syntactic choice in conjunction with other factors influencing constituent order. However, going beyond Temperley’s corpus study, we confirm the utility of incorporating a feature for minimizing dependency length into machine-learned models with hundreds of thousands of features found to be useful in previous parsing and realization work, and investigate the extent to which these features can counterbalance a dependency length minimization preference in cases where canonical word order considerations should prevail.

## 2.2 Surface Realization with Combinatory Categorical Grammar (CCG)

We provide here a brief overview of CCG and the OpenCCG realizer; for further details, see the works cited below.

CCG (Steedman, 2000) is a unification-based categorial grammar formalism defined almost entirely in terms of lexical entries that encode sub-

Feature Type	Example
LexCat + Word	s/s/np + before
LexCat + POS	s/s/np + IN
Rule	$s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np$
Rule + Word	$s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np + bought$
Rule + POS	$s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np + VBD$
Word-Word	$\langle company, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np, bought \rangle$
Word-POS	$\langle company, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np, VBD \rangle$
POS-Word	$\langle NN, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np, bought \rangle$
Word + $\Delta_w$	$\langle bought, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np \rangle + d_w$
POS + $\Delta_w$	$\langle VBD, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np \rangle + d_w$
Word + $\Delta_p$	$\langle bought, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np \rangle + d_p$
POS + $\Delta_p$	$\langle VBD, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np \rangle + d_p$
Word + $\Delta_v$	$\langle bought, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np \rangle + d_v$
POS + $\Delta_v$	$\langle VBD, s_{dcl} \rightarrow np\ s_{dcl}\ \backslash np \rangle + d_v$

Table 3: Basic and dependency features from Clark & Curran’s (2007) normal form model; distances are in intervening words, punctuation marks and verbs, and are capped at 3, 3 and 2, respectively

categorization as well as syntactic features (e.g. number and agreement). OpenCCG is a parsing/generation library which includes a hybrid symbolic-statistical chart realizer (White, 2006; White and Rajkumar, 2009). The input to the OpenCCG realizer is a semantic graph, where each node has a lexical predication and a set of semantic features; nodes are connected via dependency relations. Internally, such graphs are represented using Hybrid Logic Dependency Semantics (HLDS), a dependency-based approach to representing linguistic meaning (Baldrige and Kruijff, 2002). Alternative realizations are ranked using integrated  $n$ -gram or averaged perceptron scoring models. In the experiments reported below, the inputs are derived from the gold standard derivations in the CCGbank (Hockenmaier and Steedman, 2007), and the outputs are the highest-scoring realizations found during the realizer’s chart-based search.<sup>1</sup>

### 3 Feature Design

In the realm of paraphrasing using tree linearization, Kempen and Harbusch (2004) explore features which have later been appropriated into classification approaches for surface realization (Filippova and Strube, 2007). Prominent features include in-

<sup>1</sup>The realizer can also be run using inputs derived from OpenCCG’s parser, though informal experiments suggest that parse errors tend to decrease generation quality.

formation status, animacy and phrase length. In the case of ranking models for surface realization, by far the most comprehensive experiments involving linguistically motivated features are reported in work of Cahill for German realization ranking (Cahill et al., 2007; Cahill and Riester, 2009). Apart from language model and Lexical Functional Grammar (LFG)  $c$ -structure and  $f$ -structure based features, Cahill also designed and incorporated features modeling information status considerations.

The feature sets explored in this paper extend those in previous work on realization ranking with OpenCCG using averaged perceptron models (White and Rajkumar, 2009; Rajkumar et al., 2009; Rajkumar and White, 2010) to include more comprehensive ordering features. The feature classes are listed below, where DEPLEN, HOCKENMAIER and DEPORD are novel, and the rest are as in earlier OpenCCG models. The inclusion of the DEPORD features is intended to yield a model with a similarly rich set of ordering features as Cahill and Forster’s (2009) realization ranking model for German. Except where otherwise indicated, features are integer-valued, representing counts of occurrences in a derivation.

**DEPLEN** The total of the length between all semantic heads and dependents for a realization, where length is in intervening words<sup>2</sup> excluding punctuation. For length purposes, collapsed named entities were counted as a single word in the experiments reported here.

**GRAMS** The log probabilities of the word sequence scored using three different  $n$ -gram models: a trigram word model, a trigram word model with named entity classes replacing words, and a trigram model over POS tags and supertags.

**HOCKENMAIER** As an extra component of the generative baseline, the log probability of the derivation according to (a reimplementation

<sup>2</sup>We also experimented with two other definitions of dependency length described in the literature, namely (1) counting only nouns and verbs to approximate counting by discourse referents (Gibson, 1998) and (2) omitting function words to approximate prosodic weight (Anttila et al., 2010); however, realization ranking accuracy was slightly worse than counting all non-punctuation words.

Feature Type	Example
HeadBroadPos + Rel + Precedes + HeadWord + DepWord	⟨VB, Arg0, dep, wants, he⟩
... + HeadWord + DepPOS	⟨VB, Arg0, dep, wants, PRP⟩
... + HeadPOS + DepWord	⟨VB, Arg0, dep, VBZ, he⟩
... + HeadWord + DepPOS	⟨VB, Arg0, dep, VBZ, PRP⟩
HeadBroadPos + Side + DepWord1 + DepWord2	⟨NN, left, an, important⟩
... + DepWord1 + DepPOS2	⟨NN, left, an, JJ⟩
... + DepPOS1 + DepWord2	⟨NN, left, DT, important⟩
... + DepPOS1 + DepPOS2	⟨NN, left, DT, JJ⟩
... + Rel1 + Rel2	⟨NN, left, Det, Mod⟩

Table 4: Basic head-dependent and sibling dependent ordering features

of) Hockenmaier’s (2003) generative syntactic model.

**DISCRIMINATIVE NGRAMS** Sequences from each of the  $n$ -gram models in the perceptron model.

**AGREEMENT** Features for subject-verb and animacy agreement as well as balanced punctuation.

**C&C NF BASE** The features from Clark & Curran’s (2007) normal form model, listed in Table 3, minus the distance features.

**C&C NF DISTANCE** The distance features from the C&C normal form model, where the distance between a head and its dependent is measured in intervening words, punctuation marks or verbs; caps of 3, 3 and 2 (resp.) on the distances have the effect of binning longer distances.

**DEPORD** Several classes of features for ordering heads and dependents as well as sibling dependents on the same side of the head. The basic features—using words, POS tags and dependency relations, grouped by the broad POS tag of the head—are shown in Table 4. There are also similar features using words and a word class (instead of words and POS tags), where the class is either the named entity class, COLOR for color words, PRO for pronouns, one of 60-odd suffixes culled from the web, or HYPHEN or CAP for hyphenated or capitalized words. Additionally, there are features for detecting definiteness of an NP or PP (where the definiteness value is used in place of the POS tag).

Model	# Alph Feats	# Model Feats

## 4 Evaluation

### 4.1 Experimental Conditions

We followed the averaged perceptron training procedure of White and Rajkumar (2009) with a couple of updates. First, as noted earlier, we used a reimplementation of Hockenmaier’s (2003) generative syntactic model as an extra component of our generative baseline; and second, only five epochs of training were used, which was found to work as well as using additional epochs on the development set. As in the earlier work, the models were trained on the standard training sections (02–21) of an enhanced version of the CCGbank, using a lexico-grammar extracted from these sections.

The models tested in the experiments reported below are summarized in Table 5. The three groups of models are designed to test the impact of the dependency length feature when added to feature sets of increasing complexity. In more detail, the GLOBAL and DEPLEN-GLOBAL models contain dense features on entire derivations; their values are the log probabilities of the three  $n$ -gram mod-

Model	Dep Len	Ngram Mods	Hockenmaier	Discr Ngrams	Agreement	C&C NF Base	C&C NF Dist	Dep Ord
GLOBAL	N	Y	Y	N	N	N	N	N
DEPLEN-GLOBAL	Y	Y	Y	N	N	N	N	N
DEPORD-NONF	N	Y	Y	Y	Y	N	N	Y
DEPORD-NODIST	N	Y	Y	Y	Y	Y	N	Y
DEPLEN-NODIST	Y	Y	Y	Y	Y	Y	N	Y
DEPORD-NF	N	Y	Y	Y	Y	Y	Y	Y
DEPLEN	Y	Y	Y	Y	Y	Y	Y	Y

Table 5: Legend for experimental conditions

els used in the earlier work along with the Hockenmaier model (and the dependency length feature, in DEPLEN-GLOBAL). The second group is centered on DEPORD-NODIST, which contains all features except the dependency length feature and the distance features in Clark & Curran’s normal form model, which may indirectly capture some dependency length minimization preferences. In addition to DEPLEN-NODIST—where the dependency length feature is added—this group also contains DEPORD-NONF, which is designed to test (as a side comparison) whether the Clark & Curran normal form base features are still useful even when used in conjunction with the new dependency ordering features. In the final group, DEPORD-NF contains all the features examined in this paper except the dependency length feature, while DEPLEN contains all the features including the dependency length feature. Note that the learned weight of the total dependency length feature was negative in each case, as expected.

Table 6 shows the sizes of the various models. For each model, the alphabet—whose size increases to over a million features—is the set of applicable features found to have discriminative value in at least 5 training examples; from these, a subset are made active (i.e., take on a non-zero weight) through perceptron updates when the feature value differs between the model-best and oracle-best realization.

## 4.2 BLEU Results

Following the usual practice in the realization ranking, we first evaluate our results quantitatively using exact matches and BLEU (Papineni et al., 2002), a corpus similarity metric developed for MT evaluation. Realization results for the development and

Model	% Exact	BLEU	Signif
<b>Sect 00</b>			
GLOBAL	33.03	0.8292	-
DEPLEN-GLOBAL	34.73	<b>0.8345</b>	***
DEPORD-NONF	42.33	0.8534	**
DEPORD-NODIST	43.12	0.8560	-
DEPLEN-NODIST	43.87	<b>0.8587</b>	***

DEPLEN-NODIST	42.95	<b>0.8603</b>	***
DEPORD-NF	41.32	0.8577	-
DEPLEN	42.05	<b>0.8596</b>	**

Table 7: Development (Section 00) & test (Section 23) set results—exact match percentage and BLEU scores, along with statistical significance of BLEU compared to the unmarked model in each group (\* =  $p < 0.1$ , \*\* =  $p < 0.05$ , \*\*\* =  $p < 0.01$ ); significant within-group winners (at  $p < 0.05$ ) are shown in bold

test sections appear in Table 7. For all three model groups, the dependency length feature yields significant increases in BLEU scores, even in comparison to the model (DEPORD-NF) containing Clark & Curran’s distance features in addition to the new dependency ordering features (as well as all other features but total dependency length). The second group additionally shows that the Clark & Curran normal form base features do indeed have a significant impact on BLEU scores even when used with

Model	% DL Lower	% DL Greater	DL Mean	Signif
GOLD	n.a.	n.a.	41.02	-
GLOBAL	17.23	21.59	42.40	***
DEPLEN-GLOBAL	24.37	12.81	40.29	***
DEPORD-NONF	15.76	19.34	42.34	***
DEPORD-NODIST	14.58	19.06	42.03	***
DEPLEN-NODIST	17.75	14.82	40.87	n.s.
DEPORD-NF	14.96	17.65	41.58	***
DEPLEN	16.28	14.78	40.97	n.s.

Table 8: Dependency length compared to corpus—percentage of realizations with dependency length less than and greater than gold standard, along with mean dependency length, whose significance is tested against gold; 1671 development set (Section 00) complete realizations analyzed

the new dependency ordering model, as DEPORD-NONF is significantly worse than DEPORD-NODIST (the impact of the distance features is evident in the increases from the second group to the third group). As with the dev set, the dependency length feature yielded a significant increase in BLEU scores for each comparison on the test set also.

For each group, the statistical significance of the difference in BLEU scores between a model and the unmarked model (-) is determined by bootstrap resampling (Koehn, 2004).<sup>3</sup> Note that although the differences in BLEU scores are small, they end up being statistically significant because the models frequently yield the same top scoring realization, and reliably deliver improvements in the cases where they differ. In particular, note that DEPLEN and DEPORD-NF agree on the best realization 81% of the time, while DEPLEN-NODIST and DEPORD-NODIST have 78.1% agreement, and DEPLEN-GLOBAL and GLOBAL show 77.4% agreement; by comparison, DEPORD-NODIST and GLOBAL only agree on the best realization 51.1% of the time.

### 4.3 Detailed Analyses

The effect of the dependency length feature on the distribution of dependency lengths is illustrated in Table 8. The table shows the mean of the total dependency length of each realized derivation com-

<sup>3</sup>Kudos to Kevin Gimpel for making his resampling scripts available from [http://www.ark.cs.cmu.edu/MT/paired\\_bootstrap\\_v13a.tar.gz](http://www.ark.cs.cmu.edu/MT/paired_bootstrap_v13a.tar.gz).

Model	% Short / Long	% Long / Short	% Eq	% Single Constit

Table 9: Distribution of various kinds of post-verbal constituents in the development set (Section 00); 4692 gold cases considered

pared to the corresponding gold standard derivation, as well as the number of derivations with greater and lower dependency length. According to paired t-tests, the mean dependency lengths for the DEPLEN-NODIST and DEPLEN models do not differ significantly from the gold standard. In contrast, the mean dependency length of all the models that do not include the dependency length feature does differ significantly ( $p < 0.001$ ) from the gold standard. Additionally, all these models have more realizations with dependency length greater than the gold standard, in comparison to the dependency length minimizing models; this shows the efficacy of the dependency length feature in approximating the gold standard. Interestingly, the DEPLEN-GLOBAL model significantly undershoots the gold standard on mean dependency length, and has the most skewed distribution of sentences with greater vs. lesser dependency length than the gold standard.

Apart from studying dependency length directly, we also looked at one of the attested effects of dependency length minimization, viz. the tendency to prefer short-long post-verbal constituents in production (Temperley, 2007). The relative lengths of adjacent post-verbal constituents were computed and their distribution is shown in Table 9. While calculating length, punctuation marks were excluded. Four kinds of constituents were found in the post-verbal domain. For every verb, apart from single constituents and equal length constituents, short-long and long-short sequences were also observed. Table 9 demonstrates that for both the gold standard corpus as well as the realizer models, short-long constituents were more frequent than long-short or equal length constituents. This follows the trend re-

Model	% Light / Heavy	% Heavy / Light	Signif
GOLD	8.60	0.36	-
GLOBAL	7.73	2.02	***
DEPLEN-GLOBAL	8.35	0.75	**
DEPORD-NONF	7.98	1.15	***
DEPORD-NODIST	8.04	1.12	***
DEPLEN-NODIST	8.23	0.45	n.s.
DEPORD-NF	8.26	0.71	**
DEPLEN	8.36	0.51	n.s.

Table 10: Distribution of heavy unequal constituents (length difference > 5) in Section 00; 4692 gold cases considered and significance tested against the gold standard using a  $\chi$ -square test

ported by previous corpus studies of English (Temperley, 2007; Wasow and Arnold, 2003). The figures reported here show the tendency of the DEPLEN\* models to be closer to the gold standard than the other models, especially in the case of short-long constituents.

We also performed an analysis of relative constituent lengths focusing on light-heavy and heavy-light cases; specifically, we examined unequal length constituent sequences where the length difference of the constituents was greater than 5, and the shorter constituent was under 5 words. Table 10 shows the results. Using a  $\chi$ -square test, the distribution of heavy unequal length constituent counts in the DEPLEN-NODIST and DEPLEN models does not significantly differ from that of the gold standard. In contrast, for all the other models, the counts do differ significantly from the gold standard.

#### 4.4 Examples

Table 11 shows examples of how the dependency length feature (DEPLEN) affects the output even in comparison to a model (DEPORD) with a rich set of discriminative syntactic and dependency ordering features, but no features directly targeting relative weight. In wsj\_0015.7, the dependency length model produces an exact match, while the DEPORD model fails to shift the short temporal adverbial *next year* next to the verb, leaving a confusingly repetitive *this year next year* at the end of the sentence. In wsj\_0020.1, the dependency length model produces a nearly exact match with just an equally ac-

ceptable inversion of *closely watching*. By contrast, the DEPORD model mistakenly shifts the direct object *South Korea, Taiwan and Saudia Arabia* to the end of the sentence where it is difficult to understand following two very long intervening phrases. In wsj\_0021.8, both models mysteriously put *not* in front of the auxiliary and leave out the complementizer, but DEPORD also mistakenly leaves *before* at the end of the verb phrase where it is again apt to be interpreted as modifying the preceding verb. In wsj\_0075.13, both models put the temporal modifier *on Thursday* in its canonical VP-final position, despite this order running counter to dependency length minimization. Finally, wsj\_0014.2 shows a case where DEPORD is nearly an exact match (except for a missing comma), but the dependency length model fronts the PP *on the 12-member board*, where it is grammatical but rather marked (and not motivated in the discourse context).

#### 4.5 Interim Discussion

The experiments show a consistent positive effect of the dependency length feature in improving BLEU scores and achieving a better match with the corpus distributions of dependency length and short/long constituent orders. The results in Table 10 are particularly encouraging, as they show that minimizing dependency length reduces the number of realizations in which a heavy constituent precedes a light one down to essentially the level of the corpus, thereby eliminating many realizations that can be expected to have egregious errors like those shown in Table 11.

Intriguingly, there is some evidence that a negatively weighted total dependency length feature can go too far in minimizing dependency length, in the absence of other informative features to counterbalance it. In particular, the DEPLEN-GLOBAL model in Table 8 has significantly lower dependency length than the corpus, but in the richer models with discriminative syntactic and dependency ordering features, there are no significant differences. It may still be though that additional features are necessary to counteract the tendency towards dependency length minimization, for example to ensure that initial constituents play their intended role in establishing and continuing topics in discourse, as also observed in Table 11.

#### 4.6 Targeted Human Evaluation

To determine whether heavy-light ordering differences often represent ordering errors (including egregious ones), rather than simply representing acceptable variation, we conducted a targeted human evaluation on examples of this kind. Specifically, for each of the DEPLEN\* models and their corresponding models without the dependency length feature, we chose the 25 sentences from the development section whose realizations exhibited the greatest difference in dependency length between sibling constituents appearing in opposite orders, and asked two judges (not the authors) to choose which of the two realizations best expressed the meaning of the reference sentence in a grammatical and fluent way, with the choice forced (2AFC). Table 12 shows the results. Agreement between the judges was high,

Model	% Preferred	% Agr	Signif
GLOBAL	22	-	-
DEPLEN-GLOBAL	78	84	***
DEPORD-NODIST	24	-	-
DEPLEN-NODIST	76	92	***
DEPORD-NF	26	-	-
DEPLEN	74	96	***

Table 12: Targeted human evaluation—percentage of realizations preferred by two human judges in a 2AFC test among the 25 development set sentences with the greatest differences in dependency length, with a binomial test for significance

with only one disagreement on the realizations from the DEPLEN and DEPORD-NF models (involving an acceptable paraphrase in our judgment), and only four disagreements on the DEPLEN-GLOBAL and GLOBAL realizations. Pooling the judgments, the preference for the DEPLEN\* models was well above the chance level of 50% according to a binomial test ( $p < 0.001$  in each case). Inspecting the data ourselves, we found that many of the items did indeed involve egregious ordering errors that the DEPLEN\* models managed to avoid.

## 5 Related Work

As noted in the introduction, to the best of our knowledge this paper is the first to examine the impact of dependency length minimization on realization ranking. While there have been quite a few papers to date reporting results on Penn Treebank data, since the various systems make different assumptions regarding the specificity of their inputs, all but the most broad-brushed comparisons remain impossible at present, and thus detailed studies such as the present one can only be made within the context of different models for the same system. Some progress on this issue has been made in the context of the Generation Challenges Surface Realization Shared Task (Belz et al., 2011), but it remains to be seen to what extent fair cross-system comparisons using common inputs can be achieved.

For (very) rough comparison purposes, Table 13 lists our results in the context of those reported for various other systems on PTB Section 23. As the table shows, the OpenCCG scores are quite competitive, exceeded only by Callaway’s (2005) extensively hand-crafted system as well as Bohnet et al.’s (2011) system on shared task shallow inputs (-S), which performs much better than their system on deep inputs (-D) that more closely resemble OpenCCG’s.

## 6 Conclusions

In this paper, we have investigated dependency length minimization in the context of realization ranking, focusing on its potential to eliminate egregious ordering errors as well as better match the distributional characteristics of sentence orderings in news text. When added to a state-of-the-art, com-

System	Coverage	BLEU	% Exact
Callaway (05)	98.5%	0.9321	57.5
Bohnet et al.-S (11)	100%	0.8911	-
<b>OpenCCG (12)</b>	97.1%	0.8596	42.1
OpenCCG (09)	97.1%	0.8506	40.5
Ringger et al. (04)	100%	0.836	35.7
Bohnet et al.-D (11)	100%	0.7943	-
Langkilde-Geary (02)	83%	0.757	28.2
Guo et al. (08)	100%	0.7440	19.8
Hogan et al. (07)	≈100%	0.6882	-
OpenCCG (08)	96.0%	0.6701	16.0
Nakanishi et al. (05)	90.8%	0.7733	-

Table 13: PTB Section 23 BLEU scores and exact match percentages in the NLG literature (Nakanishi et al.’s results are for sentences of length 20 or less)

prehensive realization ranking model, we showed that including a dense, global feature for minimizing total dependency length yields statistically significant improvements in BLEU scores and significantly reduces the number of heavy-light ordering errors. Going beyond the BLEU metric, we also conducted a targeted human evaluation to confirm the utility of the dependency length feature in models of varying richness. Interestingly, even with the richest model, in some cases we found that the dependency length feature still appears to go too far in minimizing dependency length, suggesting that further counter-balancing features—especially ones for the sentence-initial position (Filippova and Strube, 2009)—warrant investigation in future work.

## Abstract

We present a new approach to the problem of automatic text summarization called Automatic Summarization using Reinforcement Learning (ASRL) in this paper, which models the process of constructing a summary within the framework of reinforcement learning and attempts to optimize the given score function with the given feature representation of a summary. We demonstrate that the method of reinforcement learning can be adapted to automatic summarization problems naturally and simply, and other summarizing techniques, such as sentence compression, can be easily adapted as actions of the framework.

The experimental results indicated ASRL was superior to the best performing method in DUC2004 and comparable to the state of the art ILP-style method, in terms of ROUGE scores. The results also revealed ASRL can search for sub-optimal solutions efficiently under conditions for effectively selecting features and the score function.

## 1 Introduction

Automatic text summarization aims to automatically produce a short and well-organized summary of single or multiple documents (Mani, 2001). Automatic summarization, especially multi-document summarization, has been an increasingly important task in recent years, because of the exponential explosion of available information. The brief summary that the summarization system produces allows readers to quickly and easily understand the content of original documents without having to read each individ-

ual document, and it should be helpful for dealing with enormous amounts of information.

The extractive approach to automatic summarization is a popular and well-known approach in this field, which creates a summary by directly selecting some textual units (e.g., words and sentences) from the original documents, because it is difficult to genuinely evaluate and guarantee the linguistic quality of the produced summary.

One of the most well-known extractive approaches is maximal marginal relevance (MMR), which scores each textual unit and extracts the unit that has the highest score in terms of the MMR criteria (Goldstein et al., 2000). Greedy MMR-style algorithms are widely used; however, they cannot take into account the whole quality of the summary due to their greediness, although a summary should convey all the information in given documents. Global inference algorithms for the extractive approach have been researched widely in recent years (Filatova and Hatzivassiloglou, 2004; McDonald, 2007; Takamura and Okumura, 2009) to consider whether the summary is “good” as a whole. These algorithms formulate the problem as integer linear programming (ILP) to optimize the score; however, as ILP is non-deterministic polynomial-time hard (NP-hard), the time complexity is very large. Consequently, we need some more efficient algorithm for calculations.

We present a new approach to the problem of automatic text summarization called Automatic Summarization using Reinforcement Learning (ASRL), which models the process of construction of a summary within the framework of reinforcement learn-

ing and attempts to optimize the given score function with the given feature representation of a summary. We demonstrate that the method of reinforcement learning can be adapted to problems with automatic summarization naturally and simply, and other summarizing techniques, such as sentence compression, can be easily adapted as actions of the framework, which should be helpful to enhance the quality of the summary that is produced. This is the first paper utilizing reinforcement learning for problems with automatic summarization of text.

We evaluated ASRL with the DUC2004 summarization task 2, and the experimental results revealed ASRL is superior to the best method of performance in DUC2004 and comparable with the state of the art ILP-style method, based on maximum coverage with the knapsack constraint problem, in terms of ROUGE scores with experimental settings. We also evaluated ASRL in terms of optimality and execution time. The experimental results indicated ASRL can search the state space efficiently for some sub-optimal solutions under the condition of effectively selecting features and the score function, and produce a summary whose score denotes the expectation of the score of the same features' states. The evaluation of the quality of a produced summary only depends on the given score function, and therefore it is easy to adapt the new method of evaluation without having to modify the structure of the framework.

## 2 Formulation of Extractive Approach

We first focus on the extractive approach, which is directly used to produce a summary by extracting some textual units, by avoiding the difficulty of having to consider the genuine linguistic quality of a summary.

The given document (or documents) in extractive summarization approaches is reduced to the set of textual units:  $D = \{x_1, x_2, \dots, x_n\}$ , where  $n$  is the size of the set, and  $x_i$  denotes individual textual units. Note that any textual unit is permitted, such as *character*, *word*, *sentence*, *phrase*, and *conceptual unit*. If we determine a *sentence* is a textual unit to be extracted, the formulated problem is a problem of extracting sentences from the source document, which is one of the most popular settings for sum-

marization tasks.

Next, we define the score function,  $score(S)$ , for any subset of the document:  $S \subset D$ . Subset  $S$  is one of the summaries of the given document. The aim of this summarization problem is to find the summary that maximizes this function when the score function is given. The score function is typically defined by taking into consideration the tradeoff between relevance and redundancy.

Then, we define length function  $L(S)$ , which indicates the length of summary  $S$ . The length is also arbitrary, which can be based on the *character*, *word*, and *sentence*. We assume the limitation of summary length  $K$  is given in summarization tasks.

Finally, we define the extractive approach of the automatic summarization problem as:

$$\begin{aligned} S^* &= \arg \max_{S \subset D} score(S) \\ \text{s.t.} \quad &L(S) \leq K. \end{aligned} \quad (1)$$

## 3 Motivation

We can regard the extractive approach as a search problem. It is extremely difficult to solve this search problem because the final result of evaluation given by the given score function is not available until it finishes, and we therefore need to try all combinations of textual units. Consequently, the score function, which denotes some criterion for the quality of a summary, tends to be determined so that the function can be decomposed to components and it is solved with global inference algorithms, such as ILP. However, both decomposing the score function properly and utilizing the evaluation of half-way process of searches are generally difficult. For example, let us assume that we design the score function by using some complex semantic considerations to take into account the readability of a summary, and the score is efficiently calculated if the whole summary is given. Then, formulating the problem as a global inference problem and solving it with methods of integer linear programming might generally be difficult, because of the complex composition of the score function, despite the ease with which the whole summary is evaluated. The readability score might be based on extremely complex calculations of dependency relations, or a great deal of external knowledge the summarizer cannot know

merely from the source documents. In fact, it is ideal that we can only directly utilize the score function, in the sense that we do not have to consider the decomposed form of the given score function.

We need to consider the problem with automatic summarization to be the same as that with reinforcement learning to handle these problems. Reinforcement learning is one of the solutions to three problems.

- The learning of the agent only depends on the reward provided by the environment.
- Furthermore, the reward is delayed, in the sense that the agent cannot immediately know the actual evaluation of the executed action.
- The agent only estimates the value of the state with the information on rewards, without knowledge of the actual form of the score function, to maximize future rewards.

We suggest the formulation of the problem as we have just described will enable us to freely design the score function without limitations and expand the capabilities of automatic summarization.

## 4 Models of Extractive Approach for Reinforcement Learning

### 4.1 Reinforcement Learning

Reinforcement learning is a powerful method of solving planning problems, especially problems formulated as Markov decision processes (MDPs) (Sutton and Barto, 1998). The agent of reinforcement learning repeats three steps until terminated at each episode in the learning process.

1. The agent observes current *state*  $s$  from the *environment*, contained in state space  $\mathcal{S}$ .
2. Next, it determines and executes next *action*  $a$  according to current policy  $\pi$ . Action  $a$  is contained in the action space limited by the current state:  $\mathcal{A}(s)$ , which is a subset of whole action space  $\mathcal{A} = \bigcup_{s \in \mathcal{S}} \mathcal{A}(s)$ . Policy  $\pi$  is the strategy for selecting action, represented as a conditional distribution of actions:  $p(a|s)$ .
3. It then observes next state  $s'$  and receives *reward*  $r$  from the environment.

The aim of reinforcement learning is to find optimal policy  $\pi^*$  only with information on sample trajectories and to reward the experienced agent.

We describe how to adapt the extractive approach to the problem of reinforcement learning in the sections that follow.

### 4.2 State

A state denotes a summary. We represent state  $s$  as a tuple of summary  $S$  (a set of textual units) and additional state variables:  $s = (S, A, f)$ . We assume  $s$  has the history of actions  $A$  that the agent executed to achieve this state. Additionally,  $s$  has the binary state variable,  $f \in \{0, 1\}$ , which denotes whether  $s$  is a terminal state or not. Initial state  $s_0$  is  $(\emptyset, \emptyset, 0)$ .

We assume the  $d$ -dimensional feature representation of state  $s$ :  $\phi(s) \in \mathbb{R}^d$ , which only depends on the feature of summary  $\phi'(S) \in \mathbb{R}^{d-1}$ . Given  $\phi'(S)$ , we define the features as:

$$\phi(s) = \begin{cases} (\phi'(S), 0)^T & (L(S) \leq K) \\ (\mathbf{0}, 1)^T & (K < L(S)) \end{cases} \quad (2)$$

This definition denotes that summaries that violate the length limitation are shrunk to a single feature,  $(\mathbf{0}, 1)^T$ , which means it is not a summary.

Note the features of the state only depend on the features of the summary, not on the executed actions to achieve the state. Unlike naive search methods, this property has the potential for different states to be represented as the same vector, which has the same features. The agent, however, should search as many possible states as it can. Therefore, the generalization function of the feature representation is of utmost importance. The accurate selection of features contributes to reducing the search space and provides efficient learning as will be discussed later.

### 4.3 Action

An action denotes a transition operation that produces a new state from a current state. We assumed all actions were deterministic in this study. We define  $\text{insert}_i (1 \leq i \leq n)$  actions, each of which inserts textual unit  $x_i$  to the current state unless the state is terminated, as described in the following di-

agram:

$$\begin{pmatrix} s_t \\ S_t \\ A_t \\ 0 \end{pmatrix} \xrightarrow{a_t \text{ insert}_i} \begin{pmatrix} s_{t+1} \\ S_t \cup \{x_i\} \\ A_t \cup \{\mathbf{insert}_i\} \\ 0 \end{pmatrix}. \quad (3)$$

In addition to insertion actions, we define **finish** that terminates the current episode in reinforcement learning:

$$\begin{pmatrix} s_t \\ S_t \\ A_t \\ 0 \end{pmatrix} \xrightarrow{\mathbf{finish}} \begin{pmatrix} s_{t+1} \\ S_t \\ A_t \cup \{\mathbf{finish}\} \\ 1 \end{pmatrix} \quad (4)$$

Note that  $f_t = 1$  means state  $s_t$  is a terminal state.

Then, the whole action set,  $\mathcal{A}$ , is defined by **insert<sub>i</sub>** and **finish**:

$$\mathcal{A} = \{\mathbf{insert}_1, \mathbf{insert}_2, \dots, \mathbf{insert}_n, \mathbf{finish}\}. \quad (5)$$

We can calculate the available actions limited by state  $s_t$ :

$$\mathcal{A}(s_t) = \begin{cases} \mathcal{A} \setminus A_t & (L(S_t) \leq K) \\ \{\mathbf{finish}\} & (K < L(S_t)) \end{cases}. \quad (6)$$

This definition means that the agent may execute one of the actions that have not yet been executed in this episode, and it has no choice but to finish if the summary of the current state already violates length limitations.

#### 4.4 Reward

The agent receives a reward from the environment as some kind of criterion of how good the action the agent executed was. If the current state is  $s_t$ , the agent executes  $a_t$ , and the state makes a transition into  $s_{t+1}$ ; then, the agent receives the reward,  $r_{t+1}$ :

$$r_{t+1} = \begin{cases} \text{score}(S_t) & (a_t = \mathbf{finish}, L(S_t) \leq K) \\ -R_{\text{penalty}} & (a_t = \mathbf{finish}, K < L(S_t)), \\ 0 & (\text{otherwise}) \end{cases}, \quad (7)$$

where  $R_{\text{penalty}} > 0$ .

The agent can receive the score awarded by the given score function if and only if the executed action is **finish** and the summary length is appropriate. If the summary length is inappropriate but the

executed action is **finish**, the environment awards a penalty to the agent. The most important point of this definition is that the agent receives nothing under the condition where the next state is not terminated. In this sense, the reward is delayed. Due to this definition, maximizing the expectation of future rewards is equivalent to maximizing the given score function, and we do not need to consider the decomposed form of the score function, i.e., we only need to consider the final score of the whole summary.

#### 4.5 Value Function Approximation

Our aim is to find the optimal policy. This is achieved by obtaining the optimal *state value function*,  $V^*(s)$ , because if we obtain this, the greedy policy is optimal, which determines the action so as to maximize the state value after the transition occurred. Therefore, our aim is equivalent to finding  $V^*(s)$ . Let us try to estimate the *state value function* with parameter  $\theta \in \mathbb{R}^d$ :

$$V(s) = \theta^T \phi(s). \quad (8)$$

We can also represent and estimate the *action value function*,  $Q(s, a)$ , by using  $V(s)$ :

$$Q(s, a) = r + \gamma V(s'), \quad (9)$$

where the execution of  $a$  causes the state transition from  $s$  to  $s'$  and the agent receives reward  $r$ , and  $\gamma (0 \leq \gamma \leq 1)$  is the discount rate. Note that all actions are deterministic in this study.

By using these value functions, we define the policy as the conditional distribution,  $p(a|s; \theta, \tau)$ , which is parameterized by  $\theta$  and a temperature parameter  $\tau$ :

$$p(a|s; \theta, \tau) = \frac{e^{Q(s,a)/\tau}}{\sum_{a'} e^{Q(s,a')/\tau}}. \quad (10)$$

Temperature  $\tau$  decreases as learning progresses, which causes the policy to be greedier. This softmax selection strategy is called Boltzmann selection.

#### 4.6 Learning Algorithm

The goal of learning is to estimate  $\theta$ . We use the TD ( $\lambda$ ) algorithm with function approximation (Sutton and Barto, 1998). Algorithm 1 represents the whole system of our method, called Automatic Summarization using Reinforcement Learning (ASRL)

---

**Algorithm 1** ASRL

---

**Input:** document  $D = \{x_1, x_2, \dots, x_n\}$ ,  
score function  $score(S)$

- 1: initialize  $\theta = \mathbf{0}$
- 2: **for**  $k = 1$  **to**  $N$  **do**
- 3:    $s \leftarrow (\emptyset, \emptyset, 0)$   
      // initial state
- 4:    $e = \mathbf{0}$
- 5:   **while**  $s$  is not terminated **do**
- 6:      $a \sim p(a|s; \theta, \tau_k)$   
      // selects action with current policy
- 7:      $(s', r) \leftarrow \text{execute}(s, a)$   
      // observes next state and receive reward
- 8:      $\delta \leftarrow r + \gamma \theta^T \phi(s') - \theta^T \phi(s)$   
      // calculates TD-error
- 9:      $e \leftarrow \gamma \lambda e + \phi(s)$   
      // updates the eligibility trace
- 10:     $\theta \leftarrow \theta + \alpha_k \delta e$   
      // learning with current learning rate
- 11:     $s \leftarrow s'$
- 12:    **end while**
- 13: **end for**
- 14:  $s \leftarrow (\emptyset, \emptyset, 0)$
- 15: **while**  $s$  is not terminated **do**
- 16:    $a \leftarrow \max_a Q(s, a)$   
      // selects action greedily  
      with the learned policy
- 17:    $(s', r) \leftarrow \text{execute}(s, a)$
- 18:    $s \leftarrow s'$
- 19: **end while**
- 20: **return** the summary of  $s$

---

in this paper.  $N$  is the number of learning episodes, and  $e \in \mathbb{R}^d$  and  $\lambda (0 \leq \lambda \leq 1)$  correspond to the eligibility trace and the trace decay parameter. The eligibility trace,  $e$ , conveys all information on the features of states that the agent previously experienced, with previously decaying influences of features due to decay parameter  $\lambda$  and discount rate  $\gamma$  (Line 9).

Line 1 initializes parameter  $\theta$  to start up its learning. The following procedures from Lines 2 to 13 learn  $\theta$  with the TD ( $\lambda$ ) algorithm, by using information on actual interactions with the environment. Learning rate  $\alpha_k$  and temperature parameter  $\tau_k$  decay as the learning episode progresses. The best summary with the obtained policy is calculated in steps from Lines 14 to 19. If the agent can estimate

$\theta$  properly, greedy output is the optimal solution.

## 5 Models of Combined Approach for Reinforcement Learning

We formulated the extractive approach as a problem with reinforcement learning in the previous section. In fact, we can also formulate a more general model of summarization, since evaluation only depends on the final state and it is not actually very important to regard the given documents as a set of textual units contained in the original documents.

We explain how to take into account other methods within the ASRL framework by modifying the models in this section, with an example of sentence compression. We assume that we have a method of sentence compression,  $comp(x)$ , and that a textual unit to be extracted is a sentence. What we have to do is to only simply modify the definitions of the state and action. Note that this is just one example of the combined method. Even other summarization systems can be similarly adapted to ASRL.

### 5.1 State

We do not want to execute sentence compression twice, so we have to modify the state variables to convey the information:  $s = (S, A, c, f)$ , where  $c \in \{0, 1\}$ , and  $S, A$ , and  $f$  are the same definitions as previously described.

### 5.2 Action

We add deterministic action **comp** to  $\mathcal{A}$ , which produces the new summary constructed by compressing the last inserted sentence of the current summary:

$$\begin{array}{c} s_t \quad a_t \quad s_{t+1} \\ \left( \begin{array}{c} S_t \\ A_t \\ 0 \\ 0 \end{array} \right) \xrightarrow{\text{comp}} \left( \begin{array}{c} S_t \setminus \{x_c\} \cup \{comp(x_c)\} \\ A_t \cup \{\mathbf{comp}\} \\ 1 \\ 0 \end{array} \right), \quad (11) \end{array}$$

where  $x_c$  is the last sentence that is inserted into  $S_t$ . Next, we modify **insert<sub>i</sub>** and **finish**:

$$\begin{array}{c} s_t \quad a_t \quad s_{t+1} \\ \left( \begin{array}{c} S_t \\ A_t \\ c_t \\ 0 \end{array} \right) \xrightarrow{\text{insert}_i} \left( \begin{array}{c} S_t \cup \{x_i\} \\ A_t \cup \{\mathbf{insert}_i\} \\ 0 \\ 0 \end{array} \right) \quad (12) \end{array}$$

$$\begin{pmatrix} s_t & a_t & s_{t+1} \\ S_t \\ A_t \\ c_t \\ 0 \end{pmatrix} \xrightarrow{\text{finish}} \begin{pmatrix} S_t \\ A_t \cup \{\text{finish}\} \\ c_t \\ 1 \end{pmatrix}. \quad (13)$$

Note **comp**  $\in A(s_t)$  may be executed if and only if  $c_t = 0$ . **insert**<sub>*i*</sub> resets  $c$  to 0.

## 6 Experiments

We conducted three experiments in this study. First, we evaluated our method with ROUGE metrics (Lin, 2004), in terms of ROUGE-1, ROUGE-2, and ROUGE-L. Second, we conducted an experiment on measuring the optimization capabilities of ASRL, with the scores we obtained and the execution time. Third, we evaluated ASRL taking into consideration sentence compression by using a very naive method, in terms of ROUGE-1, ROUGE-2, and ROUGE-3.

### 6.1 Experimental Settings

We used sentences as textual units for the extractive approach in this research. Each sentence and document were represented as a bag-of-words vector with *tf\*idf* values, with stopwords removed. All tokens were stemmed by using Porter’s stemmer (Porter, 1980).

We experimented with our proposed method on the dataset of DUC2004 task2. This is a multi-document summarization task that contains 50 document clusters, each of which has 10 documents. We set up the length limitation to 665 bytes, used in the evaluation of DUC2004.

We set up the parameters of ASRL where the number of episodes  $N = 300$ , the training rate  $\alpha_k = 0.001 \cdot 101 / (100 + k^{1.1})$ , and the temperature  $\tau_k = 1.0 \cdot 0.987^{k-1}$  where  $k$  was the number of episodes that decayed as learning progressed. Both discount rate  $\gamma$  and trace decay parameter  $\lambda$  were fixed to 1 for episodic tasks. The penalty,  $R_{penalty}$ , was fixed to 1.

We used the following score function in this study:

$$\begin{aligned} score(S) = & \sum_{x_i \in S} \lambda_s Rel(x_i) \\ & - \sum_{x_i, x_j \in S, i < j} (1 - \lambda_s) Red(x_i, x_j), \quad (14) \end{aligned}$$

where

$$Rel(x_i) = Sim(x_i, D) + Pos(x_i)^{-1} \quad (15)$$

$$Red(x_i, x_j) = Sim(x_i, x_j). \quad (16)$$

$\lambda_s$  is the parameter for the trade-off between relevance and redundancy,  $Sim(x_i, D)$  and  $Sim(x_i, x_j)$  correspond to the cosine similarities between sentence  $x_i$  and the sentence set of the given original documents  $D$ , and between sentence  $x_i$  and sentence  $x_j$ .  $Pos(x_i)$  is the position of the occurrence of  $x_i$  when we index sentences in each document from top to bottom with one origin. This score function was determined by reference to McDonald (2007). We set  $\lambda_s = 0.9$  in this experiment.

We designed  $\phi'(S)$ , i.e., the vector representation of a summary, to adapt it to the summarization problem as follows.

- **Coverage of important words:** The elements are the top 100 words in terms of the *tf\*idf* of the given document with binary representation.
- **Coverage ratio:** This is calculated by counting up the number of top 100 elements included in the summary.
- **Redundancy ratio:** This is calculated by counting up the number of elements that excessively cover the top 100 elements.
- **Length ratio:** This is the ratio between the length of the summary and length limitation  $K$ .
- **Position:** This feature takes into consideration the position of sentence occurrences. It is calculated with  $\sum_{x \in S} Pos(x)^{-1}$ .

Consequently,  $\phi'(S)$  is a 104-dimensional vector.

We executed ASRL 10 times with the settings previously described and used all the results for evaluation.

We used the dataset of DUC2003, which is a similar task that contains 30 document clusters and each cluster had 10 documents, to determine  $\tau_k$  and  $\lambda_s$ . We determined the parameters so that they would converge properly and become close to the optimal solutions calculated by ILP, under the conditions that the described feature representation and the score function were given.

	ROUGE-1	ROUGE-2	ROUGE-L
ASRL	0.39013	0.09479	0.33769
MCKP	0.39033	0.09613	0.34225
PEER65	0.38279	0.09217	0.33099
ILP	0.34712	0.07528	0.31241
GREEDY	0.30618	0.06400	0.27507

Table 1: Results of ROUGE evaluation compared with other peers in DUC2004. Scores for ILP and GREEDY have statistically significant differences from scores of ASRL.

## 6.2 Evaluation

We compared ASRL with four other conventional methods.

- **GREEDY**: This method is a simple greedy algorithm, which repeats the selection of the sentence with the highest score of the remaining sentences by using an MMR-like method of scoring as follows:

$$x = \arg \max_{x \in D \setminus S} [\lambda_s Rel(x) - (1 - \lambda_s) \max_{x_i \in S} Red(x, x_i)], \quad (17)$$

where  $S$  is the current summary.

- **ILP**: This indicates the method proposed by McDonald (2007) for maximizing the score function (14) with integer linear programming.
- **PEER65**: This is the best performing system in task 2 of the DUC2004 competition in terms of ROUGE-1 proposed by Conroy et al. (2004).
- **MCKP**: This method was proposed by Takamura and Okamura (2009). MCKP defines an automatic summarization problem as a maximum coverage problem with a knapsack constraint, which uses *conceptual units* (Filatova and Hatzivassiloglou, 2004), and composes the meaning of sentences, as textual units and attempts to cover as many units as possible under the knapsack constraint.

## 7 Results

### 7.1 Evaluation with ROUGE

We evaluated our method of ASRL with ROUGE, in terms of ROUGE-1, ROUGE-2, and ROUGE-L.

	ROUGE-1	ROUGE-2	ROUGE-L
ASRL.0	0.39274	0.09537	0.34010
ASRL.1	0.39243	0.09683	0.33855
ASRL.2	0.39241	0.09597	0.34070
ASRL.3	0.39190	0.09580	0.33898
ASRL.4	0.39054	0.09579	0.33663
ASRL.5	0.38911	0.09395	0.33551
ASRL.6	0.38866	0.09392	0.33701
ASRL.7	0.38854	0.09338	0.33661
ASRL.8	0.38821	0.09363	0.33833
ASRL.9	0.38532	0.09281	0.33321

Table 2: Results of ROUGE evaluation for each ASRL peer of 10 results in DUC2004. ASRL did not converge with stable solution with these experimental settings because of property of randomness.

The experimental results are summarized in Tables 1 and 2. Table 1 lists the results for the comparison and Table 2 lists all the results for ASRL peers.

The results imply ASRL is superior to PEER65, ILP, and GREEDY, and comparable to MCKP with these experimental settings in terms of ROUGE metrics. Note that ASRL is a kind of approximate method, because actions are selected probabilistically and the method of reinforcement learning occasionally converges with some sub-optimal solution. This can be expected from Table 2, which indicates the results vary although each ASRL solution converged with some solution. However, in this experiment, ASRL achieved higher ROUGE scores than ILP, which achieved optimal solutions. This seems to have been caused by the properties of the features, which we will discuss later. It seems this feature representation is useful for efficiently searching the feature space. The method of mapping a state to features is, however, approximate in the sense that some states will shrink to the same feature vector, and ASRL therefore has no tendency to converge with some stable solution.

### 7.2 Evaluation of Optimization Capabilities

Since we proposed our method as an approach to approximate optimization, there was the possibility of convergence with some sub-optimal solution as previously discussed. We also evaluated our approach from the point of view of the obtained scores and the execution time to confirm whether our method had

Figure 1: Average score for each episode in ASRL in DUC2004. Horizontal lines indicate scores of summaries obtained with ILP and GREEDY.

optimization capabilities.

The experimental results are plotted in Figures 1 and 2. Figure 1 plots the average for the rewards (i.e., scores) that the agent obtained for each episode. The horizontal line for ILP is the average for the optimal scores of (14). The score in ASRL increases as the number of episodes increases, and overtakes the score of GREEDY at some episode. The agent attempts to come close to the optimal score line of ILP but seems to fail, and finally converges to some local optimal solution. We should increase the number of episodes, adjust parameters  $\alpha$  and  $\tau$ , and select more appropriate features for the state to improve the optimization capabilities of ASRL.

Figure 2 plots the execution time for each peer. The horizontal axis is the number of textual units, i.e., the number of sentences in this experiment. The vertical axis is the execution time taken by the task. The plots of ASRL and ILP fit a linear function for the former and an exponential function for the latter. The experimental results indicate that while the execution time for ILP tends to increase exponentially, that for ASRL increases linearly. The time complexity of ASRL is linear with respect to the number of actions because the agent has to select the next action from the available actions for each episode, whose time complexity is naively  $O(|A|)$ . As  $\text{insert}_i$  actions are dominant in the extractive

Figure 2: Execution time on number of textual units for each problem in DUC2004. Plot of ASRL is fitted to linear function and that of ILP is fitted to exponential function.

approach, the execution time increases linearly with respect to the number of textual units. However, ILP has to take into account the combinations of textual units, whose number increases exponentially.

In conclusion, both the experimental results indicate that ASRL efficiently calculated a summary that was sub-optimal, but that was of relatively high-quality in terms of ROUGE metrics, with the experimental settings we used.

### 7.3 Evaluation of Effects of Sentence Compression

We also evaluated the combined approach with sentence compression. We evaluated the method described in Section 5 called ASRLC in this experiment for the sake of convenience. We used a very naive method of sentence compression for this experiment, which compressed a sentence to only important words, i.e., selecting word order by using the  $tf*idf$  score to compress the length to about half. This method of compression did not take into consideration either readability or linguistic quality. Note we wanted to confirm what effect the other methods would have, and we expected this to improve the ROUGE-1 score. We used the ROUGE-3 score in this evaluation instead of ROUGE-L, to confirm whether naive sentence compression occurred.

The experimental results are summarized in Ta-

	ROUGE-1	ROUGE-2	ROUGE-3
ASRL	0.39013	0.09479	0.03435
ASRLC	0.39141	0.09259	0.03239

Table 3: Evaluation of combined methods.

ble 3, which indicates ROUGE-1 increases but ROUGE-2 and ROUGE-3 decrease as expected. The variations, however, are small. This phenomenon was reported by Lin (2003) in that the effectiveness of sentence compression by local optimization at the sentence level was insufficient. Therefore, we would have to consider the range of applications with the combined method.

## 8 Discussion

### 8.1 Local Optimality of ASRL

We will discuss why ASRL seems to converge with some “good” local optimum with the described experimental settings in this section.

Since our model of the state value function was simply linear and our parameter estimation was implemented by TD ( $\lambda$ ), which is a simple method in RL, it seems simply employing more efficient or state-of-the-art reinforcement learning methods may improve the performance of ASRL, such as GTD and GTD2 (Sutton et al., 2009b; Sutton et al., 2009a). These methods basically only contribute to faster convergence, and the score that they will converge to might not differ significantly. As a result, it would not matter much which method was used for optimization.

The main point of this problem is modeling the feature representation of states, and this causes sub-optimality. The vector representation of states shrinks the different states to a single representation, i.e., the agent regards states whose features are similar to be similar states. Due to this property, the policy of reinforcement learning is learned to maximize *the expected score* of each feature vector, which includes many states. Such sub-optimality *averagely balanced* by the feature representation raises the possibility of achieving states that have a high-quality summary with a low score, since we do not have a genuine score function.

Thus, the most important thing in our method is to intentionally design the features of states and

the score function, so that the agent can generalize states, while taking into consideration truly-essential features for the required summarization. It would be useful if the forms of features and the score function could be arbitrarily designed by the user because there is the capability of obtaining a high-quality summaries.

### 8.2 Potential of Combined Method

Other useful methods, even other summarization systems, can easily be adapted to ASRL as was described in Section 5. The experimental results revealed that sentence compression has some effect. In fact, all operations that produce a new summary from an old summary can be used, i.e., even other summarizing methods can be employed for an action. We assumed a general combined method may have a great deal of potential to enhance the quality of summaries.

### 8.3 Can We Obtain “a Global Policy”?

We formulated each summarization task as a reinforcement learning task in this paper, i.e., where each learned policy differs. As this may be a little unnatural, we wanted to obtain a single learned policy, i.e., a global policy.

However, we assessed that we cannot achieve a global policy with these feature and score function settings because the best vector, which is the feature representation of the summary that achieves an optimal score under the current settings, seems to vary for each cluster, even if the domain of the clusters is the same (e.g., a news domain). Having said that, we simultaneously surmised that we could obtain a global policy if we could obtain a highly general, crucial, and efficient feature representation of a summary. We also think a global policy is essential in terms of reinforcement learning and we intend to attempt to achieve this in future work.

## 9 Conclusion

We presented a new approach to the problem of automatic text summarization called ASRL in this paper, which models the process of constructing a summary with the framework of reinforcement learning and attempts to optimize the given score function with the given feature representation.

The experimental results demonstrated ASRL tends to converge sub-optimally, and excessively depends on the formulation of features and the score function. Although it is difficult, we believe this formulation would enable us to improve the quality of summaries by designing them freely.

We intend to employ the ROUGE score as the score function in future work, and obtain the parameters of the state value function. Using these results, we will attempt to obtain a single learned policy by employing the ROUGE score or human evaluations as rewards. We also intend to consider efficient features and a score to achieve stable convergence. In addition, we plan to use other methods of function approximation, such as RBF networks.

# Large Scale Decipherment for Out-of-Domain Machine Translation

**Qing Dou and Kevin Knight**  
Information Sciences Institute  
Department of Computer Science  
University of Southern California  
{qdou, knight}@isi.edu

## Abstract

We apply slice sampling to Bayesian decipherment and use our new decipherment framework to improve out-of-domain machine translation. Compared with the state of the art algorithm, our approach is highly scalable and produces better results, which allows us to decipher ciphertext with billions of tokens and hundreds of thousands of word types with high accuracy. We decipher a large amount of monolingual data to improve out-of-domain translation and achieve significant gains of up to 3.8 BLEU points.

## 1 Introduction

Nowadays, state of the art statistical machine translation (SMT) systems are built using large amounts of bilingual parallel corpora. Those corpora are used to estimate probabilities of word-to-word translation, word sequences rearrangement, and even syntactic transformation. Unfortunately, as parallel corpora are expensive and not available for every domain, performance of SMT systems drops significantly when translating out-of-domain texts (Callison-Burch et al., 2008).

In general, it is easier to obtain in-domain monolingual corpora. Is it possible to use domain specific monolingual data to improve an MT system trained on parallel texts from a different domain? Some researchers have attempted to do this by adding a domain specific dictionary (Wu et al., 2008), or mining unseen words (Daumé and Jagarlamudi, 2011) using one of several translation lexicon induction techniques (Haghighi et al., 2008; Koehn and Knight,

2002; Rapp, 1995). However, a dictionary is not always available, and it is difficult to assign probabilities to a translation lexicon.

(Ravi and Knight, 2011b) have shown that one can use decipherment to learn a full translation model from non-parallel data. Their approach is able to find translations, and assign probabilities to them. But their work also has certain limitations. First of all, the corpus they use to build the translation system has a very small vocabulary. Secondly, although their algorithm is able to handle word substitution ciphers with limited vocabulary, its deciphering accuracy is low.

The contributions of this work are:

- We improve previous decipherment work by introducing a more efficient sampling algorithm. In experiments, our new method improves deciphering accuracy from 82.5% to 88.1% on (Ravi and Knight, 2011b)'s domain specific data set. Furthermore, we also solve a very large word substitution cipher built from the English Gigaword corpus and achieve 92.2% deciphering accuracy on news text.
- With the ability to handle a much larger vocabulary, we learn a domain specific translation table from a large amount of monolingual data and use the translation table to improve out-of-domain machine translation. In experiments, we observe significant gains of up to 3.8 BLEU points. Unlike previous works, the translation table we build from monolingual data do not only contain unseen words but also words seen in parallel data.

## 2 Word Substitution Ciphers

Before we present our new decipherment framework, we quickly review word substitution decipherment.

Recently, there has been an increasing interest in decipherment work (Ravi and Knight, 2011a; Ravi and Knight, 2008). While letter substitution ciphers can be solved easily, nobody has been able to solve a word substitution cipher with high accuracy.

As shown in Figure 1, a word substitution cipher is generated by replacing each word in a natural language (plaintext) sequence with a cipher token according to a substitution table. The mapping in the table is deterministic – each plaintext word type is only encoded with one unique cipher token. Solving a word substitution cipher means recovering the original plaintext from the ciphertext without knowing the substitution table. The only thing we rely on is knowledge about the underlying language.

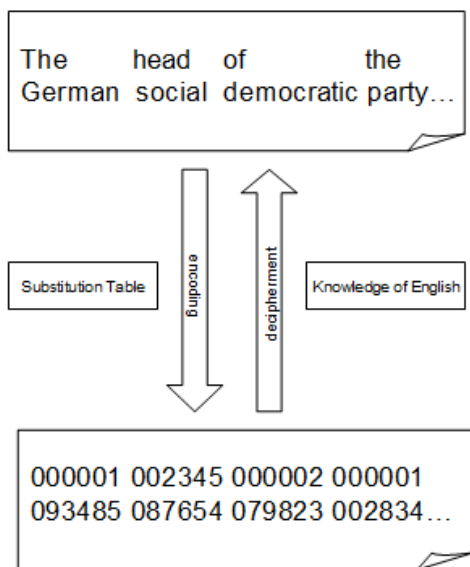

Figure 1: Encoding and Decipherment of a Word Substitution Cipher

How can we solve a word substitution cipher? The approach is similar to those taken by cryptanalysts who try to recover keys that convert encrypted texts to readable texts. Suppose we observe a large cipher string  $f$  and want to decipher it into English  $e$ . We can follow the work in (Ravi and Knight, 2011b) and assume that the cipher string  $f$  is generated in the following way:

- Generate English plaintext sequence  $e = e_1, e_2 \dots e_n$  with probability  $P(e)$ .
- Replace each English plaintext token  $e_i$  with a cipher token  $f_i$  with probability  $P(f_i|e_i)$ .

Based on the above generative story, we write the probability of the cipher string  $f$  as:

$$P(f)_\theta = \sum_e P(e) \cdot \prod_i^n P_\theta(f_i|e_i) \quad (1)$$

We use this equation as an objective function for maximum likelihood training. In the equation,  $P(e)$  is given by an ngram language model, which is trained using a large amount of monolingual texts. The rest of the task is to manipulate channel probabilities  $P_\theta(f_i|e_i)$  so that the probability of the observed texts  $P(f)_\theta$  is maximized.

Theoretically, we can directly apply EM, as proposed in (Knight et al., 2006), or Bayesian decipherment (Ravi and Knight, 2011a) to solve the problem. However, unlike letter substitution ciphers, word substitution ciphers pose much greater challenges to algorithm scalability. To solve a word substitution cipher, the EM algorithm has a computational complexity of  $O(N \cdot V^2 \cdot R)$  and the complexity of Bayesian method is  $O(N \cdot V \cdot R)$ , where  $V$  is the size of plaintext vocabulary,  $N$  is the length of ciphertext, and  $R$  is the number of iterations. In the world of word substitution ciphers, both  $V$  and  $N$  are very large, making these approaches impractical. (Ravi and Knight, 2011b) propose several modifications to the existing algorithms. However, the modified algorithms are only an approximation of the original algorithms and produce poor deciphering accuracy, and they are still unable to handle very large scale ciphers.

To address the above problems, we propose the following two new improvements to previous decipherment methods.

- We apply slice sampling (Neal, 2000) to scale up to ciphers with a very large vocabulary.
- Instead of deciphering using the original ciphertext, we break the ciphertext into bigrams, collect their counts, and use the bigrams with their counts for decipherment.

The new improvements allow us to solve a word substitution cipher with billions of tokens and hundreds of thousands of word types. Through better approximation, we achieve a significant increase in deciphering accuracy. In the following section, we present details of our new approach.

### 3 Slice Sampling for Bayesian Decipherment

In this section, we first give an introduction to Bayesian decipherment and then describe how to use slice sampling for it.

#### 3.1 Bayesian Decipherment

Bayesian inference has been widely used in natural language processing (Goldwater and Griffiths, 2007; Blunsom et al., 2009; Ravi and Knight, 2011b). It is very attractive for problems like word substitution ciphers for the following reasons. First, there are no memory bottlenecks as compared to EM, which has an  $O(N \cdot V^2)$  space complexity. Second, priors encourage the model to learn a sparse distribution.

The inference is usually performed using Gibbs sampling. For decipherment, a Gibbs sampler keeps drawing samples from plaintext sequences according to derivation probability  $P(d)$ :

$$P(d) = P(e) \cdot \prod_i^n P(c_i|e_i) \quad (2)$$

In Bayesian inference,  $P(e)$  is still given by an ngram language model, while the channel probability is modeled by the Chinese Restaurant Process (CRP):

$$P(c_i|e_i) = \frac{\alpha \cdot \text{prior} + \text{count}(c_i, e_i)}{\alpha + \text{count}(e_i)} \quad (3)$$

Where *prior* is the base distribution (we set prior to  $\frac{1}{C}$  in all our experiments, where  $C$  is the number of word types in ciphertext), and *count*, also called “cache”, records events that occurred in the history. Each sampling operation involves changing a plaintext token  $e_i$ , which has  $V$  possible choices, where  $V$  is the plaintext vocabulary size, and the final sample is chosen with probability  $\frac{P(d)}{\sum_{n=1}^V P(d)}$ .

#### 3.2 Slice Sampling

With Gibbs sampling, one has to evaluate all possible plaintext word types (10k—1M) for each sample decision. This become intractable when the vocabulary is large and the ciphertext is long. Slice sampling (Neal, 2000) can solve this problem by automatically adjusting the number of samples to be considered for each sampling operation.

Suppose the derivation probability for current sample is  $P(\text{current}_s)$ . Then slice sampling draws a sample in two steps:

- Select a threshold  $T$  uniformly from the range  $\{0, P(\text{current}_s)\}$ .
- Draw a new sample  $\text{new}_s$  uniformly from a pool of candidates:  $\{\text{new}_s | P(\text{new}_s) > T\}$ .

From the above two steps, we can see that given a threshold  $T$ , we only need to consider those samples whose probability is higher than the threshold. This will lead to a significant reduction on the number of samples to be considered, if probabilities of the most samples are below  $T$ . In practice, the first step is easy to implement, while it is difficult to make the second step efficient. An obvious way to collect candidate samples is to go over all possible samples and record those with probabilities higher than  $T$ . However, doing this will not save any time. Fortunately, for Bayesian decipherment, we are able to complete the second step efficiently.

According to Equation 1, the probability of the current sample is given by a language model  $P(e)$  and a channel model  $P(c|e)$ . The language model is usually an ngram language model. Suppose our current sample  $\text{current}_s$  contains English tokens  $X$ ,  $Y$ , and  $Z$  at position  $i - 1$ ,  $i$ , and  $i + 1$  respectively. Let  $c_i$  be the cipher token at position  $i$ . To obtain a new sample, we just need to change token  $Y$  to  $Y'$ . Since the rest of the sample stays the same, we only need to calculate the probability of any trigram<sup>1</sup>:  $P(XY'Z)$  and the channel model probability:  $P(c_i|Y')$ , and multiply them together as shown in Equation 4.

$$P(XY'Z) \cdot P(c_i|Y') \quad (4)$$

<sup>1</sup>The probability is given by a bigram language model.

In slice sampling, each sampling operation has two steps. For the first step, we choose a threshold  $T$  uniformly between 0 and  $P(XYZ) \cdot P(c_i|Y)$ . For the second step, there are two cases.

First, we notice that two types of  $Y'$  are more likely to pass the threshold  $T$ : (1) Those that have a very high trigram probability, and (2) those that have high channel model probability. To find candidates that have high trigram probability, we build sorted lists ranked by  $P(XY'Z)$ , which can be pre-computed off-line. We only keep the top  $K$  English words for each of the sorted list. When the last item  $Y_K$  in the list satisfies  $P(XY_kZ) \cdot prior < T$ , We draw a sample in the following way: set  $A = \{Y' | P(XY'Z) \cdot prior > T\}$  and set  $B = \{Y' | count(c_i, Y') > 0\}$ , then we only need to sample  $Y'$  uniformly from  $A \cup B$  until Equation 4 is greater than  $T$ .<sup>2</sup>

Second, what happens when the last item  $Y_K$  in the list does not satisfy  $P(XY_kZ) \cdot prior < T$ ? Then we always choose a word  $Y'$  randomly and accept it as a new sample if Equation 4 is greater than  $T$ .

Our algorithm alternates between the two cases. The actual number of choices the algorithm looks at depends on the  $K$  and the total number of possible choices. In different experiments, we find that when  $K = 500$ , the algorithm only looks at 0.06% of all possible choices. When  $K = 2000$ , this further reduces to 0.007%.

### 3.3 Deciphering with Bigrams

Since we can decipher with a bigram language model, we posit that a frequency list of ciphertext bigrams may contain enough information for decipherment. In our letter substitution experiments, we find that breaking ciphertext into bigrams doesn't hurt decipherment accuracy. Table 1 shows how full English sentences in the original data are broken into bigrams and their counts.

Instead of doing sampling on full sentences, we treat each bigram as a full "sentence". There are

<sup>2</sup>It is easy to prove that all other candidates that are not in the sorted list and with  $count(c_i, Y') = 0$  have an upper bound probability:  $P(XY_kZ) \cdot prior$ . Therefore, they are ignored when  $P(XY_kZ) \cdot prior < T$ .

	took	our	2
man they took our land .	they	took	2
they took our arable land .	land	.	2
	man	they	1
	arable	land	1

Table 1: Converting full sentences to bigrams

two advantages to use bigrams and their counts for decipherment.

First of all, the bigrams and counts are a much more compact representation of the original ciphertext with full sentences. For instance, after breaking a billion tokens from the English Gigaword corpus, we find only 29m bigrams and 58m tokens, which is only 1/17 of the original text. In practice, we further discard all bigrams with low frequency, which makes the ciphertext even shorter.

Secondly, using bigrams significantly reduces the number of sorted lists (from  $|V|^2$  to  $2|V|$ ) mentioned in the previous section. The number of lists reduces from  $|V|^2$  to  $2|V|$  because words in a bigram only have one neighbor. Therefore, for any word  $W$  in a bigram, we need only  $2|V|$  lists ("words to the right of  $W$ " and "words to the left of  $W$ ") instead of  $|V|^2$  lists ("pairs of words that surround  $W$ ").

### 3.4 Iterative Sampling

Although we can directly apply slice sampling on a large number of bigrams, we find that gradually including less frequent bigrams into a sampling process saves deciphering time – we call this iterative sampling:

- Break the ciphertext into bigrams and collect their counts
- Keep bigrams whose counts are greater than a threshold  $\alpha$ . Then initialize the first sample randomly and use slice sampling to perform maximum likelihood training. In the end, extract a translation table  $T$  according to the final sample.
- Lower the threshold  $\alpha$  to include more bigrams into the sampling process. Initialize the first sample using the translation table obtained from the previous sampling run (for each ci-

pher token  $f$ , choose a plaintext token  $e$  whose  $P(e|f)$  is the largest). Perform sampling again.

- Repeat until  $\alpha = 1$ .

### 3.5 Parallel Sampling

Inspired by (Newman et al., 2009), our parallel sampling procedure is described below:

- Collect bigrams and their counts from ciphertext and split the bigrams into  $N$  parts.
- Run slice sampling on each part for 5 iterations independently.
- Combine counts from each part to form a new count table and run sampling again on each part using the new table.<sup>3</sup>

## 4 Decipherment Experiments

In this section, we evaluate our new sampling algorithm in two different experiments. In the first experiment, we compare our method with (Ravi and Knight, 2011b) on their data set to prove correctness of our approach. In the second experiment, we scale up to the whole English Gigaword corpus and achieve a much higher deciphering accuracy.

### 4.1 Deciphering Transtac Corpus

#### 4.1.1 Data

We split the Transtac corpus the same way it was split in (Ravi and Knight, 2011b). The data used to create ciphertext consists of 1 million tokens, and 3397 word types. The data for language model training contains 2.7 million tokens and 25761 word types.<sup>4</sup> The ciphertext is created by replacing each English word with a cipher word.

We use a bigram language model for decipherment training. When the training terminates, a translation table with probability  $P(c|e)$  is built based on the counts collected from the final sample. For decoding, we employ a trigram language model using full sentences. We use Moses (Koehn et al., 2007)

<sup>3</sup>Except for combining the counts to form a new count table, other parameters remain the same. For instance, each part  $i$  has its own prior set to  $\frac{1}{C_i}$ , where  $C_i$  is the number of word types in that part of ciphertext.

<sup>4</sup>In practice, we replaced singletons with a “UNK” symbol, leaving around 16904 word types.

Method	Deciphering Accuracy
Ravi and Knight	80.0 (with bigram LM) 82.5 (with trigram LM)
Slice Sampling	88.1 (with bigram LM)

Table 2: Decipherment Accuracy on Transtac Corpus from (Ravi and Knight, 2011b)

Gold	Decoded
man i’ve come to file a complaint against some people .	man i’ve come to hand a telephone lines some people .
man they took our land .	man they took our farm .
they took our arable land .	they took our slide door .
okay man .	okay man .
eighty donums .	miflih donums .

Table 3: Sample Decoding Results on Transtac Corpus from (Ravi and Knight, 2011b)

to perform the decoding. We set the distortion limit to 0 and cube the translation probabilities. Essentially, Moses tries to find an English sequence  $e$  that maximizes  $P(e) \cdot P(c|e)^3$

#### 4.1.2 Results

We evaluate the performance of our algorithm by decipherment accuracy, which measures the percentage of correctly deciphered cipher tokens. Table 2 compares the deciphering accuracy with the state of the art algorithm.

Results show that our algorithm improves the deciphering accuracy to 88.1%, which amounts to 33% reduction in error rate. This justifies our claim: doing better approximation using slice sampling improves decipherment accuracy.

Table 3 shows the first 5 decoding results and compares them with the gold plaintext. From the table we can see that the algorithm recovered the majority of the plaintext correctly.

### 4.2 Deciphering Gigaword Corpus

To prove the scalability of our new approach, we apply it to solve a much larger word substitution cipher built from English Gigaword corpus. The corpus contains news articles from different news agencies

and has a much larger vocabulary compared with the Transtac corpus.

#### 4.2.1 Data

We split the corpus into two parts chronologically. Each part contains approximately 1.2 billion tokens. We use the first part to build a word substitution cipher, which is 10k times longer than the one in the previous experiment, and the second part to build a bigram language model.<sup>5</sup>

#### 4.2.2 Results

We first use a single machine and apply iterative sampling to solve a 68 million token cipher. Then we use the result from the first step to initialize our parallel sampling process, which uses as many as 100 machines. For evaluation, we calculate deciphering accuracy over the first 1000 sentences (33k tokens).

After 2000 iterations of the parallel sampling process, the deciphering accuracy reaches 92.2%. Figure 2 shows the learning curve of the algorithm. It can be seen from the graph that both token and type accuracy increase as more and more data becomes available.

Figure 2: Learning curve for a very large word substitution cipher: Both token and type accuracy rise as more and more ciphertext becomes available.

<sup>5</sup>Before building the language model, we replace low frequency word types with an "UNK" symbol, leaving 129k unique word types.

## 5 Improving Out-of-Domain Machine Translation

Domain specific machine translation (MT) is a challenge for statistical machine translation (SMT) systems trained on parallel corpora. It is common to see a significant drop in translation quality when translating out-of-domain texts. Although it is hard to find parallel corpora for any specific domain, it is relatively easy to find domain specific monolingual corpora. In this section, we show how to use our new decipherment framework to learn a domain specific translation table and use it to improve out-of-domain translations.

### 5.1 Baseline SMT System

We build a state of the art phrase-based SMT system using Moses (Koehn et al., 2007). The baseline system has 3 models: a translation model, a reordering model, and a language model. The language model can be trained on monolingual data, and the rest are trained on parallel data. By default, Moses uses the following 8 features to score a candidate translation:

- direct and inverse translation probabilities
- direct and inverse lexical weighting
- phrase penalty
- a language model
- a re-ordering model
- word penalty

Each of the 8 features has its own weight, which can be tuned on a held-out set using minimum error rate training. (Och, 2003). In the following sections, we describe how to use decipherment to learn domain specific translation probabilities, and use the new features to improve the baseline.

### 5.2 Learning a New Translation Table with Decipherment

From a decipherment perspective, machine translation is a much more complex task than solving a word substitution cipher and poses three major challenges:

- Mappings between languages are nondeterministic, as words can have multiple translations

- Re-ordering of words
- Insertion and deletion of words

Fortunately, our decipherment model does not assume deterministic mapping and is able to discover multiple translations. For the reordering problem, we treat Spanish as a simple word substitution for French. Despite the simplification in the assumption, we still expect to learn a useful word-to-word lexicon via decipherment and use the lexicon to improve our baseline.

**Problem formulation:** By ignoring word reorderings, we can formulate MT decipherment problem as word substitution decipherment. We view source language  $f$  as ciphertext and target language  $e$  as plaintext. Our goal is to decipher  $f$  into  $e$  and estimate translation probabilities based on the decipherment.

**Probabilistic decipherment:** Similar to solving a word substitution cipher, all we have to do here is to estimate the translation model parameters  $P_\theta(f|e)$  using a large amount of monolingual data in  $f$  and  $e$  respectively. According to Equation 5, our objective is to estimate the model parameters so that the probability of source text  $P(f)$  is maximized.

$$\arg \max_{\theta} \sum_e P(e) \cdot \prod_i^n P_\theta(f_i|e_i) \quad (5)$$

**Building a translation table:** Once the sampling process completes, we estimate translation probability  $P(f|e)$  from the final sample using maximum likelihood estimation. We also decipher from the reverse direction to estimate  $P(e|f)$ . Finally, we build a phrase table by taking translation pairs seen in both decipherments.

### 5.3 Combining Phrase Tables

We now have two phrase tables: one learnt from parallel corpus and one learnt from non-parallel monolingual corpus through decipherment. The phrase table learnt through decipherment only contains word to word translations, and each translation option only has two scores. Moses has a function to decode with multiple phrase tables, so we just need to add the newly learnt phrase table and specify two more weights for the scores in it. During decoding, if a source word only appears in the decipherment table,

Train	French: 28.5 million tokens Spanish: 26.6 million tokens
Tune	French: 28k tokens Spanish: 26k tokens
Test	French: 30k tokens Spanish: 28k tokens

Table 4: Europarl Training, Tuning, and Testing Data

that table’s translation will be used. If a source word exists in both tables, Moses will create two separate decoding paths and choose the best one after taking other features into account. If a word is not seen in either of the tables, it is copied literally to the output.

## 6 MT Experiments and Results

### 6.1 Data

In our MT experiments, we translate French into Spanish and use the following corpora to learn our translation systems:

- Europarl Corpus (Koehn, 2005): The Europarl parallel corpus is extracted from the proceedings of the European Parliament and includes versions in 11 European languages. The corpus contains articles from the political domain and is used to train our baseline system. We use the 6th version of the corpus. After cleaning, there are 1.3 million lines left for training. We use the last 2k lines for tuning and testing (1k for each), and the rest for training. Details of training, tuning, and testing data are listed in Table 4.
- EMEA Corpus (Tiedemann, 2009): EMEA is a parallel corpus made out of PDF documents from the European Medicines Agency. It contains articles from the medical domain, which is a good test bed for out-of-domain tasks. We use the first 2k pairs of sentences for tuning and testing (1k for each), and use the rest (1.1 million lines) for decipherment training. We split the training corpus in ways that no parallel sentences are included in the training set. The splitting methods are listed in Table 5.

For decipherment training, we use lexical translation tables learned from the Europarl corpus to ini-

<b>Comparable EMEA :</b> French: Every odd line, 8.7 million tokens Spanish: Every even line, 8.1 million tokens
<b>Non-parallel EMEA:</b> French: First 550k sentences, 9.1 million tokens Spanish: Last 550k sentences, 7.7 million tokens

Table 5: EMEA Decipherment Training Data

tialize our sampling process.

## 6.2 Results

BLEU (Papineni et al., 2002) is used as a standard evaluation metric. We compare the following 3 systems in our experiments, and present the results in Table 6.

- **Baseline:** Trained on Europarl
- **Decipher-CP:** Trained on Europarl + Comparable EMEA
- **Decipher-NP:** Trained on Europarl + Non-Parallel EMEA

Our baseline system achieves 38.2 BLEU score on Europarl test set. In the second row of Table 6, the test set changes to EMEA, and the baseline BLEU score drops to 24.9. In the third row, the baseline score rises to 30.5 with a language model built from EMEA corpus. Although it is much higher than the previous baseline, we further improve it by including a new phrase table learnt from domain specific monolingual data. In a real out-of-domain task, we are unlikely to have any parallel data to tune weights for the new phrase table. Therefore, we can only set it manually. In experiments, each score in the new phrase table has a weight of 5, and the BLEU score rises up to 33.2. In the fourth row of the table, we assume that there is a small amount of domain specific parallel data for tuning. With better weights, our baseline BLEU score increases to 37.3, and our combined systems increase to 41.1 and 39.7 respectively. In the last row of the table, we compare the combined systems with an even better baseline. This time, the baseline is given half of the EMEA tuning set for training and uses the other half

French	Spanish	$P(fr es)$	$P(es fr)$
<	<	0.32	1.00
hépatique	hepático hepática	0.88 0.76	0.08 0.85
injectable	inyectable	0.91	0.92
dl	dl	1.00	0.70
>	>	0.32	1.00
ribavirine	ribavirina	0.40	1.00
olanzapine	olanzapina	0.57	1.00
clairance	aclaramiento	0.99	0.64
pelliculés	recubiertos	1.00	1.00
pharmacocinétique	farmacocinético	1.00	1.00

Table 7: 10 most frequent OOV words in the table learnt from non-parallel EMEA corpus

for weight tuning. Results show that our combined systems still outperform the baseline.

The phrase table learnt from monolingual data consists of both observed and unknown words. Table 7 shows the top 10 most frequent OOV words in the table learnt from non-parallel EMEA corpus. Among the 10 words, 9 have correct translations. It is interesting to see that our algorithm finds multiple correct translations for the word “hépatique”. The only mistake in the table is sensible as French word “pelliculés” is translated into “recubiertos con película” in Spanish.

## 7 Conclusion and Future Work

We apply slice sampling to Bayesian Decipherment and show significant improvement in deciphering accuracy compared with the state of the art algorithm. Our method is not only accurate but also highly scalable. In experiments, we decipher at the scale of the English Gigaword corpus, which contains over billions of tokens and hundreds of thousands word types. We further show the value of our new decipherment algorithm by using it to improve out-of-domain translation. In the future, we will work with more language pairs, especially those with significant word re-orderings. Moreover, the monolingual corpora used in the experiments are far smaller than what our algorithm can handle. We will continue to work in scenarios where large amount of monolingual data is readily available.

Train Data	Tune Data	Tune LM	Test Data	Test LM	Baseline	Decipher-CP	Decipher-NP
Europarl	Europarl	Europarl	Europarl	Europarl	38.2		
Europarl	Europarl	Europarl	EMEA	Europarl	24.9		
Europarl	Europarl	Europarl	EMEA	EMEA	30.5	33.2 (+2.7)	32.4 (+1.9)
Europarl	EMEA	EMEA	EMEA	EMEA	37.3	41.1 (+3.8)	39.7 (+2.4)
Europarl + EMEA	EMEA	EMEA	EMEA	EMEA	67.4	68.7 (+1.3)	68.7 (+1.3)

Table 6: MT experiment results: The table shows how much the combined systems outperform the baseline system in different experiments. Each row has a different set of training, tuning, and testing data. Baseline is trained on parallel data only. Tune LM and Test LM specify language models used for tuning and testing respectively. Decipher-CP and Decipher-NP use a phrase table learnt from comparable and non-parallel EMEA corpus respectively.

## 8 Acknowledgments

This work was supported by NSF Grant 0904684. The authors would like to thank Philip Koehn, David Chiang, Jason Riesa, Ashish Vaswani, and Hui Zhang for their comments and suggestions.

## Abstract

Tense is a small element to a sentence, however, error tense can raise odd grammars and result in misunderstanding. Recently, tense has drawn attention in many natural language processing applications. However, most of current Statistical Machine Translation (SMT) systems mainly depend on translation model and language model. They never consider and make full use of tense information. In this paper, we propose n-gram-based tense models for SMT and successfully integrate them into a state-of-the-art phrase-based SMT system via two additional features. Experimental results on the NIST Chinese-English translation task show that our proposed tense models are very effective, contributing performance improvement by 0.62 BLUE points over a strong baseline.

## 1 Introduction

For many NLP applications, such as event extraction and summarization, tense has been regarded as a key factor in providing temporal order. However, tense information has been largely overlooked by current SMT research. Consider the following example:

**SRC:** 这项禁运是冷战的结果,不能反映现在的情势,更未反映中国与欧盟间的伙伴关系。

**REF:** The embargo **is** a result of the Cold War and **does** not reflect the present situation nor the partnership between China and the EU.

**MOSES:** the embargo **is** the result of the cold war, not reflect the present situation, it **did** not reflect the partnership with the european union.

\*Corresponding author.

Although the translated text produced by Moses<sup>1</sup> is understandable, it has very odd tense combination from the grammatical aspect, i.e. with tense inconsistency (*is/does* in REF vs. *is/did* in Moses). Obviously, slight modification, such as changing “is” into “was”, can much improve the readability of the translated text. It is also interesting to note that such modification can much affect the evaluation. If we change “did” to “does”, the BLEU-4 score increases from 22.65 to 27.86 (as matching the 4-gram “does not reflect the” in REF). However, if we change “is” to “was”, the BLEU score decreases from 22.65 to 21.44.

The above example seems special. To testify its impact on SMT in wider range, we design a special experiment based on the 2005 NIST MT data (see section 6.1). This data has 4 references. We choose one reference and modify its sentences with error tense<sup>2</sup>. After that, we use other 3 references to measure this reference. The modified reference leads to a sharp drop in BLEU-4 score, from 52.46 to 50.27 in all. So it is not a random phenomenon that tense can affect translation results.

The key is how to detect tense errors and choose correct tenses during the translation procedure. By carefully comparing the references with Moses output, we obtain the following useful observations,

**Observation(1):** to most simple sentences, coordinate verbs should be translated with the same tense while they have different tense in Moses output;

**Observation(2):** to some compound sentences,

<sup>1</sup><http://www.statmt.org/moses/>

<sup>2</sup>Such changes are small by mainly modifying one auxiliary verb for a sentence, such as “*is* → *was*”, “*has* → *had*”.

the subordinate clause should have the consistent tense with its main clause while Moses fails;

**Observation(3):** the diversity of tense usage in a document is common. However, in most cases, the neighbored sentences tends to share the same main tense. In some extreme examples, one tense (past or present), even dominates the whole document.

One possible solution to model above observations is using rules. Dorr (2002) refers to six basic English tense structures and defines the possible paired combinations of “present, past, future”. But the practical cases are very complicated, especially in news domain. There are a lot of complicated sentences in news articles. Our preliminary investigation shows that such six paired combinations can only cover limited real cases in Chinese-English SMT.

This paper proposes a simple yet effective method to model above observations. For each target sentence in the training corpus, we first parse it and extract its tense sequence. Then, a target-side tense n-gram model is constructed. Such model can be used to estimate the rationality of tense combination in a sentence and thus supervise SMT to reduce tense inconsistency errors against **Observations (1)** and **(2)** in the sentence-level. In comparison, **Observation (3)** actually reflects the tense distributions among one document. After extracting each main tense for each sentence, we build another tense n-gram model in the document-level. For clarity, this paper denotes document-level tense as “inter-tense” and sentence-level tense as “intra-tense”.

After that, we propose to integrate such tense models into SMT systems in a dynamic way. It is well known there are many errors in the current MT output (David et al., 2006). Unlike previously making trouble with reference texts, the BLEU-4 score cannot be influenced obviously by modifying a small part of abnormal sentences in a static way. In our system, both inter-tense and intra-tense model are integrated into a SMT system via additional features and thus can supervise the decoding procedure. During decoding, once some words with correct tense can be determined, with the help of language model and other related features, the small component—“tense”—can affect surrounding words and improve the performance of the whole sentence. Our experimental results (see the examples in Sec-

tion 6.4) show the effectiveness of this way.

Rather than the rule-based model, our models are fully statistical-based. So they can be easily scaled up and integrated into either phrase-based or syntax-based SMT systems. In this paper, we employ a strong phrase-based SMT baseline system, as proposed in Gong et al. (2011), which uses document as translation unit, for better incorporating document-level information.

The rest of this paper is organized as follows: Section 2 reviews the related work. Section 3 and 4 are related to tense models. Section 3 describes the pre-processing work for building tense models. Section 4 presents how to build target-side tense models and discuss their characteristics. Section 5 shows our way of integrating such tense models into a SMT system. Section 6 gives the experimental results. Finally, we conclude this paper in Section 7.

## 2 Related Work

In this section, we focus on related work on integrating the tense information into SMT. Since both inter- and intra-tense models need to analyze and extract tense information, we also give a brief overview on tense prediction (or tagging).

### 2.1 Tense Prediction

The tense prediction task often needs to build a model based on a large corpus annotated with temporal relations and thus its focus is on how to recognize, interpret and normalize time expressions. As a representative, Lapata and Lascarides (2006) proposed a simple yet effective data-intensive approach. In particular, they trained models on main and subordinate clauses connected with some special temporal marker words, such as “after” and “before”, and employed them in temporal inference.

Another typical task is cross-lingual tense prediction. Some languages, such as English, are inflectional, whose verbs can express tense via certain stems or suffix, while others, such as Chinese often lack inflectional forms. Take Chinese to English translation as example, if Chinese text contains particle word “了(Le)”, the nearest Chinese verb prefers to be translated into English verb with the past tense. Ye and Zhang (2005), Ye et al. (2007) and Liu et al. (2011) focus on labeling the tenses for keywords in

source-side language.

Ye and Zhang (2005) first built a small amount of manually-labeled data, which provide the tense mapping from Chinese text to English text. Then, they trained a CRF-based tense classifier to label tense on Chinese documents. Ye et al. (2007) further reported that syntactic features contribute most to the marking of aspectual information. Liu et al. (2011) proposed a parallel mapping method to automatically generate annotated data. In particular, they used English verbs to label tense information for Chinese verbs via a parallel Chinese-English corpus.

It is reasonable to label such source-side verb to supervise the translation process since the tense of English sentence is often determined by verbs. The problem is that due to the diversity of English verb inflection, it is difficult to map such Chinese tense information into the English text. To our best knowledge, although above works attempt to serve for SMT, all of them fail to address how to integrate them into a SMT system.

## 2.2 Machine Translation with Tense

Dorr (1992) described a two-level knowledge representation model based on Lexical Conceptual Structures (LCS) for machine translation which integrates the aspectual information and the lexical-semantic information. Her system is based on an inter-lingual model and does not belong to a SMT system.

Olsen et al. (2001) relied on LCS to generate appropriately-tensed English translations for Chinese. In particular, they addressed tense reconstruction on a binary taxonomy (present and past) for Chinese text and reported that incorporating lexical aspect features of telicity can obtain a 20% to 35% boost in accuracy on tense realization.

Ye et al. (2006) showed that incorporating latent features into tense classifiers can boost the performance. They reported the tense resolution results based on the best-ranked translation text produced by a SMT system. However, they did not report the variation of translation performance after introducing tense information.

## 3 Preprocessing for Tense Modeling

In this paper, tense modeling is done on the target-side language. Since our experiments are done on Chinese to English SMT, our tense models are learned only from the English text. In the literature, the taxonomy of English tenses typically includes three basic tenses (i.e. present, past and future) plus their combination with the progressive and perfective aspects. Here, we consider four basic tenses: present, past, future and UNK (unknown) and ignore the aspectual information. Furthermore, we assume that one sentence has only one main tense but maybe has many subordinate tenses.

This section describes the preprocessing work of building tense models, which mainly involves how to extract tense sequence via tense verbs.

### 3.1 Tense Verbs

Lapata et al.(2006) used syntactic parse trees to find clauses connected with special aspect markers and collected them to train some special classifiers for temporal inference. Inspired by their work, we use the Stanford parser<sup>3</sup> to parse tense sequence for each sentence.

Take the following three typical sentences as examples, (a) is a simple sentence which contains two coordinate verbs, while (b) and (c) are compound sentences and (b) contains a quoted text.

(a) Japan's constitution renounces the right to go to war and prohibits the nation from having military forces except for self-defense.

(b) "We also hope Hong Kong will not be affected by diseases like the severe acute respiratory syndrome again!" , added Ms. Yang.

(c) Cheng said he felt at home in Hong Kong and he sincerely wished Hong Kong more peaceful and more prosperous.

Figure 1 shows the parse tree with Penn Treebank style for each sentence, which has strict level structures and POS tags for all the terminal words. Here, the level structures mainly contribute to extract main tense for each sentence (to be described in Section 3.2) and POS tags are utilized to detect *tense verbs*, i.e. verbs with tense information.

Normally, POS tags in the parse tree can distinguish five different forms of verbs: the base form (tagged as VB), and forms with overt endings D for

<sup>3</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

Figure 1: The Stanford parse trees with Penn Treebank style

past tense, G for present participle, N for past participle, and Z for third person singular present. It is worth noting that VB, VBG and VBN cannot determine the specific tenses by themselves. In addition, the verbs with POS tag “MD” need to be specially considered to distinguish future tense from other tenses.

Algorithm 1 illustrates how to determine what tense a node has. If the return value is not “UNK”, the node belongs to a *tense verb*.

---

**Algorithm 1** Determine the tense of a node.

---

**Input:**

The *TreeNode* of one parse tree, *leafnode*;

**Output:**

The tense, *tense*;

- 1:  $tense = \text{“UNK”}$
  - 2: Obtaining the POS tag  $lpostag$  from *leafnode*;
  - 3: Obtaining the word  $lword$  from *leafnode*;
  - 4: **if** ( $lpostag$  in [ $\text{“VBP”}$ ,  $\text{“VBZ”}$ ]) **then**
  - 5:      $tense = \text{“present”}$
  - 6: **else if** ( $lpostag == \text{“VBD”}$ ) **then**
  - 7:      $tense = \text{“past”}$
  - 8: **else if** ( $lpostag == \text{“MD”}$ ) **then**
  - 9:     **if** ( $lword$  in [ $\text{“will”}$ ,  $\text{“ll”}$ ,  $\text{“shall”}$ ]) **then**
  - 10:          $tense = \text{“future”}$
  - 11:     **else if** ( $lword$  in [ $\text{“would”}$ ,  $\text{“could”}$ ]) **then**
  - 12:          $tense = \text{“past”}$
  - 13:     **else**
  - 14:          $tense = \text{“present”}$
  - 15:     **end if**
  - 16: **end if**
  - 17: **return**  $tense$ ;
- 

### 3.2 Tense Extraction Based on Tense Verbs

As described in Section 1, the inter-tense (document-level) refers to the main tense of one sentence and the intra-tense (sentence-level) corresponds to all tense sequence of one sentence. This section introduces how to recognize the main tense and extract all useful tense sequence for each sentence.

The idea of determining the main tense is to find the *tense verb* located in the top level of a parse tree. According to the Penn Treebank style, the method to determine the main tense can be described as follows:

- (1) Traverse the parse tree top-down until a tree node containing more than one child is identified, denoted as  $S_m$ .
- (2) Consider each child of  $S_m$  with tag “VP”, recursively traverse such “VP” node to find a tense verb. If found, use it as the main tense and return the tense; if not, go to step (3).
- (3) Consider each child of  $S_m$  with tag “S”, which actually corresponds to subordinate clause of this sentence. Starting from the first subordinate clause, apply the similar policy of step (2) to find the tense verb. If not found, search remaining subordinate clauses.
- (4) If no tense verb found, return “UNK” as the main tense.

Here, “VP” nodes dominated by  $S_m$  **directly** are preferred over those located in subordinate clauses. This is to ensure that the main tense is decided by the top-level tense verb.

Take Figure 1 as an example, the main tense of sentence (a) and (b) can be determined only by step (2). The tense verb of “(VBZ renounces)” dominated in the “VP” tag determines that (a) is in present tense. Similarly the node “(VBD added)” indicates that (b) is in past tense. Sentence (c) needs to be further treated by step (3) since there is no “VP” nodes dominated by  $S_m$  directly. The node “(VBD said)” located in the first subordinate clause shows its main tense is “past”.

The next task is to extract the tense sequence for each sentence. They are determined by all tense verbs in this sentence according to the strict top-down order. For example, the tense sequence of sentence (a), (b) and (c) are {present, present}, {present, future, past} and {past, past, past}. In order to explore whether the main tense of intra-tense model has an impact on SMT or not, we introduce a special marker “\*” to denote the main tense. So the tense sequence marked with main tense of (a), (b) and (c) are {present\*, present}, {present, future, past\*} and {past\*, past, past}. It is worth noting, the intra-tense model (see Section 4) based on the latter tense sequence is different to the former.

## 4 N-gram-based Tense Models

### 4.1 Tense N-gram Estimation

After applying the previous method to extract tense for an English text corpus, we can obtain a big tense corpus.

Given the current tense is indexed as  $t_i$ , we call the previous  $n - 1$  tenses plus the current tense as tense n-gram.

Based on the tense corpus, tense n-gram statistics can be done according to the Formula 1.

$$P(t_i|t_{(i-(n-1))}, \dots, t_{(i-1)}) = \frac{\text{count}(t_{(i-(n-1))}, \dots, t_{(i-1)}, t_i)}{\text{count}(t_{(i-(n-1))}, \dots, t_{(i-1)})} \quad (1)$$

Here, the function of “count” return the tense n-gram frequency. In order to avoid doing specific smoothing work, we estimate tense n-gram probability using SRI language modeling (SRILM) tool (Stolcke, 2002).

To compute the probability of intra-tense n-gram, we first extract all tense sequence for each sentence

and put them into a new file. Based on this new file, we can get the intra-tense n-gram model via SRILM tool.

To compute the probability of inter-tense n-gram, we need to extract the main tense for each sentence at first. Then, for each document, we re-organized the main tenses of all sentences into a special line. After putting all these special lines into a new file, we can use SRILM to obtain the inter-tense n-gram model.

### 4.2 Characteristic of Tense N-gram Models

We construct n-gram-based tense models on English Gigaword corpus (LDC2003T05). This corpus is used to build language model for most SMT systems. It includes 30221 documents (we remove such files: file size is less than 1K or the number of continuous “UNK” tenses is greater than 5).

Figure 2 shows the unigram and bigram probabilities (**Log10-style**) for intra-tense and inter-tense.

The part (a) and (c) in Figure 2 refer to unigram. The horizontal axis indicates tense type, and the vertical axis shows its probabilities. The parts (a) and (c) also indicate “present” and “past” are two main tense types in news domain.

The part (b) and (d) refer to bigram. The horizontal axis indicates history tense. Each different colorful bar indicates one current tense. The vertical axis shows the transfer possibilities from a history tense to a current tense.

The part (b)<sup>4</sup> reflects transfer possibilities of tense types in one sentence. It also slightly reflects some linguistic information. For example, in one sentence, the probability of co-occurrence of “present → present”, “past → past” and “future → present” is more than other combinations, which can be against tense inconsistency errors described in Observation (1) and (2) (see Section 1). However, it seems strange that “present → past” exceeds “present → future”. We checked our corpus and found a lot of sentences like this—“the bill has been . . . , he said. ”.

The part (d) shows tense type can be switched between two neighbored sentences. However, it shows the strong tendency to use the same tense type for

<sup>4</sup>The co-occurrence of the “UNK” tense and other tense types in one sentence cannot happen, so the “UNK” tense is omitted.

Figure 2: statistics of intra-tense and inter-tense N-gram

neighborhood sentences. This statistics conform to the previous **observation (3)** very much.

## 5 Integrating N-gram-based Tense Models into SMT

In this section, we discuss how to integrate the previous tense models into a SMT system.

### 5.1 Basic phrase-based SMT system

It is well known that the translation process of SMT can be modeled as obtaining the best translation  $e$  of the source sentence  $f$  by maximizing following posterior probability (Brown et al., 1993):

$$\begin{aligned} e_{best} &= \arg \max_e P(e|f) \\ &= \arg \max_e P(f|e)P_{lm}(e) \end{aligned} \quad (2)$$

where  $P(e|f)$  is a translation model and  $P_{lm}$  is a language model.

Our baseline is a modified Moses, which follows Koehn et al. (2003) and adopts similar six groups of features. Besides, the log-linear model (Och and Ney, 2000) is employed to linearly interpolate these features for obtaining the best translation according to the formula 3:

$$e_{best} = \arg \max_e \sum_{m=1}^M \lambda_m h_m(e, f) \quad (3)$$

where  $h_m(e, f)$  is a feature function, and  $\lambda_m$  is the weight of  $h_m(e, f)$  optimized by a discriminative training method on a held-out development data (Och, 2003).

### 5.2 The Workflow of Our System

Our system works as follows:

When a hypothesis has covered all source-side words during the decoding procedure, the decoder

first obtains tense sequence for such hypothesis and computes intra-tense feature  $F_s$  (see Section 5.3). At the same time, it recognizes the main tense of this hypothesis and associate the main tense of previous sentence to compute inter-tense feature  $F_m$  (see Section 5.3).

Next, the decoder uses such two additional feature values to re-score this hypothesis automatically and choose one hypothesis with highest score as the final translation.

After translating one sentence, the decoder caches its main tense and pass it to the next sentence. When one document has been processed, the decoder cleans this cache.

In order to successfully implement above workflow, we should firstly design some related features, then resolve another key problem of determining tense (especially main tense) for SMT output. They are described in Section 5.3 and 5.4 respectively.

### 5.3 Two Additional Features

Although the previous tense models show strong tendency to use the consistent tenses for one sentence or one document, other tense combinations also can be permitted. So we should use such models in a soft and dynamic way. We design two features: inter-tense feature and intra-tense feature. And the weight of each feature is tuned by the MERT script in Moses packages.

Given main tense sequence of one document  $t_1, \dots, t_m$ , the inter-tense feature  $F_m$  is calculated according to the following formula:

$$F_m = \prod_{i=2}^m P(t_i | t_{i-(n-1)}, \dots, t_{i-1}) \quad (4)$$

The  $P(\cdot)$  of formula 4 can be estimated by the formula 1. It is worth noting the first sentence of one

document often scares tense information since it corresponds to the title at most cases. To the first sentence, the  $P(\cdot)$  value is set to  $\frac{1}{4}$  (4 tense types).

Given tense sequence of one sentence  $s_1, \dots, s_e$  ( $e > 1$ ), the intra-tense feature  $F_s$  is calculated as follows:

$$F_s = \sqrt[e-1]{\prod_{i=2}^e P(s_i | s_{i-(n-1)}, \dots, s_{(i-1)})} \quad (5)$$

Here the square-root operator is used to avoid punishing translations with long tense sequence. It is worth noting if the sentence only contains one tense, the  $P(\cdot)$  value of formula 5 is also set to  $\frac{1}{4}$ .

Since the average length of intra-tense sequence is about 2.5, we mainly consider intra-tense bigram model and thus  $n$  equals to 2.<sup>5</sup>

#### 5.4 Determining Tense For SMT Output

The current SMT systems often produce odd translations partly because of abnormal word ordering and uncompleted text etc. For these abnormal translated texts, the syntactic parser cannot work well in our initial experiments, so the previous method to parse main tense and tense sequence of regular texts cannot be applied here too.

Fortunately, the solely utilization of Stanford POS tagger for our SMT output is not bad although it has the same issues described in Och et al. (2002). The reason may be that phrase-based SMT contains short contexts that POS tagger can utilize while the syntax parser fails.

Once obtaining a completed hypothesis, the decoder will pass it to the Stanford POS tagger and according to *tense verbs* to get all tense sequence for this hypothesis. However, since the POS tagger can not return the information about level structures, the decoder cannot recognize the main tense from such tense sequence.

Liu et al. (2011) once used target-side verbs to label tense of source-side verbs. It is natural to consider whether Chinese verbs can provide similar clues in an opposite direction.

Since Chinese verbs have good correlation with English verbs (described in section 6.2), we obtain

<sup>5</sup>In our experiment, the intra-tense bigram model can obtain the comparable performance to the trigram model. And the inter-tense trigram model can not exceed the bigram one.

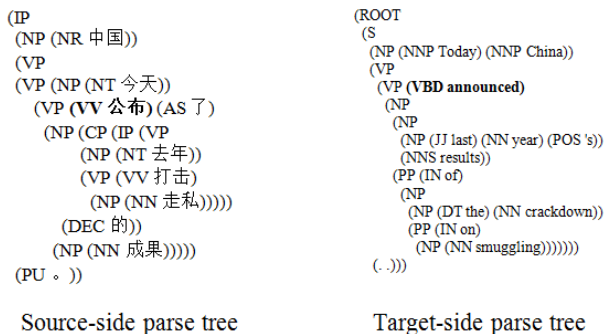

Figure 3: trees for parallel sentences

main tense for SMT output according to such *tense verb*, which corresponds to the “VV”(Chinese POS labels are different to English ones, “VV” refers to Chinese verb) node in the top level of the source-side parse tree. Take Figure 3 as an example, the English node “(VBD announced)” is a *tense verb* which can tell the main tense for this English sentence. The Chinese verb “(VV公布)” in the top-level of the Chinese parse tree is just the corresponding part for this English verb.

So, before translating one sentence, the decoder first parses it and records the location of one Chinese “VV” node which located in the top-level, denotes this location as  $S_{area}$ .

Once a completed hypothesis is generated, according to the phrase alignment information, the decoder can map  $S_{area}$  into the English location  $T_{area}$  and obtain the main tense according to the POS tags in  $T_{area}$ .

If  $T_{area}$  does not contain *tense verb*, such as the verb POS tags in the list of {VB, VBN, VBG}, which cannot tell tense type by themselves, our system permits to find main tense in the left/right 3 words neighbored to  $T_{area}$ . And the proportion that the top-level verb of Chinese has a verb correspondence in English can reach to 83% in this way.

## 6 Experimentation

### 6.1 Experimental Setting for SMT

In our experiment, SRI language modeling toolkit was used to train a 5-Gram general language model on the Xinhua portion of the Gigaword corpus. Word alignment was performed on the training parallel corpus using GIZA++ (Och and Ney, 2000) in two directions. For evaluation, the NIST

BLEU script (version 13) with the default setting is used to calculate the BLEU score (Papineni et al., 2002), which measures case-insensitive matching of 4-grams. To see whether an improvement is statistically significant, we also conduct significance tests using the paired bootstrap approach (Koehn, 2004). In this paper, “\*\*\*” and “\*\*” denote p-values equal to 0.05, and bigger than 0.05, which mean significantly better, moderately better respectively.

Corpus		Sentences	Documents
Role	Name		
Train	FBIS	228455	10000
Dev	NIST2003	919	100
Test	NIST2005	1082	100

Table 1: Corpus statistics

We use FBIS as the training data, the 2003 NIST MT evaluation test data as the development data, and the 2005 NIST MT test data as the test data. Table 1 shows the statistics of these data sets (with document boundaries annotated).

## 6.2 The Correlation of Chinese Verbs and English Verbs

In this section, an additional experiment is designed to show English Verbs have close correspondence with Chinese Verbs.

We use the Stanford POS tagger to tag the Chinese and English sentences in our training corpus respectively at first. Then we utilize Giza++ to build alignment for these special Word-POS pairs. According to the alignment results, we find the corresponding relation for some special POS tags in two languages.

Chinese Verb POS	English POS	Number	
VV	Verb POS	VBD	89830
		VBP	27276
		VBZ	32588
		MD	40378
		VBG	86025
		VBN	75019
		VB	153596
	In sum:	504712	
	Other Non-Verb	149318	
Verb Corresponding Ratio		0.77169	

Table 2: The Chinese and English Verb Pos Alignment

The “Number” column of Table 2 shows the numbers of Chinese words with “VV” tag corresponding to English words with different verb POS tags.

We found Chinese verbs have more than 77% possibilities to align to English verbs in total. However, our method will fail when some special Chinese sentences only contain noun predicates.

## 6.3 Experimental Results

All the experiment results are showed on the table 3. Our Baseline is a modified Moses. The major modification is input and output module in order to translate using document as unit. The performance of our baseline exceeds the baseline reported by Gong et al. (2011) about 2 percent based on the similar training and test corpus.

System	BLEU Dev(%)	BLEU on Test(%)	
		BLEU	NIST
Moses_Md(Baseline)	29.21	28.30	8.4528
Baseline+ $F_m$	30.56	28.87(***)	8.7935
Baseline+ $F_s$	31.28	28.61(**)	8.5645
Baseline+ $F_s(*)$	31.04	28.74(**)	8.6271
Baseline+ $F_m+F_s$	31.75	28.88(***)	8.7987
Baseline+ $F_m+F_s(*)$	31.42	28.92(***)	8.8201

Table 3: The performance of using different feature combinations

The system denoted as “Baseline+ $F_m$ ” integrates the inter-tense feature. The performance boosts 0.57(\*\*\*) in BLEU score.

The system denoted as “Baseline+ $F_s$ ” integrates the intra-tense feature into the baseline. The improvement is less than the inter-tense model, only 0.31(\*\*). It seems the tenses in one sentence has more flexible formats than the document-level ones. It is worth noting, this method can gain higher performance on the develop data than the one of “Baseline+ $F_m$ ” while fail to improve the test data. Maybe the related weight is tuned over-fit.

The system denoted as “Baseline+ $F_s(*)$ ” is slightly different from “Baseline+ $F_s$ ”. This experiment is to check whether the main tense has an impact on intra-tense model or not (see Section 3.2). Here, the intra-tense model based on the tense sequence with main tense marker is slightly different to the model showed in Figure 2. The results are slightly better than the previous system by 0.13.

Finally, we use the two features together (Baseline+ $F_m+F_s$ ). The best way improved the performance by 0.62(\*\*\*) in BLEU score over our baseline.

## 6.4 Discussion

Table 4 shows special examples whose intra-tenses are changed in our proposed system. The example 1 and 2 show such modification can improve the BLEU score but the example 3 obtains negative impact. From these examples, we can see not only tense verbs have changed but also their surrounding words have subtle variation.

No.	BLEU	Translation sentence
1	8.64	Baseline: the gulf countries , the bahraini royal family members by the military career of part of the banned to their marriage stories like children , <b>have</b> become the theme of television films .
	19.71	Ours: the gulf country <b>is</b> a member of the bahraini royal family , a risk by military career <b>risks</b> part of the banned to their marriage like children , <b>has</b> become a story of the television and film industry .
2	17.16	Baseline:economists <b>said</b> that the sharp appreciation of the euro , in the recent investigation <b>continues</b> to have an impact on economic confidence , it <b>is</b> estimated that the economy is expected to rebound to pick up .
	24.25	Ours: economists <b>said</b> that the sharp appreciation of the euro , in the recent investigation <b>continued</b> to have an impact on economic confidence and therefore no reason to predict the economy expected to pick up a rebound .
3	73.03	Baseline: the middle east news agency <b>said</b> that , after the concerns of all parties concerned in the middle east peace process , israel and palestine , egypt , the united states , russia and several european countries <b>will</b> hold a meeting in washington .
	72.95	Ours: the middle east news agency <b>said</b> that after the concerns of all parties in the middle east peace process , israel and palestine , egypt , the united states , russia and several european countries <b>held</b> a meeting in washington .

Table 4: Examples with tense variation using intra-tense model

From the results showed on Table 3, the document-level tense model seems more effective than the sentence-level one. We manually choose and analyzed 5 documents with significant improvement in the test data. The part (a) of Figure 4 shows the main tense distributions of one reference. The main tense distributions for the baseline and our proposed system are showed in the part (b) and (c) respectively. These documents have different numbers of sentences but all less than 10. The vertical axis indicates different tense: 1 to “past”, 2 to “present”, 3 to “future” and 4 to “UNK”. It is obvious that our system has closer distributions to the ones of this reference.

The examples in Table 5 indicate the joint impact of inter-tense and intra-tense model on SMT. Sen-

### Baseline:

- 1)israel **has** imposed a main road to protest by mortars attack .
- 2)the palestinian leader also **visited** the west bank cities and towns to bethlehem , which in the past four years , the israeli authorities **allowed** the palestinian leading figures attended the ceremony .

### Ours:

- 1)israel **has** imposed a main road to protest against the mortars attack .
- 2)leader of the palestinian liberation organization **have** also been allowed to go to the west bank towns , bethlehem in the past four years . this **is** the first time the israeli authorities **allow** palestinian leading figures attended the ceremony .

Table 5: the joint impact of inter- tense and intra-tense models on SMT

tence 1) and 2) are two neighbored sentences in one document. Both the reference and our output tend to use the same main tense type, but the former is in “past” tense and the latter is in “present” tense. The baseline cannot show such tendency. Although our main tense is different to the reference one, the consistent tenses in document level bring better translation results than the baseline. And the tenses in sentence level also show better consistency than the baseline.

## 7 Conclusion

This paper explores document-level SMT from the tense perspective. In particular, we focus on how to build document-level and sentence-level tense models and how to integrate such models into a popular SMT system.

Compared with the inter-tense model which greatly improves the performance of SMT, the intra-tense model needs to be further explored. The reasons are many folds, e.g. the failure to exclude quoted texts when modeling intra-tense, since tenses in quoted texts behave much diversely from normal texts. In the future work, we will focus on modeling intra-tense variation according to specific sentence types and using more features to improve it.

Figure 4: the comparison of the inter-tense distributions for reference, baseline and our proposed system

## Abstract

We propose a novel, language-independent approach for improving machine translation from a resource-poor language to  $X$  by *adapting* a large bi-text for a related resource-rich language and  $X$  (the same target language). We assume a small bi-text for the resource-poor language to  $X$  pair, which we use to learn word-level and phrase-level paraphrases and cross-lingual morphological variants between the resource-rich and the resource-poor language; we then adapt the former to get closer to the latter. Our experiments for Indonesian/Malay–English translation show that using the large adapted resource-rich bi-text yields 6.7 BLEU points of improvement over the unadapted one and 2.6 BLEU points over the original small bi-text. Moreover, combining the small bi-text with the adapted bi-text outperforms the corresponding combinations with the unadapted bi-text by 1.5–3 BLEU points. We also demonstrate applicability to other languages and domains.

## 1 Introduction

Statistical machine translation (SMT) systems learn how to translate from large sentence-aligned bilingual corpora of human-generated translations, called *bi-texts*. Unfortunately, collecting sufficiently large, high-quality bi-texts is hard, and thus most of the 6,500+ world languages remain resource-poor. Fortunately, many of these resource-poor languages are related to some resource-rich language, with whom they overlap in vocabulary and share cognates, which offers opportunities for bi-text reuse.

Example pairs of such resource rich–poor languages include Spanish–Catalan, Finnish–Estonian, Swedish–Norwegian, Russian–Ukrainian, Irish–Gaelic Scottish, Standard German–Swiss German, Modern Standard Arabic–Dialectical Arabic (e.g., Gulf, Egyptian), Turkish–Azerbaijani, etc.

Previous work has already demonstrated the benefits of using a bi-text for a related resource-rich language to  $X$  (e.g.,  $X$ =English) to improve machine translation from a resource-poor language to  $X$  (Nakov and Ng, 2009; Nakov and Ng, 2012). Here we take a different, orthogonal approach: we *adapt* the resource-rich language to get closer to the resource-poor one.

We assume a small bi-text for the resource-poor language, which we use to learn word-level and phrase-level paraphrases and cross-lingual morphological variants between the two languages. Assuming translation into the same target language  $X$ , we adapt (the source side of) a large training bi-text for a related resource-rich language and  $X$ .

Training on the adapted large bi-text yields very significant improvements in translation quality compared to both (a) training on the unadapted version, and (b) training on the small bi-text for the resource-poor language. We further achieve very sizable improvements when combining the small bi-text with the large adapted bi-text, compared to combining the former with the unadapted bi-text.

While we focus on adapting Malay to look like Indonesian in our experiments, we also demonstrate the applicability of our approach to another language pair, Bulgarian–Macedonian, which is also from a different domain.

## 2 Related Work

One relevant line of research is on machine translation between closely related languages, which is arguably simpler than general SMT, and thus can be handled using word-for-word translation, manual language-specific rules that take care of the necessary morphological and syntactic transformations, or character-level translation/transliteration. This has been tried for a number of language pairs including Czech–Slovak (Hajič et al., 2000), Turkish–Crimean Tatar (Altintas and Cicekli, 2002), Irish–Scottish Gaelic (Scannell, 2006), and Bulgarian–Macedonian (Nakov and Tiedemann, 2012). In contrast, we have a different objective – we do not carry out full translation but rather adaptation since our ultimate goal is to translate into a third language  $X$ .

A special case of this same line of research is the translation between dialects of the same language, e.g., between Cantonese and Mandarin (Zhang, 1998), or between a dialect of a language and a standard version of that language, e.g., between some Arabic dialect (e.g., Egyptian) and Modern Standard Arabic (Bakr et al., 2008; Sawaf, 2010; Salloum and Habash, 2011). Here again, manual rules and/or language-specific tools are typically used. In the case of Arabic dialects, a further complication arises by the informal status of the dialects, which are not standardized and not used in formal contexts but rather only in informal online communities<sup>1</sup> such as social networks, chats, Twitter and SMS messages. This causes further mismatch in domain and genre.

Thus, translating from Arabic dialects to Modern Standard Arabic requires, among other things, normalizing informal text to a formal form. In fact, this is a more general problem, which arises with informal sources like SMS messages and Tweets for just any language (Aw et al., 2006; Han and Baldwin, 2011). Here the main focus is on coping with spelling errors, abbreviations, and slang, which are typically addressed using string edit distance, while also taking pronunciation into account. This is different from our task, where we try to adapt good, formal text from one language into another.

A second relevant line of research is on language adaptation and normalization, when done specifically for improving SMT into another language.

For example, Marujo et al. (2011) described a rule-based system for adapting Brazilian Portuguese (BP) to European Portuguese (EP), which they used to adapt BP–English bi-texts to EP–English. They report small improvements in BLEU for EP–English translation when training on the adapted “EP”–En bi-text compared to using the unadapted BP–En (38.55 vs. 38.29), or when an EP–English bi-text is used in addition to the adapted/unadapted one (41.07 vs. 40.91 BLEU). Unlike this work, which heavily relied on language-specific rules, our approach is statistical, and largely language-independent; moreover, our improvements are much more sizable.

A third relevant line of research is on reusing bi-texts between related languages without or with very little adaptation, which works well for very closely related languages. For example, our previous work (Nakov and Ng, 2009; Nakov and Ng, 2012) experimented with various techniques for combining a small bi-text for a resource-poor language (Indonesian or Spanish, pretending that Spanish is resource-poor) with a much larger bi-text for a related resource-rich language (Malay or Portuguese); the target language of all bi-texts was English. However, our previous work did not attempt language adaptation, except for very simple transliteration for Portuguese–Spanish that ignored context entirely; since it could not substitute one word for a completely different word, it did not help much for Malay–Indonesian, which use unified spelling. Still, once we have language-adapted the large bi-text, it makes sense to try to combine it further with the small bi-text; thus, below we will directly compare and combine these two approaches.

Another alternative, which we do not explore in this work, is to use cascaded translation using a pivot language (Utiyama and Isahara, 2007; Cohn and Lapata, 2007; Wu and Wang, 2009). Unfortunately, using the resource-rich language as a pivot (poor→rich→ $X$ ) would require an additional parallel poor–rich bi-text, which we do not have. Pivoting over the target  $X$  (rich→ $X$ →poor) for the purpose of language adaptation, on the other hand, would miss the opportunity to exploit the relationship between the resource-poor and the resource-rich language; this would also be circular since the first step would ask an SMT system to translate its own training data (we only have one rich– $X$  bi-text).

<sup>1</sup>The Egyptian Wikipedia is one notable exception.

### 3 Malay and Indonesian

Malay and Indonesian are closely related, mutually intelligible Austronesian languages with 180 million speakers combined. They have a unified spelling, with occasional differences, e.g., *kerana* vs. *karena* ('because'), *Inggeris* vs. *Inggris* ('English'), and *wang* vs. *uang* ('money').

They differ more substantially in vocabulary, mostly because of loan words, where Malay typically follows the English pronunciation, while Indonesian tends to follow Dutch, e.g., *televisyen* vs. *televisei*, *Julai* vs. *Juli*, and *Jordan* vs. *Yordania*.

While there are many cognates between the two languages, there are also a lot of false friends, e.g., *polisi* means *policy* in Malay but *police* in Indonesian. There are also many partial cognates, e.g., *nanti* means both *will* (future tense marker) and *later* in Malay but only *later* in Indonesian.

Thus, fluent Malay and fluent Indonesian can differ substantially. Consider, for example, Article 1 of the *Universal Declaration of Human Rights*:<sup>2</sup>

- *Semua manusia dilahirkan bebas dan samarata dari segi kemuliaan dan hak-hak. Mereka mempunyai pemikiran dan perasaan hati dan hendaklah bertindak di antara satu sama lain dengan semangat persaudaraan. (Malay)*
- *Semua orang dilahirkan merdeka dan mempunyai martabat dan hak-hak yang sama. Mereka dikaruniai akal dan hati nurani dan hendaknya bergaul satu sama lain dalam semangat persaudaraan. (Indonesian)*

There is only 50% overlap at the word level, but the actual vocabulary overlap is much higher, e.g., there is only one word in the Malay text that does not exist in Indonesian: *samarata* ('equal'). Other differences are due to the use of different morphological forms, e.g., *hendaklah* vs. *hendaknya* ('conscience'), derivational variants of *hendak* ('want').

Of course, word choice in translation is often a matter of taste. Thus, we asked a native speaker of Indonesian to adapt the Malay version to Indonesian while preserving as many words as possible:

- *Semua manusia dilahirkan bebas dan mempunyai martabat dan hak-hak yang sama. Mereka mempunyai pemikiran dan perasaan dan hendaklah bergaul satu sama lain dalam semangat persaudaraan. (Indonesian)*

<sup>2</sup>English: *All human beings are born free and equal in dignity and rights. They are endowed with reason and conscience and should act towards one another in a spirit of brotherhood.*

Obtaining this latter version from the original Malay text requires three word-level operations: (1) deletion of *dari*, *segi*, (2) insertion of *yang*, *sama*, and (3) substitution of *samarata* with *mempunyai*.

Unfortunately, we do not have parallel Malay-Indonesian text, which complicates the process of learning when to apply these operations. Thus, below we restrict our attention to the simplest and most common operation of word substitution only, leaving the other two<sup>3</sup> operations for future work.

Note that word substitution is enough in many cases, e.g., it is all that is needed for the following Malay-Indonesian sentence pair:<sup>4</sup>

- *KDNK Malaysia dijangka cecah 8 peratus pada tahun 2010.*
- *PDB Malaysia akan mencapai 8 persen pada tahun 2010.*

### 4 Method

We improve machine translation from a resource-poor language (Indonesian) to English by *adapting* a bi-text for a related resource-rich language (Malay) and English, using *word-level* and *phrase-level* paraphrases and cross-lingual morphological variants.

#### 4.1 Word-Level Paraphrasing

Given a Malay sentence, we generate a confusion network containing multiple Indonesian word-level paraphrase options for each Malay word. Each such Indonesian option is associated with a corresponding weight in the network, which is defined as the probability of this option being a translation of the original Malay word (see Eq. 1 below). We decode this confusion network using a large Indonesian language model, thus generating a ranked list of  $n$  corresponding adapted "Indonesian" sentences.

Then, we pair each such adapted "Indonesian" sentence with the English counter-part for the Malay sentence it was derived from, thus obtaining a synthetic "Indonesian"-English bi-text. Finally, we combine this synthetic bi-text with the original Indonesian-English one to train the final Indonesian-English SMT system.

Below we first describe how we generate word-level Indonesian options and corresponding weights for the Malay words. Then, we explain how we build, decode, and improve the confusion network.

<sup>3</sup>There are other potentially useful operations, e.g., a correct translation for the Malay *samarata* can be obtained by splitting it into the Indonesian sequence *sama rata*.

<sup>4</sup>*Malaysia's GDP is expected to reach 8 percent in 2010.*

### 4.1.1 Inducing Word-Level Paraphrases

We use pivoting over English to induce potential Indonesian translations for a given Malay word.

First, we generate separate word-level alignments for the Indonesian–English and the Malay–English bi-texts. Then, we induce Indonesian–Malay word translation pairs assuming that if an Indonesian word  $i$  and a Malay word  $m$  are aligned to the same English word  $e$ , they could be mutual translations. Each translation pair is associated with a conditional probability, estimated by pivoting over English:

$$\Pr(i|m) = \sum_e \Pr(i|e)\Pr(e|m) \quad (1)$$

$\Pr(i|e)$  and  $\Pr(e|m)$  are estimated using maximum likelihood from the word alignments. Following (Callison-Burch et al., 2006), we further assume that  $i$  is conditionally independent of  $m$  given  $e$ .

### 4.1.2 Confusion Network Construction

Given a Malay sentence, we construct an Indonesian confusion network, where each Malay word is augmented with a set of network transitions: possible Indonesian word translations. The weight of such a transition is the conditional Indonesian–Malay translation probability as calculated by Eq. 1; the original Malay word is assigned a weight of 1.

Note that we paraphrase *each* word in the input Malay sentence as opposed to only those Malay words that we believe not to exist in Indonesian, e.g., because they do not appear in our Indonesian monolingual text. This is necessary because of the large number of false friends and partial cognates between Malay and Indonesian (see Section 3).

Finally, we decode the confusion network for a Malay sentence using a large Indonesian language model, and we extract an  $n$ -best list.<sup>5</sup> Table 1 shows the 10-best adapted “Indonesian” sentences<sup>6</sup> we generated for the confusion network in Figure 1.

### 4.1.3 Further Refinements

Many of our paraphrases are bad: some have very low probabilities, while others involve rare words for which the probability estimates are unreliable.

<sup>5</sup>For balance, in case of less than  $n$  adaptations for a Malay sentence, we randomly repeat some of the available ones.

<sup>6</sup>According to a native Indonesian speaker, options 1 and 3 in Table 1 are perfect adaptations, options 2 and 5 have a wrong word order, and the rest are grammatical though not perfect.

Moreover, the options we propose for a Malay word are inherently restricted to the small Indonesian vocabulary of the Indonesian–English bi-text. Below we describe how we address these issues.

**Score-based filtering.** We filter out translation pairs whose probabilities (Eq. 1) are lower than some threshold (tuned on the dev dataset), e.g., 0.01.

**Improved estimations for  $\Pr(i|e)$ .** We concatenate  $k$  copies of the Indonesian–English bi-text and one copy of the Malay–English bi-text, where the value of  $k$  is selected so that we have roughly the same number of Indonesian and Malay sentences. Then, we generate word-level alignments for the resulting bi-text. Finally, we truncate these alignments keeping them for one copy of the original Indonesian–English bi-text only. Thus, we end up with improved word alignments for the Indonesian–English bi-text, and with better estimations for Eq. 1. Since Malay and Indonesian share many cognates, this improves word alignments for Indonesian words that occur rarely in the small Indonesian–English bi-text but are relatively frequent in the larger Malay–English one; it also helps for some frequent words.

**Cross-lingual morphological variants.** We increase the Indonesian options for a Malay word using morphology. Since the set of Indonesian options for a Malay word in pivoting is restricted to the Indonesian vocabulary of the small Indonesian–English bi-text, this is a severe limitation of pivoting. Thus, assuming a large monolingual Indonesian text, we first build a lexicon of the words in the text. Then, we lemmatize these words using two different lemmatizers: the Malay lemmatizer of Baldwin and Awab (2006), and a similar Indonesian lemmatizer. Since these two analyzers have different strengths and weaknesses, we combine their outputs to increase recall. Next, we group all Indonesian words that share the same lemma, e.g., for *minum*, we obtain  $\{\textit{diminum}, \textit{diminumkan}, \textit{diminumnya}, \textit{makan-minum}, \textit{makananminuman}, \textit{meminum}, \textit{meminumkan}, \textit{meminumnya}, \textit{meminumminuman}, \textit{minum}, \textit{minum-minum}, \textit{minum-minuman}, \textit{minuman}, \textit{minumanku}, \textit{minumannya}, \textit{peminum}, \textit{peminumnya}, \textit{perminum}, \textit{terminum}\}$ . Since Malay and Indonesian are subject to the same morphological processes and share many lemmata, we use such groups to propose Indonesian translation options for a Malay word. We first lemmatize the target Malay word, and then we find all groups of Indonesian words the Malay lemmata belong to.

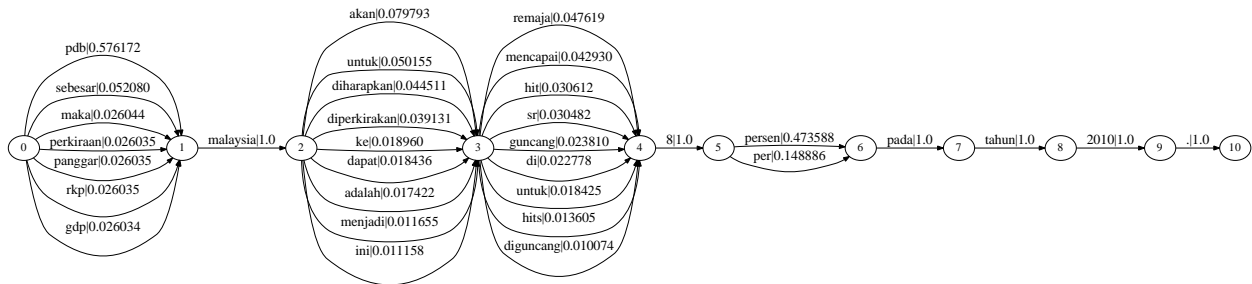

Figure 1: Indonesian confusion network for the Malay sentence “KDNK Malaysia dijangka cecah 8 peratus pada tahun 2010.” Arcs with scores below 0.01 are omitted, and words that exist in Indonesian are not paraphrased (for better readability).

Rank	“Indonesian” Sentence			
1	pdb	malaysia	akan	mencapai 8 persen pada tahun 2010 .
2	pdb	malaysia	untuk	mencapai 8 persen pada tahun 2010 .
3	pdb	malaysia	diperkirakan	mencapai 8 persen pada tahun 2010 .
4	maka	malaysia	akan	mencapai 8 persen pada tahun 2010 .
5	maka	malaysia	untuk	mencapai 8 persen pada tahun 2010 .
6	pdb	malaysia	dapat	mencapai 8 persen pada tahun 2010 .
7	maka	malaysia	diperkirakan	mencapai 8 persen pada tahun 2010 .
8	sebesar	malaysia	akan	mencapai 8 persen pada tahun 2010 .
9	pdb	malaysia	diharapkan	mencapai 8 persen pada tahun 2010 .
10	pdb	malaysia	ini	mencapai 8 persen pada tahun 2010 .

Table 1: The 10-best “Indonesian” sentences extracted from the confusion network in Figure 1.

The union of these groups is the set of morphological variants that we will add to the confusion network as additional options for the Malay word.<sup>7</sup> For example, given *seperminuman* (‘drinking’) in the Malay input, we first find its stem *minum*, and then we get the above example set of Indonesian words, which contains some reasonable substitutes such as *minuman* (‘drink’). In the confusion network, the weight of the original Malay word is set to 1, while the weight of a morphological option is one minus the minimum edit distance ratio (Ristad and Yianilos, 1998) between it and the Malay word, multiplied by the highest probability for all pivoting variants for the Malay word.

## 4.2 Phrase-Level Paraphrasing

*Word-level* paraphrasing ignores context when generating Indonesian variants, relying on the Indonesian language model to make the right contextual choice. We also try to model context more directly by generating adaptation options at the *phrase level*.

<sup>7</sup>While the different morphological forms typically have different meanings, e.g., *minum* (‘drink’) vs. *peminum* (‘drinker’), in some cases the forms could have the same translation in English, e.g., *minum* (‘drink’, verb) vs. *minuman* (‘drink’, noun). This is our motivation for trying morphological variants, even though they are almost exclusively derivational, and thus quite risky as translational variants; see also (Nakov and Ng, 2011).

**Phrase-level paraphrase induction.** We use standard phrase-based SMT techniques to build separate phrase tables for the Indonesian–English and the Malay–English bi-texts, where we have four conditional probabilities: forward/reverse phrase translation probability, and forward/reverse lexicalized phrase translation probability. We pivot over English to generate Indonesian–Malay phrase pairs, whose probabilities are derived from the corresponding ones in the two phrase tables using Eq. 1.

**Cross-lingual morphological variants.** While phrase-level paraphrasing models context better, it remains limited in the size of its Indonesian vocabulary by the small Indonesian–English bi-text, just like word-level paraphrasing was. We address this by transforming the sentences in the *development* and the *test* Indonesian–English bi-texts into confusion networks, where we add Malay morphological variants for the Indonesian words, weighting them as before. Note that we do not alter the training bi-text.

## 4.3 Combining Bi-texts

We combine the Indonesian–English and the synthetic “Indonesian”–English bi-texts as follows:

**Simple concatenation.** Assuming the two bi-texts are of comparable quality, we simply train an SMT system on their concatenation.

**Balanced concatenation with repetitions.** However, the two bi-texts are not directly comparable and are clearly not equally good as a source of training data for an Indonesian-English SMT system. For one thing, the “Indonesian”–English bi-text is obtained from  $n$ -best lists, i.e., it has exactly  $n$  very similar variants for each Malay sentence. Moreover, the original Malay–English bi-text is much larger in size than the Indonesian–English one, and now it has been further expanded  $n$  times in order to become an “Indonesian”–English bi-text, which means that it will dominate the concatenation due to its size. In order to counter-balance this, we repeat the smaller Indonesian–English bi-text enough times so that we can make the number of sentences it contains roughly the same as for the “Indonesian”–English bi-text; then we concatenate the two bi-texts and we train an SMT system on the resulting bi-text.

**Sophisticated phrase table combination.** Finally, we experiment with a method for combining phrase tables proposed in (Nakov and Ng, 2009; Nakov and Ng, 2012). The first phrase table is extracted from word alignments for the balanced concatenation with repetitions, which are then truncated so that they are kept for only one copy of the Indonesian–English bi-text. The second table is built from the simple concatenation. The two tables are then merged as follows: all phrase pairs from the first one are retained, and to them are added those phrase pairs from the second one that are not present in the first one. Each phrase pair retains its original scores, which are further augmented with 1–3 additional feature scores indicating its origin: the first/second/third feature is 1 if the pair came from the first/second/both table(s), and 0 otherwise. We experiment using all three, the first two, or the first feature only; we also try setting the features to 0.5 instead of 0. This makes the following six combinations (0, 00, 000, .5, .5.5, .5.5.5); on testing, we use the one that achieves the highest BLEU score on the development set.

Other possibilities for combining the phrase tables include using alternative decoding paths (Birch et al., 2007), simple linear interpolation, and direct phrase table merging with extra features (Callison-Burch et al., 2006); they were previously found inferior to the last two approaches above (Nakov and Ng, 2009; Nakov and Ng, 2012).

## 5 Experiments

We run two kinds of experiments: (a) *isolated*, where we train on the synthetic “Indonesian”–English bi-text only, and (b) *combined*, where we combine it with the Indonesian–English bi-text.

### 5.1 Datasets

In our experiments, we use the following datasets, normally required for Indonesian–English SMT:

- **Indonesian–English train bi-text (*IN2EN*):** 28,383 sentence pairs; 915,192 English tokens; 796,787 Indonesian tokens;
- **Indon.–English dev bi-text (*IN2EN-dev*):** 2,000 sentence pairs; 36,584 English tokens; 35,708 Indonesian tokens;
- **Indon.–English test bi-text (*IN2EN-test*):** 2,018 sentence pairs; 37,101 English tokens; 35,509 Indonesian tokens;
- **Monolingual English text (*EN-LM*):** 174,443 sentences; 5,071,988 English tokens.

We also use a Malay–English set (to be turned into “Indonesian”–English), and monolingual Indonesian text (for decoding the confusion network):

- **Malay–English train bi-text (*ML2EN*):** 290,000 sentence pairs; 8,638,780 English tokens; 8,061,729 Malay tokens;
- **Monolingual Indonesian text (*IN-LM*):** 1,132,082 sentences; 20,452,064 Indonesian tokens.

### 5.2 Baseline Systems

We build five baseline systems – two using a single bi-text, *ML2EN* or *IN2EN*, and three combining *ML2EN* and *IN2EN*, using simple concatenation, balanced concatenation, and sophisticated phrase table combination. The last combination is a very strong baseline and the most relevant one we need to improve upon.

### 5.3 Isolated Experiments

The isolated experiments only use the adapted “Indonesian”–English bi-text, which allows for a direct comparison to using *ML2EN* / *IN2EN* only.

#### 5.3.1 Word-Level Paraphrasing

In our word-level paraphrasing experiments, we adapt Malay to Indonesian using three kinds of confusion networks (see Section 4.1.3 for details):

- *CN:pivot* – using word-level pivoting only;
- *CN:pivot'* – using word-level pivoting, with probabilities from word alignments for *IN2EN* that were improved using *ML2EN*;
- *CN:pivot'+morph* – *CN:pivot'* augmented with cross-lingual morphological variants.

There are two parameter values to be tuned on *IN2EN-dev* for the above confusion networks: (1) the minimum pivoting probability threshold for the Malay-Indonesian word-level paraphrases, and (2) the number of  $n$ -best Indonesian-adapted sentences that are to be generated for each input Malay sentence. We try  $\{0.001, 0.005, 0.01, 0.05\}$  for the threshold and  $\{1, 5, 10\}$  for  $n$ .

### 5.3.2 Phrase-Level Paraphrasing

In our phrase-level paraphrasing experiments, we use pivoted phrase tables (PPT) with the following features for each phrase table entry (in addition to the phrase penalty; see Section 4.2 for more details):

- *PPT:1* – only uses the forward conditional translation probability;
- *PPT:4* – uses all four conditional probabilities;
- *PPT:4::CN:morph* – *PPT:4* but used with a cross-lingual morphological confusion network for the dev/test Indonesian sentences.

Here we tune one parameter only: the number of  $n$ -best Indonesian-adapted sentences to be generated for each input Malay sentence; we try  $\{1, 5, 10\}$ .

### 5.4 Combined Experiments

These experiments assess the impact of our adaptation approach when combined with the original Indonesian–English bi-text *IN2EN* as opposed to combining *ML2EN* with *IN2EN* (as was in the last three baselines). We experiment with the same three combinations: simple concatenation, balanced concatenation, and sophisticated phrase table combination. We tune the parameters as before; for the last combination, we further tune the six extra feature combinations (see Section 4.3 for details).

## 6 Results and Discussion

For all tables, statistically significant improvements ( $p < 0.01$ ), according to Collins et al. (2005)’s sign test, over the baseline are in **bold**; in case of two baselines, underline is used for the second baseline.

System	BLEU
<i>ML2EN</i>	14.50
<i>IN2EN</i>	18.67
Simple concatenation	<b>18.49</b>
Balanced concatenation	<b><u>19.79</u></b>
Sophisticated phrase table combination	<b><u>20.10</u></b> <sub>(.5.5)</sub>

Table 2: **The five baselines.** The subscript indicates the parameters found on *IN2EN-dev* and used for *IN2EN-test*. The scores that are statistically significantly better than *ML2EN* and *IN2EN* ( $p < 0.01$ , Collins’ sign test) are shown in **bold** and are underlined, respectively.

### 6.1 Baseline Experiments

The results for the baseline systems are shown in Table 2. We can see that training on *ML2EN* instead of *IN2EN* yields over 4 points absolute drop in BLEU (Papineni et al., 2002) score, even though *ML2EN* is about 10 times larger than *IN2EN* and both bi-texts are from the same domain. This confirms the existence of important differences between Malay and Indonesian. While simple concatenation does not help, balanced concatenation with repetitions improves by 1.12 BLEU points over *IN2EN*, which shows the importance of giving *IN2EN* a proper weight in the combined bi-text. This is further re-confirmed by the sophisticated phrase table combination, which yields an additional absolute gain of 0.31 BLEU points.

### 6.2 Isolated Experiments

Table 3 shows the results for the isolated experiments. We can see that word-level paraphrasing improves by up to 5.56 and 1.39 BLEU points over the two baselines (both statistically significant). Compared to *ML2EN*, *CN:pivot* yields an absolute improvement of 4.41 BLEU points, *CN:pivot'* adds another 0.59, and *CN:pivot'+morph* adds 0.56 more. The scores for TER (v. 0.7.25) and METEOR (v. 1.3) are on par with those for BLEU (NIST v. 13).

Table 3 further shows that the optimal parameters for the word-level SMT systems (*CN:\**) involve a very low probability cutoff, and a high number of  $n$ -best sentences. This shows that they are robust to noise, probably because bad source-side phrases are unlikely to match the test-time input. Note also the effect of repetitions: good word choices are shared by many  $n$ -best sentences, and thus they would have higher probabilities compared to bad word choices.

System	<i>n</i> -gram precision				BLEU	TER	METEOR
	1-gr.	2-gr.	3-gr.	4-gr.			
<i>ML2EN</i> (baseline)	48.34	19.22	9.54	4.98	14.50	67.14	43.28
<i>IN2EN</i> (baseline)	55.04	23.90	12.87	7.18	18.67	61.99	54.34
<i>CN:pivot</i>	54.50	24.41	13.09	7.35	<b>18.91</b> <sup>(+4.41,+0.24)</sup> <sub>(0.005,10best)</sub>	61.94	51.07
<i>CN:pivot'</i>	55.05	25.09	13.60	7.69	<b>19.50</b> <sup>(+5.00,+0.83)</sup> <sub>(0.001,10best)</sub>	61.25	51.97
(i) <i>CN:pivot' + morph</i>	55.97	25.73	14.06	7.99	<b>20.06</b> <sup>(+5.56,+1.39)</sup> <sub>(0.005,10best)</sub>	60.31	55.65
<i>PPT:1</i>	55.11	25.04	13.66	7.80	<b>19.58</b> <sup>(+5.08,+0.91)</sup> <sub>(10best)</sub>	60.92	51.93
<i>PPT:4</i>	56.64	26.20	14.53	8.40	<b>20.63</b> <sup>(+6.13,+1.96)</sup> <sub>(10best)</sub>	59.33	54.23
(ii) <i>PPT:4::CN:morph</i>	56.91	26.53	14.76	8.55	<b>20.89</b> <sup>(+6.39,+2.22)</sup> <sub>(10best)</sub>	59.30	57.19
System combination: (i) + (ii)	57.73	27.00	15.03	8.71	<b>21.24</b> <sup>(+6.74,+2.57)</sup>	58.19	54.63

Table 3: **Isolated experiments.** The subscript shows the best tuning parameters, and the superscript shows the absolute test improvement over the *ML2EN* and the *IN2EN* baselines. The last line shows system combination results.

Combination with	Combining <i>IN2EN</i> with an adapted version of <i>ML2EN</i>		
	Simple Concatenation	Balanced Concatenation	Sophisticated Combination
(i) + <i>ML2EN</i> (unadapted; baseline)	18.49	19.79	20.10 <sub>(.5,5)</sub>
+ <i>CN:pivot</i>	<b>19.99</b> <sup>(+1.50)</sup> <sub>(0.001,1best)</sub>	20.16 <sup>(+0.37)</sup> <sub>(0.001,10best)</sub>	20.32 <sup>(+0.22)</sup> <sub>(0.01,10best,.5,5)</sub>
+ <i>CN:pivot'</i>	<b>20.03</b> <sup>(+1.54)</sup> <sub>(0.05,1best)</sub>	<b>20.80</b> <sup>(+1.01)</sup> <sub>(0.05,10best)</sub>	<b>20.55</b> <sup>(+0.45)</sup> <sub>(0.05,10best,.5,5)</sub>
(ii) + <i>CN:pivot' + morph</i>	<b>20.60</b> <sup>(+2.11)</sup> <sub>(0.01,10best)</sub>	<b>21.15</b> <sup>(+1.36)</sup> <sub>(0.01,10best)</sub>	<b>21.05</b> <sup>(+0.95)</sup> <sub>(0.01,5best,00)</sub>
+ <i>PPT:1</i>	<b>20.61</b> <sup>(+2.12)</sup> <sub>(1best)</sub>	<b>20.71</b> <sup>(+0.92)</sup> <sub>(10best)</sub>	20.32 <sup>(+0.22)</sup> <sub>(1best,000)</sub>
+ <i>PPT:4</i>	<b>20.75</b> <sup>(+2.26)</sup> <sub>(1best)</sub>	<b>21.08</b> <sup>(+1.29)</sup> <sub>(5best)</sub>	<b>20.76</b> <sup>(+0.66)</sup> <sub>(10best,.5,5,5)</sub>
(iii) + <i>PPT:4::CN:morph</i>	<b>21.01</b> <sup>(+2.52)</sup> <sub>(1best)</sub>	<b>21.31</b> <sup>(+1.52)</sup> <sub>(5best)</sub>	<b>20.98</b> <sup>(+0.88)</sup> <sub>(10best,.5)</sub>
System combination: (i) + (ii) + (iii)	<b>21.55</b> <sup>(+3.06)</sup>	<b>21.64</b> <sup>(+1.85)</sup>	<b>21.62</b> <sup>(+1.52)</sup>

Table 4: **Combined experiments: BLEU.** The best tuning parameter values are in subscript, and the absolute test improvement over the corresponding baseline (on top of each column) is in superscript.

The gap between *ML2EN* and *IN2EN* for unigram precision could be explained by vocabulary differences between Malay and Indonesian. Compared to *IN2EN*, all *CN:\** models have higher 2/3/4-gram precision. However, *CN:pivot* has lower unigram precision, which could be due to bad word alignments, as the results for *CN:pivot'* show.

When morphological variants are further added, the unigram precision improves by almost 1% absolute over *CN:pivot'*. This shows the importance of morphology for overcoming the limitations of the small Indonesian vocabulary of the *IN2EN* bi-text.

The lower part of Table 3 shows that phrase-level paraphrasing performs a bit better. This confirms the importance of modeling context for closely-related languages like Malay and Indonesian, which are rich in false friends and partial cognates. We further see that using more scores in the phrase table is better. Extending the Indonesian vocabulary with cross-lingual morphological variants is still helpful, though not as much as at the word-level.

Finally, the combination of the output of the best PPT and the best CN systems using MEMT (Heafield and Lavie, 2010) yields even further improvements, which shows that the two kinds of paraphrases are complementary. The best overall BLEU score for our isolated experiments is 21.24, which is better than the results for all five baselines in Table 2, including the three bi-text combination baselines, which only achieve up to 20.10 BLEU.

### 6.3 Combined Experiments

Table 4 shows the performance of the three bi-text combination strategies (see Section 4.3 for additional details) when applied to combine *IN2EN* (1) with the original *ML2EN* and (2) with various adapted versions of it.

We can see that for the word-level paraphrasing experiments (*CN:\**), all combinations except for *CN:pivot* perform significantly better than their corresponding baselines, but the improvements are most sizeable for the simple concatenation.

Note that while there is a difference of 0.31 BLEU points between the balanced concatenation and the sophisticated combination for the original *ML2EN*, they differ little for the adapted versions. This is probably due to the sophisticated combination assuming that the second bi-text is worse than the first one, which is not really the case for the adapted versions: as Table 3 shows, they all outperform *IN2EN*.

Overall, phrase-level paraphrasing performs a bit better than word-level paraphrasing, and system combination with MEMT improves even further. This is consistent with the isolated experiments.

## 7 Further Analysis

**Paraphrasing non-Indonesian words only.** In *CN*:\* above, we paraphrased *each* word in the Malay input, because of false friends like *polisi* and partial cognates like *nanti*. This risks proposing worse alternatives, e.g., changing *beliau* (‘he’, respectful) to *ia* (‘he’, casual), which confusion network weights and LM would not always handle. Thus, we tried paraphrasing non-Indonesian words only, i.e., those not in *IN-LM*. Since *IN-LM* occasionally contains some Malay-specific words, we also tried paraphrasing words that occur at most  $t$  times in *IN-LM*. Table 5 shows that this hurts by up to 1 BLEU point for  $t = 0$ ; 10, and a bit less for  $t = 20$ ; 40.

System	BLEU
<i>CN:pivot</i> , $t = 0$	17.88 <sub>(0.01,5best)</sub>
<i>CN:pivot</i> , $t = 10$	17.88 <sub>(0.05,10best)</sub>
<i>CN:pivot</i> , $t = 20$	18.14 <sub>(0.01,5best)</sub>
<i>CN:pivot</i> , $t = 40$	18.34 <sub>(0.01,5best)</sub>
<i>CN:pivot</i> (i.e., paraphrase all)	18.91 <sub>(0.005,10best)</sub>

Table 5: **Paraphrasing non-Indonesian words only:** those appearing at most  $t$  times in *IN-LM*.

**Manual evaluation.** We asked a native Indonesian speaker who does not speak Malay to judge whether our “Indonesian” adaptations are more understandable to him than the original Malay input for 100 random sentences. We presented him with two extreme systems: (a) the conservative *CN:pivot,t=0* vs. (b) *CN:pivot'+morph*. Since the latter is noisy, the top 3 choices were judged for it. Table 6 shows that *CN:pivot,t=0* is better/equal to the original 53%/31% of the time. In contrast, *CN:pivot'+morph* is typically worse than the original; even compared to the best in top 3, the better:worse ratio is 45%:43%.

Still, this latter model works better, which means that phrase-based SMT systems are robust to noise and prefer more variety. Note also that the judgments were at the sentence level, while phrases are sub-sentential, i.e., there can be many good phrases in a “bad” sentence.

System	Better	Equal	Worse
<i>CN:pivot</i> , $t = 0_{(Rank1)}$	53%	31%	16%
<i>CN:pivot'+morph</i> <sub>(Rank1)</sub>	38%	8%	54%
<i>CN:pivot'+morph</i> <sub>(Rank2)</sub>	41%	9%	50%
<i>CN:pivot'+morph</i> <sub>(Rank3)</sub>	32%	11%	57%
<i>CN:pivot'+morph</i> <sub>(Ranks:1-3)</sub>	45%	12%	43%

Table 6: **Human judgments: Malay vs. “Indonesian”.** The parameter values are those from Tables 3 and 5.

**Reversed Adaptation.** In all experiments above, we were adapting the Malay sentences to look like Indonesian. Here we try to reverse the direction of adaptation, i.e., to adapt Indonesian to Malay: we thus build a “Malay” confusion network for each dev/test Indonesian sentence to be used as an input to a Malay–English SMT system trained on the *ML2EN* dataset. We tried two variations of this idea:

- **lattice:** Use Indonesian-to-Malay confusion networks directly as input to the *ML2EN* SMT system, i.e., tune a log-linear model using confusion networks for the source side of the *IN2EN-dev* dataset, and then evaluate the tuned system using confusion networks for the source side of the *IN2EN-test* dataset.
- **1-best:** Use the 1-best output from the Indonesian-to-Malay confusion network for each sentence of *IN2EN-dev* and *IN2EN-test*. Then pair each 1-best output with the corresponding English sentence. Finally, get an adapted “Malay”–English development set and an adapted “Malay”–English test set, and use them to tune and evaluate the *ML2EN* SMT system.

Table 7 shows that both variations perform worse than *CN:pivot*. We believe this is because *lattice* encodes many options, but does not use a Malay LM, while *1-best* uses a Malay LM, but has to commit to 1-best. In contrast, *CN:pivot* uses both  $n$ -best outputs and an Indonesian LM; designing a similar setup for reversed adaptation is a research direction we would like to pursue in future work.

System	BLEU
<i>CN:pivot</i> (Malay→Indonesian)	18.91 <sub>(0.005,10best)</sub>
<i>CN:pivot</i> (Indonesian→Malay) – lattice	17.22 <sub>(0.05)</sub>
<i>CN:pivot</i> (Indonesian→Malay) – 1-best	17.77 <sub>(0.001)</sub>

Table 7: **Reversed adaptation: Indonesian to Malay.**

**Adapting Macedonian to Bulgarian.** We experimented with another pair of closely-related languages,<sup>8</sup> Macedonian (*MK*) and Bulgarian (*BG*), using data from a different, non-newswire domain: the OPUS corpus of movie subtitles (Tiedemann, 2009). We used datasets of sizes that are comparable to those in the previous experiments: 160K *MK2EN* and 1.5M *BG2EN* sentence pairs (1.2M and 11.5M *EN* words). Since the sentences were short, we used 10K *MK2EN* sentence pairs for tuning and testing (77K and 72K English words). For the LM, we used 9.2M Macedonian and 433M English words.

Table 8 shows that both *CN:\** and *PPT:\** yield statistically significant improvements over balanced concatenation with unadapted *BG2EN*; system combination with MEMT improves even further. This indicates that our approach can work for other pairs of related languages and even for other domains.

We should note though that the improvements here are less sizeable than for Indonesian/Malay. This may be due to our monolingual *MK* dataset being smaller (10M *MK* vs. 20M *IN* words), and too noisy, containing many OCR errors, typos, concatenated words, and even some Bulgarian text. Moreover, Macedonian and Bulgarian are arguably somewhat more dissimilar than Malay and Indonesian.

System	BLEU	TER	METEOR
<i>BG2EN</i> (baseline)	24.57	57.64	41.60
<i>MK2EN</i> (baseline)	26.46	54.55	46.15
<b>Balanced concatenation of <i>MK2EN</i> with an adapted <i>BG2EN</i></b>			
+ <i>BG2EN</i> (unadapted)	<b>27.33</b>	54.61	48.16
+ <i>CN:pivot'</i> + <i>morph</i>	<b>27.97</b> <sup>(+0.64,+1.51)</sup>	54.08	49.65
+ <i>PPT:4::CN:morph</i>	<b>28.38</b> <sup>(+1.05,+1.92)</sup>	53.35	48.21
Combining last three	<b>29.05</b> <sup>(+1.72,+2.59)</sup>	52.31	50.96

Table 8: **Improving Macedonian–English SMT by adapting Bulgarian to Macedonian.**

<sup>8</sup>There is a heated political and linguistic debate about whether Macedonian represents a separate language or is a regional literary form of Bulgarian. Since there are no clear criteria for distinguishing a dialect from a language, linguists are divided on this issue. Politically, the Macedonian remains unrecognized as a language by Bulgaria and Greece.

## 8 Conclusion and Future Work

We have presented a novel approach for improving machine translation for a resource-poor language by *adapting* a bi-text for a related resource-rich language, using confusion networks, word/phrase-level paraphrasing, and morphological analysis.

We have achieved very significant improvements over several baselines (6.7 BLEU points over an unadapted version of *ML2EN*, 2.6 BLEU points over *IN2EN*, and 1.5–3 BLEU points over three bi-text combinations of *ML2EN* and *IN2EN*), thus proving the potential of the idea. We have further demonstrated the applicability of the general approach to other languages and domains.

In future work, we would like to add word deletion, insertion, splitting, and concatenation as allowed editing operations. We further want to explore tighter integration of word-based and phrase-based paraphrasing. Finally, we plan experiments with other language pairs and application to other linguistic problems.

### Acknowledgments

We would like to give special thanks to Harta Wijaya and Aldrian Obaja Muis, native speakers of Indonesian, for their help in the linguistic analysis of the input and output of our system. We would also like to thank the anonymous reviewers for their constructive comments and suggestions, which have helped us improve the quality of this paper.

This research is supported by the Singapore National Research Foundation under its International Research Centre @ Singapore Funding Initiative and administered by the IDM Programme Office.

## Abstract

The possibility of deleting a word from a sentence without violating its syntactic correctness belongs to traditionally known manifestations of syntactic dependency. We introduce a novel unsupervised parsing approach that is based on a new  $n$ -gram reducibility measure. We perform experiments across 18 languages available in CoNLL data and we show that our approach achieves better accuracy for the majority of the languages than previously reported results.

## 1 Introduction

The true nature of the notion of dependency (after removing sedimentary deposits of rules imposed only by more or less arbitrary conventions) remains still somewhat vague and elusive. This holds in spite of a seemingly strong background intuition and even after a decade of formalized large-scale dependency-based resources being available to the research community. It is undeniable that a huge progress has been reached in the field of supervised dependency parsing, especially due to the CoNLL shared task series. However, when it comes to unsupervised parsing, there are surprisingly few clues we could rely on.

As mentioned e.g. by Kübler et al. (2009), one of the traditional linguistic criteria for recognizing dependency relations (including their head-dependent orientation) is that a head  $H$  of a construction  $C$  determines the syntactic category of  $C$  and can often replace  $C$ . Or, in words of Dependency Analysis by

Reduction (Lopatková et al., 2005), stepwise deletion of dependent elements within a sentence preserves its syntactic correctness. A similar idea of dependency analysis by splitting a sentence into all possible acceptable fragments is used by Gerdes and Kahane (2011).

Of course, all the above works had to respond to the notorious fact that there are many language phenomena precluding the ideal (word by word) sentence reducibility (e.g. in the case of prepositional groups, or in the case of subjects in English finite clauses). However, we disregard their solutions tentatively and borrow only the very core of the reducibility idea: if a word can be removed from a sentence without damaging it, then it is likely to be dependent on some other (still present) word.

As it is usual with dichotomies in natural languages, it seems more adequate to use a continuous scale instead of the reducible-irreducible opposition. That is why we introduce a simple reducibility measure based on  $n$ -gram corpus statistics. We employ this reducibility measure as the main feature in our unsupervised parsing procedure.

The procedure is based on a commonly used Bayesian inference technique called Gibbs sampling (Gilks et al., 1996). In our sampler, the more reducible a given token is, the more likely it is to be sampled as a dependant and not as a head. After certain number of sampling iterations, for each sentence a final dependency tree is created (one token per node, including punctuation) that maximizes the product of edge probabilities gathered along the sampling history.

Our approach allows to utilize information from

very large corpora. While the computationally demanding sampling procedure can be applied only on limited data, the unrepeated precomputation of statistics for reducibility estimates can easily exploit much larger data.

We are not aware of any other published work on unsupervised parsing employing reducibility or a similar idea. Dominating approaches in unsupervised parsing are typically based on repeated patterns, and not on the possibility of a deletion inside a pattern. It seems that the two views of dependency (frequent co-occurrence of head-dependant pair, versus reducibility of the dependant) are rather complementary, so fruitful combinations can be hopefully expected in future.

The remainder of this paper is structured as follows. Section 2 briefly outlines the state of the art in unsupervised dependency parsing. Our measure of reducibility based on a large monolingual corpus is presented in Section 3. Section 4 shows our models which serve for generating probability estimates for edge sampling described in Section 5. Experimental parsing results for languages included in CoNLL shared task treebanks are summarized in Section 6. Section 7 concludes this article.

## 2 Related Work

The most popular approach in unsupervised dependency parsing of the recent years is to employ Dependency Model with Valence (DMV), which was introduced by Klein and Manning (2004). The inference algorithm was further improved by Smith (2007) and Cohen et al. (2008). Headden, Johnson and McClosky (2009) introduced the Extended Valence Grammar (EVG) and added lexicalization and smoothing. Blunsom and Cohn (2010) use tree substitution grammars, which allow learning larger dependency fragments.

Unfortunately, many of these works show results only for English.<sup>1</sup> However, the main feature of unsupervised methods should be their applicability across a wide range of languages. Such experiments were done by Spitkovsky (2011b; 2011c), where the parsing algorithm was evaluated on all 19 languages included in CoNLL 2006 (Buchholz and

Marsi, 2006) and 2007 (Nivre et al., 2007) shared tasks.

The fully unsupervised linguistic analysis (Spitkovsky et al., 2011a) shows that the unsupervised part-of-speech tags may be more useful for this task than the supervised ones.

Another possibility for obtaining dependency structures for languages without any linguistically annotated resources can be the projection using a parallel treebank with a resource-rich language (typically English). McDonald et al. (2011) showed that such projection produce better structures than the current unsupervised parsers do. However, our task is different. We would like to produce structures that are not burdened by any linguistic conventions.

In this paper, we describe a novel approach to unsupervised dependency parsing. Our model differs from DMV, since we employ the *reducibility* feature and use *fertility* of nodes instead of generating *STOP* signs.

We use Gibbs sampling procedure for inference instead of Variational Bayes, which has been more common for induction of linguistic structures. Gibbs sampling algorithm for grammar induction was used also by Mareček and Žabokrtský (2011). However, their sampling algorithm produces generally non-projective trees. Our sampler, which is described in Section 5, introduces a completely different small-change operator that guarantees projective edges.

## 3 Computing Reducibility scores

We call a word (or a sequence of words) in a sentence *reducible*, if the sentence after removing the word remains grammatically correct. Although we cannot automatically recognize grammaticality of such newly created sentence, we can search for it in a large corpus. If we find it, we assume the word was reducible in the original sentence.

Since the number of such reducible word sequences found in any corpus will be low, we determine the reducibility scores from their individual types (part-of-speech tags). This then implicitly allows some sharing of the scores between different word sequences.

The necessity to search for the whole sentences in the corpus and not only for some smaller context (considering, for example, just left and right neigh-

<sup>1</sup>The state-of-the-art unsupervised parsers achieve more than 50% of attachment score measured on the Penn Treebank.

bor), which would lead to lower sparsity, is rationalized by the following example:

*Their children went to school.*  
*I took their children to school.*

The verb ‘*went*’ would be reducible in the context ‘*their children went to school*’, because the sequence ‘*their children to school*’ occurs in the second sentence. One could find such examples frequently even for large contexts. For instance, verbs in free word-order languages can be placed almost at any position in a sentence; therefore, without the full sentence context, they would have to be considered as reducible. To prevent this, we decided to work exclusively with the full sentence context instead of shorter contexts.

Other way that would lead to lower sparsity would be searching for sequences of part-of-speech tags instead of sequences of word forms. However, this also does not bring desired results. For instance, the two following sentence patterns

DT NNS VBD IN DT NN .  
 DT NNS VBD DT NN .

are quite frequent in English and we can deduce from them that the preposition *IN* is reducible. But this is of course a wrong deduction, since the preposition cannot be removed from the prepositional phrase. Using part-of-speech tags instead of word forms is thus not suitable for computing reducibility scores.

Although we search for reducible sequences of word forms in the corpus, we compute reducibility scores for sequences of part-of-speech tags. This requires to have the corpus morphologically disambiguated. A sequences of part-of-speech tags will be denoted as “PoS n-gram” in the following text.

Assume a PoS n-gram  $g = [t_1, \dots, t_n]$ . We go through the corpus and search for all its occurrences. For each such occurrence, we remove the respective words from the current sentence and check in the corpus whether the rest of the sentence occurs at least once elsewhere in the corpus.<sup>2</sup> If so, then such occurrence of PoS n-gram is reducible, otherwise it is not. We denote the number of such reducible oc-

<sup>2</sup>We do not take into account sentences with less than 10 words, because they could be nominal (without any verb) and might influence the reducibility scores of verbs.

currences of PoS n-gram  $g$  by  $r(g)$ . The number of all its occurrences is  $c(g)$ .

The relative reducibility  $R(g)$  of a PoS n-gram  $g$  is then computed as

$$R(g) = \frac{1}{N} \frac{r(g) + \sigma_1}{c(g) + \sigma_2}, \quad (1)$$

where the normalization constant  $N$ , which expresses relative reducibility over all the PoS n-grams (denoted by  $G$ ), causes the scores are concentrated around the value 1.

$$N = \frac{\sum_{g \in G} (r(g) + \sigma_1)}{\sum_{g \in G} (c(g) + \sigma_2)} \quad (2)$$

Smoothing constants  $\sigma_1$  and  $\sigma_2$ , which prevent reducibility scores from being equal to zero, are set to

$$\sigma_1 = \frac{\sum_{g \in G} r(g)}{\sum_{g \in G} c(g)}, \quad \sigma_2 = 1 \quad (3)$$

This setting causes that even if a given PoS n-gram is not reducible anywhere in the corpus, its reducibility score is  $1/(c(g) + 1)$ .

Tables 1, 2, and 3 show reducibility scores of the most frequent PoS n-grams of three selected languages: English, German, and Czech. If we consider only unigrams, we can see that the scores for verbs are often among the lowest. Verbs are followed by prepositions and nouns, and the scores for adjectives

and adverbs are very high for all three examined languages. That is desired, because the reducible unigrams will more likely become leaves in dependency trees. Considering bigrams, the couples [*determiner – noun*], [*adjective – noun*], and [*preposition – noun*] obtained reasonably high scores. However, there are also n-grams such as the German trigram [*determiner – noun – preposition*] (ART-NN-APPR) whose reducibility score is undesirably high.<sup>3</sup>

## 4 Models

We introduce a new generative model that is different from the widely used Dependency Model with Valence (DMV). In DMV (Klein and Manning, 2004) and in the extended model EVG (Headden III et al., 2009), there is a *STOP* sign indicating that no more dependents in a given direction will be generated. Given a certain head, all its dependents in left direction are generated first, then the *STOP* sign in that direction, then all its right dependents and then *STOP* in the other direction. This process continues recursively for all generated dependents.

Our model introduces *fertility* of a node, which substitutes the *STOP* sign. For a given head, we first generate the number of its left and right children

<sup>3</sup>The high reducibility score of ART-NN-APPR was probably caused by German particles, which have the same PoS tag as prepositions.

(*fertility model*) and then we fill these positions by generating its individual dependents (*edge model*). If a zero fertility is generated in both the directions, the head becomes a leaf.

Besides the fertility model and the edge model, we use two more models (*subtree model* and *distance model*), which force the generated trees to have more desired shape.<sup>4</sup>

### 4.1 Fertility Model

We express a fertility of a node by a pair of numbers: the number of its left dependents and the number of its right dependents. For example, fertility “1-3” means that the node has one left and three right dependents, fertility “0-0” indicates that it is a leaf. Fertility is conditioned by part-of-speech tag of the node and it is computed following the Chinese restaurant process. This means that if a specific fertility has been frequent for a given PoS tag in the past, it is more likely to be generated again. The formula for computing probability of fertility  $f_i$  of a word on the position  $i$  in the corpus is as follows:

$$P_f(f_i|t_i) = \frac{c^{-i}(\text{“}t_i, f_i\text{”}) + \alpha P_0(f_i)}{c^{-i}(\text{“}t_i\text{”}) + \alpha}, \quad (4)$$

<sup>4</sup>In fact, the *subtree model* and the *distance model* disrupt a bit the generative story, because the probabilities do not sum up to one when they are used. However, they proved to help with inducing better linguistic structures.

where  $t_i$  is part-of-speech tag of the word on the position  $i$ ,  $c^{-i}(\text{"}t_i, f_i\text{"})$  stands for the count of words with PoS tag  $t_i$  and fertility  $f_i$  in the history, and  $P_0$  is a prior probability for the given fertility which depends on the total number of node dependents denoted by  $|f_i|$  (the sum of numbers of left and right dependents):

$$P_0(f_i) = \frac{1}{2^{|f_i|+1}} \quad (5)$$

This prior probability has a nice property: for a given number of nodes, the product of fertility probabilities over all the nodes is equal for all possible dependency trees. This ensures the stability of this model during the inference.

Besides the basic fertility model, we introduce also an extended fertility model, which uses frequency of a given word form for generating number of children. We assume that the most frequent words are mostly function words (e.g. determiners, prepositions, auxiliary verbs, conjunctions). Such words tend to have a stable number of children, for example (i) some function words are exclusively leaves, (ii) prepositions have just one child, and (iii) attachment of auxiliary verbs depends on the annotation style, but number of their children is also not very variable. The higher the frequency of a word form, the higher probability mass is concentrated on one specific number of children and the lower Dirichlet hyperparameter  $\alpha$  in Equation 4 is needed. The extended fertility is described by equation

$$P'_f(f_i|t_i, w_i) = \frac{c^{-i}(\text{"}t_i, f_i\text{"}) + \frac{\alpha_e}{F(w_i)} P_0(f_i)}{c^{-i}(\text{"}t_i\text{"}) + \frac{\alpha_e}{F(w_i)}}, \quad (6)$$

where  $F(w_i)$  is a frequency of the word  $w_i$ , which is computed as a number of words  $w_i$  in our corpus divided by number of all words.

## 4.2 Edge Model

After the fertility (number of left and right dependents) is generated, the individual slots are filled using the *edge model*. A part-of-speech tag of each dependent is conditioned by part-of-speech tag of the head and the edge direction (position of the dependent related to the head).<sup>5</sup>

<sup>5</sup>For the edge model purposes, the PoS tag of the technical root is set to '<root>' and it is in the zero-th position in the

Similarly as for the fertility model, we employ Chinese restaurant process to assign probabilities of individual dependent.

$$P_e(t_j|t_i, d_j) = \frac{c^{-i}(\text{"}t_i, t_j, d_j\text{"}) + \beta}{c^{-i}(\text{"}t_i, d_j\text{"}) + \beta|T|}, \quad (7)$$

where  $t_i$  and  $t_j$  are the part-of-speech tags of the head and the generated dependent respectively;  $d_j$  is a direction of edge between the words  $i$  and  $j$ , which can have two values: *left* and *right*.  $c^{-i}(\text{"}t_i, t_j, d_j\text{"})$  stands for the count of edges  $t_i \leftarrow t_j$  with the direction  $d_j$  in the history,  $|T|$  is a number of unique tags in the corpus and  $\beta$  is a Dirichlet hyperparameter.

## 4.3 Distance Model

*Distance model* is an auxiliary model that prevents the resulting trees from being too flat. Ideally, it would not be needed, but experiments showed that it helps to infer better trees. This simple model says that shorter edges are more probable than longer ones. We define probability of a distance between a word and its parent as its inverse value,<sup>6</sup> which is then normalized by the normalization constant  $\epsilon_d$ .

$$P_d(i, j) = \frac{1}{\epsilon_d} \left( \frac{1}{|i - j|} \right)^\gamma \quad (8)$$

The hyperparameter  $\gamma$  determines the weight of this model.

## 4.4 Subtree Model

The subtree model uses the reducibility measure. It plays an important role since it forces the reducible words to be leaves and reducible n-grams to be subtrees. Words with low reducibility are forced towards the root of the tree. We define  $desc(i)$  as a sequence of tags  $[t_l, \dots, t_r]$  that corresponds to all the descendants of the word  $w_i$  including  $w_i$ , i.e. the whole subtree of  $w_i$ . The probability of such subtree is proportional to its reducibility  $R(desc(i))$ . The hyperparameter  $\delta$  determines the weight of the model;  $\epsilon_s$  is a normalization constant.

$$P_s(i) = \frac{1}{\epsilon_s} R(desc(i))^\delta \quad (9)$$

sentence, so the head word of the sentence is always its right dependent.

<sup>6</sup>Distance between any word and the technical root of the dependency tree was set to 10. Since each technical root has only one dependent, this value does not affect the model.

## 4.5 Probability of the Whole Treebank

We want to maximize the probability of the whole generated treebank, which is computed as follows:

$$P_{treebank} = \prod_{i=1}^n (P'_f(f_i|t_i, w_i)) \quad (10)$$

$$P_e(t_i|t_{\pi(i)}, d_i) \quad (11)$$

$$P_d(i, \pi(i)) \quad (12)$$

$$P_s(i), \quad (13)$$

where  $\pi(i)$  denotes the parent of the word on the position  $i$ . We multiply the probabilities of fertility, edge, distance from parent, and subtree over all words (nodes) in the corpus. The extended fertility model  $P'_f$  can be substituted by its basic variant  $P_f$ .

## 5 Sampling Algorithm

For stochastic searching for the most probable dependency trees, we employ Gibbs sampling, a standard Markov Chain Monte Carlo technique (Gilks et al., 1996). In each iteration, we loop over all words in the corpus in a random order and change the dependencies in their neighborhood (a small change described in Section 5.2). In the end, “average” trees based on the whole sampling are built.

### 5.1 Initialization

Before the sampling starts, we initialize the projective trees randomly. For doing so, we tried the following two initializers:

- For each sentence, we choose randomly one word as the head and attach all other words to it.
- We are picking one word after another in a random order and we attach it to the nearest left (or right) neighbor that has not been attached yet. The left-right choice is made by a coin flip. If it is not possible to attach a word to one side, we attach it to the other side. The last unattached word becomes the head of the sentence.

While the first method generates only flat trees, the second one can generate all possible projective trees. However, the sampler converges to similar results for both the initializations. Therefore we conclude that the choice of the initialization mechanism

Figure 1: Arrow and bracketing notation of a projective dependency tree.

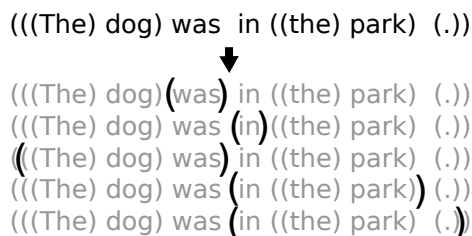

Figure 2: An example of small change in a projective tree. The bracket (in the park) is removed and there are five possibilities how to replace it.

is not so important here and we choose the first one due to its simplicity.

### 5.2 Small Change Operator

We use the bracketing notation for illustrating the small change operator. Each projective dependency tree consisting of  $n$  words can be expressed by  $n$  pairs of brackets. Each bracket pair belongs to one node and delimits its descendants from the rest of the sentence. Furthermore, each bracketed segment contains just one word that is not embedded deeper; this node is the segment head. An example of this notation is in Figure 1.

The small change is then very simple. We remove one pair of brackets and add another, so that the conditions defined above are not violated. An example of such change is in Figure 2.

From the perspective of dependency structures, the small change can be described as follows:

1. Pick a random non-root word  $w$  (the word *in* in our example) and find its parent  $p$  (the word *was*).
2. Find all other children of  $w$  and  $p$  (the words *dog*, *park*, and *.*) and denote this set by  $C$ .
3. Choose the new head out of  $w$  and  $p$ . Mark the new head as  $g$  and the second candidate as  $d$ . Attach  $d$  to  $g$ .

4. Select a neighborhood  $D$  adjacent to the word  $d$  as a continuous subset of  $C$  and attach all words from  $D$  to  $d$ .  $D$  may be also empty.
5. Attach the remaining words from  $C$  that were not in  $D$  to the new head  $g$ .

### 5.3 Building “Average” Trees

The “burn-in” period is set to 10 iterations. After this period, we begin to count how many times an edge occurs at a particular location in the corpus. These counts are collected over the whole corpus with the collection-rate 0.01.<sup>7</sup>

When the sampling is finished, we build final dependency trees based on the edge counts obtained during the sampling. We employ the maximum spanning tree (MST) algorithm (Chu and Liu, 1965) to find them; the weights of edges for computing MST correspond to the number of times they were present during the sampling. This averaging method was used also by Mareček and Žabokrtský (2011).

Other possibilities for obtaining final dependency trees would be using Eisner’s projective algorithm (Eisner, 1996) or using annealing method (favoring more likely changes) at the end of the sampling. However, the general non-projective MST algorithm enable non-projective edges, which are by no means negligible in treebanks (Havelka, 2007).

## 6 Experiments and Evaluation

We evaluate our parser on 20 treebanks (18 languages) included in CoNLL shared tasks 2006 (Buchholz and Marsi, 2006) and 2007 (Nivre et al., 2007).

Similarly to some previous papers on unsupervised parsing (Gillenwater et al., 2011; Spitkovsky et al., 2011b), the tuning experiments were performed on English only. We used English for checking functionality of the individual models and for optimizing hyperparameter values. The best configuration of the parser achieved on English development data was then used for parsing all other languages. This simulates the situation in which we have only one treebank (English) on which we can tune our parser and we want to parse other languages for which we have no manually annotated treebanks.

<sup>7</sup>After each small change is made, the edges from the whole corpus are collected with a probability 0.01.

Table 4: Wikipedia texts statistics

### 6.1 Data

We need two kinds of data for our experiments: a smaller treebank, which is used for sampling and for evaluation, and a large corpus, from which we compute n-gram reducibility scores.

The treebanks are taken from the CoNLL shared task 2006 and 2007. The experiments are performed for all languages except for Chinese.<sup>8</sup> We use only the testing parts of the treebanks (the files `test.conll`) for the dependency tree induction. As a source of the part-of-speech tags, we use the fine-grained gold PoS tags, which are in the fifth column in the CoNLL format.

For obtaining reducibility scores, we used the W2C corpus<sup>9</sup> of Wikipedia articles, which was downloaded by Majliš and Žabokrtský (2012). Their statistics across languages are shown in Table 4. To make them useful, the necessary preprocessing steps must have been done. The texts were first automatically segmented and tokenized<sup>10</sup> and then they were part-of-speech tagged by TnT tagger (Brants, 2000), which was trained on the respective CoNLL training data (the files `train.conll`). The quality of such tagging is not very high, since we do not use any lexicons<sup>11</sup> or pretrained models. However, it is sufficient for obtaining good reducibility scores.

<sup>8</sup>We do not have appropriate Chinese segmenter that would segment Chinese texts in the same way as in CoNLL.

<sup>9</sup><http://ufal.mff.cuni.cz/~majlis/w2c/>

<sup>10</sup>The segmentation to sentences and tokenization was performed using the TectoMT framework (Popel and Žabokrtský, 2010).

<sup>11</sup>Using lexicons or another pretrained models for tagging means using other sources of human annotated data, which is not allowed if we want to compare our results with others.

## 6.2 Setting the Hyperparameters

The applicability of individual models and their parameters were tested on development data set of English (the file `en/dtest.conll` in CoNLL shared task 2007).

After several experiments, we have observed that the extended fertility model provides better results than the basic fertility model; the parser using the basic fertility model achieved 44.1% attachment score for English, whereas the extended fertility model increased the score to 46.8%. The four hyperparameters  $\alpha_e$  (extended fertility model),  $\beta$  (edge model),  $\gamma$  (distance model), and  $\delta$  (subtree model), were set by a grid search algorithm,<sup>12</sup> which found the following optimal values:

$$\alpha_e = 0.01, \quad \beta = 1, \quad \gamma = 1.5, \quad \delta = 1$$

In informal experiments, parameters were tuned also for other treebanks and we found out that they vary across languages. Therefore, adjusting the hyperparameters on another language would probably change the scores significantly.

## 6.3 Evaluation

The best setting from the experiments on English is now used for evaluating our parser on all CoNLL languages. To be able to compare our parser attachment score to previously published results, the following steps must be done:

- We take the testing part of each treebank (the file `test.conll`) and remove all the punctuation marks. If the punctuation node is not a leaf, its children are attached to the parent of the removed node.
- Some previous papers report results on up-to-10-words sentences only. Therefore we extract such sentences from the test data and evaluate on this subsets as well.

<sup>12</sup>Here we make use of manually annotated trees. However, we use only English treebank as we are setting only four numbers out of several previously given values (e.g.  $\alpha_e$  out of 0.01, 0.1, 1, 10). These numbers could be tuned also by inspecting the outputs. So we believe this method can be treated as unsupervised.

CoNLL		$\leq 10$ tokens		all sentences	
language	year	gil11	our	spi11	our
Arabic	06	–	40.5	16.6	<b>26.5</b>

Turkish	07	–	13.0	<b>35.9</b>	15.7
<i>Average:</i>		50.3*	<b>54.7*</b>	37.4	<b>40.0</b>

Table 5: Comparison of directed attachment scores with previously reported results on CoNLL treebanks. The column “gil11” contains results reported by Gillenwater et al (2011) (see the best configuration in Table 7 in their paper). They provided only results on sentences of up to 10 tokens from CoNLL 2006 treebanks. Results in the column “spi11” are taken from Spitkovsky et al (2011b), best configuration in Table 6 in their paper. The average score in the last line is computed across all comparable results, i.e. for comparison with “gil11” only the CoNLL’06 results are averaged (\*). Our parser was not evaluated on Turkish CoNLL’06 data and Chinese data, because we have not them available.

The resulting scores are given in Table 5. We compare our results with results previously reported by Gillenwater (2011) and Spitkovsky (2011b), who used the CoNLL data for evaluation too. Since they provide results for several configurations of their parsers, we choose only the best one from each the paper. We define the best configuration as the one

with the highest average attachment score across all the tested languages.

We can see that our parser outperforms the previously published ones. In one case, it is better for 8 out of 10 data sets, in the other case, it is better for 14 out of 20 data sets. The average attachment scores, which are computed only from the results present for both compared parsers, also confirm the improvement.

However, it is important to note that we used an additional source of information, namely large unannotated corpora for computing reducibility scores, while the others used only the CoNLL data.

## 6.4 Error Analysis

Our main motivation for developing an unsupervised dependency parser was that we wanted to be able to parse any language. However, the experiments show that our parser fails for some languages. In this section, we try to analyze and explain some of the most substantial types of errors.

**Auxiliary verbs in Slovenian** – In the Slovenian treebank, many verbs are composed of two words: main verb (marked as `Verb-main`) and auxiliary verb (`Verb-copula`). Our parser choose the auxiliary verb as the head and the main verb and all its dependants become its children. That is why the attachment score is so poor (only 18.1%). In fact, the induced structure is not so bad. The main verb is switched with the auxiliary one which causes also the wrong attachment of all its dependants.

**Articles in German** – Attachment of about one half of German articles is wrong. Instead of the article being attached below the appropriate noun, the noun is attached below the article. It is a similar problem as the aforementioned Slovenian auxiliary verbs. The dependency between content and function word is switched and the dependants of the content word are attached to the function word. Klein and Manning (2004) observed a similar behavior in their experiments with DMV.

**Noun phrases in English** – The structure of phrases that consist of more nouns are often induced badly. This is caused probably by ignoring word forms. For example, the structure of the sequence ‘`NN NN NN`’ can be hardly recognized by our parser.

fert.	edge	dist.	subtr.	en	de	cs	
				19.8	18.4	26.7	
		<i>(random baseline)</i>			8.71	13.7	14.9
✓				18.9	20.2	26.5	
	✓			23.6	19.5	25.3	
		✓		28.2	23.7	33.5	
			✓	21.2	22.9	23.5

✓	✓		✓	14.1	18.1	34.6	
✓		✓	✓	36.1	32.2	38.9	
	✓	✓	✓	34.8	26.7	42.4	
✓	✓	✓	✓	<b>46.8</b>	<b>36.5</b>	<b>47.2</b>	

Table 6: Ablation analysis. Unlabeled attachment scores for different combinations of model components (fertility model, edge model, distance model and subtree model). The scores are computed on all sentences of the development data. Punctuation is included into the evaluation.

## 6.5 Ablation Analysis

To investigate the impact of individual components of the model, we run the parser for all possible component combinations. We choose three languages along the scale of word order freedom: English (very rigid word order), Czech (relatively free word order), and German (somewhere in the middle). The attachment scores are shown in Table 6. If no model is used for the inference and the sampling algorithm samples completely random trees, we get the *random baseline* score, which is 19.8% for English<sup>13</sup>. From the perspective of the *subtree model*, which implements the reducibility feature, we can see that it is the most useful model here. Alone, it improves the score for English to 28.2%. If we do not use it, the score decreases from 46.8% (when all models are used) to 30.7%. Very important is also the distance model which eliminates the possibility of attaching all words to one head word. If we omit

<sup>13</sup>This relatively high baseline scores are caused by the MST algorithm, which chooses the most frequent edges from random trees i.e. the shortest ones.

it, the score for English falls drastically to 14.1%. Some combinations of models have their scores far below the baseline. This is caused by the fact that some regularities have been found but the structures are induced differently and thus all attachments are wrong.

## 6.6 Induction without Wikipedia Corpus

We have performed also experiments using exclusively the CoNLL data. However, the numbers of reducible words in CoNLL training set were very low (50 words at maximum in CoNLL 2006 training data and 10 words at maximum in CoNLL 2007 training data). This led to completely unreliable reducibility scores and the consequent poor results.

## 7 Conclusions and Future Work

We have shown that employing the reducibility feature is useful in unsupervised dependency parsing task. We extracted the n-gram reducibility scores from a large corpus, and then made the computationally demanding inference on smaller data using only these scores. We evaluated our parser on 18 languages included in CoNLL and for 14 of them, we achieved higher attachment scores than previously published results.

The most errors were caused by function words, which sometimes take over the dependents of adjacent content words. This can be caused by the fact that the reducibility cannot handle function words correctly, because they must be reduced together with a content word, not one after another.

In future work, we would like to estimate the hyperparameters automatically. Furthermore, we would like to get rid of manually designed PoS tags and use some kind of unsupervised clusters in order to have all the annotation process completely unsupervised. We would also like to employ lexicalized models that should help in situations in which the PoS tags are too coarse.

Finally, we would like to move towards deeper syntactic structures, where the tree would be formed only by content words and the function words would be treated in a different way.

## Software

The source code of our unsupervised dependency parser including the script for computing reducibility scores from large corpora is available at <http://ufal.mff.cuni.cz/~marecek/udp>.

## Abstract

In this paper, we show that significant improvements in the accuracy of well-known transition-based parsers can be obtained, without sacrificing efficiency, by enriching the parsers with simple transitions that act on buffer nodes.

First, we show how adding a specific transition to create either a left or right arc of length one between the first two buffer nodes produces improvements in the accuracy of Nivre’s arc-eager projective parser on a number of datasets from the CoNLL-X shared task. Then, we show that accuracy can also be improved by adding transitions involving the topmost stack node and the second buffer node (allowing a limited form of non-projectivity).

None of these transitions has a negative impact on the computational complexity of the algorithm. Although the experiments in this paper use the arc-eager parser, the approach is generic enough to be applicable to any stack-based dependency parser.

## 1 Introduction

Dependency parsing has become a very active research area in natural language processing in recent years. The dependency representation of syntax simplifies the syntactic parsing task, since no non-lexical nodes need to be postulated by the parsers; while being convenient in practice, since dependency representations directly show the head-modifier and head-complement relationships which form the basis of predicate-argument structure. This

has led to the development of various data-driven dependency parsers, such as those by Yamada and Matsumoto (2003), Nivre et al. (2004), McDonald et al. (2005), Martins et al. (2009), Huang and Sagae (2010) or Tratz and Hovy (2011), which can be trained directly from annotated data and produce accurate analyses very efficiently.

Most current data-driven dependency parsers can be classified into two families, commonly called **graph-based** and **transition-based** parsers (McDonald and Nivre, 2011). Graph-based parsers (Eisner, 1996; McDonald et al., 2005) are based on global optimization of models that work by scoring subtrees. On the other hand, transition-based parsers (Yamada and Matsumoto, 2003; Nivre et al., 2004), which are the focus of this work, use local training to make greedy decisions that deterministically select the next parser state. Among the advantages of transition-based parsers are the linear time complexity of many of them and the possibility of using rich feature models (Zhang and Nivre, 2011).

In particular, many transition-based parsers (Nivre et al., 2004; Attardi, 2006; Sagae and Tsujii, 2008; Nivre, 2009; Huang and Sagae, 2010; Gómez-Rodríguez and Nivre, 2010) are **stack-based** (Nivre, 2008), meaning that they keep a stack of partially processed tokens and an input buffer of unread tokens. In this paper, we show how the accuracy of this kind of parsers can be improved, without compromising efficiency, by extending their set of available transitions with **buffer transitions**. These are transitions that create a dependency arc involving some node in the buffer, which would typically be considered unavailable for linking by these algo-

rithms. The rationale is that buffer transitions construct some “easy” dependency arcs in advance, before the involved nodes reach the stack, so that the classifier’s job when choosing among standard transitions is simplified.

To test the approach, we use the well-known arc-eager parser by (Nivre, 2003; Nivre et al., 2004) as a baseline, showing improvements in accuracy on most datasets of the CoNLL-X shared task (Buchholz and Marsi, 2006). However, the techniques discussed in this paper are generic and can also be applied to other stack-based dependency parsers.

The rest of this paper is structured as follows: Section 2 is an introduction to transition-based parsers and the arc-eager parsing algorithm. Section 3 presents the first novel contribution of this paper, **projective buffer transitions**, and discusses their empirical results on CoNLL-X datasets. Section 4 does the same for a more complex set of transitions, **non-projective buffer transitions**. Finally, Section 5 discusses related work and Section 6 sums up the conclusions and points out avenues for future work.

## 2 Preliminaries

We now briefly present some basic definitions for transition-based dependency parsing; a more thorough explanation can be found in (Nivre, 2008).

### 2.1 Dependency graphs

Let  $w = w_1 \dots w_n$  be an input string. A **dependency graph** for  $w$  is a directed graph  $G = (V_w, A)$ ; where  $V_w = \{0, 1, \dots, n\}$  is a set of nodes, and  $A \subseteq V_w \times L \times V_w$  is a set of labelled arcs. Each node in  $V_w$  encodes the position of a token in  $w$ , where 0 is a dummy node used as artificial root. An arc  $(i, l, j)$  will also be called a **dependency link** labelled  $l$  from  $i$  to  $j$ . We say that  $i$  is the syntactic **head** of  $j$  and, conversely, that  $j$  is a **dependent** of  $i$ . The **length** of the arc  $(i, l, j)$  is the value  $|j - i|$ .

Most dependency representations of syntax do not allow arbitrary dependency graphs. Instead, they require dependency graphs to be **forests**, i.e., acyclic graphs where each node has at most one head. In this paper, we will work with parsers that assume dependency graphs  $G = (V_w, A)$  to satisfy the following properties:

- Single-head: every node has at most one in-

coming arc (if  $(i, l, j) \in A$ , then for every  $k \neq i$ ,  $(k, l', j) \notin A$ ).

- Acyclicity: there are no directed cycles in  $G$ .
- Node 0 is a root, i.e., there are no arcs of the form  $(i, l, 0)$  in  $A$ .

A dependency forest with a single root (i.e., where all the nodes but one have at least one incoming arc) is called a **tree**. Every dependency forest can trivially be represented as a tree by adding arcs from the dummy root node 0 to every other root node.

For reasons of computational efficiency, many dependency parsers are restricted to work with forests satisfying an additional restriction called **projectivity**. A dependency forest is said to be **projective** if the set of nodes reachable by traversing zero or more arcs from any given node  $k$  corresponds to a continuous substring of the input (i.e., is an interval  $\{x \in V_w \mid i \leq x \leq j\}$ ). For trees with a dummy root node at position 0, this is equivalent to not allowing dependency links to cross when drawn above the nodes (planarity).

### 2.2 Transition systems

A **transition system** is a nondeterministic state machine that maps input strings to dependency graphs. In this paper, we will focus on **stack-based transition systems**. A stack-based transition system is a quadruple  $S = (C, T, c_s, C_t)$  where

- $C$  is a set of parser **configurations**. Each configuration is of the form  $c = (\sigma, \beta, A)$  where  $\sigma$  is a list of nodes of  $V_w$  called the **stack**,  $\beta$  is a list of nodes of  $V_w$  called the **buffer**, and  $A$  is a set of dependency arcs,
- $T$  is a finite set of **transitions**, each of which is a partial function  $t : C \rightarrow C$ ,
- $c_s$  is an initialization function, mapping a sentence  $w_1 \dots w_n$  to an **initial configuration**  $c_s = ([0], [1, \dots, n], \emptyset)$ ,
- $C_t$  is the set of **terminal configurations**  $C_t = (\sigma, [], A) \in C$ .

Transition systems are nondeterministic devices, since several transitions may be applicable to the same configuration. To obtain a deterministic parser

from a transition system, a classifier is trained to greedily select the best transition at each state. This training is typically done by using an **oracle**, which is a function  $o : C \rightarrow T$  that selects a single transition at each configuration, given a tree in the training set. The classifier is then trained to approximate this oracle when the target tree is unknown.

### 2.3 The arc-eager parser

Nivre’s arc-eager dependency parser (Nivre, 2003; Nivre et al., 2004) is one of the most widely known and used transition-based parsers (see for example (Zhang and Clark, 2008; Zhang and Nivre, 2011)). This parser works by reading the input sentence from left to right and creating dependency links as soon as possible. This means that links are created in a strict left-to-right order, and implies that while leftward links are built in a bottom-up fashion, a rightward link  $a \rightarrow b$  will be created before the node  $b$  has collected its right dependents.

The arc-eager transition system has the following four transitions (note that, for convenience, we write a stack with node  $i$  on top as  $\sigma|i$ , and a buffer whose first node is  $i$  as  $i|\beta$ ):

- **SHIFT** :  $(\sigma, i|\beta, A) \Rightarrow (\sigma|i, \beta, A)$ .
- **REDUCE** :  $(\sigma|i, \beta, A) \Rightarrow (\sigma, \beta, A)$ . Precondition:  $\exists k, l' \mid (k, l', i) \in A$ .
- **LEFT-ARC<sub>l</sub>** :  $(\sigma|i, j|\beta, A) \Rightarrow (\sigma, j|\beta, A \cup \{(j, l, i)\})$ . Preconditions:  $i \neq 0$  and  $\exists k, l' \mid (k, l', i) \in A$  (single-head)
- **RIGHT-ARC<sub>l</sub>** :  $(\sigma|i, j|\beta, A) \Rightarrow (\sigma|i|j, \beta, A \cup \{(i, l, j)\})$ .

The **SHIFT** transition reads an input word by removing the first node from the buffer and placing it on top of the stack. The **REDUCE** transition pops the stack, and it can only be executed if the topmost stack node has already been assigned a head. The **LEFT-ARC** transition creates an arc from the first node in the buffer to the node on top of the stack, and then pops the stack. It can only be executed if the node on top of the stack does not already have a head. Finally, the **RIGHT-ARC** transition creates an arc from the top of the stack to the first buffer node, and then removes the latter from the buffer and moves it to the stack.

The arc-eager parser has linear time complexity. In principle, it is restricted to projective dependency forests, but it can be used in conjunction with the pseudo-projective transformation (Nivre et al., 2006) in order to capture a restricted subset of non-projective forests. Using this setup, it scored as one of the top two systems in the CoNLL-X shared task.

## 3 Projective buffer transitions

In this section, we show that the accuracy of stack-based transition systems can benefit from adding one of a pair of new transitions, which we call **projective buffer transitions**, to their transition sets.

### 3.1 The transitions

The two projective buffer transitions are defined as follows:

- **LEFT-BUFFER-ARC<sub>l</sub>** :  $(\sigma, i|j|\beta, A) \Rightarrow (\sigma, j|\beta, A \cup \{(j, l, i)\})$ .
- **RIGHT-BUFFER-ARC<sub>l</sub>** :  $(\sigma, i|j|\beta, A) \Rightarrow (\sigma, i|\beta, A \cup \{(i, l, j)\})$ .

The **LEFT-BUFFER-ARC** transition creates a leftward dependency link from the second node to the first node in the buffer, and then removes the first node from the buffer. Conversely, the **RIGHT-BUFFER-ARC** transition creates a rightward dependency link from the first node to the second node in the buffer, and then removes the second node. We call these transitions projective buffer transitions because, since they act on contiguous buffer nodes, they can only create projective arcs.

Adding one (or both) of these transitions to a projective or non-projective stack-based transition system does not affect its correctness, as long as this starting system cannot generate configurations  $(\sigma, \beta, A)$  where a buffer node has a head in  $A^1$ : it cannot affect completeness because we are not removing existing transitions, and therefore any dependency graph that the original system could build

<sup>1</sup>Most stack-based transition systems in the literature disallow such configurations. However, in parsers that allow them (such as those defined by Gómez-Rodríguez and Nivre (2010)), projective buffer transitions can still be added without affecting correctness if we impose explicit single-head and acyclicity preconditions on them. We have not included these preconditions by default for simplicity of presentation.

will still be obtainable by the augmented one; and it cannot affect soundness (be it for projective dependency forests or for any superset of them) because the new transitions can only create projective arcs and cannot violate the single-head or acyclicity constraints, given that a buffer node cannot have a head.

The idea behind projective buffer transitions is to create dependency arcs of length one (i.e., arcs involving contiguous nodes) *in advance* of the standard arc-building transitions that need at least one of the nodes to get to the stack (LEFT-ARC and RIGHT-ARC in the case of the arc-eager transition system).

Our hypothesis is that, as it is known that short-distance dependencies are easier to learn for transition-based parsers than long-distance ones (McDonald and Nivre, 2007), handling these short arcs in advance and removing their dependent nodes will make it easier for the classifier to learn how to make decisions involving the standard arc transitions.

Note that the fact that projective buffer transitions create arcs of length 1 is not explicit in the definition of the transitions. For instance, if we add the LEFT-BUFFER-ARC<sub>l</sub> transition only to the arc-eager transition system, LEFT-BUFFER-ARC<sub>l</sub> will only be able to create arcs of length 1, since it is easy to see that the first two buffer nodes are contiguous in all the accessible configurations. However, if we add RIGHT-BUFFER-ARC<sub>l</sub>, this transition will have the potential to create arcs of length greater than 1: for example, if two consecutive RIGHT-BUFFER-ARC<sub>l</sub> transitions are applied starting from a configuration  $(\sigma, i|i + 1|i + 2|\beta, A)$ , the second application will create an arc  $i \rightarrow i + 2$  of length 2.

Although we could have added the length-1 restriction to the transition definitions, we have chosen the more generic approach of leaving it to the oracle instead. While the oracle typically used for the arc-eager system follows the simple principle of executing transitions that create an arc as soon as it has the chance to, adding projective buffer transitions opens up new possibilities: we may now have several ways of creating an arc, and we have to decide in which cases we train the parser to use one of the buffer transitions and in which cases we prefer to train it to ignore the buffer transitions and delegate to the standard ones. Following the hypothesis explained above, our policy has been to train the

parser to use buffer transitions whenever possible for arcs of length one, and to not use them for arcs of length larger than one. To test this idea, we also conducted experiments with the alternative policy “use buffer transitions whenever possible, regardless of arc length”: as expected, the obtained accuracies were (slightly) worse.

The chosen oracle policy is generic and can be plugged into any stack-based parser: for a given transition, first check whether it is possible to build a gold-standard arc of length 1 with a projective buffer transition.<sup>2</sup> If so, choose that transition, and if not, just delegate to the original parser’s oracle.

## 3.2 Experiments

To empirically evaluate the effect of projective buffer transitions on parsing accuracy, we have conducted experiments on eight datasets of the CoNLL-X shared task (Buchholz and Marsi, 2006): Arabic (Hajič et al., 2004), Chinese (Chen et al., 2003), Czech (Hajič et al., 2006), Danish (Kromann, 2003), German (Brants et al., 2002), Portuguese (Afonso et al., 2002), Swedish (Nilsson et al., 2005) and Turkish (Oflaizer et al., 2003; Atalay et al., 2003).

As our baseline parser, we use the arc-eager projective transition system by Nivre (2003). Table 1 compares the accuracy obtained by this system alone with that obtained when the LEFT-BUFFER-ARC and RIGHT-BUFFER-ARC transitions are added to it as explained in Section 3.1.

Accuracy is reported in terms of labelled (LAS) and unlabelled (UAS) attachment score. We used SVM classifiers from the LIBSVM package (Chang and Lin, 2001) for all languages except for Chinese, Czech and German. In these, we used the LIBLINEAR package (Fan et al., 2008) for classification, since it reduces training time in these larger datasets. Feature models for all parsers were specifically tuned for each language.<sup>3</sup>

<sup>2</sup>In this context, “possible” means that we can create the arc without losing the possibility of creating other gold-standard arcs. In the case of RIGHT-BUFFER-ARC, this involves checking that the candidate dependent node has no dependents in the gold-standard tree (if it has any, we cannot remove it from the stack or it would not be able to collect its dependents, so we do not use the buffer transition).

<sup>3</sup>All the experimental settings and feature models used are included in the supplementary material and also available at <http://www.grupolys.org/~cgomezr/exp/>.

Table 1: Parsing accuracy (LAS and UAS, excluding punctuation) of Nivre’s arc-eager parser without modification (NE), with the LEFT-BUFFER-ARC transition added (NE+LBA) and with the RIGHT-BUFFER-ARC transition added (NE+RBA). Best results for each language are shown in boldface.

As can be seen in Table 1, adding a projective buffer transition improves the performance of the parser in seven out of the eight tested languages. The improvements in LAS are statistically significant at the .01 level<sup>4</sup> in the Arabic and Czech treebanks.

Note that the decision of *which* buffer transition to add strongly depends on the dataset. In the majority of the treebanks, we can see that when the LEFT-BUFFER-ARC transition improves performance the RIGHT-BUFFER-ARC transition harms it, and vice versa. The exceptions are Czech, where both transitions are beneficial, and Swedish, where both are harmful. Therefore, when using projective buffer transitions in practice, the language and annotation scheme should be taken into account (or tests should be made) to decide which one to use.

Table 2 hints at the reason for this treebank-sensitiveness. By analyzing the relative frequency of leftward and rightward dependency links (and, in particular, of leftward and rightward links of length 1) in the different treebanks, we see a reasonably clear tendency: the LEFT-BUFFER-ARC transition works better in treebanks that contain a large proportion of *rightward* arcs of length 1, and the RIGHT-BUFFER-ARC transition works better in treebanks with a large proportion of *leftward* arcs of length 1. Note that, while this might seem counterintuitive at a first glance, it is coherent with the hypothesis that we formulated in Section 3.1: the

Language	L%	R%	L1%	R1%	Best PBT

Turkish	77.8	22.2	47.2	10.4	RBA

Table 2: Analysis of the datasets used in the experiments in terms of: percentage of leftward and rightward links (L%, R%), percentage of leftward and rightward links of length 1 (L1%, R1%), and which projective buffer transition works better for each dataset according to the results in Table 1 (LBA = LEFT-BUFFER-ARC, RBA = RIGHT-BUFFER-ARC). Languages where both transitions are beneficial (Czech) or harmful (Swedish) are marked with an asterisk.

advantage of projective buffer transitions is not that they build arcs more accurately than standard arc-building transitions (in fact the opposite might be expected, since they work on nodes while they are still on the buffer and we have less information about their surrounding nodes in our feature models), but that they make it easier for the classifier to decide among standard transitions. The analysis on Table 2 agrees with that explanation: LEFT-BUFFER-ARC improves performance in treebanks where it is not used too often but it can filter out leftward arcs of length 1, making it easier for the parser to be accurate on rightward arcs of length 1; and the converse happens for RIGHT-BUFFER-ARC.

<sup>4</sup>Statistical significance was assessed using Dan Bikel’s randomized parsing evaluation comparator: <http://www.cis.upenn.edu/~dbikel/software.html#comparator>

Table 3: Labelled precision of the arcs built by each transition of Nivre’s arc-eager parser without modification (NE), with a projective buffer transition added (NE+LBA, NE+RBA) and with both projective buffer transitions added (NE+LBA+RBA). We mark a standard LEFT-ARC (LA) or RIGHT-ARC (RA) transition with an asterisk (LA\*, RA\*) when it is acting only on a “hard” subset of leftward (rightward) arcs, and thus its precision is not directly comparable to that of (LA, RA). Best results for each language and transition are shown in boldface.

To further test this idea, we computed the labelled precision of each individual transition of the parsers with and without projective buffer transitions, as shown in Table 3. As we can see, projective buffer transitions achieve better precision than standard transitions, but this is not surprising since they act only on “easy” arcs of length 1. Therefore, this high precision does not mean that they actually build arcs more accurately than the standard transitions, since it is not measured on the same set of arcs. Similarly, adding a projective buffer transition decreases the precision of its corresponding standard transition, but this is because the standard transition is then dealing only with “harder” arcs of length greater than 1, not because it is making more errors. A more interesting insight comes from comparing transitions that are acting on the same target set of arcs: we see that, in the languages where LEFT-BUFFER-ARC is beneficial, the addition of this transition always improves the precision of the standard RIGHT-ARC transition; and the converse happens with RIGHT-BUFFER-ARC with respect to LEFT-ARC. This further backs the hypothesis that the filtering of “easy” links achieved by projective buffer transitions makes it easier for the classifier to decide among standard transitions.

We also conducted experiments adding both transitions at the same time (NE+LBA+RBA), but the results were worse than adding the suitable transition for each dataset. Table 3 hints at the reason: the precision of buffer transitions noticeably decreases when both of them are added at the same time, presumably because it is difficult for the classifier to

decide between both with the restricted feature information available for buffer nodes.

To further put the obtained results into context, Table 4 compares the performance of the arc-eager parser with the projective buffer transition most suitable for each dataset with the results obtained by the parser with the pseudo-projective transformation by Nivre et al. (2006) in the CoNLL-X shared task, one of the top two performing systems in that event. The reader should be aware that the purpose of this table is only to provide a broad idea of how our approach performs with respect to a well-known reference point, and not to make a detailed comparison, since the two parsers have not been tuned in homogeneous conditions: on the one hand, we had access to the CoNLL-X test sets which were unavailable

System	Arabic	Danish

for the participants in the shared task; on the other hand, we did not fine-tune the classifier parameters for each dataset like Nivre et al. (2006), but used default values for all languages.

As can be seen in the table, even though the pseudo-projective parser is able to capture non-projective syntactic phenomena, the algorithm with projective buffer transitions (which is strictly projective) outperforms it in four of the eight treebanks, including non-projective treebanks such as the German one.

Furthermore, to our knowledge, our LAS results for Arabic and Danish are currently the best published results for a single-parser system on these datasets, not only outperforming the systems participating in CoNLL-X but also other parsers tested on these treebanks in more recent years (see Table 5).

Finally, it is worth noting that adding projective buffer transitions has no negative impact on efficiency, either in terms of computational complexity or of empirical runtime. Since each projective buffer transition removes a node from the buffer, no more than  $n$  such transitions can be executed for a sentence of length  $n$ , so adding these transitions cannot increase the complexity of a transition-based parser. In the particular case of the arc-eager parser, using projective buffer transitions reduces the average number of transitions needed to obtain a given dependency forest, as some nodes can be dispatched by a single transition rather than being shifted and later popped from the stack. In practice, we observed that the training and parsing times of the arc-eager parser with projective buffer transitions were slightly faster than without them on the Arabic, Chinese, Swedish and Turkish treebanks, and slightly slower than without them on the other four treebanks, so adding these transitions does not seem to

noticeably degrade (or improve) practical efficiency.

## 4 Non-projective buffer transitions

We now present a second set of transitions that still follow the idea of early processing of some dependency arcs, as in Section 3; but which are able to create arcs skipping over a buffer node, so that they can create some non-projective arcs. For this reason, we call them **non-projective buffer transitions**.

### 4.1 The transitions

The two non-projective buffer transitions are defined as follows:

- **LEFT-NONPROJ-BUFFER-ARC<sub>l</sub>** :  
 $(\sigma|i, j|k|\beta, A) \Rightarrow (\sigma, j|k|\beta, A \cup \{(k, l, i)\})$ .  
 Preconditions:  $i \neq 0$  and  $\nexists m, l' \mid (m, l', i) \in A$  (single-head)
- **RIGHT-NONPROJ-BUFFER-ARC<sub>l</sub>** :  
 $(\sigma|i, j|k|\beta, A) \Rightarrow (\sigma|i, j|\beta, A \cup \{(i, l, k)\})$ .

The **LEFT-NONPROJ-BUFFER-ARC** transition creates a leftward arc from the second buffer node to the node on top of the stack, and then pops the stack. It can only be executed if the node on top of the stack does not already have a head. The **RIGHT-NONPROJ-BUFFER-ARC** transition creates an arc from the top of the stack to the second node in the buffer, and then removes the latter from the buffer. Note that these transitions are analogous to projective buffer transitions, and they use the second node in the buffer in the same way, but they create arcs involving the node on top of the stack rather than the first buffer node. This change makes the precondition that checks for a head necessary for the transition **LEFT-NONPROJ-BUFFER-ARC** to respect the single-head constraint, since many stack-based parsers can generate configurations where the node on top of the stack has a head.

We call these transitions non-projective buffer transitions because, as they act on non-contiguous nodes in the stack and buffer, they allow the creation of a limited set of non-projective dependency arcs. This means that, when added to a projective parser, they will increase its coverage.<sup>5</sup> On the other hand,

<sup>5</sup>They may also increase the coverage of parsers allowing restricted forms of non-projectivity, but that depends on the par-

Table 6: Parsing accuracy (LAS and UAS, excluding punctuation) of Nivre’s arc-eager parser without modification (NE), with the LEFT-NONPROJ-BUFFER-ARC transition added (NE+LNBA) and with the RIGHT-NONPROJ-BUFFER-ARC transition added (NE+RNBA). Best results for each language are shown in boldface.

adding these transitions to a stack-based transition system does not affect soundness under the same conditions and for the same reasons explained for projective buffer transitions in Section 3.1.

Note that the fact that non-projective buffer transitions are able to create non-projective dependency arcs does not mean that *all* the arcs that they build are non-projective, since an arc on non-contiguous nodes in the stack and buffer may or may not cross other arcs. This means that non-projective buffer transitions serve a dual purpose: not only they increase coverage, but they also can create some “easy” dependency links in advance of standard transitions, just like projective buffer transitions.

Contrary to projective buffer transitions, we do not impose any arc length restrictions on non-projective buffer transitions (either as a hard constraint in the transitions themselves or as a policy in the training oracle), since we would like the increase in coverage to be as large as possible. We wish to allow the parsers to create non-projective arcs in a straightforward way and without compromising efficiency. Therefore, to train the parser with these transitions, we use an oracle that employs them whenever possible, and delegates to the original parser’s oracle otherwise.

## 4.2 Experiments

We evaluate the impact of non-projective buffer transitions on parsing accuracy by using the same base-

---

ticular subset of non-projective structures captured by each such parser.

line parser, datasets and experimental settings as for projective buffer transitions in Section 3.2. As can be seen in Table 6, adding a non-projective buffer transition to the arc-eager parser improves its performance on all eight datasets. The improvements in LAS are statistically significant at the .01 level (Dan Bikel’s comparator) for Chinese, Czech and Turkish. Note that the Chinese treebank is fully projective, this means that non-projective buffer transitions are also beneficial when creating projective arcs.

While with projective buffer transitions we observed that each of them was beneficial for about half of the treebanks, and we related this to the amount of leftward and rightward links of length 1 in each; in the case of non-projective buffer transitions we do not observe this tendency. In this case, LEFT-NONPROJ-BUFFER-ARC works better than RIGHT-NONPROJ-BUFFER-ARC in all datasets except for Turkish and Arabic.

As with the projective transitions, we gathered data about the individual precision of each of the transitions. The results were similar to those for the projective transitions, and show that adding a non-projective buffer transition improves the precision of the standard transitions. We also experimentally checked that adding both non-projective buffer transitions at the same time (NE+LNBA+RNBA) achieved worse performance than adding only the most suitable transition for each dataset.

Table 7 compares the performance of the arc-eager parser with the best non-projective buffer transition for each dataset with the results obtained by

Table 8: Comparison of the precision and recall for projective (PP, PR) and non-projective (NP, NR) arcs, averaged over all datasets, obtained by Nivre’s arc-eager parser with and without non-projective buffer transitions (NE+LNBA/RNBA, NE) and the parser with the pseudo-projective transformation (Nivre et al., 2006).

the parser with the pseudo-projective transformation by Nivre et al. (2006) in the CoNLL-X shared task. Note that, like the one in Table 4, this should not be interpreted as a homogeneous comparison. We can see that the algorithm with non-projective buffer transitions obtains better LAS in five out of the eight treebanks. Precision and recall data on projective and non-projective arcs (Table 8) show that, while our parser does not capture as many non-projective arcs as the pseudo-projective transformation (unsurprisingly, as it can only build non-projective arcs in one direction: that of the particular non-projective buffer transition used for each dataset); it does so with greater precision and is more accurate than that algorithm in projective arcs.

Like projective buffer transitions, non-projective transitions do not increase the computational complexity of stack-based parsers. The observed training and parsing times for the arc-eager parser with non-projective buffer transitions showed a small

overhead with respect to the original arc-eager (7.1% average increase in training time, 17.0% in parsing time). For comparison, running the arc-eager parser with the pseudo-projective transformation (Nivre et al., 2006) on the same machine produced a 23.5% increase in training time and a 87.5% increase in parsing time.

## 5 Related work

The approach of adding an extra transition to a parser to improve its accuracy has been applied in the past by Choi and Palmer (2011). In that paper, the LEFT-ARC transition from Nivre’s arc-eager transition system is added to a list-based parser. However, the goal of that transition is different from ours (selecting between projective and non-projective parsing, rather than building some arcs in advance) and the approach is specific to one algorithm while ours is generic – for example, the LEFT-ARC transition cannot be added to the arc-standard and arc-eager parsers, or to extensions of those like the ones by Attardi (2006) or Nivre (2009), because these already have it.

The idea of creating dependency arcs of length 1 in advance to help the classifier has been used by Cheng et al. (2006). However, their system creates such arcs in a separate preprocessing step rather than dynamically by adding a transition to the parser, and our approach obtains better LAS and UAS results on all the tested datasets.

The projective buffer transitions presented here bear some resemblance to the easy-first parser by Goldberg and Elhadad (2010), which allows creation of dependency arcs between any pair of contiguous nodes and is based on the idea of “easy” dependency links being created first. However, while the easy-first parser is an entirely new  $O(n \log(n))$  algorithm, our approach is a generic extension for stack-based parsers that does not increase their complexity (so, for example, applying it to the arc-eager system as in the experiments in this paper yields  $O(n)$  complexity).

Non-projective transitions that create dependency arcs between non-contiguous nodes have been used in the transition-based parser by Attardi (2006). However, the transitions in that parser do not use the second buffer node, since they are not intended

to create some arcs in advance. The non-projective buffer transitions presented in this paper can also be added to Attardi's parser.

## 6 Discussion

We have presented a set of two transitions, called *projective buffer transitions*, and showed that adding one of them to Nivre's arc-eager parser improves its accuracy in seven out of eight tested datasets from the CoNLL-X shared task. Furthermore, adding one of a set of *non-projective buffer transitions* achieves accuracy improvements in all of the eight datasets. The obtained improvements are statistically significant for several of the treebanks, and the parser with projective buffer transitions surpassed the best published single-parser LAS results on two of them. This comes at no cost either on computational complexity or (in the case of projective transitions) on empirical training and parsing times with respect to the original parser.

While we have chosen Nivre's well-known arc-eager parser as our baseline, we have shown that these transitions can be added to any stack-based dependency parser, and we are not aware of any specific property of arc-eager that would make them work better in practice on this parser than on others. Therefore, future work will include an evaluation of the impact of buffer transitions on more transition-based parsers. Other research directions involve investigating the set of non-projective arcs allowed by non-projective buffer transitions, defining different variants of buffer transitions (such as non-projective buffer transitions that work with nodes located deeper in the buffer) or using projective and non-projective buffer transitions at the same time.

# Generalized Higher-Order Dependency Parsing with Cube Pruning

Hao Zhang Ryan McDonald

Google, Inc.

{haozhang,ryanmcd}@google.com

## Abstract

State-of-the-art graph-based parsers use features over higher-order dependencies that rely on decoding algorithms that are slow and difficult to generalize. On the other hand, transition-based dependency parsers can easily utilize such features without increasing the linear complexity of the shift-reduce system beyond a constant. In this paper, we attempt to address this imbalance for graph-based parsing by generalizing the Eisner (1996) algorithm to handle arbitrary features over higher-order dependencies. The generalization is at the cost of asymptotic efficiency. To account for this, cube pruning for decoding is utilized (Chiang, 2007). For the first time, label tuple and structural features such as valencies can be scored efficiently with third-order features in a graph-based parser. Our parser achieves the state-of-art unlabeled accuracy of 93.06% and labeled accuracy of 91.86% on the standard test set for English, at a faster speed than a reimplementation of the third-order model of Koo et al. (2010).

## 1 Introduction

The trade-off between rich features and exact decoding in dependency parsing has been well documented (McDonald and Nivre, 2007; Nivre and McDonald, 2008). Graph-based parsers typically trade-off rich feature scope for exact (or near exact) decoding, whereas transition-based parsers make the opposite trade-off. Recent research on both parsing paradigms has attempted to address this.

In the transition-based parsing literature, the focus has been on increasing the search space of the

system at decoding time, as expanding the feature scope is often trivial and in most cases only leads to a constant-time increase in parser complexity. The most common approach is to use beam search (Duan et al., 2007; Johansson and Nugues, 2007; Titov and Henderson, 2007; Zhang and Clark, 2008; Zhang and Nivre, 2011), but more principled dynamic programming solutions have been proposed (Huang and Sagae, 2010). In all cases inference remains approximate, though a larger search space is explored.

In the graph-based parsing literature, the main thrust of research has been on extending the Eisner chart-parsing algorithm (Eisner, 1996) to incorporate higher-order features (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010). A similar line of research investigated the use of integer linear programming (ILP) formulations of parsing (Riedel and Clarke, 2006; Martins et al., 2009; Martins et al., 2010). Both solutions allow for exact inference with higher-order features, but typically at a high cost in terms of efficiency. Furthermore, specialized algorithms are required that deeply exploit the structural properties of the given model. Upgrading a parser to score new types of higher-order dependencies thus requires significant changes to the underlying decoding algorithm. This is in stark contrast to transition-based systems, which simply require the definition of new feature extractors.

In this paper, we abandon exact search in graph-based parsing in favor of freedom in feature scope. We propose a parsing algorithm that keeps the backbone Eisner chart-parsing algorithm for first-order parsing unchanged. Incorporating higher-order features only involves changing the scoring function of

potential parses in each chart cell by expanding the signature of each chart item to include all the non-local context required to compute features. The core chart-parsing algorithm remains the same regardless of which features are incorporated. To control complexity we use cube pruning (Chiang, 2007) with the beam size  $k$  in each cell. Furthermore, dynamic programming in the style of Huang and Sagae (2010) can be done by merging  $k$ -best items that are equivalent in scoring. Thus, our method is an application of integrated decoding with a language model in MT (Chiang, 2007) to dependency parsing, which has previously been applied to constituent parsing (Huang, 2008). However, unlike Huang, we only have one decoding pass and a single trained model, while Huang’s constituent parser maintains a separate generative base model from a following discriminative re-ranking model. We draw connections to related work in Section 6.

Our chart-based approximate search algorithm allows for features on dependencies of an arbitrary order — as well as over non-local structural properties of the parse trees — to be scored at will. In this paper, we use first to third-order features of greater varieties than Koo and Collins (2010). Additionally, we look at higher-order dependency arc-label features, which is novel to graph-based parsing, though commonly exploited in transition-based parsing (Zhang and Nivre, 2011). This is because adding label tuple features would introduce a large constant factor of  $O(|L|^3)$ , where  $|L|$  is the size of the label set  $L$ , into the complexity for exact third-order parsing. In our formulation, only the top-ranked labelled arcs would survive in each cell. As a result, label features can be scored without combinatorial explosion. In addition, we explore the use of valency features counting how many modifiers a word can have on its left and right side. In the past, only re-rankers on  $k$ -best lists of parses produced by a simpler model use such features due to the difficulty of incorporating them into search (Hall, 2007).

The final parser with all these features is both accurate and fast. In standard experiments for English, the unlabeled attachment score (UAS) is 93.06%, and the labeled attachment score (LAS) is 91.86%. The UAS score is state-of-art. The speed of our parser is 220 tokens per second, which is over 4 times faster than an exact third-order parser that at-

Figure 1: Example Sentence.

tains UAS of 92.81% and comparable to the state-of-the-art transition-based system of Zhang and Nivre (2011) that employs beam search.

## 2 Graph-based Dependency Parsing

Dependency parsers produce directed relationships between *head* words and their syntactic *modifiers*. Each word modifies exactly one head, but can have any number of modifiers itself. The *root* of a sentence is a designated special symbol which all words in the sentence directly or indirectly modify. Thus, the dependency graph for a sentence is constrained to be a directed tree. The directed syntactic relationships, aka dependency arcs or dependencies for short, can often be labeled to indicate their syntactic role. Figure 1 gives an example dependency tree.

For a sentence  $x = x_1 \dots x_n$ , dependency parsing is the search for the set of head-modifier dependency arcs  $y^*$  such that  $y^* = \operatorname{argmax}_{y \in \mathcal{Y}(x)} f(x, y)$ , where  $f$  is a scoring function. As mentioned before,  $y^*$  must represent a directed tree.  $|\mathcal{Y}(x)|$  is then the set of valid dependency trees for  $x$  and grows exponentially with respect to its length  $|x|$ . We further define  $L$  as the set of possible arc labels and use the notation  $(i \xrightarrow{l} j) \in y$  to indicate that there is a dependency from head word  $x_i$  to modifier  $x_j$  with label  $l$  in dependency tree  $y$ .

In practice,  $f(x, y)$  is factorized into scoring functions on parts of  $(x, y)$ . For example, in first-order dependency parsing (McDonald et al., 2005),  $f(x, y)$  is factored by the individual arcs:

$$y^* = \operatorname{argmax}_{y \in \mathcal{Y}(x)} f(x, y) = \operatorname{argmax}_{y \in \mathcal{Y}(x)} \sum_{(i \xrightarrow{l} j) \in y} f(i \xrightarrow{l} j)$$

The factorization of dependency structures into arcs enables an efficient dynamic programming algorithm with running time  $O(|x|^3)$  (Eisner, 1996), for the large family of projective dependency structures.

Figure 2 shows the parsing logic for the Eisner algorithm. It has two types of dynamic programming states: *complete items* and *incomplete items*.

Complete items correspond to half-constituents, and are represented as triangles graphically. Incomplete items correspond to dependency arcs, and are represented as trapezoids. The Eisner algorithm is the basis for the more specialized variants of higher-order projective dependency parsing.

Second-order sibling models (McDonald and Pereira, 2006) score adjacent arcs with a common head. In order to score them efficiently, a new state corresponding to modifier pairs was introduced to the chart-parsing algorithm. Due to the careful factorization, the asymptotic complexity of the revised algorithm remains  $O(|x|^3)$ . The resulting scoring function is:

$$y^* = \operatorname{argmax}_{y \in \mathcal{Y}(x)} \sum_{(i \xrightarrow{l} j, i \xrightarrow{l'} k) \in y} f(i \xrightarrow{l} j, i \xrightarrow{l'} k)$$

where  $(i \xrightarrow{l} j, i \xrightarrow{l'} k) \in y$  indicates two adjacent head-modifier relationships in dependency tree  $y$ , one from  $x_i$  to  $x_j$  with label  $l$  and another from  $x_i$  to  $x_k$  with label  $l'$ . Words  $x_j$  and  $x_k$  are commonly referred to as *siblings*. In order to maintain cubic parsing complexity, adjacent dependencies are scored only if the modifiers occur on the same side in the sentence relative to the head.

Second-order grandchild models (Carreras, 2007) score adjacent arcs in length-two head-modifier chains. For example, if word  $x_i$  modifies word  $x_j$  with label  $l$ , but itself has a dependency to modifier  $x_k$  with label  $l'$ , then we would add a scoring function  $f(j \xrightarrow{l} i \xrightarrow{l'} k)$ . These are called *grandchild* models as they can score dependencies between a word and its modifier’s modifiers, i.e.,  $x_k$  is the grandchild of  $x_j$  in the above example. The states in the Eisner algorithm need to be augmented with the indices to the outermost modifiers in order to score the outermost grandchildren. The resulting algorithm becomes  $O(|x|^4)$ .

Finally, third-order models (Koo and Collins, 2010) score arc triples such as three adjacent sibling modifiers, called *tri-siblings*, or structures looking at both horizontal contexts and vertical contexts, e.g., *grand-siblings* that score a word, its modifier and its adjacent grandchildren. To accommodate the scorers for these sub-graphs, even more specialized dynamic programming states were introduced. The Koo and Collins (2010) factorization enables

Figure 2: Structures and rules for parsing first-order models with the (Eisner, 1996) algorithm. This shows only the construction of right-pointing dependencies and not the symmetric case of left-pointing dependencies.

the scoring of certain types of third-order dependencies with  $O(|x|^4)$  decoder run-time complexity.

Each of these higher-order parsing algorithms makes a clever factorization for the specific model in consideration to keep complexity as low as possible. However, this results in a loss of generality.

### 3 Generalizing Eisner’s Algorithm

In this section, we generalize the Eisner algorithm without introducing new parsing rules. The generalization is straight-forward: expand the dynamic programming state to incorporate feature histories. This is done on top of the two distinct chart items in the  $O(|x|^3)$  Eisner chart-parsing algorithm (Figure 2). The advantage of this approach is that it maintains the simplicity of the original Eisner algorithm. Unfortunately, it can increase the run-time complexity of the algorithm substantially, but we will employ cube pruning to regain tractability. Because our higher-order dependency parsing algorithm is based on the Eisner algorithm, it is currently limited to produce projective trees only.

#### 3.1 Arbitrary $n$ -th-order dependency parsing

We start with the simplest case of sibling models. If we want to score sibling arcs, at rule (b) in Figure 2, we can see that the complete item lying between the head and the modifier (the middle of the three items) does not contain information about the outermost modifier of the head, which is the previous dependency constructed and the sibling to the modifier of the dependency currently being constructed. This fact suggests that, in order to score modifier bigrams, the complete item states should be augmented by the outermost modifier. We can augment the chart items with such information, which

Figure 3: Structures and rules for parsing models based on modifier bigrams, with a generalized (Eisner, 1996) algorithm. Here the dashed arrows indicate additional information stored in each chart-cell. Specifically the previous modifier in complete chart items.

is shown in Figure 3. It refines the complete items by storing the previously constructed dependency to the outermost modifiers. Note that now the signature of the complete items is not simply the end-point indexes, but contains the index of the outer modifier.

Using this chart item augmentation it is now possible to score both first-order arcs as well as second-order sibling arcs. In fact, by symmetry, the new dynamic program can also score the leftmost and rightmost grandchildren of a head-modifier pair, in rule (a) and rule (b) respectively. By counting the number of free variables in each parsing rule, we see that the parsing complexity is  $O(|x|^5)$ , which is higher than both McDonald and Pereira (2006) and Carreras (2007). The added complexity comes from the fact that it is now possible to score a third-order dependency consisting of the head, the modifier, the sibling, and the outermost grandchild jointly.

We can go further to augment the complete and incomplete states with more parsing history. Figure 4 shows one possible next step of generalization. We generalize the states to keep track of the latest two modifiers of the head. As a result, it becomes possible to score tri-siblings involving three adjacent modifiers and grand-siblings involving two outermost grandchildren – both of which comprise the third-order Model 2 of Koo and Collins (2010) – plus potentially any additional interactions of these roles. Figure 5 shows another possible generalization. We keep modifier chains up to length two in the complete states. The added history enables the computation of features for great-grandchildren relationships:  $(h \xrightarrow{l} m \xrightarrow{l'} gc \xrightarrow{l''} ggc)$ .

In general, we can augment the complete and incomplete states with  $n$  variables representing the

Figure 4: Structures and rules for parsing models based on modifier trigrams in horizontal contexts, with a generalized (Eisner, 1996) algorithm. Here the dashed arrows indicate the previous two modifiers to the head in each chart item.

Figure 5: Structures and rules for parsing models based on modifier trigrams in vertical contexts, with a generalized (Eisner, 1996) algorithm. Here the dashed arrows indicate the modifier to the head and the modifier’s modifier, forming a modifier chain of length two.

possible parsing histories and loop over the cross product of the histories in the innermost loop of Eisner algorithm. The cardinality of the cross product is  $|x|^n \cdot |x|^n$ . Thus, the complexity of the algorithm augmented by  $n$  variables is  $O(|x|^3 \cdot |x|^{2n}) = O(|x|^{3+2n})$ , where  $n \geq 0$ . Note that this complexity is for unlabeled parsing. A factor of  $|L|$  for all or a subset of the encoded arcs must be multiplied in when predicting labeled parse structures.

### 3.2 History-based dependency parsing

The previous  $n$  modifiers, either horizontal or vertical, is a potential signature of parsing history. We can put arbitrary signatures of parsing history into the chart items so that when we score a new item, we can draw the distinguishing power of features based on an arbitrarily deep history. For example, consider the *position* of a modifier, which is the position in which it occurs amongst its siblings relative to the location of the head. We can store the position of the last modifier into both chart states. In complete states, this signature tells us the position of the outermost modifier, which is the valency of the head in the left or right half-constituent.

In the extreme case, we can use full subtrees as histories, although the cardinality of the set of histories would quickly become exponential, especially when one considers label ambiguity. Regardless, the high complexity associated with this generalization, even for second or third-order models, requires us to appeal to approximate search algorithms.

### 3.3 Advantage of the generalization

The complexity analysis earlier in this section reveals the advantage of such a generalization scheme. It factorizes a dynamic programming state for dependency parsing into two parts: 1) the structural state, which consists of the boundaries of incomplete and complete chart items, and accounts for the  $O(|x|^3)$  term in the analysis, and 2) the feature history, which is a signature of the internal content of a sub-parse and accounts for the  $O(|x|^{2n})$  term. The rules of the deductive parsing system – the Eisner algorithm – stay the same as long as the structural representation is unchanged. To generalize the parser to handle richer features, one can simply enrich the feature signature and the scoring function without changing the structural state. A natural grouping of states follows where all sub-parses sharing the same chart boundaries are grouped together. This grouping will enable the cube pruning in Section 4 for approximate search.

There is another advantage of keeping the Eisner parsing logic unchanged: derivations one-to-one correspond to dependency parse trees. Augmenting the complete and incomplete states does not introduce spurious ambiguity. This grouping view is useful for proving this point. Introducing higher order features in each chart item will cause sub-derivations to be re-ranked only. As a result, the final Viterbi parse can differ from the one from the standard Eisners algorithm. But the one-to-one correspondence still holds.

## 4 Approximate Search with Cube Pruning

In machine translation decoding, an  $n$ -gram language model can be incorporated into a translation model by augmenting the dynamic programming states for the translation model with the boundary  $n - 1$  words on the target side. The complexity for exact search involves a factor of  $|x|^{4n-4}$  in the

hierarchical phrase-based model of Chiang (2007), where  $|x|$  is the input sentence length. The standard technique is to force a beam size  $k$  on each translation state so that the possible combinations of language model histories is bounded by  $k^2$ . Furthermore, if the list of  $k$  language model states are sorted from the lowest cost to the highest cost, we can assume the best combinations will still be among the combinations of the top items from each list, although the incorporation of  $n$ -gram features breaks the monotonic property of the underlying semi-ring.

Cube pruning is based on this approximation (Chiang, 2007). It starts with the combination of the top items in the lists to be combined. At each step, it puts the neighbors of the current best combination, which consists of going one position down in one of the  $k$ -best lists, into a priority queue. The algorithm stops when  $k$  items have been popped off from the queue. At the final step, it sorts the popped items since they can be out-of-order. It reduces the combination complexity from  $O(k^2)$  to  $O(k \cdot \log(k))$ .

Our history-augmented parsing is analogous to MT decoding. The possible higher-order histories can similarly be limited to at most  $k$  in each complete or incomplete item. The core loop of the generalized algorithm which has a complexity of  $O(|x|^{2n})$  can similarly be reduced to  $O(k \cdot \log(k))$ . Therefore, the whole parsing algorithm remains  $O(|x|^3)$  regardless how deep we look into parsing history. Figure 6 illustrates the computation. We apply rule (b) to combine two lists of augmented complete items and keep the combinations with the highest model scores. With cube pruning, we only explore cells at (0, 0), (0, 1), (1, 0), (2, 0), and (1, 1), without the need to evaluate scoring functions for the remaining cells in the table. Similar computation happens with rule (a).

In this example cube pruning does find the highest scoring combination, i.e., cell (1, 1). However, note that the scores are not monotonic in the order in which we search these cells as non-local features are used to score the combinations. Thus, cube pruning may not find the highest scoring combination. This approximation is at the heart of cube pruning.

### 4.1 Recombination

The significance of using feature signatures is that when two combinations result in a state with the

identical feature signature the one with the highest score survives. This is the core principle of dynamic programming. We call it *recombination*. It denotes the same meaning as *state-merging* in Huang and Sagae (2010) for transition-based parsers.

In cube pruning, with recombination, the  $k$ -best items in each chart cell are locally optimal (in the pruned search space) over all sub-trees with an equivalent state for future combinations. The cube pruning algorithm without recombination degenerates to a recursive  $k$ -best re-scoring algorithm since each of the  $k$ -best items would be unique by itself as a sub-tree. It should be noted that by working on a chart (or a forest, equivalently) the algorithm is already applying recombination at a coarser level.

In machine translation, due to its large search space and the abstract nature of an  $n$ -gram language model, it is more common to see many sub-trees with the same language model feature signature, making recombination crucial (Chiang, 2007). In constituent parser reranking (Huang, 2008), recombination is less likely to happen since the reranking features capture peculiarities of local tree structures. For dependency parsing, we hypothesize that the higher-order features are more similar to the  $n$ -gram language model features in MT as they tend to be common features among many sub-trees. But as the feature set becomes richer, recombination tends to have a smaller effect. We will discuss the empirical results on recombination in Section 5.4.

## 5 Experiments

We define the scoring function  $f(x, y)$  as a linear classifier between a vector of features and a corresponding weight vector, i.e.,  $f(x, y) = w \cdot \phi(x, y)$ . The feature function  $\phi$  decomposes with respect to scoring function  $f$ . We train the weights to optimize the first-best structure. We use the max-loss variant of the margin infused relaxed algorithm (MIRA) (Crammer et al., 2006) with a hamming-loss margin as is common in the dependency parsing literature (Martins et al., 2009; Martins et al., 2010). MIRA only requires a first-best decoding algorithm, which in our case is the approximate chart-based parsing algorithms defined in Sections 3 and 4. Because our decoding algorithm is approximate, this may lead to invalid updates given to the optimizer (Huang and

Figure 6: Combining two lists of complete items with cube pruning.

Fayong, 2012). However, we found that ignoring or modifying such updates led to negligible differences in practice. In all our experiments, we train MIRA for 8 epochs and use a beam of  $k = 5$  during decoding. Both these values were determined on the English development data.

### 5.1 Features

The feature templates we use are drawn from the past work on graph-based parsing and transition-based parsing. The base templates for the higher-order dependencies are close to Koo and Collins (2010), with the major exception that our features include label-tuple information. The basic features include identities, part of speech tags, and labels of the words in dependency structures. These atomic features are conjoined with the directions of arcs to create composite  $n$ -gram features. The higher-order dependency features can be categorized into the following sub-groups, where we use  $h$  to indicate the head,  $m$  the modifier,  $s$  the modifier’s sibling and  $gc$  a grandchild word in a dependency part.

- (labeled) modifier features:  $(h \xrightarrow{l} m)$
- (labeled) sibling features:  $(h \xrightarrow{l} m, h \xrightarrow{l'} s)$
- (labeled) outermost grandchild features:  
 $(h \xrightarrow{l} m \xrightarrow{l'} gc)$
- (labeled) tri-sibling features:  
 $(h \xrightarrow{l} m, h \xrightarrow{l'} s, h \xrightarrow{l''} s_2)$
- (labeled) grand-sibling features:  
 $(h \xrightarrow{l} m \xrightarrow{l'} gc, h \xrightarrow{l} m \xrightarrow{l''} gc_2),$

- (labeled) sibling and grandchild conjoined features:

$$(h \xrightarrow{l} m, h \xrightarrow{l'} s, m \xrightarrow{l''} gc)$$

The general history features include valencies of words conjoined with the directions of the dominating arcs. The positions of the modifiers are also conjoined with the higher-order dependency features in the previous list.

The features that are new compared to Koo and Collins (2010) are the label tuple features, the sibling and grandchild conjoined features, and the valency features. We determine this feature set based on experiments on the development data for English. In Section 5.3 we examine the impact of these new features on parser performance.

## 5.2 Main Results

Our first set of results are on English dependencies. We used the Penn WSJ Treebank converted to dependencies with Penn2Malt<sup>1</sup> conversion software specifying Yamada and Matsumoto head rules and Malt label set. We used the standard splits of this data: sections 2-21 for training; section 22 for validation; and section 23 for evaluation. We evaluated our parsers using standard labeled accuracy scores (LAS) and unlabeled accuracy scores (UAS) excluding punctuation. We report run-times in tokens per second. Part-of-speech tags are predicted as input using a linear-chain CRF.

Results are given in Table 1. We compare our method to a state-of-the-art graph-based parser (Koo and Collins, 2010) as well as a state-of-the-art transition-based parser that uses a beam (Zhang and Nivre, 2011) and the dynamic programming transition-based parser of Huang and Sagae (2010). Additionally, we compare to our own implementation of exact first to third-order graph-based parsing and the transition-based system of Zhang and Nivre (2011) with varying beam sizes.

There are a number of points to make. First, approximate decoding with rich features and cube pruning gives state-of-the-art labeled and unlabeled parsing accuracies relative to previously reported results. This includes the best graph-based parsing results of Koo and Collins (2010), which has near identical performance, as well as the best beam-based and dynamic-programming-based transition

<i>Parser</i>	<i>UAS</i>	<i>LAS</i>	<i>Toks/Sec</i>
Huang and Sagae (2010)	92.1-	-	-
Zhang and Nivre (2011)	92.9-	91.8-	-
Zhang and Nivre (reimpl.) (beam=64)	92.73	91.67	760
Zhang and Nivre (reimpl.) (beam=256)	92.75	91.71	190
Koo and Collins (2010)	93.04	-	-
1 <sup>st</sup> -order exact (reimpl.)	91.80	90.50	2070
2 <sup>nd</sup> -order exact (reimpl.)	92.40	91.12	1110
3 <sup>rd</sup> -order exact (reimpl.)	92.81	- <sup>†</sup>	50
this paper	93.06	91.86	220

Table 1: Comparing this work in terms of parsing accuracy compared to state-of-the-art baselines on the English test data. We also report results for a re-implementation of exact first to third-order graph-based parsing and a re-implementation of Zhang and Nivre (2011) in order to compare parser speed. <sup>†</sup>Our exact third-order implementation currently only supports unlabeled parsing.

parsers (Huang and Sagae, 2010; Zhang and Nivre, 2011). Second, at a similar toks/sec parser speed, our method achieves better performance than the transition-based model of Zhang and Nivre (2011) with a beam of 256. Finally, compared to an implementation of an exact third-order parser – which provides us with an apples-to-apples comparison in terms of features and runtime – approximate decoding with cube pruning is both more accurate and while being 4-5 times as fast. It is more accurate as it can easily incorporate more complex features and it is faster since its asymptotic complexity is lower. We should point out that our third-order reimplementation is a purely unlabeled parser as we do not have an implementation of an exact labeled third-order parser. This likely under estimates its accuracy, but also significantly overestimates its speed.

Next, we looked at the impact of our system on non-English treebanks. Specifically we focused on two sets of data. The first is the Chinese Treebank converted to dependencies. Here we use the identical training/validation/evaluation splits and experimental set-up as Zhang and Nivre (2011). Additionally, we evaluate our system on eight other languages from the CoNLL 2006/2007 shared-task (Buchholz and Marsi, 2006; Nivre et al., 2007). We selected the following four data sets since they are primarily projective treebanks (<1.0% non-projective arcs): Bulgarian and Spanish from CoNLL 2006 as well as Catalan and Italian from CoNLL 2007. Currently our method is restricted to predicting strictly projective trees as it

<sup>1</sup><http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html>

uses the Eisner chart parsing algorithm as its backbone. We also report results from four additional CoNLL data sets reported in Rush and Petrov (2012) in order to directly compare accuracy. These are German, Japanese, Portuguese and Swedish. For all data sets we measure UAS and LAS excluding punctuation and use gold tags as input to the parser as is standard for these data sets.

Results are given in Table 2. Here we compare to our re-implementations of Zhang and Nivre (2011), exact first to third-order parsing and Rush and Petrov (2012) for the data sets in which they reported results. We again see that approximate decoding with rich features and cube pruning has higher accuracy than transition-based parsing with a large beam. In particular, for the ZH-CTB data set, our system is currently the best reported result. Furthermore, our system returns comparable accuracy with exact third-order parsing, while being significantly faster and more flexible.

### 5.3 Ablation studies

In this section, we analyze the contributions from each of the feature groups. Each row in Table 3 uses a super set of features than the previous row. All systems use our proposed generalized higher-order parser with cube-pruning. I.e., they are all using the Eisner chart-parsing algorithm with expanded feature signatures. The only difference between systems is the set of features used. This allows us to see the improvement from additional features.

The first row uses no higher-order features. It is equivalent to the first-order model from Table 1. The only difference is that it uses the  $k$ -best algorithm to find the first-best, so it has additional overhead compared to the standard Viterbi algorithm. Each of the following rows gets a higher accuracy than its previous row by adding more higher order features. Putting in the sibling and grandchild conjoined features and the valency features yields a further improvement over the approximation of Koo and Collins (2010). Thus, the addition of new higher-order features, including valency, extra third-order, and label tuple features, results in increased accuracy. However, this is not without cost as the run-time in terms of tokens/sec decreases (300 to 220). But this decrease is not asymptotic, as it would be if one were to exactly search over our final model

<i>Higher-order Features</i>	<i>UAS</i>	<i>LAS</i>	<i>Toks/Sec</i>
none	91.74	90.46	1510
McDonald (2006) features + labels	92.48	91.25	860
Carreras (2007) features + labels	92.85	91.66	540
Koo (2010) features + labels	92.92	91.75	300
all features	93.06	91.86	220

Table 3: Generalized higher-order parsing with cube pruning using different feature sets.

<i>Beam</i>	<i>Recombination</i>	<i>UAS</i>	<i>LAS</i>	<i>Toks/Sec</i>
2	no	92.86	91.63	280
2	yes	92.89	91.65	260
5	no	93.05	91.85	240
5	yes	93.06	91.86	230
10	yes	93.05	91.85	140

Table 4: Showing the effect of better search on accuracy and speed on the English test data with a fixed model.

with these additional features, e.g., valency would at least multiply an additional  $O(n)$  factor.

### 5.4 Impact of Search Errors

Since our decoding algorithm is not exact, it could return sub-optimal outputs under the current model. We analyze the effect of search errors on accuracies in Table 4. We vary the beam size at each cell and switch the option for signature-based recombination to make search better or worse to see how much impact it has on the final accuracy.

The results indicate that a relatively small per-cell beam is good enough. Going from a beam of 2 to 5 increases accuracy notably, but going to a larger beam size has little effect but at a cost in terms of efficiency. This suggests that most of the parser ambiguity is represented in the top-5 feature signatures at each chart cell. Furthermore, recombination does help slightly, but more so at smaller beam sizes.

If we keep the beam size constant but enlarge the feature scope from second-order to third-order, one would expect more search errors to occur. We measured this empirically by computing the number of sentences where the gold tree had a higher model score than the predicted tree in the English evaluation data. Indeed, larger feature scopes do lead to more search errors, but the absolute number of search errors is usually quite small – there are only 19 search errors using second-order features and 32 search errors using third-order plus valency features out of 2416 English test sentences. Part of the reason for this is that there are only 12 la-

Table 2: UAS/LAS for experiments on non-English treebanks. Numbers in bold are the highest scoring system. Zhang and Nivre is a reimplementation of Zhang and Nivre (2011) with beams of size 64 and 256. Rush and Petrov are the UAS results reported in Rush and Petrov (2012). N<sup>th</sup>-order exact are implementations of exact 1st-3rd order dependency parsing. <sup>†</sup>For reference, Zhang and Nivre (2011) report 86.0/84.4, which is previously the best result reported on this data set. <sup>‡</sup>It should be noted that Rush and Petrov (2012) do not jointly optimize labeled and unlabeled dependency structure, which we found to often help. This, plus extra features, accounts for the differences in UAS.

bels in the Penn2Malt label set, which results in little non-structural ambiguity. In contrast, Stanford-style dependencies contain a much larger set of labels (50) with more fine-grained syntactic distinctions (De Marneffe et al., 2006). Training and testing a model using this dependency representation<sup>2</sup> increases the number of search errors of the full model to 126 out 2416 sentences. But that is still only 5% of all sentences and significantly smaller when measured per dependency.

## 6 Related Work

As mentioned in the introduction, there has been numerous studies on trying to reconcile the rich-features versus exact decoding trade-off in dependency parsing. In the transition-based parsing literature this has included the use of beam search to increase the search space (Duan et al., 2007; Johansson and Nugues, 2007; Titov and Henderson, 2007; Zhang and Clark, 2008; Zhang and Nivre, 2011). Huang and Sagae (2010) took a more principled approach proposing a method combining shift-reduce parsing with dynamic programming. They showed how feature signatures can be compiled into dy-

namic programming states and how best-first search can be used to find the optimal transition sequence. However, when the feature scope becomes large, then the state-space and resulting search space can be either intractable or simply non-practical to explore. Thus, they resort to an approximate beam search that still exploring an exponentially-larger space than greedy or beam-search transition-based systems. One can view the contribution in this paper as being the complement of the work of Huang and Sagae (2010) for graph-based systems. Our approach also uses approximate decoding in order to exploit arbitrary feature scope, while still exploring an exponentially-large search space. The primary difference is how the system is parameterized, over dependency sub-graphs or transitions. Another critical difference is that a chart-based algorithm, though still subject to search errors, is less likely to be hindered by an error made at one word position because it searches over many parallel alternatives in a bottom-up search as opposed to a left-to-right pass.

In the graph-based parsing literature, exact parsing algorithms for higher-order features have been studied extensively (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010), but at a high computational cost as increasing the order of a model typically results in an asymptotic increase in

<sup>2</sup>This model gets 90.4/92.8 LAS/UAS which is comparable to the UAS of 92.7 reported by Rush and Petrov (2012).

running time. ILP formulations of parsing (Riedel and Clarke, 2006; Martins et al., 2009; Martins et al., 2010) also allow for exact inference with higher-order features, but again at a high computational cost as ILP’s have, in the worst-case, exponential run-time with respect to the sentence length. Studies that have abandoned exact inference have focused on sampling (Nakagawa, 2007), belief propagation (Smith and Eisner, 2008), Lagrangian relaxation (Koo et al., 2010; Martins et al., 2011), and more recently structured prediction cascades (Weiss and Taskar, 2010; Rush and Petrov, 2012). However, these approximations themselves are often computationally expensive, requiring multiple decoding/sampling stages in order to produce an output. All the methods above, both exact and approximate, require specialized algorithms for every new feature that is beyond the scope of the previous factorization. In our method, the same parsing algorithm can be utilized (Eisner’s + cube pruning) just with slight different feature signatures.

Our proposed parsing model draws heavily on the work of Huang (2008). Huang introduced the idea of “forest rescoring”, which uses cube pruning to enable the incorporation of non-local features into a constituency parsing model providing state-of-the-art performance. This paper is the extension of such ideas to dependency parsing, also giving state-of-the-art results. An important difference between our formulation and forest rescoring is that we only have one decoding pass and a single trained model, while forest rescoring, as formulated by Huang (2008), separates a generative base model from a following discriminative re-ranking model. Hence, our formulation is more akin to the one pass decoding algorithm of Chiang (2007) for integrated decoding with a language model in machine translation. This also distinguishes it from previous work on dependency parse re-ranking (Hall, 2007) as we are not re-ranking/re-scoring the output of a base model but using a single decoding algorithm and learned model at training and testing.

This work is largely orthogonal to other attempts to speed up chart parsing algorithms. This includes work on coarse-to-fine parsing (Charniak and Johnson, 2005; Petrov and Klein, 2007; Rush and Petrov, 2012), chart-cell closing and pruning (Roark and Hollingshead, 2008; Roark and Hollingshead,

2009), and dynamic beam-width prediction (Bodenstab et al., 2011). Of particular note, Rush and Petrov (2012) report run-times far better than our cube pruning system. At the heart of their system is a linear time vine-parsing stage that prunes most of the search space before higher-order parsing. This effectively makes their final system linear time in practice as the higher order models have far fewer parts to consider. One could easily use the same first-pass pruner in our cube-pruning framework.

In our study we use cube pruning only for decoding and rely on inference-based learning algorithms to train model parameters. Gimpel and Smith (2009) extended cube pruning concepts to partition-function and marginal calculations, which would enable the training of probabilistic graphical models.

Finally, due to its use of the Eisner chart-parsing algorithm as a backbone, our model is fundamentally limited to predicting projective dependency structures. Investigating extensions of this work to the non-projective case is an area of future study. Work on defining bottom-up chart-parsing algorithms for non-projective dependency trees could potentially serve as a mechanism to solving this problem (Gómez-Rodríguez et al., 2009; Kuhlmann and Satta, 2009; Gómez-Rodríguez et al., 2010).

## 7 Conclusion

In this paper we presented a method for generalized higher-order dependency parsing. The method works by augmenting the dynamic programming signatures of the Eisner chart-parsing algorithm and then controlling complexity via cube pruning. The resulting system has the flexibility to incorporate arbitrary feature history while still exploring an exponential search space efficiently. Empirical results show that the system gives state-of-the-art accuracies across numerous data sets while still maintaining practical parsing speeds – as much as 4-5 times faster than exact third-order decoding.

**Acknowledgments:** We would like to thank Sasha Rush and Slav Petrov for help modifying their hypergraph parsing code. We would also like to thank the parsing team at Google for providing interesting discussions and new ideas while we conducted this work, as well as comments on earlier drafts of the paper.

# Universal Grapheme-to-Phoneme Prediction Over Latin Alphabets

Young-Bum Kim and Benjamin Snyder

University of Wisconsin-Madison

{ybkim, bsnyder}@cs.wisc.edu

## Abstract

We consider the problem of inducing grapheme-to-phoneme mappings for unknown languages written in a Latin alphabet. First, we collect a data-set of 107 languages with known grapheme-phoneme relationships, along with a short text in each language. We then cast our task in the framework of supervised learning, where each known language serves as a training example, and predictions are made on unknown languages. We induce an undirected graphical model that learns phonotactic regularities, thus relating textual patterns to plausible phonemic interpretations across the entire range of languages. Our model correctly predicts grapheme-phoneme pairs with over 88% F1-measure.

## 1 Introduction

Written language is one of the defining technologies of human civilization, and has been independently invented at least three times through the course of history (Daniels and Bright, 1996). In many ways written language reflects its more primary spoken counterpart. Both are subject to some of the same forces of change, including human migration, cultural influence, and imposition by empire. In other ways, written language harkens further to the past, reflecting aspects of languages long since gone from their spoken forms. In this paper, we argue that this imperfect relationship between written symbol and spoken sound can be automatically inferred from textual patterns. By examining data for over 100 languages, we train a statistical model to automat-

ically relate graphemic patterns in text to phonemic sequences for never-before-seen languages.

We focus here on the the alphabet, a writing system that has come down to us from the Sumerians. In an idealized alphabetic system, each phoneme in the language is unambiguously represented by a single grapheme. In practice of course, this ideal is never achieved. When existing alphabets are melded onto new languages, they must be imperfectly adapted to a new sound system. In this paper, we exploit the fact that a single alphabet, that of the Romans, has been adapted to a very large variety of languages.

Recent research has demonstrated the effectiveness of cross-lingual analysis. The joint analysis of several languages can increase model accuracy, and enable the development of computational tools for languages with minimal linguistic resources. Previous work has focused on settings where just a handful of languages are available. We treat the task of grapheme-to-phoneme analysis as a test case for larger scale multilingual learning, harnessing information from dozens of languages.

On a more practical note, accurately relating graphemes and phonemes to one another is crucial for tasks such as automatic speech recognition and text-to-speech generation. While pronunciation dictionaries and transcribed audio are available for some languages, these resources are entirely lacking for the vast majority of the world's languages. Thus, automatic and generic methods for determining sound-symbol relationships are needed.

Our paper is based on the following line of reasoning: that character-level textual patterns mirror

phonotactic regularities; that phonotactic regularities are shared across related languages and universally constrained; and that textual patterns for a newly observed language may thus reveal its underlying phonemics. Our task can be viewed as an easy case of lost language decipherment – one where the underlying alphabetic system is widely known.

Nevertheless, the task of grapheme-to-phoneme prediction is challenging. Characters in the Roman alphabet can take a wide range of phonemic values across the world’s languages. For example, depending on the language, the grapheme “c” can represent the following phonemes:<sup>1</sup>

- /k/ (unvoiced velar plosive)
- /ç/ (unvoiced palatal plosive)
- /s/ (unvoiced alveolar fricative)
- // (dental click)
- /dʒ/ (affricated voiced postalveolar fricative)
- /tʃ/ (affricated unvoiced postalveolar fricative)
- /ts/ (affricated unvoiced alveolar fricative)

To make matters worse, the same language may use a single grapheme to ambiguously represent *multiple* phonemes. For example, English orthography uses “c” to represent both /k/ and /s/. Our task is thus to select a *subset* of phonemes for each language’s graphemes. We cast the subset selection problem as a set of related binary prediction problems, one for each possible grapheme-phoneme pair. Taken together, these predictions yield the grapheme-phoneme mapping for that language.

We develop a probabilistic undirected graphical model for this prediction problem, where a large set of languages serve as training data and a single held-out language serves as test data. Each training and test language yields an instance of the graph, bound

<sup>1</sup>For some brief background on phonetics, see Section 2. Note that we use the term “phoneme” throughout the paper, though we also refer to “phonetic” properties. As we are dealing with texts (written in a roughly phonemic writing system), we have no access to the true contextual phonetic realizations, and even using IPA symbols to relate symbols across languages is somewhat theoretically suspect.

together through a shared set of features and parameter values to allow cross-lingual learning and generalization.

In the graph corresponding to a given language, each node represents a grapheme-phoneme pair ( $g : p$ ). The node is labeled with a binary value to indicate whether grapheme  $g$  can represent phoneme  $p$  in the language. In order to allow coupled labelings across the various grapheme-phoneme pairs of the language, we employ a connected graph structure, with an automatically learned topology shared across the languages. The node and edge features are derived from textual co-occurrence statistics for the graphemes of each language, as well as general information about the language’s family and region. Parameters are jointly optimized over the training languages to maximize the likelihood of the node labelings given the observed feature values. See Figure 1 for a snippet of the model.

We apply our model to a novel data-set consisting of grapheme-phoneme mappings for 107 languages with Roman alphabets and short texts. In this setting, we consider each language in turn as the test language, and train our model on the remaining 106 languages. Our highest performing model achieves an F1-measure of 88%, yielding perfect predictions for over 21% of languages. These results compare quite favorably to several baselines.

Our experiments lead to several conclusions. (i) Character co-occurrence features alone are not sufficient for cross-lingual predictive accuracy in this task. Instead, we map raw contextual counts to more linguistically meaningful generalizations to learn effective cross-lingual patterns. (ii) A connected graph topology is crucial for learning linguistically coherent grapheme-to-phoneme mappings. Without any edges, our model yields perfect mappings for only 10% of test languages. By employing structure learning and including the induced edges, we more than double the number of test languages with perfect predictions. (iii) Finally, an analysis of our grapheme-phoneme predictions shows that they do not achieve certain global characteristics observed across true phoneme inventories. In particular, the level of “feature economy” in our predictions is too low, suggesting an avenue for future research.

Figure 1: **A snippet of our undirected graphical model.** The binary-valued nodes represent whether a particular grapheme-phoneme pair is allowed by the language. Sparse edges are automatically induced to allow joint training and prediction over related inventory decisions.

## 2 Background and Related Work

In this section, we provide some background on phonetics and phoneme inventories. We also review prior work on grapheme-to-phoneme prediction and multilingual modeling.

### 2.1 Phoneme Inventories

The sounds of the world’s languages are produced through a wide variety of articulatory mechanisms. Consonants are sounds produced through a partial or complete stricture of the vocal tract, and can be roughly categorized along three independent dimensions: (i) *Voicing*: whether or not oscillation of the vocal folds accompanies the sound. For example, /t/ and /d/ differ only in that the latter is voiced. (ii) *Place of Articulation*: where in the anatomy of the vocal tract the stricture is made. For example, /p/ is a bilabial (the lips touching one another) while /k/ is a velar (tongue touching the soft palate). (iii) *Manner of Articulation*: the manner in which the airflow is regulated. For example, /m/ is a nasal (air flowing through the nostrils), while /p/ is a plosive (obstructed air suddenly released through the mouth).

In contrast, vowels are voiced sounds produced with an open vocal tract. They are categorized primarily based on the position of the tongue and lips, along three dimensions: (i) *Roundedness*: whether or not the lips are rounded during production of

the sound; (ii) *Height*: the vertical position of the tongue; (iii) *Backness*: how far forward the tongue lies.

Linguists have noted several statistical regularities found in phoneme inventories throughout the world. *Feature economy* refers to the idea that languages tend to minimize the number of differentiating characteristics (e.g. different kinds of voicing, manner, and place) that are used to distinguish consonant phonemes from one another (Clements, 2003). In other words, once an articulatory feature is used to mark off one phoneme from another, it will likely be used again to differentiate other phoneme pairs in the same language. The principle of *Maximal perceptual contrast* refers to the idea that the set of vowels employed by a language will be located in phonetic space to maximize their perceptual distances from one another, thus relieving the perceptual burden of the listener (Liljencrants and Lindblom, 1972). In an analysis of our results, we will observe that our model’s predictions do not always follow these principles.

Finally, researchers have noted that languages exhibit set patterns in how they sequence their phonemes (Kenstowicz and Kisseberth, 1979). Certain sequences are forbidden outright by languages, while others are avoided or favored. While many of these patterns are language-specific, others seem more general, either reflecting anatomical con-

straints, common language ancestry, or universal aspects of the human language system. These phonotactic regularities and constraints are mirrored in graphemic patterns, and as our experiments show, can be explicitly modeled to achieve high accuracy in our task.

## 2.2 Grapheme-to-Phoneme Prediction

Much prior work has gone into developing methods for accurate grapheme-to-phoneme prediction. The common assumption underlying this research has been that some sort of knowledge, usually in the form of a pronunciation dictionary or phonemically annotated text, is available for the language at hand. The focus has been on developing techniques for dealing with the phonemic ambiguity present both in annotated and unseen words. For example, Jiampojarn and Kondrak (Jiampojarn and Kondrak, 2010) develop a method for aligning pairs of written and phonemically transcribed strings; Dwyer and Kondrak (Dwyer and Kondrak, 2009) develop a method for accurate letter-to-phoneme conversion while minimizing the number of training examples; Reddy and Goldsmith (Reddy and Goldsmith, 2010) develop an MDL-based approach to finding subword units that align well to phonemes.

A related line of work has grown around the task of machine transliteration. In this task, the goal is to automatically transliterate a name in one language into the written form of another language. Often this involves some level of phonetic analysis in one or both languages. Notable recent work in this vein includes research by Sproat et al (Sproat et al., 2006) on transliteration between Chinese and English using comparable corpora, and Ravi and Knight (Ravi and Knight, 2009) who take a decipherment approach to this problem.

Our work differs from all previous work on grapheme-to-phoneme prediction in that (i) we assume no knowledge for our target language beyond a small unannotated text (and possibly some region or language family information), and (ii) our goal is to construct the inventory of mappings between the language's letters and its phonemes (the latter of which we do not know ahead of time). When a grapheme maps to more than one phoneme, we do not attempt to disambiguate particular instances of that grapheme in words.

A final thread of related work is the task of quantitatively categorizing writing systems according to their levels of phonography and logography (Sproat, 2000; Penn and Choma, 2006). As our data-set consists entirely of Latin-based writing systems, our work can be viewed as a more fine-grained computational exploration of the space of writing systems, with a focus on phonographic systems with the Latin pedigree.

## 2.3 Multilingual Analysis

An influential thread of previous multilingual work starts with the observation that rich linguistic resources exist for some languages but not others. The idea then is to *project* linguistic information from one language onto others via parallel data. Yarowsky and his collaborators first developed this idea and applied it to the problems of part-of-speech tagging, noun-phrase bracketing, and morphology induction (Yarowsky and Wicentowski, 2000; Yarowsky et al., 2000; Yarowsky and Ngai, 2001), and other researchers have applied the idea to syntactic and semantic analysis (Hwa et al., 2005; Padó and Lapata, 2006) In these cases, the existence of a bilingual parallel text along with highly accurate predictions for one of the languages was assumed.

Another line of work assumes the existence of bilingual parallel texts without the use of any supervision (Dagan et al., 1991; Resnik and Yarowsky, 1997). This idea has been developed and applied to a wide variety tasks, including morphological analysis (Snyder and Barzilay, 2008a; Snyder and Barzilay, 2008b), part-of-speech induction (Snyder et al., 2008; Snyder et al., 2009a; Naseem et al., 2009), and grammar induction (Snyder et al., 2009b; Blunsom et al., 2009; Burkett et al., 2010). An even more recent line of work does away with the assumption of parallel texts and performs joint unsupervised induction for various languages through the use of coupled priors in the context of grammar induction (Cohen and Smith, 2009; Berg-Kirkpatrick and Klein, 2010).

In contrast to these previous approaches, the method we propose does not assume the existence of any parallel text, but instead assumes that labeled data exists for a wide variety of languages. In this regard, our work most closely resembles recent work which trains a universal morphological analyzer us-

	phonemes	#lang	ent
a	/a/ /e/ /a/ /ə/ /ʌ/	106	1.25
c	/c/ /dʒ/ /k/ /s/ /tʃ/ /tʃ/ /l/	62	2.33

Table 1: Ambiguous graphemes and the set of phonemes that they may represent among our set of 107 languages.

ing a structured nearest neighbor approach for 8 languages (Kim et al., 2011). Our work extends this idea to a new task and also considers a much larger set of languages. As our results will indicate, we found that a nearest neighbor approach was not as effective as our proposed model-based approach.

### 3 Data and Features

In this section we discuss the data and features used in our experiments.

#### 3.1 Data

The data for our experiments comes from three sources: (i) grapheme-phoneme mappings from an online encyclopedia, (ii) translations of the Universal Declaration of Human Rights (UDHR)<sup>2</sup>, and (iii) entries from the World Atlas of Language Structures (WALS) (Haspelmath and Bibiko, 2005).

To start, we downloaded and transcribed image files containing grapheme-phoneme mappings for several hundred languages from an online en-

<sup>2</sup><http://www.ohchr.org/en/udhr/pages/introduction.aspx>

cyclopedia of writing systems<sup>3</sup>. We then cross-referenced the languages with the World Atlas of Language Structures (WALS) database (Haspelmath and Bibiko, 2005) as well as the translations available for the Universal Declaration of Human Rights (UDHR). Our final set of 107 languages includes those which appeared consistently in all three sources and that employ a Latin alphabet. See Figure 2 for a world map annotated with the locations listed in the WALS database for these languages, as well as their language families. As seen from the figure, these languages cover a wide array of language families and regions.

We then analyzed the phoneme inventories for the 107 languages. We decided to focus our attention on graphemes which are widely used across these languages with a diverse set of phonemic values. We measured the ambiguity of each grapheme by calculating the entropy of its phoneme sets across the languages, and found that 17 graphemes had entropy > 0.5 and appeared in at least 15 languages. Table 1 lists these graphemes, the set of phonemes that they can represent, the number of languages in our data-set which employ them, and the entropy of their phoneme-sets across these languages. The data, along with the feature vectors discussed below, are published as part of this paper.

#### 3.2 Features

The key intuition underlying this work is that graphemic patterns in text can reveal the phonemes which they represent. A crucial step in operationalizing this intuition lies in defining input features that have cross-lingual predictive value. We divide our feature set into three categories.

**Text Context Features:** These features represent the textual environment of each grapheme in a language. For each grapheme  $g$ , we consider counts of graphemes to the immediate left and right of  $g$  in the UDHR text. We define five feature templates, including counts of (1) single graphemes to the left of  $g$ , (2) single graphemes to the right of  $g$ , (3) pairs of graphemes to the left of  $g$ , (4) pairs of graphemes to the right of  $g$ , and (5) pairs of graphemes surrounding  $g$ . As our experiments below show, this set of features on its own performs poorly. It seems that

<sup>3</sup><http://www.omniglot.com/writing/langalph.htm#latin>

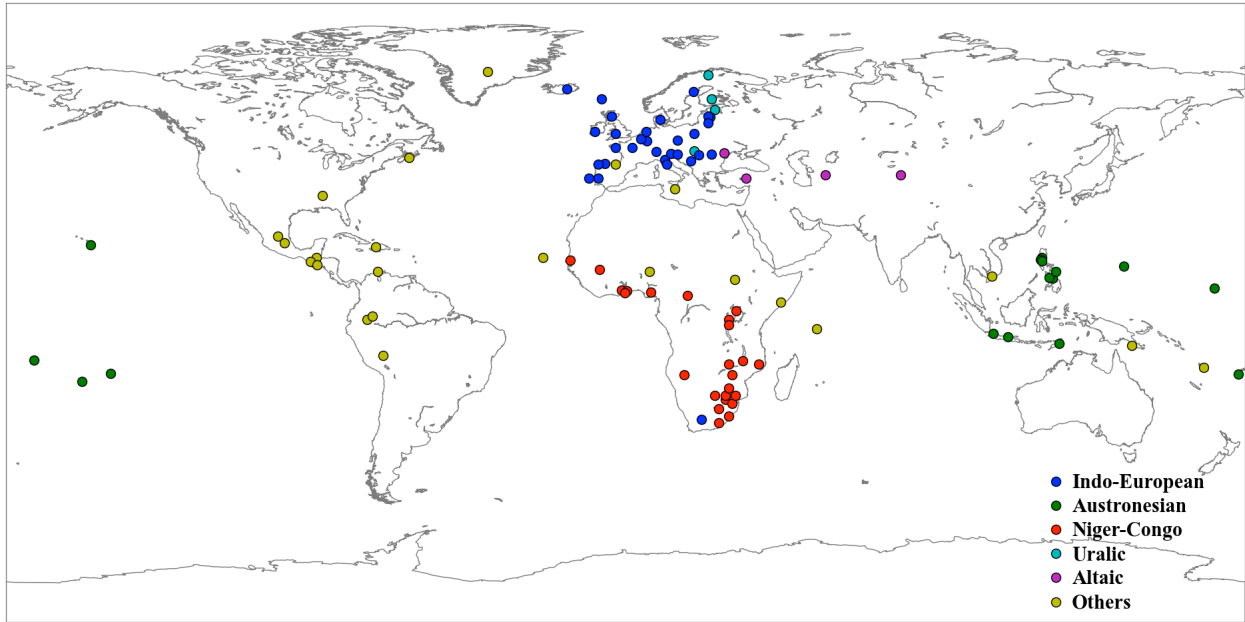

Figure 2: Map and language families of languages in our data-set

these features are too language specific and not abstract enough to yield effective cross-lingual generalization. Our next set of features was designed to alleviate this problem.

**Phonemic Context Features:** A perfect feature-set would depend on the entire set of grapheme-to-phoneme predictions for a language. In other words, we would ideally map *all* the graphemes in our text to phonemes, and then consider the plausibility of the resulting phoneme sequences. In practice, of course, this is impossible, as the set of possible grapheme-to-phoneme mappings is exponentially large. As an imperfect proxy for this idea, we made the following observation: for most Latin graphemes, the most common phonemic value across languages is the identical IPA symbol of that grapheme (e.g. the most common phoneme for *g* is /g/, the most common phoneme for *t* is /t/, etc). Using this observation, we again consider all contexts in which a grapheme appears, but this time map the surrounding graphemes to their IPA phoneme equivalents. We then consider various linguistic properties of these surrounding “phonemes” – whether they are vowels or consonants, whether they are voiced or not, their manner and places of articulation – and create phonetic context features. The process

is illustrated in Figure 3. The intuition here is that these features can (noisily) capture the *phonotactic context* of a grapheme, allowing our model to learn general phonotactic constraints. As our experiments below demonstrate, these features proved to be quite powerful.

**Language Family Features:** Finally, we consider features drawn from the WALS database which capture general information about the language – specifically, its region (e.g. Europe), its small language family (e.g. Germanic), and its large language family (e.g. Indo-European). These features allow our model to capture family and region specific phonetic biases. For example, African languages are more likely to use *c* and *q* to represent clicks than are European languages. As we mention below, we also consider conjunctions of all features. Thus, a language family feature can combine with a phonetic context feature to represent a family specific phonotactic constraint. Interestingly, our experiments below show that these features are not needed for highly accurate prediction.

### 3.3 Feature Discretization and Filtering

It is well known that many learning techniques perform best when continuous features are binned and

Figure 3: **Generating phonetic context features.** First, character context features are extracted for each grapheme. The features drawn here give the counts of the character to the immediate left of the grapheme. Next, the contextual characters are noisily converted to phones using their IPA notation. Finally, phonetic context features are extracted. In this case, phones /k/ and /g/ combine to give a “velar” count of 22, while /g/ and /b/ combine to give a “voiced” count of 10.

converted to binary values (Dougherty et al., 1995). As a preprocessing step, we therefore discretize and filter the count-based features outlined above. We adopt the technique of Recursive Minimal Entropy Partitioning (Fayyad and Irani, 1993). This technique recursively partitions feature values so as to minimize the conditional entropy of the labels. Partitioning stops when the gain in label entropy falls below the number of additional bits in overhead needed to describe the new feature split. This leads to a (local) minimum description length discretization.

We noticed that most of our raw features (especially the text features) could not achieve even a single split point without increasing description length, as they were not well correlated with the labels. We decided to use this heuristic as a feature selection technique, discarding such features. After this discretization and filtering, we took the resulting binary features and added their pairwise conjunctions to the set. This process was conducted separately for each leave-one-out scenario, without observation of the test language labels. Table 2 shows the total number of features before the discretization/filtering as well as the typical numbers of features obtained after filtering (the exact numbers depend on the training/test split).

## 4 Model

Using the features described above, we develop an undirected graphical model approach to our predic-

	Raw	Filtered
# Text Features	28,474	1,848
# Phonemic Features	28,948	7,799
# Family Features	66	32
Total	57,488	9,679

Table 2: **Number of features** in each category before and after discretization/filtering. Note that the pair-wise conjunction features are not included in these counts.

tion task. Corresponding to each training language is an instance of our undirected graph, labeled with its true grapheme-phoneme mapping. We learn weights over our features which optimally relate the input features of the training languages to their observed labels. At test-time, the learned weights are used to predict the labeling of the held-out test language.

More formally, we assume a set of graph nodes  $1, \dots, m$  with edges between some pairs of nodes  $(i, j)$ . Each node corresponds to a grapheme-phoneme pair  $(g : p)$  and can be labeled with a binary value. For each training language  $\ell$ , we observe a text  $\mathbf{x}^{(\ell)}$  and a binary labeling of the graph nodes  $\mathbf{y}^{(\ell)}$ . For each node  $i$ , we also obtain a feature vector  $f_i(\mathbf{x}^{(\ell)})$ , by examining the language’s text and extracting textual and noisy phonetic patterns (as detailed in the previous section). We obtain similar feature vectors for edges  $(i, j)$ :  $g_{jk}(\mathbf{x}^{(\ell)})$ . We then parameterize the probability of each labeling using a log-linear form over node and edge factors:<sup>4</sup>

<sup>4</sup>The delta function  $\delta(p)$  evaluates to 1 when predicate  $p$  is

$$\begin{aligned}
\log P(\mathbf{y}^{(\ell)}|\mathbf{x}^{(\ell)}) &= \sum_i \lambda_i \cdot [f_i(\mathbf{x}^{(\ell)}) \delta(y_i^{(\ell)} = 1)] \\
&+ \sum_{j,k} \lambda_{jk1} \cdot [g_{jk}(\mathbf{x}^{(\ell)}) \delta(y_j^{(\ell)} = 1 \wedge y_k^{(\ell)} = 1)] \\
&+ \sum_{j,k} \lambda_{jk2} \cdot [g_{jk}(\mathbf{x}^{(\ell)}) \delta(y_j^{(\ell)} = 1 \wedge y_k^{(\ell)} = 0)] \\
&+ \sum_{j,k} \lambda_{jk3} \cdot [g_{jk}(\mathbf{x}^{(\ell)}) \delta(y_j^{(\ell)} = 0 \wedge y_k^{(\ell)} = 1)] \\
&- \log Z(\mathbf{x}^{(\ell)}, \lambda)
\end{aligned}$$

The first term sums over nodes  $i$  in the graph. For each  $i$ , we extract a feature vector  $f_i(\mathbf{x}^{(\ell)})$ . If the label of node  $i$  is 1, we take the dot product of the feature vector and corresponding parameters, otherwise the term is zeroed out. Likewise for the graph edges  $j, k$ : we extract a feature vector, and depending on the labels of the two vertices  $y_j$  and  $y_k$ , take a dot product with the relevant parameters. The final term is a normalization constant to ensure that the probabilities sum to one over all possible labelings of the graph.

Before learning our parameters, we first automatically induce the set of edges in our graph, using the PC graph structure learning algorithm (Spirtes et al., 2000). This procedure starts with a fully connected undirected graph structure, and iteratively removes edges between nodes that are conditionally independent given other neighboring nodes in the graph according to a statistical independence test over all training languages. In our graphs we have 75 nodes, and thus 2,775 potential edges. Running the structure learning algorithm on our data yields sparse graphs, typically consisting of about 50 edges. In each leave-one-out scenario, a single structure is learned for all languages.

Once the graph structure has been induced, we learn parameter values by maximizing the L2-penalized conditional log-likelihood over all training languages:<sup>5</sup>

$$L(\lambda) = \sum_{\ell} \log P(\mathbf{y}^{(\ell)}|\mathbf{x}^{(\ell)}) - C\|\lambda\|^2$$

true, and to 0 when  $p$  is false.

<sup>5</sup>In our experiments, we used an L2 penalty weight of .5 for node features and .1 for edge features. Similar results are observed for a wide range of values.

The gradient takes the standard form of a difference between expected and observed feature counts (Lafferty et al., 2001). Expected counts, as well as predicted assignments at test-time, are computed using loopy belief propagation (Murphy et al., 1999). Numerical optimization is performed using L-BFGS (Liu and Nocedal, 1989).

## 5 Experiments

In this section, we describe the set of experiments performed to evaluate the performance of our model. Besides our primary undirected graphical model, we also consider several baselines and variants, in order to assess the contribution of our model’s graph structure as well as the features used. In all cases, we perform leave-one-out cross-validation over the 107 languages in our data-set.

### 5.1 Baselines

Our baselines include:

1. A majority baseline, where the most common binary value is chosen for each grapheme-phoneme pair,
2. two linear SVM’s, one trained using the discretized and filtered features described in Section 3.2, and the other using the raw continuous features,
3. a Nearest Neighbor classifier, which chooses the closest training language for each grapheme-phoneme pair in the discretized feature space, and predicts its label, and
4. a variant of our model with no edges between nodes (essentially reducing to a set of independent log-linear classifiers).

### 5.2 Evaluation

We report our results using three evaluation metrics of increasing coarseness.

1. **Phoneme-level:** For individual grapheme-phoneme pairs (e.g. a:/v/, a:/ʌ/, c:/k/, c:/tʃ/) our task consists of a set of binary predictions, and can thus be evaluated in terms of precision, recall, and F1-measure. We report micro-averages of these quantities across all

	Phoneme			Grapheme Accuracy	Language Accuracy
	Precision	Recall	F1		
MAJORITY	80.47	57.47	67.06	55.54	2.8
SVM CONTINUOUS	79.87	64.48	79.87	59.07	3.74
SVM DISCRETE	90.55	78.27	83.97	70.78	8.41
NEAREST NEIGHBOR	85.35	79.43	82.28	67.97	2.8
MODEL: NO EDGES	89.35	82.05	85.54	73.96	10.28
FULL MODEL	91.06	83.98	87.37	78.58	<b>21.5</b>
MODEL: NO FAMILY	<b>92.43</b>	<b>84.67</b>	<b>88.38</b>	<b>80.04</b>	19.63
MODEL: NO TEXT	89.58	81.43	85.31	75.86	15.89
MODEL: NO PHONETIC	86.52	74.19	79.88	69.6	9.35

Table 3: The performance of baselines and variants of our model, evaluated at the phoneme-level (binary predictions), whole-grapheme accuracy, and whole-language accuracy.

grapheme-phoneme pairs in all leave-one-out test languages.

2. **Grapheme-level:** We also report grapheme-level accuracy. For this metric, we consider each grapheme  $g$  and examine its predicted labels over all its possible phonemes:  $(g : p_1), (g : p_2), \dots, (g : p_k)$ . If all  $k$  binary predictions are correct, then the grapheme’s phoneme-set has been correctly predicted. We report the percentage of all graphemes with such correct predictions (micro-averaged over all graphemes in all test language scenarios).
3. **Language-level:** Finally, we assess language-wide performance. For this metric, we report the percentage of test languages for which our model achieves perfect predictions on all grapheme-phoneme pairs, yielding a perfect mapping.

### 5.3 Results

The results for the baselines and our model are shown in Table 3. The majority baseline yields 67% F1-measure on the phoneme-level binary prediction task, with 56% grapheme accuracy, and about 3% language accuracy.

Using undiscretized raw count features, the SVM improves phoneme-level performance to about 80% F1, but fails to provide any improvement on grapheme or language performance. In contrast, the SVM using discretized and filtered features achieves performance gains in all three categories, achieving 71% grapheme accuracy and 8% language accuracy.

The nearest neighbor baseline achieves performance somewhere in between the two SVM variants.

The unconnected version of our model achieves similar, though slightly improved performance over the discretized SVM. Adding the automatically induced edges into our model leads to significant gains across all three categories. Phoneme-level F1 reaches 87%, grapheme accuracy hits 79%, and language accuracy more than doubles, achieving 22%. It is perhaps not surprising that the biggest relative gains are seen at the language level: by jointly learning and predicting an entire language’s grapheme-phoneme inventory, our model ensures that language-level coherence is maintained.

Recall that three sets of features are used by our models. (1) language family and region features, (2) textual context features, and (3) phonetic context features. We now assess the relative merits of each set by considering our model’s performance when the set has been removed. Table 3 shows several striking results from this experiment. First, it appears that dropping the region and language family features actually improves performance. This result is somewhat surprising, as we expected these features to be quite informative. However, it appears that whatever information they convey is redundant when considering the text-based feature sets. We next observe that dropping the textual context features leads to a small drop in performance. Finally, we see that dropping the phonetic context features seriously degrades our model’s accuracy. Achieving robust cross-linguistic generalization apparently requires a level of feature abstraction not achieved by

character-level context features alone.

## 6 Global Inventory Analysis

In the previous section we saw that our model achieves relatively high performance in predicting grapheme-phoneme relationships for never-before-seen languages. In this section we analyze the predicted phoneme inventories and ask whether they display the statistical properties observed in the gold-standard mappings.

As outlined in Section 2, consonant phonemes can be represented by the three articulatory features of voicing, manner, and place. The principle of feature economy states that phoneme inventories will be organized to minimize the number of distinct articulatory features used in the language, while maximizing the number of resulting phonemes. This principle has several implications. First, we can measure the *economy index* of a consonant system by computing the ratio of the number of consonantal phonemes to the number of articulatory features used in their production:  $\frac{\#consonants}{\#features}$  (Clements, 2003). The higher this value, the more economical the sound system.

Secondly, for each articulatory dimension we can calculate the empirical distribution over values observed across the consonants of the language. Since consonants are produced as combinations of the three articulatory dimensions, the greatest number of consonants (for a given set of utilized feature values) will be produced when the distributions are close to uniform. Thus, we can measure how economical each feature dimension is by computing the entropy of its distribution over consonants. For example, in an economical system, we would expect roughly half the consonants to be voiced, and half to be unvoiced.

Table 4 shows the results of this analysis. First, we notice that the average entropy of voiced vs. unvoiced consonants is nearly identical in both cases, close to the optimal value. However, when we examine the dimensions of place and manner, we notice that the entropy induced by our model is not as high as that of the true consonant inventories, implying a suboptimal allocation of consonants. In fact, when we examine the economy index (ratio of consonants to features), we indeed find that – on aver-

	$H(\text{voice})$	$H(\text{place})$	$H(\text{manner})$	Economy Index
True	0.9739	2.7355	2.4725	1.6536
Predicted	0.9733	2.6715	2.4163	1.6337

Table 4: Measures of feature economy applied to the predicted and true consonant inventories (averaged over all 107 languages).

age – our model’s predictions are not as economical as the gold standard. This analysis suggests that we might obtain a more powerful predictive model by taking the principle of feature economy into account.

## 7 Conclusions

In this paper, we considered a novel problem: that of automatically relating written symbols to spoken sounds for an unknown language using a known writing system – the Latin alphabet. We constructed a data-set consisting of grapheme-phoneme mappings and a short text for over 100 languages. This data allows us to cast our problem in the supervised learning framework, where each observed language serves as a training example, and predictions are made on a new language. Our model automatically learns how to relate textual patterns of the unknown language to plausible phonemic interpretations using induced phonotactic regularities.

## Abstract

Many linguistic and textual processes involve transduction of strings. We show how to learn a stochastic transducer from an unorganized collection of strings (rather than string pairs). The role of the transducer is to organize the collection. Our generative model explains similarities among the strings by supposing that some strings in the collection were not generated *ab initio*, but were instead derived by transduction from other, “similar” strings in the collection. Our variational EM learning algorithm alternately reestimates this phylogeny and the transducer parameters. The final learned transducer can quickly link any test name into the final phylogeny, thereby locating variants of the test name. We find that our method can effectively find name variants in a corpus of web strings used to refer to persons in Wikipedia, improving over standard untrained distances such as Jaro-Winkler and Levenshtein distance.

## 1 Introduction

Systematic relationships between pairs of strings are at the core of problems such as transliteration (Knight and Graehl, 1998), morphology (Dreyer and Eisner, 2011), cross-document coreference resolution (Bagga and Baldwin, 1998), canonicalization (Culotta et al., 2007), and paraphrasing (Barzilay and Lee, 2003). Stochastic transducers such as probabilistic finite-state transducers are often used to capture such relationships. They model a conditional distribution  $p(y | x)$ , and are ordinarily trained on input-output *pairs* of strings (Dreyer et al., 2008).

In this paper, we are interested in learning from an *unorganized* collection of strings, some of which might have been derived from others by *transformative linguistic processes* such as abbreviation, morphological derivation, historical sound or spelling change, loanword formation, translation, transliteration, editing, or transcription error. We assume that each string was derived from at most one parent, but may give rise to any number of children.

The difficulty is that most or all of these parent-child relationships are unobserved. We must reconstruct this evolutionary phylogeny. At the same time, we must fit the parameters of a model of the relevant linguistic process  $p(y | x)$ , which says what sort of children  $y$  might plausibly be derived from parent  $x$ . Learning this model of  $p(y | x)$  helps us organize the training collection by reconstructing its phylogeny, and also permits us to generalize to new forms.

We will focus on the problem of name variation. We observe a collection of person names—full names, nicknames, abbreviated or misspelled names, etc. Some of these names can refer to the same person; we hope to detect this. It would be an unlikely coincidence if two mentions of John Jacob Jingleheimer Schmidt referred to different people, since this is a long and unusual name. Similarly, John Jacob Jinglehimer Smith and Dr. J. J. Jingleheimer may also be related names for this person. That is, these names may be derived from one another, via unseen relationships, although we cannot be sure.

Readers may be reminded of unsupervised clustering, in which “suspiciously similar” points can be explained as having been generated by the same cluster. Since each name is linked to at most one parent, our setting resembles single-link clustering—with a learned, asymmetric distance measure  $p(y | x)$ .

We will propose a generative process that makes explicit assumptions about how strings are copied with mutation. It is assumed to have generated all the names in the collection, in an unknown order. Given learned parameters, we can ask the model whether a name Dr. J. J. Jingleheimer in the collection is more likely to have been generated from scratch, or derived from some previous name.

### 1.1 Related Work

Several previous papers have also considered learning transducers or other models of word pairs when

the pairing between inputs and outputs is not given. Most commonly, one observes parallel or comparable corpora in two languages, and must reconstruct a matching from one language’s words to the other’s before training on the resulting pairs (Schafer, 2006b; Klementiev and Roth, 2006; Haghghi et al., 2008; Snyder et al., 2010; Sajjad et al., 2011).

Hall and Klein (2010) extend this setting to more than two languages, where the phylogenetic tree is known. A given lexeme (abstract word) can be realized in each language by at most one word (string type), derived from the parent language’s realization of the same lexeme. The system must match words that share an underlying lexeme (i.e., cognates), creating a matching of each language’s vocabulary to its parent language’s vocabulary. A further challenge is that the parent words are *unobserved* ancestral forms.

Similarly, Dreyer and Eisner (2011) organize words into morphological paradigms of a given structure. Again words with the same underlying lexeme (i.e., morphemes) must be identified. A lexeme can be realized in each grammatical inflection (such as “first person plural present”) by exactly one word type, related to other inflected forms of the same lexeme, which as above may be unobserved. Their inference setting is closer to ours because the input is an unorganized collection of words—input words are not tagged with their grammatical inflections. This contrasts with the usual multilingual setting where each word is tagged with its true language.

In one way, our problem differs significantly from the above problems. We are interested in random variation that may occur *within* a language as well as across languages. A person name may have *unboundedly* many different variants. This is unlike the above problems, in which a lexeme has at most  $K$  realizations, where  $K$  is the (small) number of languages or inflections.<sup>1</sup> We cannot assign the observed strings to positions in an existing structure that is shared across all lexemes, such as a given phylogenetic tree whose  $K$  nodes represent languages, or a given inflectional grid whose  $K$  cells represent grammatical inflections. Rather, we must organize

<sup>1</sup>In the above problems, one learns a set of  $O(K)$  or  $O(K^2)$  specialized transducers that relate Latin to Italian, singular to plural, etc. We instead use one global mutation model that applies to all names—but see footnote 14 on incorporating specialized transductions (Latin to Italian) within our mutation model.

them into a idiosyncratic phylogenetic tree whose nodes are the string types or tokens themselves.

Names and words are not the only non-biological objects that are copied with mutation. Documents, database records, bibliographic entries, code, and images can evolve in the same way. Reconstructing these relationships has been considered by a number of papers on authorship attribution, near-duplicate detection, deduplication, record linkage, and plagiarism detection. A few such papers reconstruct a phylogeny, as in the case of chain letters (Bennett et al., 2003), malware (Karim et al., 2005), or images (Dias et al., 2012). In fact, the last of these uses the same minimum spanning tree method that we apply in §5.3. However, these papers do not *train* a similarity measure as we do. To our knowledge, these two techniques have not been combined outside biology.

In molecular evolutionary analysis, phylogenetic techniques *have* often been combined with estimation of some parametric model of mutation (Tamura et al., 2011). However, names mutate differently from biological sequences, and our mutation model for names (§4, §8) reflects that. We also posit a specific process (§3) that generates the name phylogeny.

## 2 An Example

A fragment of a phylogeny for person names is shown in Figure 1. Our procedure learned this automatically from a collection of name tokens, without observing any input/output pairs. The nodes of the phylogeny are the observed name types,<sup>2</sup> each one associated with a count of observed tokens.

Each arrow corresponds to a hypothesized mutation. These mutations reflect linguistic processes such as misspelling, initialism, nicknaming, transliteration, etc. As an exception, however, each arrow from the distinguished root node  $\diamond$  generates an initial name for a new entity. The descendants of this initial name are other names that subsequently evolved for that entity. Thus, the child subtrees of  $\diamond$  give a partition of the name types into entities.

Thanks to the phylogeny, the seemingly disparate names Ghareeb Nawaz and Muinuddin Chishti are seen to refer to the same entity. They may be traced back to their common ancestor Khawaja Gharib-

<sup>2</sup>We cannot currently hypothesize unobserved intermediate forms, e.g., common ancestors of similar strings. See §6.2.

Figure 1: A portion of a spanning tree found by our model.

nawaz Muinuddin Hasan Chisty, from which both were derived via successive mutations.

Not shown in Figure 1 is our learned family  $p$  of conditional probability distributions, which models the likely mutations in this corpus. Our EM learning procedure found  $p$  jointly with the phylogeny. Specifically, it alternated between improving  $p$  and improving the distribution over phylogenies. At the end, we extracted the single best phylogeny.

Together, the learned  $p$  and the phylogeny in Figure 1 form an *explanation* of the observed collection of names. What makes it more probable than other explanations? Informally, two properties:

- Each node in the tree is plausibly derived from its parent. More precisely, the product of the edge probabilities under  $p$  is comparatively high. A different  $p$  would have reduced the probability of the events in this phylogeny. A different phylogeny would have involved a more improbable collection of events, such as replacing Chishti with Pynchon, or generating many unrelated copies of Pynchon directly from  $\diamond$ .
- In the phylogeny, the parent names tend to be used often enough that it is plausible for variants of these names to have emerged. Our model says that new tokens are derived from previously generated tokens. Thus—other things equal—Barack Obama is more plausibly a variant of Barack Obama, Jr. than of Barack Obama, Sr. (which has fewer tokens).

### 3 A Generative Model of Tokens

Our model should reflect the *reasons* that name variation exists. A named entity has the form  $y = (e, w)$  where  $w$  is a string being used to refer to entity  $e$ . A

single entity  $e$  may be referred to on different occasions by different name strings  $w$ . We suppose that this is the result of *copying* the entity with occasional *mutation* of its name (as in asexual reproduction).

Thus, we assume the following simple generative process that produces an *ordered sequence* of tokens  $y_1, y_2, \dots$ , where  $y_i = (e_i, w_i)$ .

- After the first  $k$  tokens  $y_1, \dots, y_k$  have been generated, the author responsible for generating  $y_{k+1}$  must choose whom to talk about next. She is likely to think of someone she has heard about often in the past. So to make this choice, she selects one of the previous tokens  $y_i$  uniformly at random, each having probability  $1/(k + \alpha)$ ; or else she selects  $\diamond$ , with probability  $\alpha/(k + \alpha)$ .
- If the author selected a previous token  $y_i$ , then with probability  $1 - \mu$  she copies it faithfully, so  $y_{k+1} = y_i$ . But with probability  $\mu$ , she instead draws a mutated token  $y_{k+1} = (e_{k+1}, w_{k+1})$  from the mutation model  $p(\cdot \mid y_i)$ . This preserves the entity ( $e_{k+1} = e_i$  with probability 1), but the new name  $w_{k+1}$  is a stochastic transduction of  $w_i$  drawn from  $p(\cdot \mid w_i)$ .<sup>3</sup> For example, in referring to  $e_i$ , the author may shorten and respell  $w_i = \text{Khawaja Gharib Nawaz}$  into  $w_{k+1} = \text{Ghareeb Nawaz}$  (Figure 1).
- If the author selected  $\diamond$ , she must choose a fresh entity  $y_{k+1} = (e_{k+1}, w_{k+1})$  to talk about. So she sets  $e_{k+1}$  to a newly created entity, sampling its name  $w_{k+1}$  from the distribution  $p(\cdot \mid \diamond)$ . For example,  $w_{k+1} = \text{Thomas Ruggles Pynchon, Jr.}$  (Figure 1). Nothing prevents  $w_{k+1}$  from being a name that is already in use for another entity (i.e.,  $w_{k+1}$  may equal  $w_j$  for some  $j \leq k$ ).

<sup>3</sup>Straightforward extensions are to allow a variable mutation rate  $\mu(y_i)$  that depends on properties of  $y_i$ , and to allow  $w_{k+1}$  to depend on known properties of  $e_i$ . See footnote 14 for further discussion of enriched tokens.

### 3.1 Relationship to other models

If we ignore the name strings, we can see that the sequence of entities  $e_1, e_2, \dots, e_N$  is being generated from a Chinese restaurant process (CRP) with concentration parameter  $\alpha$ . To the extent that  $\alpha$  is low (so that  $\diamond$  is rarely used), a few randomly chosen entities will dominate the corpus.

The CRP is equivalent to sampling  $e_1, e_2, \dots$  IID from an unknown distribution that was itself drawn from a Dirichlet process with concentration  $\alpha$ . This is indeed a standard model of a distribution over entities. For example, Hall et al. (2008) use it to model venues in bibliographic entries.

From this characterization of the CRP, one can see that any permutation of this entity sequence would have the same probability. That is, our distribution over sequences of *entities*  $e$  is **exchangeable**.

However, our distribution over sequences of *named entities*  $y = (e, w)$  is **non-exchangeable**. It assigns different probabilities to different orderings of the same tokens. This is because our model posits that later authors are influenced by earlier authors, copying entity names from them with mutation. So ordering is important. The mutation process is not symmetric—for example, Figure 1 reflects a tendency to shorten rather than lengthen names.

Non-exchangeability is one way that our present model differs from (parametric) transformation models (Eisner, 2002) and (non-parametric) transformation processes (Andrews and Eisner, 2011). These too are defined using mutation of strings or other types. From a transformation process, one can draw a distribution over types, from which the tokens are then sampled IID. This results in an *exchangeable* sequence of tokens, just as in the Dirichlet process.

We avoid transformation models here for three reasons. (1) Inference is more expensive. (2) A transformation process seems less realistic as a model of authorship. It constructs a distribution over derivational *paths*, similar to the paths in Figure 1. It effectively says that each token is generated by recapitulating some previously used path from  $\diamond$ , but with some chance of deviating *at each step*. For an author to generate a name token this way, she would have to know the whole derivational history of the previous name she was adapting. Our present model instead allows an author simply to select a name she

previously saw and copy or mutate its surface form. (3) One should presumably prefer to explain a novel name  $y$  as a mutation of a *frequent* name  $x$ , other things equal (§2). But surprisingly, inference under the transformation process does not prefer this.<sup>4</sup>

Another view of our present model comes from the literature on random graphs (e.g., for modeling social networks or the link structure of the web). In a *preferential attachment* model, a graph’s vertices are added one by one, and each vertex selects some previous vertices as its neighbors. Our phylogeny is a *preferential attachment tree*, a random *directed* graph in which each vertex selects a *single* previous vertex as its parent. Specifically, it is a *random recursive tree* (Smythe and Mahmoud, 1995) whose vertices are the tokens.<sup>5</sup> To this simple random topology we have added a random labeling process with mutation. The first  $\alpha$  vertices are labeled with  $\diamond$ .

## 4 A Mutation Model for Strings

Our model in §3 samples the next token  $y$ , when it is not simply a faithful copy, from  $p(y | x)$  or  $p(y | \diamond)$ . The key step there is to sample the name string  $w_y$  from  $p(w_y | w_x)$  or  $p(w_y | \diamond)$ .

Our model of these distributions could easily incorporate detailed linguistic knowledge of the mutation process (see §8). Here we describe the specific model that we use in our experiments. Like many such models, it can be regarded as a stochastic finite-state string-to-string transducer parameterized by  $\theta$ .

There is much prior work on stochastic models of edit distance (Ristad and Yianilos, 1998; Bilenko and Mooney, 2003; Oncina and Sebban, 2006; Schafer, 2006a; Bouchard-Côté et al., 2008; Dreyer et al., 2008, among others). For the present experiments, we designed a moderately simple one that employs (1) conditioning on one character of right context, (2) latent “edit” and “no-edit” regions to capture the fact that groups of edits are often made in close proximity, and (3) some simple special handling for the distribution conditioned on the root  $p(w_y | \diamond)$ .

We assume a stochastic mutation process which, when given an input string  $w_x$ , edits it from left to

<sup>4</sup>The very fact that  $x$  has been frequently observed demonstrates that it has often chosen to **stop** mutating. This implies that it is likely to choose **stop** again rather than mutate into  $y$ .

<sup>5</sup>This is not the tree shown in Figure 1, whose vertices are types rather than tokens.

right into an output string  $w_y$ . Then  $p(w_y | w_x)$  is the total probability of all operation sequences on  $w_x$  that would produce  $w_y$ . This total can be computed in time  $O(|w_x| \cdot |w_y|)$  by dynamic programming.

Our process has four character-level edit operations: copy, substitute, insert, delete. It also has a distinguished no-edit operation that behaves exactly like copy. At each step, the process first randomly chooses whether to edit or no-edit, conditioned only on whether the previous operation was an edit. If it chooses to edit, it chooses a random edit type with some probability conditioned on the next input character. In the case of insert or substitute, it then randomly chooses an output character, conditioned on the type of edit *and* the next input character.

It is common to mutate a name by editing contiguous substrings (e.g., words). Contiguous regions of copying versus editing can be modeled by a low probability of transitioning between no-edit and edit regions.<sup>6</sup> Note that an edit region may include some copy edits (or substitute edits that replace a character with itself) without leaving the edit region. This is why we distinguish copy from no-edit.

Input and output strings are augmented with a trailing EOS (“end-of-string”) symbol that is seen by the single-character lookahead. If the next character is EOS, the only available edit is insert. Alternatively, if the process selects no-edit, then EOS is copied to the output string and the process terminates.

In the case of  $p(w_y | \diamond)$ , the input string is empty, and both input and output are augmented with a trailing EOS’ character that behaves like EOS. Then  $w_y$  is generated by a sequence of insertions followed by a copy. These are conditioned as usual on the next character, here EOS’, so the model can learn to insert more or different characters when the input is  $\diamond$ .

The parameters  $\theta$  determining the conditional probabilities of the different operations and characters are estimated with backoff smoothing.

## 5 Inference

The input to inference is a collection of named entity tokens  $y$ . Most are *untagged tokens* of the form  $y = (?, w)$ . In a semi-supervised setting, however, some

<sup>6</sup>This somewhat resembles the traditional affine gap penalty in computational biology (Gusfield, 1997), which makes deletions or insertions cheaper if they are consecutive. We instead make consecutive edits cheaper regardless of the edit type.

of the tokens may be *tagged tokens* of the form  $y = (e, w)$ , whose true entity is known. The entity tags place a constraint on the phylogeny, since each child subtree of  $\diamond$  must correspond to exactly one entity.

### 5.1 An unrealistically supervised setting

Suppose we were lucky enough to fully observe the *sequence* of named entity tokens  $y_i = (e_i, w_i)$  produced by our generative model. That is, suppose all tokens were tagged *and we knew their ordering*.

Yet there would still be something to infer: which tokens were derived from which previous tokens. This phylogeny is described by a spanning tree over the tokens. Let us see how to infer it.

For each potential edge  $x \rightarrow y$  between named entity tokens, define  $\delta(y | x)$  to be the probability of choosing  $x$  and copying it (possibly with mutation) to obtain  $y$ . So

$$\delta(y_j | \diamond) = \alpha p(y_j | \diamond) \quad (1)$$

$$\delta(y_j | y_i) = \mu p(y_j | y_i) + (1 - \mu)\mathbb{1}(y_j = y_i) \quad (2)$$

except that if  $i \geq j$  or if  $e_i \neq e_j$ , then  $\delta(y_j | y_i) = 0$  (since  $y_j$  can only be derived from an *earlier* token  $y_i$  with the *same* entity).

Now the prior probability of generating  $y_1, \dots, y_N$  with a given phylogenetic tree is easily seen to be a product over all tree edges,  $\prod_j \delta(y_j | \text{pa}(y_j))$  where  $\text{pa}(y_j)$  is the parent of  $y_j$ . As a result, it is known that the following are *efficient to compute* from the  $(N + 1) \times (N + 1)$  matrix of  $\delta$  values (see §5.3):

- (a) the max-probability spanning tree
- (b) the total probability of all spanning trees
- (c) the marginal probability of each edge, under the posterior distribution on spanning trees

(a) is our single best guess of the phylogeny. We use this during evaluation. (b) gives the model likelihood, i.e., the total probability of the observed data  $y_1, \dots, y_N$ . To locally maximize the model likelihood, (c) can serve as the E step of our EM algorithm (§6) for tuning our mutation model. The M step then retrains the mutation model’s parameters  $\theta$  on input-output pairs  $w_i \rightarrow w_j$ , weighting each pair by its edge’s posterior marginal probability (c), since that is the expected count of a  $w_i \rightarrow w_j$  mutation. This computation is iterated.

## 5.2 The unsupervised setting

Now we turn to a real setting—fully unsupervised data. Two issues will force us to use an approximate inference algorithm. First, we have an *untagged* corpus: a token’s entity tag  $e$  is never observed. Second, the *order* of the tokens is not observed, so we do not know which other tokens are candidate parents.

Our first approximation is to consider only phylogenies over *types* rather than tokens.<sup>7</sup> The type phylogeny in Figure 1 represents a set of possible token phylogenies. Each node of Figure 1 represents an untagged name type  $y = (?, w)$ . By grouping all  $n_y$  tokens of this type into a single node, we mean that the *first* token of  $y$  was derived by mutation from the parent node, while each *later* token of  $y$  was derived by copying an (unspecified) earlier token of  $y$ .

A token phylogeny *cannot* be represented in this way if two or more tokens of  $y$  were created by mutations. In that case, their name strings are equal only *by coincidence*. They may have different parents (perhaps of different entities), whereas the  $y$  node in a type phylogeny can have only one parent.

We argue, however, that these unrepresentable token phylogenies are comparatively unlikely *a posteriori* and can be reasonably ignored during inference. The first token of  $y$  is necessarily a mutation, but later tokens are much more likely to be copies. The probability of generating a later token  $y$  by copying some previous token is *at least*

$$(1 - \mu)/(N + \alpha),$$

while the probability of generating it in some other way is *at most*

$$\max(\alpha p(y | \diamond), \mu \max_{x \in \mathcal{Y}} p(y | x))$$

where  $\mathcal{Y}$  is the set of observed types. The second probability is typically much smaller: an author is unlikely to invent exactly the observed string  $y$ , certainly from  $\diamond$  but even by mutating a similar string  $x$  (especially when the mutation rate  $\mu$  is small).

How do we evaluate a type phylogeny? Consider the probability of generating untagged tokens

<sup>7</sup>Working over types improves the quality of our second approximation, and also speeds up the spanning tree algorithms. §6 explains how to regard this approximation as variational EM.

$y_1, \dots, y_N$  in that order and respecting the phylogeny:

$$\left( \prod_{k=1}^N \frac{1}{k + \alpha} \right) \prod_{y \in \mathcal{Y}} g(y | \text{pa}(y)) \left( \prod_{i=1}^{n_y-1} i (1 - \mu) \right) \quad (3)$$

where  $g(y | \text{pa}(y))$  is a factor for generating the *first* token of  $y$  from its parent  $\text{pa}(y)$ , defined by

$$g(y | \diamond) = \alpha \cdot p(y | \diamond) \quad (4)$$

$$g(y | x) = \mu \cdot (\# \text{ tokens of } x \text{ preceding first token of } y) \cdot p(y | x) \quad (5)$$

But we do not actually know the token order: by assumption, our input corpus is only an *unordered* bag of tokens. So we must treat the hidden ordering like any other hidden variable and maximize the *marginal* likelihood, which sums (3) over all *possible* orderings (permutations). This sum can be regarded as the number of permutations  $N!$  (which is fixed given the corpus) times the expectation of (3) for a permutation chosen uniformly at random.

This leads to our second approximation. We approximate this expectation of the product (3) with a product of expectations of its individual factors.<sup>8</sup> To find the expectation of (5), observe that the *expected* number of tokens of  $x$  that precede the first token of  $y$  is  $n_x/(n_y + 1)$ , since each of the  $n_x$  tokens of  $x$  has a  $1/(n_y + 1)$  chance of falling before all  $n_y$  tokens of  $y$ . It follows that the approximated probability of generating all tokens in *some* order, with our given type parentage, is *proportional to*

$$\prod_{y \in \mathcal{Y}} \delta(y | \text{pa}(y)) \quad (6)$$

where

$$\delta(y | \diamond) = \alpha \cdot p(y | \diamond) \quad (7)$$

$$\delta(y | x) = \mu \cdot p(y | x) \cdot n_x/(n_y + 1) \quad (8)$$

and the constant of proportionality depends on the corpus.

The above equations are analogous to those in §5.1. Again, the approximate posterior probability of a given type parentage tree is *edge-factored*—it is the product of individual edge weights defined by  $\delta$ . Thus, we are again eligible to use the spanning tree algorithms in §5.3 below.

<sup>8</sup>In general this is an overestimate for each phylogeny.

Notice that the ratio  $\alpha/\mu$  controls the preference for an entity to descend from  $\diamond$  versus an existing entity. Thus, by tuning this ratio, we can control the number of entities inferred by our method, where each entity corresponds to one of the child subtrees of  $\diamond$ .

Also note that  $n_x$  in the numerator of (8) means that  $y$ 's parent is more likely to be frequent. Also,  $n_y + 1$  in the denominator means that a frequent  $y$  is not as likely to have any parent  $x \neq \diamond$ , because its first token probably falls early in the sequence where there are fewer available parents  $x \neq \diamond$ .

### 5.3 Spanning tree algorithms

Define a complete directed graph  $G$  over the vertices  $\mathcal{Y} \cup \{\diamond\}$ . The weight of an edge  $x \rightarrow y$  is defined by  $\delta(y | x)$ . The (approximate) posterior probability of a given phylogeny given our evidence, is proportional to the product of the  $\delta$  values of its edges.

Formally, let  $\mathcal{T}_\diamond(G)$  denote the set of spanning trees of  $G$  rooted at  $\diamond$ , and define the weight of a particular spanning tree  $T \in \mathcal{T}_\diamond(G)$  to be the product of the weights of its edges:

$$w(T) = \prod_{(x \rightarrow y) \in T} \delta(y | x) \quad (9)$$

Then the posterior probability of spanning tree  $T$  is

$$p_\theta(T) = \frac{w(T)}{Z(G)} \quad (10)$$

where  $Z(G) = \sum_{T \in \mathcal{T}_\diamond(G)} w(T)$  is the partition function, i.e. the total probability of generating the data  $G$  via any spanning tree of the form we consider. This distribution is determined by the parameters  $\theta$  of the transducer  $p_\theta$ , along with the ratio  $\alpha/\mu$ .

There exist several algorithms to find the single maximum-probability spanning tree, notably Tarjan's implementation of the Chu-Liu-Edmonds algorithm, which runs in  $O(m \log n)$  for a sparse graph or  $O(n^2)$  for a dense graph (Tarjan, 1977). Figure 1 shows a spanning tree found by our model using Tarjan's algorithm. Here  $n$  is the number of vertices (in our case, types and  $\diamond$ ), while  $m$  is the number of edges (which we can keep small by pruning, §6.1).

## 6 Training the Transducer with EM

Our inference algorithm assumes that we know the transducer parameters  $\theta$ . We now explain how to op-

imize  $\theta$  to maximize the marginal likelihood of the training data. This marginal likelihood sums over all the other latent variables in the model—the spanning tree, the alignments between strings, and the hidden token ordering.

The EM procedure repeats the following until convergence:

**E-step:** Given  $\theta$ , compute the posterior marginal probabilities  $c_{xy}$  of all possible phylogeny edges.

**M-step** Given all  $c_{xy}$ , retrain  $\theta$  to assign a high conditional probability to the mutations on the probable edges.

We actually use a variational EM algorithm: our E step approximates the true distribution  $q$  over all phylogenies with the closest distribution  $p$  that assigns positive probability only to type-based phylogenies. This distribution is given by (10) and minimizes  $\text{KL}(p || q)$ . We argued in section §5.2 that it should be a good approximation. The posterior marginal probability of a directed edge from vertex  $x$  to vertex  $y$ , according to (10), is

$$c_{xy} = \sum_{T \in \mathcal{T}_\diamond(G): (x \rightarrow y) \in T} p_\theta(T) \quad (11)$$

The probability  $c_{xy}$  is a ‘‘pseudocount’’ for the expected number of mutations from  $x$  to  $y$ . This is at most 1 under our assumptions.

Calculating  $c_{xy}$  requires summing over all spanning trees of  $G$ , of which there are  $n^{n-2}$  for a fully connected graph with  $n$  vertices. Fortunately, Tutte (1984) shows how to compute this sum by the following method, which extends Kirchhoff's classical matrix-tree theorem to weighted directed graphs. This result has previously been employed in non-projective dependency parsing (Koo et al., 2007; Smith and Smith, 2007).

Let  $\mathbf{L} \in \mathbb{R}^{n \times n}$  denote the Laplacian of  $G$ , namely

$$\mathbf{L} = \begin{cases} \sum_{x'} \delta(y | x') & \text{if } x = y \\ -\delta(y | x) & \text{if } x \neq y \end{cases} \quad (12)$$

Tutte's theorem relates the determinant of the Laplacian to the spanning trees in graph  $G$ . In particular, the cofactor  $\mathbf{L}^{0,0}$  is equal to the sum of the weights

of all directed spanning trees rooted at 0, which (supposing  $\diamond$  is indexed at 0) yields the partition function  $Z(G)$ .

The edge marginals of interest are related to the log partition function by

$$c_{xy} = \frac{\partial Z(G)}{\partial \delta(y | x)} \quad (13)$$

which has the closed-form solution

$$c_{xy} = \begin{cases} \delta(y | \diamond) \mathbf{L}_{yy}^{-1} & \text{if } x = y \\ \delta(y | x) (\mathbf{L}_{xx}^{-1} - \mathbf{L}_{xy}^{-1}) & \text{if } x \neq y \end{cases} \quad (14)$$

Thus, the problem of computing edge marginals reduces to that of computing a matrix inverse, which may be done in  $O(n^3)$  time.

At the M step, we retrain the mutation model parameters  $\theta$  to maximize  $\sum_{xy} c_{xy} \log p(w_y | w_x)$ . This is tantamount to maximum conditional likelihood training on a supervised collection of  $(w_x, w_y)$  pairs that are respectively weighted by  $c_{xy}$ .

The M step is nontrivial because the term  $p(w_y | w_x)$  sums over a hidden alignment between two strings. It may be performed by an inner loop of EM, where the E step uses dynamic programming to efficiently consider all possible alignments, as in (Ristad and Yianilos, 1996). In practice, we have found it effective to take only a single step of this inner loop. Such a Generalized EM procedure enjoys the same convergence properties as EM, but may reach a local optimum faster (Dempster et al., 1977).

## 6.1 Pruning the graph

For large graphs, it is essential to prune the number of edges to avoid considering all  $n(n - 1)$  input-output pairs. To prune the graph, we eliminate all edges between strings that do not share any common trigrams (case- and diacritic-insensitive), by setting their matrix entries to 0. As a result, the graph Laplacian is a sparse matrix, which often allows faster matrix inversion using preconditioned iterative algorithms. Furthermore, pruned edges do not appear in any spanning tree, so the E step will find that their posterior marginal probabilities are 0. This means that the input-output pairs corresponding to these edges can be ignored when re-estimating the transducer parameters in the M step. We found that prun-

ing significantly improves training time with no appreciable loss in performance.<sup>9</sup>

## 6.2 Training with unobserved tokens?

A deficiency of our method is that it assumes that authors of our corpus have *only* been exposed to previous tokens in our corpus. In principle, one could also train with  $U$  additional tokens  $(e, w)$  where we observe neither  $e$  nor  $w$ , for very large  $U$ . This is the “universe of discourse” in which our authors operate.<sup>10</sup> In this case, we would need (expensive) new algorithms to reconstruct the strings  $w$ . However, this model could infer a more realistic phylogeny by positing unobserved ancestral or intermediate forms that relate the observed tokens, as in transformation models (Eisner, 2002; Andrews and Eisner, 2011).

## 7 Experimental Evaluation

### 7.1 Data preparation

**Scraping Wikipedia.** Wikipedia documents many variant names for entities. As a result, it has frequently been used as a source for mining name variations, both within and across languages (Parton et al., 2008; Cucerzan, 2007). We used Wikipedia to create a list of name aliases for different entities. Specifically, we mined English Wikipedia<sup>11</sup> for all redirects: page names that lead directly to another page. Redirects are created by Wikipedia users for resolving common name variants to the correct page. For example, the pages titled Barack Obama Junior and Barack Hussein Obama automatically redirect to the page titled Barack Obama. This redirection implies that the first two are name variants of the third. Collecting all such links within English Wikipedia yields a large number of aliases for each page. However, many redirects are for topics other than individual people, and these would be poor examples of name variation. In addition, some phrases

<sup>9</sup>For instance, on a dataset of approximately 6000 distinct names, pruning reduced the number of outgoing edges at each vertex to fewer than 100 per vertex.

<sup>10</sup>Notice that the  $N$  observed tokens would be approximately exchangeable in this setting: they are unlikely to depend on one another when  $N \ll U$ , and hence their order no longer matters much. In effect, generating the  $U$  hidden tokens constructs a rich distribution (analogous to a sample from the Dirichlet process) from which the  $N$  observed tokens are then sampled IID.

Figure 2: Sample alias lists scraped from Wikipedia. Note that only partial alias lists are shown for space reasons.

that redirect to an entity are descriptions rather than names. For example, 44th President of the United States also links to Barack Obama, but it is not a name variant.

**Freebase filtering.** To improve data quality we used Freebase, a structured knowledge base that incorporates information from Wikipedia. Among its structured information are entity types, including the type “person.” We filtered the Wikipedia redirect collection to remove pairs where the target page was not listed as a person in Freebase. Additionally, to remove redirects that were not proper names (44th President of the United States), we applied a series of rule based filters to remove bad aliases: removing numerical names, parentheticals after names, quotation marks, and names longer than 5 tokens, since we found that these long names were rarely person names (e.g. United States Ambassador to the European Union, Success Through a Positive Mental Attitude which links to the author Napoleon Hill.) While not perfect, these modifications dramatically improved quality. The result was a list of 78,079 different person entities, each with one or more known names or aliases. Some typical names are shown in Figure 2.

**Estimating empirical type counts.** Our method is really intended to be run on a corpus of string tokens. However, for experimental purposes, we instead use the above dataset of string *types* because this allows us to use the “ground truth” given by the Wikipedia redirects. To synthesize token counts, empirical token frequencies for each type were estimated from the LDC Gigaword corpus,<sup>12</sup> which is a corpus of newswire text spanning several years. Wikipedia name types that did not appear in Gigaword were assigned a “backoff count” of one. Note that by virtue of the domain, many misspellings will

<sup>12</sup>LDC Catalog No. LDC2003T05.

not appear; however, edges “popular” names (which may be canonical names) will be assigned higher weight.

## 7.2 Experiments

We begin by evaluating the generalization ability of a transducer trained using a transformation model. To do so, we measure log-likelihood on held-out entity title and alias pairs. We then verify that the generalization ability according to log-likelihood translates into gains for a name matching task. For the experiments in this section, we use  $\alpha = 0.9$  and  $\mu = 0.1$ .<sup>13</sup>

**Held-out log-likelihood.** We construct pairs of entity title (input) and alias (output) names from the Wikipedia data. For different amounts of supervised data, we trained the transformation model on the training set, and plotted the log-likelihood of held-out test data for the transducer parameters at each iteration of EM. The held-out test set is constructed from a disjoint set of Wikipedia entities, the same number of entities as in the training set. We used different corpora of 1000 and 1500 entities for train and test.

**Name matching.** For each alias  $a$  in a test set (not seen at training time), we produce a ranking of test entity titles  $t$  according to transducer probabilities  $p_{\theta}(a | t)$ . A good transducer should assign high probability to transformations from the correct title for the alias. Mean reciprocal rank (MRR) is a commonly used metric to estimate the quality of a ranking, which we report in Figure 4. The reported mean is over all aliases in the test data. In addition to evaluating the ranking for different initializations of our transducer, we compare to two baselines: Levenshtein distance and Jaro-Winkler similarity. Jaro-Winkler is a measure on strings that was specifically designed for record linkage (Winkler, 1999). The

<sup>13</sup>We did not find these parameters to be sensitive.

(a) 1000 entities.

(b) 1500 entities.

Figure 3: Learning curves for different initializations of the transducer parameters. Above, “sup=100” (for instance) means that 100 entities were used as training data to initialize the transducer parameters (constructing pairs between all title-alias pairs for those Wikipedia entities).

Figure 4: Mean reciprocal rank (MRR) results for different training conditions: “sup10” means that 10 entities (roughly 40 name pairs) were used as training data for the transducer; “semi10” means that the “sup10” model was used as initialization before re-estimating the parameters using our model; “unsup” is the transducer trained using our model without any initial supervision; “sup” is trained on all 1500 entities in the training set (an upper bound on performance); “jwink” and “lev” correspond to Jaro-Winkler and Levenshtein distance baselines.

matching experiments were performed on a corpus of 1500 entities (with separate corpora of the same size for training and test).

## 8 Conclusions and Future Work

We have presented a new unsupervised method for learning string-to-string transducers. It learns from a collection of related strings whose relationships are unknown. The key idea is that some strings are mutations of common strings that occurred earlier. We compute a distribution over the unknown phylogenetic tree that relates these strings, and use it to rees-

timate the transducer parameters via EM.

One direction for future work would be more sophisticated transduction models than the one we developed in §4. For names, this could include learning common nicknames (nonparametrically); explicitly modeling abbreviation processes such as initials; conditioning on name components such as title and middle name; and transliterating across languages.<sup>14</sup> In other domains, one could model bibliographic entry propagation, derivational morphology, or historical sound change (again using language tags).

Another future direction would be to incorporate the context of tokens in order to help reconstruct which tokens are coreferent. For example, we might extend the generative story to generate a context for token  $(e, w)$  conditioned on  $e$ . Combining contextual similarity with string similarity has previously proved very useful for identifying cognates (Schafer and Yarowsky, 2002; Schafer, 2006b; Bergsma and Van Durme, 2011). In our setting it would help to distinguish people with identical names, as well as determining whether two people with similar names are really the same.

<sup>14</sup>These last two points suggest that the mutation model should operate not on simple (entity, string) pairs, but on richer representations in which the name has been parsed into its components (Eisenstein et al., 2011), labeled with a language ID, and perhaps labeled with a phonological pronunciation. These additional properties of a named entity may be either observed or latent in training data. For example, if  $w_y$  and  $\ell_y$  denote the string and language of name  $y$ , then define  $p(y | x) = p(\ell_y | \ell_x) \cdot p(w_y | \ell_y, \ell_x, w_x)$ . The second factor captures transliteration from language  $\ell_x$  to language  $\ell_y$ , e.g., by using §4’s model with an  $(\ell_x, \ell_y)$ -specific parameter setting.

## Abstract

We present results of a novel experiment to investigate speech production in conversational data that links speech rate to information density. We provide the first evidence for an association between syntactic surprisal and word duration in recorded speech. Using the AMI corpus which contains transcriptions of focus group meetings with precise word durations, we show that word durations correlate with syntactic surprisal estimated from the incremental Roark parser over and above simpler measures, such as word duration estimated from a state-of-the-art text-to-speech system and word frequencies, and that the syntactic surprisal estimates are better predictors of word durations than a simpler version of surprisal based on trigram probabilities. This result supports the uniform information density (UID) hypothesis and points a way to more realistic artificial speech generation.

## 1 Introduction

The uniform information density (UID) hypothesis suggests that speakers try to distribute information uniformly across their utterances (Frank and Jaeger, 2008). Information density can be measured in terms of the surprisal incurred at each word, where surprisal is defined as the negative log-probability of an event. This paper sets out to test whether UID holds across different linguistic levels, i.e. whether speakers adapt word duration during production to syntactic surprisal, such that words with higher surprisal have longer durations than words with lower surprisal. We investigate this question in a corpus

of transcribed speech from a mix of native and non-native English speakers, a population that is a non-trivial component of the user base for language technologies developed for English. This data reflects a casual, uncontrolled conversational environment.

Using linear mixed-effects modeling, we found that syntactic surprisal as calculated from a top-down incremental PCFG parser accounts for a significant amount of variation in spoken word duration, using an HMM-trained text-to-speech system as a baseline. The findings of this paper provide additional support the uniform information density hypothesis and furthermore have implications for the design of text-to-speech systems, which currently do not take into account higher-level linguistic information such as syntactic surprisal (or even word frequencies) for their word duration models.

### 1.1 Related work

The use of word-level surprisal as a predictor of processing difficulty is based on the notion that processing difficulty results when a word is encountered that is unexpected given its preceding context. The amount of surprisal on a word  $w_i$  can be formalized as the log of the inverse conditional probability of  $w_i$  given the preceding words in the sentence  $w_1 \dots w_{i-1}$ , or  $-\log P(w_i|w_{1..i-1})$ . If this probability is low, then the word is unexpected, and surprisal is high. Surprisal can be estimated in different ways, e.g. from word sequences (n-grams) or with respect to the possible syntactic structures covering a sentence prefix (see Section 4).

Hale (2001) showed that surprisal calculated from a probabilistic Earley parser correctly predicts well-

known processing phenomena that were believed to emerge from structural ambiguities (e.g., garden paths) and Levy (2008) further demonstrated the relevance of surprisal to human sentence processing difficulty on a range of syntactic processing difficulty phenomena.

There is existing work in correlating information-theoretic measures of linguistic redundancy to the observed duration of speech units. Aylett and Turk (2006) demonstrate that the contextual predictability of a syllable (n-gram log probability) has an inverse relationship to syllable duration in speech. Their experiments were performed using a carefully articulated speech synthesis training corpus.

This type of work fits into a larger programme of understanding how speakers schedule utterances to avoid high variation in the transmission of linguistic information over time, also known as the Uniform Information Density (UID) hypothesis (Florian Jaeger, 2010). Levy and Jaeger (2007) show that the reduction of optional *that*-complementizers in English is related to trigram surprisal; low surprisal predicts a high likelihood of reduction. Florian Jaeger (2010) shows the same result of increased reduction when the complementizer is more predictable according to information density calculated in terms of the main verb's subcategorization frequency.

Frank and Jaeger (2008) provide evidence that a UID account can predict the use of reduced forms of “be”, “have”, and “not” in English. They use the surprisal of the candidate word itself as well as surprisals of the word before and after, computing bigram and trigram estimates directly from the corpus without smoothing or backoff.

Jurafsky et al. (2001) report a corpus study similar to ours, showing that words that are more predictable from context are reduced. As measures of word predictability, they use bigram and trigram models, as well as joint probabilities, but not syntactic surprisal.

Within the same theme of utterance duration vs. information content, Piantadosi et al. (2011) performed a study using Google-derived n-gram datasets on the lexica of multiple languages, including English, Portuguese, and Czech. For every word in a given language's lexicon, they calculated 2-, 3-, and 4-gram surprisal values using the Google dataset

for every occurrence of the word, and then they took the mean surprisal for that word over all occurrences. The 3-gram surprisal values in particular were a better predictor of orthographic length than unigram frequency, providing evidence for the use of information content and contextual predictability as improvement over a Zipf's Law view of communicative efficiency. This is an n-gram approach to supporting the UID hypothesis.

However, there is some counter-evidence for the UID-based view. Kuperman et al. (2007) analyzed the relationship between linguistic unit predictability and syllable duration in read-aloud speech in Dutch. Dutch makes use of interfix morphemes *-s-* and *-e(n)-* in certain contexts to make compound nouns, preferring a null interfix in most cases. For example, the Dutch noun *kandidaatsexamen* (“Bachelor's examination”) is composed of *kandidaat-*, *-s-*, and *-examen*.

Kuperman et al. find that the greater the predictability of the interfix from the morphological context (i.e., the surrounding members of the compound), the *longer* the duration of the pronunciation of the interfix. To illustrate, if *-s-* is more expected after *kandidaat* or if *kandidaatsexamen* is a frequent compound, we would therefore expect the *-s-* to be pronounced longer, given the correlations they found. Their finding runs counter to a strong view of UID's fine-grained control over speech rate, but it is focused on the morphological level. They hypothesize that this counter-intuitive result may be driven by complex paradigmatic constraints in the choice of morpheme.

Our work, however, focuses on the syntactic level rather than the paradigmatic. What we seek to answer in our work is the extent to which an information density-based analysis can not only be applied to real speech data in context but also be derived from higher-level syntactic analyses, a combination hitherto little explored. Existing broad-coverage work on syntactic surprisal has largely focused on comprehension phenomena, such as Demberg and Keller (2008), Roark et al. (2009), and Frank (2010). We provide a production study in a vein similar to that of Kuperman et al., but show that frequency effects work in the expected direction at the syntactic level. This in turn expands upon the view supported by n-gram-based work such as that

of Piantadosi et al. (2011); Levy and Jaeger (2007); Jurafsky et al. (2001), showing that information content above the n-gram level is important in guiding spoken language production in humans.

## 1.2 Implications for Potential Applications

Spoken dialogue systems are of increasing economic and technological importance in recent times, particularly as it is now feasible to include this technology in everything from small consumer devices to industrial equipment. With this increase in importance, there is also unsurprisingly growing scientific emphasis in understanding its usability and safety characteristics. Recent work (Fang et al., 2009; Taube-Schiff and Segalowitz, 2005) has shown that linguistic information presentation has an effect on user behaviour, but the overall granularity of this behaviour is still not well-understood.

Other potential applications exist in any place where text-to-speech technologies can be applied, such as in real-time spoken machine translation and communications systems for the disabled.

In demonstrating that we can observe speakers behaving in the manner predicted by the UID hypothesis in conversational contexts, we provide evidence for a finer-level of granularity necessary for controlling the rate of information presentation in artificial systems.

## 1.3 AMI corpus

The Augmented Multi-Party Interaction (AMI) corpus is a collection of recorded, transcribed conversations spanning 100 hours of simulated meetings. The corpus contains a number of data streams including speech, video, and whiteboard writing. Transcription of the meetings was performed manually, and the transcripts contain word-level time bounds that were produced by an automatic speech recognition system.

The freely-available AMI corpus is one of a very small number of efforts that contain orthographic transcriptions that are time-aligned at a word level. We chose it for the realism of the setting in which it was recorded; the physical presence of multiple speakers in an unstructured discussion reflects a potentially high level of noise in which we would be looking for surprisal correspondences, potentially

increasing the application value of the correspondences we find.

## 1.4 Organization

The remainder of this paper proceeds as follows. In section 2, we describe at a high level the procedure we used to test our hypothesis that parser-derived surprisal values can partly account for utterance-duration variation. Then (section 3.2) we discuss the MARY text-to-speech system, from which we derive “canonical” word utterance durations. We describe the way we process and filter the AMI meeting corpus in section 3.1. In section 4, we describe in detail our predictors, frequency counts, trigram surprisal, and Roark parser surprisal. Sections 5 and 6 describe how we use linear mixed effects modeling to find significant correlations between our predictors and the response variable, and we finally make some concluding remarks in section 7.

## 2 Design

The overall design of our experiment is schematically depicted in Figure 1. We extract the words and the word-by-word timings from the AMI corpus, keeping track of each word’s position in the corpus by conversation ID, speaker turn, and chronological order. As we describe in the next section, we filter the words for anomalies.

After pre-processing, for each word in the corpus, we extract the following predictors: canonical speech durations from the MARY text-to-speech system, logarithmic word frequencies, n-gram surprisal, and surprisal values produced by the Roark (2001a); Roark et al. (2009) parser (see Section 4). The next sections describe how and from where these values are obtained<sup>1</sup>.

Finally, we run mixed effects regression model analyses (Baayen et al., 2008) with the observed durations as a response variable and the predictors mentioned above in order to detect whether syntactic surprisal is a significant positive predictor of spoken word durations above and beyond the more basic effects of canonical word duration and word frequency.

---

<sup>1</sup>We will make this data widely available upon publication.

Figure 1: Schematic overview of experiment.

### 3 Experimental materials

#### 3.1 Corpus preparation

The AMI corpus is provided in the NITE XML Toolkit (NXT) format. We developed a custom interpreter to assemble the relevant data streams: words, meeting IDs, speaker IDs, speaker turns, and observed word durations.

In addition to grouping and re-ordering the information found in the original XML corpus, two more steps were taken to eliminate confounding noise from the data. Non-words (e.g. “uhm”, “uh-hmm”, etc.) were filtered out, as were incomplete words or incorrectly transcribed words (e.g. “recogn”, “some-thi”, etc); the criterion for rejection was presence in the English Gigaword corpus with subsequent minor corrections by hand, e.g., mapping unseen verbs

back into the corpus and correcting obvious common misspellings.<sup>2</sup>

Finally, turns that did not make for complete sentences, e.g., utterances that were interrupted in mid-

<sup>2</sup> A reviewer asks about the extent to which our Gigaword filtering process may remove words we might want to keep but admit words we want to reject. As Gigaword is mostly newswire text, we do not expect the latter case to hold often. AMI is hand-transcribed and uses consistent spellings for non-word interjections (easy to remove), and any spelling mistakes would have to coincide exactly with a Gigaword mistake.

The other way around (rejecting what should be allowed) is easier to check, and we find that of 13K word types in AMI, about 7.2% are rejected for non-appearance in Gigaword, after filtering for interjections like “mm-hmm”. However, we manually checked them and returned all but 2.9% of word types to the corpus. These tend to be very low-frequency types. The manual check suggests that ultimately there would be few false rejections.

sentence, were filtered out in order to maximize the proportion of complete parses in surprisal calculation.

### 3.2 Word duration model

In order to investigate whether there is an association between high/low surprisal and increased/decreased word duration, one needs to have a baseline measure of what constitutes the “canonical” duration of each word—in other words, to account for the fact that some words have longer pronunciations than others. As one reviewer notes, one way of estimating word durations would be to calculate the average duration of each word in the corpus. However, this approach would be insensitive to the phonological, syllabic and phrasal context that a word occurs in, which can have a large effect on word duration. Therefore, we use word duration estimates from the state-of-the-art open-source text-to-speech system MARY (Schröder et al., 2008, version 4.3.1), with the default voice package included in this version (`cmu-slt-hsmm`).

The `cmu-slt-hsmm` voice package uses a Hidden Markov model, trained on the female US English section of the CMU ARCTIC database (Kominek and Black, 2003), to predict prosodic attributes of each individual synthesized phone, including duration. Training was carried out using a version of the HTS system (Zen et al., 2007), modified for using the MARY context features (Schröder et al., 2008) for estimating the parameters of the model and for decoding. Those features include<sup>3</sup>:

- phonological features of the current and neighboring phonemes
- syllabic and lexical features (e.g. syllable stress, (estimated) part-of-speech, position of syllable in word)
- phrasal / sentential features (e.g. sentence/phrase boundaries, neighboring pauses and punctuation)

For each word in the AMI corpus, we obtained two alternative estimates of word duration:

<sup>3</sup>For further information about how HMM-based voices for MARY TTS are trained, see <http://mary.opendfki.de/wiki/HMMVoiceCreation>

one version which is independent of a word’s sentential context, and a second version which does take into account the sentential context (such as phrasal/sentential and across-word-boundaries phonological features) the word occurs in. In other words, we obtain MARY word duration estimates in the second version by running individual whole sentences through MARY, segmented by standard punctuation marks used in the AMI corpus transcriptions. For each version, we obtained phone durations using MARY and calculate the total duration of a word as the sum of the estimated phone durations for that word. These durations serve as the “canonical” baselines to which the observed durations of the words in the AMI corpus are compared.

### 3.3 Word frequency baselines

In order to account for the effects of simple word frequency on utterance duration, we extracted two types of frequency counts. One was taken directly from the AMI corpus alone. The other was taken from a 151 million-word (4.3 million full-paragraph) sample of the English Gigaword corpus. These came from the following newswire sources: Agence France Press, Associated Press Worldstream, New York Times Newswire, and the Xinhua News Agency English Service. These sources are organized by month-of-year. We selected the subset of Gigaword by randomly selecting month-of-year files from those sources with uniform probability. Punctuation was stripped from the beginnings and ends of words before taking the frequency counts.

## 4 Surprisal models

For predicting the surprisal of utterances in context, two different types of models were used— n-gram probabilities models, as well as Roark’s 2001 incremental top-down parser capable of calculating prefix probabilities. We also estimated word frequencies to account for words being spoken more quickly due to their higher frequency which is independent of structural surprisal.

The n-gram probabilities models, while being fast in both training and application, inherently capture very limited contextual influences on surprisal. The full-fledged parser, on the other hand, quantifies sur-

prisal based in the prefix probability of the complete sentence prefix and captures long-distance effects by conditioning on c-commanding lexical items as well as non-local node labels such as parents, grandparents and siblings from the left context.

**CMU n-grams** We used the CMU Statistical Natural Language Modeling Toolkit to provide a convenient way to calculate n-grams probabilities. For the prediction of surprisal, we calculated 3-gram models, 4-gram models and 5-gram models with Witten-Bell smoothing. Different n-gram models were trained on the full Gigaword corpus, as well as the AMI corpus.

To avoid overfitting, the AMI text corpus was split into 10 sub-corpora of equal word counts, preserving coherence of meetings. N-gram probabilities were then calculated for each of the sub-corpora using models trained on the 9 others.

We also produced a trigram model using the text of chapter 2–21 of the Penn Treebank’s (PTB) underlying Wall Street Journal corpus. This consists of approximately one million tokens. We generated this model because it is the underlying training data for the Roark parser, described below.

**Syntactic Surprisal from Roark parser** In order to capture the effect of syntactically expected vs. unexpected events, we can calculate the syntactic surprisal of each word in a sentence. The syntactic surprisal at word  $S_{w_i}$  is defined as the difference between the prefix probability at word  $w_i$  and the prefix probability at word  $w_{i-1}$ . The prefix probability at word  $w_i$  is the sum of the probabilities of all trees  $T$  spanning words  $w_1 \dots w_i$ ; see also (Levy, 2008; Demberg and Keller, 2008).

$$S_{w_i} = \log \sum_T P(T, w_1..w_{i-1}) - \log \sum_T P(T, w_1..w_i)$$

The top-down incremental Roark parser (Roark, 2001a) has the characteristic that all partial left-to-right parses are *rooted*: they form a single tree with one root. A set of heuristics ensures that rule application occurs only through node expansion within the connected structure.<sup>4</sup> The grammar-derived prefix probabilities of a given sentence prefix can there-

<sup>4</sup>The formulae for the calculation of the prefix probabilities from the PCFG rules can be found in Roark et al. (2009).

Figure 2: Top-ranked partial parse of *A puppy is to a dog what a kitten is to a cat.*, stopping at the second *a* and providing the Roark parser surprisal values by word. The branch with dashed lines and struck-out symbols represents an analysis abandoned at the appearance of the *a*.

fore be calculated directly by multiplying the probabilities of all rules used to generate the prefix tree. The Roark parser shares this characteristic of generating fully connected structures with Earley parsers (Earley, 1970) and left corner parsers (Rosenkrantz and II, 1970).

The Roark parser uses a beam search. As the amount of probability mass lost has been shown to be small (Roark, 2001b), the surprisal estimates can be assumed to be a good approximation. The beam width of the parser search is controlled by a “base parsing threshold”, which defines the distance in terms of natural log-probability between the most probable parse and the least probable parse within the beam. For the experiments reported here, the parsing beam was set to 21 (default setting is 12). A wider beam also reduces the effects of pruning.

The parser was trained on Wall Street Journal sections 2–21 and applied to parse the full sentences of the AMI corpus, collecting predicted surprisal at each word (see Figure 2 for an example).

The syntactic surprisal can be furthermore be decomposed into a structural and a lexical part: sometimes, high surprisal might be due to a word being incompatible with the high-probability syntactic structures, other times high surprisal might just be due to a lexical item being unexpected. It is inter-

esting to evaluate these two aspects of syntactic surprisal separately, and the Roark parser conveniently outputs both surprisal estimates. Structural surprisal is estimated from the occurrence counts of the application of syntactic rules during the parse discounting the effect of lexical probabilities, while lexical surprisal is calculated from the probabilities of the derivational step from the POS-tag to lexical item.

## 5 Linear mixed effects modelling

In order to test whether surprisal estimates correlate with speech durations, we use linear mixed effects models (LME, Pinheiro and Bates (2000)). This type of model can be thought of as a generalization of linear regression that allows the inclusion of random factors as well as fixed factors. We treat speakers as a random factor, which means that our models contain an intercept term for each speaker, representing the individual differences in speech rates. Furthermore, we include a random slope for the predictors (e.g. frequency, canonical duration, surprisal), essentially accounting for idiosyncrasies of a participant with respect to the predictor, such that only the part of the variance that is common to all participants and is attributed to that predictor.

In a first step, we fit a baseline model with all predictors related to a word's canonical duration and its frequency as well as their random slopes to the observed word durations. Models with more than two random slopes generally did not converge. We therefore included in the baseline model only the two best random slopes (in terms of model fit). We then calculated the residuals of that model, the part of the observed word durations that cannot be accounted for through canonical word durations or word frequency.

For each of our predictors of interest (n-gram surprisal, syntactic surprisal), we then fit another linear mixed-effects model with random slopes to the residuals of the baseline model. This two-step procedure allows us to make sure to avoid problems of collinearity between e.g. surprisal and word frequency or canonical duration. A simpler (but less conservative) method is to directly add the predictors of interest to the baseline model. Results for both modelling variants lead to the same conclusions for our model, so we here report the more conserva-

tive two-step model. We compare models based on the Akaike Information Criterion (AIC).

## 6 Results

Our baseline model uses speech durations from the AMI corpus as the response variable and canonical duration estimates from the MARY TTS system and log word frequencies as predictors. We exclude from the analysis all data points with zero duration (effectively, punctuation) or a real duration longer than 2 seconds. Furthermore, we exclude all words which were never seen in Gigaword and any words for which syntactic surprisal couldn't be estimated. This leaves us with 771,234 out of the 799,997 data points with positive duration.

**MARY duration models** As mentioned in the earlier sections, we have calculated different versions of the MARY estimated word durations: one model without the sentential context and one model with the sentential context. In our regression analyses, we find, as expected, that the model which includes sentential context achieves a much better fit with the actually measured word durations from the AMI corpus (AIC = 32167) than the model without context (AIC = 70917).

**Word frequency estimates** We estimated word frequencies from several different resources, from the AMI corpus to have a spoken domain frequency and from Gigaword as a very large resource. We find that both frequency estimates significantly improve model fit over a model that does not contain frequency estimates. Including both frequency estimates improves model fit with respect to a model that includes just one of the predictors (all  $p < 0.0001$ ).

Furthermore, including into the regression an interaction of estimated word duration and word frequency also significantly increases model fit ( $p < 0.0001$ ). This means that words which are short and frequent have longer duration than would be estimated by adding up their length and frequency effects.

**Baseline model** Fixed effects of the fitted model are shown in Table 2. We see a highly significant effect in the expected direction for both the canonical duration estimate and word frequency. The positive

coefficient for MARY\_CONTEXT means that TTS duration estimates are positively correlated with the measured word durations. The negative coefficient for WORDFREQUENCY means that more frequent words are spoken faster than less frequent words. Finally, the negative coefficient for the interaction between word durations and frequencies means that the duration estimate for short frequent and long infrequent words is less extreme than otherwise predicted by the main effects of duration and frequency.

Srprsl	.29	.40	.48	-.71	-.73	-.50	.50	.73

Table 1: Correlations (pearson) of model predictors.

Note though that the predictors are also correlated (for correlations of the main predictors used in these analyses, see Table 1), so there is some collinearity in the below model. Since we are less interested in the exact coefficients and significance sizes for these baseline predictors, this does not have to bother us too much. What is more important, is that we remove any collinearity between the baseline predictors and our predictors of interest, i.e. the surprisal estimates from the ngram models and parser. Therefore, we run separate regression models for these predictors on the residuals of the baseline model.

**N-gram estimates** We estimated 3-gram, 4-gram and 5-gram models on the AMI corpus (9-fold-

cross), the Penn Treebank and the Gigaword Corpus. We found that coefficient estimates and significance levels of the resulting models were comparable. This is not surprising, given that 4-gram and 5-gram models were backing off to 3-grams or smaller contexts for more than 95% of cases on the AMI and PTB corpora (both ca. 1m words), and thus were correlated at  $p > .98$ . On the Gigaword Corpus, the larger contexts were seen more often (5-grams: 11%, 4-grams: 36%), but still correlation with 3-grams were high at ( $p > .96$ ).

N-gram model surprisal estimated on newspaper texts from PTB or Gigaword were statistically significant positive predictors of spoken word durations beyond simple word frequencies (but PTB ngram surprisal did not improve fit over models containing Gigaword frequency estimates). Counter-intuitively however, ngram models estimated based on the AMI corpus have a small *negative* coefficient in models that already include word frequency as a predictor – residuals of an AMI-estimated ngram model with respect to word frequency are very noisy and do not show a clear correlation anymore with word durations.

**Surprisal** Surprisal effects were found to have a robust significant positive coefficient, meaning that words with higher surprisal are spoken more slowly / clearly than expected when taking into account only canonical word duration and word frequency. Surprisal achieves a better model fit than any of the n-gram models, based on a comparison of AICs, and Surprisal significantly improved model fit over a model including frequencies and ngram models based on AMI and Gigaword. Table 4 shows the estimate for SURPRISAL on the residuals of the model in Table 2.

Table 4: Linear mixed effects model of surprisal (based on Roark parser) with random intercept for speaker and random slope. The response variable is residual word durations from the model shown in Table 3.

Surprisal estimated from the Roark parser also remains a significant positive predictor when regressed against the residuals of a baseline model including both 3-gram surprisal from the AMI corpus and 4-gram surprisal from the Gigaword corpus. In order to make really sure that the observed surprisal effect has indeed to do with syntax and can not be explained away as a frequency effect, we also calculated frequency estimates for the corpus based on the Penn Treebank. The significant positive surprisal effect remains stable, also when run on the residuals of a model which includes PTB trigrams and PTB frequencies.

It is difficult from these regression models to intuitively grasp the size of the effect of a particular predictor on reading times, since one would have to know the exact range and distribution of each predictor. To provide some intuition, we calculate the estimated effect size of Roark surprisal on speech durations. Per Roark surprisal “unit”, the model estimates a 7 msec difference<sup>5</sup>. The range of Roark surprisal in our data set is roughly from 0 to 25, with most values between 2 and 15. For a word like “thing” which in one instance in the AMI corpus was estimated with a surprisal of 2.179 and in another instance as 16.277, the estimated difference in duration between these instances would thus be 104msec, which is certainly an audible difference. (Full range for Roark surprisal: 174msec, whereas full range for gigaword 4gram surprisal is 35 msec.)

When analysing the surprisal effect in more detail, we find that both the syntactic component of surprisal and its lexical component are significant positive predictors of word durations, as well as the interaction between them, which has a negative slope. A model with the separate components and their in-

<sup>5</sup>2.4msec for a unit of residualized Roark surprisal, but it is even less intuitive what that means, hence we calculate with non-residualized surprisal here.

Table 5: Linear mixed effects model of residual speech durations wrt. baseline model from Table 3, with random intercept for speaker and random slope for structural and lexical component of surprisal, estimated using the Roark parser.

teraction achieves a better model fit (in AIC and BIC scores) than a model with only the full surprisal effect. The detailed model is shown in Table 5.

To summarize, the positive coefficient of surprisal means that words which carry a lot of information from a structural point of view are spoken more slowly than words that carry less such information. These results thus provide good evidence for our hypothesis that the predictability of syntactic structure affects phonetic realization and that speakers use speech rate to achieve more uniform information density.

**Native vs. non-native speakers** Finally, we also compared effects in our native vs. non-native speaker populations, see Table 6. Both populations show the same effects and tell the same story (note that significance values can’t be compared as the sample sizes are different). It might be possible to interpret the findings in the sense that native speakers are more proficient at adapting their speech rate to (syntactic) complexity to achieve more uniform information density, given the slightly higher coefficient and significance for Surprisal for native speakers. Since the effects are statistically significant for both groups, we don’t want to make too strong claims about differences between the groups.

## 7 Conclusions and future work

We have shown evidence in this work that syntactic surprisal effects in transcribed speech data can be detected through word utterance duration in both native and non-native speech, and we did so using a meeting corpus not specifically designed to isolate these effects. This result is the potential foundation for further work in applied, experimental, and

Table 6: Native speakers are possibly slightly better at adapting their speech rate to syntactic surprisal than non-native speakers. Surprisal value is for model with residuals of other predictors as dependent variable.

theoretical psycholinguistics. It provides additional direct support for approaches based on the UID hypothesis.

From an applied perspective, the fact that frequency and syntactic surprisal have a significant effect beyond what a HMM-trained TTS model would predict for individual words is a case for further research into incorporating syntactic models into speech production systems. Our methodology immediately provides a framework for estimating the word-by-word effect on duration for increased naturalness in TTS output. This is relevant to spoken dialogue systems because it appears that synthesized speech requires a greater level of attention from the dialogue system users when compared to the same words delivered in natural speech (Delogu et al., 1998). Some of this effect may be attributable to peaks in information density which are caused by current generation systems not compensating for areas of high information density through speech rate, lexical and structural choice.

Furthermore, syntax and semantics have been observed to interact with the mode of speech delivery. Eye-tracking experiments by Swift et al. (2002) showed that there was a synthetic vs. natural speech difference in the time required to pay attention to an object referred to using definite articles, but not indefinite articles. Our result points a way towards a direction for explaining of this phenomenon by demonstrating that the differences between current-technology artificial speech and natural speech can be partially explained through higher-level syntactic

features.

However, further experimentation is required on other measures of syntactic complexity (e.g. DLT, Gibson (2000)) as well as other levels of representation such as the semantic level. From a theoretical and neuroanatomical perspective, the finding that a measure of syntactic ambiguity reduction has an effect on the phonological layer of production has additional implications for the organization of the human language production system.

## Abstract

In this paper we explore the utility of sentiment analysis and semantic word classes for improving why-question answering on a large-scale web corpus. Our work is motivated by the observation that a why-question and its answer often follow the pattern that *if something undesirable happens, the reason is also often something undesirable*, and *if something desirable happens, the reason is also often something desirable*. To the best of our knowledge, this is the first work that introduces sentiment analysis to non-factoid question answering. We combine this simple idea with semantic word classes for ranking answers to why-questions and show that on a set of 850 why-questions our method gains 15.2% improvement in precision at the top-1 answer over a baseline state-of-the-art QA system that achieved the best performance in a shared task of Japanese non-factoid QA in NTCIR-6.

## 1 Introduction

Question Answering (QA) research for factoid questions has recently achieved great success as demonstrated by IBM's Watson at Jeopardy: its accuracy has been reported to be around 85% on factoid questions (Ferrucci et al., 2010). Although recent shared QA tasks (Voorhees, 2004; Peñas et al., 2011; Fukumoto et al., 2007) have stimulated the research community to move beyond factoid QA, comparatively little attention has been paid to QA for non-factoid questions such as *why* questions and *how to* questions, and the performance of the state-of-art non-factoid QA systems reported in the literature (Murata et al., 2007; Surdeanu et al., 2011; Verberne et

al., 2010) remains considerably lower than that of factoid QA (i.e., 34% in MRR at top-150 results on why-questions (Verberne et al., 2010)).

In this paper we explore the utility of sentiment analysis (Pang et al., 2002; Turney, 2002; Nakagawa et al., 2010) and semantic word classes for improving why-question answering (why-QA) on a large-scale web corpus. The inspiration behind this work is the observation that why-questions and their answers often have the following tendency:

- *if something undesirable happens, the reason is often also something undesirable*, and
- *if something desirable happens, its reason is often also desirable*.

Consider the following question **Q1**, and its answer candidates **A1-1** and **A1-2**.

- **Q1**: Why does cancer occur?
- **A1-1**: Carcinogens such as nitrosamine and benzopyrene *may increase the risk of cancer* by altering DNA in cells.
- **A1-2**: Maintaining a healthy weight *may lower the risk of* various types of cancer.

Here **A1-1** describes an undesirable event related to cancer, while **A1-2** suggests a desirable action for its prevention. Our hypothesis suggests that **A1-1** is more appropriate for answering **Q1**. If this hypothesis holds, we can obtain a significant improvement in performance on why-QA tasks by exploiting the sentiment orientation<sup>1</sup> of expressions obtainable

<sup>1</sup> In this paper we denote the *desirable/undesirable* polarity of an expression by the term “sentiment orientation” instead of “semantic orientation” to avoid confusion with our different notion of “semantic word classes.”

by automatic sentiment analysis of questions and answers.

A second observation motivating this work is that there are often significant associations between the lexico-semantic classes of words in a question and those in its answer sentence. For instance, questions concerning diseases like **Q1** often have answers that include references to specific semantic word classes such as chemicals (like **A1-1**), viruses, body parts, and so on. Capturing such statistical correlations between diseases and harmful substances may lead to higher why-QA performance. For this purpose we use classes of semantically similar words that were automatically acquired from a large web corpus using an EM-based clustering method (Kazama and Torisawa, 2008).

Another issue is that simply introducing the sentiment orientation of words or phrases in question and answer sentences in a naive way is insufficient, since answer candidate sentences may contain multiple sentiment expressions with different polarities in answer candidates (i.e., about 33% of correct answers had such multiple sentiment expressions with different polarities in our test set). For example, if **A1-2** contained a second sentiment expression with negative polarity like the example below,

“Trusting a specific food *is not effective* for preventing cancer, but maintaining a healthy weight *may help lower the risk of* various types of cancer.”

both **A1-1** and **A1-2** would contain sentiment expressions with the same polarity as that of **Q1**. Thus, it is difficult to expect that the sentiment orientation alone will work well for recognizing **A1-1** as a correct answer to **Q1**. To address this problem, we consider the combination of sentiment polarity and the contents of sentiment expressions associated with the polarity in questions and their answer candidates as well. To deal with the data sparseness problem arising in using the content of sentiment expressions, we developed a feature set that combines the polarity and the semantic word classes effectively.

We exploit these two main ideas (concerned with the sentiment orientation and the semantic classes described so far) for training a supervised classifier to rank answer candidates to why-questions. Through a series of experiments on 850 Japanese why-questions, we showed that the proposed seman-

tic features were effective in identifying correct answers, and our proposed method obtained more than 15% improvement in precision of its top answer (P@1) over our baseline, which achieved the best performance in the non-factoid QA task in NTCIR-6 (Murata et al., 2007). We also show that our method can potentially perform with high precision (64.8% in P@1) when answer candidates containing at least one correct answer are given to our re-ranker.

## 2 Approach

Our proposed method is composed of *answer retrieval* and *answer re-ranking*. The first step, answer retrieval, extracts a set of answer candidates to a why-question from 600 million Japanese Web corpus. The answer retrieval is our implementation of the state-of-art method that has shown the best performance in the shared task of Japanese non-factoid QA in NTCIR-6 (Murata et al., 2007; Fukumoto et al., 2007). The second step, answer re-ranking, is the focus of this work.

### 2.1 Answer Retrieval

We use Solr<sup>2</sup> to retrieve documents from a 600 million Japanese Web page corpus<sup>3</sup> for a given why-question. Let a set of content words in a why-question be  $T = \{t_1, \dots, t_n\}$ . Two boolean queries for a why-question, “ $t_1$  AND  $\dots$  AND  $t_n$ ” and “ $t_1$  OR  $\dots$  OR  $t_n$ ,” are given to Solr and top-300 documents for each query are retrieved. Note that retrieved documents by each query have different coverage and relevance to a given why-question. To keep balance between the coverage and relevance of retrieved documents, we use a set of retrieved documents by these two queries for obtaining answer candidates. Each document in the result of document retrieval is split into a set of answer candidates consisting of five subsequent sentences<sup>4</sup>. Subsequent answer candidates can share up to two sentences to avoid errors due to wrong document segmentation.

<sup>2</sup> <http://lucene.apache.org/solr>

<sup>3</sup> To the best of our knowledge, few Japanese non-factoid QA systems in the literature have used such a large-scale corpus.

<sup>4</sup> The length of acceptable answer candidates for why-QA in the literature ranges from one sentence to two paragraphs (Fukumoto et al., 2007; Murata et al., 2007; Higashinaka and Isozaki, 2008; Verberne et al., 2007; Verberne et al., 2010).

Answer candidate  $ac$  for question  $q$  is ranked according to scoring function  $S(q, ac)$  given in Eq. (1) (Murata et al., 2007). Murata et al. (2007)’s method uses text search to look for answer candidates containing terms from the question with additional clue terms referring to “reason” or “cause.” Following the original method we used *riyuu* (*reason*), *genin* (*cause*) and *youin* (*cause*) as clue terms. The top-20 answer candidates for each question are passed on to the next step, which is answer re-ranking.  $S(q, ac)$  assigns a score to answer candidates like  $tf-idf$ , where  $1/dist(t_1, t_2)$  functions like  $tf$  and  $1/df(t_2)$  is  $idf$  for given terms  $t_1$  and  $t_2$  that are shared by  $q$  and  $ac$ .

$$S(q, ac) = \max_{t_1 \in T} \sum_{t_2 \in T} \phi \times \log(ts(t_1, t_2)) \quad (1)$$

$$ts(t_1, t_2) = \frac{N}{2 \times dist(t_1, t_2) \times df(t_2)}$$

Here  $T$  is a set of terms including nouns, verbs, and adjectives in question  $q$  that appear in answer candidate  $ac$ . Note that the clue terms are added to  $T$  if they exist in  $ac$ .  $N$  is the total number of documents (600 million),  $dist(t_1, t_2)$  represents the distance (the number of characters) between  $t_1$  and  $t_2$  in answer candidate  $ac$ ,  $df(t)$  is the document frequency of term  $t$ , and  $\phi \in \{0, 1\}$  is an indicator, where  $\phi = 1$  if  $ts(t_1, t_2) > 1$ ,  $\phi = 0$  otherwise.

## 2.2 Answer Re-ranking

Our re-ranker is a supervised classifier (SVMs) (Vapnik, 1995) that uses three types of feature sets: features expressing morphological and syntactic analysis of questions and answer candidates, features representing semantic word classes appearing in questions and answer candidates, and features from sentiment analysis. All answer candidates of a question are ranked in a descending order of their score given by SVMs. We trained and tested the re-ranker using 10-fold cross validation on a corpus composed of 850 why-questions and their top-20 answer candidates provided by the answer retrieval procedure in Section 2.1. The answer candidates were manually annotated by three human annotators (not by the authors). Our corpus construction method is described in more detail in Section 4.

## 3 Features for Answer Re-ranking

This section describes our feature sets for answer re-ranking: features expressing morphological and syntactic analysis (MSA), features representing semantic word class (SWC), and features indicating sentiment analysis (SA). MSA, which has been widely used for re-ranking answers in the literature, is used to identify associations between questions and answers at the morpheme, word phrase, and syntactic dependency levels. The other two feature sets are proposed in this paper. SWC is devised for identifying semantic word class associations between questions and answers. SA is used for identifying sentiment orientation associations between questions and answers as well as expressing the combination of each sentiment expression and its polarity. Table 1 summarizes the respective feature sets, each of which is described in detail below.

### 3.1 Morphological and Syntactic Analysis

MSA including  $n$ -grams of morphemes, words, and syntactic dependencies has been widely used for re-ranking answers in non-factoid QA (Higashinaka and Isozaki, 2008; Surdeanu et al., 2011; Verberne et al., 2007; Verberne et al., 2010). We use MSA as a baseline feature set in this work.

We represent all sentences in a question and its answer candidate in three ways: morphemes, word phrases (*bunsetsu*<sup>5</sup>) and syntactic dependency chains. These are obtained using a morphological analyzer<sup>6</sup> and a dependency parser<sup>7</sup>. From each question and answer candidate we extract  $n$ -grams of morphemes, word phrases, and syntactic dependencies, where  $n$  ranges from 1 to 3. Syntactic dependency  $n$ -grams are defined as a syntactic dependency chain containing  $n$  word phrases. Syntactic dependency 1-grams coincide with word phrase 1-grams, so they are ignored.

Table 1 defines four types of MSA (MSA1 to MSA4). MSA1 is  $n$ -gram features from all sentences in a question and its answer candidates and distinguishes an  $n$ -gram feature found in a question from that same feature found in answer candidates. MSA2 contains  $n$ -grams found in the answer

<sup>5</sup> A *bunsetsu* is a syntactic constituent composed of a content word and several function words such as post-positions and case markers. It is the smallest unit of syntactic analysis in Japanese.

<sup>6</sup> <http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN>

<sup>7</sup> <http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP>

<b>MSA1</b>	Morpheme $n$ -grams, word phrase $n$ -grams, and syntactic dependency $n$ -grams in a question and its answer candidate, where $n$ ranges from 1 to 3. $n$ -grams in a question and those in an answer candidate are distinguished.
<b>MSA2</b>	<b>MSA1</b> 's $n$ -grams in an answer candidate that contain a question term.
<b>MSA3</b>	<b>MSA1</b> 's $n$ -grams that contain a clue term including <i>riyuu</i> (reason), <i>genin</i> (cause) and <i>youin</i> (cause). These $n$ -grams in a question and those in an answer candidate are distinguished.
<b>MSA4</b>	The ratio of the number of question terms in an answer candidate to the total number of question terms.
<b>SWC1</b>	Word class $n$ -grams in a question and its answer candidate. These $n$ -grams in a question and those in an answer candidate are distinguished.
<b>SWC2</b>	<b>SWC1</b> 's $n$ -grams in an answer candidate whose original <b>MSA1</b> 's $n$ -grams contain any question term.
<b>SA@W1</b>	Word polarity $n$ -grams in a question and its answer candidate. These $n$ -grams in a question and those in an answer candidate are distinguished.
<b>SA@W2</b>	<b>SA@W1</b> 's $n$ -grams in an answer candidate whose original <b>MSA1</b> $n$ -grams contain any question term.
<b>SA@W3</b>	Joint class-polarity $n$ -grams in a question and its answer candidate. These $n$ -grams in a question and those in an answer candidate are distinguished.
<b>SA@W4</b>	<b>SA@W3</b> 's $n$ -grams in an answer candidates whose original <b>MSA1</b> $n$ -grams contain any question term.
<b>SA@P1</b>	The indicator for polarity agreement between sentiment phrases, one in a question and the other in an answer candidate: 1 if any pair of such sentiment phrases has polarity in agreement, 0 otherwise.
<b>SA@P2</b>	The phrase-polarity, positive or negative, of a pair of sentiment phrases for which the indicator in <b>SA@P1</b> is 1.
<b>SA@P3</b>	Morpheme $n$ -grams, word phrase $n$ -grams, and syntactic dependency $n$ -grams in sentiment phrases are coupled with their phrase-polarity, where $n$ ranges from 1 to 3. These $n$ -grams in a question and those in an answer candidate are distinguished.
<b>SA@P4</b>	<b>SA@P3</b> 's $n$ -grams in an answer candidates that contain a question term.
<b>SA@P5</b>	The ratio of the number of question terms in sentences that have sentiment phrases in answer candidates to the total number of question terms.
<b>SA@P6</b>	Word class $n$ -grams in sentiment phrases are coupled with phrase-polarity. These $n$ -grams in a question and those in an answer candidate are distinguished.
<b>SA@P7</b>	<b>SA@P6</b> 's $n$ -grams in an answer candidates, whose original <b>MSA1</b> 's $n$ -grams include any question term.
<b>SA@P8</b>	Joint class-polarity $n$ -grams in sentiment phrases of a question and its answer candidate are coupled with phrase-polarity of the sentiment phrases. These $n$ -grams in a question and those in an answer candidate are distinguished.
<b>SA@P9</b>	<b>SA@P8</b> 's $n$ -grams in an answer candidates, whose original <b>MSA1</b> 's $n$ -grams include any question term.
<b>SA@P10</b>	A pair of <b>SA@P6</b> 's $n$ -grams, one from sentiment phrases in a question and the other from those in an answer candidate, where the two sentiment phrases should have the same sentiment orientation.

Table 1: Features used in training our re-ranker

candidates that themselves contain a term from the question (e.g., “*types of cancer*” in example **A1-2**). **MSA3** is the  $n$ -gram feature that contains one of the clue terms used for answer retrieval (*riyuu* (reason), *genin* (cause) or *youin* (cause)). Here too,  $n$ -grams obtained from the questions and answer candidates are distinguished. Finally, **MSA4** is the percentage of the question terms found in an answer candidate.

### 3.2 Semantic Word Class

*Semantic word classes* are sets of semantically similar words. We construct these semantic word classes by using the noun clustering algorithm proposed in Kazama and Torisawa (2008). The algorithm follows the distributional hypothesis, which states that semantically similar words tend to appear in similar contexts (Harris, 1954). By treating syntactic dependency relations between words as “contexts,” the clustering method defines a probabilistic model of noun-verb dependencies with hidden classes as:

$$p(n, v, r) = \sum_c p(n|c)p(\langle v, r \rangle|c)p(c) \quad (2)$$

Here,  $n$  is a noun,  $v$  is a verb or noun on which  $n$  depends via a grammatical relation  $r$  (post-positions in Japanese), and  $c$  is a hidden class. Dependency relation frequencies were obtained from our 600-million page web corpus, and model parameters  $p(n|c)$ ,  $p(\langle v, r \rangle|c)$  and  $p(c)$  were estimated using the EM algorithm (Hofmann, 1999). We successfully clustered 5.5 million nouns into 500 classes. For each noun  $n$ , EM clustering estimates a probability distribution over hidden variables representing semantic classes. From this distribution we obtained discrete semantic word classes by assigning each noun  $n$  to semantic class  $c = \operatorname{argmax}_{c^*} p(c^*|n)$ . The resulting classes actually form clean semantic categories such as *chemicals*, *nutrients*, *diseases* and *conditions*, in our examples of Q1 and Q2. The following are the top-10 words (English translation) according to  $p(c|n)$  for these classes.

**chemicals:** acetylene, hydrogenation product, phosphoric monoester, methacrylate, levoglucosan, ammonium salt, halogenated organic compound, benzonitrile, alkyne, nitrosamine

**nutrients:** glucide, carbohydrate, mineral, salt, sugar, water, fat, vitamin, nutrients, protein

**diseases:** pneumonia, neuritis, cancer, oral leukoplakia, pachymeningitis, acidosis, encephalitis, abdominal injury, valvulitis, gingivitis

**conditions:** proficiency, decrepitude, deficiency, impurity, abnormalities, floated, crisis, displacement, condition, shortage

Semantic word class (SWC) features are used to capture associations between semantic classes of words in the question and those in the answer candidates. For example:

- **Q2:** Why does rickets ( $W_{disease}$ ) occur in children?
- **A2:** Deficiency ( $W_{condition}$ ) of vitamin D ( $W_{nutrients}$ ) can cause rickets ( $W_{disease}$ ).

$W_{condition}$ ,  $W_{disease}$  and  $W_{nutrients}$  represent semantic word classes of *conditions*, *diseases* and *nutrients*, respectively. If this question-answer pair is given to the classifier as a positive training sample, we expect it to learn that if a disease name appears in a question then, everything else being equal, answers including nutrient names are more likely to be correct. Note that in principle the same association could be learned between word pairs, i.e., *rickets* and *vitamin D*. However, we found that word level associations are often too specific, and because of data sparseness this knowledge cannot easily be generalized to unseen questions. This is our main motivation for introducing broad coverage semantic word classes into the feature set.

We call the feature set with the word classes SWC and use two types of SWC, as shown in Table 1. To obtain the first type (SWC1), we convert all nouns in the MSA1  $n$ -grams into their respective word classes, and keep all  $n$ -grams that contain at least one word class. We call these features *word class n-grams*. Again, word class  $n$ -grams obtained from questions are distinguished from the ones in answer candidates. For example, we extract “ $W_{disease}$  occur” as a word class 2-gram from **Q2**.

The second type of SWC, SWC2, represents word class  $n$ -grams in an answer candidate, in which question terms are replaced by their respective semantic word classes. For example,  $W_{disease}$  in word class 2-gram “cause  $W_{disease}$ ” from **A2** is the semantic word class of *rickets*, one of the question

terms. These features capture the correspondence between semantic word classes in the question and answer candidates.

### 3.3 Sentiment Analysis

Sentiment analysis (SA) features are classified into word-polarity and phrase-polarity features. We use *opinion extraction tool*<sup>8</sup> and sentiment orientation lexicon in the tool for these features.

#### 3.3.1 Opinion Extraction Tool

*Opinion extraction tool* is a software, the implementation of Nakagawa et al. (2010). It extracts linguistic expressions representing opinions (henceforth, we call them sentiment phrases) from a Japanese sentence and then identifies the polarity of these sentiment phrases using machine learning techniques. For example, *rickets occur* in **Q2** and *Deficiency of vitamin D can cause rickets* in **A2** can be identified as sentiment phrases with a negative polarity. The tool identifies sentiment phrases and their polarity by using polarities of words and dependency subtrees as evidence, where these polarities are given in a word polarity dictionary.

In this paper, we use a trained model and a word polarity dictionary (containing about 35,000 entries) distributed via the ALAGIN forum<sup>9</sup> for our sentiment analysis. Table 2 shows the performance of *opinion extraction tool*, precision (P), recall (R) and F-value (F), in this setting (reported in the Japanese homepage of this tool). In the evaluation of sentiment-phrase extraction, an extracted sentiment phrase is determined as correct if its head word is the same as one in the gold standard. Polarity classification is evaluated under the condition that all of the sentiment phrases are correctly extracted.

	P	R	F
Sentiment-phrase extraction	0.602	0.408	0.486
Polarity classification (pos.)	0.873	0.893	0.883
Polarity classification (neg.)	0.866	0.842	0.854

Table 2: The performance of *opinion extraction tool*

#### 3.3.2 Word Polarity (SA@W)

Polarities of words are identified by simply looking up the word polarity dictionary of *opinion ex-*

<sup>8</sup> Available at [http://alaginrc.nict.go.jp/opinion/index\\_e.html](http://alaginrc.nict.go.jp/opinion/index_e.html)

<sup>9</sup> <http://www.alagin.jp/index-e.html>. Only the members of the ALAGIN forum can access these resources.

*traction tool*. Word polarity features are used for identifying associations between the polarity of words in a question and that in a correct answer. For example:

- **Q2:** Why does rickets ( $W^-$ ) occur in children?
- **A2:** Deficiency ( $W^-$ ) of vitamin D can cause rickets ( $W^-$ ).

Here,  $W^-$  represents negative word polarities. We expect our classifier to learn from this question and answer pair that if a word with negative polarity appears in a question then its correct answer is likely to contain a negative polarity word as well.

SA@W1 and SA@W2 in Table 1 are sentiment analysis features from *word polarity n-grams*, which contain at least one word that has word polarities. We obtain these *n-grams* by converting all nouns in MSA1 *n-grams* into their word polarities through dictionary lookup. For example, from Q2 in the above example we extract “ $W^-$  occur” as a word polarity 2-gram. SA@W1 is concerned with *all* word polarity *n-grams* in questions and answer candidates. For SA@W2, we restrict word polarity *n-grams* from SA@W1 to those whose original *n-gram* include a question term.

Furthermore, word polarities are coupled with semantic word classes so that our classifier can identify meaningful combinations of both. For example, *deficiency* in A2 can be represented as  $W^-_{condition}$  by its respective semantic word class and word polarity, which allows for the representation of *undesirable conditions*. This in turn lets our system learn meaningful correlations between words expressing these kind of negative conditions and their connection to questions asking about diseases. SA@W3 and SA@W4 are features from this combination. They are defined in the same way as SA@W1 and SA@W2 except that word polarities are replaced with the combination of semantic word classes and word polarities. We call *n-grams* in SA@W3 and SA@W4 *joint (word) class-polarity n-grams*.

### 3.3.3 Phrase Polarity (SA@P)

*Opinion extraction tool* is applied to question and its answer candidate to identify sentiment phrases and their phrase-polarities. In preliminary tests we found that sentiment phrases do not help to identify correct answers if answer sentences including the sentiment phrases do not have any term from the

question. So we restrict the target sentiment phrases to those acquired from sentences containing at least one question term. From these sentiment phrases we extract three categories of features.

First, SA@P1 and SA@P2 are features concerned with phrase-polarity agreement between sentiment phrases in a question and its answer candidate. We consider all possible pairs of sentiment phrases from the question and answer. If any such pair agrees in phrase-polarity, an indicator for the agreement and its polarity in the agreement become features SA@P1 and SA@P2, respectively.

Secondly, following the original hypothesis underlying this paper, we assume that sentiment phrases often represent the core part of the correct answer (e.g., A2 above) and it is important to express the content of the sentiment phrases in features. SA@P3 and SA@P4 were devised for this purpose. SA@P3 represents this sentiment phrase contents as *n-grams* of morphemes, words, and syntactic dependencies of sentiment phrases, together with their phrase-polarity. Furthermore, SA@P4 is the subset of SA@P3 *n-grams* restricted to those that include terms found in the question, and SA@P5 indicates the percentage of sentiment *n-grams* from the question that are found in a given answer candidate.

Finally, features SA@P6 through SA@P9 use semantic word classes to generalize the content features mentioned above. These features consist of word class *n-grams* and joint class-polarity *n-grams* taken from sentiment phrases, together with their phrase polarity. Similar to the definition of SA@P4, for SA@P7 and SA@P9 we restrict ourselves to *n-grams* containing a question term. SA@P10 represents the semantic content of two sentiment phrases with the same sentiment orientation (one from a question and the other from an answer candidate) using word class *n-grams*, together with the phrase-polarity in agreement.

## 4 Test Set

We prepared three sets of why-questions (QS1, QS2 and QS3) and used these questions to build two test sets for our experiments.

Why-questions in QS1 are taken from the Japanese version of *Yahoo! Answers* (called *Yahoo! Chiebukuro*)<sup>10</sup>. We automatically extracted

<sup>10</sup> We used “Yahoo! Chiebukuro Data (2nd edition)” which is

questions consisting of a single sentence and containing the interrogative *naze* (*why*), and our annotators verified that these questions are meaningful without further context. For example, they discarded questions like “Why doesn’t the WBC (world boxing council) make an objection to the WBC (World baseball classic)?” (the object of the objection is unclear) and “Why do minors trade at the auction even though it is disallowed by the rules” (information about which auction is not provided).

Because questions in *Yahoo! Answers* are aimed at human readers, users often “set the stage” by giving lots of background information about their question. This often leads to large stylistic differences between the questions in *Yahoo! Answers* and those typically posed to a QA system. We therefore created a second set of why-questions, **QS2**, whose style should be more appropriate for a QA system (examples showing these differences are given in the supplementary materials of this paper). Six human annotators (not the authors) were asked to create why-questions in their own words, keeping in mind that the questions they create are for a QA system. In addition, the annotators were asked to verify on the Web that the questions they created ask about some real event or phenomena. For example, a question like “Why does Mars appear blue?” is disallowed in QS2 because “Mars appears blue” is false. Note that the correct answer to these questions does not have to be either in our target corpus or in real-world Web texts. These two sets of why-questions, QS1 and QS2, are used to build a test set for evaluating our proposed method.

Finally, **QS3** contains why-questions that have at least one answer in our target corpus (600 million Japanese Web page corpus). For creating such why-questions, four human annotators (not the authors) were given a text passage composed of three continuous sentences and asked to locate the reasons for some event as described in this passage. Then they created a why-question for which the description is a correct answer. Because randomly selected passages from our target corpus have little chance of generating good why-questions we extracted passages from our target corpus that include at least one of the clue terms used in our answer retrieval step (i.e. *riyuu* (*reason*), *genin* (*cause*), or *youin* (*cause*)). This set-

---

provided by Yahoo Japan Corporation and contains 16 million questions asked from April, 2004 to April 2009.

ting may not necessarily reflect a “real world” distribution of why-questions, in which ideally a wide range of people ask questions that may or may not have an answer in our corpus. However, QS3 allows us to evaluate our method under the *idealized* conditions where we have a perfect answer retrieval module whose answer candidates always contain at least one correct answer (the source passage used for creating the why-question). This setting allows us to estimate the *ideal-case* performance of our method. Under these circumstances we found that our method achieves almost 65% precision in P@1, which suggests that it can potentially perform with high precision if the answer candidates given by the answer retrieval module contain at least one correct answer. This is the main purpose of QS3. Additionally, we use QS3 for building training data, to check whether questions that do not reflect the real-world distribution of why-questions are useful for improving the system’s performance on “real-world” questions (see Section 5.1).

In addition, we checked QS1, QS2 and QS3 for questions having the same topic, to avoid the possibility that the distribution of questions is biased towards certain topics. We manually extracted the questions’ topic words and randomly selected a single representative question from all questions with the same topic. For example, “Why does Twitter only allow 140 characters?” and “Why is Twitter so popular?” both have as topic *Twitter*. In the end we obtained 250 questions in QS1, 250 questions in QS2 and 350 questions in QS3.

For evaluation we prepared two test sets, Set1 and Set2. *Set1* contains question-answer pairs whose questions are taken from QS1 and QS2. In our experiment, we evaluate systems with 10-fold cross validation on Set1. *Set2* has question-answer pairs whose questions are from QS3. Set2 is mainly used for estimating estimate the ideal-case performance of our method with a perfect answer retrieval module. Furthermore Set2 is used as additional training data in evaluating systems with 10-fold cross validation on Set1. We used our answer retrieval system to obtain the top-20 answer candidates for each question, and all question-answer (candidate) pairs were checked by three annotators, where their inter-rater agreement (Fleiss’ kappa) was 0.634, indicating substantial agreement. Finally, correct answers to each question were determined by majority vote.

Q1:二酸化炭素などの温室効果ガスが増えると海面水位が上昇するといわれているのはなぜですか? (Why does the increase of greenhouse gases such as carbon dioxide in the atmosphere lead to a rise of ocean level?)
A1: .. 化石燃料等の使用が増えるにつれて、温室効果ガスが大気中に大量に放出され、その濃度が増加し、大気中に吸収される熱が増えたことにより、地球規模での気温上昇が進行しています。これが地球温暖化です。... 温暖化による海水膨張と両極の氷解で、海面が平均9～88cm上昇すると警告しています。 (The burning of fossil fuels contributes to the increase of atmospheric concentrations of greenhouse gases and this makes the atmosphere absorb more thermal radiation. As a result, Earth's average surface temperature increases. This is global warming. ... There are warnings that the increase of sea water and melting of polar ice due to the global warming may cause sea-surface height to rise by 9–88 cm on average.)
Q2:ヘモグロビンが不足すると体が酸素不足になるのはなぜですか? (Why does hemoglobin deficiency cause lack of oxygen in the human body?)
A2:... ヘモグロビンは酸素を体の中に運び、いらなくなった二酸化炭素を持ち帰り、肺から外に出すなど重要な働きをしています。もし鉄分が不足してヘモグロビンが少ししか作られないと、全身に運ばれる酸素の量が減少し、カラダが酸素不足になります。.. (... Hemoglobin has an important role in the human body of carrying oxygen to the organs and transferring carbon dioxide back to the lungs, to be dispensed from the organism. If the amount of hemoglobin produced by the body is insufficient due to iron deficiency, the amount of oxygen delivered throughout the body decreases, causing oxygen deficiency. ... )

Table 3: Correct question-answer pairs in our test set

Table 3 shows a sample of correct question-answer pairs in our test set. Please see the supplementary materials of this paper for more examples.

Note that word and phrase polarities are not considered by the annotators in building our test sets and these polarities are automatically identified using a word polarity dictionary and *opinion extraction tool*. We confirmed that about 35% of questions and 40% of answer candidates had at least one sentiment phrase by *opinion extraction tool*, and about 45% of questions and 85% of answer candidates contained at least one word having polarity by a word polarity dictionary.

## 5 Experiments

We use TinySVM<sup>11</sup> with a linear kernel for training our re-ranker. Evaluation was done by P@1 (Precision of the top answer) and MAP (Mean Average Precision). P@1 measures how many questions have a correct top answer candidate. MAP, widely used in evaluation of IR systems, measures the overall quality of the top- $n$  answer candidates ( $n=20$  in this experiment) using the formula:

$$MAP = \frac{1}{|Q|} \sum_{q \in Q} \frac{\sum_{k=1}^n (Prec(k) \times rel(k))}{|A_q|} \quad (3)$$

Here  $Q$  is a set of why-questions,  $A_q$  is a set of correct answers to why-question  $q \in Q$ ,  $Prec(k)$  is the precision at cut-off  $k$  in the top- $n$  answer candidates,  $rel(k)$  is an indicator, 1 if the item at rank  $k$  is a correct answer in  $A_q$ , 0 otherwise.

We evaluated all systems using 10-fold cross validation in two ways. In the first setting we performed 10-fold cross validation on Set1. Set1 con-

sists of 10,000 question-answer pairs (500 questions with their 20 answer candidates), and was partitioned into 10 subsamples such that the questions in one subsample do not overlap with those of the other subsamples. 9 subsamples (9,000 question-answer pairs) were used as training data and the remaining subsample (1,000 question-answer pairs) was retained as test data. This experiment is called **CV(Set1)**. It shows the effect of answer re-ranking when evaluating our proposed method with training data built with real world why-questions alone. In the second setting, we used the same 10 subsamples of Set1 as in CV(Set1) and exploited Set2 (composed of 7,000 question-answer pairs) as additional training data for 10-fold cross validation. As a result, in each fold 16,000 question-answer pairs (9,000 from Set1 and 7,000 from Set2) were used as training data for re-rankers, and all systems were evaluated on the remaining 1,000 question-answer pair subsample from Set1. We call this setting **CV(Set1+Set2)**. It verifies whether training data that does not necessarily reflect a real-world distribution of why-questions can improve why-QA performance on real-world questions.

### 5.1 Results

Table 4 shows the evaluation results of six different systems. For each system, we represent the performance in P@1 and MAP. B-QA is a system of our answer retrieval and the other five re-rank top-20 answer candidates using their own re-ranker.

**B-QA:** our answer retrieval system, our implementation of Murata et al. (2007).

**B-Ranker:** a system that has a re-ranker trained with morphological and syntactic analysis (MSA) features alone.

<sup>11</sup> <http://chasen.org/~taku/software/TinySVM/>

System	CV(Set1)		CV(Set1+Set2)	
	P@1	MAP	P@1	MAP
B-QA	0.222 (0.368)	0.270 (0.447)	0.222 (0.368)	0.270 (0.447)
B-Ranker	0.256 (0.424)	0.319 (0.528)	0.274 (0.454)	0.323 (0.535)
B-Ranker+CR	0.262 (0.434)	0.319 (0.528)	0.278 (0.460)	0.325 (0.538)
B-Ranker+WN	0.257 (0.425)	0.320 (0.530)	0.275 (0.455)	0.325 (0.538)
Proposed	<b>0.336 (0.56)</b>	<b>0.377 (0.624)</b>	<b>0.374 (0.619)</b>	<b>0.391 (0.647)</b>
<i>UpperBound</i>	0.604 (1)	0.604 (1)	0.604 (1)	0.604 (1)

Table 4: Comparison of systems

**B-Ranker+CR:** a system has a re-ranker trained with our MSA features and the causal relation (CR) features used in Higashinaka and Isozaki (2008). The CR features include binary features indicating whether an answer candidate contains a causal relation pattern, which causal relation pattern the answer candidate has, and whether the question-answer pair contains a causal relation instance — cause in the answer, effect in the question). We acquired causal relation instances from our target corpus using the method from (De Saeger et al., 2009), and exploited the *top*-100,000 causal relation instances and the patterns that extracted them for CR features. Note that these CR features are introduced only for comparing our semantic features with ones in Higashinaka and Isozaki (2008) and they are not a part of our method.

**B-Ranker+WN:** its re-ranker is trained with our MSA features and the WordNet features in Verberne et al. (2010). The WordNet features include the percentage of the question terms and their synonyms in WordNet synsets found in an answer candidate and the semantic relatedness score between a question and its answer candidate, the average of the concept similarity between each question term and all of the answer terms by *WordNet::Similarity* (Pedersen et al., 2004). We used the Japanese WordNet 1.1 (Bond et al., 2009) for these WordNet features. Note that the Japanese WordNet 1.1 has 93,834 Japanese words linked to 57,238 WordNet synsets, while the English WordNet 3.0 covers 155,287 words linked to 117,659 synsets. Due to this lower coverage, the WordNet features in Japanese may have a less power for finding a correct answer than those in English used in Verberne et al. (2010).

**Proposed:** our proposed method. All of the MSA, SWC and SA features are used for training our

re-ranker.

**UpperBound:** a system that ranks all  $n$  correct answers as the top  $n$  results of the 20 answer candidates if there are any. This indicates the performance upperbound in this experiment. The relative performance of each system compared to *UpperBound* is shown in parentheses.

The proposed method achieved the best performance both in CV(Set1) and CV(Set1+Set2). Our method shows a significant improvement (11.4–15.2% in P@1 and 10.7–12.1% in MAP) over our answer retrieval method, B-QA. Its improvement over B-Ranker, B-Ranker+CR and B-Ranker+WN (7.6–10% in P@1 and 5.7–6.6% in MAP) shows the effectiveness of our proposed feature set over the features used in previous works. Both B-Ranker+CR and B-Ranker+WN did not show significant performance improvement over B-Ranker. At least in our setting, the causal relation and WordNet features did not prove effective. The performance gap between B-Ranker and B-QA (3.4–5.2% in P@1 and 4.9–5.3% in MAP) suggests the effectiveness of re-ranking. All systems consistently show better performance in CV(Set1+Set2) than CV(Set1). This suggests that training data built with why-questions that does not reflect real-world distribution of why-questions is useful in training re-rankers.

We investigate the contribution of each type of features to the performance by removing one feature set from the all feature sets in training our re-ranker. In this experiment, we split *SA* into *SA@W* (features expressing words and their polarity) and *SA@P* (features expressing phrases and their polarity) to investigate their contribution either. The results are summarized in Table 5.

In Table 5, **MSA+SWC+SA** represents our proposed method using all feature sets. The performance gap between **MSA+SWC+SA** and the others confirms that all the features contributed to a higher

System	CV(Set1)		CV(Set1+Set2)	
	P@1	MAP	P@1	MAP
SWC+SA	0.302	0.324	0.314	0.332
MSA+SWC	0.308	0.349	0.318	0.358
MSA+SA	0.300	0.352	0.314	0.364
MSA+SWC+SA@W	0.312	0.358	0.325	0.365
MSA+SWC+SA@P	0.323	0.369	0.358	0.384
MSA+SWC+SA	<b>0.336</b>	<b>0.377</b>	<b>0.374</b>	<b>0.391</b>
<i>UpperBound</i>	0.604	0.604	0.604	0.604

Table 5: Evaluation with different combination of feature sets used in training our re-ranker

performance. The significant performance improvement by *SA* (features from sentiment analysis) and *SWC* (features from semantic word classes) (The gap between **MSA+SWC+SA** and **MSA+SWC** was 2.8–6% and that between **MSA+SWC+SA** and **MSA+SA** was 3.6%–6% in P@1) supports the hypothesis for sentiment analysis and semantic word classes in this paper.

Though the performance gap between **MSA+SWC+SA** and **MSA+SWC+SA@P** (1.3%–1.6% in P@1) shows that SA@W is useful in training our re-ranker, we found that **MSA+SWC+SA@W** made only 0.4–0.7% improvement over **MSA+SWC**. We believe that this is mainly because SA@W and SWC are based on semantic and sentiment information at the word level, and these often capture a similar type of information. For instance, disease names that are grouped together into one class in SWC are typically classified as negative in SA@W. Therefore the similarity in the information provided by SA@W and SWC causes a classifier trained with both of these features to obtain only a minor improvement over a classifier using only one of the features.

To estimate the *ideal-case* performance of our proposed method, we made another experiment by using Set1 as training data for our re-ranker and Set2 as test data for evaluating our proposed method. Here, we assume a perfect answer retrieval module that adds the source passage that was used for generating the original why-question in Set2 as a correct answer to the set of existing answer candidates, giving 21 answer candidates. The performance of our method in this setting was 64.8% in P@1 and 66.6% in MAP. This evaluation result suggests that our re-ranker can potentially perform with high precision when at least one correct answer in answer candidates is given by the answer retrieval module.

## 6 Related Work

In the QA literature, Higashinaka and Isozaki (2008), Verberne et al. (2010), and Surdeanu et al. (2011) are closest to our work. The first two deal with why-questions, the last with how-questions. Similar to our method, they use machine learning techniques to re-rank answer candidates to non-factoid questions based on various combinations of syntactic, semantic and other statistical features such as the density and frequency of question terms in the answer candidates and patterns for causal relations in the answer candidates. Especially for why-QA, Higashinaka and Isozaki (2008) used causal relation features and Verberne et al. (2010) exploited WordNet features as a kind of semantic features for training their re-ranker, where we used these features, respectively, for B-Ranker+CR and B-Ranker+WN in our experiment.

Our work differs from the above approaches in that we propose semantic word classes and sentiment analysis as a new type of semantic features, and show their usefulness in why-QA. Sentiment analysis has been used before on the slightly unusual task of opinion question answering, where the system is asked to answer subjective opinion questions (Stoyanov et al., 2005; Dang, 2008; Li et al., 2009). To the best of our knowledge though, no previous work has systematically explored the use of sentiment analysis in a general QA setting beyond opinion questions.

## 7 Conclusion

In this paper, we have explored the utility of sentiment analysis and semantic word classes for ranking answer candidates to why-questions. We proposed a set of semantic features that exploit sentiment analysis and semantic word classes obtained from large-scale noun clustering, and used them to train an answer candidate re-ranker. Through a series of experiments on 850 why-questions, we showed that the proposed semantic features were effective in identifying correct answers, and our proposed method obtained more than 15% improvement in precision of its top answer (P@1) over our baseline, a state-of-the-art IR based QA system. We plan to use new semantic knowledge such as semantic orientation, excitatory or inhibitory, proposed in Hashimoto et al. (2012) for improving why-QA.

## Abstract

The Linked Data initiative comprises structured databases in the Semantic-Web data model RDF. Exploring this heterogeneous data by structured query languages is tedious and error-prone even for skilled users. To ease the task, this paper presents a methodology for translating natural language questions into structured SPARQL queries over linked-data sources.

Our method is based on an integer linear program to solve several disambiguation tasks jointly: the segmentation of questions into phrases; the mapping of phrases to semantic entities, classes, and relations; and the construction of SPARQL triple patterns. Our solution harnesses the rich type system provided by knowledge bases in the web of linked data, to constrain our semantic-coherence objective function. We present experiments on both the question translation and the resulting query answering.

and discover relevant information. As linked data is in RDF format, the standard approach would be to run structured queries in triple-pattern-based languages like SPARQL, but only expert programmers are able to precisely specify their information needs and cope with the high heterogeneity of the data (and absence or very high complexity of schema information). For less initiated users the only option to query this rich data is by keyword search (e.g., via services like sig.ma (Tummarello et al., 2010)). None of these approaches is satisfactory. Instead, the by far most convenient approach would be to search in knowledge bases and the Web of linked data by means of natural-language questions.

As an example, consider a quiz question like “Which female actor played in Casablanca and is married to a writer who was born in Rome?”. The answer could be found by querying several linked data sources together, like the IMDB-style LinkedMDB movie database and the DBpedia knowledge base, exploiting that there are entity-level `sameAs` links between these collections. One can think of different formulations of the example question, such as “Which actress from Casablanca is married to a writer from Rome?”. A possible SPARQL formulation, assuming a user familiar with the schema of the underlying knowledge base(s), could consist of the following six triple patterns (joined by shared-variable bindings): `?x hasGender female, ?x isa actor, ?x actedIn Casablanca_(film), ?x marriedTo ?w, ?w isa writer, ?w bornIn Rome`. This complex query, which involves multiple joins, would yield good results, but it is difficult for the user to come

## 1 Introduction

### 1.1 Motivation

Recently, very large, structured, and semantically rich knowledge bases have become available. Examples are Yago (Suchanek et al., 2007), DBpedia (Auer et al., 2007), and Freebase (Bollacker et al., 2008). DBpedia forms the nucleus of the Web of Linked Data (Heath and Bizer, 2011), which interconnects hundreds of RDF data sources with a total of 30 billion subject-property-object (SPO) triples.

The diversity of linked-data sources and their high heterogeneity make it difficult for humans to search

up with the precise choices for relations, classes, and entities. This would require familiarity with the contents of the knowledge base, which no average user is expected to have. Our goal is to automatically create such structured queries by mapping the user’s question into this representation. Keyword search is usually not a viable alternative when the information need involves joining multiple triples to construct the final result, notwithstanding good attempts like that of Pound et al. (2010). In the example, the obvious keyword query “female actress Casablanca married writer born Rome” lacks a clear specification of the relations among the different entities.

## 1.2 Problem

Given a natural language question  $q_{NL}$  and a knowledge base  $KB$ , our goal is to translate  $q_{NL}$  into a formal query  $q_{FL}$  that captures the information need expressed by  $q_{NL}$ .

We focus on input questions that put the emphasis on entities, classes, and relations between them. We do not consider aggregations (counting, max/min, etc.) and negations. As a result, we generate structured queries of the form known as conjunctive queries or select-project-join queries in database terminology. Our target language is SPARQL 1.0, where the above focus leads to queries that consist of multiple triple patterns, that is, conjunctions of SPO search conditions. We do not use any pre-existing query templates, but generate queries from scratch as they involve a variable number of joins with a priori unknown join structure.

A major challenge is in the ambiguity of the phrases occurring in a natural-language question. Phrases can denote entities (e.g., the city of Casablanca or the movie Casablanca), classes (e.g., actresses, movies, married people), or relations/properties (e.g., `marriedTo` between people, `played` between people and movies). A priori, we do not know if a phrase should be mapped to an entity, a class, or a relation. In fact, some phrases may denote any of these three kinds of targets. For example, a phrase like “wrote score for” in a question about film music composers, could map to the composer-film relation `wroteSoundtrackForFilm`, to the class of `movieSoundtracks` (a subclass of music pieces), or to an entity like the movie “The Score”. Depending on the choice, we may arrive at a structurally

good query (with triple patterns that can actually be joined) or at a meaningless and non-executable query (with disconnected triple patterns). This generalized disambiguation problem is much more challenging than the more focused task of named entity disambiguation (NED). It is also different from general word sense disambiguation (WSD), which focuses on the meaning of individual words (e.g., mapping them to WordNet synsets).

## 1.3 Contribution

In our approach, we introduce new elements towards making translation of questions into SPARQL triple patterns more expressive and robust. Most importantly, we solve the disambiguation and mapping tasks jointly, by encoding them into a comprehensive integer linear program (ILP): the segmentation of questions into meaningful phrases, the mapping of phrases to semantic entities, classes, and relations, and the construction of SPARQL triple patterns. The ILP harnesses the richness of large knowledge bases like Yago2 (Hoffart et al., 2011b), which has information not only about entities and relations, but also about surface names and textual patterns by which web sources refer to them. For example, Yago2 knows that “Casablanca” can refer to the city or the film, and “played in” is a pattern that can denote the `actedIn` relation. In addition, we can leverage the rich type system of semantic classes. For example, knowing that Casablanca is a film, for translating “played in” we can focus on relations with a type signature whose range includes films, as opposed to sports teams, for example. Such information is encoded in judiciously designed constraints for the ILP. Although we intensively harness Yago2, our approach does not depend on a specific choice of knowledge base or language resource for type information and phrase/name dictionaries. Other knowledge bases such as DBpedia can be easily plugged in.

Based on these ideas, we have developed a framework and system, called DEANNA (DEep Answers for maNy Naturally Asked questions), that comprises a full suite of components for question decomposition, mapping constituents into the semantic concept space, generating alternative candidate mappings, and computing a coherent mapping of all constituents into a set of SPARQL triple patterns that

can be directly executed on one or more linked data sources.

## 2 Background

We use the Yago2 knowledge base, with its rich type system, as a semantic backbone. Yago2 is composed of instances of binary relations derived from Wikipedia and WordNet. The instances, called *facts*, provide both ontological information and instance data. Figure 1 shows sample facts from Yago2. Each fact is composed of *semantic items* that can be divided into relations, entities, and classes. Entities and classes together are referred to as *concepts*.

Subject	Predicate	Object
film	subclassOf	production
Casablanca_(film)	type	film
"Casablanca"	means	Casablanca_(film)
"Casablanca"	means	Casablanca_Morocco
Ingrid.Bergman	actedIn	Casablanca_(film)

Figure 1: Sample knowledge base

Examples of relations are `type`, `subclassOf`, and `actedIn`. Each relation has a type signature: classes for the relation’s domain and range. Classes, such as `person` and `film` group entities. Entities are represented in canonical form such as `Ingrid.Bergman` and `Casablanca_(film)`. A special type of entities are literals, such as strings, numbers, and dates.

## 3 Framework

Given a natural language question, Figure 2 shows the tasks DEANNA performs to translate a question into a structured query. The first three steps prepare the input for constructing a disambiguation graph for mapping the phrases in a question onto entities, classes, and relations, in a coherent manner. The fourth step formulates this generalized disambiguation problem as an ILP with complex constraints and computes the best solution using an ILP solver. Finally, the fifth and sixth step together use the disambiguated mapping to construct an executable SPARQL query.

A question sentence is a sequence of tokens,  $q_{NL} = (t_0, t_1, \dots, t_n)$ . A phrase is a contiguous subsequence of tokens  $(t_i, t_{i+1}, \dots, t_{i+l}) \subseteq q_{NL}, 0 \leq i, 0 \leq l \leq n$ . The input question is fed into the following pipeline of six steps:

1. **Phrase detection.** Phrases are detected that potentially correspond to semantic items such as

‘Who’, ‘played in’, ‘movie’ and ‘Casablanca’.

2. **Phrase mapping** to semantic items. This includes finding that the phrase ‘played in’ can either refer to the semantic relation `actedIn` or to `playedForTeam` and that the phrase ‘Casablanca’ can potentially refer to `Casablanca_(film)` or `Casablanca_Morocco`. This step merely constructs a candidate space for the mapping. The actual disambiguation is addressed by step 4, discussed below.

3. **Q-unit generation.** Intuitively, a *q-unit* is a triple composed of phrases. Their generation and role will be discussed in detail in the next section.

4. **Joint disambiguation**, where the ambiguities in the phrase-to-semantic-item mapping are resolved. This entails resolving the ambiguity in phrase borders, and above all, choosing the best fitting candidates from the semantic space of entities, classes, and relations. Here, we determine for our running example that ‘played in’ refers to the semantic relation `actedIn` and not to `playedForTeam` and the phrase ‘Casablanca’ refers to `Casablanca_(film)` and not `Casablanca_Morocco`.

5. **Semantic items grouping** to form semantic triples. For example, we determine that the relation `marriedTo` connects `person` referred to by ‘Who’ and `writer` to form the semantic triple `person marriedTo writer`. This is done via q-units.

6. **Query generation.** For SPARQL queries, semantic triples such as `person marriedTo writer` have to be mapped to suitable triple patterns with appropriate join conditions expressed through common variables: `?x type person, ?x marriedTo ?w, and ?w type writer` for the example.

### 3.1 Phrase Detection

A *detected phrase*  $p$  is a pair  $\langle Toks, l \rangle$  where  $Toks$  is a phrase and  $l$  is a label,  $l \in \{concept, relation\}$ , indicating whether a phrase is a relation phrase or a concept phrase.  $P_r$  is the set of all detected relation phrases and  $P_c$  is the set of all detected concept phrases.

One special type of detected relation phrase is the *null phrase*, where no relation is explicitly mentioned, but can be induced. The most prominent example of this is the case of adjectives, such as ‘Australian movie’, where we know there is a relation being expressed between ‘Australia’ and ‘movie’.

We use multiple detectors for detecting phrases of

Figure 2: Architecture of DEANNA.

different types. For concept detection, we use a detector that works against a phrase-concept dictionary which looks as follows:

```
{‘Rome’, ‘eternal city’} → Rome
{‘Casablanca’} → Casablanca.(film)
```

We experimented with using third-party named entity recognizers but the results were not satisfactory. This dictionary was mostly constructed as part of the knowledge base, independently of the question-to-query translation task in the form of instances of the `means` relation in Yago2, an example of which is shown in Figure 1

For relation detection, we experimented with various approaches. We mainly rely on a relation detector based on ReVerb (Fader et al., 2011) with additional POS tag patterns, in addition to our own which looks for patterns in dependency parses.

### 3.2 Phrase Mapping

After phrases are detected, each phrase is mapped to a set of semantic items. The mapping of concept phrases also relies on the phrase-concept dictionary.

To map relation phrases, we rely on a corpus of textual patterns to relation mappings of the form:

```
{‘play’, ‘star in’, ‘act’, ‘leading role’} → actedIn
{‘married’, ‘spouse’, ‘wife’} → marriedTo
```

Distinct phrase occurrences will map to different semantic item instances. We discuss why this is important when we discuss the construction of the disambiguation graph and variable assignment in the structured query.

### 3.3 Dependency Parsing & Q-Unit Generation

Dependency parsing identifies triples of tokens, or *triploids*,  $\langle t_{rel}, t_{arg1}, t_{arg2} \rangle$ , where  $t_{rel}, t_{arg1}, t_{arg2} \in q_{NL}$  are seeds for phrases, with the triploid acting as a seed for a potential SPARQL triple pattern. Here,  $t_{rel}$  is the seed for the relation phrase, while  $t_{arg1}$  and  $t_{arg2}$  are seeds for the two arguments. At this point, there is no attempt to assign subject/object roles to the arguments.

Triploids are collected by looking for specific dependency patterns in dependency graphs (de Marneffe et al., 2006). The most prominent pattern we look for is a verb and its arguments. Other patterns include adjectives and their arguments, prepositionally modified tokens and objects of prepositions.

By combining triploids with detected phrases, we obtain *q-units*. A q-unit is a triple of sets of phrases,  $\langle \{p_{rel} \in P_r\}, \{p_{arg1} \in P_c\}, \{p_{arg2} \in P_c\} \rangle$ , where  $t_{rel} \in p_{rel}$  and similarly for  $arg_1$  and  $arg_2$ . Conceptually, one can view a q-unit as a placeholder node with three sets of edges, each connecting the same q-node to a phrase that corresponds to a relation or concept phrase in the same q-unit. This notion of nodes and edges will be made more concrete when we present our disambiguation graph construction.

### 3.4 Disambiguation of Phrase Mappings

The core contribution of this paper is a framework for disambiguating phrases into semantic items – covering relations, classes, and entities in a unified manner. This can be seen as a joint task combining

named entity disambiguation for entities, word sense disambiguation for classes (common nouns), and relation extraction. The next section presents the disambiguation framework in detail.

### 3.5 Query Generation

Once phrases are mapped to unique semantic items, we proceed to generate queries in two steps. First, semantic items are grouped into triples. This is done using the triploids generated earlier. The power of using a knowledge base is that we have a rich type system that allows us to tell if two semantic items are compatible or not. Each relation has a type signature and we check whether the candidate items are compatible with the signature.

We did not assign subject/object roles in triploids and q-units because a natural language relation phrase might express the inverse of a semantic relation, e.g., the natural language expression ‘directed by’ and the relation `isDirectorOf` with respect to the movies domain are inverses of each other. Therefore, we check which assignment of `arg1` and `arg2` is compatible with the semantic relation. If both arrangements are compatible, then we give preference to the assignment given by the dependency parsers.

Once semantic items are grouped into triples, it is an easy task to expand them to SPARQL triple patterns. This is done by replacing each semantic class with a distinct type-constrained variable. Note that this is the reason why each distinct phrase maps to a distinct instance of a semantic class, to ensure correct variable assignment. This becomes clear when we consider the question “Which singer is married to a singer?”, which requires two distinct variables each constrained to bind to an entity of type `singer`.

## 4 Joint Disambiguation

The goal of the disambiguation step is to compute a partial mapping of phrases onto semantic items, such that each phrase is assigned to at most one semantic item. This step also resolves the phrase-boundary ambiguity, by enforcing that only non-overlapping phrases are mapped. As the result of disambiguating one phrase can influence the mapping of other phrases, we consider all phrases jointly in one big disambiguation task.

In the following, we construct a disambiguation graph that encodes all possible mappings. We impose a variety of complex constraints (mutual exclusion among overlapping phrases, type constraints among the selected semantic items, etc.), and define an objective function that aims to maximize the joint quality of the mapping. The graph construction itself may resemble similar models used in NED (e.g., (Milne and Witten, 2008; Kulkarni et al., 2009; Hof-fart et al., 2011a)). Recall, however, that our task is more complex because we jointly consider entities, classes, and relations in the candidate space of possible mappings. Because of this complication and to capture our complex constraints, we do not employ graph algorithms, but model the general disambiguation problem as an ILP.

### 4.1 Disambiguation Graph

Joint disambiguation takes place over a disambiguation graph  $DG = (V, E)$ , where  $V = V_s \cup V_p \cup V_q$  and  $E = E_{sim} \cup E_{coh} \cup E_q$ , where:

- $V_s$  is the set of semantic items,  $v_s \in V_s$  is an *s-node*.
- $V_p$  is the set of phrases,  $v_p \in V_p$  is called a *p-node*. We denote the set of p-nodes corresponding to relation phrases by  $V_{rp}$  and the set of p-nodes corresponding to concept phrases by  $V_{rc}$ .
- $V_q$  is a set of placeholder nodes for q-units, called *q-nodes*. They represent phrase triples.
- $E_{sim} \subseteq V_p \times V_s$  is a set of weighted *similarity edges* that capture the strength of the mapping of a phrase to a semantic item.
- $E_{coh} \subseteq V_s \times V_s$  is a set of weighted *coherence edges* that capture the semantic coherence between two semantic items. Semantic coherence is discussed in more detail later in this section.
- $E_q \subseteq V_q \times V_p \times d$ , where  $d \in \{rel, arg_1, arg_2\}$  is a *q-edge*. Each such edge connects a placeholder q-node to a p-node with a specific role as a relation, or one of the two arguments. A q-unit, as presented earlier, can be seen as a q-node along with its outgoing q-edges.

Figure 3 shows the disambiguation graph for our running example (excluding coherence edges between s-nodes).

### 4.2 Edge Weights

We next describe how the weights on similarity edges and semantic coherence edges are defined.

Figure 3: Disambiguation graph for the running example.

#### 4.2.1 Semantic Coherence

Semantic coherence,  $Coh_{sem}$ , captures to what extent two semantic items occur in the same context. This is different from semantic similarity ( $Sim_{sem}$ ), which is usually evaluated using the distance between nodes in a taxonomy (Resnik, 1995). While we expect  $Sim_{sem}(George\_Bush, Woody\_Allen)$  to be higher than  $Sim_{sem}(Woody\_Allen, Terminator)$  we would like  $Coh_{sem}(Woody\_Allen, Terminator)$ , both of which are from the entertainment domain, to be higher than  $Coh_{sem}(George\_Bush, Woody\_Allen)$ .

For Yago2, we characterize an entity  $e$  by its *inlinks*  $InLinks(e)$ : the set of Yago2 entities whose corresponding Wikipedia pages link to the entity.

To be able to compare semantic items of different semantic types (entities, relations, and classes), we need to extend this to classes and relations. For class  $c$  with entities  $e$ , its inlinks are defined as follows:

$$InLinks(c) = \bigcup_{e \in c} InLinks(e)$$

For relations, we only consider those that map entities to entities (e.g. `actedIn`, `produced`), for which we define the set of inlinks as follows:

$$InLinks(r) = \bigcup_{(e_1, e_2) \in r} (InLinks(e_1) \cap InLinks(e_2))$$

The intuition behind this is that when the two arguments of an instance of the relation co-occur, then the relation is being expressed.

We define the semantic coherence ( $Coh_{sem}$ ) between two semantic items  $s_1$  and  $s_2$  as the Jaccard coefficient of their sets of inlinks.

#### 4.2.2 Similarity Weights

Similarity weights are computed differently for entities, classes, and relations. For entities, we use a normalized prior score based on how often a phrase refers to a certain entity in Wikipedia. For classes, we use a normalized prior that reflects the number of members in a class. Finally, for relations, similarity reflects the maximum n-gram similarity between the phrase and any of the relation’s surface forms. We use Lucene for indexing and searching the relation surface forms.

#### 4.3 Disambiguation Graph Processing

The result of disambiguation is a subgraph of the disambiguation graph, yielding the most coherent mappings. We employ an ILP to this end. Before describing our ILP, we state some necessary definitions:

- Triple dimensions:  $d \in \{rel, arg_1, arg_2\}$
- Tokens:  $T = \{t_0, t_1, \dots, t_n\}$ .
- Phrases:  $P = \{p_0, p_1, \dots, p_k\}$ .
- Semantic items:  $S = \{s_0, s_1, \dots, s_l\}$ .
- Token occurrences:  $\mathcal{P}(t) = \{p \in P \mid t \in p\}$ .
- $X_i \in \{0, 1\}$  indicates if  $p$ -node  $i$  is selected.
- $Y_{ij} \in \{0, 1\}$  indicates if  $p$ -node  $i$  maps to  $s$ -node  $j$ .
- $Z_{kl} \in \{0, 1\}$  indicates if  $s$ -nodes  $k, l$  are *both* selected so that their coherence edge matters.
- $Q_{mnd} \in \{0, 1\}$  indicates if the  $q$ -edge between  $q$ -node  $m$  and  $p$ -node  $n$  for  $d$  is selected.
- $C_j, E_j$  and  $R_j$  are  $\{0, 1\}$  constants indicating if  $s$ -node  $j$  is a class, entity, or relation, resp.
- $w_{ij}$  is the weight for a  $p$ - $s$  similarity edge.
- $v_{kl}$  is the weight for an  $s$ - $s$  semantic coherence edge.
- $t_{rc} \in \{0, 1\}$  indicates if the relation  $s$ -node  $r$  is type-compatible with the concept  $s$ -node  $c$ .

Given the above definitions, our objective function is

$$\begin{aligned} \text{maximize} \quad & \alpha \sum_{i,j} w_{ij} Y_{ij} + \beta \sum_{k,l} v_{kl} Z_{kl} + \\ & \gamma \sum_{m,n,d} Q_{mnd} \end{aligned}$$

subject to the following constraints:

1. A  $p$ -node can be assigned to one  $s$ -node *at most*:

$$\sum_j Y_{ij} \leq 1, \forall i$$

2. If a  $p$ - $s$  similarity edge is chosen, then the respective  $p$ -node must be chosen:

$$Y_{ij} \leq X_i, \forall j$$

3. If  $s$ -nodes  $k$  and  $l$  are chosen ( $Z_{kl} = 1$ ), then there are  $p$ -nodes mapping to each of the  $s$ -nodes  $k$  and  $l$  ( $Y_{ik} = 1$  for some  $i$  and  $Y_{jl} = 1$  for some  $j$ ):

$$Z_{kl} \leq \sum_i Y_{ik} \text{ and } Z_{kl} \leq \sum_j Y_{jl}$$

4. No token can appear as part of two phrases:

$$\sum_{i \in \mathcal{P}(t)} X_i \leq 1, \forall t \in T$$

5. At most one  $q$ -edge is selected for a dimension:

$$\sum_n Q_{mnd} \leq 1, \forall m, d$$

6. If the  $q$ -edge  $mnd$  is chosen ( $Q_{mnd} = 1$ ) then  $p$ -node  $n$  must be selected:

$$Q_{mnd} \leq X_n, \forall m, d$$

7. Each semantic triple should include a relation:

$$E_r \geq Q_{mn'd} + X_{n'} + Y_{n'r} - 2 \quad \forall m, n', r, d = rel$$

8. Each triple should have at least one class:

$$C_{c_1} + C_{c_2} \geq Q_{mn''d_1} + X_{n''} + Y_{n''c_1} + Q_{mn'''d_2} + X_{n'''} + Y_{n'''c_2} - 5, \\ \forall m, n'', n''', r, c_1, c_2, d_1 = arg1, d_2 = arg2$$

This is not invoked for existential questions that return Boolean answers and are translated to `ASK` queries in SPARQL. An example is the question “Did Tom Cruise act in Top Gun?”, which can be translated to `ASK {Tom_Cruise actedIn Top_Gun}`.

9. Type constraints are respected (through  $q$ -edges):

$$t_{rc_1} + t_{rc_2} \geq Q_{mn'd_1} + X_{n'} + Y_{n'r} + Q_{mn''d_2} + X_{n''} + Y_{n''c_1} + Q_{mn'''d_3} + X_{n'''} + Y_{n'''c_2} - 7 \\ \forall m, n', n'', n''', r, c_1, c_2, \\ d_1 = rel, d_2 = arg1, d_3 = arg2$$

The above is a sophisticated ILP, and most likely NP-hard. However, even with ten thousands of variables it is within the regime of modern ILP solvers. In our experiments, we used Gurobi (Gur, 2011), and achieved run-times – typically of a few seconds.

Figure 4: Computed subgraph for the running example.

Figure 4 shows the resulting subgraph for the disambiguation graph of Figure 3. Note how common  $p$ -nodes between  $q$ -units capture joins.

## 5 Evaluation

### 5.1 Datasets

Our experiments are based on two collections of questions: the QALD-1 task for question answering over linked data (QAL, 2011) and a collection of questions used in (Elbassuoni et al., 2011; Elbassuoni et al., 2009) in the context of the NAGA project, for informative ranking of SPARQL query answers (Elbassuoni et al. (2009) evaluated the SPARQL queries, but the underlying questions are formulated in natural language.) The NAGA collection is based on linking data from IMDB with the Yago2 knowledge base. This is an interesting linked-data case: IMDB provides data about movies, actors, directors, and movie plots (in the form of descriptive keywords and phrases); Yago2 adds semantic types and relational facts for the participating entities. Yago2 provides nearly 3 million concepts and 100 relations, of which 41 lie within the scope of our framework.

Typical example questions for these two collections are: “Which software has been published by Mean Hamster Software?” for QALD-1, and “Which director has won the Academy Award for Best director and is married to an actress that has won the Academy Award for Best Actress?” for NAGA. For both collections, some questions are out-of-scope for our setting, because they mention entities or relations that are not available in the underlying datasets, contain date or time comparisons, or involve aggregation such as counting. After re-

moving these questions, our test set consists of 27 QALD-1 training questions out of a total of 50 and 44 NAGA questions, out of a total of 87. We used the 19 questions from the QALD-1 test set that are within the scope of our method for tuning the hyper-parameters ( $\alpha, \beta, \gamma$ ) in the ILP objective function.

## 5.2 Evaluation Metrics

We evaluated the output of DEANNA at three stages in the processing pipeline: a) after the disambiguation of phrases, b) after the generation of the SPARQL query, and c) after obtaining answers from the underlying linked-data sources. This way, we could obtain insights into our building blocks, in addition to assessing the end-to-end performance. In particular, we could assess the goodness of the question-to-query translation *independently* of the actual answer quality which may depend on particularities of the underlying datasets (e.g., slight mismatches between query terminology and the names in the data.)

At each of the three stages, the output was shown to two human assessors who judged whether an output item was good or not. If the two were in disagreement, then a third person resolved the judgment.

For the *disambiguation* stage, the judges looked at each q-node/s-node pair, in the context of the question and the underlying data schemas, and determined whether the mapping was correct or not and whether any expected mappings were missing. For the *query-generation* stage, the judges looked at each triple pattern and determined whether the pattern was meaningful for the question or not and whether any expected triple pattern was missing. Note that, because our approach does not use any query templates, the same question may generate semantically equivalent queries that differ widely in terms of their structure. Hence, we rely on our evaluation metrics that are based on triple patterns, as there is no gold-standard query for a given question. For the *query-answering* stage, the judges were asked to identify if the result sets for the generated queries are satisfactory.

With these assessments, we computed overall quality measures by both micro-averaging and macro-averaging. Micro-averaging aggregates over all assessed items (e.g., q-node/s-node pairs or triple

patterns) regardless of the questions to which they belong. Macro-averaging first aggregates the items for the same question, and then averages the quality measure over all questions.

For a question  $q$  and item set  $s$  in one of the stages of evaluation, let  $correct(q, s)$  be the number of correct items in  $s$ ,  $ideal(q)$  be the size of the ideal item set and  $retrieved(q, s)$  be the number of retrieved items, we define coverage and precision as follows:

$$cov(q, s) = correct(q, s)/ideal(q)$$

$$prec(q, s) = correct(q, s)/retrieved(q, s).$$

## 5.3 Results & Discussion

### 5.3.1 Disambiguation

Table 1 shows the results for disambiguation in terms of macro and micro coverage and precision. For both datasets, coverage is high as few mappings are missing. We obtain perfect precision for QALD-1 as no mapping that we generate is incorrect, while for NAGA we generate few incorrect mappings.

### 5.3.2 Query Generation

Table 2 shows the same metrics for the generated triple patterns. The results are similar to those for disambiguation. Missing or incorrect triple patterns can be attributed to (i) incorrect mappings in the disambiguation stage or (ii) incorrect detection of dependencies between phrases despite having the correct mappings.

### 5.3.3 Question Answering

Table 3 shows the results for query answering. Here, we attempt to generate answers to questions by executing the generated queries over the datasets. The table shows the number of questions for which the system successfully generated SPARQL queries (#queries), and among those, how many resulted in satisfactory answers as judged by our evaluators (#satisfactory). Answers were considered unsatisfactory when: 1) the generated SPARQL query was wrong, 2) the result set was empty due to the incompleteness of the underlying knowledge base, or 3) a small fraction of the result set was relevant to the question. For both sets of questions, most of the queries that were perceived unsatisfactory were ones that returned no answers. Table 4 shows a set of example QALD questions, the corresponding SPARQL queries and sample answers.

Benchmark	QALD-1	NAGA
<i>cov<sub>macro</sub></i>	0.973	0.934
<i>prec<sub>macro</sub></i>	1.000	0.934
<i>cov<sub>micro</sub></i>	0.963	0.945
<i>prec<sub>micro</sub></i>	1.000	0.941

Table 1: Disambiguation

Benchmark	QALD-1	NAGA
<i>cov<sub>macro</sub></i>	0.975	0.894
<i>prec<sub>macro</sub></i>	1.000	0.941
<i>cov<sub>micro</sub></i>	0.956	0.847
<i>prec<sub>micro</sub></i>	1.000	0.906

Table 2: Query generation

Benchmark	QALD-1	NAGA
#questions	27	44
#queries	20	41
#satisfactory	10	15
#relaxed	+3	+3

Table 3: Query answering

Question	Generated Query	Sample Answers
1. Who was the wife of President Lincoln?	?x marriedTo Abraham.Lincoln . ?x type person	Mary_Todd.Lincoln
2. In which films did Julia Roberts as well as Richard Gere play?	?x type movie .Richard.Gere actedIn ?x . Julia.Roberts actedIn ?x	Runaway.Bride Pretty.Woman
3. Which actors were born in Germany?	?x type actor . ?x bornIn Germany	NONE

Table 4: Example questions, the generated SPARQL queries and their answers

Queries that produced *no* answers, such as the third query in Table 4 were further relaxed using an incarnation of the techniques described in (Elbasuoni et al., 2009), by retaining the triple patterns expressing type constraints and relaxing all other triple patterns. Relaxing a triple pattern was done by replacing all entities with variables and casting entity mentions into keywords that are attached to the relaxed triple pattern. For example, the QALD question “Which actors were born in Germany?” was translated into the following SPARQL query: `?x type actor . ?x bornIn Germany` which produced no answers when run over the Yago2 knowledge base since the relation `bornIn` relates people to cities and not countries in Yago2. The query was then relaxed into: `?x type actor . ?x bornIn ?z[Germany]`. This relaxed (and keyword-augmented) triple-pattern query was then processed the same way as triple-pattern queries without any keywords. The results of such query were then ranked based on how well they match the keyword conditions specified in the relaxed query using the ranking model in (Elbasuoni et al., 2009). Using this technique, the top ranked results for the relaxed query were all actors born in German cities as shown in Table 5.

After relaxation, the judges again assessed the results of the relaxed queries and determined whether they were satisfactory or not. The number of additional queries that obtained satisfactory answers after relaxation are shown under `#relaxed` in Table 3.

The evaluation data, in addition to a demonstration of our system (Yahya et al., 2012), can be found at <http://mpi-inf.mpg.de/yago-naga/deanna/>.

## 6 Related Work

Question answering has a long history in NLP and IR research. The Web and Wikipedia have proved to be a valuable resource for answering fact-oriented questions. State-of-the-art methods (Hirschman and Gaizauskas, 2001; Kwok et al., 2001; Zheng, 2002; Katz et al., 2007; Dang et al., 2007; Voorhees, 2003) cast the user’s question into a keyword query to a Web search engine (perhaps with phrases for location and person names or other proper nouns). Key to finding good results is to retrieve and rank sentences or short passages that contain all or most keywords and are likely to yield good answers. Together with trained classifiers for the question type (and thus the desired answer type), this methodology performs fairly well for both factoid and list questions.

IBM’s Watson project (Ferrucci et al., 2010) demonstrated a new kind of *deep QA*. A key element in Watson’s approach is to decompose complex questions into several cues and sub-cues, with the aim of generating answers from matches for the various cues (tapping into the Web and Wikipedia). Knowledge bases like DBpedia (Auer et al., 2007), Freebase (Bollacker et al., 2008), and Yago (Suchanek et al., 2007) are used for both answering parts of questions that can be translated to structured form (Chu-Carroll et al., 2012) and type-checking possible answer candidates and thus filtering out spurious results (Kalyanpur et al., 2011).

The recent QALD-1 initiative (QAL, 2011) proposed a benchmark task to translate questions into SPARQL queries over linked-data sources like DBpedia and MusicBrainz. FREyA (Damljanovic et al., 2011), the best performing system, relies on

Q: ?x type actor . ?x wasBornIn ?z[Germany]
Martin_Lawrence type actor . Martin_Lawrence wasBornIn Frankfurt.am.Main
Robert_Schwentke type actor . Robert_Schwentke wasBornIn Stuttgart
Willy_Millowitsch type actor . Willy_Millowitsch wasBornIn Cologne
Jerry_Zaks type actor . Jerry_Zaks wasBornIn Stuttgart

Table 5: Top-4 results for the QALD question “Which actors were born in Germany?” after relaxation

interaction with the user to interpret the question. Earlier work on mapping questions into structured queries includes the work by Frank et al. (2007) and Unger and Cimiano (2011). Frank et al. (2007) used lexical-conceptual templates for query generation. However, this work did not address the crucial issue of disambiguating the constituents of the question. In Pythia, Unger and Cimiano (2011) relied on an ontology-driven grammar for the question language so that questions could be directly mapped onto the vocabulary of the underlying ontology. Such grammars are obviously hard to craft for very large, complex, and evolving knowledge bases. Nalix is an attempt to bring question answering to XML data (Li, Yang, and Jagadish, 2007) by mapping questions to XQuery expressions, relying on human interaction to resolve possible ambiguity.

Very recently, Unger et al. (2012) developed a template-based approach based on Pythia, where questions are automatically mapped to structured queries in a two step process. First, a set of query templates are generated for a question, independent of the knowledge base, determining the structure of the query. After that, each template is instantiated with semantic items from the knowledge base. This performs reasonably well for the QALD-1 benchmark: out of 50 test questions, 34 could be mapped, and 19 were correctly answered.

Efforts on user-friendly exploration of structured data include keyword search over relational databases (Bhalotia et al., 2002) and structured keyword search (Pound et al., 2010). The latter is a compromise between full natural language and structured queries, where the user provides the structure and the system takes care of the disambiguation of keyword phrases.

Our joint disambiguation method was inspired by recent work on NED (Milne and Witten, 2008; Kulkarni et al., 2009; Hoffart et al., 2011a) and WSD (Navigli, 2009). In contrast to this prior work on related problems, our graph construction and

constraints are more complex, as we address the joint mapping of arbitrary phrases onto entities, classes, or relations. Moreover, instead of graph algorithms or factor-graph learning, we use an ILP for solving the ambiguity problem. This way, we can accommodate expressive constraints, while being able to disambiguate all phrases in a few seconds.

DEANNA uses dictionaries of names and phrases for entities, classes, and relations. Spitkovsky and Chang (2012) recently released a huge dictionary of pairs of phrases and Wikipedia links, derived from Google’s Web index. For relations, Nakashole et al. (2012) released PATTY, a large taxonomy of patterns with semantic types.

## 7 Conclusions and Future Work

We presented a method for translating natural-language questions into structured queries. The novelty of this method lies in modeling several mapping stages as a joint ILP problem. We harness type signatures and other information from large-scale knowledge bases. Although our model, in principle, leads to high combinatorial complexity, we observed that the Gurobi solver could handle our judiciously designed ILP very efficiently. Our experimental studies showed very high precision and good coverage of the query translation, and good results in the actual question answers.

Future work includes relaxing some of the limitations that our current approach still has. First, questions with aggregations cannot be handled at this point. Second, queries sometimes return empty answers although they perfectly capture the original question, but the underlying data sources are incomplete or represent the relevant information in an unexpected manner. We plan to extend our approach of combining structured data with textual descriptions, and generate queries that combine structured search predicates with keyword or phrase matching.

# Answering Opinion Questions on Products by Exploiting Hierarchical Organization of Consumer Reviews

Jianxing Yu, Zheng-Jun Zha, Tat-Seng Chua

School of Computing

National University of Singapore

{jianxing, zhazj, chuats}@comp.nus.edu.sg

## Abstract

This paper proposes to generate appropriate answers for opinion questions about products by exploiting the hierarchical organization of consumer reviews. The hierarchy organizes product aspects as nodes following their parent-child relations. For each aspect, the reviews and corresponding opinions on this aspect are stored. We develop a new framework for opinion Questions Answering, which enables accurate question analysis and effective answer generation by making use of the hierarchy. In particular, we first identify the (explicit/implicit) product aspects asked in the questions and their sub-aspects by referring to the hierarchy. We then retrieve the corresponding review fragments relevant to the aspects from the hierarchy. In order to generate appropriate answers from the review fragments, we develop a multi-criteria optimization approach for answer generation by simultaneously taking into account review salience, coherence, diversity, and parent-child relations among the aspects. We conduct evaluations on 11 popular products in four domains. The evaluated corpus contains 70,359 consumer reviews and 220 questions on these products. Experimental results demonstrate the effectiveness of our approach.

## 1 Introduction

With the rapid development of E-commerce, most retail websites encourage consumers to post reviews to express their opinions on the products. For example, the review “*The battery of Nokia N95 is amazing.*” reveals positive opinion on the aspect “*bat-*

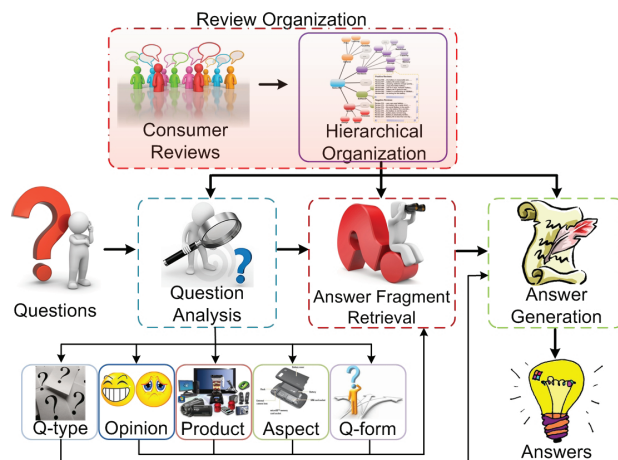

Figure 1: Overview of product opinion-QA framework

tery” of product *Nokia N95*. An *aspect* here refers to a component or an attribute of a certain product. Numerous consumer reviews are now available online, and these reviews contain rich opinionated information on various aspects of products. They are naturally a valuable resource for answering opinion questions about products, such as “*How do people think about the battery of Nokia N95?*” Opinion Question Answering (opinion-QA) on products seeks to uncover consumers’ thinking and feeling about the products or aspects of products. It is different from traditional factual QA, where the questions ask for the fact, such as “*Where is the capital of United States?*” and the answer is “*Washington, D.C.*”

For a product opinionated question, the answer should not be just a best answer. It should reflect the opinions of various segments of users, and incorpo-

rate both positive and negative viewpoints. Hence the answer should be a summarization of public opinions and comments on the product or specific aspect asked in the question (Jiang et al., 2010). In addition, it should also include public opinions and comments on the sub-aspects. Such answers would help users to understand the inherent reasons of the opinions on the asked aspect. For example, the question “*What do people think the camera of Nokia 5800?*” asks for public positive and negative opinions on the aspect “*camera*” of product “*Nokia 5800*.” The summarization of opinions on the sub-aspects such as “*lens*” and “*resolution*” would help users better understand that the public complaints on the aspect “*camera*” are due to the poor “*lens*” and/or low “*resolution*.” Moreover, the answer should be presented following the general-to-specific logic, i.e., from general aspects to specific sub-aspects. This makes the answer easier to understand by the users (Ouyang et al., 2009).

Current Opinion-QA methods mainly include three components, including question analysis that identifies aspects and opinions asked in the questions, answer fragment retrieval, and answer generation which summarizes the retrieved fragments (Lloret et al., 2011). Although existing methods show encouraging performance, they are usually not able to generate satisfactory answers due to the following drawbacks. First, current methods often identify aspects as the noun phrases in the questions. However, noun phrases contain noises that are not aspects. This gives rise to imprecise aspect identification. For example, in the question “*What reasons can I persuade my wife that people prefer the battery of Nokia N95?*” noun phrases “*wife*” and “*people*” are not aspects. Moreover, current methods relied on noun phrases are not able to reveal the implicit aspects, which are not explicitly asked in the questions. For example, the question “*Is iPhone 4 expensive?*” asks about the aspect “*price*”, but the term “*price*” does not appear in the question. Second, current methods cannot discover sub-aspects of the asked aspect due to its ignorance of parent-child relations among aspects. Third, the answers generated by the existing methods do not follow the general-to-specific logic, leading to difficulty in understanding the answers.

To overcome these problems, we can resort to

the hierarchical organization of consumer reviews on products. As illustrated in Figure 2, the hierarchy organizes product aspects as nodes, following their parent-child relations. For each aspect, the reviews and corresponding opinions on this aspect are stored. Such hierarchy can naturally facilitate to identify aspects asked in questions. While explicit aspects can be recognized by referring to the hierarchy, implicit aspects can be inferred based on the associations between sentiment terms and aspects in the hierarchy (Yu et al., 2011). The sentiment terms are discovered from the reviews on corresponding aspects. Moreover, by following the parent-child relations in the hierarchy, sub-aspects of the asked aspect can be directly acquired, and the answers can present aspects from general to specific.

Motivated by the above observations, we propose to exploit the hierarchical organization of consumer reviews for product opinion-QA. As illustrated in Figure 1, our framework first organizes consumer reviews of a certain product into a hierarchical organization. The resulting hierarchy is in turn used to help question analysis and relevant review fragments retrieval. In order to generate appropriate answers from the retrieved fragments, we develop a multi-criteria optimization approach by simultaneously taking into account review salience, coherence, and diversity. The parent-child relations among aspects are also incorporated into the approach to ensure the answers be general-to-specific. We conduct evaluations on 11 popular products in four domains. The evaluated corpus contains 70,359 consumer reviews and 220 questions on these products. More details of the dataset are discussed in Section 4. Experimental results to demonstrate the effectiveness of our approach.

The main contributions of this paper include,

- We propose to exploit the hierarchical organization of consumer reviews for answering opinion questions on products.
- With the help of the hierarchy, our proposed framework can accurately identify (explicit/implicit) aspects asked in the questions, and the corresponding sub-aspects.
- We develop a multi-criteria optimization approach to generate informative, coherent, diverse and general-to-specific answers.

Figure 2: Hierarchical organization for *Nokia N95*

The rest of this paper is organized as follows. Section 2 introduces the components of hierarchical organization of reviews, question analysis, and answer fragment retrieval. Section 3 elaborates the multi-criteria optimization approach for answer generation. Section 4 presents experimental details, while Section 5 reviews related works. Finally, Section 6 concludes this paper with future works.

## 2 Hierarchical Organization, Question Analysis, and Answer Fragment Retrieval

Let  $\mathcal{R} = \{r_1, \dots, r_{|\mathcal{R}|}\}$  denote a collection of consumer reviews of a certain product. Each review reflects consumer opinions on the product and/or product aspects. Let  $q$  denote an opinion question, which asks for public opinions on a product or some aspects of the product. The task is to retrieve the opinionated review fragments relevant to the asked product/product aspects, and summarize these fragments to form an appropriate answer to question  $q$ .

Next, we introduce the components of hierarchical organization that organizes consumer reviews into a hierarchy, question analysis which identifies the products/aspects and opinions asked in the questions, and answer fragment retrieval that retrieves review fragments relevant to the questions.

### 2.1 Hierarchical Organization of Reviews

We employ the method proposed by Yu et al. (2011) to organize consumer reviews of a product into a hierarchical organization. As shown in Figure 2, the hierarchy organizes product aspects as nodes, following their parent-child relations. In particular, this method first automatically acquires an initial aspect hierarchy from the domain knowledge and identifies aspects commented in the reviews. It then incrementally inserts the identified aspects into appropriate positions in the initial hierarchy, and finally obtains an aspect hierarchy that allocates all the newly identified aspects. The consumer reviews are then organized to their corresponding aspect nodes in the hierarchy. Sentiment classification is then performed to determine consumer opinions on the reviews.

The reported performance of Yu et al. (2011) on aspect identification, aspect hierarchy generation and sentiment classification are 0.731, 0.705, 0.787 in terms of average  $F_1$ -measure, respectively.

### 2.2 Question Analysis and Answer Fragment Retrieval

Question analysis consists of five sub-tasks: recognizing product asked in the question; identifying aspects in the question; classifying opinions that the question asks for (the asked opinion could be positive, negative or both); identifying the question type (e.g. asking for public opinions, or the reason of the opinions, etc.); and identifying the question form (i.e. comparative question or single form question).

**Recognizing the product:** A name entity recognizer<sup>1</sup> is trained to recognize the product name. In particular, we collect 420 auxiliary questions from Yahoo!Answer<sup>2</sup>, and manually annotate the product names (submitted as supplementary material in Appendix A). A name entity recognizer for product is learned on these data, with unigrams and POS tags as features. Given a testing question, the recognizer predicts each word as  $B$ ,  $I$ ,  $E$  or  $O$ , where  $B$ ,  $I$ ,  $E$  denote the begin, internal, and end of a product name respectively, and  $O$  corresponds to other words.

**Identifying aspects:** As aforementioned, simply extracting the noun phrases as aspects would import noises. Also, some “implicit” aspects do not ex-

<sup>1</sup><http://nlp.stanford.edu/software/CRF-NER.shtml>

<sup>2</sup><http://answers.yahoo.com>

PLICITLY appear in the reviews. One simple solution for these problems can resort to the review hierarchy. The hierarchy has organized product aspects, which can be used to filter the noise noun phrases for accurately identifying the explicit aspects. For the implicit aspects, we observe they are usually modified by some peculiar sentiment terms (Su et al., 2008). For example, the aspect “size” is often modified by the sentiment terms such as “large”, but seldom by the terms such as “expensive.” Thus, there are some associations between the aspects and sentiment terms. Such associations can be learned from the hierarchy and leveraged to infer the implicit aspects (Yu et al., 2011). In order to simultaneously identify the (explicit/implicit) aspects, we adopt a hierarchical classification technique. The technique simultaneously learns to identify explicit aspects, and discovers the associations between aspects and sentiment terms by multiple classifiers. In particular, given a testing question, we identify its aspect by hierarchically classify (Silla et al., 2011) it into the appropriate aspect node of a particular product hierarchy. The classification greedily searches a path in the hierarchy from top to down. The search begins at the root node, and stops at the leaf node or a specific node where the relevance score is lower than a pre-defined threshold. The relevance score on each node is determined by a SVM classifier. Multiple SVM classifiers are learned on the hierarchy, one distinct classifier for a node. The reviews that are stored in the node and its child-nodes are used as training samples. We employ the features of noun terms, and sentiment terms in the sentiment lexicon provided by MPQA project (Wilson et al., 2005).

**Classifying the opinions:** Given a set of testing questions, we first distinguish the opinion questions from the factual ones (Yu et al., 2003). Since the opinion questions often contain one or more sentiment terms, we classify them by employing the sentiment terms in the sentiment lexicon provided from MPQA project (Wilson et al., 2005). Subsequently, we learn a SVM sentiment classifier to determine the opinion polarity of the opinion questions. In particular, the reviews and corresponding opinions stored in the hierarchy are used as training samples, which are represented by the unigram features.

**Identifying the question type:** Opinion questions are often categorized into four types (Ku et al.,

2007),

- **Attitude** question, asking for public opinion on a product or product aspect, such as “*What do people think iPhone 3gs?*”
- **Reason** question, asking for the reason of public opinion on a product or product aspect, such as “*Why do people like iPhone 3gs?*”
- **Target** question, asking for the object in the public opinion, such as “*Which phone is better than Nokia N95?*”
- **Yes/No** question, asking for whether a statement is correct, such as “*Is Nokia N95 bad?*”

We formulate the question type identification as a multi-class classification problem. A multi-class SVM classifier<sup>3</sup> is learned for the classification. We collect 420 auxiliary questions from Yahoo!Answer and manually annotate their types (submitted as supplementary material in Appendix B). These questions are used for training, with POS tags and question words (i.e. why, what, how, do, is) as features.

**Identifying the question form:** Question form includes single and comparative. A question is viewed as comparative if it contains comparative adjectives and adverbs (e.g. cheaper, etc.), otherwise as the single form (Moghaddam et al., 2011). The POS tags are exploited to detect comparative adjectives (i.e. tag “*JJR*”) and adverbs (i.e. tag “*RBR*”).

After analyzing the question, we retrieve all review sentences on the asked aspect and all its sub-aspects from a certain product hierarchy, and choose the ones relevant to the opinion asked in the question. For the single form question, we view the retrieved sentences as the answer fragments. For the comparative questions, we select comparative sentences on the compared products from the retrieved sentences, and treat them as the answer fragments. Subsequently, question type is used to define the template for the answers. In particular, for the questions asking for reason and attitude, we generate the answers by summarizing corresponding answer fragments. For questions seeking for a target as the answer, we output the product names based on the majority voting of the opinions in the retrieved answer fragments. For the yes/no questions, we first generate the “yes/no” answer based on the

<sup>3</sup>[http://svmlight.joachims.org/svm\\_multiclass.html](http://svmlight.joachims.org/svm_multiclass.html)

consistency between the asked opinions and the major opinions in the answer fragments, and then summarize these fragments to form the answers.

### 3 Answer Generation

Answer generation aims to generate an appropriate answer for a given opinion question based on the retrieved answer fragments, i.e., review sentences. An answer is essentially a sequence of sentences. Hence, the task of answer generation is to select sentences from the retrieved answer fragments and order them appropriately. We formulate this task into a multi-criteria optimization problem. We incorporate multiple criteria in the answer generation process, including answer salience, coherence, and diversity. The parent-child relations between aspects is also incorporated to ensure the answer follow the general-to-specific logic. In the next subsections, we will introduce details of the proposed multi-criteria optimization approach.

#### 3.1 Formulation

We first introduce the multiple criteria and then present the optimization problem.

**Salience** is used to measure the representativeness of the answer. A good answer should consist of salient review sentences. Let  $\mathcal{S}$  denote the set of retrieved sentences. We define a binary variable  $s_i \in \{0, 1\}$  to indicate the selection of sentence  $i$  for the answer, i.e.  $s_i = 1$  (or 0) indicates that  $s_i$  is selected (or not). Let  $\omega_i$  denote the salience of sentence  $i$ . The estimation of  $\omega_i$  will be described in Section 3.2. The salience score of the answer (i.e., a set of sentences) is computed by summing up the scores of all its constituent sentences, as  $\sum_{i \in \mathcal{S}} \omega_i s_i$ .

**Coherence** is used to quantify the readability of an answer. To make the answer readable, the constituent sentences in the answer should be ordered properly. That is, the adjacent sentences should be coherent. We define  $e_{i,j} \in \{0, 1\}$  to indicate whether the sentences  $i$  and  $j$  are adjacent in the answer; where  $e_{i,j} = 1$  (or 0) means they are (or not) adjacent. The coherence between two adjacent sentences is measured by  $c_{ij}$ . The estimation of  $c_{ij}$  will be described in Section 3.3. As aforementioned, the answer is expected to be presented in a general-to-specific manner, i.e. from general aspects to specific

sub-aspects. We define  $h_{i,j}$  in Eq.1 to measure the general-to-specific coherence of sentences  $i$  and  $j$ .

$$h_{i,j} = \begin{cases} e^{-\frac{1}{level_i - level_j}}; & \text{if } level_i \neq level_j; \\ 1; & \text{otherwise,} \end{cases} \quad (1)$$

where  $level_i$  denotes level position of the aspect commented in sentence  $i$  by referring to the hierarchy, with the root level being 0. The coherence score of the answer is computed by summing up the scores of all its adjacent sentences as,  $\sum_{j \in \mathcal{S}} \sum_{i \in \mathcal{S}} h_{i,j} c_{i,j} e_{i,j}$ .

**Diversity.** A good answer should diversely cover all the important information. We introduce a matrix  $\mathcal{M}$  in Eq.2 to measure the pairwise diversities among sentences.  $\mathcal{M}_{ij}$  corresponds to the diversity between sentences  $i$  and  $j$ . When sentences  $i$  and  $j$  comment on the same aspects,  $\mathcal{M}_{ij}$  will favor to select the pair of sentences that discusses on diverse content (i.e. low similarity). Otherwise, the pair of sentences commented on different aspects is viewed to be diverse, and  $\mathcal{M}_{ij}$  is set as a constant bigger than one.

$$\mathcal{M}_{ij} = \begin{cases} 1 - \varphi & \text{if } i, j \text{ commented on same aspect} \\ \varphi & \text{otherwise,} \end{cases} \quad (2)$$

where  $\varphi$  is a constant <sup>4</sup>.

**Multi-Criteria Optimization** We integrate the above criteria into the multi-criteria optimization formulation,

$$\begin{aligned} & \max \{ \lambda_1 \cdot \sum_{i \in \mathcal{S}} \omega_i s_i + \lambda_2 \cdot \sum_{j \in \mathcal{S}} \sum_{i \in \mathcal{S}} h_{i,j} c_{i,j} e_{i,j} \\ & \quad + \lambda_3 \cdot \sum_{j \in \mathcal{S}} \sum_{i \in \mathcal{S}} s_i \mathcal{M}_{ij}; \\ & \begin{cases} s_i, e_{i,j} \in \{0, 1\}, \forall i, j; \\ \lambda_1 + \lambda_2 + \lambda_3 = 1, 0 \leq \lambda_1, \lambda_2, \lambda_3 \leq 1, \end{cases} \end{aligned} \quad (3)$$

where  $\lambda_1, \lambda_2, \lambda_3$  are the trade-off parameters.

We further incorporate the following constrains into the optimization framework, so as to derive appropriate answers.

- The length of the answer is up to  $K$ ,

$$\sum_{i \in \mathcal{S}} l_i s_i \leq K, \quad (4)$$

where  $l_i$  is the length of sentence  $i$ .

- When sentence  $i$  is not selected (i.e.  $s_i = 0$ ), the adjacency between any sentence to  $i$  is set

<sup>4</sup>Empirically set to 10 in the experiment.

to zero (i.e.  $\sum_{i \in \mathcal{S}} e_{i,j} = \sum_{i \in \mathcal{S}} e_{j,i} = 0$ ). When sentence  $i$  is selected, there are two sentences adjacent to sentence  $i$  in the answer, one before  $i$  and another after  $i$ . (i.e.  $\sum_{i \in \mathcal{S}} e_{i,j} = \sum_{i \in \mathcal{S}} e_{j,i} = 1$ ).

$$\sum_{i \in \mathcal{S}} e_{i,j} = \sum_{i \in \mathcal{S}} e_{j,i} = s_j, \quad \forall j. \quad (5)$$

- In order to avoid falling into a cycle in sentence selection, we employ the following constraints (Deshpande et al., 2009).

$$\begin{aligned} \sum_{i \in \mathcal{S}} f_{0,i} &= n + 1; \\ \sum_{i \in \mathcal{S}} f_{i,n+1} &\geq 1; \\ \sum_{i \in \mathcal{S}} f_{i,j} - \sum_{i \in \mathcal{S}} f_{j,i} &= s_j, \quad \forall j; \\ 0 \leq f_{i,j} &\leq (n + 1) \cdot e_{i,j}, \quad \forall i, j, \end{aligned} \quad (6)$$

where the variable  $f_{i,j}$  is an integer to number the selected adjacent sentences from 1 to  $n+1$ , and the first selected sentence is numbered  $f_{0,i} = n + 1$ . If the last selected sentence obtains a number  $f_{i,n+1}$  which is bigger than 1, then the selection has no cycle.

### Solution

Given the salience weights  $\omega_i|_{i=1}^{\mathcal{S}}$ , and coherence weights  $c_{i,j}|_{i,j=1}^{\mathcal{S}}$ , the above multi-criteria optimization problem can be solved by *Integer Linear Programming* (Schrijver et al., 1998). The optimal solutions  $s_i|_{i=1}^{\mathcal{S}}$  and  $e_{i,j}|_{i,j=1}^{\mathcal{S}}$  indicate the selected sentences and the order of them. In the next subsections, we will introduce the estimations of  $\omega_i|_{i=1}^{\mathcal{S}}$  and  $c_{i,j}|_{i,j=1}^{\mathcal{S}}$ .

### 3.2 Salience Weight Estimation

The salience weight of sentence  $i$  is formulated as  $\omega_i = \sum_{g=1}^G \varphi_g(i)/G$ , where  $\varphi(i)$  denotes the measurement for the importance of sentence  $i$ . We define seven measurements (i.e.  $G = 7$ ) below.

**Helpfulness:** Many forum websites provide a helpfulness score, which is used to rate the quality of a review. The sentences that come from helpful reviews are often representative (Mizil et al., 2009). We compute  $\varphi(i)$  of sentence  $i$  by using helpfulness score from its host review.

**Timeliness:** The new coming sentence often contains more updated and useful information (Liu et al., 2008).  $\varphi(i)$  is the post time of sentence  $i$ . We normalize it to  $[0, 1]$ .

**Grammaticality:** The grammatical sentence is often more readable. We employ the method in Agichtein et al. (2008) to calculate the grammar score. In particular,  $\varphi(i)$  is calculated by the KL-divergence between language models of sentence  $i$  to Wikipedia articles.

**Position:** The first sentence in a review is usually informative (He et al., 2011).  $\varphi(i)$  is computed based on the position of the sentence in the review, i.e.  $\varphi(i) = 1/\text{position}_i$ .

**Aspect Frequency:** The sentence that contains the frequent aspects is often salient (Nishikawa et al., 2010). Hence,  $\varphi(i)$  is computed as the sum of the frequency for aspects in sentence  $i$ .

**Centroid Distance:** As aforementioned, review sentences are stored in the corresponding aspect nodes in the hierarchy. The sentence that is close to the centroid of the reviews stored in an aspect node is more likely to be salient (Erkan et al., 2004).  $\varphi(i)$  is computed as the Cosine similarity between sentence  $i$  to the corresponding review cluster centroid based on the unigram features.

**Local Density:** The sentence would be informative when it is in the dense part of the aspect node in the feature space (Scott et al., 1992). We employ *Multivariate Kernel Density Estimation* to estimate the density. We first represent all the sentences stored in each node into feature vectors, with unigram as features. The density of a sentence is then calculated as  $\varphi(\mathbf{x}) = \sum_{i=1}^n K_H(\mathbf{x} - \mathbf{x}_i)/n$ , where  $\mathbf{x}$  denotes the feature vector of sentence  $i$ ,  $n$  is the size of sentences stored in the node, and  $K_H(\mathbf{x}) = (2\pi)^{-1/2} \exp(-1/2(\mathbf{x}^T \mathbf{x}))$  represents the *Gaussian* kernel.

### 3.3 Coherence Weight Estimation

The coherence  $c_{i,j}$  between sentences  $i$  and  $j$  is formulated as  $c_{i,j} = \boldsymbol{\mu} \cdot \boldsymbol{\psi}(i, j)$ , where  $\boldsymbol{\mu}$  is a weight vector, and  $\boldsymbol{\psi}(i, j)$  denotes the feature function.  $\boldsymbol{\psi}(i, j)$  takes two sentences  $i$  and  $j$  as input, and outputs a vector with each dimension indicating the present/absent of a feature. In order to capture the sequential relations among sentences, we utilize features as the *Cartesian* product over the terms of N-gram (N=1,2) and POS tags generated from sentences  $i$  and  $j$  (Lapata et al., 2003).

To learn the weight vector  $\boldsymbol{\mu}$ , we employ the *Passive-Aggressive* algorithm (Crammer et al.,

2006). It is an online learning algorithm, so that we can update the weight when more consumer reviews are available. The algorithm takes up one training sample and outputs the solution that has the highest score under the current weight. If the output differs from training samples, the weight vector is updated according to Eq.7. Since the consumer reviews often include multiple sentences, we can directly use the adjacency of these sentences as training samples. In particular, we treat the adjacent sentence pairs in the reviews as training samples (i.e.  $c_{i,j} = 1$ ).

$$\min \begin{cases} \|\mu^{i+1} - \mu^i\| \\ \mu^{i+1} \cdot \Psi(\mathbf{p}, \mathbf{q}^*) - \mu^i \cdot \Psi(\mathbf{p}, \hat{\mathbf{q}}) \geq \tau(\hat{\mathbf{q}}, \mathbf{q}^*); \\ \tau(\hat{\mathbf{q}}, \mathbf{q}^*) = \frac{2 \cdot T(\hat{\mathbf{q}}, \mathbf{q}^*)}{m(m-1)/2}, \end{cases} \quad (7)$$

where  $\mu^i$  is the current weight vector and  $\mu^{i+1}$  is the updated vector,  $\mathbf{q}^*$  and  $\hat{\mathbf{q}}$  are the gold standard and predicted sequence of sentences, respectively,  $\mathbf{p}$  denotes a set of sentences,  $\Psi(\cdot)$  is the feature function on the whole feature space (i.e.  $\sum \psi(\cdot)$ ),  $\tau(\cdot, \cdot)$  is a *Kendall's tau* lost function (Lapata et al., 2006),  $T(\cdot, \cdot)$  represents the number of inversion operations that needs to bring  $\hat{\mathbf{q}}$  to  $\mathbf{q}^*$ , and  $m$  denotes the number of sentences.

## 4 Evaluations

In this section, we evaluate the effectiveness of the proposed approach, in terms of question analysis and answer generation.

### 4.1 Data Set and Experimental Settings

We employed the product review dataset used in Yu et al. (2011) as corpus. As illustrated in Table 1, the dataset contained 70,359 reviews about 11 popular products in four domains. In addition, we created 220 questions for these products by referring to real questions in Yahoo!Answer service. We corrected the typos and grammar errors for these real questions. Each product contains 15 opinion questions and 5 factual questions, respectively. All questions were shown in Appendix C in supplementary material. Three annotators were invited to generate the gold standard. Each question was labeled by two annotators. The labels include product name, product aspect, opinion, question type and question form. The average inter-rater agreement in terms of Kappa statistics is 89%. These annotators were then invited

to read the reviews, and create the ground truth answers by selecting and ordering some review sentences. Such process is time consuming and labor-intensive. We speed up the annotation process as follows. We first collected all the review sentences in the answers generated by three evaluated methods to be discussed in Section 4.3.1. In addition, we sampled the top-N ( $N=20$ ) sentences on each asked aspect and its sub-aspects respectively, where the sentences were ranked based on their salient weights in Section 3.2. We then provided such subset of review sentences to the three annotators, and let them individually create an answer of up to 100 words (i.e.  $K=100$ ) for each question.

Product Name	Domain	Review#	Sentence#
Canon EOS 450D (Canon EOS)	camera	440	628
Fujifilm Finepix AX245W (Fujifilm)	camera	541	839
Panasonic Lumix DMC-TZ7 (Panasonic)	camera	650	1,546
Apple MacBook Pro (MacBook)	laptop	552	4,221
Samsung NC10 (Samsung)	laptop	2,712	4,946
Apple iPod Touch 2nd (iPod Touch)	MP3	4,567	10,846
Sony NWZ-S639 16GB (Sony NWZ)	MP3	341	773
BlackBerry Bold 9700 (BlackBerry)	phone	4,070	11,008
iPhone 3GS 16GB (iPhone 3GS)	phone	12,418	43,527
Nokia 5800 XpressMusic (Nokia 5800)	phone	28,129	75,001
Nokia N95	phone	15,939	44,379

Table 1: Statistics of the product review dataset, # denotes the number of the reviews/sentences.

We employed *precision* (P), *recall* (R) and  $F_1$ -measure ( $F_1$ ) as the evaluation metric for question analysis, and utilized *ROUGE* (Lin et al., 2003) as the metric to evaluate the quality of answer generation. *ROUGE* is a widely accepted standard for summarization, which measures the quality of the summarized answers by counting the overlapping N-grams between the answers generated by machine and human, respectively. In the experiment, we reported the  $F_1$ -measure of *ROUGE-1*, *ROUGE-2* and *ROUGE-SU4*, which count the overlapping unigrams, bigrams and skip-4 bigrams respectively. *ROUGE-1* can measure informativeness of the answers, while higher order *ROUGE-N* ( $N=2,4$ ) captures the matching of subsequences, which can measure the fluency and readability of the answers. For the trade-off parameters, we empirically set  $\lambda_1 = 0.4$ ,  $\lambda_2 = 0.3$  and  $\lambda_3 = 0.3$ .

### 4.2 Evaluations on Question Analysis

We first evaluated the performance of product recognition, opinion/factual question classification, opinion classification, question type and question form identification. The experimental results are shown

in Table 2. The results show that traditional methods achieve encouraging performance on the aforementioned tasks.

<i>Evaluated Topics</i>	<i>P</i>	<i>R</i>	<i>F<sub>1</sub></i>
Product recognition	0.755	0.618	0.680
Opinion/factual	0.897	0.895	0.893
Opinion classification	0.755	0.745	0.748
Question type	0.800	0.775	0.783
Question form	0.910	0.903	0.905

Table 2: Performance of question analysis.

<i>Methods</i>	<i>P</i>	<i>R</i>	<i>F<sub>1</sub></i>
Our method	<b>0.851*</b>	<b>0.763*</b>	<b>0.805*</b>
Balahur’s method	0.825	0.400	0.538

Table 3: Performance of aspect identification for question analysis. \* denotes the results (i.e.  $P$ ,  $R$ ,  $F_1$ ) are tested for statistical significance using T-Test,  $p$ -values $<0.05$ .

<i>Methods</i>	<i>P</i>	<i>R</i>	<i>F<sub>1</sub></i>
Our method	<b>0.726*</b>	<b>0.643*</b>	<b>0.682*</b>
Su’s method	0.689	0.571	0.625

Table 4: Performance of implicit aspect identification for question analysis. T-Test,  $p$ -values $<0.05$

We next examined the performance of our approach on aspect identification. The method proposed by Balahur et al. (2008) was reimplemented as the baseline, which identifies aspects based on noun phrase extraction. This method achieved good performance on the opinion QA task in TAC 2008 and was employed in subsequent works. As demonstrated in Table 3, our approach significantly outperforms Balahur’s method by over 49.4% in terms of average  $F_1$ -measure. A probable reason is that Balahur’s method relies on noun phrases, which may mis-identify some noise noun phrases as aspects, while our approach performs hierarchical classification based on the hierarchy, which can leverage the prior knowledge encoded in the hierarchy to filter out the noise and obtain accurate aspects.

Moreover, we evaluated the effectiveness of our approach on implicit aspect identification. The 70 implicit aspect questions in our question corpus were used here. The method proposed by Su et al. (2008) was reimplemented as the baseline. It identifies implicit aspects by mutual clustering, and it was

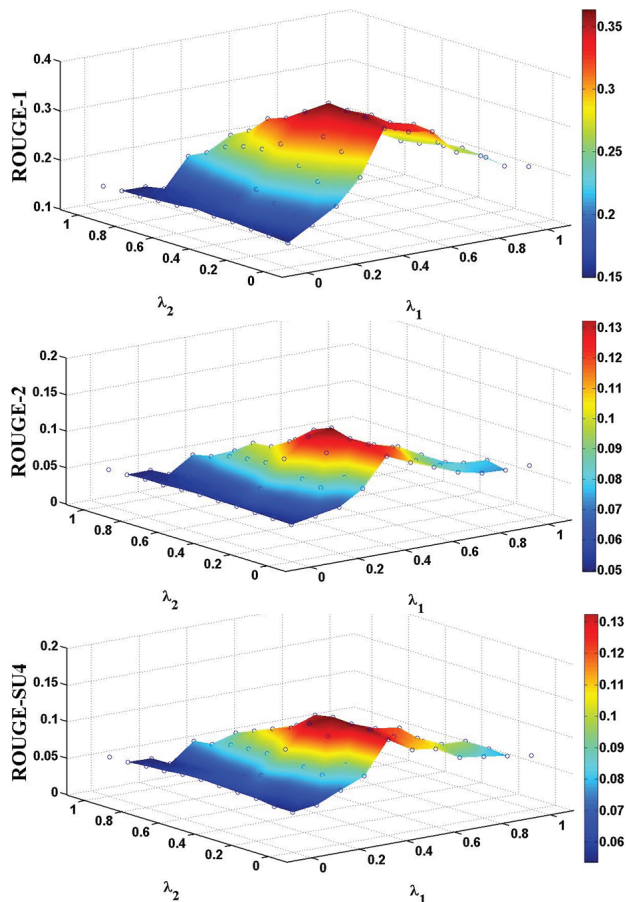

Figure 3: Evaluations on multiple optimization criteria in terms of  $ROUGE-1$ ,  $ROUGE-2$ , and  $ROUGE-SU4$ , respectively.

evaluated in Yu et al. (2011). As shown in Table 4, our approach significantly outperforms Su’s method by over 9.1% in terms of average  $F_1$ -measure. The results show that the hierarchy can help to identify implicit aspects by exploiting the underlying associations among sentiment terms and aspects.

<i>Methods</i>	<i>ROUGE1</i>	<i>ROUGE2</i>	<i>ROUGE-SU4</i>
Our method	<b>0.364*</b>	<b>0.137*</b>	<b>0.138*</b>
Li’s method	0.127	0.043	0.049
Lloret’s method	0.149	0.058	0.065

Table 5: Performance of answer generation. T-Test,  $p$ -values $<0.05$ .

### 4.3 Evaluations on Answer Generation

#### 4.3.1 Comparisons to the State-of-the-Arts

We compared our multi-criteria optimization approach against two state-of-the-arts methods: a) the

method presented in Li et al. (2009), which selects some retrieved sentences to generate the answers based on a graph-based algorithm; b) the method proposed by Lloret et al. (2011) that forms the answers by re-ranking the retrieved sentences.

As shown in Table 5, our approach outperforms Li’s method and Lloret’s method by the significant absolute gains of over 23.7%, and 21.5% respectively, in terms of average *ROUGE-1*. It improves the performance over these two methods in terms of average *ROUGE-2* by the absolute gains of over 9.41% and 7.87%, respectively; and in terms of *ROUGE-SU4* by the absolute gains of over 8.86% and 7.31%, respectively. By analyzing the results, we find that the improvements come from the use of the hierarchical organization and the answer generation algorithm which exploits multiple criteria, especially the parent-child relation among aspects. In addition, our approach can generate the answers by following the general-to-specific logic, while Li’s and Lloret’s methods fail to do so due to their ignorance of parent-child relations among aspects.

#### 4.3.2 Evaluations on the Effectiveness of Multiple Criteria

We further evaluated the effectiveness of each optimization criterion by tuning the trade-off parameters (i.e.  $\lambda_1$ ,  $\lambda_2$ , and  $\lambda_3$ ). We fixed  $\lambda_1$  as a constant in  $[0, 1]$  with 0.1 as an interval, and updated  $\lambda_2$  from 0 to  $1 - \lambda_1$ ,  $\lambda_3 = 1 - \lambda_1 - \lambda_2$ , correspondingly. The performance change is shown in Figure 3 in terms of *ROUGE-1*, *ROUGE-2*, and *ROUGE-SU4*, respectively. The best performance is achieved at  $\lambda_1 = 0.4$ ,  $\lambda_2 = 0.3$ ,  $\lambda_3 = 0.3$ . We observe the performance drops dramatically when any parameter (i.e.  $\lambda_1$ ,  $\lambda_2$ ,  $\lambda_3$ ) is close to 0 (i.e. remove any of the corresponding criterion). Thus, we can conclude that all the criteria are useful in answer generation. We also find that the performance change is sharp when  $\lambda_1$  changes. This indicates that the salience criterion is crucial for answer generation.

Table 6 shows the exemplar answers generated by our approach. Each answer first gives the statistic of positive and negative reviews. This helps user to quickly get an overview of public opinions. The summary of relevant review sentences is then presented in the answer. The answer diversely comments the asked aspect and all its avail-

able sub-aspects following the general-to-specific logic. Moreover, we feel that the answers are informative and readable.

## 5 Related Works

In this section, we review existing works related to the four components of our approach, including organization of reviews, question analysis, answer fragment retrieval, and answer generation.

For organization of reviews, Carenini et al. (2006) proposed to organize the reviews by a hand-crafted taxonomy, which was not scalable. Yu et al. (2011) exploited the domain knowledge and consumer reviews to automatically generate a hierarchy for organizing consumer reviews.

Question analysis often has to distinguish the opinion question from the factual one, and find the key points asked in the questions, such as the product aspect and product name. For example, Yu et al. (2003) proposed to separate opinions from facts at both document and sentence level, and determine the polarity on the opinionated sentences in the answer documents. Similarly, Somasundaran et al. (2007) utilized a SVM classifier to recognize opinionated sentences. The paper argued that the subjective types (i.e. sentiment and arguing) can improve the performance of opinion-QA. Later, Ku et al. (2007) proposed a two-layered classifier for question analysis, and retrieved the answer-fragments by keyword matching. In particular, they first identified the opinion questions, and classified them into six predefined question types, including holder, target, attitude, reason, majority, and yes/no. These question types and corresponding polarity on the questions were used to filter non-relevant sentences in the answer fragments.  $F_1$ -measure was employed as the evaluation metric.

For the topic of answer generation in opinion-QA, Li et al. (2009) formulated it as a sentence ranking task. They argued that the answers should be simultaneously relevant to topics and opinions asked in the questions. They thus designed the graph-based methods (i.e. PageRank and HITS) to select some high-ranked sentences to form answers. They first built a graph on the retrieved sentences, with each sentence as the node, and the similarity (i.e. Cosine similarity) between each sentences pair as the

<p><i>Question 1: What reasons do people give for preferring iPhone 3gs?</i></p> <p><i>There are 9,928 opinionated reviews about product "iphone 3gs", with 5,717 positive and 4,221 negative reviews. This phone is amazing and I would recommend it to anyone. It looks funky and cool. It is worth the money. It's great organiser, simple easy to use software. It is super fast, excellent connection via wifi or 3G. It is able to instantly access email. It's amazing and has so many free apps. The design is so simple and global. The hardware is good and reliable. The camera is a good and colors are vibrant. The touch screen is user friendly and the aesthetics are top notch. Battery is charged quickly, and power save right after stop using.</i></p>
<p><i>Question 2: Does anyone think it is expensive to get a iPhone 3GS?</i></p> <p><i>Yes.</i></p> <p><i>There are 2,645 opinionated reviews on aspect "price" about product "iphone 3gs", with 889 positive and 1,756 negative reviews.</i></p> <p><i>Throw the costly phone, apple only knows to sell stupid stuff expensively. Don't fool yourself with iPhone 3gs, believing that it costs much by Apple luxurious advertising. Apple is so greedy and it just wants to earn easy &amp; fast money by selling its techless product expensively. The phone will charge once you insert any sim card. iPhone 3gs is high-priced due to the capacitive and Apple license. You need to pay every application at the end it costs too much. The network provider will make up some of the cost of the phone on your call charges.</i></p>

Table 6: Sample answers of our approach.

weight of the corresponding edge. Given a question, its similarity to each sentence in the graph was computed. Such similarity was viewed as the relevant score to the corresponding sentence. The sentences then were ranked based on three metric, i.e. relevant score to the query, similarity score obtained from the graph algorithm over sentences, and degree of opinion matching to the query. Respectively, Lloret et al. (2011) proposed to form answers by re-ranking the retrieved sentences based on the metric of word frequency, non-redundancy and the number of noun phrases. Their method includes three components, including information retrieval, opinion mining and text summarization. Evaluations were conducted on the TAC 2008 Opinion Summarization track. Afterwards, Moghaddam et al. (2011) developed a system called *AQA* to generate answers for questions about products (i.e. opinion QA on products). It classifies the questions into five types, including target, attitude, reason, majority and yes/no. As compared to Ku et al. (2007), the question types of holder and majority are not included. They argued that product questions were seldom asked for the holders, since the holders (i.e. reviewers) were commonly shown in the reviews. Also, product questions mainly asked for majority opinions, and majority type was thus not considered. The *AQA* system includes five components, including question analysis, question expansion, high quality review retrieval, subjective sentence extraction, and answer grouping. The answers are generated by aggregat-

ing opinions in the retrieved fragments.

## 6 Conclusions and Future Works

In this paper, we have developed a new product opinion-QA framework, which exploits the hierarchical organization of consumer reviews on products. With the help of the hierarchical organization, our framework can accurately identify the aspects asked in the questions and also discover their sub-aspects. We have further formulated the answer generation from retrieved review sentences as a multi-criteria optimization problem. The multiple criteria used include answer salience, diversity, and coherence. The parent-child relations between the aspects are incorporated into the approach to ensure that the answers follow the general-to-specific logic. The proposed framework has been evaluated on 11 popular products in four domains using 220 questions on the products. Significant performance improvements were obtained. In the future, we will explore the more sophisticated NLP features to improve the proposed framework. This will be done by incorporating more NLP features in salience and coherence weights estimation.

## Acknowledgments

This work is supported in part by NUS-Tsinghua Extreme Search (NExT) project under the grant number: R-252-300-001-490. We give warm thanks to the project and anonymous reviewers for their comments.

## Abstract

In statistical machine translation, minimum error rate training (MERT) is a standard method for tuning a single weight with regard to a given development data. However, due to the diversity and uneven distribution of source sentences, there are two problems suffered by this method. First, its performance is highly dependent on the choice of a development set, which may lead to an unstable performance for testing. Second, translations become inconsistent at the sentence level since tuning is performed globally on a document level. In this paper, we propose a novel local training method to address these two problems. Unlike a global training method, such as MERT, in which a single weight is learned and used for all the input sentences, we perform training and testing in one step by learning a sentence-wise weight for each input sentence. We propose efficient incremental training methods to put the local training into practice. In NIST Chinese-to-English translation tasks, our local training method significantly outperforms MERT with the maximal improvements up to 2.0 BLEU points, meanwhile its efficiency is comparable to that of the global method.

## 1 Introduction

Och and Ney (2002) introduced the log-linear model for statistical machine translation (SMT), in which translation is considered as the following optimization problem:

$$\begin{aligned}\hat{e}(f; W) &= \arg \max_e \mathbf{P}(e|f; W) \\ &= \arg \max_e \frac{\exp \{W \cdot h(f, e)\}}{\sum_{e'} \exp \{W \cdot h(f, e')\}} \\ &= \arg \max_e \{W \cdot h(f, e)\},\end{aligned}\quad (1)$$

where  $f$  and  $e$  ( $e'$ ) are source and target sentences, respectively.  $h$  is a feature vector which is scaled by a weight  $W$ . Parameter estimation is one of the most important components in SMT, and various training methods have been proposed to tune  $W$ . Some methods are based on likelihood (Och and Ney, 2002; Blunsom et al., 2008), error rate (Och, 2003; Zhao and Chen, 2009; Pauls et al., 2009; Galley and Quirk, 2011), margin (Watanabe et al., 2007; Chiang et al., 2008) and ranking (Hopkins and May, 2011), and among which minimum error rate training (MERT) (Och, 2003) is the most popular one.

All these training methods follow the same pipeline: they train only a single weight on a given development set, and then use it to translate all the sentences in a test set. We call them a global training method. One of its advantages is that it allows us to train a single weight offline and thereby it is efficient. However, due to the diversity and uneven distribution of source sentences (Li et al., 2010), there are some shortcomings in this pipeline.

Firstly, on the document level, the performance of these methods is dependent on the choice of a development set, which may potentially lead to an unstable translation performance for testing. As referred in our experiment, the BLEU points on NIST08 are

Figure 1: (a). An Example candidate space of dimensionality two.  $score$  is a evaluation metric of  $e$ . (b). The non-linearly separable classification problem transformed from (a) via tuning as ranking (Hopkins and May, 2011). Since score of  $e_{11}$  is greater than that of  $e_{12}$ ,  $\langle 1, 0 \rangle$  corresponds to a positive example denoted as “\*”, and  $\langle -1, 0 \rangle$  corresponds to a negative example denoted as “•”. Since the transformed classification problem is not linearly separable, there does not exist a single weight which can obtain  $e_{11}$  and  $e_{21}$  as translation results meanwhile. However, one can obtain  $e_{11}$  and  $e_{21}$  with weights:  $\langle 1, 1 \rangle$  and  $\langle -1, 1 \rangle$ , respectively.

19.04 when the Moses system is tuned on NIST02 by MERT. However, its performance is improved to 21.28 points when tuned on NIST06. The automatic selection of a development set may partially address the problem. However it is inefficient since tuning requires iteratively decoding an entire development set, which is impractical for an online service.

Secondly, translation becomes inconsistent on the sentence level (Ma et al., 2011). Global training method such as MERT tries to optimize the weight towards the best performance for the whole set, and it can not necessarily always obtain good translation for every sentence in the development set. The reason is that different sentences may need different optimal weights, and MERT can not find a single weight to satisfy all of the sentences. **Figure 1(a)** shows such an example, in which a development set contains two sentences  $f_1$  and  $f_2$  with translations  $e$  and feature vectors  $h$ . When we tune examples in **Figure 1(a)** by MERT, it can be regarded as a non-linearly separable classification problem illustrated in **Figure 1(b)**. Therefore, there exists no single weight  $W$  which simultaneously obtains  $e_{11}$  and  $e_{21}$  as translation for  $f_1$  and  $f_2$  via Equation (1). However, we can achieve this with two weights:  $\langle 1, 1 \rangle$  for  $f_1$  and  $\langle -1, 1 \rangle$  for  $f_2$ .

In this paper, inspired by KNN-SVM (Zhang et al., 2006), we propose a local training method, which trains sentence-wise weights instead of a single weight, to address the above two problems. Compared with global training methods, such as

MERT, in which training and testing are separated, our method works in an online fashion, in which training is performed during testing. This online fashion has an advantage in that it can adapt the weights for each of the test sentences, by dynamically tuning the weights on translation examples which are similar to these test sentences. Similar to the method of development set automatical selection, the local training method may also suffer the problem of efficiency. To put it into practice, we propose incremental training methods which avoid retraining and iterative decoding on a development set.

Our local training method has two advantages: firstly, it significantly outperforms MERT, especially when test set is different from the development set; secondly, it improves the translation consistency. Experiments on NIST Chinese-to-English translation tasks show that our local training method significantly gains over MERT, with the maximum improvements up to 2.0 BLEU, and its efficiency is comparable to that of the global training method.

## 2 Local Training and Testing

The local training method (Bottou and Vapnik, 1992) is widely employed in computer vision (Zhang et al., 2006; Cheng et al., 2010). Compared with the global training method which tries to fit a single weight on the training data, the local one learns weights based on the local neighborhood information for each test example. It is superior to

the global one when the data sets are not evenly distributed (Bottou and Vapnik, 1992; Zhang et al., 2006).

---

### Algorithm 1 Naive Local Training Method

---

**Input:**  $T = \{t_i\}_{i=1}^N$  (test set),  $K$  (retrieval size),  $Dev$  (development set),  $D$  (retrieval data)

**Output:** Translation results of  $T$

- 1: **for all** sentence  $t_i$  such that  $1 \leq i \leq N$  **do**
  - 2: Retrieve the training examples  $D^i$  with size  $K$  for  $t_i$  from  $D$  according to a similarity;
  - 3: Train a local weight  $W^i$  based on  $Dev$  and  $D^i$ ;
  - 4: Decode  $t_i$  with  $W^i$ ;
  - 5: **end for**
- 

Suppose  $T$  be a test set,  $Dev$  a development set, and  $D$  a retrieval data. The local training in SMT is described in the **Algorithm 1**. For each sentence  $t_i$  in test set, training examples  $D^i$  is retrieved from  $D$  using a similarity measure (line 2), a weight  $W^i$  is optimized on  $Dev$  and  $D^i$  (line 3)<sup>1</sup>, and, finally,  $t_i$  is decoded with  $W^i$  for testing (line 4). At the end of this algorithm, it returns the translation results for  $T$ . Note that weights are adapted for each test sentence  $t_i$  in line 3 by utilizing the translation examples  $D^i$  which are similar to  $t_i$ . Thus, our local training method can be considered as an adaptation of translation weights.

Algorithm 1 suffers a problem of training efficiency in line 3. It is impractical to train a weight  $W^i$  on  $Dev$  and  $D^i$  from scratch for every sentence, since iteratively decoding  $Dev$  and  $D^i$  is time consuming when we apply MERT. To address this problem, we propose a novel incremental approach which is based on a two-phase training.

On the first phase, we use a global training method, like MERT, to tune a baseline weight on the development set  $Dev$  in an offline manner. On the second phase, we utilize the retrieved examples to incrementally tune sentence-wise local weights based on the baseline weight. This method can not only consider the common characteristics learnt from the  $Dev$ , but also take into account the knowl-

<sup>1</sup>Usually, the quality of development set  $Dev$  is high, since it is manually produced with multiple references. This is the main reason why  $Dev$  is used as a part of new development set to train  $W^i$ .

edge for each individual sentence learnt from similar examples during testing. On the phase of incremental training, we perform decoding only once for retrieved examples  $D^i$ , though several rounds of decoding are possible and potentially better if one does not seriously care about training speed. Furthermore, instead of on-the-fly decoding, we decode the retrieval data  $D$  offline using the parameter from our baseline weight and its nbest translation candidates are saved with training examples to increase the training efficiency.

---

### Algorithm 2 Local Training Method Based on Incremental Training

---

**Input:**  $T = \{t_i\}_{i=1}^N$  (test set),  $K$  (retrieval size),  $Dev$  (development set),  $D = \{\langle f_s, \mathbf{r}_s \rangle\}_{s=1}^{s=S}$  (retrieval data),

**Output:** Translation results of  $T$

- 1: Run global Training (such as MERT) on  $Dev$  to get a baseline weight  $W_b$ ; // **Phase 1**
  - 2: Decode each sentence in  $D$  to get  $D = \{\langle f_s, \mathbf{c}_s, \mathbf{r}_s \rangle\}_{s=1}^{s=S}$ ;
  - 3: **for all** sentence  $t_i$  such that  $1 \leq i \leq N$  **do**
  - 4: Retrieve  $K$  training examples  $D^i = \{\langle f_j^i, \mathbf{c}_j^i, \mathbf{r}_j^i \rangle\}_{j=1}^{j=K}$  for  $t_i$  from  $D$  according to a similarity;
  - 5: Incrementally train a local weight  $W^i$  based on  $W_b$  and  $D^i$ ; // **Phase 2**
  - 6: Decode  $t_i$  with  $W^i$ ;
  - 7: **end for**
- 

The two-phase local training algorithm is described in **Algorithm 2**, where  $\mathbf{c}_s$  and  $\mathbf{r}_s$  denote the translation candidate set and reference set for each sentence  $f_s$  in retrieval data, respectively, and  $K$  is the retrieval size. It globally trains a baseline weight  $W_b$  (line 1), and decodes each sentence in retrieval data  $D$  with the weight  $W_b$  (line 2). For each sentence  $t_i$  in test set  $T$ , it first retrieves training examples  $D^i$  from  $D$  (line 4), and then it runs local training to tune a local weight  $W^i$  (line 5) and performs testing with  $W^i$  for  $t_i$  (line 6). Please note that the two-phase training contains global training in line 1 and local training in line 5.

From Algorithm 2, one can see that our method is effective even if the test set is unknown, for example, in the scenario of online translation services, since the global training on development set and decoding

on retrieval data can be performed offline.

In the next two sections, we will discuss the details about the similarity metric in line 4 and the incremental training in line 5 of Algorithm 2.

### 3 Acquiring Training Examples

In line 4 of Algorithm 2, to retrieve training examples for the sentence  $t_i$ , we first need a metric to retrieve similar translation examples. We assume that the metric satisfy the property: more similar the test sentence and translation examples are, the better translation result one obtains when decoding the test sentence with the weight trained on the translation examples.

The metric we consider here is derived from an example-based machine translation. To retrieve translation examples for a test sentence, (Watanabe and Sumita, 2003) defined a metric based on the combination of edit distance and TF-IDF (Manning and Schütze, 1999) as follows:

$$\text{dist}(f_1, f_2) = \theta \times \text{edit-dist}(f_1, f_2) + (1 - \theta) \times \text{tf-idf}(f_1, f_2), \quad (2)$$

where  $\theta(0 \leq \theta \leq 1)$  is an interpolation weight,  $f_i(i = 1, 2)$  is a word sequence and can be also considered as a document. In this paper, we extract similar examples from training data. Like example-based translation in which similar source sentences have similar translations, we assume that the optimal translation weights of the similar source sentences are closer.

### 4 Incremental Training Based on Ultraconservative Update

Compared with retraining mode, incremental training can improve the training efficiency. In the field of machine learning research, incremental training has been employed in the work (Cauwenberghs and Poggio, 2001; Shilton et al., 2005), but there is little work for tuning parameters of statistical machine translation. The biggest difficulty lies in that the feature vector of a given training example, i.e. translation example, is unavailable until actually decoding the example, since the derivation is a latent variable. In this section, we will investigate the incremental training methods in SMT scenario.

Following the notations in Algorithm 2,  $W_b$  is the baseline weight,  $D^i = \{(f_j^i, c_j^i, r_j^i)\}_{j=1}^K$  denotes training examples for  $t_i$ . For the sake of brevity, we will drop the index  $i$ ,  $D^i = \{(f_j, c_j, r_j)\}_{j=1}^K$ , in the rest of this paper. Our goal is to find an optimal weight, denoted by  $W^i$ , which is a local weight and used for decoding the sentence  $t_i$ . Unlike the global method which performs tuning on the whole development set  $Dev + D^i$  as in Algorithm 1,  $W^i$  can be incrementally learned by optimizing on  $D^i$  based on  $W_b$ . We employ the idea of ultraconservative update (Crammer and Singer, 2003; Crammer et al., 2006) to propose two incremental methods for local training in Algorithm 2 as follows.

Ultraconservative update is an efficient way to consider the trade-off between the progress made on development set  $Dev$  and the progress made on  $D^i$ . It desires that the optimal weight  $W^i$  is not only close to the baseline weight  $W_b$ , but also achieves the low loss over the retrieved examples  $D^i$ . The idea of ultraconservative update can be formalized as follows:

$$\min_W \left\{ \mathbf{d}(W, W_b) + \lambda \cdot \text{Loss}(D^i, W) \right\}, \quad (3)$$

where  $\mathbf{d}(W, W_b)$  is a distance metric over a pair of weights  $W$  and  $W_b$ . It penalizes the weights far away from  $W_b$  and it is  $L_2$  norm in this paper.  $\text{Loss}(D^i, W)$  is a loss function of  $W$  defined on  $D^i$  and it evaluates the performance of  $W$  over  $D^i$ .  $\lambda$  is a positive hyperparameter. If  $D^i$  is more similar to the test sentence  $t_i$ , the better performance will be achieved for the larger  $\lambda$ . In particular, if  $D^i$  consists of only a single sentence  $t_i$ , the best performance will be obtained when  $\lambda$  goes to infinity.

#### 4.1 Margin Based Ultraconservative Update

MIRA(Crammer and Singer, 2003; Crammer et al., 2006) is a form of ultraconservative update in (3) whose  $\text{Loss}$  is defined as hinge loss based on margin over the pairwise translation candidates in  $D^i$ . It tries to minimize the following quadratic program:

$$\frac{1}{2} \|W - W_b\|^2 + \frac{\lambda}{K} \sum_{j=1}^K \max_{1 \leq n \leq |e_j|} (\ell_{jn} - W \cdot \Delta h(f_j, e_{jn}))$$

with

$$\Delta h(f_j, e_{jn}) = h(f_j, e_j) - h(f_j, e_{jn}), \quad (4)$$

where  $h(f_j, e)$  is the feature vector of candidate  $e$ ,  $e_{jn}$  is a translation member of  $f_j$  in  $\mathbf{c}_j$ ,  $e_j$  is the oracle one in  $\mathbf{c}_j$ ,  $\ell_{jn}$  is a loss between  $e_j$  and  $e_{jn}$  and it is the same as referred in (Chiang et al., 2008), and  $|\mathbf{c}_j|$  denotes the number of members in  $\mathbf{c}_j$ .

Different from (Watanabe et al., 2007; Chiang et al., 2008) employing the MIRA to globally train SMT, in this paper, we apply MIRA as one of local training method for SMT and we call it as margin based ultraconservative update (MBUU for shortly) to highlight its advantage of incremental training in line 5 of Algorithm 2.

Further, there is another difference between MBUU and MIRA in (Watanabe et al., 2007; Chiang et al., 2008). MBUU is a batch update mode which updates the weight with all training examples, but MIRA is an online one which updates with each example (Watanabe et al., 2007) or part of examples (Chiang et al., 2008). Therefore, MBUU is more ultraconservative.

## 4.2 Error Rate Based Ultraconservative Update

Instead of taking into account the margin-based hinge loss between a pair of translations as the  $\mathbf{Loss}$  in (3), we directly optimize the error rate of translation candidates with respect to their references in  $D^i$ . Formally, the objective function of error rate based ultraconservative update (EBUU) is as follows:

$$\frac{1}{2} \|W - W_b\|^2 + \frac{\lambda}{K} \sum_{j=1}^K \mathbf{Error}(\mathbf{r}_j; \hat{e}(f_j; W)), \quad (5)$$

where  $\hat{e}(f_j; W)$  is defined in Equation (1), and  $\mathbf{Error}(\mathbf{r}_j, e)$  is the sentence-wise minus BLEU (Papineni et al., 2002) of a candidate  $e$  with respect to  $\mathbf{r}_j$ .

Due to the existence of  $L_2$  norm in objective function (5), the optimization algorithm MERT can not be applied for this question since the exact line search routine does not hold here. Motivated by (Och, 2003; Smith and Eisner, 2006), we approximate the  $\mathbf{Error}$  in (5) by the expected loss, and then derive the following function:

$$\frac{1}{2} \|W - W_b\|^2 + \frac{\lambda}{K} \sum_{j=1}^K \sum_e \mathbf{Error}(\mathbf{r}_j; e) \mathbf{P}_\alpha(e|f_j; W), \quad (6)$$

Systems	NIST02	NIST05	NIST06	NIST08
Moses	30.39	26.31	25.34	19.07
Moses_hier	33.68	26.94	26.28	18.65
In-Hiero	31.24	27.07	26.32	19.03

Table 1: The performance comparison of the baseline In-Hiero VS Moses and Moses\_hier.

with

$$\mathbf{P}_\alpha(e|f_j; W) = \frac{\exp[\alpha W \cdot h(f_j, e)]}{\sum_{e' \in \mathbf{c}_j} \exp[\alpha W \cdot h(f_j, e')]}, \quad (7)$$

where  $\alpha > 0$  is a real number valued smoother. One can see that, in the extreme case, for  $\alpha \rightarrow \infty$ , (6) converges to (5).

We apply the gradient decent method to minimize the function (6), as it is smooth with respect to  $\lambda$ . Since the function (6) is non-convex, the solution obtained by gradient descent method may depend on the initial point. In this paper, we set the initial point as  $W_b$  in order to achieve a desirable solution.

## 5 Experiments and Results

### 5.1 Setting

We conduct our experiments on the Chinese-to-English translation task. The training data is FBIS corpus consisting of about 240k sentence pairs. The development set is NIST02 evaluation data, and the test datasets are NIST05, NIST06, and NIST08.

We run GIZA++ (Och and Ney, 2000) on the training corpus in both directions (Koehn et al., 2003) to obtain the word alignment for each sentence pair. We train a 4-gram language model on the Xinhua portion of the English Gigaword corpus using the SRILM Toolkits (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen and Goodman, 1998). In our experiments the translation performances are measured by case-insensitive BLEU4 metric (Papineni et al., 2002) and we use mteval-v13a.pl as the evaluation tool. The significance testing is performed by paired bootstrap re-sampling (Koehn, 2004).

We use an in-house developed hierarchical phrase-based translation (Chiang, 2005) as our baseline system, and we denote it as **In-Hiero**. To obtain satisfactory baseline performance, we tune In-Hiero system for 5 times using MERT, and then se-

Methods	Steps	Seconds
Global method	Decoding	2.0
Local method	Retrieval	+0.6
	Local training	+0.3

Table 2: The efficiency of the local training and testing measured by sentence averaged runtime.

Methods		NIST05	NIST06	NIST08
Global	MERT	27.07	26.32	19.03
Local	MBUU	27.75 <sup>+</sup>	27.88 <sup>+</sup>	20.84 <sup>+</sup>
	EBUU	27.85 <sup>+</sup>	27.99 <sup>+</sup>	21.08 <sup>+</sup>

Table 3: The performance comparison of local training methods (MBUU and EBUU) and a global method (MERT). NIST05 is the set used to tune  $\lambda$  for MBUU and EBUU, and NIST06 and NIST08 are test sets. + means the local method is significantly better than MERT with  $p < 0.05$ .

lect the best-performing one as our baseline for the following experiments. As Table 1 indicates, our baseline In-Hiero is comparable to the phrase-based MT (Moses) and the hierarchical phrase-based MT (Moses\_hier) implemented in Moses, an open source MT toolkit<sup>2</sup> (Koehn et al., 2007). Both of these systems are with default setting. All three systems are trained by MERT with 100 best candidates.

To compare the local training method in Algorithm 2, we use a standard global training method, MERT, as the baseline training method. We do not compare with Algorithm 1, in which retraining is performed for each input sentence, since retraining for the whole test set is impractical given that each sentence-wise retraining may take some hours or even days. Therefore, we just compare Algorithm 2 with MERT.

## 5.2 Runtime Results

To run the Algorithm 2, we tune the baseline weight  $W_b$  on NIST02 by MERT<sup>3</sup>. The retrieval data is set as the training data, i.e. FBIS corpus, and the retrieval size is 100. We translate retrieval data with  $W_b$  to obtain their 100 best translation candidates. We use the simple linear interpolated TF-IDF metric with  $\theta = 0.1$  in Section 3 as the retrieval metric.

<sup>2</sup>See web: <http://www.statmt.org>

<sup>3</sup> $W_b$  is exactly the weight of In-Hiero in Table 1.

	NIST05	NIST06	NIST08
NIST02	0.665	0.571	0.506

Table 4: The similarity of development and three test datasets.

For an efficient tuning, the retrieval process is parallelized as follows: the examples are assigned to 4 CPUs so that each CPU accepts a query and returns its top-100 results, then all these top-100 results are merged into the final top-100 retrieved examples together with their translation candidates. In our experiments, we employ the two incremental training methods, i.e. MBUU and EBUU. Both of the hyperparameters  $\lambda$  are tuned on NIST05 and set as 0.018 and 0.06 for MBUU and EBUU, respectively. In the incremental training step, only one CPU is employed.

Table 2 depicts that testing each sentence with local training method takes 2.9 seconds, which is comparable to the testing time 2.0 seconds with global training method<sup>4</sup>. This shows that the local method is efficient. Further, compared to the retrieval, the local training is not the bottleneck. Actually, if we use LSH technique (Andoni and Indyk, 2008) in retrieval process, the local method can be easily scaled to a larger training data.

## 5.3 Results and Analysis

Table 3 shows the main results of our local training methods. The EBUU training method significantly outperforms the MERT baseline, and the improvement even achieves up to 2.0 BLEU points on NIST08. We can also see that EBUU and MBUU are comparable on these three test sets. Both of these two local training methods achieve significant improvements over the MERT baseline, which proves the effectiveness of our local training method over global training method.

Although both local methods MBUU and EBUU achieved improvements on all the datasets, their gains on NIST06 and NIST08 are significantly higher than those achieved on NIST05 test dataset. We conjecture that, the more different a test set and a development set are, the more potential improvem-

<sup>4</sup>The runtime excludes the time of tuning and decoding on  $D$  in Algorithm 2, since both of them can be performed offline.

Figure 2: The performance of EBUU for different  $\lambda$  over all the test datasets. The horizontal axis denotes the values of  $\lambda$  in function (6), and the vertical one denotes the BLEU points.

Methods	Dev	NIST08
MERT	NIST02	19.03
	NIST05	20.06
	NIST06	21.28
EBUU	NIST02	21.08

Table 5: The comparison of MERT with different development datasets and local training method based on EBUU.

nts local training has for the sentences in this test set. To test our hypothesis, we measured the similarity between the development set and a test set by the average value<sup>5</sup> of accumulated TF-IDF scores of development dataset and each sentence in test datasets. Table 4 shows that NIST06 and NIST08 are more different from NIS02 than NIST05, thus, this is potentially the reason why local training is more effective on NIST06 and NIST08.

As mentioned in Section 1, the global training methods such as MERT are highly dependent on development sets, which can be seen in Table 5. Therefore, the translation performance will be degraded if one chooses a development data which is not close

<sup>5</sup>Instead of using the similarity between two documents development and test datasets, we define the similarity as the average similarity of the development set and the sentences in test set. The reason is that it reduces its dependency on the number of sentences in test dataset, which may cause a bias.

Methods	Number	Percents
MERT	1735	42.3%
EBUU	1606	39.1%

Table 6: The statistics of sentences with 0.0 sentence-level BLEU points over three test datasets.

to the test data. We can see that, with the help of the local training, we still gain much even if we selected an unsatisfactory development data.

As also mentioned in Section 1, the global methods do not care about the sentence level performance. Table 6 depicts that there are 1735 sentences with zero BLEU points in all the three test datasets for MERT. Besides obtaining improvements on document level as referred in Table 3, the local training methods can also achieve consistent improvements on sentence level and thus can improve the users' experiences.

The hyperparameters  $\lambda$  in both MBUU (4) and EBUU (6) has an important influence on translation performance. Figure 2 shows such influence for EBUU on the test datasets. We can see that, the performances on all these datasets improve as  $\lambda$  becomes closer to 0.06 from 0, and the performance continues improving when  $\lambda$  passes over 0.06 on NIST08 test set, where the performance constantly improves up to 2.6 BLEU points over baseline. As mentioned in Section 4, if the retrieved examples are very similar to the test sentence, the better performance will be achieved with the larger  $\lambda$ . Therefore, it is reasonable that the performances improved when  $\lambda$  increased from 0 to 0.06. Further, the turning point appearing at 0.06 proves that the ultra-conservative update is necessary. We can also see that the performance on NIST08 consistently improves and achieves the maximum gain when  $\lambda$  arrives at 0.1, but those on both NIST05 and NIST06 achieves the best when it arrives at 0.06. This phenomenon can also be interpreted in Table 4 as the lowest similarity between the development and NIST08 datasets.

Generally, the better performance may be achieved when more examples are retrieved. Actually, in Table 7 there seems to be little dependency between the numbers of examples retrieved and the translation qualities, although they are positively re-

Retrieval Size	NIST05	NIST06	NIST08

lated approximately.

Table 8 presents the performance of the oracle translations selected from the 1-best translation results of MERT and EBUU. Clearly, there exists more potential improvement for local training method.

## 6 Related Work

Several works have proposed discriminative techniques to train log-linear model for SMT. (Och and Ney, 2002; Blunsom et al., 2008) used maximum likelihood estimation to learn weights for MT. (Och, 2003; Moore and Quirk, 2008; Zhao and Chen, 2009; Galley and Quirk, 2011) employed an evaluation metric as a loss function and directly optimized it. (Watanabe et al., 2007; Chiang et al., 2008; Hopkins and May, 2011) proposed other optimization objectives by introducing a margin-based and ranking-based indirect loss functions.

All the methods mentioned above train a single weight for the whole development set, whereas our local training method learns a weight for each sentence. Further, our translation framework integrates the training and testing into one unit, instead of treating them separately. One of the advantages is that it can adapt the weights for each of the test sentences.

Our method resorts to some translation examples, which is similar as example-based translation or translation memory (Watanabe and Sumita, 2003; He et al., 2010; Ma et al., 2011). Instead of using translation examples to construct translation rules for enlarging the decoding space, we employed them

to discriminatively learn local weights.

Similar to (Hildebrand et al., 2005; Lü et al., 2007), our method also employs IR methods to retrieve examples for a given test set. Their methods utilize the retrieved examples to acquire translation model and can be seen as the adaptation of translation model. However, ours uses the retrieved examples to tune the weights and thus can be considered as the adaptation of tuning. Furthermore, since ours does not change the translation model which needs to run GIZA++ and it incrementally trains local weights, our method can be applied for online translation service.

## 7 Conclusion and Future Work

This paper proposes a novel local training framework for SMT. It has two characteristics, which are different from global training methods such as MERT. First, instead of training only one weight for document level, it trains a single weight for sentence level. Second, instead of considering the training and testing as two separate units, we unify the training and testing into one unit, which can employ the information of test sentences and perform sentence-wise local adaptation of weights.

Local training can not only alleviate the problem of the development data selection, but also reduce the risk of sentence-wise bad translation results, thus consistently improve the translation performance. Experiments show gains up to 2.0 BLEU points compared with a MERT baseline. With the help of incremental training methods, the time incurred by local training was negligible and the local training and testing totally took 2.9 seconds for each sentence.

In the future work, we will further investigate the local training method, since there are more room for improvements as observed in our experiments. We will test our method on other translation models and larger training data<sup>6</sup>.

## Abstract

In this paper we first describe the technology of automatic annotation transformation, which is based on the annotation adaptation algorithm (Jiang et al., 2009). It can automatically transform a human-annotated corpus from one annotation guideline to another. We then propose two optimization strategies, iterative training and predict-self reestimation, to further improve the accuracy of annotation guideline transformation. Experiments on Chinese word segmentation show that, the iterative training strategy together with predict-self reestimation brings significant improvement over the simple annotation transformation baseline, and leads to classifiers with significantly higher accuracy and several times faster processing than annotation adaptation does. On the Penn Chinese Treebank 5.0, it achieves an F-measure of 98.43%, significantly outperforms previous works although using a single classifier with only local features.

## 1 Introduction

Annotation guideline adaptation depicts a general pipeline to integrate the knowledge of corpora with different underlying annotation guidelines (Jiang et al., 2009). In annotation adaptation two classifiers are cascaded together, where the classification results of the lower classifier are used as guiding features of the upper classifier, in order to achieve more accurate classification. This method can automatically adapt the divergence between different annotation guidelines and bring improvement to Chi-

nese word segmentation. However, the need of cascaded classification decisions makes it less practical for tasks of high computational complexity such as parsing, and less efficient to incorporate more than two annotated corpora.

In this paper, we first describe the algorithm of automatic annotation transformation. It is based on the annotation adaptation algorithm, and it focuses on the automatic transformation (rather than adaptation) of a human-annotated corpus from one annotation guideline to another. First, a classifier is trained on the corpus with an annotation guideline not desired, it is used to classify the corpus with the annotation guideline we want, so as to obtain a corpus with parallel annotation guidelines. Then a second classifier is trained on the parallelly annotated corpus to learn the statistical regularity of annotation transformation, and it is used to process the previous corpus to transform its annotation guideline to that of the target corpus. Instead of the online knowledge integration methodology of annotation adaptation, annotation transformation can lead to improved classification accuracy in an offline manner by using the transformed corpora as additional training data for the classifier. This method leads to an enhanced classifier with much faster processing than the cascaded classifiers in annotation adaptation.

We then propose two optimization strategies, iterative training and predict-self reestimation, to further improve the accuracy of annotation transformation. Although the transformation classifiers can only be trained on corpora with autogenerated (rather than gold) parallel annotations, an iterative training procedure can gradually improve the trans-

formation accuracy by iteratively optimizing the parallelly annotated corpora. Both source-to-target and target-to-source annotation transformations are performed in each training iteration, and the transformed corpora are used to provide better annotations for the parallelly annotated corpora of the next iteration; then the better parallelly annotated corpora will result in more accurate transformation classifiers, which will generate better transformed corpora in the new iteration. The predict-self reestimation is based on the following hypothesis, a better transformation result should be easier to be transformed back to the original form. The predict-self heuristic is also validated by Daumé III (2009) in unsupervised dependency parsing.

Experiments in Chinese word segmentation show that, the iterative training strategy together with predict-self reestimation brings significant improvement over the simple annotation transformation baseline. We perform optimized annotation transformation from the People’s Daily (Yu et al., 2001) to the Penn Chinese Treebank 5.0 (CTB) (Xue et al., 2005), in order to improve the word segmenter with CTB annotation guideline. Compared to annotation adaptation, the optimized annotation transformation strategy leads to classifiers with significantly higher accuracy and several times faster processing on the same data sets. On CTB 5.0, it achieves an F-measure of 98.43%, significantly outperforms previous works although using a single classifier with only local features.

The rest of the paper is organized as follows. Section 2 describes the classification-based Chinese word segmentation method. Section 3 details the simple annotation transformation algorithm and the two optimization methods. After the introduction of related works in section 4, we give the experimental results on Chinese word segmentation in section 5.

## 2 Classification-Based Chinese Word Segmentation

Chinese word segmentation can be formalized as the problem of sequence labeling (Xue and Shen, 2003), where each character in the sentence is given a boundary tag denoting its position in a word. Following Ng and Low (2004), joint word segmentation and part-of-speech (POS) tagging can also be

---

1: Input: Training examples  $(x_i, y_i)$ 
2:  $\vec{\alpha} \leftarrow \mathbf{0}$ 
3: for  $t \leftarrow 1 .. T$  do
4:   for  $i \leftarrow 1 .. N$  do
5:      $z_i \leftarrow \operatorname{argmax}_{z \in \mathbf{GEN}(x_i)} \Phi(x_i, z) \cdot \vec{\alpha}$ 
6:     if  $z_i \neq y_i$  then
7:        $\vec{\alpha} \leftarrow \vec{\alpha} + \Phi(x_i, y_i) - \Phi(x_i, z_i)$ 
8: Output: Parameters  $\vec{\alpha}$ 

```

---

solved in a character classification approach by extending the boundary tags to include POS information. For word segmentation we adopt the 4 boundary tags of Ng and Low (2004),  $b, m, e$  and  $s$ , where  $b, m$  and  $e$  mean the beginning, the middle and the end of a word, and  $s$  indicates a single-character word. The word segmentation result can be generated by splitting the labeled character sequence into subsequences of pattern  $s$  or  $bm^*e$ , indicating single-character words or multi-character words, respectively.

We choose the perceptron algorithm (Collins, 2002) to train the character classifier. It is an online training algorithm and has been successfully used in many NLP tasks, including POS tagging (Collins, 2002), parsing (Collins and Roark, 2004) and word segmentation (Zhang and Clark, 2007; Jiang et al., 2008; Zhang and Clark, 2010).

The training procedure learns a discriminative model mapping from the inputs  $x \in X$  to the outputs  $y \in Y$ , where  $X$  is the set of sentences in the training corpus and  $Y$  is the set of corresponding labeled results. We use the function  $\mathbf{GEN}(x)$  to enumerate the candidate results of an input  $x$ , and the function  $\Phi$  to map a training example  $(x, y) \in X \times Y$  to a feature vector  $\Phi(x, y) \in R^d$ . Given the character sequence  $x$ , the decoder finds the output  $F(x)$  that maximizes the score function:

$$\begin{aligned}
 F(x) &= \operatorname{argmax}_{y \in \mathbf{GEN}(x)} \mathbf{S}(y | \vec{\alpha}, \Phi, x) \\
 &= \operatorname{argmax}_{y \in \mathbf{GEN}(x)} \Phi(x, y) \cdot \vec{\alpha}
 \end{aligned} \tag{1}$$

Where  $\vec{\alpha} \in R^d$  is the parameter vector (that is, the discriminative model) and  $\Phi(x, y) \cdot \vec{\alpha}$  is the inner product of  $\Phi(x, y)$  and  $\vec{\alpha}$ .

Algorithm 1 shows the perceptron algorithm for tuning the parameter  $\vec{\alpha}$ . The ‘‘averaged parameters’’

technology (Collins, 2002) is used for better performance. The feature templates for the classifier is shown in Table 1.  $C_0$  denotes the current character, while  $C_{-i}/C_i$  denote the  $i$ th character to the left/right of  $C_0$ . The function  $Pu(\cdot)$  returns *true* for a punctuation character and *false* for others, the function  $T(\cdot)$  classifies a character into four types: number, date, English letter and others.

### 3 Iterative and Predict-Self Annotation Transformation

This section first describes the technology of automatic annotation transformation, then introduces the two optimization strategies, iterative training and predict-self reestimation. Iterative training takes a global view, it conducts several rounds of bidirectional annotation transformations, and improve the transformation performance round by round. Predict-self reestimation takes a local view instead, it considers each training sentence, and improves the transformation performance by taking into account the predication result of the reverse transformation. The two strategies can be adopted jointly to obtain better transformation performance.

#### 3.1 Automatic Annotation Transformation

Annotation adaptation can integrate the knowledge from two corpora with different underling annotation guidelines. First, a classifier (source classifier) is trained on the corpus (source corpus) with an annotation standard (source annotation) not desired, it is then used to classify the corpus (target corpus) with the annotation standard (target annotation) we want. Then a second classifier (transformation classifier<sup>1</sup>) is trained on the target corpus with

<sup>1</sup>It is called *target classifier* in (Jiang et al., 2009). We think that *transformation classifier* better reflects its role, the

	$T(C_{-2})T(C_{-1})T(C_0)T(C_1)T(C_2) \circ \alpha$		

Table 2: Feature templates for annotation transformation, where  $\alpha$  is short for  $\alpha(C_0)$ , representing the source annotation of  $C_0$ .

the source classifier’s classification result as guiding features. In decoding, a raw sentence is first decoded by the source classifier, and then inputted into the transformation classifier together with the annotations given by the source classifier, so as to obtain an improved classification result.

However, annotation adaptation has a drawback, it has to cascade two classifiers in decoding to integrate the knowledge in two corpora, thus seriously degrades the processing speed. This paper describes a variant of annotation adaptation, name annotation transformation, aiming at automatic transformation (rather than adaptation) between annotation standards of human-annotated corpora. In annotation transformation, a source classifier and a transformation classifier are trained in the same way as in annotation adaptation. The transformation classifier is used to process the source corpus, with the classification label derived from the segmented sentences as the guiding features, so as to relabel the source corpus with the target annotation guideline. By integrating the target corpus and the transformed source corpus for the training of the character classifier, improved classification accuracy can be achieved.

Both the source classifier and the transformation classifier are trained with the perceptron algorithm. The feature templates used for the source classifier are the same with those for the baseline

renaming also avoids name confusion in the optimized annotation transformation.

character classifier. The feature templates for the transformation classifier are the same with those in annotation adaptation, as listed in Table 2. Algorithm 2 shows the overall training algorithm for annotation transformation.  $\mathcal{C}_s$  and  $\mathcal{C}_t$  denote the source corpus and the target corpus;  $\mathcal{M}_s$  and  $\mathcal{M}_{s \rightarrow t}$  denote the source classifier and the transformation classifier;  $\mathcal{C}_p^q$  denotes the  $p$  corpus re-labeled in  $q$  annotation guideline, for example  $\mathcal{C}_s^t$  is the source corpus transformed to target annotation guideline; Functions TRAIN and TRANSTRRAIN both invoke the perceptron algorithm, yet with different feature sets; Functions ANNOTATE and TRANSANNOTATE call the function DECODE with different models (source/transformation classifiers), feature functions (without/with guiding features), and inputs (raw/source-annotated sentences).

The best training iterations for the functions TRAIN and TRANSTRRAIN are determined on the developing sets of the source corpus and the target corpus, respectively. In the algorithm the parameters corresponding to developing sets are omitted for simplicity. Compared to the online knowledge integration methodology of annotation adaptation, annotation transformation leads to improved performance in an offline manner by integrating corpora before the training procedure. This manner could achieve processing several times as fast as the cascaded classifiers in annotation adaptation. In the following we will describe the two optimization strategies in details.

### 3.2 Iterative Training for Annotation Transformation

The training of annotation transformation is based on an auto-generated (rather than gold) parallelly annotated corpus, where the source annotation is pro-

---

**Algorithm 3** Iterative annotation transformation.

```

---

vided by the source classifier. Therefore, the performance of transformation training is correspondingly determined by the accuracy of the source classifier.

We propose an iterative training procedure to gradually improve the transformation accuracy by iteratively optimizing the parallelly annotated corpora. In each training iteration, both source-to-target and target-to-source annotation transformations are performed, and the transformed corpora are used to provide better annotations for the parallelly annotated corpora of the next iteration. Then in the new iteration, the better parallelly annotated corpora will result in more accurate transformation classifiers, so as to generate better transformed corpora.

Algorithm 3 shows the overall procedure of the iterative training method. The loop of lines 6-13 iteratively performs source-to-target and target-to-source annotation transformations. The source annotations of the parallelly annotated corpora,  $\mathcal{C}_t^s$  and  $\mathcal{C}_s^t$ , are initialized by applying the source and target classifiers respectively on the target and source corpora (lines 2-5). In each training iteration, the transformation classifiers are trained on the current parallelly annotated corpora (lines 7-8), they are used to produce the transformed corpora (lines 9-10) which provide better annotations for the parallelly annotated corpora of the next iteration. The iterative training terminates when the performance of the classifier trained on the merged corpus  $\mathcal{C}_s^t \cup \mathcal{C}_t$  converges.

The discriminative training of TRANSTRAIN predicts the target annotations with the guidance of source annotations. In the first iteration, the transformed corpora generated by the transformation classifiers are better than the initialized ones generated by the source and target classifiers, due to the assistance of the guiding features. In the following iterations, the transformed corpora provide better annotations for the parallelly annotated corpora of the subsequent iteration, the transformation accuracy will improve gradually along with optimization of the parallelly annotated corpora until convergence.

### 3.3 Predict-Self Reestimation for Annotation Transformation

The predict-self hypothesis is implicit in many unsupervised learning approaches, such as Markov random field. This methodology has also been successfully used by Daumé III (2009) in unsupervised dependency parsing. The basic idea of predict-self is that, if a prediction is a better candidate for an input, it can be easier converted back to the original input by a reverse procedure. If applied to the task of annotation transformation, predict-self indicates that a better transformation candidate following the target annotation guideline can be easier transformed back to the original form following the source annotation guideline.

The most intuitionistic strategy to introduce the predict-self methodology into annotation transformation is using a reversed annotation transformation procedure to filter out unreliable predictions of the previous transformation. In detail, a source-to-target annotation transformation is performed on the source annotated sentence to obtain a prediction that follows the target annotation guideline, then a second, target-to-source transformation is performed on this prediction result to check whether it can be transformed back to the previous source annotation. Transformation results failing in this reversal verification are discarded, so this strategy is named predict-self filtration.

A more precious strategy can be called predict-self reestimation. Instead of using the reversed transformation procedure for filtration, the reestimation strategy integrates the scores given by the source-to-target and target-to-source annotation

transformation models when evaluating the transformation candidates. By properly tuning the relative weights of the two transformation directions, better transformation performance would be achieved. The scores of the two transformation models are weighted integrated in a log-linear manner:

$$\begin{aligned} \mathbf{S}^+(y|\mathcal{M}_{s\rightarrow t}, \mathcal{M}_{t\rightarrow s}, \Phi, x) \\ = (1 - \lambda) \times \mathbf{S}(y|\mathcal{M}_{s\rightarrow t}, \Phi, x) \\ + \lambda \times \mathbf{S}(x|\mathcal{M}_{t\rightarrow s}, \Phi, y) \end{aligned} \quad (2)$$

The weight parameter  $\lambda$  is tuned on the developing set. To integrating the predict-self reestimation into the iterative transformation training, a reversed transformation model is introduced and the enhanced scoring function above is used when the function TRANSANNOTATE invokes the function DECODE.

## 4 Related Works

Researches focused on the automatic adaptation between different corpora can be roughly classified into two kinds, adaptation between different domains (with different statistical distribution) (Blitzer et al., 2006; Daumé III, 2007), and adaptation between different annotation guidelines (Jiang et al., 2009; Zhu et al., 2011). There are also some efforts that totally or partially resort to manual transformation rules, to conduct treebank conversion (Cahill and Mccarthy, 2002; Hockenmaier and Steedman, 2007; Clark and Curran, 2009), and word segmentation guideline transformation (Gao et al., 2004; Mi et al., 2008). This work focuses on the automatic transformation between annotation guidelines, and proposes better annotation transformation technologies to improve the transformation accuracy and the utilization rate of human-annotated knowledge.

The iterative training procedure proposed in this work shares some similarity with the co-training algorithm in parsing (Sarkar, 2001), where the training procedure lets two different models learn from each other during parsing the raw text. The key idea of co-training is utilize the complementarity of different parsing models to mine additional training data from raw text, while iterative training for annotation transformation emphasizes the iterative optimization of the parallelly annotated corpora used

to train the transformation models. The predict-self methodology is implicit in many unsupervised learning approaches, it has been successfully used by (Daumé III, 2009) in unsupervised dependency parsing. We adapt this idea to the scenario of annotation transformation to improve transformation accuracy.

In recent years many works have been devoted to the word segmentation task. For example, the introduction of global training or complicated features (Zhang and Clark, 2007; Zhang and Clark, 2010); the investigation of word structures (Li, 2011); the strategies of hybrid, joint or stacked modeling (Nakagawa and Uchimoto, 2007; Kruegkrai et al., 2009; Wang et al., 2010; Sun, 2011), and the semi-supervised and unsupervised technologies utilizing raw text (Zhao and Kit, 2008; Johnson and Goldwater, 2009; Mochihashi et al., 2009; Hewlett and Cohen, 2011). We estimate that the annotation transformation technologies can be adopted jointly with complicated features, system combination and semi-supervised/unsupervised technologies to further improve segmentation performance.

## 5 Experiments and Analysis

We perform annotation transformation from People’s Daily (PD) (Yu et al., 2001) to Penn Chinese Treebank 5.0 (CTB) (Xue et al., 2005), following the same experimental setting as the annotation adaptation work (Jiang et al., 2009) for convenience of comparison. The two corpora are segmented following different segmentation guidelines and differ largely in quantity of data. CTB is smaller in size with about 0.5M words, while PD is much larger, containing nearly 6M words.

Train on	Test on ( $F_1\%$ )	
	CTB	SPD
CTB	97.35	86.65(↓ 10.70)
SPD	91.23(↓ 3.02)	94.25

Table 4: Performance of the perceptron classifiers for Chinese word segmentation.

Model	Time (s)	Accuracy ( $F_1\%$ )
Merging	<b>1.33</b>	93.79
Anno. Adapt.	4.39	97.67
Anno. Trans.	<b>1.33</b>	<b>97.69</b>
Baseline	1.21	97.35

Table 5: Comparison of the baseline annotation transformation, annotation adaptation and a simple corpus merging strategy.

To approximate more general scenarios of annotation adaptation problems, we extract from PD a subset which is comparable to CTB in size. We randomly select 20,000 sentences (0.45M words) from the PD training data as the new training set, and 1000/1000 sentences from the PD test data as the new test/developing set.<sup>2</sup> We name the smaller version of PD as SPD. The balanced source corpus and target corpus also facilitate the investigation of annotation transformation.

### 5.1 Baseline Classifiers for Word Segmentation

We train the baseline perceptron classifiers described in section 2 on the training sets of SPD and CTB, using the developing sets to determine the best training iterations. The performance measurement indicators for word segmentation is balanced F-measure,  $F = 2PR/(P + R)$ , a function of Precision  $P$  and Recall  $R$ . where  $P$  is the percentage of words in segmentation result that are segmented correctly, and  $R$  is the percentage of correctly segmented words in the gold standard words.

Accuracies of the baseline classifiers are listed in Table 4. We also report the performance of the classifiers on the test sets of the opposite corpora. Experimental results are in line with our expectations. A classifier performs better in its corresponding test set, and performs significantly worse on a test set following a different annotation guideline.

<sup>2</sup>There are many extremely long sentences in original PD corpus, we split them into normal sentences according to period punctuations.

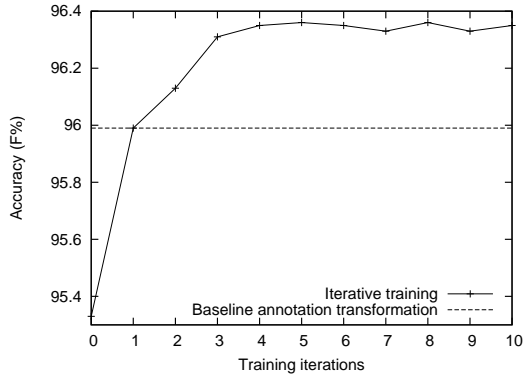

Figure 1: Learning curve of iterative training for annotation transformation.

## 5.2 Annotation Transformation vs. Annotation Adaptation

Experiments of annotation transformation are conducted on the direction of SPD-to-CTB. The transformed corpus can be merged into the regular corpus, so as to train an enhanced classifier. As comparison, the cascaded model of annotation adaptation (Jiang et al., 2009) is faithfully implemented (yet using our feature representation) and tested on the same adaptation direction.

Table 5 shows the performances of the classifiers resulted by the baseline annotation transformation and annotation adaptation, as well as the classifier trained on the directly merged corpus. The time costs for decoding are also listed to facilitate the comparison of practicality. We find that the simple corpus merging strategy leads to dramatic decrease in accuracy, due to the different and incompatible annotation guidelines. The baseline annotation transformation method leads to a classifier with accuracy increment comparable to that of the annotation adaptation strategy, while consuming only one third of the decoding time.

## 5.3 Iterative Training with Predict-Self Reestimation

We adopt the iterative training strategy to the baseline annotation transformation model. The CTB developing set is used to determine the best training iteration for annotation transformation from SPD to CTB. After each iteration, we test the performance of the classifier trained on the merged corpus. Figure 1 shows the performance curve, with iterations

Figure 2: Performance of predict-self filtration and predict-self reestimation.

Figure 3: Learning curve of iterative training with predict-self reestimation for annotation transformation.

ranging from 1 to 10. The performance of the baseline annotation transformation model is naturally included in the curve (located at iteration 1). The curve shows that the performance of the classifier trained on the merged corpus consistently improves from iteration 2 to iteration 5.

Experimental results of predict-self filtration and predict-self reestimation are shown in Figure 2. The curve shows the performance of the predict-self reestimation according to a series of weight parameters, ranging from 0 to 1 with step 0.05. The point at  $\lambda = 0$  shows the performance of the baseline annotation transformation strategy. The upper horizontal line shows the performance of predict-self filtration. We find that predict-self filtration brings slight improvement over the baseline, and predict-self reestimation outperforms the filtration strategy when  $\lambda$  falls in a proper range. An initial analysis on the experimental results of predict-self filtration

Opt. Trans.	<b>1.37</b>	<b>98.43</b>
<b>Previous Works</b>		
(Jiang et al., 2008)		97.85
(Kruengkrai et al., 2009)		97.87
(Zhang and Clark, 2010)		97.79
(Sun, 2011)		98.17

Table 6: The performance of the iterative annotation transformation with predict-self reestimation compared with annotation adaptation.

shows that, the filtration discards 5% of the training sentences and these discarded sentences contain nearly 10% of training words. It can be confirmed that the sentences discarded by predict-self filtration are much longer and more complicated. With a properly tuned weight, predict-self reestimation can make better use of the training data. The best F-measure improvement achieved over the annotation transformation baseline is 0.3 points, a little worse than that brought by iterative training.

Figure 3 shows the performance curve of iterative annotation transformation with predict-self reestimation. We find that the predict-self reestimation brings improvement to the iterative training at each iteration. The maximum performance is achieved at iteration 4. The corresponding model is evaluated on the test set of CTB, table 6 shows the experimental results. Compared to annotation adaptation, the optimized annotation transformation strategy leads to a classifier with significantly higher accuracy and several times faster processing. When using the whole PD as the source corpus, the final classifier<sup>3</sup> achieves an F-measure of 98.43%, significantly outperforms previous works although using a single classifier with only local features. Of course, the comparison between our system and previous works without using additional training data is unfair. This work aim to find another way to improve Chinese word segmentation, which focuses on the collection of more training data instead of mak-

<sup>3</sup>The predict-self reestimation ratio  $\lambda$  is fixed after the first training iteration for efficiency.

ing full use of a certain corpus. We believe that the performance can be further improved by adopting the advanced technologies of previous works, such as complicated features and model combination.

Considering the fact that today some corpora for word segmentation are really large (usually tens of thousands of sentences), it is necessary to obtain the latest CTB and investigate whether and how much does annotation transformation bring improvement to a much higher baseline. On the other hand, it is valuable to conduct experiments with more source-annotated training data, such as the SIGHAN dataset, to investigate the trend of improvement along with the increment of the additional annotated sentences. It is also valuable to evaluate the improved word segmenter on the out-of-domain datasets. However, currently most corpora for Chinese word segmentation do not explicitly distinguish the domains of their data sections, it makes such evaluations difficult to conduct.

## 6 Conclusion and Future Works

In this paper, we first describe an annotation transformation algorithm to automatically transform a human-annotated corpus from one annotation guideline to another. Then we propose two optimization strategies, iterative training and predict-self reestimation, to further improve the accuracy of annotation guideline transformation. On Chinese word segmentation, the optimized annotation transformation strategy leads to classifiers with obviously better performance and several times faster processing on the same datasets, compared to annotation adaptation. When adopting the whole PD as the source corpus, the final classifier significantly outperforms previous works on CTB 5.0, although using a single classifier with only local features.

As future works, we will investigate the acceleration of the iterative training and the weight parameter tuning, and extend the optimized annotation transformation strategy to joint Chinese word segmentation and POS tagging, parsing and other NLP tasks.

## Abstract

Microblog normalisation methods often utilise complex models and struggle to differentiate between correctly-spelled unknown words and lexical variants of known words. In this paper, we propose a method for constructing a dictionary of lexical variants of known words that facilitates lexical normalisation via simple string substitution (e.g. *tomorrow* for *tmrw*). We use context information to generate possible variant and normalisation pairs and then rank these by string similarity. Highly-ranked pairs are selected to populate the dictionary. We show that a dictionary-based approach achieves state-of-the-art performance for both F-score and word error rate on a standard dataset. Compared with other methods, this approach offers a fast, lightweight and easy-to-use solution, and is thus suitable for high-volume microblog pre-processing.

## 1 Lexical Normalisation

A staggering number of short text “microblog” messages are produced every day through social media such as Twitter (Twitter, 2011). The immense volume of real-time, user-generated microblogs that flows through sites has been shown to have utility in applications such as disaster detection (Sakaki et al., 2010), sentiment analysis (Jiang et al., 2011; González-Ibáñez et al., 2011), and event discovery (Weng and Lee, 2011; Benson et al., 2011). However, due to the spontaneous nature of the posts, microblogs are notoriously noisy, containing many non-standard forms — e.g., *tmrw* “tomorrow” and *2day* “today” — which degrade the performance of

natural language processing (NLP) tools (Ritter et al., 2010; Han and Baldwin, 2011). To reduce this effect, attempts have been made to adapt NLP tools to microblog data (Gimpel et al., 2011; Foster et al., 2011; Liu et al., 2011b; Ritter et al., 2011). An alternative approach is to pre-normalise non-standard lexical variants to their standard orthography (Liu et al., 2011a; Han and Baldwin, 2011; Xue et al., 2011; Gouws et al., 2011). For example, *se u 2morw!!!* would be normalised to *see you tomorrow!* The normalisation approach is especially attractive as a pre-processing step for applications which rely on keyword match or word frequency statistics. For example, *earthqu*, *eathquake*, and *earthquakeee* — all attested in a Twitter corpus — have the standard form *earthquake*; by normalising these types to their standard form, better coverage can be achieved for keyword-based methods, and better word frequency estimates can be obtained.

In this paper, we focus on the task of lexical normalisation of English Twitter messages, in which out-of-vocabulary (OOV) tokens are normalised to their in-vocabulary (IV) standard form, i.e., a standard form that is in a dictionary. Following other recent work on lexical normalisation (Liu et al., 2011a; Han and Baldwin, 2011; Gouws et al., 2011; Liu et al., 2012), we specifically focus on one-to-one normalisation in which one OOV token is normalised to one IV word.

Naturally, not all OOV words in microblogs are lexical variants of IV words: named entities, e.g., are prevalent in microblogs, but not all named entities are included in our dictionary. One challenge for lexical normalisation is therefore to dis-

tinguish those OOV tokens that require normalisation from those that are well-formed. Recent unsupervised approaches have not attempted to distinguish such tokens from other types of OOV tokens (Cook and Stevenson, 2009; Liu et al., 2011a), limiting their applicability to real-world normalisation tasks. Other approaches (Han and Baldwin, 2011; Gouws et al., 2011) have followed a cascaded approach in which lexical variants are first identified, and then normalised. However, such two-step approaches suffer from poor lexical variant identification performance, which is propagated to the normalisation step. Motivated by the observation that most lexical variants have an unambiguous standard form (especially for longer tokens), and that a lexical variant and its standard form typically occur in similar contexts, in this paper we propose methods for automatically constructing a lexical normalisation dictionary — a dictionary whose entries consist of (lexical variant, standard form) pairs — that enables type-based normalisation.

Despite the simplicity of this dictionary-based normalisation method, we show it to outperform previously-proposed approaches. This very fast, lightweight solution is suitable for real-time processing of the large volume of streaming microblog data available from Twitter, and offers a simple solution to the lexical variant detection problem that hinders other normalisation methods. Furthermore, this dictionary-based method can be easily integrated with other more-complex normalisation approaches (Liu et al., 2011a; Han and Baldwin, 2011; Gouws et al., 2011) to produce hybrid systems.

After discussing related work in Section 2, we present an overview of our dictionary-based approach to normalisation in Section 3. In Sections 4 and 5 we experimentally select the optimised context similarity parameters and string similarity re-ranking method. We present experimental results on the unseen test data in Section 6, and offer some concluding remarks in Section 7.

## 2 Related Work

Given a token  $t$ , lexical normalisation is the task of finding  $\arg \max P(s|t) \propto \arg \max P(t|s)P(s)$ , where  $s$  is the standard form, i.e., an IV word. Standardly in lexical normalisation,  $t$  is assumed to be an

OOV token, relative to a fixed dictionary. In practice, not all OOV tokens should be normalised; i.e., only lexical variants (e.g., *tmrw* “tomorrow”) should be normalised and tokens that are OOV but otherwise not lexical variants (e.g., *iPad* “iPad”) should be unchanged. Most work in this area focuses only on the normalisation task itself, oftentimes assuming that the task of lexical variant detection has already been completed.

Various approaches have been proposed to estimate the error model,  $P(t|s)$ . For example, in work on spell-checking, Brill and Moore (2000) improve on a standard edit-distance approach by considering multi-character edit operations; Toutanova and Moore (2002) build on this by incorporating phonological information. Li et al. (2006) utilise distributional similarity (Lin, 1998) to correct misspelled search queries.

In text message normalisation, Choudhury et al. (2007) model the letter transformations and emissions using a hidden Markov model (Rabiner, 1989). Cook and Stevenson (2009) and Xue et al. (2011) propose multiple simple error models, each of which captures a particular way in which lexical variants are formed, such as phonetic spelling (e.g., *epik* “epic”) or clipping (e.g., *walkin* “walking”). Nevertheless, optimally weighting the various error models in these approaches is challenging.

Without pre-categorising lexical variants into different types, Liu et al. (2011a) collect Google search snippets from carefully-designed queries from which they then extract noisy lexical variant-standard form pairs. These pairs are used to train a conditional random field (Lafferty et al., 2001) to estimate  $P(t|s)$  at the character level. One shortcoming of querying a search engine to obtain training pairs is it tends to be costly in terms of time and bandwidth. Here we exploit microblog data directly to derive (lexical variant, standard form) pairs, instead of relying on external resources. In more-recent work, Liu et al. (2012) endeavour to improve the accuracy of top- $n$  normalisation candidates by integrating human cognitive inference, character-level transformations and spell checking in their normalisation model. The encouraging results shift the focus to reranking and promoting the correct normalisation to the top- $l$  position. However, like much previous work on lexical normalisation, this work

assumes perfect lexical variant detection.

Aw et al. (2006) and Kaufmann and Kalita (2010) consider normalisation as a machine translation task from lexical variants to standard forms using off-the-shelf tools. These methods do not assume that lexical variants have been pre-identified; however, these methods do rely on large quantities of labelled training data, which is not available for microblogs.

Recently, Han and Baldwin (2011) and Gouws et al. (2011) propose two-step unsupervised approaches to normalisation, in which lexical variants are first identified, and then normalised. They approach lexical variant detection by using a context fitness classifier (Han and Baldwin, 2011) or through dictionary lookup (Gouws et al., 2011). However, the lexical variant detection of both methods is rather unreliable, indicating the challenge of this aspect of normalisation. Both of these approaches incorporate a relatively small normalisation dictionary to capture frequent lexical variants with high precision. In particular, Gouws et al. (2011) produce a small normalisation lexicon based on distributional similarity and string similarity (Lodhi et al., 2002). Our method adopts a similar strategy using distributional/string similarity, but instead of constructing a small lexicon for pre-processing, we build a much wider-coverage normalisation dictionary and opt for a fully lexicon-based end-to-end normalisation approach. In contrast to the normalisation dictionaries of Han and Baldwin (2011) and Gouws et al. (2011) which focus on very frequent lexical variants, we focus on moderate frequency lexical variants of a minimum character length, which tend to have unambiguous standard forms; our intention is to produce normalisation lexicons that are complementary to those currently available. Furthermore, we investigate the impact of a variety of contextual and string similarity measures on the quality of the resulting lexicons. In summary, our dictionary-based normalisation approach is a lightweight end-to-end method which performs both lexical variant detection and normalisation, and thus is suitable for practical online pre-processing, despite its simplicity.

### 3 A Lexical Normalisation Dictionary

Before discussing our method for creating a normalisation dictionary, we first discuss the feasibility of such an approach.

#### 3.1 Feasibility

Dictionary lookup approaches to normalisation have been shown to have high precision but low recall (Han and Baldwin, 2011; Gouws et al., 2011). Frequent (lexical variant, standard form) pairs such as (*u, you*) are typically included in the dictionaries used by such methods, while less-frequent items such as (*g0tta, gotta*) are generally omitted. Because of the degree of lexical creativity and large number of non-standard forms observed on Twitter, a wide-coverage normalisation dictionary would be expensive to construct manually. Based on the assumption that lexical variants occur in similar contexts to their standard forms, however, it should be possible to automatically construct a normalisation dictionary with wider coverage than is currently available.

Dictionary lookup is a type-based approach to normalisation, i.e., every token instance of a given type will always be normalised in the same way. However, lexical variants can be ambiguous, e.g., *y* corresponds to “you” in *yeah, y r right! LOL* but “why” in *AM CONFUSED!!! y you did that?* Nevertheless, the relative occurrence of ambiguous lexical variants is small (Liu et al., 2011a), and it has been observed that while shorter variants such as *y* are often ambiguous, longer variants tend to be unambiguous. For example *bthday* and *4eva* are unlikely to have standard forms other than “birthday” and “forever”, respectively. Therefore, the normalisation lexicons we produce will only contain entries for OOVs with character length greater than a specified threshold, which are likely to have an unambiguous standard form.

#### 3.2 Overview of approach

Our method for constructing a normalisation dictionary is as follows:

**Input:** Tokenised English tweets

1. Extract (OOV, IV) pairs based on distributional similarity.

## 2. Re-rank the extracted pairs by string similarity.

**Output:** A list of (OOV, IV) pairs ordered by string similarity; select the top- $n$  pairs for inclusion in the normalisation lexicon.

In Step 1, we leverage large volumes of Twitter data to identify the most distributionally-similar IV type for each OOV type. The result of this process is a set of (OOV, IV) pairs, ranked by distributional similarity. The extracted pairs will include (lexical variant, standard form) pairs, such as (*tmrw*, *tomorrow*), but will also contain false positives such as (*Tuesday*, *Sunday*) — *Tuesday* is a lexical variant, but its standard form is not “Sunday” — and (*Youtube*, *web*) — *Youtube* is an OOV named entity, not a lexical variant. Nevertheless, lexical variants are typically formed from their standard forms through regular processes (Thurlow, 2003) — e.g., the omission of characters — and from this perspective *Sunday* and *web* are not plausible standard forms for *Tuesday* and *Youtube*, respectively. In Step 2, we therefore capture this intuition to re-rank the extracted pairs by string similarity. The top- $n$  items in this re-ranked list then form the normalisation lexicon, which is based only on development data.

Although computationally-expensive to build, this dictionary can be created offline. Once built, it then offers a very fast approach to normalisation.

We can only reliably compute distributional similarity for types that are moderately frequent in a corpus. Nevertheless, many lexical variants are sufficiently frequent to be able to compute distributional similarity, and can potentially make their way into our normalisation lexicon. This approach is not suitable for normalising low-frequency lexical variants, nor is it suitable for shorter lexical variant types which — as discussed in Section 3.1 — are more likely to have an ambiguous standard form. Nevertheless, previously-proposed normalisation methods that can handle such phenomena also rely in part on a normalisation lexicon. The normalisation lexicons we create can therefore be easily integrated with previous approaches to form hybrid normalisation systems.

## 4 Contextually-similar Pair Generation

Our objective is to extract contextually-similar (OOV, IV) pairs from a large-scale collection of mi-

croblog data. Fundamentally, the surrounding words define the primary context, but there are different ways of representing context and different similarity measures we can use, which may influence the quality of generated normalisation pairs.

In representing the context, we experimentally explore the following factors: (1) context window size (from 1 to 3 tokens on both sides); (2)  $n$ -gram order of the context tokens (unigram, bigram, trigram); (3) whether context words are indexed for relative position or not; and (4) whether we use all context tokens, or only IV words. Because high-accuracy linguistic processing tools for Twitter are still under exploration (Liu et al., 2011b; Gimpel et al., 2011; Ritter et al., 2011; Foster et al., 2011), we do not consider richer representations of context, for example, incorporating information about part-of-speech tags or syntax. We also experiment with a number of simple but widely-used geometric and information theoretic distance/similarity measures. In particular, we use Kullback–Leibler (KL) divergence (Kullback and Leibler, 1951), Jensen–Shannon (JS) divergence (Lin, 1991), Euclidean distance and Cosine distance.

We use a corpus of 10 million English tweets to do parameter tuning over, and a larger corpus of tweets in the final candidate ranking. All tweets were collected from September 2010 to January 2011 via the Twitter API.<sup>1</sup> From the raw data we extract English tweets using a language identification tool (Lui and Baldwin, 2011), and then apply a simplified Twitter tokeniser (adapted from O’Connor et al. (2010)). We use the Aspell dictionary (v6.06)<sup>2</sup> to determine whether a word is IV, and only include in our normalisation dictionary OOV tokens with at least 64 occurrences in the corpus and character length  $\geq 4$ , both of which were determined through empirical observation. For each OOV word type in the corpus, we select the most similar IV type to form (OOV, IV) pairs. To further narrow the search space, we only consider IV words which are morphophonemically similar to the OOV type, following settings in Han and Baldwin (2011).<sup>3</sup>

<sup>1</sup><https://dev.twitter.com/docs/streaming-api/methods>

<sup>2</sup><http://aspell.net/>

<sup>3</sup>We only consider IV words within an edit distance of 2 or a phonemic edit distance of 1 from the OOV type, and we further

In order to evaluate the generated pairs, we randomly selected 1000 OOV words from the 10 million tweet corpus. We set up an annotation task on Amazon Mechanical Turk,<sup>4</sup> presenting five independent annotators with each word type (with no context) and asking for corrections where appropriate. For instance, given *tmrw*, the annotators would likely identify it as a non-standard variant of “tomorrow”. For correct OOV words like *iPad*, on the other hand, we would expect them to leave the word unchanged. If 3 or more of the 5 annotators make the same suggestion (in the form of either a canonical spelling or leaving the word unchanged), we include this in our gold standard for evaluation. In total, this resulted in 351 lexical variants and 282 correct OOV words, accounting for 63.3% of the 1000 OOV words. These 633 OOV words were used as (OOV, IV) pairs for parameter tuning. The remainder of the 1000 OOV words were ignored on the grounds that there was not sufficient consensus amongst the annotators.<sup>5</sup>

Contextually-similar pair generation aims to include as many correct normalisation pairs as possible. We evaluate the quality of the normalisation pairs using “Cumulative Gain” (CG):

$$CG = \sum_{i=1}^{N'} rel'_i$$

Suppose there are  $N'$  correct generated pairs  $(oov_i, iv_i)$ , each of which is weighted by  $rel'_i$ , the frequency of  $oov_i$  to indicate its relative importance; for example,  $(thinkin, thinking)$  has a higher weight than  $(gOttA, gotta)$  because *thinkin* is more frequent than *gOttA* in our corpus. In this evaluation we don’t consider the position of normalisation pairs, and nor do we penalise incorrect pairs. Instead, we push distinguishing between correct and incorrect pairs into the downstream re-ranking step in which we incorporate string similarity information.

Given the development data and CG, we run an exhaustive search of parameter combinations over

only consider the top 30% most-frequent of these IV words.

<sup>4</sup><https://www.mturk.com/mturk/welcome>

<sup>5</sup>Note that the objective of this annotation task is to identify lexical variants that have agreed-upon standard forms irrespective of context, as a special case of the more general task of lexical normalisation (where context may or may not play a significant role in the determination of the normalisation).

our development corpus. The five best parameter combinations are shown in Table 1. We notice the CG is almost identical for the top combinations. As a context window size of 3 incurs a heavy processing and memory overhead over a size of 2, we use the 3rd-best parameter combination for subsequent experiments, namely: context window of  $\pm 2$  tokens, token bigrams, positional index, and KL divergence as our distance measure.

To better understand the sensitivity of the method to each parameter, we perform a post-hoc parameter analysis relative to a default setting (as underlined in Table 2), altering one parameter at a time. The results in Table 2 show that bigrams outperform other  $n$ -gram orders by a large margin (note that the evaluation is based on a log scale), and information-theoretic measures are superior to the geometric measures. Furthermore, it also indicates using the positional indexing better captures context. However, there is little to distinguish context modelling with just IV words or all tokens. Similarly, the context window size has relatively little impact on the overall performance, supporting our earlier observation from Table 1.

## 5 Pair Re-ranking by String Similarity

Once the contextually-similar (OOV, IV) pairs are generated using the selected parameters in Section 4, we further re-rank this set of pairs in an attempt to boost morphophonemically-similar pairs like  $(bananaz, bananas)$ , and penalise noisy pairs like  $(paninis, beans)$ .

Instead of using the small 10 million tweet corpus, from this step onwards, we use a larger corpus of 80 million English tweets (collected over the same period as the development corpus) to develop a larger-scale normalisation dictionary. This is because once pairs are generated, re-ranking based on string comparison is much faster. We only include in the dictionary OOV words with a token frequency  $> 15$  to include more OOV types than in Section 4, and again apply a minimum length cutoff of 4 characters.

To measure how well our re-ranking method promotes correct pairs and demotes incorrect pairs (including both OOV words that should not be normalised, e.g.  $(Youtube, web)$ , and incorrect normal-

Rank	Window size	$n$ -gram	Positional index?	Lex. choice	Sim/distance measure	$\log(\text{CG})$

isations for lexical variants, e.g. (*bcuz, cause*)), we modify our evaluation metric from Section 4 to evaluate the *ranking* at different points, using Discounted Cumulative Gain ( $\text{DCG}@N$ : Jarvelin and Kekalainen (2002)):

$$\text{DCG}@N = rel_1 + \sum_{i=2}^N \frac{rel_i}{\log_2(i)}$$

where  $rel_i$  again represents the frequency of the OOV, but it can be gain (a positive number) or loss (a negative number), depending on whether the  $i$ th pair is correct or incorrect. Because we also expect correct pairs to be ranked higher than incorrect pairs,  $\text{DCG}@N$  takes both factors into account.

Given the generated pairs and the evaluation metric, we first consider three baselines: no re-ranking (i.e., the final ranking is that of the contextual similarity scores), and re-rankings of the pairs based on the frequencies of the OOVs in the Twitter corpus, and the IV unigram frequencies in the Google Web 1T corpus (Brants and Franz, 2006) to get less-noisy frequency estimates. We also compared a variety of re-rankings based on a number of string similarity measures that have been previously considered in normalisation work (reviewed in Section 2). We experiment with standard edit distance (Levenshtein, 1966), edit distance over double metaphone codes (phonetic edit distance: (Philips, 2000)), longest common subsequence ratio over the consonant edit distance of the paired words (hereafter, denoted as

consonant edit distance: (Contractor et al., 2010)), and a string subsequence kernel (Lodhi et al., 2002).

In Figure 1, we present the  $\text{DCG}@N$  results for each of our ranking methods at different rank cut-offs. Ranking by OOV frequency is motivated by the assumption that lexical variants are frequently used by social media users. This is confirmed by our findings that lexical pairs like (*goin, going*) and (*nite, night*) are at the top of the ranking. However, many proper nouns and named entities are also used frequently and ranked at the top, mixed with lexical variants like (*Facebook, speech*) and (*Youtube, web*). In ranking by IV word frequency, we assume the lexical variants are usually derived from frequently-used IV equivalents, e.g. (*abou, about*). However, many less-frequent lexical variant types have high-frequency (IV) normalisations. For instance, the highest-frequency IV word *the* has more than 40 OOV lexical variants, such as *ttthe* and *thhe*. These less-frequent types occupy the top positions, reducing the cumulative gain. Compared with these two baselines, ranking by default contextual similarity scores delivers promising results. It successfully ranks many more intuitive normalisation pairs at the top, such as (*2day, today*) and (*wknd, weekend*), but also ranks some incorrect pairs highly, such as (*needa, gotta*).

The string similarity-based methods perform better than our baselines in general. Through manual analysis, we found that standard edit dis-

tance ranking is fairly accurate for lexical variants with low edit distance to their standard forms, but fails to identify heavily-altered variants like (*tmrw, tomorrow*). Consonant edit distance is similar to standard edit distance, but places many longer words at the top of the ranking. Edit distance over double metaphone codes (phonetic edit distance) performs particularly well for lexical variants that include character repetitions — commonly used for emphasis on Twitter — because such repetitions do not typically alter the phonetic codes. Compared with the other methods, the string subsequence kernel delivers encouraging results. It measures common character subsequences of length  $n$  between (OOV, IV) pairs. Because it is computationally expensive to calculate similarity for larger  $n$ , we choose  $n=2$ , following Gouws et al. (2011). As  $N$  (the lexicon size cut-off) increases, the performance drops more slowly than the other methods. Although this method fails to rank heavily-altered variants such as (*4get, forget*) highly, it typically works well for longer words. Given that we focus on longer OOVs (specifically those longer than 4 characters), this ultimately isn’t a great handicap.

## 6 Evaluation

Given the re-ranked pairs from Section 5, here we apply them to a token-level normalisation task using the normalisation dataset of Han and Baldwin (2011).

### 6.1 Metrics

We evaluate using the standard evaluation metrics of precision (P), recall (R) and F-score (F) as detailed below. We also consider the false alarm rate (FA) and word error rate (WER), also as shown below. FA measures the negative effects of applying normalisation; a good approach to normalisation should not (incorrectly) normalise tokens that are already in their standard form and do not require normalisation.<sup>6</sup> WER, like F-score, shows the overall benefits of normalisation, but unlike F-score, measures how many token-level edits are required for the output to be the same as the ground truth data. In general, dictionaries with a high F-score/low WER and low FA

<sup>6</sup>FA + P ≤ 1 because some lexical variants might be incorrectly normalised.

are preferable.

$$\begin{aligned}
 P &= \frac{\# \text{ correctly normalised tokens}}{\# \text{ normalised tokens}} \\
 R &= \frac{\# \text{ correctly normalised tokens}}{\# \text{ tokens requiring normalisation}} \\
 F &= \frac{2PR}{P + R} \\
 FA &= \frac{\# \text{ incorrectly normalised tokens}}{\# \text{ normalised tokens}} \\
 WER &= \frac{\# \text{ token edits needed after normalisation}}{\# \text{ all tokens}}
 \end{aligned}$$

### 6.2 Results

We select the three best re-ranking methods, and best cut-off  $N$  for each method, based on the highest DCG@ $N$  value for a given method over the development data, as presented in Figure 1. Namely, they are string subsequence kernel (S-dict,  $N=40,000$ ), double metaphone edit distance (DM-dict,  $N=10,000$ ) and default contextual similarity without re-ranking (C-dict,  $N=10,000$ ).<sup>7</sup>

We evaluate each of the learned dictionaries in Table 3. We also compare each dictionary with the performance of the manually-constructed Internet slang dictionary (HB-dict) used by Han and Baldwin (2011), the small automatically-derived dictionary of Gouws et al. (2011) (GHM-dict), and combinations of the different dictionaries. In addition, the contribution of these dictionaries in hybrid normalisation approaches is also presented, in which we first normalise OOVs using a given dictionary (combined or otherwise), and then apply the normalisation method of Gouws et al. (2011) based on consonant edit distance (GHM-norm), or the approach of Han and Baldwin (2011) based on the summation of many unsupervised approaches (HB-norm), to the remaining OOVs. Results are shown in Table 3, and discussed below.

#### 6.2.1 Individual Dictionaries

Overall, the individual dictionaries derived by the re-ranking methods (DM-dict, S-dict) perform bet-

<sup>7</sup>We also experimented with combining ranks using Mean Reciprocal Rank. However, the combined rank didn’t improve performance on the development data. We plan to explore other ranking aggregation methods in future work.

Figure 1: Re-ranking based on different string similarity methods.

ter than that based on contextual similarity (C-dict) in terms of precision and false alarm rate, indicating the importance of re-ranking. Even though C-dict delivers higher recall — indicating that many lexical variants are correctly normalised — this is offset by its high false alarm rate, which is particularly undesirable in normalisation. Because S-dict has better performance than DM-dict in terms of both F-score and WER, and a much lower false alarm rate than C-dict, subsequent results are presented using S-dict only.

Both HB-dict and GHM-dict achieve better than 90% precision with moderate recall. Compared to these methods, S-dict is not competitive in terms of either precision or recall. This result seems rather discouraging. However, considering that S-dict is an automatically-constructed dictionary targeting lexical variants of varying frequency, it is not surprising that the precision is worse than that of HB-dict — which is manually-constructed — and GHM-dict — which includes entries only for more-frequent OOVs for which distributional similarity is more accurate. Additionally, the recall of S-dict is hampered by the

restriction on lexical variant token length of 4 characters.

## 6.2.2 Combined Dictionaries

Next we look to combining HB-dict, GHM-dict and S-dict. In combining the dictionaries, a given OOV word can be listed with different standard forms in different dictionaries. In such cases we use the following preferences for dictionaries — motivated by our confidence in the normalisation pairs of the dictionaries — to resolve conflicts: HB-dict > GHM-dict > S-dict.

When we combine dictionaries in the second section of Table 3, we find that they contain complementary information: in each case the recall and F-score are higher for the combined dictionary than any of the individual dictionaries. The combination of HB-dict+GHM-dict produces only a small improvement in terms of F-score over HB-dict (the better-performing dictionary) suggesting that, as claimed, HB-dict and GHM-dict share many frequent normalisation pairs. HB-dict+S-dict and GHM-dict+S-dict, on the other hand, improve sub-

Method	Precision	Recall	F-Score	False Alarm	Word Error Rate
C-dict	0.474	0.218	0.299	0.298	0.103
DM-dict	0.727	0.106	0.185	0.145	0.102
S-dict	0.700	0.179	0.285	0.162	0.097
HB-dict	0.915	0.435	0.590	0.048	0.066
GHM-dict	<b>0.982</b>	0.319	0.482	<b>0.000</b>	0.076
HB-dict+S-dict	0.840	0.601	0.701	0.090	0.052
GHM-dict+S-dict	0.863	0.498	0.632	0.072	0.061
HB-dict+GHM-dict	0.920	0.465	0.618	0.045	0.063
HB-dict+GHM-dict+S-dict	0.847	0.630	<b>0.723</b>	0.086	<b>0.049</b>
GHM-dict+GHM-norm	0.338	0.578	0.427	0.458	0.135
HB-dict+GHM-dict+S-dict+GHM-norm	0.406	0.715	0.518	0.468	0.124
HB-dict+HB-norm	0.515	0.771	0.618	0.332	0.081
HB-dict+GHM-dict+S-dict+HB-norm	0.527	<b>0.789</b>	0.632	0.332	0.079

Table 3: Normalisation results using our derived dictionaries (contextual similarity (C-dict); double metaphone rendering (DM-dict); string subsequence kernel scores (S-dict)), the dictionary of Gouws et al. (2011) (GHM-dict), the Internet slang dictionary (HB-dict) from Han and Baldwin (2011), and combinations of these dictionaries. In addition, we combine the dictionaries with the normalisation method of Gouws et al. (2011) (GHM-norm) and the combined unsupervised approach of Han and Baldwin (2011) (HB-norm).

stantially over HB-dict and GHM-dict, respectively, indicating that S-dict contains markedly different entries to both HB-dict and GHM-dict. The best F-score and WER are obtained using the combination of all three dictionaries, HB-dict+GHM-dict+S-dict. Furthermore, the difference between the results using HB-dict+GHM-dict+S-dict and HB-dict+GHM-dict is statistically significant ( $p < 0.01$ ), based on the computationally-intensive Monte Carlo method of Yeh (2000), demonstrating the contribution of S-dict.

### 6.2.3 Hybrid Approaches

The methods of Gouws et al. (2011) (i.e. GHM-dict+GHM-norm) and Han and Baldwin (2011) (i.e. HB-dict+HB-norm) have lower precision and higher false alarm rates than the dictionary-based approaches; this is largely caused by lexical variant detection errors.<sup>8</sup> Using all dictionaries in combination with these methods — HB-dict+GHM-dict+S-dict+GHM-norm and HB-dict+GHM-dict+S-dict+HB-norm — gives some improvements, but the false alarm rates remain high. Despite the limitations of a pure dictionary-based approach to normalisation — discussed in Section 3.1 — the current best practical approach to normal-

<sup>8</sup>Here we report results that do not assume perfect detection of lexical variants, unlike the original published results in each case.

Error type	OOV	Standard form	
		Dict.	Gold
(a) plurals	<i>playe</i>	<i>players</i>	<i>player</i>
(b) negation	<i>unlike</i>	<i>like</i>	<i>dislike</i>
(c) possessives	<i>anyones</i>	<i>anyone</i>	<i>anyone's</i>
(d) correct OOVs	<i>iphone</i>	<i>phone</i>	<i>iphone</i>
(e) test data errors	<i>durin</i>	<i>during</i>	<i>durin</i>
(f) ambiguity	<i>siging</i>	<i>signing</i>	<i>singing</i>

Table 4: Error types in the combined dictionary (HB-dict+GHM-dict+S-dict)

isation is to use a lexicon, combining hand-built and automatically-learned normalisation dictionaries.

### 6.3 Discussion and Error Analysis

We first manually analyse the errors in the combined dictionary (HB-dict+GHM-dict+S-dict) and give examples of each error type in Table 4. The most frequent word errors are caused by slight morphological variations, including plural forms (a), negations (b), possessive cases (c), and OOVs that are correct and do not require normalisation (d). In addition, we also notice some missing annotations where lexical variants are skipped by human annotations but captured by our method (e). Ambiguity (f) definitely exists in longer OOVs, however, these cases do not appear to have a strong negative impact on the normalisation performance. An example of a remain-

Length cut-off ( $N$ )	#Variants	Precision	Recall ( $\geq N$ )	Recall (all)	False Alarm
$\geq 4$	556	0.700	0.381	0.179	0.162
$\geq 5$	382	0.814	0.471	0.152	0.122
$\geq 6$	254	0.804	0.484	0.104	0.131
$\geq 7$	138	0.793	0.471	0.055	0.122

Table 5: S-dict normalisation results broken down according to OOV token length. Recall is presented both over the subset of instances of length  $\geq N$  in the data (“Recall ( $\geq N$ )”), and over the entirety of the dataset (“Recall (all)”); “#Variants” is the number of token instances of the indicated length in the test dataset.

ing miscellaneous error is *bday* “birthday”, which is mis-normalised as *day*.

To further study the influence of OOV word length relative to the normalisation performance, we conduct a fine-grained analysis of the performance of the derived dictionary (S-dict) in Table 5, broken down across different OOV word lengths. The results generally support our hypothesis that our method works better for longer OOV words. The derived dictionary is much more reliable for longer tokens (length 5, 6, and 7 characters) in terms of precision and false alarm. Although the recall is relatively modest, in the future we intend to improve recall by mining more normalisation pairs from larger collections of microblog data.

## 7 Conclusions and Future Work

In this paper, we describe a method for automatically constructing a normalisation dictionary that supports normalisation of microblog text through direct substitution of lexical variants with their standard forms. After investigating the impact of different distributional and string similarity methods on the quality of the dictionary, we present experimental results on a standard dataset showing that our proposed methods acquire high quality (lexical variant, standard form) pairs, with reasonable coverage, and achieve state-of-the-art end-to-end lexical normalisation performance on a real-world token-level task. Furthermore, this dictionary-lookup method combines the detection and normalisation of lexical variants into a simple, lightweight solution which is suitable for processing of high-volume microblog feeds.

In the future, we intend to improve our dictionary by leveraging the constantly-growing volume of microblog data, and considering alternative ways to combine distributional and string similarity. In addition

to direct evaluation, we also want to explore the benefits of applying normalisation for downstream social media text processing applications, e.g. event detection.

## Abstract

“Grounded” language learning employs training data in the form of sentences paired with relevant but ambiguous perceptual contexts. Börschinger et al. (2011) introduced an approach to grounded language learning based on unsupervised PCFG induction. Their approach works well when each sentence potentially refers to one of a small set of possible meanings, such as in the sportscasting task. However, it does not scale to problems with a large set of potential meanings for each sentence, such as the navigation instruction following task studied by Chen and Mooney (2011). This paper presents an enhancement of the PCFG approach that scales to such problems with highly-ambiguous supervision. Experimental results on the navigation task demonstrates the effectiveness of our approach.

## 1 Introduction

The ultimate goal of “grounded” language learning is to develop computational systems that can acquire language more like a human child. Given only supervision in the form of sentences paired with relevant but ambiguous perceptual contexts, a system should learn to interpret and/or generate language describing situations and events in the world. For example, systems have learned to commentate simulated robot soccer games by learning from sample sportscasts (Chen and Mooney, 2008; Liang et al., 2009; Börschinger et al., 2011), or understand navigation instructions by learning from action traces

produced when following the directions (Chen and Mooney, 2011; Tellex et al., 2011).

Börschinger et al. (2011) recently introduced an approach to grounded language learning using unsupervised induction of *probabilistic context free grammars* (PCFGs) to learn from ambiguous contextual supervision. Their approach first constructs a large set of production rules from sentences paired with descriptions of their ambiguous context, and then trains the parameters of this grammar using EM. Parsing a novel sentence with this grammar gives a parse tree which contains the formal *meaning representation* (MR) for this sentence. This approach works quite well on the sportscasting task originally introduced by Chen and Mooney (2008). In this task, each sentence in a natural-language commentary describing activity in a simulated robot soccer game is paired with the small set of actions observed within the past 5 seconds, one of which is usually described by the sentence. Even with this low level of ambiguity in a constrained domain, their method constructs a PCFG with about 33,000 productions. More fundamentally, their approach is restricted to a finite set of potential meaning representations, and the grammar size grows at least linearly with the number of possible MRs, which in turn is inevitably exponential in the number of objects and actions in the domain.

The navigation task studied by Chen and Mooney (2011) provides much more ambiguous supervision. In this task, each instructional sentence is paired with a formal *landmarks plan* (represented as a large graph) that includes a full description of the observed actions and world-states that result when

someone follows this instruction. An instruction generally refers to a subgraph of this large graph. Therefore, there are a combinatorial number of possible meanings to which a given sentence can refer.

Chen and Mooney (2011) circumvent this combinatorial problem by never explicitly enumerating the exponential number of potential meanings for each sentence. Their system first induces a semantic lexicon that maps words and short phrases to formal representations of actions and objects in the world. This lexicon is learned by finding words and phrases whose occurrence highly correlates with specific observed actions and objects in the simulated environment when executing the corresponding instruction. This learned lexicon is then used to directly infer a formal MR for observed instructional sentences using a greedy covering algorithm. These inferred MRs are then used to train a supervised semantic parser capable of mapping novel sentences to their formal meanings.

We present a novel enhancement of Börschinger et al.’s PCFG approach that uses Chen and Mooney’s lexicon learner to avoid a combinatorial explosion in the number of productions. The learned lexicon is first used to build a hierarchy of semantic *lexemes* (i.e. lexicon entries) called the *Lexeme Hierarchy Graph* (LHG) for each ambiguous landmarks plan in the training data. The intuition behind utilizing an LHG is that the MR for each lexeme constitutes a semantic concept that corresponds to some natural-language (NL) word or phrase. Therefore, the LHG represents how complex semantic concepts are composed of simpler semantic concepts and ultimately connected to NL words and phrases. Börschinger et al.’s approach instead produces NL groundings at the level of atomic MR constituents, which causes an explosion in the number of PCFG productions for complex MR languages. We estimated that Börschinger et al.’s approach would require more than  $20!$  ( $> 10^{18}$ ) productions for our navigation problem.<sup>1</sup> On the other hand, our method, which uses correspondences from the LHG at the semantic concept level, constructs a more focused PCFG of tractable size. It then extracts the MR for a novel

---

<sup>1</sup>The corpus contains quite a few examples with landmarks plans containing more than 20 actions. This results in at least  $20!$  permutations representing possible alignments between actions and NL words.

sentence from the most-probable parse tree for the resulting PCFG. Our approach can produce a large, combinatorial number of different MRs for a wide range of novel sentences by composing relevant MR components from the resulting parse tree, whereas Börschinger et al.’s approach is only able to output MRs that are explicitly included as a nonterminals in the original learned PCFG.

The remainder of the paper is organized as follows. Section 2 reviews Börschinger et al.’s PCFG approach as well as the navigation task and data. Section 3 describes our enhanced PCFG approach and Section 4 presents an experimental evaluation of it. Then, Section 5 discusses the unique aspects of our approach and Section 6 describes additional related work. Finally, Section 7 presents future research directions and Section 8 gives our conclusions.

## 2 Background

### 2.1 Existing PCFG Approach

Our approach extends that of Börschinger et al. (2011), which in turn was inspired by a series of previous techniques (Lu et al., 2008; Liang et al., 2009; Kim and Mooney, 2010) following the idea of constructing correspondences between NL and MR in a single probabilistic generative framework. Particularly, their approach automatically constructs a PCFG that generates NL sentences from MRs, which indicates how atomic MR constituents are probabilistically related to NL words. The nonterminals in the grammar correspond to complete MRs, MR constituents, and NL phrases. The nonterminal for a composite MR generates each of its MR constituents, and each atomic MR,  $x$ , generates an NL phrase,  $Phrase_x$ . Each  $Phrase_x$  then generates a sequence of  $Word_x$ ’s for describing  $x$ , and each  $Word_x$  can generate each possible word in the natural language. This allows the system to learn the words and phrases used to describe each atomic MR by properly weighting these rules. Figure 1 shows one possible derivation tree for a sample NL-MR pair and the PCFG rules that are constructed for it. Once a set of productions are assembled, their probabilities are learned using the Inside-Outside algorithm. Computing the most probable parse for a novel sentence with the trained PCFG provides its

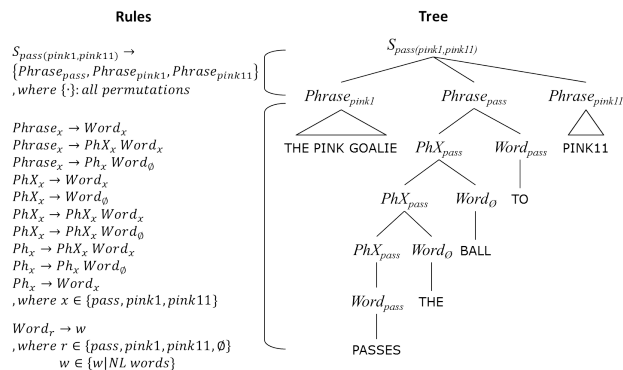

Figure 1: Derivation tree for the NL/MR pair: THE PINK GOALIE PASSES THE BALL TO PINK11 /  $pass(pink1, pink11)$ . Left side shows PCFG rules that are added for each stage (full MR to atomic MRs, and atomic MRs to NL words).

preferred MR interpretation in the topmost nonterminal.

Unfortunately, as discussed earlier, this approach only works for finite MR languages, and the grammar becomes intractably large even for finite but complex MRs. It effectively assumes that MRs are fairly small and includes every possible MR constituent as a nonterminal in the PCFG. This is not tractable for more complex MRs. Therefore, our extension incorporates a learned lexicon to constrain the space of productions, thereby making the size of the PCFG tractable for complex MRs, and even giving it the ability to handle infinite MR languages. Moreover, when processing novel sentences, our approach can produce a large space of novel MRs that were not anticipated during training, which is not the case for Börschinger et al.’s approach.

## 2.2 Navigation Task and Dataset

We employ the task and data introduced by Chen and Mooney (2011) whose goal is to interpret and follow NL navigation instructions in a virtual world. Figure 2 shows a sample execution path in a particular virtual world. The challenge is learning to perform this task by simply observing humans following instructions. Formally, given training data of the form  $\{(e_1, a_1, w_1), \dots, (e_n, a_n, w_n)\}$ , where  $e_i$  is an NL instruction,  $a_i$  is an observed action sequence, and  $w_i$  is the current world state (patterns of floors and walls, positions of any objects, etc.), we want to produce the correct actions  $a_j$  for a novel  $(e_j, w_j)$ .

Figure 2: Sample virtual world from Chen and Mooney (2011) of interconnecting hallways with different floor and wall patterns and objects indicated by letters (e.g. “H” for hatrack).

Instruction:	"at the easel, go left and then take a right onto the blue path at the corner"
Landmarks plan:	<b>Travel</b> ( steps: 1 ), <b>Verify</b> ( at: <b>EASEL</b> , side: CONCRETE HALLWAY ) , <b>Turn</b> ( <b>LEFT</b> ) , Verify ( front: CONCRETE HALLWAY ) , <b>Travel</b> ( steps: 1 ) , <b>Verify</b> ( side: <b>BLUE HALLWAY</b> , front: <b>WALL</b> ) , <b>Turn</b> ( <b>RIGHT</b> ) , <b>Verify</b> ( back: <b>WALL</b> , front: <b>BLUE HALLWAY</b> , front: <b>CHAIR</b> , front: <b>HATRACK</b> , left: <b>WALL</b> , right: <b>EASEL</b> )

Figure 3: Sample instruction with its constructed landmarks plan, components in bold compose the correct plan.

In order to learn, their system infers the intended formal plan  $p_i$  (the MR for a sentence) which produced the action sequence  $a_i$  from the instruction  $e_i$ . However, there is a large space of possible plans for any given action sequence. Chen and Mooney first construct a formal *landmarks plan*,  $c_i$ , for each  $a_i$ , which is a graph representing the context of every action and the world-state encountered during the execution of the sequence. The correct plan MR,  $p_i$ , is assumed to be a subgraph of  $c_i$ , and this causes a combinatorial matching problem between  $e_i$  and  $c_i$  in order to learn the correct meaning of  $e_i$  among all the possible subgraphs of  $c_i$ . The landmarks and correct plans for a sample instruction are shown in Figure 3, illustrating the complexity of the MRs.

Instead of directly solving the combinatorial correspondence problem, they first learn a semantic lex-

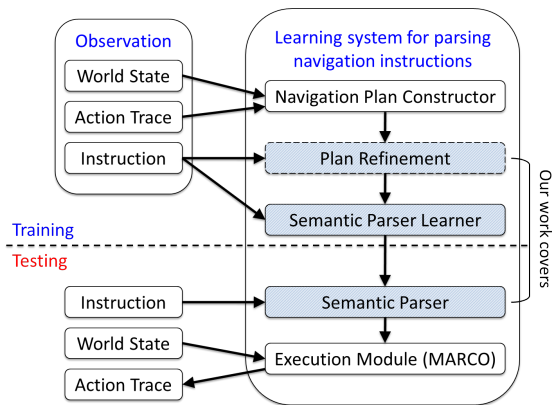

Figure 4: An overview of Chen and Mooney (2011)’s system. Our method replaces the plan refinement and semantic parser parts.

icon that maps words and short phrases to small subgraphs representing their inferred meanings from the  $(e_i, c_i)$  pairs. The lexicon is learned by evaluating pairs of  $n$ -grams,  $w_j$ , and MR graphs,  $m_j$ , and scoring them based on how much more likely  $m_j$  is a subgraph of the context  $c_i$  when  $w$  occurs in the corresponding instruction  $e_i$ . This process is similar to other “cross-situational” approaches to learning word meanings (Siskind, 1996; Thompson and Mooney, 2003). Then, a *plan refinement* step estimates  $p_i$  from  $c_i$  by greedily selecting high-scoring lexemes of the form  $(w_j, m_j)$  whose words and phrases  $(w_j)$  cover the instruction  $e_i$  and introduce components  $(m_j)$  from the landmarks plan  $c_i$ . The refined plans are used to construct supervised training data  $(e_i, p_i)$  for a supervised semantic-parser learner. The trained semantic parser can parse a novel instruction into a formal plan, which is finally executed for end-to-end evaluation. Figure 4 illustrates the overall system.

As this figure indicates, our new PCFG method replaces the plan refinement and semantic parser components in their system with a unified model that both disambiguates the training data and learns a semantic parser. We use the landmarks plans and the learned lexicon produced by Chen and Mooney (2011) as inputs to our system.<sup>2</sup>

<sup>2</sup>In our experiments, we used the top 1,000 lexemes learned by Chen and Mooney (2011).

### 3 Our PCFG Approach

Like Börschinger et al. (2011), our approach learns a semantic parser directly from ambiguous supervision, specifically NL instructions paired with their complete landmarks plans as context. Our method incorporates the semantic lexemes as building blocks to find correspondences between NL words and semantic concepts represented by the lexeme MRs, instead of building connections between NL words and every possible MR constituent as in Börschinger et al.’s approach. Particularly, we utilize the hierarchical subgraph relationships between the MRs in the learned semantic lexicon to produce a smaller, more focused set of PCFG rules.<sup>3</sup> The intuition behind our approach is analogous to the hierarchical relations between nonterminals in syntactic parsing, where higher-level categories such as S, VP, or NP are further divided into smaller categories such as V, N, or Det, thereby forming a hierarchical structure. Inspired by this idea, we introduce a directed acyclic graph called the Lexeme Hierarchy Graph (LHG) which represents the hierarchical relationships between lexeme MRs. Since complex lexeme MRs represent complicated semantic concepts while simple MRs represent simple concepts, it is natural to construct a hierarchy amongst them. The LHGs for all of the training examples are used to construct production rules for the PCFG, which are then parametrized using EM. Finally, a novel sentence is semantically parsed by computing its most-probable parse using the trained PCFG, and then its MR is extracted from the resulting parse tree.

#### 3.1 Constructing a Lexeme Hierarchy Graph

An LHG represents the hierarchy of lexical meanings relevant to a particular training instance by encoding the subgraph relations between the MRs of relevant lexemes. Algorithm 1 describes how an LHG is constructed for an ambiguous training pair of a sentence and its corresponding context,  $(e_i, c_i)$ . First, we obtain all relevant lexemes  $(w_j^i, m_j^i)$  in the lexicon  $L$ , where the MR  $m_j^i$  is a subgraph of the context  $c_i$  (denoted as  $m_j^i \subset c_i$ ). These lexemes are

<sup>3</sup>The total number of PCFG rules constructed for our navigation training sets is about 18,000, while Börschinger et al.’s method produces 33,000 rules for the much simpler sportscasting domain.

---

**Algorithm 1** LEXEME HIERARCHY GRAPH (LHG)
 

---

**Input:** Training instance  $(e_i, c_i)$ , Lexicon  $L$

**Output:** Lexeme hierarchy graph for  $(e_i, c_i)$

Find relevant lexemes  $(w_1^i, m_1^i), \dots, (w_n^i, m_n^i)$

s.t.  $m_j^i \subset c_i$

Create a starting node  $T$ ;  $MR(T) \leftarrow c_i$

**for all**  $m_j^i$  in the descending order of size **do**

    Create a node  $T_j^i$ ;  $MR(T_j^i) \leftarrow m_j^i$

    PLACELEXEME( $T_j^i, T$ )

**end for**

**procedure** PLACELEXEME( $T', T$ )

**for all** children  $T_j$  of  $T$  **do**

        Add  $T'$  as child of  $T$

**end if**

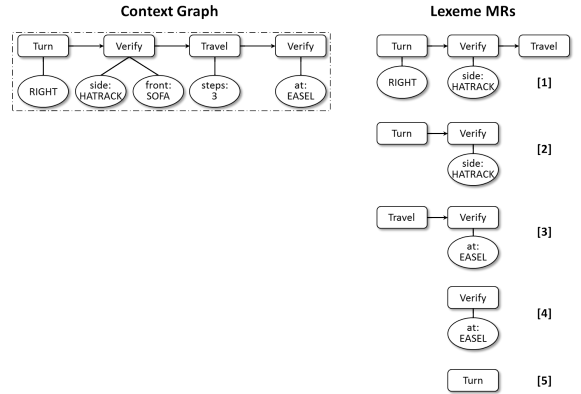

**end procedure**

---

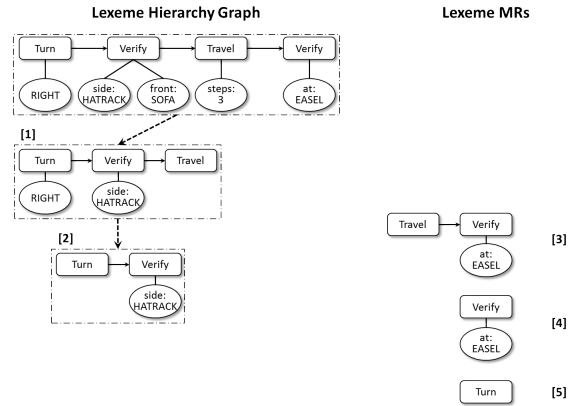

sorted in descending order based on the number of nodes in their MRs  $m_j^i$ . Then, after setting the context  $c_i$  as the MR of the root node ( $MR(T) \leftarrow c_i$ ), lexemes are inserted, in order, into the graph to create a hierarchy of MRs, where each child's MR is a subgraph of the MR of each of its parents. Figure 5 illustrates a sample construction of an LHG for the following landmarks plan ( $c_i$ ):

Turn (RIGHT),  
 Verify (side:HATRACK, front:SOFA),  
 Travel (steps:3),  
 Verify (at:EASEL)

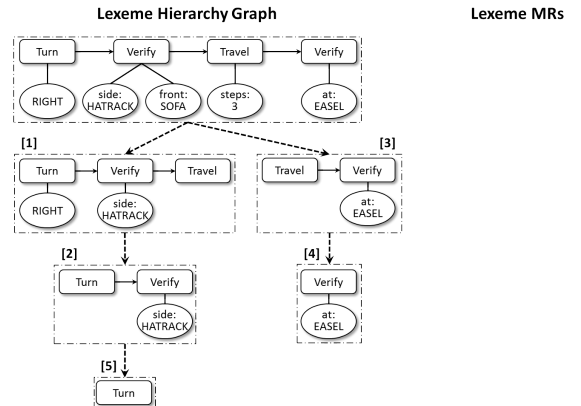

The initial LHG may contain nodes with too many children. This is a problem, because when we subsequently extract PCFG rules, we need to add a production for every  $k$ -permutation of the children of each node (see Section 3.2). To reduce the branching factor in the LHG, we introduce *pseudo-lexeme* nodes by repeatedly combining the two most similar children of each node. Pseudocode for the process is shown in Algorithm 2. The MR for a pseudo-lexeme is the minimal graph,  $m'$ , that is a supergraph of both of the lexeme MRs that it combines. The pair of

(a) All relevant lexemes are obtained for the training example and ordered by the number of nodes in their MR.

(b) Lexeme MR [1] is added as a child of the top node. MR [2] is a subgraph of [1], so it is added as its child.

(c) MR [3] is not a subgraph of [1] or [2], so it is added as a child of the root. MR [4] is added under [3], and MR [5] is recursively filtered down and added under [2].

Figure 5: Sample LHG construction.

**end procedure**

---

most similar children,  $(m_i, m_j)$ , is determined by measuring the fraction of the nodes in  $m_i$  and  $m_j$  that overlap with their minimum extension  $m'$  and is calculated as follows:

$$Sim(m_i, m_j, m') = \frac{|m_i| + |m_j|}{2|m'|}$$

where  $|m|$  is the number of nodes in the MR  $m$ . Adding pseudo-lexemes also has another advantage. They can be considered to be higher-level semantic concepts composed of two or more sub-concepts. These higher-level concepts will likely occur in other training examples as well, which allows for more flexible interpretations. For example, assuming the rule  $A \rightarrow BCD$  is constructed from an LHG, we will introduce a pseudo lexeme  $E$  and build two rules  $A \rightarrow BE$  and  $E \rightarrow CD$ . It is likely that  $E$  also occurs in another rule constructed from other training examples such as  $E \rightarrow FGD$ . This increases the model’s expressive power by supporting additional derivations such as  $A \rightarrow^* BFGD$ , providing more flexibility when parsing novel NL sentences.

### 3.2 Composing PCFG Rules

The next step composes PCFG rules from the LHGs and is summarized in Figure 6. We basically follow the scheme of Börschinger et al. (2011), but instead of generating NL words from each atomic MR, words are generated from each lexeme MR,

$Root \rightarrow S_c, \quad \forall c \in contexts$

$\forall non-leaf\ node\ and\ its\ MR\ m$

$S_m \rightarrow \{S_{m_1}, \dots, S_{m_n}\},$

where  $m_1, \dots, m_n$ : children lexeme MR of  $m$ ,

$\{\cdot\}$ : all  $k$ -permutations for  $k = 1, \dots, n$

$\forall lexeme\ MR\ m$

$S_m \rightarrow Phrase_m$

$Phrase_m \rightarrow Word_m$

$Phrase_m \rightarrow PhX_m Word_m$

$Phrase_m \rightarrow Ph_m Word_\emptyset$

$PhX_m \rightarrow Word_m$

$PhX_m \rightarrow Word_\emptyset$

$Word_m \rightarrow s,$

$Word_m \rightarrow w,$

$PhX_m \rightarrow PhX_m Word_m$

$PhX_m \rightarrow PhX_m Word_\emptyset$

$Ph_m \rightarrow PhX_m Word_m$

$Ph_m \rightarrow Ph_m Word_\emptyset$

$Ph_m \rightarrow Word_m$

$\forall s\ s.t.\ (s, m) \in lexicon\ L$

$\forall word\ w \in s\ s.t.\ (s, m) \in lexicon\ L$

$Word_\emptyset \rightarrow w,$

$\forall word\ w \in NLs$

Figure 6: Summary of the rule generation process.  $NLs$  refer to the set of NL words in the corpus. Lexeme rules come from the schemata of Börschinger et al. (2011), and allow every lexeme MR to generate one or more NL words. Note that pseudo-lexeme nodes do not produce NL words.

and smaller lexeme MRs are generated from more complex ones as given by the LHGs. A nonterminal  $S_m$  is generated for the MR,  $m$ , of each LHG node. Then, for every LHG node,  $T$ , with MR,  $m$ , we add rules of the form  $S_m \rightarrow S_{m_i} \dots S_{m_j}$ , where the RHS is some  $k$ -permutation of the nonterminals for the MRs of the children of node  $T$ . Börschinger et al. assume that every atomic MR generates at least one NL word. However, since we do not know which subgraph of the overall context (i.e.  $c_i$ , the MR of the root node) conveys the intended plan and is therefore expressed in the NL instruction, we must allow each ordered subset of the children of a node (i.e. each  $k$ -permutation) to be a possible generation.

The rest of the process more closely follows Börschinger et al.’s. Every MR,  $m$ , of a lexeme node<sup>4</sup> generates a rule  $S_m \rightarrow Phrase_m$ , and every  $Phrase_m$  generates a sequence of NL words, including one or more “content words” ( $Word_m$ ) for expressing  $m$  and zero or more “extraneous” words ( $Word_\emptyset$ ). While Börschinger et al. have  $Word_m$  generate all possible NL words (each of which are

<sup>4</sup>We exclude pseudo-lexeme nodes in this process, because they should only generate words through generating lexemes.

subsequently weighted by EM training), in our approach, each  $Word_m$  only produces the NL phrase associated with  $m$  in the lexicon, or individual words that appear in this phrase. The words not covered by  $Word_m$  also can be generated by  $Word_\emptyset$  which has rules for every word.  $Ph_m$  and  $PhX_m$  ensure that  $Phrase_m$  produces at least one  $Word_m$ , where  $PhX_m$  indicates that one or more  $Word_m$ 's have already been generated, and  $Ph_m$  indicates that no  $Word_m$  has yet been generated.

### 3.3 Parsing Novel NL Sentences

To learn the parameters of the resulting PCFG, we use the Inside-Outside algorithm.<sup>5</sup> Then, the standard probabilistic CKY algorithm is used to produce the most probable parse for novel NL sentences (Jurafsky and Martin, 2000).

Börschinger et al. (2011) simply read the MR,  $m$ , for a sentence off the top  $S_m$  nonterminal of the most probable parse tree. However, in our approach, the correct MR is constructed by properly composing the appropriate subset of lexeme MRs from the most-probable parse tree. This allows the system to produce a wide variety of novel MRs for novel sentences, as long as the correct MR is a subgraph of the complete context ( $c_i$ ) for at least one of the training sentences.

First, the parse tree is pruned to remove all subtrees starting with  $Phrase_x$  nodes. This leaves a tree consisting of the *Root* and a set of  $S_m$  nodes. The pruned subtrees only concern generating NL words and phrases from the selected MRs. The remaining tree shows which MR constituents were selected from the available context, from which the sentence is then generated. Each leaf in the pruned tree represents an MR constituent that was used to generate a phrase in the sentence. These are the constituents we want to assemble and compose into a final MR for the sentence.

Algorithm 3 describes the procedure for extracting the final MR from the pruned parse tree. Figure 7 graphically depicts a sample trace of this algorithm. The algorithm recursively traverses the parse tree. When a leaf-node is reached, it marks all of the nodes in its MR. After traversing all of its children,

<sup>5</sup>We used the implementation available at <http://web.science.mq.edu.au/~mjohnson/Software.htm> which was also used by Börschinger et al. (2011).

---

a node in the MR for the current parse-tree node is marked iff its corresponding node in any of the children's MRs were marked. The final output is the MR constructed by removing all of the unmarked nodes from the MR for the root node.

## 4 Experimental Evaluation

For evaluation, we used the same data and methodology as Chen and Mooney (2011). Please see their paper for more details.

### 4.1 Data

We used the English instructions and follower data collected by MacMahon et al. (2006).<sup>6</sup> This data contains 706 route instructions for three virtual worlds. The instructions were produced by six instructors for 126 unique starting and ending location pairs spread evenly across the three worlds, and there were 1 to 15 human followers for each instruction who executed an average of 10.4 actions per instruction. Each instruction is a paragraph consisting of an average of 5.0 sentences, each containing an average of 7.8 words. Chen and Mooney constructed the additional single-sentence corpus by matching each sentence with the majority of human

<sup>6</sup>Available at <http://www.cs.utexas.edu/users/ml/clamp/navigation/>

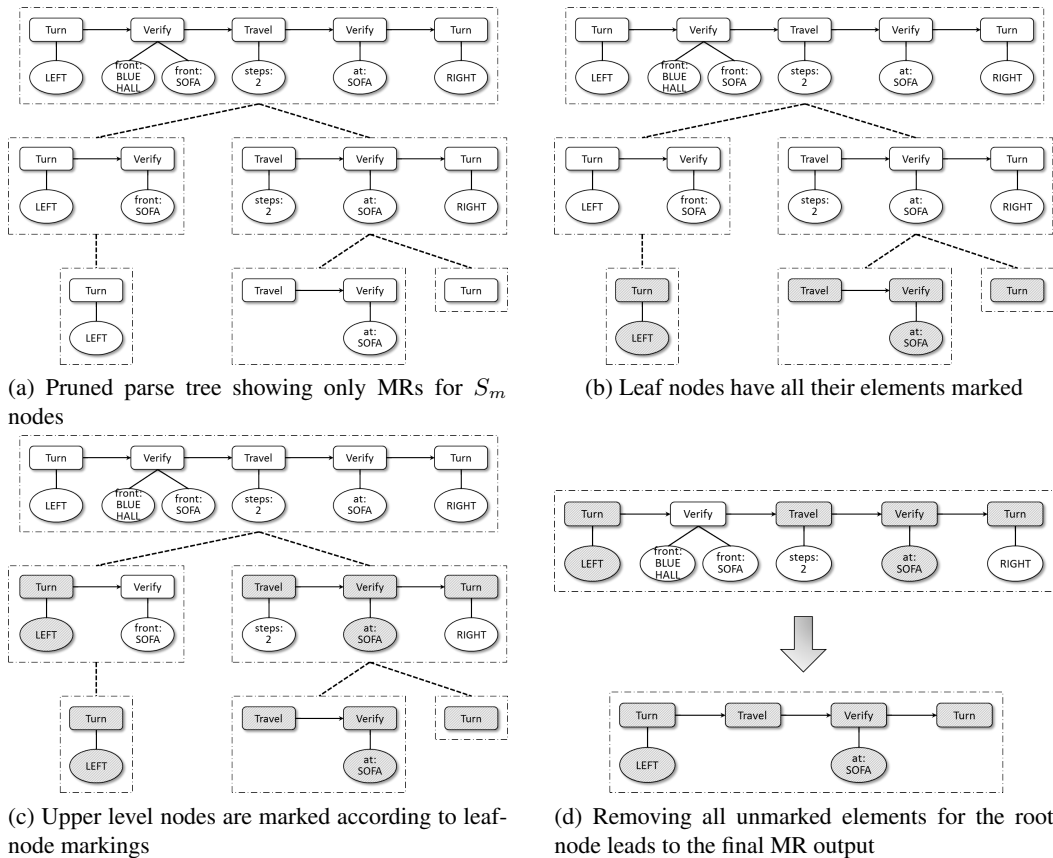

Figure 7: Sample construction of MR output from pruned parse tree.

followers’ actions. We use this single-sentence version for training, but use both the single-sentence and the original paragraph version for testing. Each sentence was manually annotated with a “gold standard” execution plan, which is used for evaluation but not for training.

## 4.2 Methodology and Results

Experiments were conducted using “leave one environment out” cross-validation, training on two environments and testing on the third, averaging over all three test environments. We perform direct comparison to the best results of Chen and Mooney (2011) (referred to as CM). A Wilcoxon signed-rank test is performed for statistical significance, and ‘\*’ denotes significant differences ( $p < .01$ ) in the tables.

### Semantic Parsing Results

We first evaluated how well our system learns to map novel NL sentences for new test environments into their correct MRs. Partial semantic-parsing accuracy (Chen and Mooney, 2011) is calculated by

	Precision	Recall	F1
Our system	87.58	*65.41	*74.81
CM	*90.22	55.10	68.37

Table 1: Test accuracy for semantic parsing. ‘\*’ denotes difference is statistically significant.

comparing the system’s MR output to the hand-annotated gold standard. Accuracy is measured in terms of precision, recall, and F1 for individual MR constituents (thereby awarding partial credit for approximately correct MRs).

Table 1 demonstrates that our method outperforms CM by 6 points in F1. Our PCFG-based approach is able to probabilistically disambiguate the training data as well as simultaneously learn a statistical semantic parser within a single framework. This results in better overall performance compared to CM, since they lose potentially useful information, particularly during the refinement stage, due to the separate disjoint components of the system.

	Single-sentence	Paragraph
Our system	<b>*57.22%</b>	<b>*20.17%</b>
CM	54.40%	16.18%

Table 2: Successful plan execution rates for novel test data. ‘\*’ means statistical significance.

### Navigation Plan Execution Results

Next, we test the end-to-end system by executing the parsed navigation plans for test instructions in novel environments to see if they reach the exact desired destinations in the environment. Table 2 shows the successful end-to-end navigation-task completion rate for both single-sentences and complete paragraph instructions.

Again, our system outperforms CM’s best results since more accurate semantic parsing produces more successful plans. However, the difference in performance is smaller than that observed for semantic parsing. This is because the redundancy in the human generated instructions allows an incorrect semantic parse to be successful, as long as the errors do not affect its ability to guide the system to the correct destination.

## 5 Discussion

Our approach improves on Börschinger et al. (2011)’s method in the following ways:

- The building blocks for associating NL and MR are semantic lexemes instead of atomic MR constituents. This prevents the number of constructed PCFG rules from becoming intractably large as happens with Börschinger et al.’s approach. As previously mentioned, lexeme MRs are intuitively analogous to syntactic categories in that complex lexeme MRs represent complicated semantic concepts whereas higher-level syntactic categories such as S, VP, or NP represent complex syntactic structures.
- Our approach has the ability to produce previously unseen MRs, whereas Börschinger et al. can only generate an MR if it is explicitly included in the PCFG rules constructed from the training data. Even though our MR parse is restricted to be a subgraph of some training context,  $c_i$ , our model allows for exponentially many combinations.

In addition, our approach can produce a wider range of MR outputs than Chen and Mooney

(2011)’s even though we use their semantic lexicon as input. Their system deterministically builds a supervised training set by greedily selecting high-scoring lexemes, thus implicitly including only high-scoring lexemes during training. On the other hand, our probabilistic approach also considers relatively low-scoring but useful lexemes, thereby utilizing more semantic concepts in the lexicon. In particular, this explains why our approach obtains higher *recall* in the evaluation of semantic parsing.

Even though we have demonstrated our approach on the specific task of following navigation instructions, it is straightforward to apply it to other language-grounding tasks where NL sentences potentially refer to some subset of states, events, or actions in the world, as long as this overall context can be represented as a semantic graph or logical form. Since the semantic lexicon is an input to our system, other approaches to lexicon learning are also easily incorporated.

## 6 Related Work

Most work on learning semantic parsers that map natural-language sentences to formal representations of their meaning have relied upon totally supervised training data consisting of NL/MR pairs (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Kate and Mooney, 2006; Wong and Mooney, 2007; Zettlemoyer and Collins, 2007; Lu et al., 2008; Zettlemoyer and Collins, 2009). Several recent approaches have investigated grounded learning from ambiguous supervision extracted from perceptual context. A number of approaches (Kate and Mooney, 2007; Chen and Mooney, 2008; Chen et al., 2010; Kim and Mooney, 2010; Börschinger et al., 2011) assume training data consisting of a set of sentences each associated with a small set of MRs, one of which is usually the correct meaning of the sentence. Many of these approaches (Kate and Mooney, 2007; Chen and Mooney, 2008; Chen et al., 2010) disambiguate the data and match NL sentences to their correct MR by iteratively retraining a supervised semantic parser. Kim and Mooney (2010) proposed a generative semantic parsing model that first chooses which MRs to describe and then generates a hybrid tree structure (Lu et al., 2008) containing both the MR and NL sentence. They train

this model on ambiguous data using EM. As previously discussed, Börschinger et al. (2011) use a PCFG generative model and also train it on ambiguous data using EM. Liang et al. (2009) assume each sentence maps to one *or more* semantic records (i.e. MRs) and trains a hierarchical semi-Markov generative model using EM, and then finds a Viterbi alignment between NL words and records and their constituents. Several recent projects (Branavan et al., 2009; Vogel and Jurafsky, 2010) use NL instructions to guide *reinforcement learning* from independent exploration with delayed rewards. These systems do not even need the ambiguous supervision obtained from observing humans follow instructions; however, they do not learn semantic parsers that map sentences to complex, structural representations of their meaning.

Interpreting and executing NL navigation instructions is our primary task, and several other recent projects have studied related problems. Shimizu and Haas (2009) present a system that parses natural language instructions into actions. However, they limit the number of possible actions to only 15 and treat the problem as a sequence labeling problem that is solved using a CRF with supervised training. Matuszek et al. (2010) developed a system that learns to map NL instructions to executable commands for a robot navigating in an environment constructed by a laser range finder. However, their approach has limitations of ignoring any objects or other landmarks in the environment to which the instructions can refer. There are several recent projects (Vogel and Jurafsky, 2010; Kollar et al., 2010; Tellex et al., 2011) which learn to follow instructions in more linguistically complex environments. However, they assume predefined spatial words, direct matching between NL words and the names of objects and other landmarks in the MR, and/or an existing syntactic parser. By contrast, our work does not assume any prior linguistic knowledge, syntactic, lexical, or semantic, and must *learn* the mapping between NL words and phrases and the MR terms describing landmarks.

## 7 Future Work

In the future, we would like to develop a better lexicon learner since our PCFG approach critically relies on the quality of the learned lexicon. Particu-

larly, we would like to investigate how syntactic information (such as part-of-speech tags induced using unsupervised learning) could be used to improve semantic-lexicon learning. For example, some of the current lexicon entries violate the general constraint that nouns usually refer to objects and verbs to actions. Ideally, the lexicon learner would be able to induce and then utilize this sort of relationship between syntax and semantics.

In addition, we want to investigate the use of *discriminative reranking* (Collins, 2000), which has proven effective in various other NLP tasks. We would expect the final MR output to improve if a discriminative model, which uses additional global features, is used to rerank the top- $k$  parses produced by our generative PCFG model.

## 8 Conclusions

We have presented a novel method for learning a semantic parser given only highly ambiguous supervision. Our model enhances Börschinger et al. (2011)’s approach to reducing the problem of grounded learning of semantic parsers to PCFG induction. We use a learned semantic lexicon to aid the construction of a smaller and more focused set of PCFG productions. This allows the approach to scale to complex MR languages that define a large (potentially infinite) space of representations for capturing the meaning of sentences. By contrast, the previous PCFG approach requires a finite MR language and its grammar grows intractably large for even moderately complex MR languages. In addition, our algorithm for composing MRs from the final parse tree provides the flexibility to produce a wide range of novel MRs that were not seen during training. Evaluations on a previous corpus of navigational instructions for virtual environments has demonstrated the effectiveness of our method compared to a recent competing system.

## Acknowledgments

We thank the anonymous reviewers and David Chen for useful comments that helped improve this paper. This work was funded by NSF grants IIS-0712907 and IIS-1016312. Experiments were performed on the Mastodon Cluster, provided by NSF grant EIA-0303609.

## Abstract

A *forced derivation tree (FDT)* of a sentence pair  $\{f, e\}$  denotes a derivation tree that can translate  $f$  into its accurate target translation  $e$ . In this paper, we present an approach that leverages structured knowledge contained in FDTs to train component models for statistical machine translation (SMT) systems. We first describe how to generate different FDTs for each sentence pair in training corpus, and then present how to infer the optimal FDTs based on their derivation and alignment qualities. As the first step in this line of research, we verify the effectiveness of our approach in a BTG-based phrasal system, and propose four FDT-based component models. Experiments are carried out on large scale English-to-Japanese and Chinese-to-English translation tasks, and significant improvements are reported on both translation quality and alignment quality.

## 1 Introduction

Most of today's SMT systems depends heavily on parallel corpora aligned at the word-level to train their different component models. However, such annotations do have their drawbacks in training.

On one hand, word links predicted by automatic aligners such as GIZA++ (Och and Ney, 2004) often contain errors. This problem gets even worse on language pairs that differ substantially in word orders, such as English and Japanese/Korean/German. The descent of the word alignment quality will lead to inaccurate component models straightforwardly.

On the other hand, several component models are designed to supervise the decoding procedures,

which usually rely on training examples extracted from word-aligned sentence pairs, such as distortion models (Tillman, 2004; Xiong et al., 2006; Galley and Manning, 2008) and sequence models (Banchs et al., 2005; Quirk and Menezes, 2006; Vaswani et al., 2011). Ideally, training examples of models are expected to match most of the situations that could be met in decoding procedures. But actually, plain structures of word alignments are too coarse to provide enough knowledge to ensure this expectation.

This paper presents an FDT-based model training approach to SMT systems by leveraging structured knowledge contained in FDTs. An FDT of a sentence pair  $\{f, e\}$  denotes a derivation tree that can translate  $f$  into its accurate target translation  $e$ . The principle advantage of this work is two-fold. First, using alignments induced from the 1-best FDTs of all sentence pairs, the overall alignment quality of training corpus can be improved. Second, comparing to word alignments, FDTs can provide richer structured knowledge for various component models to extract training instances. Our FDT-based model training approach performs via three steps: (1) **generation**, where an *FDT space* composed of different FDTs is generated for each sentence pair in training corpus by the *forced decoding* technique; (2) **inference**, where the optimal FDTs are extracted from the FDT space of each sentence pair based on both derivation and alignment qualities measured by a *memory-based re-ranking model*; (3) **training**, where various component models are trained based on the optimal FDTs extracted in the inference step.

Our FDT-based model training approach can be adapted to SMT systems with arbitrary paradigms.

As the first step in this line of research, our approach is verified in a phrase-based SMT system on both English-to-Japanese and Chinese-to-English translation tasks. Significant improvements are reported on both translation quality (up to 1.31 BLEU) and word alignment quality (up to 3.15 F-score).

## 2 Forced Derivation Tree for SMT

A forced derivation tree (**FDT**) of a sentence pair  $\{f, e\}$  can be defined as a pair  $\mathcal{G} = \langle \mathcal{D}, \mathcal{A} \rangle$ :

- $\mathcal{D}$  denotes a derivation that can translate  $f$  into  $e$  accurately, using a set of translation rules.
- $\mathcal{A}$  denotes a set of word links  $(i, j)$  indicating that  $e_i \in e$  aligns to  $f_j \in f$ .

In this section, we first describe how to generate FDTs for each sentence pair in training corpus, which is denoted as the *generation* step, and then present how to select the optimal FDT for each sentence pair, which is denoted as the *inference* step. We leave a real application of FDTs to the model training in a phrase-based SMT system in Section 3.

### 2.1 Generation

We first describe how to generate multiple FDTs for each sentence pair in training corpus  $\mathcal{C}$  based on the forced decoding (**FD**) technique, which performs via the following four steps:

1. Train component models needed for a specific SMT paradigm  $\mathcal{M}$  based on training corpus  $\mathcal{C}$ ;
2. Perform MERT on the development data set to obtain a set of optimized feature weights;
3. For each  $\{f, e\} \in \mathcal{C}$ , translate  $f$  into accurate  $e$  based on  $\mathcal{M}$ , component models trained in step 1, and feature weights optimized in step 2;
4. For each  $\{f, e\} \in \mathcal{C}$ , output the hypergraph (Huang and Chiang, 2005)  $\mathcal{H}(f, e)$  generated in step 3 as its *FDT space*.

In step 3: (1) all partial hypotheses that do not match any sequence in  $e$  will be discarded; (2) derivations covering identical source and target words but with different alignments will be kept as different partial candidates, as they can produce different FDTs for

the same sentence pair. For each  $\{f, e\}$ , the probability of each  $\mathcal{G} \in \mathcal{H}(f, e)$  is computed as:

$$p(\mathcal{G}|\mathcal{H}(f, e)) = \frac{\exp\{\psi(\mathcal{G})\}}{\sum_{\mathcal{G}' \in \mathcal{H}(f, e)} \exp\{\psi(\mathcal{G}')\}} \quad (1)$$

where  $\psi(\mathcal{G})$  is the FD model score assigned to  $\mathcal{G}$ .

For each sentence pair, different alignment candidates can be induced from its different forced derivation trees generated in the generation step, because FD can use phrase pairs with different internal word links extracted from other sentence pairs to reconstruct the given sentence pair, which could lead to better word alignment candidates.

### 2.2 Inference

Given an FDT space  $\mathcal{H}(f, e)$ , we propose a memory-based re-ranking model (**MRM**), which selects the best FDT  $\hat{\mathcal{G}}$  as follows:

$$\begin{aligned} \hat{\mathcal{G}} &= \underset{\mathcal{G} \in \mathcal{H}(f, e)}{\operatorname{argmax}} \frac{\exp\{\sum_i \lambda_i h_i(\mathcal{G})\}}{\sum_{\mathcal{G}' \in \mathcal{H}(f, e)} \exp\{\sum_i \lambda_i h_i(\mathcal{G}')\}} \\ &= \underset{\mathcal{G} \in \mathcal{H}(f, e)}{\operatorname{argmax}} \sum_i \lambda_i h_i(\mathcal{G}) \end{aligned} \quad (2)$$

where  $h_i(\mathcal{G})$  is feature function and  $\lambda_i$  is its feature weight. Here, *memory* means the whole translation history that happened in the generation step will be used as the evidence to help us compute features.

From the definition we can see that the quality of an FDT directly relates to two aspects: its derivation  $\mathcal{D}$  and alignments  $\mathcal{A}$ . So two kinds of features are used to measure the overall quality of each FDT.

(I) The features in the first category measure the derivation quality of each FDT, including:

- $h(\bar{e}|\bar{f})$ , source-to-target translation probability of a translation rule  $r = \{\bar{f}, \bar{e}\}$ .

$$h(\bar{e}|\bar{f}) = \frac{\sum_{\{f, e\} \in \mathcal{C}} \operatorname{frac}_{\mathcal{H}(f, e)}(\bar{f}, \bar{e})}{\sum_{\{f, e\} \in \mathcal{C}} \sum_{e'} \operatorname{frac}_{\mathcal{H}(f, e)}(\bar{f}, e')} \quad (3)$$

$\operatorname{frac}_{\mathcal{H}(f, e)}(\bar{f}, \bar{e})$  denotes the fractional count of  $r$  used in generating  $\mathcal{H}(f, e)$ :

$$\operatorname{frac}_{\mathcal{H}(f, e)}(\bar{f}, \bar{e}) = \sum_{\mathcal{G} \in \mathcal{H}(f, e)} 1_r(\mathcal{G}) p(\mathcal{G}|\mathcal{H}(f, e))$$

$1_r(\mathcal{G})$  is an indicator function that equals 1 when  $r$  is used in  $\mathcal{G}$  and 0 otherwise. In practice, we use  $p_{\mathcal{H}(f, e)}(r)$  of  $r$  to approximate

$frac_{\mathcal{H}(f,e)}(\bar{f}, \bar{e})$  when the size of  $\mathcal{H}(f, e)$  is too large to enumerate all FDTs:

$$p_{\mathcal{H}(f,e)}(r) = \frac{\omega(r)\mathcal{O}(\text{head}(r))\prod_{v\in\text{tail}(r)}\mathcal{I}(v)}{\mathcal{Z}(f)}$$

where  $\omega(r)$  is the weight of translation rule  $r$  in the FDT space  $\mathcal{H}(f, e)$ ,  $\mathcal{Z}$  is a normalization factor that equals to the inside probability of the root node in  $\mathcal{H}(f, e)$ ,  $\mathcal{I}(v)$  and  $\mathcal{O}(v)$  are the standard inside and outside probabilities of a node  $v$  in  $\mathcal{H}(f, e)$ ,  $\text{head}(r)$  and  $\text{tail}(r)$  are the head node and a set of tail nodes of a translation rule  $r$  in  $\mathcal{H}(f, e)$  respectively.

- $h(\bar{f}|\bar{e})$ , target-to-source translation probability of a translation rule  $r = \{\bar{f}, \bar{e}\}$ .

$$h(\bar{f}|\bar{e}) = \frac{\sum_{\{f,e\}\in\mathcal{C}}frac_{\mathcal{H}(f,e)}(\bar{f}, \bar{e})}{\sum_{\{f,e\}\in\mathcal{C}}\sum_{\bar{f}'}frac_{\mathcal{H}(f,e)}(\bar{f}', \bar{e})} \quad (4)$$

- $h_{\#}(r)$ , smoothed usage count for translation rule  $r = \{\bar{f}, \bar{e}\}$  in the whole generation step.

$$h_{\#}(r) = \frac{1}{1 + e^{\{-\sum_{\{f,e\}\in\mathcal{C}}frac_{\mathcal{H}(f,e)}(\bar{f}, \bar{e})\}}} \quad (5)$$

In this paper, the sigmoid function is used to make sure that the feature values of different translation rules are in a proper value range.

- $h_r(\mathcal{G})$ , number of translation rules used in  $\mathcal{G}$ .
- $h_d(\mathcal{G})$ , structure-based score of  $\mathcal{G}$ . For FDTs generated by phrase-based paradigms, it can be computed by distortion models; while for FDTs generated by syntax-based paradigms, it can be computed by either parsing models or syntactic LMs (Charniak et al., 2003).

The overfitting issue in the generation step can be alleviated by leveraging memory-based features in the inference step.  $h_{\#}(r)$  is used to penalize those long translation rules which tend to occur in only a few training sentences and are used few times in FD,  $h_r(\mathcal{G})$  adjust our MRM to prefer FDTs consisting of more translation rules,  $h_d(\mathcal{G})$  is used to select FDTs with better parse tree-like structures, which can be induced from their derivations directly.

(II) The features in the second category measure the alignment quality of each FDT, including:

- word pair translation probabilities trained from IBM models (Brown et al., 1993);
- log-likelihood ratio (Moore, 2005);
- conditional link probability (Moore, 2005);
- count of unlinked words;
- counts of inversion and concatenation.

Many alignment-inspired features can be used in MRM. This paper only uses those commonly-used ones that have already been proved useful in many previous work (Moore, 2005; Moore et al., 2006; Fraser and Marcu, 2006; Liu et al., 2010).

Following the common practice in SMT research, the MERT algorithm (Och, 2003) is used to tune feature weights in MRM. Due to the fact that all FDTs of each sentence pair share identical translation, we cannot use BLEU as the error criterion any more. Instead, alignment F-score is used as the alternative. We will show in Section 5 that after the inference step, alignment quality can be improved by replacing original alignments of each sentence pair with alignments induced from its 1-best FDT. Future work could experiment with other error criterions, such as reordering-based loss functions (Birch et al., 2010; Talbot et al., 2011; Birch and Osborne, 2011) or span F1 (DeNero and Uszkoreit, 2011).

### 3 Training in Phrase-based SMT

As the first step in this line of research, we explore the usage of FDT-based model training method in a phrase-based SMT system (Xiong et al., 2006), which employs Bracketing Transduction Grammar (BTG) (Wu, 1997) to parse parallel sentences. The reason of choosing this system is due to the prominent advantages of BTG, such as the simplicity of the grammar and the good coverage of syntactic diversities between different language pairs. We first describe more details of FDTs under BTG. Then, four FDT-based component models are presented.

#### 3.1 BTG-based FDT

Given a sentence pair  $f = \{f_0, \dots, f_J\}$  and  $e = \{e_0, \dots, e_I\}$  in training corpus, its FDT  $\mathcal{G}$  generated based on BTG is a binary tree, which is presented by a set of terminal translation states  $\mathcal{T}$  and a set of non-terminal translation states  $\mathcal{N}$ , where:

Figure 1:  $\mathcal{S} = \{\bar{f}_{[i,j]}, \bar{e}_{[i',j']}, \bar{\mathcal{A}}, m, m', \mathcal{R}\}$  is denoted by the dark-shaded rectangle pair. It can be split into two child translation states,  $\mathcal{S}_l$ , which is denoted by the light-shaded rectangle pair, and  $\mathcal{S}_r$ , which is denoted by the white rectangle pair. Dash lines within rectangle pairs denote their internal alignments and solid lines with rows denote BTG rules. (a) uses  $[\cdot]$  to combine two translation states, while (b) uses  $\langle \cdot \rangle$ . Both  $\mathcal{S}_l$  and  $\mathcal{S}_r$  belong to  $\mathcal{T} \cup \mathcal{N}$ .

- each *terminal translation state*  $\mathcal{S} \in \mathcal{T}$  is a 3-tuple  $\{\bar{f}_{[i,j]}, \bar{e}_{[i',j']}, \bar{\mathcal{A}}\}$ , in which  $\bar{f}_{[i,j]}$  denotes the word sequence that covers the source span  $[i, j]$  of  $f$ ,  $\bar{e}_{[i',j']}$  denotes the target translation of  $\bar{f}_{[i,j]}$ , which is the word sequence that covers the target span  $[i', j']$  of  $e$  at the same time,  $\bar{\mathcal{A}}$  is a set of word links that aligns  $\bar{f}_{[i,j]}$  and  $\bar{e}_{[i',j']}$ .
- each *non-terminal translation state*  $\mathcal{S} \in \mathcal{N}$  is a 5-tuple  $\{\bar{f}_{[i,j]}, \bar{e}_{[i',j']}, \bar{\mathcal{A}}, m, m', \mathcal{R}\}$ <sup>1</sup>. The first 3 elements have the same meanings as in  $\mathcal{T}$ , while  $m$  and  $m'$  denote two split points that divide  $\mathcal{S}$  into two child translation states,  $\mathcal{S}_l$  and  $\mathcal{S}_r$ ,  $\mathcal{R}$  denotes a BTG rule, which is either a  $[\cdot]$  operation or a  $\langle \cdot \rangle$  operation<sup>2</sup>. The relationship between  $\mathcal{S}_l$ ,  $\mathcal{S}_r$  and  $\mathcal{S}$  is illustrated in Figure 1.

All terminal translation states of the sentence pair  $\{f, e\}$  are disjoint but cover  $f_{[0,J+1]}$  and  $e_{[0,I+1]}$  at the same time, where  $J = |f|$  and  $I = |e|$ , and all non-terminal translation states correspond to the partial decoding states generated during decoding.

### 3.2 FDT-based Translation Model

First, an FDT-based translation model (**FDT-TM**) is presented for our BTG-based system.

<sup>1</sup>We sometimes omit  $m, m'$  and  $\mathcal{R}$  for a simplicity reason.

<sup>2</sup>A  $[\cdot]$  operation combines the translations of two consecutive source spans  $[i, m]$  and  $[m, j]$  in a monotonic way; while a  $\langle \cdot \rangle$  operation combines them in an inverted way.

Given sentence pairs in training corpus with their corresponding FDT spaces, we train FDT-TM in two different ways: (1) The first only uses the 1-best FDT of each sentence pair. Based on each alignment  $\mathcal{A}$  induced from each 1-best FDT  $\mathcal{G}$ , all possible bilingual phrases are extracted. Then, the maximum likelihood estimation (MLE) is used to compute probabilities and generate an FDT-TM. (2) The second uses the  $n$ -best FDTs of each sentence pair, which is motivated by several studies (Venugopal et al., 2008; Liu et al., 2009). For each sentence pair  $\{f, e\}$ , we first induce  $n$  alignments  $\{\mathcal{A}_1, \dots, \mathcal{A}_n\}$  from the top  $n$  FDTs  $\Omega = \{\mathcal{G}_1, \dots, \mathcal{G}_n\} \subset \mathcal{H}(f, e)$ . Each  $\mathcal{A}_k$  is annotated with the posterior probability of its corresponding FDT  $\mathcal{G}_k$  as follows:

$$p(\mathcal{A}_k | \mathcal{G}_k) = \frac{\exp\{\sum_i \lambda_i h_i(\mathcal{G}_k)\}}{\sum_{\mathcal{G}_{k'} \in \Omega} \exp\{\sum_i \lambda_i h_i(\mathcal{G}_{k'})\}} \quad (6)$$

where  $\sum_i \lambda_i h_i(\mathcal{G}_k)$  is the model score assigned to  $\mathcal{G}_k$  by MRM. Then, all possible bilingual phrases are extracted from the expanded training corpus built using  $n$ -best alignments for each sentence pair. The count of each phrase pair is now computed as the sum of posterior probabilities, instead of the sum of absolute frequencies. Last, MLE is used to compute probabilities and generate an FDT-TM.

### 3.3 FDT-based Distortion Model

In Xiong’s BTG system, training instances of the distortion model (DM) are pruned based on heuristic rules, aiming to keep the training size acceptable. But this will cause the examples remained cannot cover all reordering cases that could be met in real decoding procedures. To overcome this drawback, we propose an FDT-based DM (**FDT-DM**).

Given the 1-best FDT  $\mathcal{G}$  of a sentence pair  $\{f, e\}$ , all non-terminal translation states  $\{\mathcal{S}_1, \dots, \mathcal{S}_K\}$  are first extracted. For each  $\mathcal{S}_k$ , we split it into two child translation states  $\mathcal{S}_{kl}$  and  $\mathcal{S}_{kr}$ . A training instance can be then obtained, using the BTG operation  $\mathcal{R} \in \mathcal{S}_k$  as its class label and boundary words of two translation blocks  $(\bar{f}_{\mathcal{S}_{kl}}, \bar{e}_{\mathcal{S}_{kl}})$  and  $(\bar{f}_{\mathcal{S}_{kr}}, \bar{e}_{\mathcal{S}_{kr}})$  contained in  $\mathcal{S}_{kl}$  and  $\mathcal{S}_{kr}$  as its features. Last, the FDT-DM is trained based on all training instances by a MaxEnt toolkit, which can cover both local and global reordering situations due to its training instance extraction mechanism. Figure 2 shows an example of extracting training instances from an FDT.

{0, (new, 新しい) (books, 本)}  
 {1, (need, が必要です) (new books, 新しい本)}

Figure 2: An example of extracting training instances from an FDT, where solid lines with rows denote BTG operations and dash lines denote alignments. Two instances can be extracted from this FDT, where 0 and 1 denote a  $[\cdot]$  operation and a  $\langle \cdot \rangle$  operation respectively. In DM training, the number (0 or 1) in each instance is used as a label, while boundary words are extracted from each instance’s two phrase pairs and used as lexical features.

### 3.4 FDT-based Source Language Model

We next propose an FDT-based source language model (**FDT-SLM**).

Given the 1-best FDT  $\mathcal{G}$  of a sentence pair  $\{f, e\}$ , we first extract a reordered source word sequence  $f' = \{f'_0, \dots, f'_j\}$  from  $\mathcal{G}$ , based on the order of terminal translation states in  $\mathcal{G}$  which covers the target translation  $e$  from left to right. This procedure can be illustrated by Algorithm 1. Then, all reordered source sentences of training corpus are used to train a source LM. During decoding, each time when a new hypothesis is generated, we obtain its reordered source word sequence as well, compute a LM score based on FDT-SLM and use it as a new feature:

$$h_{SLM}(f') = \prod_{k=1}^J p(f'_k | f'_{k-n+1}, \dots, f'_{k-1}) \quad (7)$$

### 3.5 FDT-based Rule Sequence Model

The last contribution in this section is an FDT-based rule sequence model (**FDT-RSM**).

Given the 1-best FDT  $\mathcal{G}$  of a sentence pair  $\{f, e\}$ , we first extract a sequence of translation rule applications  $\{r_1, \dots, r_K\}$  based on Algorithm 2, where

---

#### Algorithm 1: Sequence Extraction in FDT-SLM

---

- 1 let  $f' = \emptyset$ ;
  - 2 let  $\bar{\mathcal{S}} = \{\mathcal{S}_{1'}, \dots, \mathcal{S}_{K'}\}$  represents an ordered sequence of terminal translation states whose target phrases cover  $e$  from left to right orderly;
  - 3 **foreach**  $\mathcal{S} \in \bar{\mathcal{S}}$  in the left-to-right order **do**
  - 4 | extract  $\bar{f}_{[i,j]}$  from  $\mathcal{S}$ ;
  - 5 | append  $\bar{f}_{[i,j]}$  to  $f'$ ;
  - 6 | append a blank space to  $f'$ ;
  - 7 **end**
  - 8 **return**  $f'$  as a reordered source word sequence.
- 

$r_k = (\bar{f}_{[i,j]}, \bar{e}_{[i',j']})$  denotes the  $k^{th}$  phrase pair. Figure 3 gives an example of extracting a rule sequence from an FDT. An FDT-RSM is trained based on all rule sequences extracted from training corpus. During decoding, each time when a new hypothesis is generated, we compute an FDT-RSM score based on its rule sequence and use it as a new feature:

$$h_{RSM}(f, e) = \prod_{k=1}^K p(r_k | r_{k-n+1}, \dots, r_{k-1}) \quad (8)$$

---

#### Algorithm 2: Sequence Extraction in FDT-RSM

---

- 1 let  $r' = \emptyset$ ;
  - 2 let  $\bar{\mathcal{S}} = \{\mathcal{S}_{1'}, \dots, \mathcal{S}_{K'}\}$  represents an ordered sequence of terminal translation states whose target phrases cover  $e$  from left to right orderly;
  - 3 **foreach**  $\mathcal{S} \in \bar{\mathcal{S}}$  in the left-to-right order **do**
  - 4 | extract a phrase pair  $(\bar{f}_{[i,j]}, \bar{e}_{[i',j']})$  from  $\mathcal{S}$ ;
  - 5 | add  $r_k = (\bar{f}_{[i,j]}, \bar{e}_{[i',j']})$  to  $r'$ ;
  - 6 **end**
  - 7 **return**  $r'$  as a rule sequence.
- 

The main difference between FDT-SLM and FDT-RSM is that the former is trained based on monolingual n-grams; while the latter is trained based on bilingual phrases. Although these two models are trained and computed in an LM style, they are used as reordering features, because they help SMT decoder find better decoding sequences.

Of course, the usage of FDTs need not be limited to the BTG-based system, and we consider using FDTs generated by SCFG-based systems or traditional left-to-right phrase-based systems in future.

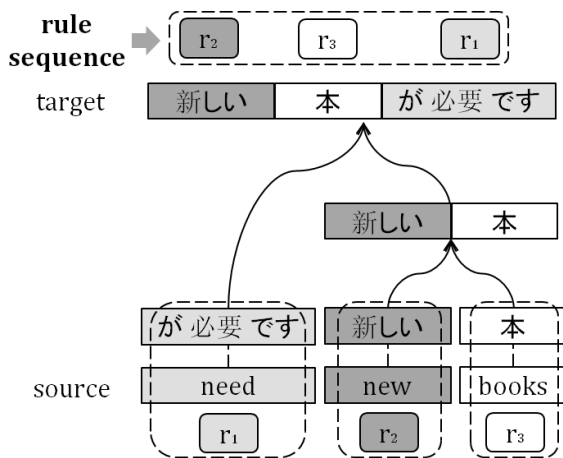

Figure 3: An example of extracting a rule sequence from an FDT. In order to generate the correct target translation, the desired rule sequence should be  $r_2 \Rightarrow r_3 \Rightarrow r_1$ .

## 4 Related Work

### 4.1 Forced Decoding/Alignment

Schwartz (2008) used forced decoding to leverage multilingual corpus to improve translation quality; Shen et al. (2008) used forced alignment to train a better phrase segmentation model; Wuebker et al. (2010) used forced alignment to re-estimate translation probabilities using a leaving-one-out strategy. We consider the usage of FD in Section 2.1 to be a direct extension of these approaches, but one that generates FDTs for parallel data rather than focusing on phrase segmentation or probability estimation.

### 4.2 Pre-reordering

Pre-reordering (PRO) techniques (Collins et al., 2005; Xu et al., 2009; Genzel et al., 2010; Lee et al., 2010) used features from syntactic parse trees to reorder source sentences at training and translation time. A parser is often indispensable to provide syntactic information for such methods. Recently, DeNero and Uszkoreit (2011) proposed an approach that induced parse trees automatically from word-aligned training corpus to perform PRO for a phrase-based SMT system, instead of relying on treebanks. First, binary parse trees are induced from word-aligned training corpus. Based on them, a monolingual parsing model and a tree reordering model are trained to pre-reorder source words into the target-language-like order. Their work is distinct from ours

because it focused on inducing sentence structures for the PRO task, but mirrors ours in demonstrating that there is a potential role for structure-based training corpus in SMT model training.

### 4.3 Distortion Models

Lexicalized distortion models (Tillman, 2004; Zens and Ney, 2006; Xiong et al., 2006; Galley and Manning, 2008;) are widely used in phrase-based SMT systems. Training instances of these models are extracted from word-aligned sentence pairs. Due to efficiency reasons, only parts of all instances are kept and used in DM training, which cannot cover all possible reordering situations that could be met in decoding. In FDT-DM, by contrast, training instances are extracted from FDTs. Such instances take both local and global reordering cases into consideration.

### 4.4 Sequence Models

Feng et al. (2010) proposed an SLM in a phrase-based SMT system. They used it as a reordering feature in the sense that it helped the decoder to find correct decoding sequences. The difference between their model and our FDT-SLM is that, in their work, the reordered source sequences are extracted based on word alignments only; while in our FDT-SLM, such sequences are obtained based on FDTs.

Quirk and Menezes (2006) proposed a Minimal Translation Unit (MTU)-based sequence model and used it in their treelet system; Vaswani et al. (2011) proposed a rule Markov model to capture dependencies between minimal rules for a top-down tree-to-string system. The key difference between FDT-RSM and previous work is that the rule sequences are extracted from FDTs, and no parser is needed.

## 5 Experiments

### 5.1 Data and Metric

Experiments are carried out on English-to-Japanese (E-J) and Chinese-to-English (C-E) MT tasks.

For *E-J task*, bilingual data used contains 13.3M sentence pairs after pre-processing. The Japanese side of bilingual data is used to train a 4-gram LM. The development set (*dev*) which contains 2,000 sentences is used to optimize the log-linear SMT model. Two test sets are used for evaluation, which contain 5,000 sentences (*test-1*) and 999 sentences

(*test-2*) respectively. In all evaluation data sets, each source sentence has only one reference translation.

For *C-E task*, bilingual data used contains 0.5M sentence pairs with high translation quality, including LDC2003E07, LDC2003E14, LDC2005T06, LDC2005T10, LDC2005E83, LDC2006E26, LDC2006E34, LDC2006E85 and LDC2006E92. A 5-gram LM is trained on the Xinhua portion of LDC English Gigaword Version 3.0. NIST 2004 (*MT04*) data set is used as dev set, and evaluation results are measured on NIST 2005 (*MT05*) and NIST 2008 (*MT08*) data sets. In all evaluation data sets, each source sentence has four reference translations.

Default word alignments for both SMT tasks are performed by GIZA++ with the *intersect-diag-grow* refinement. Translation quality is measured in terms of *case-insensitive BLEU* (Papineni et al., 2002) and reported in percentage numbers.

## 5.2 Baseline System

The phrase-based SMT system proposed by Xiong et al. (2006) is used as the baseline system, with a MaxEnt principle-based lexicalized reordering model integrated, which is used to handle reorderings in decoding. The maximum lengths for the source and target phrases are 5 and 7 on E-J task, and 3 and 5 on C-E task. The beam size is set to 20.

## 5.3 Translation Quality on E-J Task

We first evaluate the effectiveness of our FDT-based model training approach on E-J translation task, and present evaluation results in Table 1, in which *BTG* denotes the performance of the baseline system.

*FDT-TM* denotes the improved system that uses FDT-TM proposed in Section 3.2 instead of original phrase table. As described in Section 3.2, we tried different sizes of n-best FDTs to induce alignments for phrase extraction and found the optimal choice is 5. Besides, in order to make full use of the training corpus, for those sentence pairs that are failed in FD, we just use their original word alignments to extract bilingual phrases. We can see from Table 1 that FDT-TM outperforms the BTG system significantly.

*FDT-DM* denotes the improved system that uses FDT-DM proposed in Section 3.3 instead of original distortion model. Comparing to baseline DM which has length limitation on training instances, training examples of FDT-DM are extracted from 1-

best FDTs without any restriction. This makes our new DM can cover both local and global reordering situations that might be met in decoding procedures. We can see from Table 1 that using FDT-DM, significant improvements can be achieved.

*FDT-SLM* denotes the improved system that uses FDT-SLM proposed in Section 3.4 as an additional feature, in which the maximum n-gram order is 4. However, from Table 1 we notice that with FDT-SLM integrated, only 0.2 BLEU improvements can be obtained. We analyze decoding-logs and find that the reordered source sequences of n-best translations are very similar, which, we think, can explain why improvements of using this model are so limited.

*FDT-RSM* denotes the improved system that uses FDT-RSM proposed in Section 3.5 as an additional feature. The maximum order of this model is 3. From Table 1 we can see that FDT-RSM outperforms BTG significantly, with up to 0.48 BLEU improvements. Comparing to FDT-SLM, FDT-RSM performs slightly better as well. We think it is due to the fact that bilingual phrases can provide more discriminative power than monolingual n-grams do.

Last, all these four FDT-based models (FDT-TM, FDT-DM, FDT-SLM and FDT-RSM) are put together to form an improved system that is denoted as *FDT-ALL*. It can provide an averaged 1.2 BLEU improvements on these three evaluation data sets.

BLEU	dev	test-1	test-2
BTG	20.60	20.27	13.15
FDT-TM	21.21	20.71(+0.44)	13.98(+0.83)
FDT-DM	21.13	20.79(+0.52)	14.25(+1.10)
FDT-SLM	20.84	20.50(+0.23)	13.36(+0.21)
FDT-RSM	21.07	20.75(+0.48)	13.59(+0.44)
FDT-ALL	<b>21.83</b>	<b>21.34(+1.07)</b>	<b>14.46(+1.31)</b>
PRO	21.89	21.81	14.69

Table 1: FDT-based model training on E-J task.

Pre-reordering (*PRO*) is often used on language pairs, e.g. English and Japanese, with very different word orders. So we compare our method with PRO as well. We re-implement the PRO method proposed by Genzel (2010) and show its results in Table 1. On dev and test-2, FDT-ALL performs comparable to PRO, with no syntactic information needed at all.

## 5.4 Translation Quality on C-E Task

We then evaluate the effectiveness of our FDT-based model training approach on C-E translation task, and present evaluation results in Table 2, from which we can see significant improvements as well.

BLEU	MT03	MT05	MT08
BTG	38.73	38.01	23.78
FDT-TM	39.14	38.31(+0.30)	24.30(+0.52)
FDT-DM	39.27	38.56(+0.55)	24.50(+0.72)
FDT-SLM	38.97	38.22(+0.21)	24.04(+0.26)
FDT-RSM	39.06	38.33(+0.32)	24.13(+0.35)
<b>FDT-ALL</b>	<b>39.59</b>	<b>38.72(+0.71)</b>	<b>24.67(+0.89)</b>

Table 2: FDT-based model training on C-E task

Comparing to numbers in Table 1, the gains coming from the first two FDT-based models become small on C-E task. This might be due to the fact that the word alignment quality in C-E task is more reliable than that in E-J task for TM and DM training.

## 5.5 Effect on Alignment Quality

We compare the qualities of alignments predicted by GIZA++ and alignments induced from 1-best FDTs.

For E-J task, 575 English-Japanese sentence pairs are manually annotated with word alignments. 382 sentence pairs are used as the dev set, and the other 193 sentence pairs are used as the test set. For C-E task, 491 Chinese-English sentence pairs are manually annotated with word alignments. 250 sentence pairs are used as the dev set, and the other 241 sentence pairs are used as the test set. Both Japanese and Chinese sentences are adapted to our own word segmentation standards respectively. Table 3 shows the comparison results. Comparing to C-E language pair (S-V-O), E-J language pair (S-O-V) has much lower F-scores, due to its very different word order.

F-score	from GIZA++	from 1-best FDTs
dev <sub>EJ</sub>	54.75%	57.93%(+3.18%)
test <sub>EJ</sub>	55.32%	58.47%(+3.15%)
dev <sub>CE</sub>	81.32%	83.37%(+2.05%)
test <sub>CE</sub>	80.61%	82.51%(+1.90%)

Table 3: Comparison of alignment qualities predicted by GIZA++ and induced from 1-best FDTs.

From Table 3 we can see that the F-score improves on all language pairs when using alignments induced from 1-best FDTs, rather than GIZA++.

## 5.6 Effect on Classification Accuracy

In the BTG system, the MaxEnt model is used as a binary classifier to predict reordering operations of neighbor translation blocks. As the baseline DM and our FDT-DM have different mechanisms on training instance extraction procedures, we compare the classification accuracies of these two DMs in Table 4 to show the effect of different training instances. The MaxEnt toolkit (Zhang, 2004) is used to optimize feature weights using the l-BFGS method (Byrd et al., 1995). We set the iteration number to 200 and Gaussian prior to 1 for avoiding overfitting. Table 4 shows that when using training instances extracted from FDTs, classification accuracy of reorderings improves on both E-J and C-E tasks. This is because FDTs can provide more deterministic and structured knowledge for training instance extraction, which can cover both local and global reordering cases.

	baseline DM	FDT-based DM
E-J	93.67%	95.60%(+1.93%)
C-E	95.85%	97.52%(+1.67%)

Table 4: Comparison of classification accuracies of DMs based on instances extracted by different mechanisms.

## 6 Conclusions

In this paper, we have presented an FDT-based model training approach to SMT. As the first step in this research direction, we have verified our method on a phrase-based SMT system, and proposed four FDT-based component models. Experiments on both E-J and C-E tasks have demonstrated the effectiveness of our approach. Summing up, comparing to plain word alignments, FDTs provide richer structured knowledge for more accurate SMT model training. Several potential research topics can be explored in future. For example, FDTs can be used in a pre-reordering framework. This is feasible in the sense that FDTs can provide both tree-like structures and reordering information. We also plan to adapt our FDT-based model training approach to SCFG-based and traditional left-to-right phrase-based systems.

## Abstract

Distant supervision for relation extraction (RE) – gathering training data by aligning a database of facts with text – is an efficient approach to scale RE to thousands of different relations. However, this introduces a challenging learning scenario where the relation expressed by a pair of entities found in a sentence is unknown. For example, a sentence containing *Balzac* and *France* may express *BornIn* or *Died*, an unknown relation, or no relation at all. Because of this, traditional supervised learning, which assumes that each example is explicitly mapped to a label, is not appropriate. We propose a novel approach to multi-instance multi-label learning for RE, which jointly models all the instances of a pair of entities in text and all their labels using a graphical model with latent variables. Our model performs competitively on two difficult domains.

## 1 Introduction

Information extraction (IE), defined as the task of extracting structured information (e.g., events, binary relations, etc.) from free text, has received renewed interest in the “big data” era, when petabytes of natural-language text containing thousands of different structure types are readily available. However, traditional supervised methods are unlikely to scale in this context, as training data is either limited or nonexistent for most of these structures. One of the most promising approaches to IE that addresses this limitation is *distant supervision*, which generates training data automatically by aligning a

$$DB = \left( \begin{array}{l} \text{BornIn}(\text{Barack Obama, United States}) \\ \text{EmployedBy}(\text{Barack Obama, United States}) \end{array} \right)$$

Sentence	Latent Label
Barack Obama is the 44th and current President of the United States.	<i>EmployedBy</i>
Obama was born in the United States just as he has always said.	<i>BornIn</i>
United States President Barack Obama meets with Chinese Vice President Xi Jinping today.	<i>EmployedBy</i>
Obama ran for the United States Senate in 2004.	–

Figure 1: Training sentences generated through distant supervision for a database containing two facts.

database of facts with text (Craven and Kumlien, 1999; Bunescu and Mooney, 2007).

In this paper we focus on distant supervision for relation extraction (RE), a subproblem of IE that addresses the extraction of labeled relations between two named entities. Figure 1 shows a simple example for a RE domain with two labels. Distant supervision introduces two modeling challenges, which we highlight in the table. The first challenge is that some training examples obtained through this heuristic are not valid, e.g., the last sentence in Figure 1 is not a correct example for any of the known labels for the tuple. The percentage of such false positives can be quite high. For example, Riedel et al. (2010) report up to 31% of false positives in a corpus that matches Freebase relations with New York Times articles. The second challenge is that the same pair of entities may have multiple labels and it is unclear which label is instantiated by any textual mention of the given tuple. For example, in Figure 1, the tuple (*Barack Obama, United States*) has two valid labels: *BornIn* and *EmployedBy*, each (latently) instantiated in different sentences. In the

Figure 2: Overview of multi-instance multi-label learning. To contrast, in traditional supervised learning there is one instance and one label per object. For relation extraction the object is a tuple of two named entities. Each mention of this tuple in text generates a different instance.

Riedel corpus, 7.5% of the entity tuples in the training partition have more than one label.

We summarize this multi-instance multi-label (MIML) learning problem in Figure 2. In this paper we propose a novel graphical model, which we called `MIML-RE`, that targets MIML learning for relation extraction. Our work makes the following contributions:

- (a) To our knowledge, `MIML-RE` is the first RE approach that jointly models both multiple instances (by modeling the latent labels assigned to instances) and multiple labels (by providing a simple method to capture dependencies between labels). For example, our model learns that certain labels tend to be generated jointly while others cannot be jointly assigned to the same tuple.
- (b) We show that `MIML-RE` performs competitively on two difficult domains.

## 2 Related Work

Distant supervision for IE was introduced by Craven and Kumlien (1999), who focused on the extraction of binary relations between proteins and cells/tissues/diseases/drugs using the Yeast Protein Database as a source of distant supervision. Since then, the approach grew in popularity (Bunescu and Mooney, 2007; Bellare and McCallum, 2007; Wu and Weld, 2007; Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011; Nguyen and Moschitti, 2011; Sun et al., 2011; Surdeanu et al., 2011a). However, most of these approaches make one or more approximations in learning. For example, most proposals heuristically transform distant supervision to traditional supervised learning (i.e., single-instance single-label) (Bellare and McCallum, 2007; Wu and Weld, 2007; Mintz et al., 2009; Nguyen and Moschitti, 2011; Sun et al., 2011; Surdeanu

et al., 2011a). Bunescu and Mooney (2007) and Riedel et al. (2010) model distant supervision for relation extraction as a multi-instance single-label problem, which allows multiple mentions for the same tuple but disallows more than one label per object. Our work is closest to Hoffmann et al. (2011). They address the same problem we do (binary relation extraction) with a MIML model, but they make two approximations. First, they use a deterministic model that aggregates latent instance labels into a set of labels for the corresponding tuple by OR-ing the classification results. We use instead an object-level classifier that is trained jointly with the classifier that assigns latent labels to instances and can capture dependencies between labels. Second, they use a Perceptron-style additive parameter update approach, whereas we train in a Bayesian framework. We show in Section 5 that these approximations generally have a negative impact on performance.

MIML learning has been used in fields other than natural language processing. For example, Zhou and Zhang (2007) use MIML for scene classification. In this problem, each image may be assigned multiple labels corresponding to the different scenes captured. Furthermore, each image contains a set of patches, which forms the bag of instances assigned to the given object (image). Zhou and Zhang propose two algorithms that reduce the MIML problem to a more traditional supervised learning task. In one algorithm, for example, they convert the task to a multi-instance single-label problem by creating a separate bag for each label. Due to this, the proposed approach cannot model inter-label dependencies. Moreover, the authors make a series of approximations, e.g., they assume that each instance in a bag shares the bag’s overall label. We instead model all these issues explicitly in our approach.

In general, our approach belongs to the category of models that learn in the presence of incomplete or incorrect labels. There has been interest among machine learning researchers in the general problem of noisy data, especially in the area of instance-based learning. Brodley and Friedl (1999) summarize past approaches and present a simple, all-purpose method to filter out incorrect data before training. While potentially applicable to our problem, this approach is completely general and cannot incorporate our domain-specific knowledge about how the noisy

data is generated.

### 3 Distant Supervision for Relation Extraction

Here we focus on distant supervision for the extraction of *relations between two entities*. We define a *relation* as the construct  $r(e_1, e_2)$ , where  $r$  is the relation name, e.g., *BornIn* in Figure 1, and  $e_1$  and  $e_2$  are two entity names, e.g., *Barack Obama* and *United States*. Note that there are entity tuples  $(e_1, e_2)$  that participate in multiple relations,  $r_1, \dots, r_i$ . In other words, the tuple  $(e_1, e_2)$  is the object illustrated in Figure 2 and the different relation names are the labels. We define an *entity mention* as a sequence of text tokens that matches the corresponding entity name in some text, and *relation mention* (for a given relation  $r(e_1, e_2)$ ) as a pair of entity mentions of  $e_1$  and  $e_2$  in the same sentence. Relation mentions thus correspond to the instances in Figure 2.<sup>1</sup> As the latter definition indicates, we focus on the extraction of relations expressed in a single sentence. Furthermore, we assume that entity mentions are extracted by a different process, such as a named entity recognizer.

We define the task of *relation extraction* as a function that takes as input a document collection ( $\mathcal{C}$ ), a set of entity mentions extracted from  $\mathcal{C}$  ( $\mathcal{E}$ ), a set of known relation labels ( $\mathcal{L}$ ) and an extraction model, and outputs a set of relations ( $\mathcal{R}$ ) such that any of the relations extracted is supported by at least one sentence in  $\mathcal{C}$ . To train the extraction model, we use a database of relations ( $\mathcal{D}$ ) that are instantiated at least once in  $\mathcal{C}$ . Using distant supervision,  $\mathcal{D}$  is aligned with sentences in  $\mathcal{C}$ , producing relation mentions for all relations in  $\mathcal{D}$ .

### 4 Model

Our model assumes that each relation mention involving an entity pair has exactly one label, but allows the pair to exhibit multiple labels across different mentions. Since we do not know the actual relation label of a mention in the distantly supervised setting, we model it using a latent variable  $z$  that can take one of the  $k$  pre-specified relation labels as well as an additional *NIL* label, if no relation is expressed by the corresponding mention. We model the multiple relation labels an entity pair can assume

<sup>1</sup>For this reason, we use relation mention and relation instance interchangeably in this paper.

Figure 3: MIML model plate diagram. We unrolled the  $y$  plate to emphasize that it is a collection of binary classifiers (one per relation label), whereas the  $z$  classifier is multi-class. Each  $z$  and  $y_j$  classifier has an additional prior parameter, which is omitted here for clarity.

using a multi-label classifier that takes as input the latent relation types of the all the mentions involving that pair. The two-layer hierarchical model is shown graphically in Figure 3, and is described more formally below. The model includes one multi-class classifier (for  $z$ ) and a set of binary classifiers (for each  $y_j$ ). The  $z$  classifier assigns latent labels from  $\mathcal{L}$  to individual relation mentions or *NIL* if no relation is expressed by the mention. Each  $y_j$  classifier decides if relation  $j$  holds for the given entity tuple, using the mention-level classifications as input. Specifically, in the figure:

- $n$  is the number of distinct entity tuples in  $\mathcal{D}$ ;
- $M_i$  is the set of mentions for the  $i$ th entity pair;
- $x$  is a sentence and  $z$  is the latent relation classification for that sentence;
- $w_z$  is the weight vector for the multi-class mention-level classifier;
- $k$  is the number of known relation labels in  $\mathcal{L}$ ;
- $y_j$  is the top-level classification decision for the entity pair as to whether the  $j$ th relation holds;
- $w_j$  is the weight vector for the binary top-level classifier for the  $j$ th relation.

Additionally, we define  $P_i$  ( $N_i$ ) as the set of all known positive (negative) relation labels for the  $i$ th entity tuple. In this paper, we construct  $N_i$  as  $\mathcal{L} \setminus P_i$ , but, in general, other scenarios are possible. For example, both Sun et al. (2011) and Surdeanu et

al. (2011a) proposed models where  $N_i$  for the  $i$ th tuple  $(e_1, e_2)$  is defined as:  $\{r_j \mid r_j(e_1, e_k) \in \mathcal{D}, e_k \neq e_2, r_j \notin P_i\}$ , which is a subset of  $\mathcal{L} \setminus P_i$ . That is, entity  $e_2$  is considered a negative example for relation  $r_j$  (in the context of entity  $e_1$ ) only if  $r_j$  exists in the training data with a different value.

The addition of the object-level layer (for  $\mathbf{y}$ ) is an important contribution of this work. This layer can capture information that cannot be modeled by the mention-level classifier. For example, it can learn that two relation labels (e.g., *BornIn* and *SpouseOf*) cannot be generated jointly for the same entity tuple. So, if the  $z$  classifier outputs both these labels for different mentions of the same tuple, the  $\mathbf{y}$  layer can cancel one of them. Furthermore, the  $\mathbf{y}$  classifiers can learn when two labels tend to appear jointly, e.g., *CapitalOf* and *Contained* between two locations, and use this occurrence as positive reinforcement for these labels. We discuss the features that implement these ideas in Section 5.

#### 4.1 Training

We train the proposed model using hard discriminative Expectation Maximization (EM). In the Expectation (E) step we assign latent mention labels using the current model (i.e., the mention and relation level classifiers). In the Maximization (M) step we retrain the model to maximize the log likelihood of the data using the current latent assignments.

In the equations that follow, we refer to  $\mathbf{w}_1, \dots, \mathbf{w}_k$  collectively as  $\mathbf{w}_y$  for compactness. The vector  $\mathbf{z}_i$  contains the latent mention-level classifications for the  $i$ th entity pair, while  $\mathbf{y}_i$  represents the corresponding set of gold-standard labels (that is,  $y_i^{(r)} = 1$  if  $r \in P_i$ , and  $y_i^{(r)} = 0$  for  $r \in N_i$ .) Using these notations, the log-likelihood of the data is given by:

$$\begin{aligned} LL(\mathbf{w}_y, \mathbf{w}_z) &= \sum_{i=1}^n \log p(\mathbf{y}_i | \mathbf{x}_i, \mathbf{w}_y, \mathbf{w}_z) \\ &= \sum_{i=1}^n \log \sum_{\mathbf{z}_i} p(\mathbf{y}_i, \mathbf{z}_i | \mathbf{x}_i, \mathbf{w}_y, \mathbf{w}_z) \end{aligned}$$

The joint probability in the inner summation can be broken up into simpler parts:

$$\begin{aligned} p(\mathbf{y}_i, \mathbf{z}_i | \mathbf{x}_i, \mathbf{w}_y, \mathbf{w}_z) &= p(\mathbf{z}_i | \mathbf{x}_i, \mathbf{w}_z) p(\mathbf{y}_i | \mathbf{z}_i, \mathbf{w}_y) \\ &= \prod_{m \in M_i} p(z_i^{(m)} | x_i^{(m)}, \mathbf{w}_z) \prod_{r \in P_i \cup N_i} p(y_i^{(r)} | \mathbf{z}_i, \mathbf{w}_y^{(r)}) \end{aligned}$$

where the last step follows from conditional independence. Thus the log-likelihood for this problem is not convex (it includes a sum of products). However, we can still use EM, but the optimization focuses on maximizing the lower bound of the log-likelihood, i.e., we maximize the above joint probability for each entity pair in the database. Rewriting this probability in log space, we obtain:

$$\begin{aligned} \log p(\mathbf{y}_i, \mathbf{z}_i | \mathbf{x}_i, \mathbf{w}_y, \mathbf{w}_z) &= \sum_{m \in M_i} \log p(z_i^{(m)} | x_i^{(m)}, \mathbf{w}_z) + \\ &\quad \sum_{r \in P_i \cup N_i} \log p(y_i^{(r)} | \mathbf{z}_i, \mathbf{w}_y^{(r)}) \end{aligned} \quad (1)$$

The algorithm proceeds as follows.

**E-step:** In this step we infer the mention-level classifications  $\mathbf{z}_i$  for each entity tuple, given all its mentions, the gold labels  $\mathbf{y}_i$ , and current model, i.e.,  $\mathbf{w}_z$  and  $\mathbf{w}_y$  weights. Formally, we seek to find:

$$\mathbf{z}_i^* = \arg \max_{\mathbf{z}} p(\mathbf{z} | \mathbf{y}_i, \mathbf{x}_i, \mathbf{w}_y, \mathbf{w}_z)$$

However it is computationally intractable to consider all vectors  $\mathbf{z}$  as there is an exponential number of possible assignments, so we approximate and consider each mention separately. Concretely,

$$\begin{aligned} p(z_i^{(m)} | \mathbf{y}_i, \mathbf{x}_i, \mathbf{w}_y, \mathbf{w}_z) &\propto p(\mathbf{y}_i, z_i^{(m)} | \mathbf{x}_i, \mathbf{w}_y, \mathbf{w}_z) \\ &\approx p(z_i^{(m)} | x_i^{(m)}, \mathbf{w}_z) p(\mathbf{y}_i | \mathbf{z}_i', \mathbf{w}_y) \\ &= p(z_i^{(m)} | x_i^{(m)}, \mathbf{w}_z) \prod_{r \in P_i \cup N_i} p(y_i^{(r)} | \mathbf{z}_i', \mathbf{w}_y^{(r)}) \end{aligned}$$

where  $\mathbf{z}_i'$  contains the previously inferred mention labels for group  $i$ , with the exception of component  $m$  whose label is replaced by  $z_i^{(m)}$ . So for  $i = 1, \dots, n$ , and for each  $m \in M_i$  we calculate:

$$z_i^{(m)*} = \arg \max_z p(z | x_i^{(m)}, \mathbf{w}_z) \times \quad (2)$$

$$\prod_{r \in P_i \cup N_i} p(y_i^{(r)} | \mathbf{z}_i', \mathbf{w}_y^{(r)})$$

Intuitively, the above equation indicates that mention labels are chosen to maximize: (a) the probabilities assigned by the mention-level model; (b) the probability that the correct relation labels are assigned to the corresponding tuple; and (c) the probability that the labels known to be incorrect are *not* assigned to the tuple. For example, if a particular mention label receives a high mention-level probability but it is known to be a negative label for that tuple, it will receive a low overall score.

**M-step:** In this step we find  $\mathbf{w}_y, \mathbf{w}_z$  that maximize the lower bound of the log-likelihood, i.e., the probability in equation (1), given the current assignments for  $\mathbf{z}_i$ . From equation (1) it is clear that this can be maximized separately with respect to  $\mathbf{w}_y$  and  $\mathbf{w}_z$ . Intuitively, this step amounts to learning the weights for the mention-level classifier ( $\mathbf{w}_z$ ) and the weights for each of the  $k$  top-level classifiers ( $\mathbf{w}_y$ ). The updates are given by:

$$\mathbf{w}_z^* = \arg \max_{\mathbf{w}} \sum_{i=1}^n \sum_{m \in M_i} \log p(z_i^{(m)*} | x_i^{(m)}, \mathbf{w}) \quad (3)$$

$$\mathbf{w}_y^{(r)*} = \arg \max_{\mathbf{w}} \sum_{1 \leq i \leq n \text{ s.t. } r \in P_i \cup N_i} \log p(y_i^{(r)} | \mathbf{z}_i^*, \mathbf{w}) \quad (4)$$

Note that these are standard updates for logistic regression. We obtained these weights using  $k + 1$  logistic classifiers: one multi-class classifier for  $\mathbf{w}_z$  and  $k$  binary classifiers for each relation label  $r \in \mathcal{L}$ . We implemented all using the L2-regularized logistic regression from the publicly-downloadable Stanford CoreNLP package.<sup>2</sup> The main difference between the classifiers is how features are generated: the mention-level classifier computes its features based on  $x_i$ , whereas the relation-level classifiers generate features based on the current assignments for  $\mathbf{z}_i$  and the corresponding relation label  $r$ . We discuss the actual features used in our experiments in Section 5.

## 4.2 Inference

Given an entity tuple, we obtain its relation labels as follows. We first classify its mentions:

$$z_i^{(m)*} = \arg \max_z p(z | x_i^{(m)}, \mathbf{w}_z) \quad (5)$$

<sup>2</sup>[nlp.stanford.edu/software/corenlp.shtml](http://nlp.stanford.edu/software/corenlp.shtml)

then decide on the final relation labels using the top-level classifiers:

$$y_i^{(r)*} = \arg \max_{y \in \{0,1\}} p(y | \mathbf{z}_i^*, \mathbf{w}_y^{(r)}) \quad (6)$$

## 4.3 Implementation Details

We discuss next several details that are crucial for the correct implementation of the above model.

**Initialization:** Since EM is not guaranteed to converge at the global maximum of the observed data likelihood, it is important to provide it with good starting values. In our context, the initial values are labels assigned to  $\mathbf{z}_i$ , which are required to compute equation (2) in the first iteration ( $\mathbf{z}_i'$ ). We generate these values using a local logistic regression classifier that uses the same features as the mention-level classifier in the joint model but treats each relation mention independently. We train this classifier using “traditional” distant supervision: for each relation in the database  $\mathcal{D}$  we assume that all the corresponding mentions are positive examples for the corresponding label (Mintz et al., 2009). Note that this heuristic repeats relation mentions with different labels for the tuples that participate in multiple relations. For example, all the relation mentions in Figure 1 will yield datums with both the *EmployedBy* and *BornIn* labels. Despite this limitation, we found that this is a better initialization heuristic than random assignment.

For the second part of equation (2), we initialize the relation-level classifier with a model that replicates the *at least one* heuristic of Hoffmann et al. (2011). Each  $\mathbf{w}_y^{(r)}$  model has a single feature with a high positive weight that is triggered when label  $r$  is assigned to any of the mentions in  $\mathbf{z}_i^*$ .

**Avoiding overfitting:** A naïve implementation of our approach leads to an unrealistic training scenario where the  $z$  classifier generates predictions (in equation (2)) for the same datums it has seen in training in the previous iteration. To avoid this overfitting problem we used cross validation: we divided the training tuples in  $K$  distinct folds and trained  $K$  different mention-level classifiers. Each classifier outputs  $p(z | x_i^{(m)}, \mathbf{w}_z)$  for tuples in a given fold during the E-step (equation (2)) and is trained (equation (3)) using tuples from all other folds.

At testing time, we compute  $p(z|x_i^{(m)}, \mathbf{w}_z)$  in equation (5) as the average of the probabilities of the above set of mention classifiers:

$$p(z|x_i^{(m)}, \mathbf{w}_z) = \frac{\sum_{j=1}^K p(z|x_i^{(m)}, \mathbf{w}_z^j)}{K}$$

where  $\mathbf{w}_z^j$  are the weights of the mention classifier responsible for fold  $j$ . We found that this simple bagging model performs slightly better in practice (a couple of tenths of a percent) than training a single mention classifier on the latent mention labels generated in the last training iteration.

**Inference during training:** During the inference process in the E-step, the algorithm incrementally “flips” mention labels based on equation (2), for each group of mentions  $M_i$ . Thus,  $\mathbf{z}_i^j$  changes as the algorithm progresses, which may impact the label assigned to the remaining mentions in that group. To avoid any potential bias introduced by the arbitrary order of mentions as seen in the data, we randomize each group  $M_i$  before we inspect its mentions.

## 5 Experimental Results

### 5.1 Data

We evaluate our algorithm on two corpora. The first was developed by Riedel et al. (2010) by aligning Freebase<sup>3</sup> relations with the New York Times (NYT) corpus. They used the Stanford named entity recognizer (Finkel et al., 2005) to find entity mentions in text and constructed relation mentions only between entity mentions in the same sentence.

Riedel et al. (2010) observes that evaluating on this corpus underestimates true extraction accuracy because Freebase is incomplete. Thus, some relations extracted during testing will be incorrectly marked as wrong, simply because Freebase has no information on them. To mitigate this issue, Riedel et al. (2010) and Hoffman et al. (2011) perform a second evaluation where they compute the accuracy of labels assigned to a set of relation mentions that they manually annotated. To avoid any potential annotation biases, we instead evaluate on a second corpus that has comprehensive annotations generated by experts for all test relations.

We constructed this second dataset using mainly resources distributed for the 2010 and 2011 KBP

<sup>3</sup>freebase.com

shared tasks (Ji et al., 2010; Ji et al., 2011). We generated training relations from the knowledge base provided by the task organizers, which is a subset of the English Wikipedia infoboxes from a 2008 snapshot. Similarly to the corpus of Riedel et al., these infoboxes contain open-domain relations between named entities, but with a different focus. For example, more than half of the relations in the evaluation data are alternate names of organizations or persons (e.g., *org:alternate\_names*) or relations associated with employment and membership (e.g., *per:employee\_of*) (Ji et al., 2011). We aligned these relations against a document collection that merges two distinct sources: (a) the collection provided by the shared task, which contains approximately 1.5 million documents from a variety of sources, including newswire, blogs and telephone conversation transcripts; and (b) a complete snapshot of the English Wikipedia from June 2010. During training, for each entity tuple  $(e_1, e_2)$ , we retrieved up to 50 sentences that contain both entity mentions.<sup>4</sup> We used Stanford’s CoreNLP package to find entity mentions in text and, similarly to Riedel et al. (2010), we construct relation mention candidates only between entity mentions in the same sentence. We analyzed a set of over 2,000 relation mentions and we found that 39% of the mentions where  $e_1$  is an organization name and 36% of mentions where  $e_1$  is a person name do not express the corresponding relation.

At evaluation time, the KBP shared task requires the extraction of all relations  $r(e_1, e_2)$  given a query that contains only the first entity  $e_1$ . To accommodate this setup, we adjusted our sentence extraction component to use just  $e_1$  as the retrieval query and we kept up to 50 sentences that contain a mention of the input entity for each evaluation query. For tuning and testing we used the 200 queries from the 2010 and 2011 evaluations. We randomly selected 40 queries for development and used the remaining 160 for the formal evaluation.

To address the large number of negative examples in training, Riedel et al. subsampled them randomly with a retention probability of 10%. For the KBP corpus, we followed the same strategy, but we used

<sup>4</sup>Sentences were ranked using the similarity between their parent document and the query that concatenates the two entity names. We used the default Lucene similarity measure.

	# of gold relations in training	# of gold relations in testing	% of gold entity tuples with more than one label in training	% of gold entity tuples with multiple mentions in text in training	% of mentions that do not express their relation	# of relation labels
Riedel	4,700	1,950	7.5%	46.4%	up to 31%	51
KBP	183,062	3,334	2.8%	65.1%	up to 39%	41

Table 1: Statistics about the two corpora used in this paper. Some of the numbers for the Riedel dataset is from (Riedel et al., 2010; Hoffmann et al., 2011).

a subsampling probability of 5% because this led to the best results in development for all models.

Table 1 provides additional statistics about the two corpora. The table indicates that having multiple mentions for an entity tuple is a very common phenomenon in both corpora, and that having multiple labels per tuple is more common in the Riedel dataset than KBP (7.5% vs. 2.8%).

## 5.2 Features

Our model requires two sets of features: one for the mention classifier ( $z$ ) and one for the relation classifier ( $y$ ). In the Riedel dataset, we used the same features as Riedel et al. (2010) and Hoffmann et al. (2011) for the mention classifier. In the KBP dataset, we used a feature set that was developed in our previous work (Surdeanu et al., 2011b). These features can be grouped in three classes: (a) features that model the two entities, such as their head words; (b) features that model the syntactic context of the relation mention, such as the dependency path between the two entity mentions; and (c) features that model the surface context, such as the sequence of part of speech tags between the two entity mentions. We used these features for all the models evaluated on the KBP dataset.<sup>5</sup>

For the relation-level classifier, we developed two feature groups. The first models Hoffmann et al.’s *at least one* heuristic using a single feature, which is set to true if at least one mention in  $\mathbf{z}_i$  has the label  $r$ , which is modeled by the current relation classifier. The second group models the dependencies between relation labels. This is implemented by a set of  $|\mathcal{L}| - 1$  features, where feature  $j$  is instantiated whenever the label modeled ( $r$ ) is predicted jointly with another label  $r_j$  ( $r_j \in \mathcal{L}, r_j \neq r$ ) in  $\mathbf{z}_i$ . These features learn both positive and negative reinforcements between labels. For example, if labels

<sup>5</sup>To avoid an excessive number of features in the KBP experiments, we removed features seen less than five times in training.

$r_1$  and  $r_2$  tend to be generated jointly, the feature for the corresponding dependency will receive a positive weight in the models for  $r_1$  and  $r_2$ . Similarly, if  $r_1$  and  $r_2$  cannot be generated jointly, the model will assign a negative weight to feature 2 in  $r_1$ ’s classifier and to feature 1 in  $r_2$ ’s classifier. Note that this feature is asymmetric, i.e., feature 1 in  $r_2$ ’s classifier may have a different value than feature 2 in  $r_1$ ’s classifier, depending on the accuracy of the individual predictions for  $r_1$  and  $r_2$ .

## 5.3 Baselines

We compare our approach against three models:

*Mintz++* – This is the model used to initialize the mention-level classifier in our model. As discussed in Section 4.3, this model follows the “traditional” distant supervision heuristic, similarly to (Mintz et al., 2009). However, our implementation has several advantages over the original model: (a) we model each relation mention independently, whereas Mintz et al. collapsed all the mentions of the same entity tuple into a single datum; (b) we allow multi-label outputs for a given entity tuple at prediction time by OR-ing the predictions for the individual relation mentions corresponding to the tuple (similarly to (Hoffmann et al., 2011))<sup>6</sup>; and (c) we use the simple bagging strategy described in Section 4.3 to combine multiple models. Empirically, we observed that these changes yield a significant improvement over the original proposal. For this reason, we consider this model a strong baseline on its own.

*Riedel* – This is the “at-least-once” model reported in (Riedel et al., 2010), which had the best performance in that work. This approach models the task as a multi-instance single-label problem. Note that this is the only model shown here that does not allow multi-label outputs for an entity tuple.

<sup>6</sup>We also allow multiple labels per tuple at training time, in which case we replicate the corresponding datum for each label. However, this did not improve performance significantly compared to selecting a single label per datum during training.

*Hoffmann* – This is the “MultiR” model, which performed the best in (Hoffmann et al., 2011). This models RE as a MIML problem, but learns using a Perceptron algorithm and uses a deterministic “at least one” decision instead of a relation classifier. We used Hoffman’s publicly released code<sup>7</sup> for the experiments on the Riedel dataset and our own implementation for the KBP experiments.<sup>8</sup>

## 5.4 Results

We tuned all models using three-fold cross validation for the Riedel dataset and using the development queries for the KBP dataset. `MIML-RE` has two parameters that require tuning: the number of EM epochs ( $T$ ) and the number of folds for the mention classifiers ( $K$ ).<sup>9</sup> The values obtained after tuning are  $T = 15, K = 5$  for the Riedel dataset and  $T = 8, K = 3$  for KBP. Similarly, we tuned the number of epochs for the Hoffmann model on the KBP dataset, obtaining an optimal value of 20.

On the Riedel dataset we evaluate all models using standard precision and recall measures. For the KBP evaluation we used the official KBP scorer,<sup>10</sup> with two changes: (a) we score with the parameter `anydoc` set to true, which configures the scorer to accept relation mentions as correct regardless of their supporting document; and (b) we score only on the subset of gold relations that have at least one mention in our sentences. The first decision is necessary because the gold KBP answers contain supporting documents only from the corpus provided by the organizers but we retrieve candidate answers from multiple collections. The second is required because the focus of this work is not on sentence retrieval but on RE, which should be evaluated in isolation.<sup>11</sup>

Similarly to previous work, we report precision/recall curves in Figure 4. We evaluate two variants of `MIML-RE`: one that includes all the features for the  $y$  model, and another (`MIML-RE`

`At-Least-One`) which has only the *at least one* feature. For all the Bayesian models implemented here, we sorted the predicted relations by the noisy-or score of the top predictions for their mentions. Formally, we rank a relation  $r$  predicted for group  $i$ , i.e.,  $r \in \mathbf{y}_i^*$ , using:

$$\text{noisyOr}_i(r) = 1 - \prod_{m \in M_i} (1 - s_i^{(m)}(r))$$

where  $s_i^{(m)}(r) = p(r|x_i^{(m)}, \mathbf{w}_z)$  if  $r = z_i^{(m)*}$  or 0 otherwise. The noisy-or formula performs well for ranking because it integrates model confidence (the higher the probabilities, the higher the score) and redundancy (the more mentions are predicted with a label, the higher that label’s score). Note that the above ranking score does not include the probability of the relation classifier (equation (6)) for `MIML-RE`. While we use equation (6) to generate  $\mathbf{y}_i^*$ , we found that the corresponding probabilities are too coarse to provide a good ranking score. This is caused by the fact that our relation-level classifier works with a small number of (noisy) features. Lastly, for our implementation of the Hoffmann et al. model, we used their ranking heuristic (sorting predictions by the maximum extraction score for that relation).

## 6 Discussion

Figure 4 indicates that `MIML-RE` generally outperforms the current state of the art. In the Riedel dataset, `MIML-RE` has higher overall recall than the Riedel et al. model, and, for the same recall point, `MIML-RE`’s precision is between 2 and 15 points higher. For most of the curve, our model obtains better precision for the same recall point than the Hoffmann model, which currently has the best reported results on this dataset. The difference is as high as 5 precision points around the middle of the curve. The Hoffmann model performs better close to the extremities of the curve (low/high recall). Nevertheless, we argue that our model is more stable than Hoffmann’s: `MIML-RE` yields a smoother precision/recall curve, without most of the depressions seen in the Hoffmann results. In the KBP dataset, `MIML-RE` performs consistently better than our implementation of Hoffmann’s model, with higher precision values for the same recall point, and much higher overall recall. We believe that these differences are caused by our Bayesian framework,

<sup>7</sup>[cs.washington.edu/homes/raphaelh/mr/](http://cs.washington.edu/homes/raphaelh/mr/)

<sup>8</sup>The decision to reimplement the Hoffmann model was a practical one, driven by incompatibilities between their implementation and our KBP framework.

<sup>9</sup>We could also tune the prior parameters for both our model and Mintz++, but we found in early experiments that the default value of 1 yields the best scores for all priors.

<sup>10</sup>[nlp.cs.qc.cuny.edu/kbp/2011/scoring.html](http://nlp.cs.qc.cuny.edu/kbp/2011/scoring.html)

<sup>11</sup>Due to these changes, the scores reported in this paper are not directly comparable with the shared task scores.

Figure 4: Results in the Riedel dataset (top) and the KBP dataset (bottom). The Hoffmann scores in the KBP dataset were generated using our implementation. The other Hoffmann and Riedel results were taken from their papers.

which provides a more formal implementation of the MIML problem.

Figure 4 also indicates that `MIML-RE` yields a consistent improvement over `Mintz++` (with the exception of a few points in the low-recall portion of the KBP curves). The difference in precision for the same recall point is as high as 25 precision points in the Riedel dataset and up to 5 points in KBP. Overall, the best F1 score of `MIML-RE` is slightly over 1 point higher than the best F1 score of `Mintz++` in the Riedel dataset and 3 points higher in KBP. Considering that `Mintz++` is a strong baseline and we evaluate on two challenging domains, we consider these results proof that the correct modeling of the MIML scenario is beneficial.

Lastly, Figure 4 shows that `MIML-RE` outperforms its variant without label-dependency features (`MIML-RE At-Least-One`) in the higher-recall part of the curve in the Riedel dataset. The improvement is approximately 1 F1 point throughout the last segment of the curve. The overall increase in F1 was found to be significant ( $p = 0.0296$ ) in a one-sided, paired  $t$ -test over randomly sampled test data. We see a smaller improvement in KBP (concentrated around the middle of the curve), likely because the number of entity tuples with multiple labels in training is small (see Table 1). Nevertheless, this exercise shows that, when dependencies between labels exist in a dataset, modeling them, which can be trivially done in `MIML-RE`, is useful.

	P	R	F1
Hoffmann (our implementation)	48.6	29.8	37.0
Mintz++	43.8	<b>36.8</b>	40.0
MIML-RE	<b>64.8</b>	31.6	<b>42.6</b>
MIML-RE At-Least-One	56.1	32.5	41.1

Table 2: Results at the highest F1 point in the precision/recall curve on the dataset that contains groups with at least 10 mentions.

In a similar vein, we tested the models previously described on a subset of the Riedel evaluation dataset that only includes groups with at least 10 mentions. This corpus contains approximately 2% of the groups from the original testing partition, out of which 90 tuples have at least one known label and 1410 groups serve as negative examples.

For conciseness, we do not include the entire precision/recall curves for this experiment, but summarize them in Table 2, which lists the performance peak (highest F1 score) for each of the models investigated. The table shows that MIML-RE obtains the highest F1 score overall, 1.5 points higher than MIML-RE At-Least-One and 2.6 points higher than Mintz++. More importantly, for approximately the same recall point, MIML-RE obtains a precision that is over 8 percentage points higher than that of MIML-RE At-Least-One. A post-hoc inspection of the results indicates that, indeed, MIML-RE successfully eliminates undesired labels when two (or more) incompatible labels are jointly assigned to the same tuple. Take for example the tuple (*Mexico City, Mexico*), for which the correct relation is */location/administrative\_division/country*. MIML-RE At-Least-One incorrectly predicts the additional */location/location/contains* relation, while MIML-RE does not make this prediction because it recognizes that these two labels are incompatible in general: one location cannot both be within another location and contain it. Indeed, examining the weights assigned to label-dependency features in MIML-RE, we see that the model has assigned a large negative weight to the dependency feature between */location/location/contains* and */location/administrative\_division/country* for the */location/location/contains* class. We also observe positive dependencies between labels. For example, MIML-RE learns that the relations */people/person/place\_lived* and */peo-*

*ple/person/place\_of\_birth* tend to co-occur and assigns a positive weight to this dependency feature for the corresponding classes.

These results strongly suggest that when all aspects of the MIML scenario are present, our model can successfully capture them and make use of the additional structure to improve performance.

## 7 Conclusion

In this paper we showed that distant supervision for RE, which generates training data by aligning a database of facts with text, poses a distinct multi-instance multi-label learning scenario. In this setting, each entity pair to be modeled typically has multiple instances in the text and may have multiple labels in the database. This is considerably different from traditional supervised learning, where each instance has a single, explicit label.

We argued that this MIML scenario should be formally addressed. We proposed, to our knowledge, the first approach that models all aspects of the MIML setting, i.e., the latent assignment of labels to instances and dependencies between labels assigned to the same entity pair.

We evaluated our model on two challenging domains and obtained state-of-the-art results on both. Our model performs well even when not all aspects of the MIML scenario are common, and as seen in the discussion, shows significant improvement when evaluated on entity pairs with many labels or mentions. When all aspects of the MIML scenario are present, our model is well-equipped to handle them.

The code and data used in the experiments reported in this paper are available at: <http://nlp.stanford.edu/software/mimlre.shtml>.

## Acknowledgments

## Abstract

This paper presents a new readability formula for French as a foreign language (FFL), which relies on 46 textual features representative of the lexical, syntactic, and semantic levels as well as some of the specificities of the FFL context. We report comparisons between several techniques for feature selection and various learning algorithms. Our best model, based on support vector machines (SVM), significantly outperforms previous FFL formulas. We also found that semantic features behave poorly in our case, in contrast with some previous readability studies on English as a first language.

## 1 Introduction

Whether in a first language (L1) or a second and foreign language (L2), learning to read has been and remains one of the major concerns of education. When a teacher wants to improve his/her students’ reading skills, he/she uses reading exercises, whether there are guided or independent. For this practice to be efficient, it is necessary that the texts suit the level of students (O’Connor et al., 2002). This condition is sometimes difficult to meet for teachers wishing to get off the beaten tracks by not using texts from levelled textbooks or readers.

In this context, readability formulas have long been used to help teachers faster select texts for their students. These formulas are reproducible methods that aim at matching readers and texts relative to their reading difficulty level. The Flesch (1948) and Dale and Chall (1948) formulas are probably

the best-known examples of those. They are typical of classic formulas, the first major methodological paradigm developed in the field during the 40’s and 50’s. They were kept as parsimonious as possible, using linear regression to combined two, or sometimes, three surface features, such as word mean length, sentence mean length, or proportion of out-of-simple-vocabulary words.

Later, some scholars (Kintsch and Vipond, 1979; Redish and Selzer, 1985) argued that the classic formulas suffer from several shortcomings. These formulas only take into account superficial features, ignoring other important aspects contributing to text difficulty, such as coherence, content density, inference load, etc. They also omit the interactive aspect of the reading process. In the 80’s, a second paradigm, inspired by structuro-cognitivist theories, intended to overcome these issues. It focused on higher textual dimensions, such as inference load (Kintsch and Vipond, 1979; Kemper, 1983), density of concepts (Kintsch and Vipond, 1979), or macrostructure (Meyer, 1982). However, these attempts did not achieve better results than the classic approach, even though they used more principled and more complex features.

Recently, a third paradigm, referred to as the “AI readability” by François (2011a), has emerged in the field. Studies that are part of this current share three key features: the use of a large number of texts assessed by experts (coming from textbooks, simplified newspapers or web resources) as training data ; the use of NLP-enabled features able to capture a wider range of readability factors, and the combination of those features through a machine learning

algorithm. Since the work of Si and Callan (2001), this paradigm has spawned several studies for English (Collins-Thompson and Callan, 2005; Heilman et al., 2008; Schwarm and Ostendorf, 2005; Feng et al., 2010).

However, for French, the field is far from being so thriving. To our knowledge, only two “AI readability” have been designed so far for French L1 and only one for French as a foreign language (FFL) (see Section 2). This paper reports some experiments aimed at designing a more efficient readability model for FFL. In Section 2, it is further argued why a new formula was necessary for FFL. Section 3 covers the various methodological steps required to devise the model, whose results are reported in Section 4. Finally, Section 5 discusses some interesting insights gained by this work.

## 2 Readability models for French

Readability of French never enjoyed a large success: while readability studies on English dates back to the 20’s, it is only in 1957 that the French-speaking world discovered it through the work of Conquet (1957). Since then, only a few studies focused on the topic.

The two first French L1 formulas were adaptations of the Flesch formula (Kandel and Moles, 1958; de Landsheere, 1963). It is only with Henry (1975) that French got a model fitting the particularities of the language. Henry used cloze tests to assess the level of 60 texts from primary and secondary school textbooks and trained three formulas on this corpus. It is worth mentioning that Henry’s formulas have been applied to FFL by Cornaire (1988). During the same time, Richaudeau explored a different path, as a representative of the structuro-cognitivist paradigm. He used the number of words recalled by a subject after he/she has just read a sentence as a device to measure understanding and provided an “efficiency formula” of texts (Richaudeau, 1979). Although more modern in its conception, Richaudeau’s hard-to-implement formula did not achieve the same recognition in the French speaking world as Henry’s.

After those two major efforts, few works followed. It is worth mentioning two more authors: Mesnager (1989), who designed a classic formula

for children that draw inspiration from the Dale and Chall (1948) formula and Daoust et al. (1996), who developed SATO-CALIBRAGE, a program assessing text difficulty from the first to the eleventh grade. It can be considered as the first “AI formula” for French L1, since it made use of NLP-enabled features. It is also the last formula published for French L1, if we except the adaptation of the model by Collins-Thompson and Callan (2004) to French.

As regards to French L2, the literature is even sparser. Tharp (1939) published a first formula taking into account one particularity of the L2 context: the cognates. Those are words sharing a similar form and meaning across two languages and having a facilitating effect in reading. This idea was recently replicated by Uitdenbogerd (2005), who combined a syntactic feature, the mean number of words per sentence, with the number of cognates per 100 words in her formula. Although taking into account this effect of the L1 on L2 reading is very interesting, these two studies are confined to a limited audience: English speakers learning French. As regards a more generic approach, François (2009) recently published an “AI formula” for FFL, based on logistic regression and ten features. Among those, he stressed the use of verbal tense information as a way to improve performance. However, the set of features he experimented remains limited (about 20).

From all this, it seems clear that FFL readability needs to be addressed more thoroughly, especially if we are willing to get a generic model, able to make predictions for L2 readers with any L1 background. The rest of this paper describes one such attempt.

## 3 Design of the formula

The design of an “AI readability” formula involves the same three steps as a classification problem. First, one needs to gather a gold-standard corpus large enough to reliably train the parameters of a learning algorithm, as described in Section 3.1. The next step, covered in Section 3.2, consists in defining a set of predictors, that is to say, linguistic characteristics of the texts that will be used to predict the difficulty level of new texts. Finally, the best subset of these predictors is combined within a learning algorithm to obtain the best model possible. Experiments at this level are reported in Section 3.3.

### 3.1 The corpus

A gold-standard for readability consists in texts labelled according to their difficulty. For this, it is first necessary to choose a difficulty scale used for the labels (for English L1, it is usually the 12 grade levels scale), that also constrains the output of the formula. Then, each text have to be assessed with a method able to measure the reading comprehension level of the target population.

Regarding the scale, an obvious choice for the foreign language context was the beginner/intermediate/advanced continuum, recently redefined in the Common European Framework of Reference for Languages (CEFR) (Council of Europe, 2001) as the six following levels: A1 (Breakthrough); A2 (Waystage); B1 (Threshold); B2 (Vantage); C1 (Effective Operational Proficiency) and C2 (Mastery). This scale has now become the reference for foreign language education, at least in Europe.

Assessing the reading difficulty of texts with respect to a target population of readers was a more challenging issue. Several techniques have been used in the literature, the most important of which are comprehension tests, cloze tests and expert judgements. They all postulate a given population of readers, although relying on expert judgements save the need for a sample of subjects to take a test. In this case, texts comes from textbooks whose content difficulty have been assessed by the publishers.

This last criterion is now mainstream in “AI readability”, since it is very practical and facilitates the creation of a large corpus, but it has its own shortcomings. Studies such as van Oosten et al. (2011) found that expert agreement on a same corpus of texts might be insufficient for a classification task.

For this study, we nevertheless relied on expert judgements, since we needed a large amount of labelled texts to ensure a robust statistical learning. We selected 28 FFL textbooks, published after 2001 and designed for adults or adolescents learning FFL for general purposes. From those, we extracted 2,160 texts related to a reading comprehension task and assigned to each of them the same level as the textbook it came from.

As it was expected from van Oosten et al. (2011)’s study, differences in the publishers’ conception of difficulty led to an heterogeneous labelling between

textbooks. This heterogeneity was detected in three of the six levels (A1, A2, and B1) using ANOVA based on two classic readability features as independent variables: the mean number of words per sentence and the mean number of letters per word. A subsequent qualitative analysis revealed that most of the heterogeneity was coming from textbooks following the new didactic approach recommended by the CEFR: the task-oriented approach, which focuses more on the task than the text when labelling the overall reading activity. Therefore, we decided to remove those type of textbooks from our corpus, which amounted to 5 books and 249 texts. The remaining 1,852 excerpts were kept for our experiments. Their distribution is displayed in Table 1 as regard to the number of texts and tokens.

### 3.2 The predictors

In a second step, every text of the corpus was represented as a numeric vector of 406 features, each of them representing a linguistic dimension of the text as a single number. Their implementation drew on two different sources of inspiration: the existing predictors in the English and French literature and the psycholinguistic literature on the reading process. The complete set was classified in four families, depending on the kind of information each one is supposed to represent. These families were: “lexical”, “syntactic”, “semantic”, and “specific to FFL context”. Each of them was further divided in subfamilies, described in the rest of the section <sup>1</sup>.

#### 3.2.1 Lexical Features

Lexical features have been shown to be the most important level of information in many readability studies (Chall and Dale, 1995; Lorge, 1944). It is then not surprising that a wide range of lexical predictors have been developed in the literature. Our own set comprised the following subfamilies:

**Statistics of lexical frequencies:** frequencies of words in a text are a good indicator of the text’s overall difficulty (Stenner, 1996). They are usually summarized via the mean, but we also tested the median, the interquartile range, as well as the 75<sup>th</sup> and 90<sup>th</sup> percentiles.

<sup>1</sup>Space restrictions did not enable us to formally defined each variable used in this study. The reader may consult François (2011b) for a more comprehensive description.

A1	A2	B1	B2	C1	C2	Total
430(58.561)	380(75.779)	552(176.973)	198(71.701)	184(92.327)	108(35.202)	1,852(510;543)

Table 1: Distribution of the number of texts and tokens per level in our corpus.

We used *Lexique3* (New et al., 2007) as our frequency database. It is a lexicon including about 50,000 lemmas and 125,000 inflected forms whose frequencies were obtained from movie subtitles. Since French has a rich morphology, we considered the probabilities of both lemma and inflected forms. Moreover, following an idea from Elley (1969), we also computed the above mentioned statistics for given POS words, such as content word, nouns, verbs, etc.

**Percentage of words not in a reference list:** part of the Dale and Chall (1948)’s formula, this feature is one of the most famous in readability. For our experiments, two word lists for FFL were used: the well-known – but already dated – Gougenheim et al. (1964)’s list and a second one that was found at the end of one FFL textbook: *Alter Ego* (Berthet et al., 2006). Different sizes were also experimented for both lists.

**Word length:** mean word length is another classic feature in readability (Flesch, 1948; Smith, 1961). We used various statistics based on the number of letters per word (mean, median, percentiles, etc.).

**N-grams models:** Si and Callan (2001) shown that n-grams models can successfully be applied to readability. We then used both a simple unigram approach based on the frequencies from *Lexique3*, and a more complex bigram model trained on two different corpora: the Google n-grams (Michel et al., 2011) and a corpus of newspaper articles from *Le Soir* amounting to 5,000,000 words<sup>2</sup>. Both were normalized according the length  $n$  of the text as follows:

$$P(text) = \frac{1}{n} \sum_{i=1}^n \log P(w_i|h) \quad (1)$$

where  $w_i$  is the  $i^{th}$  word and  $h$  a limited history of length 0 (unigram) or 1 (bigram).

<sup>2</sup>Smoothing algorithms used were respectively the simple Good-Turing algorithm (Gale and Sampson, 1995) for unigrams and linear interpolation (Chen and Goodman, 1999) for the bigrams.

**Lexical diversity:** the repetition effect is another factor known to affect the reading process (Bowers, 2000). It has been mainly implemented through the classic type-token ratio (TTR) that suffers from being dependent on the text length. This is why we defined a normalized TTR, which is the mean score of several TTRs, computed on text’s fragments of equal length. This way, long texts were made comparable with short ones.

**Orthographic neighborhood:** we finally suggested a new lexical variable, based on the fact that some characteristics of the orthographic neighbors<sup>3</sup> of a word are known to impact the reading of this word (Andrews, 1997). Thirteen predictors were implemented to account for the number or the frequency of the orthographic neighbors of all words in a text.

### 3.2.2 Syntactic features

The syntactic level of information is another traditional area of investigation in readability. Although most of the scholars in the field agree that it does not lead to such efficient predictors as the lexical level, they have noticed it can be combined with the latter to improve performance of readability formulas. We therefore investigated the following subfamilies:

**Sentence length:** the traditional approach to syntactic difficulty relied on the number of words per sentence. We have approached it through various statistics such as the mean, the median, or several percentiles.

**Part of speech ratios:** Bormuth (1966) demonstrated the good predictive power of some POS ratios in a text. We computed 156 ratios based on TreeTagger’s POS (Schmid, 1994). They operated as proxies for the syntactic complexity of sentences, since we did not use features based on a parser<sup>4</sup>.

<sup>3</sup>The orthographic neighbors of a word  $X$  have been defined by Coltheart (1978) as all the words of the same length as  $X$  and varying from it only by one letter (eg. FIST and GIST).

<sup>4</sup>This choice was motivated as follows. Bormuth (1966), who performed a manual annotation of the syntactic structures

**Verbs:** although the tense and moods found in a text have been hardly considered in the field, Carreiras et al. (1997) suggested that verbal aspects are important while building a mental representation of a text and therefore impact its understanding. They help the reader to distinguish between major and minor elements associated with events described by these verbs. We therefore replicated and enhanced the feature set proposed by François (2009), considering either binary indicators or proportions of the use of tenses or moods in a text.

### 3.2.3 Semantic features

The importance of semantic and cognitive factors have been particularly stressed by the structuro-cognitivist paradigm, although Miller and Kintsch (1980), as well as Kemper (1983), eventually admitted not being able to demonstrate the superiority of those new predictors over traditional ones. More recent work also reported limited evidence of this alleged superiority (Pitler and Nenkova, 2008; Feng et al., 2010). In order to clarify as much as possible the situation for FFL, we implemented the following features:

**Personnalization level:** Dale and Tyler (1934) suggested that informal texts should be easier to read and that informality might be assessed through the type of personal pronouns found in a text. On this assumption, 13 variables were defined to take into account various personal pronouns proportions in the text.

**Conceptual density:** Kintsch et al. (1975) showed that the number of propositions as well as the number of different arguments in a sentence influence its reading time. Following Kintsch's propositional model, we used *Densidées* (Lee et al., 2010) to capture conceptual complexity. It is a program able to estimate the mean number of propositions per word in a text using 35 rules relying on lexical and POS clues.

---

in its corpus, noticed that features based on parse trees were less efficient than classic ones, such as sentence length or part of speech ratios. Therefore, it seemed unlikely that the information collected by means of syntactic parsers, which are still committing a significant number of errors, at least for French, would belie these findings.

**Lexical cohesion** : the level of cohesion in a text was measured as the average cosine of all pair of adjacent sentences in the text. Each sentence was represented by a numeric weighted vector (based on words) and projected in a vector space. As suggested by Foltz and al. (1998), two methods were used to define the vector space and weight every word: the *tf-idf* (term frequency-inverse document frequency) and the latent semantic analysis (LSA). The first approach, called "word overlap", corresponds to the "noun overlap" defined by Graesser et al. (2004, 199), except that all type of POS are taken into account. For LSA, we applied a singular value decomposition (SVD), and after comparing various sizes with a cross-validation procedure, we retained a small 15-dimensional space.

### 3.2.4 Features specific to FFL

Apart from the effect of cognates (Uitdenbogerd, 2005; Tharp, 1939), few features specific to the L2 context were previously investigated. It is probably because such an approach requires to train a model for each pair of language of interest and gather suitable data for evaluation. Since our study intended to design a generic model, we focused on specific predictors affecting L2 reading, whatever the learner's mother tongue is:

**Multi-word expressions (MWE):** MWEs are acknowledged to cause problems to L2 learners for production (Bahns and Eldaw, 1993). However, the effect of MWE on the reception side remains unclear, especially for beginners. Ozasa et al. (2007) tested the mean of the absolute frequency of all MWEs in a text as an indication of its difficulty, but it appeared non significant. In a latter experiment involving a larger set of MWE-based predictors, François and Watrin (2011) detected a significant, but limited effect. We therefore replicated this set, which includes variables based on the frequencies of MWE, their syntactic structure, their number or their length. Frequencies were estimated on the same corpora as the bigram model described above (Google and *Le Soir*).

**Type of text:** Finally, we defined five simple variables aiming at identifying dialogues, such as presence of commas, ratio of punctuation, etc. as suggested by Henry (1975). This focus on dialogue was

Level of information	Tag	Description of the variable	$\rho$
Lexical	PA-Altrego	Proportion of absent words from a list of easy words	0.65 <sup>3</sup>
	X90FFFC	90 <sup>th</sup> percentile of inflected forms for content words only	-0.64 <sup>3</sup>
	ML3	Unigram model based on lemmas	-0.55 <sup>3</sup>
	NLM	Mean number of letters per word	0.48 <sup>3</sup>
	TTR	Type-token ratio based on lemma	0.28 <sup>3</sup>
	MedNeigh+Freq	Median number of more frequent neighbor for words	-0.23 <sup>3</sup>
Syntactic	NMP	Mean number of words per sentence	0.62 <sup>3</sup>
	NWS90	Length (in words) of the 90 <sup>th</sup> percentile sentence	0.61 <sup>3</sup>
	LSDaoust	Percentage of sentences longer than 30 words (Daoust et al., 1996)	0.56 <sup>3</sup>
	PPres	Presence of at least one present participle in the text	0.44 <sup>3</sup>
	PRO.PRE	Ratio of pronouns on prepositions	-0.35 <sup>3</sup>
	PPres-C	Proportion of present participle among verbs	0.41 <sup>3</sup>
	PPasse	Presence of at least one past participle	0.39 <sup>3</sup>
	Impf	Presence of at least one imperfect	0.27 <sup>3</sup>
	Subp	Presence of at least one subjunctive present	0.27 <sup>3</sup>
	Cond	Presence of at least one conditional	0.23 <sup>3</sup>
	Imperatif	Presence of at least one imperative	0.02
	Subi	Presence of at least one subjunctive imperfect	0.05
Semantic	avLocalLsa-Lem	Average intersentential cohesion measured via LSA	0.63 <sup>3</sup>
	PP1P2	Percentage of P1 and P2 personal pronouns	-0.33 <sup>3</sup>
Specific	NAColl	Proportion of MWE having the structure NOUN ADJ	0.29 <sup>3</sup>
	BINGUI	Presence of commas	0.46 <sup>3</sup>

Table 2: Spearman correlation for some predictors in our set with difficulty. A positive correlation means that the difficulty of texts increases with the value of the predictor. Signification levels are the following <sup>1</sup> :  $< 0.05$ ; <sup>2</sup> :  $< 0.01$ ; and <sup>3</sup> :  $< 0.001$ .

explained by their extensive use in foreign language teaching, especially in the first levels. Furthermore, even for L1, various scholars stressed the fact that dialogues are often written in a simpler style and have a more mundane content (Dolch, 1948; Flesch, 1948).

### 3.3 The algorithms

The last step in the development of our formula was to select the most informative subset of features and combine them in a state-of-the-art machine learning algorithm. The algorithms originally considered were six: multinomial and ordinal logistic regression (respectively MLR and OLR), classification trees, bagging, boosting (both based on decision trees) and support vector machine (SVM). However, since the logistic models and the SVM clearly outperformed the others three, we will reported only about those in the next section.

## 4 Results

The experiments based on this methodology were twofold. First, we assessed the predictive power of each of the 406 features, considered in a bivariate relationship with difficulty. Second, we selected various subsets of features for training models and

compared their performance. The two next sections summarize the main findings obtained during these two steps.

### 4.1 The efficiency of predictors

Spearman correlation was used to assess the efficiency of each predictor, to better account for non-linear relationships with the criterion. Values for some variables among the four families are reported in Table 2. In accordance with the literature, it appeared that the best family of predictors were the lexical one, followed by the syntactic one. On the contrary, semantic and specific to FFL features did not perform so well, with the exception of the LSA-based feature (*avLocalLsa-Lem*).

Of all predictors, the best was surprisingly *PA-Altrego*, a list-based variable inspired by Dale and Chall (1948), but adapted to the FFL context, since the list of easy words used came from a FFL textbook (*Alter Ego 1*). This suggests that, although the predictive power of “specific to FFL” features was low, specialization to the FFL context was beneficial at other levels.

## 4.2 The models

Once the best single predictors were identified, it was possible to combine several of them in a readability model for comparison. This required some corpus preparation. Since preliminary experiments showed that the equal prior probabilities are required to ensure a unbiased training, the whole corpus was resampled to get the same number of texts per level (108), which amounted to a total of 648 texts. We then split this smaller corpus into two sets. 240 texts were kept for development purposes, mainly feature selection and estimation of the meta-parameters  $\gamma$  and  $C$  for the SVM. The remaining 408 texts were used for evaluating performance of our readability models.

### 4.2.1 Selection of the features

Several ways of selecting the smallest “best” subset of features were compared, given that some variables are partly redundant when combined together. The first method was based on the structuro-cognitivist assumption that readability formulas should include other features than just lexico-syntactical ones, in order to maximize variety of information. Therefore, we tried an “expert” selection, keeping either the best feature among each of the four families (set **Exp1**), or the two best features (set **Exp2**)<sup>5</sup>.

These “expert” approaches were compared to an automatic selection, using either a stepwise procedure<sup>6</sup> for logistic regression (OLR and MLR) or a built-in regularization (Bishop, 2006, 10) for the SVM, based on the 46 best predictors inside each subfamily.

For the sake of comparison, we also defined two other sets: one that corresponds to a random classification (the empty subset), and a baseline, based on two classic predictors (number of letters per word and number of words per sentence), which aimed to mimic classic formulas such as those of

<sup>5</sup>For the syntactic level, since the two best variables belonged to the same subfamily (see Section 3.2) and were too highly intercorrelated, the 90<sup>th</sup> percentile of the sentence length (*NWS90*) was replaced by the best feature from another subfamily: the presence of at least one present participle (*PPres*).

<sup>6</sup>In order to suppress as much random effects as possible, the selection process was repeated 100 times via a bootstrapping .632 procedure (Tufféry, 2007, 396-371) and only the features selected at least 50 times out of 100 were kept.

Flesch (1948) or Dale and Chall (1948). A summary of the features included in each subset is available in Table 3.

### 4.2.2 Evaluation of the models

The next step then consisted in training logistic and SVM models for each of the above subsets. Their performances, reported in Table 4, were assessed using five measures: the multiple correlation ratio ( $R$ ), the accuracy ( $acc$ ), the adjacent accuracy<sup>7</sup> ( $adjacc$ ), the root mean square error ( $rmse$ ) and the mean absolute error ( $mae$ ). It should be noted that each of these measures was estimated through a ten-fold cross-validation procedure, which allowed us to compare performances of different models with a T-test.

The comparison between the models was performed in two steps. First, we computed T-tests based on  $adjacc$  to compare the models based on a same set of features (either **Exp1**, **Exp2**, or **Auto**). This allowed us to pick up the best classifier for each set. In a second step, these three best models were compared the same way, which resulted in the selection of the very best classifier. The decision of adopting the adjacent accuracy as a criterion instead of the accuracy was motivated by our conviction that our system should rather avoid serious errors (i.e. larger than one level) than be more accurate, while sometimes generating terrible mistakes. However, it appeared that both metrics were mostly consistent.

The performance of the different models are displayed in Table 4. It is first interesting to note that the baseline (based on SVM) already gives interesting results. It reaches a classification accuracy of 34%, which is about twice the random. As regards the first model (**Exp1**), based on RLM and including four predictors, it outperforms the baseline by 5%, a difference close to significance ( $t(9) = 1.77; p = 0.055$ ). Therefore, combining variables from several families seems to improve performance over the “classic” baseline, limited to lexico-syntactic features.

This finding is reinforced by the SVM model from **Exp2**, which includes eight features. It performs significantly better than the baseline ( $t(9) =$

<sup>7</sup>Heilman et al. (2008) defined it as “the proportion of predictions that were within one level of the human assigned label for the given text”.

Model name	Classifieur	Set of features
Exp1	OLR, MLR and SVM	PA-Alterego + NMP + avLocalLsa-Lem + BINGUI
Exp2	OLR, MLR and SVM	PA-Alterego + X90FFFC + NMP + PPres + avLocalLsa-Lem + PP1P2 + BINGUI + NAColl
Auto-OLR	OLR	PA-Alterego + NMP + PPres + ML3
Auto-MLR	MLR	PA-Alterego + Cond + Imperatif + Impf + PPasse + PPres + Subi + Subp + BINGUI + TTR + NWS90 + LSDaoust + MedNeigh+Freq
Auto-SVM	SVM	all the 46 variables

Table 3: Results from the two selection process: expert and automatic. Description of the features can be found in Table 2.

Model	Classifier	Parameters	R	acc	adjacc	rmse	mae
Random	/	/	/	16.6	44.4	/	/
Baseline	SVM	$\gamma = 0.05; C = 25$	0.62	34.0	68.2	1.51	1.06
Exp1	RLM	/	0.70	39.4	74.2	1.34	0.97
Exp2	SVM	$\gamma = 0.002; C = 75$	0.73	40.8	77.9	1.28	0.94
Auto-OLR	OLR	/	0.71	39.6	76.1	1.33	0.96
Auto	SVM	$\gamma = 0.004; C = 5$	0.73	49.1	79.6	1.27	0.90

Table 4: Evaluation measures for the best difficulty model from each feature set (**Exp1**, **Exp2** and **Auto**), along with values for a random classification, and the “classic” baseline.

2.36;  $p = 0.02$ ), with an accuracy gain of 7%. However, to that point, it was not clear whether this superiority was indeed a consequence of maximizing the kind of information brought to the model or merely the result of the increased number of predictor.

We thus performed another experiment to address this issue. The model **Exp1** was compared with **Auto-OLR**, the best ordinal logistic model obtained through the stepwise selection (see Tables 4 and 3), and previously discarded as a result of the T-test comparisons. Like **Exp1**, it also contains four predictors, but they are all lexical or syntactic features. Therefore, this model does not maximize the type of information. Surprisingly, we observed that **Auto-OLR** obtained similar and even slightly better performance than **Exp1** (+2% for both *acc* and *adjacc*). Thus, the claim that maximizing the source of information should yield better models did not stand on our data.

Finally, our best performing model was based on the **Auto** feature set and SVM. Its accuracy was increased by 8% in comparison with the **Exp2** model, which is clearly a significant improvement ( $t(9) = 2.61; p = 0.01$ ), and outperformed the baseline by 15%. As mentioned previously, this model includes 46 features coming from our four families. It is worth mentioning that the quality of the predictions is not the same across the levels, as shown in Table 5. They are more accurate for classes situated at both ends of the difficulty scale, namely A1, C1

and C2. For A1, this is explained because texts for beginners are more typical, having very short sentences and simple words. However, the case of C1 and C2 classes is more surprising and might be due to some specificities of the learning algorithm.

	A1	A2	B1	B2	C1	C2
<b>Adj. acc.</b>	100%	71%	67%	71%	86%	83%

Table 5: Adjacent accuracy per level, computed on one of the 10 folds. Its adjacent accuracy was 79%, which is very similar to the average value of the model.

We also assessed the specific contribution of each family of features in two ways: on one hand, we trained a model including only the features from this family; on the other hand, we trained a model including all features except those from this family. Results for the four families are displayed at Table 6.

It appeared that the lexical family was the most accurate set of predictors (40.5%) and yielded the highest loss in performance when set aside, especially for adjacent accuracy. In fact, this was the only set whose absence significantly impacted adjacent accuracy, suggesting that the other type of predictors can only improve the accuracy of predictions, but are not able to reduce the amount of critical mistakes. The second best family was, expectedly, the syntactic one. Its accuracy closely match that of the lexical set, although more severe mistakes were made, as shown by the drop in adjacent accu-

racy. Finally, our two other families was clearly inferior, but they still improved slightly the accuracy of our model, although not the adjacent accuracy.

	Family only		All except family	
	Acc.	Adj. acc.	Acc.	Adj. acc.
Lexical	40.5	75.6	41.1	73.5
Syntactic	39.3	69.5	43.2	78.4
Semantic	28.8	61.5	47.8	79.2
FFL	24.9	58.5	47.8	79.6

Table 6: Accuracy and adjacent accuracy (in percentage) for models either using only one family of predictors, or including all 46 features except those of one family.

### 4.2.3 Comparaison with previous work

Comparisons with other FFL models are difficult to provide: not only there are few formulas available for FFL, but some of these focus on a different audience, making comparability low. This is why we were able to compare our results with only two previous models.

The first of them is a classic readability formula by Kandel and Moles (1958), which is an adaptation of the Flesch (1948) formula for French:

$$Y = 207 - 1.015lp - 0.736lm \quad (2)$$

where  $Y$  is a readability score ranging from 100 (easiest) to 0 (harder);  $lp$  is the average number of words per sentence and  $lm$  is the average number of syllables per 100 words. Although it was not designed for FFL, we considered it, since it is one of the most well-known formula for French and the two features combined are very general. Their predictive power should not vary much in both contexts, as shown by Greenfield (2004) for English. We evaluated it on the same test corpus as our SVM model and obtained really lower values : a  $R$  of 0.55 and an accuracy of 33%.

The second model was that of François (2009), which is based on a multinomial logistic regression including ten features: a unigram model similar to *ML3*, the number of letters per word, the number of words per sentence, and binary variables indicating the presence of a past participle, present participle, imperfect, infinitive, conditional, future and present subjunctive tenses in the text. To our knowledge, this model is the best current generic model available for FFL. On our data, it yielded an accuracy of

41% and an adjacent accuracy of 72.7%, both estimated through a 10-fold cross-validation procedure. Therefore, our new approach achieved an accuracy gain of 8% over this state-of-the-art model, which was considered as a significant difference ( $t(9) = 3.72; p = 0.002$ ).

Apart of those two studies, Uitdenbogerd (2005) also developed recently a FFL formula. However, as explained previously, this work focused on a specific category of L2 readers, the English-speakers learning FFL, which resulted in a different problem. She reported a higher  $R$  than us (0.87 against 0.73). However, this value might be the training one and was estimated on a small amount of novel beginnings. It is therefore likely that our model generalize better, especially across genres and L2 readers with different L1 backgrounds.

## 5 Discussion and conclusion

In this paper, we introduced a new “AI readability” formula for FFL, able to predict the level of texts according to the largely-spread CEFR scale. Our model is based on a SVM classifier and combines 46 features corresponding to several levels of linguistic information. Among those, we suggested some new features: the normalized TTR and the set of variables based on several characteristics of words’ neighbors. Comparing our approach with two previously published formulas, our model significantly outperformed both these works. Therefore, it represent a robust generic solution for FFL readers willing to find various kind of texts that suit their linguistic abilities.

Besides the creation of a new FFL readability formula, this study produced two valuable insights. First, we showed that maximizing the type of linguistic information might not be the best path to go, since a model based on four lexico-syntactic features yielded predictions as accurate as those of a model relying on our *Exp1* set of variables. However, this finding might be partly accounted by the lower predictive power of the features from the semantic and specific-to-FFL family, with the notable exception of the LSA-based predictor (*avLocalLsa-Lem*), which is the third best predictor when considered alone.

This leads us to our second finding, relative to the

set of semantic features. Yet their importance was largely praised in the structuro-cognitivist paradigm and in most of the recent works, our experiments cast serious doubts about their efficiency, at least in a L2 context. Not only the expert models, to which we imposed the presence of one or two semantic predictors, did not perform the best, but none of the features from our semantic set was retained during the automatic selection of the variables for the logistic models. On the contrary, in some subsets, the LSA-based feature was sometimes considered as collinear with the other variables. Finally and foremost, we showed that dropping the semantic features did not impact significantly the performance of our best model.

With reservations one may have because of the limited number of semantic predictors in our set, these results however raise some concerns about whether the information coming from semantic variables is really different from that carried by lexico-syntactic features. Our results clearly show that this may not be the case. This conclusion contradicts the assumptions of the structuro-cognitivist paradigm, but corroborates Chall and Dale (1995)'s view that the information carried by semantic predictors is largely correlated with that of lexico-syntactical ones.

Further investigation on this issue would definitely be worthwhile, since several facts could explain these contradictory findings. First, it might be that semantic and lexical predictors are correlated because the methods used for the parameterization of the semantic factors heavily rely on lexical information. This is the case for the LSA, as well as for the propositional approach of the content density.

Alternatively, this difference with other work in L1 could be due to the L2 context. Chall and Dale (1995) explained that the lexicon and the syntax are more important for children learning to read than for more advanced readers, who then become more sensitive to organisational aspects. From the threshold hypothesis (Alderson, 1984), we know that before reaching a sufficient level of proficiency, L2 learners struggle mostly with the lexicon and the syntactic structures. This might explain why lexico-syntactic predictors were so predominant in our experiments. Some further experiments are thus needed to investigate which of these facts better ac-

count for our findings on the semantic features.

A last avenue of research worth mentioning would be to develop the family of specific-to-FFL predictors, to determine whether taking into account the impact of a given L1 language on the readability of L2 texts would increase performance over a generic model enough so that tuning efforts are worthwhile.

## Acknowledgments

Thomas François was an Aspirant F.N.R.S. when this work was performed. The writing of this paper was done while being a recipient of a Fellowship of the Belgian American Educational Foundation. We thank both for their support. We would also like to acknowledge the invaluable help of Bernadette Dethottay for the collection of the corpus used in that study.

## Abstract

We introduce *gap inheritance*, a new structural property on trees, which provides a way to quantify the degree to which intervals of descendants can be nested. Based on this property, two new classes of trees are derived that provide a closer approximation to the set of plausible natural language dependency trees than some alternative classes of trees: unlike projective trees, a word can have descendants in more than one interval; unlike spanning trees, these intervals cannot be nested in arbitrary ways. The *1-Inherit* class of trees has *exactly* the same empirical coverage of natural language sentences as the class of mildly non-projective trees, yet the optimal scoring tree can be found in an order of magnitude less time. *Gap-minding trees* (the second class) have the property that all edges into an interval of descendants come from the same node, and thus an algorithm which uses only single intervals can produce trees in which a node has descendants in multiple intervals.

## 1 Introduction

Dependency parsers vary in what *space of possible tree structures* they search over when parsing a sentence. One commonly used space is the set of *projective* trees, in which every node's descendants form a contiguous interval in the input sentence. Finding the optimal tree in the set of projective trees can be done efficiently (Eisner, 2000), even when the score of a tree depends on higher order factors (McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010). However, the projectivity assumption is too strict for all natural language dependency trees; for example, only 63.6% of Dutch

sentences from the CoNLL-X training set are projective (Table 1).

At the other end of the spectrum, some parsers search over all *spanning trees*, a class of structures much larger than the set of plausible linguistic structures. The maximum scoring directed spanning tree can be found efficiently when the score of a tree depends only on edge-based factors (McDonald et al., 2005b). However, it is NP-hard to extend MST to include sibling or grandparent factors (McDonald and Pereira, 2006; McDonald and Satta, 2007). MST-based non-projective parsers that use higher order factors (Martins et al., 2009; Koo et al., 2010), utilize different techniques than the basic MST algorithm. In addition, learning is done over a relaxation of the problem, so the inference procedures at training and at test time are not identical.
