### 3.1 Absolute pruning

Absolute pruning methods rely only on the statistics of a single phrase pair  $(\tilde{f}, \tilde{e})$ . Hence, they are independent of other phrases in the phrase table. As opposed to relative pruning methods (Section 3.2), they may prune all translations of a source phrase. Their application is easy and efficient.

- **Count-based pruning.** This method prunes a phrase pair  $(\tilde{f}, \tilde{e})$  if its observation count  $N(\tilde{f}, \tilde{e})$  is below a threshold  $\tau_c$ :

$$N(\tilde{f}, \tilde{e}) < \tau_c \quad (1)$$

- **Probability-based pruning.** This method prunes a phrase pair  $(\tilde{f}, \tilde{e})$  if its probability is below a threshold  $\tau_p$ :

$$p(\tilde{e}|\tilde{f}) < \tau_p \quad (2)$$

Here the probability  $p(\tilde{e}|\tilde{f})$  is estimated via relative frequencies.

### 3.2 Relative pruning

A potential problem with the absolute pruning methods is that it can prune all occurrences of a source phrase  $\tilde{f}$ .<sup>3</sup> Relative pruning methods avoid this by considering the full set of target phrases for a specific source phrase  $\tilde{f}$ .

- **Threshold pruning.** This method discards those phrases that are far worse than the best target phrase for a given source phrase  $\tilde{f}$ . Given a pruning threshold  $\tau_t$ , a phrase pair  $(\tilde{f}, \tilde{e})$  is discarded if:

$$p(\tilde{e}|\tilde{f}) < \tau_t \cdot \max_{\tilde{e}} \{p(\tilde{e}|\tilde{f})\} \quad (3)$$

- **Histogram pruning.** An alternative to threshold pruning is histogram pruning. For each source phrase  $\tilde{f}$ , this method preserves the  $K$  target phrases with highest probability  $p(\tilde{e}|\tilde{f})$  or, equivalently, their count  $N(\tilde{f}, \tilde{e})$ .

Note that, except for count-based pruning, none of the methods take the frequency of the source phrase into account. As we will confirm in the empirical evaluation, this will likely cause drops in translation quality, since frequent source phrases are more useful than the infrequent ones.

## 4 Significance Pruning

In this section, we briefly review significance pruning following Johnson et al. (2007). The idea of significance pruning is to test whether a source phrase  $\tilde{f}$  and a target phrase  $\tilde{e}$  co-occur more frequently in a bilingual corpus than they should just by chance. Using some simple statistics derived from the bilingual corpus, namely

- $N(\tilde{f})$  the count of the source phrase  $\tilde{f}$
- $N(\tilde{e})$  the count of the target phrase  $\tilde{e}$
- $N(\tilde{f}, \tilde{e})$  the co-occurrence count of the source phrase  $\tilde{f}$  and the target phrase  $\tilde{e}$
- $N$  the number of sentences in the bilingual corpus

<sup>3</sup>Note that it has never been systematically investigated whether this is a real problem or just speculation.

we can compute the two-by-two contingency table in Table 1.

Following Fisher’s exact test, we can calculate the probability of the contingency table via the hypergeometric distribution:

$$p_h(N(\tilde{f}, \tilde{e})) = \frac{\binom{N(\tilde{f})}{N(\tilde{f}, \tilde{e})} \cdot \binom{N-N(\tilde{f})}{N(\tilde{e})-N(\tilde{f}, \tilde{e})}}{\binom{N}{N(\tilde{e})}} \quad (4)$$

The  $p$ -value is then calculated as the sum of all probabilities that are at least as extreme. The lower the  $p$ -value, the less likely this phrase pair occurred with the observed frequency by chance; we thus prune a phrase pair  $(\tilde{f}, \tilde{e})$  if:

$$\left( \sum_{k=N(\tilde{f}, \tilde{e})}^{\infty} p_h(k) \right) > \tau_F \quad (5)$$

for some pruning threshold  $\tau_F$ . More details of this approach can be found in Johnson et al. (2007). The idea of using Fisher’s exact test was first explored by Moore (2004) in the context of word alignment.

## 5 Entropy-based Pruning

In this section, we will derive a novel entropy-based pruning criterion.

### 5.1 Motivational Example

In general, pruning the phrase table can be considered as selecting a subset of the original phrase table. When doing so, we would like to alter the original translation model distribution as little as possible. This is a key difference to previous approaches: Our goal is to remove *redundant* phrases, whereas previous approaches usually try to remove low-quality or unreliable phrases. We believe this to be an advantage of our method as it is certainly easier to measure the redundancy of phrases than it is to estimate their quality.

In Table 2, we show some example phrases from the learned French-English WMT phrase table, along with their counts and probabilities. For the French phrase *le gouvernement français*, we have, among others, two translations: *the French government* and *the government of France*. If we have to prune one of those translations, we can ask ourselves: how would the translation cost change if the

$N(\tilde{f}, \tilde{e})$	$N(\tilde{f}) - N(\tilde{f}, \tilde{e})$	$N(\tilde{f})$
$N(\tilde{e}) - N(\tilde{f}, \tilde{e})$	$N - N(\tilde{f}) - N(\tilde{e}) + N(\tilde{f}, \tilde{e})$	$N - N(\tilde{f})$
$N(\tilde{e})$	$N - N(\tilde{e})$	$N$

Table 1: Two-by-two contingency table for a phrase pair  $(\tilde{f}, \tilde{e})$ .

Source Phrase $\tilde{f}$	Target Phrase $\tilde{e}$	$N(\tilde{f}, \tilde{e})$	$p(\tilde{e} \tilde{f})$
le	the	7.6 M	0.7189
gouvernement	government	245 K	0.4106
français	French	51 K	0.6440
	of France	695	0.0046
le gouvernement français	the French government	148	0.1686
	the government of France	11	0.0128

Table 2: Example phrases from the French-English phrase table (K=thousands, M=millions).

same translation were generated from the remaining, shorter, phrases? Removing the phrase *the government of France* would increase this cost dramatically. Given the shorter phrases from the table, the probability would be  $0.7189 \cdot 0.4106 \cdot 0.0046 = 0.0014^*$ , which is about an order of a magnitude smaller than the original probability of 0.0128.

On the other hand, composing the phrase *the French government* out of shorter phrases has probability  $0.7189 \cdot 0.4106 \cdot 0.6440 = 0.1901$ , which is very close to the original probability of 0.1686. This means it is safe to discard the phrase *the French government*, since the translation cost remains essentially unchanged. By contrast, discarding the phrase *the government of France* does not have this effect: it leads to a large change in translation cost.

Note that here the pruning criterion only considers redundancy of the phrases, not the quality. Thus, we are not saying that *the government of France* is a better translation than *the French government*, only that it is less redundant.

\*We use the assumption that we can simply multiply the probabilities of the shorter phrases.

## 5.2 Entropy Criterion

Now, we are going to formalize the notion of redundancy. We would like the pruned model  $p'(\tilde{e}|\tilde{f})$  to be as similar as possible to the original model  $p(\tilde{e}|\tilde{f})$ . We use conditional Kullback-Leibler divergence, also called conditional relative entropy (Cover and Thomas, 2006), to measure the model similarity:

$$D(p(\tilde{e}|\tilde{f})||p'(\tilde{e}|\tilde{f})) = \sum_{\tilde{f}} p(\tilde{f}) \sum_{\tilde{e}} p(\tilde{e}|\tilde{f}) \log \left[ \frac{p(\tilde{e}|\tilde{f})}{p'(\tilde{e}|\tilde{f})} \right] \quad (6)$$

$$= \sum_{\tilde{f}, \tilde{e}} p(\tilde{e}, \tilde{f}) \left[ \log p(\tilde{e}|\tilde{f}) - \log p'(\tilde{e}|\tilde{f}) \right] \quad (7)$$

Computing the best pruned model of a given size would require optimizing over all subsets with that size. Since that is computationally infeasible, we instead apply the equivalent approximation that Stolcke (1998) uses for language modeling. This assumes that phrase pairs affect the relative entropy roughly independently.

We can then choose a pruning threshold  $\tau_E$  and prune those phrase pairs with a contribution to the relative entropy below that threshold. Thus, we

prune a phrase pair  $(\tilde{f}, \tilde{e})$ , if

$$p(\tilde{e}, \tilde{f}) \left[ \log p(\tilde{e}|\tilde{f}) - \log p'(\tilde{e}|\tilde{f}) \right] < \tau_E \quad (8)$$

We now address how to assign the probability  $p'(\tilde{e}|\tilde{f})$  under the pruned model. A phrase-based system selects among different segmentations of the source language sentence into phrases. If a segmentation into longer phrases does not exist, the system has to compose a translation out of shorter phrases. Thus, if a phrase pair  $(\tilde{f}, \tilde{e})$  is no longer available, the decoder has to use shorter phrases to produce the same translation. We can therefore decompose the pruned model score  $p'(\tilde{e}|\tilde{f})$  by summing over all segmentations  $s_1^K$  and all reorderings  $\pi_1^K$ :

$$p'(\tilde{e}|\tilde{f}) = \sum_{s_1^K, \pi_1^K} p(s_1^K, \pi_1^K | \tilde{f}) \cdot p(\tilde{e} | s_1^K, \pi_1^K, \tilde{f}) \quad (9)$$

Here the segmentation  $s_1^K$  divides both the source and target phrases into  $K$  sub-phrases:

$$\tilde{f} = \tilde{f}_{\pi_1} \dots \tilde{f}_{\pi_K} \text{ and } \tilde{e} = \tilde{e}_1 \dots \tilde{e}_K \quad (10)$$

The permutation  $\pi_1^K$  describes the alignment of those sub-phrases, such that the sub-phrase  $\tilde{e}_k$  is aligned to  $\tilde{f}_{\pi_k}$ . Using the normal phrase translation model, we obtain:

$$p'(\tilde{e}|\tilde{f}) = \sum_{s_1^K, \pi_1^K} p(s_1^K, \pi_1^K | \tilde{f}) \prod_{k=1}^K p(\tilde{e}_k | \tilde{f}_{\pi_k}) \quad (11)$$

Virtually all phrase-based decoders use the so-called maximum-approximation, i. e. the sum is replaced with the maximum. As we would like the pruning criterion to be similar to the search criterion used during decoding, we do the same and obtain:

$$p'(\tilde{e}|\tilde{f}) \approx \max_{s_1^K, \pi_1^K} \prod_{k=1}^K p(\tilde{e}_k | \tilde{f}_{\pi_k}) \quad (12)$$

Note that we also drop the segmentation probability, as this is not used at decoding time. This leaves the pruning criterion a function only of the model  $p(\tilde{e}|\tilde{f})$  as stored in the phrase table. There is no need for a special development or adaptation set. We can determine the best segmentation using dynamic programming, similar to decoding with a phrase-based

model. However, here the target side is constrained to the given phrase  $\tilde{e}$ .

It can happen that a phrase is not compositional, i. e., we cannot find a segmentation into shorter phrases. In these cases, we assign a small, constant probability:

$$p'(\tilde{e}|\tilde{f}) = p_c \quad (13)$$

We found that the value  $p_c = e^{-10}$  works well for many language pairs.

### 5.3 Computation

In our experiments, it was more efficient to vary the pruning threshold  $\tau_E$  without having to re-compute the entire phrase table. Therefore, we computed the entropy criterion in Equation (8) once for the whole phrase table. This introduces an approximation for the pruned model score  $p'(\tilde{e}|\tilde{f})$ . It might happen that we prune short phrases that were used as part of the best segmentation of longer phrases. As these shorter phrases should not be available, the pruned model score might be inaccurate. Although we believe this effect is minor, we leave a detailed experimental analysis for future work.

One way to avoid this approximation would be to perform entropy pruning with increasing phrase length. Starting with one-word phrases, which are trivially non-compositional, the entropy criterion would be straightforward to compute. Proceeding to two-word phrases, one would decompose the phrases into sub-phrases by looking up the probabilities of some of the unpruned one-word phrases. Once the set of unpruned two-word phrases was obtained, one would continue with three-word phrases, etc.

## 6 Experimental Evaluation

### 6.1 Data Sets

In this section, we describe the data sets used for the experiments. We perform experiments on the publicly available WMT shared translation task for the following four language pairs:

- German-English
- Czech-English
- Spanish-English

Language Pair	Number of Words	
	Foreign	English
German - English	42 M	45 M
Czech - English	56 M	65 M
Spanish - English	232 M	210 M
French - English	962 M	827 M

Table 3: Training data statistics. Number of words in the training data (M=millions).

- French-English

For each pair, we train two separate system, one for each direction. Thus it can happen that a phrase is pruned for X-to-Y, but not for Y-to-X.

These four language pairs represent a nice range of training corpora sizes, as shown in Table 3.

## 6.2 Baseline System

Pruning experiments were performed on top of the following baseline system. We used a phrase-based statistical machine translation system similar to (Zens et al., 2002; Koehn et al., 2003; Och and Ney, 2004; Zens and Ney, 2008). We trained a 4-gram language model on the target side of the bilingual corpora and a second 4-gram language model on the provided monolingual news data. All language models used Kneser-Ney smoothing.

The baseline system uses the common phrase translation models, such as  $p(\tilde{e}|\tilde{f})$  and  $p(\tilde{f}|\tilde{e})$ , lexical models, word and phrase penalty, distortion penalty as well as a lexicalized reordering model (Zens and Ney, 2006).

The word alignment was trained with six iterations of IBM model 1 (Brown et al., 1993) and 6 iterations of the HMM alignment model (Vogel et al., 1996) using a symmetric lexicon (Zens et al., 2004).

The feature weights were tuned on a development set by applying minimum error rate training (MERT) under the Bleu criterion (Och, 2003; Macherey et al., 2008). We ran MERT once with the full phrase table and then kept the feature weights fixed, i. e., we did *not* rerun MERT after pruning to avoid adding unnecessary noise. We extract phrases up to a length of six words. The baseline system already includes phrase table pruning by removing singletons and keeping up to 30 target language phrases per source phrase. We found that this does not affect transla-

Figure 1: Comparison of probability-based pruning methods for German-English.

tion quality significantly<sup>4</sup>. All pruning experiments are done on top of this.

## 6.3 Results

In this section, we present the experimental results. Translation results are reported on the WMT'07 news commentary blind set.

We will show translation quality measured with the Bleu score (Papineni et al., 2002) as a function of the phrase table size (number of phrases). Being in the upper left corner of these figures is desirable.

First, we show a comparison of several probability-based pruning methods in Figure 1. We compare

- **Prob.** Absolute pruning based on Eq. (2).
- **Thres.** Threshold pruning based on Eq. (3).
- **Hist.** Histogram pruning as described in Section 3.2.<sup>5</sup>

We observe that these three methods perform equally well. There is no difference between absolute and relative pruning methods, except that the two relative methods (Thres and Hist) are limited by

<sup>4</sup>The Bleu score drops are as follows: English-French 0.3%, French-English 0.4%, Czech-English 0.3%, all other are less than 0.1%.

<sup>5</sup>Instead of using  $p(\tilde{e}|\tilde{f})$  one could use the weighted model score including  $p(\tilde{f}|\tilde{e})$ , lexical weightings etc.; however, we found that this does not give significantly different results; but it does introduce a undesirable dependance between feature weights and phrase table pruning.

the number of source phrases. Thus, they reach a point where they cannot prune the phrase table any further. The results shown are for German-English; the results for the other languages are very similar. The results that follow use only the absolute pruning method as a representative for probability-based pruning.

In Figures 2 through 5, we show the translation quality as a function of the phrase table size. We vary the pruning thresholds to obtain different phrase table sizes. We compare four pruning methods:

- **Count.** Pruning based on the frequency of a phrase pair, c.f. Equation (1).
- **Prob.** Pruning based on the absolute probability of a phrase pair, c.f. Equation (2).
- **Fisher.** Pruning using significance tests, c.f. Equation (5).
- **Entropy.** Pruning using the novel entropy criterion, c.f. Equation (8).

Note that the x-axis of these figures is on a logarithmic scale, so the differences between the methods can be quite dramatic. For instance, entropy pruning requires less than a quarter of the number of phrases needed by count- or significance-based pruning to achieve a Spanish-English Bleu score of 34 (0.4 million phrases compared to 1.7 million phrases).

These results clearly show how the pruning methods compare:

1. Probability-based pruning performs poorly. It should be used only to prune small fractions of the phrase table.
2. Count-based pruning and significance-based pruning perform equally well. They are much better than probability-based pruning.
3. Entropy pruning consistently outperforms the other methods across translation directions and language pairs.

Figures 6 and 7 show compositionality statistics for the pruned Spanish-English phrase table (we observed similar results for the other language pairs).

Total number of phrases	4 137 M
Compositional	3 970 M
Non-compositional	167 M
of those: one-word phrases	85 M
no segmentation	82 M

Table 4: Statistics of phrase compositionality (M=millions).

Each figure shows the composition of the phrase table for a type of pruning for different phrase table sizes. Along the x-axis, we plotted the phrase table size. These are the same phrase tables used to obtain the Bleu scores in Figure 2 (left). The different shades of grey correspond to different phrase lengths. For instance, in case of the smallest phrase table for count-based pruning, the 1-word phrases account for about 30% of all phrases, the 2-word phrases account for about 35% of all phrases, etc.

With the exception of the probability-based pruning, the plots look comparable. The more aggressive the pruning, the larger the percentage of short phrases. We observe that entropy-based pruning removes many more long phrases than any of the other methods. The plot for probability-based pruning is different in that the percentage of long phrases actually increases with more aggressive pruning (i. e. smaller phrase tables). A possible explanation is that probability-based pruning does *not* take the frequency of the source phrase into account. This difference might explain the poor performance of probability-based pruning.

To analyze how many phrases are compositional, we collect statistics during the computation of the entropy criterion. These are shown in Table 4, accumulated across all language pairs and all phrases, i. e., including singleton phrases. We see that 96% of all phrases are compositional (3 970 million out of 4 137 million phrases). Furthermore, out of the 167 million non-compositional phrases, more than half (85 million phrases), are trivially non-compositional: they consist only of a single source or target language word. The number of non-trivial non-compositional phrases is, with 82 million or 2% of the total number of phrases, very small.

In Figure 8, we show the effect of the constant

Figure 2: Translation quality as a function of the phrase table size for Spanish-English (left) and English-Spanish (right).

Figure 3: Translation quality as a function of the phrase table size for French-English (left) and English-French (right).

Figure 4: Translation quality as a function of the phrase table size for Czech-English (left) and English-Czech (right).

Figure 5: Translation quality as a function of the phrase table size for German-English (left) and English-German (right).

Figure 6: Phrase length statistics for Spanish-English for probability-based (left) and count-based pruning (right).

Figure 7: Phrase length statistics for Spanish-English for significance-based (left) and entropy-based pruning (right).

$p_c$  for non-compositional phrases.<sup>6</sup> The results shown are for Spanish-English; additional experiments for the other languages and translation directions showed very similar results. Overall, there is no big difference between the values. Hence, we chose a value of 10 for all experiments.

The results in Figure 2 to Figure 5 show that entropy-based pruning clearly outperforms the alternative pruning methods. However, it is a bit hard to see from the graphs exactly how much additional savings it offers over other methods. In Table 5, we show how much of the phrase table we have to retain under various pruning criteria without losing more than one Bleu point in translation quality. We see that probability-based pruning allows only for marginal savings. Count-based and significance-based pruning results in larger savings between 70% and 90%, albeit with fairly high vari-

ability. Entropy-based pruning achieves consistently high savings between 85% and 95% of the phrase table. It always outperforms the other pruning methods and yields significant savings on top of count-based or significance-based pruning methods. Often, we can cut the required phrase table size in half compared to count or significance based pruning.

As a last experiment, we want to confirm that phrase-table pruning methods are actually better than simply reducing the maximum phrase length. In Figure 9, we show a comparison of different pruning methods and a length-based approach for Spanish-English. For the 'Length' curve, we first drop all 6-word phrases, then all 5-word phrases, etc. until we are left with only single-word phrases; the phrase length is measured as the number of source language words. We observe that entropy-based, count-based and significance-based pruning indeed outperform the length-based approach. We obtained similar results for the other languages.

<sup>6</sup>The values are in neg-log-space, i. e., a value of 10 corresponds to  $p_c = e^{-10}$ .

Method	ES-EN	EN-ES	DE-EN	EN-DE	FR-EN	EN-FR	CS-EN	EN-CS
Prob	77.3 %	82.7 %	61.2 %	67.3 %	84.8 %	94.1 %	85.6 %	86.3 %
Count	24.9 %	11.9 %	19.9 %	14.3 %	11.4 %	9.0 %	20.2 %	10.4 %
Fisher	23.5 %	12.6 %	21.7 %	14.0 %	14.5 %	13.6 %	31.9 %	9.9 %
Entropy	<b>7.2 %</b>	<b>6.0 %</b>	<b>10.2 %</b>	<b>11.1 %</b>	<b>7.1 %</b>	<b>8.1 %</b>	<b>14.8 %</b>	<b>6.4 %</b>

## 7 Conclusions

Phrase table pruning is often addressed in an ad-hoc way using the heuristics described in Section 3. We have shown that some of those do *not* work well. Choosing the wrong technique can result in significant drops in translation quality without saving much in terms of phrase table size. We introduced a novel entropy-based criterion and put phrase table pruning on a sound theoretical foundation. Furthermore, we performed a systematic experimental comparison of existing methods and the new entropy criterion. The experiments were carried out for four language pairs under small, medium and large data conditions. We can summarize our conclusions as follows:

- Probability-based pruning performs poorly when pruning large parts of the phrase table. This might be because it does not take the frequency of the source phrase into account.
- Count-based pruning performs as well as

significance-based pruning.

- Entropy-based pruning gives significantly larger savings in phrase table size than any other pruning method.
- Compared to previous work, the novel entropy-based pruning often achieves the same Bleu score with only half the number of phrases.

## 8 Future Work

Currently, we take only the model  $p(\tilde{e}|\tilde{f})$  into account when looking for the best segmentation. We might obtain a better estimate by also considering the distortion costs, which penalize reordering. We could also include other phrase models such as  $p(\tilde{f}|\tilde{e})$  and the language model.

The entropy pruning criterion could be applied to hierarchical machine translation systems (Chiang, 2007). Here, we might observe even larger reductions in phrase table size as there are many more entries.

# Probabilistic Finite State Machines for Regression-based MT Evaluation

Mengqiu Wang and Christopher D. Manning

{mengqiu,manning}@cs.stanford.edu

## Abstract

Accurate and robust metrics for automatic evaluation are key to the development of statistical machine translation (MT) systems. We first introduce a new regression model that uses a probabilistic finite state machine (pFSM) to compute weighted edit distance as predictions of translation quality. We also propose a novel pushdown automaton extension of the pFSM model for modeling word swapping and cross alignments that cannot be captured by standard edit distance models. Our models can easily incorporate a rich set of linguistic features, and automatically learn their weights, eliminating the need for ad-hoc parameter tuning. Our methods achieve state-of-the-art correlation with human judgments on two different prediction tasks across a diverse set of standard evaluations (NIST OpenMT06,08; WMT06-08).

## 1 Introduction

Research in automatic machine translation (MT) evaluation metrics has been a key driving force behind the recent advances of statistical machine translation (SMT) systems. The early seminal work on automatic MT metrics (e.g., BLEU and NIST) is largely based on  $n$ -gram matches (Papineni et al., 2002; Doddington, 2002). Despite their simplicity, these measures have shown good correlation with human judgments, and enabled large-scale evaluations across many different MT systems, without incurring the huge labor cost of human evaluation (Callison-Burch et al. (2009; 2010; 2011), *inter alia*). Recent studies have also confirmed that tuning MT systems against better MT metrics — using algorithms like

MERT (Och, 2003) — leads to better system performance (He and Way, 2009; Liu et al., 2011).

Later metrics that move beyond  $n$ -grams achieve higher accuracy and improved robustness from resources like WordNet synonyms (Miller et al., 1990), and paraphrasing (Snover et al., 2009; Denkowski and Lavie, 2010). But a common problem in these metrics is they typically resort to ad-hoc tuning methods instead of principled approaches to incorporate linguistic features. Recent models use linear or SVM regression and train them against human judgments to automatically learn feature weights, and have shown state-of-the-art correlation with human judgments (Kulesza and Shieber, 2004; Albrecht and Hwa, 2007a; Albrecht and Hwa, 2007b; Sun et al., 2008; Pado et al., 2009). The drawback, however, is they rely on time-consuming preprocessing modules to extract linguistic features (e.g., a full end-to-end textual entailment system was needed in Pado et al. (2009)), which severely limits their practical use. Furthermore, these models employ a large number of features (on the order of hundreds), and consequently make the model predictions opaque and hard to analyze.

In this paper, we propose a simple yet powerful probabilistic Finite State Machine (pFSM) for the task of MT evaluation. It is built on the backbone of weighted edit distance models, but learns to weight edit operations in a probabilistic regression framework. One of the major contributions of this paper is a novel extension of the pFSM model into a probabilistic Pushdown Automaton (pPDA), which enhances traditional edit-distance models with the ability to model phrase shift and word swapping. Furthermore, we give a new log-linear parameterization to the pFSM model, which allows it to easily incor-

porate rich linguistic features. We experiment with a set of simple features based on labeled head-modifier dependency structure, in order to test the hypothesis that modeling overall sentence structure can lead to more accurate evaluation measures.

We conducted extensive experiments on a diverse set of standard evaluation data sets (NIST OpenMT06, 08; WMT06, 07, 08). Our model achieves or surpasses state-of-the-art results on all test sets.

## 2 pFSMs for MT Regression

We start off by framing the problem of machine translation evaluation in terms of weighted edit distances calculated using probabilistic finite state machines (pFSMs). A FSM defines a language by accepting a string of input tokens in the language, and rejecting those that are not. A probabilistic FSM defines the probability that a string is in a language, extending on the concept of a FSM. Commonly used models such as HMMs,  $n$ -gram models, Markov Chains and probabilistic finite state transducers all fall in the broad family of pFSMs (Knight and Al-Onaizan, 1998; Eisner, 2002; Kumar and Byrne, 2003; Vidal et al., 2005). Unlike all the other applications of FSMs where tokens in the language are words, in our language tokens are edit operations. A string of tokens that our pFSM accepts is an edit sequence that transforms a reference translation (denoted as *ref*) into a system translation (*sys*).

Our pFSM has a unique start and stop state, and one state per edit operation (i.e., *Insert*, *Delete*, *Substitution*). The probability of an edit sequence  $\mathbf{e}$  is generated by the model is the product of the state transition probabilities in the pFSM, formally described as:

$$w(\mathbf{e} | \mathbf{s}, \mathbf{r}) = \frac{\prod_{k=1}^{|\mathbf{e}|} \exp \theta \cdot \mathbf{f}(e_{k-1}, e_k, \mathbf{s}, \mathbf{r})}{Z} \quad (1)$$

We featurize each of the state changes with a log-linear parameterization;  $\mathbf{f}$  is a set of binary feature functions defined over pairs of neighboring states (by the Markov assumption) and the input sentences, and  $\theta$  are the associated feature weights;  $r$  and  $s$  are shorthand for *ref* and *sys*;  $Z$  is a partition function. In this basic pFSM model, the feature functions are simply identity functions that emit the current state,

and the state transition sequence of the previous state and the current state.

The feature weights are then automatically learned by training a global regression model where some translational equivalence judgment score (e.g., human assessment score, or HTER (Snover et al., 2006)) for each *sys* and *ref* translation pair is the regression target ( $\hat{y}$ ). We introduce a new regression variable  $y \in \mathbb{R}$  which is the log-sum of the unnormalized weights (Eqn. (1)) of all edit sequences, formally expressed as:

$$y = \log \sum_{\mathbf{e}' \subseteq \mathbf{e}^*} \prod_{k=1}^{|\mathbf{e}'|} \exp \theta \cdot \mathbf{f}(e_{k-1}, e_k, \mathbf{s}, \mathbf{r}) \quad (2)$$

$\mathbf{e}^*$  denotes a valid edit sequence. Since the “gold” edit sequence are not given at training or prediction time, we treat the edit sequences as hidden variables and sum them out. The sum over an exponential number of edit sequences in  $\mathbf{e}^*$  is solved efficiently using a forward-backward style dynamic program. Any edit sequence that does not lead to a complete transformation of the translation pair has a probability of zero in our model. Our regression target then seeks to minimize the least squares error with respect to  $\hat{y}$ , plus a  $L2$ -norm regularizer term parameterized by  $\lambda$ :

$$\theta^* = \min_{\theta} \left\{ \sum_{\mathbf{s}_i, \mathbf{r}_i} [\hat{y}_i - (\frac{y_i}{|\mathbf{s}_i| + |\mathbf{r}_i|} + \alpha)]^2 + \lambda \|\theta\|^2 \right\} \quad (3)$$

The  $|\mathbf{s}_i| + |\mathbf{r}_i|$  is a length normalization term for the  $i$ th training instance, and  $\alpha$  is a scaling constant for adjusting to different scoring standards (e.g., 7-point scale vs. 5-point scale), whose value is automatically learned. At test time,  $y/(|\mathbf{s}| + |\mathbf{r}|) + \alpha$  is computed as the predicted score.

We replaced the standard substitution edit operation with three new operations:  $S_{word}$  for same word substitution,  $S_{lemma}$  for same lemma substitution, and  $S_{punc}$  for same punctuation substitution. In other words, all but the three matching-based substitutions are disallowed. The start state can transition into any of the edit states with a constant unit cost, and each edit state can transition into any other edit state if and only if the edit operation involved is valid at the current edit position (e.g., the model cannot transition into *Delete* state if it is already at the end of *ref*; similarly it cannot transition into  $S_{lemma}$  unless the

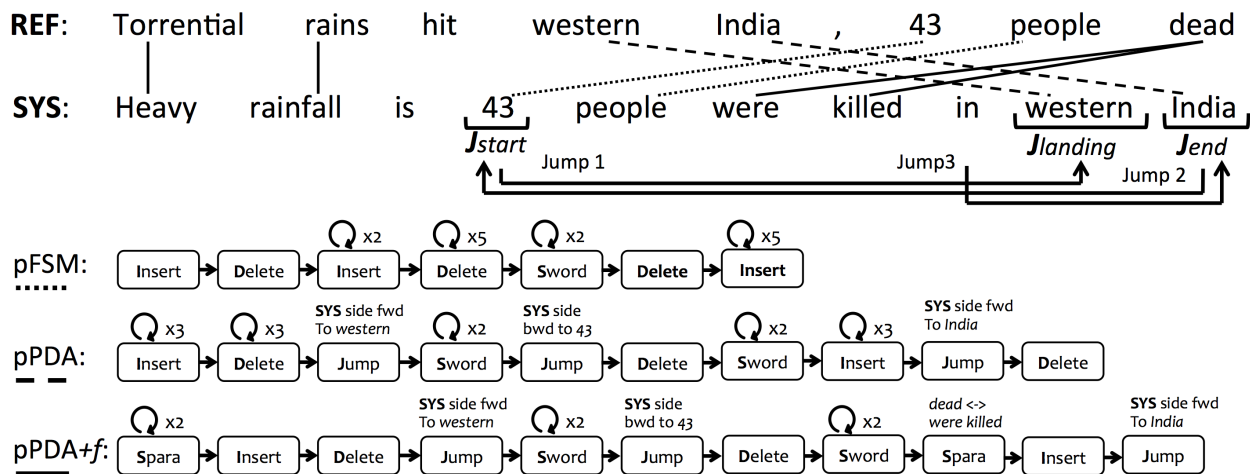

Figure 1: This diagram illustrates an example translation pair in the Chinese-English portion of OpenMT08 data set (Doc:AFP\_CMN\_20070703.0005, system09, sent 1). The three rows below are the best state transition sequences according to the three proposed models. The corresponding alignments generated by the models (pFSM, pPDA, pPDA+f) are shown with different styled lines, with later models in the order generating strictly more alignments than earlier ones. The gold human evaluation score is 6.5 (on a 7-point scale), and model predictions are: pPDA+f 5.5, pPDA 4.3, pFSM 3.1, METEORR 3.2, TERR 2.8.

lemma of the two words under edit in *sys* and *ref* match). When the end of both sentences are reached, the model transitions into the stop state and ends the edit sequence. The first row in Figure 1 starting with pFSM shows a state transition sequence for an example *sys/ref* translation pair.<sup>1</sup> There exists a one-to-one correspondence between substitution edits and word alignments. Therefore this example state transition sequence correctly generates an alignment for the word 43 and *people*.

It is helpful to compare with the TER metric (Snover et al., 2006), which is based on the idea of word error rate measured in terms of edit distance, to better understand the intuition behind our model. There are two major improvements in our model: 1) the edit operations in our model are weighted, as defined by the feature functions and weights; 2) the weights are automatically learned, instead of being uniform or manually set; and 3) we model state transitions, which can be understood as a bigram extension of the unigram edit distance model used in TER. For example, if in our learned model the feature for two consecutive  $S_{word}$  states has a positive weight, then our model would favor consecutive same word sub-

stitutions, whereas in the TER model the order of the substitution does not matter. The extended TER-plus (Snover et al., 2009) metric addresses the first problem but not the other two.

## 2.1 Soft-max Interpretation

There is also an alternative interpretation of the model as a simple soft-max approximation that is very intuitive and easy to understand. For ease of illustration, we introduce a quantity  $Q(\mathbf{e} | \mathbf{s}, \mathbf{r})$  to be the *score* of an edit sequence, defined simply as the sum of the dot product of feature values and feature weights:

$$Q(\mathbf{e} | \mathbf{s}, \mathbf{r}) = \sum_{i=1}^{|\mathbf{e}|} \theta \cdot \mathbf{f}(e_{i-1}, e_i, \mathbf{s}, \mathbf{r})$$

For the regression task, the intuition is that we want  $y$  to take on the score ( $Q$ ) of the **best** edit sequence:

$$y = \max_{\mathbf{e} \in \mathbf{e}^*} Q(\mathbf{e} | \mathbf{s}, \mathbf{r})$$

But since the *max* function is non-differentiable, we replace it with a *softmax*:

$$y = \log \underbrace{\sum_{\mathbf{e} \in \mathbf{e}^*} \exp Q(\mathbf{e} | \mathbf{s}, \mathbf{r})}_{\text{softmax}}$$

Substituting in  $Q$ , we arrive at the same objective function as (2).

<sup>1</sup>It is safe to ignore the second and third row in Figure 1 for now, their explanations are forthcoming in Section 2.2.

## 2.2 Restricted pPDA Extension

A shortcoming of edit distance models is that they cannot handle long-distance word swapping — a pervasive phenomenon found in most natural languages.<sup>2</sup> Edit operations in standard edit distance models need to obey strict incremental order in their edit position, in order to admit efficient dynamic programming solutions. The same limitation is shared by our pFSM model, where the Markov assumption is made based on the incremental order of edit positions. Although there is no known solution to the general problem of computing edit distance where long-distance swapping is permitted (Dombb et al., 2010), approximate algorithms do exist. We present a simple but novel extension of the pFSM model to a restricted probabilistic pushdown automaton (pPDA), to capture non-nested word swapping within limited distance, which covers a majority of word swapping in observed in real data (Wu, 2010).

A pPDA, in its simplest form, is a pFSM where each control state is equipped with a stack (Esparza and Kucera, 2005). The addition of stacks for each transition state endows the machine with memory, extending its expressiveness beyond that of context-free formalisms. By construction, at any stage in a normal edit sequence, the pPDA model can “jump” forward within a fixed distance (controlled by a max distance parameter) to a new edit position on either side of the sentence pair, and start a new edit subsequence from there. Assuming the jump was made on the *sys* side,<sup>3</sup> the machine remembers its current edit position in *sys* as  $J_{start}$ , and the destination position on *sys* after the jump as  $J_{landing}$ .

We constrain our model so that the only edit operations that are allowed immediately following a “jump” are from the set of substitution operations (e.g.,  $S_{word}$ ). And after at least one substitution has been made, the device can now “jump” back to  $J_{start}$ , remembering the current edit position as  $J_{end}$ . Another constraint here is that after the backward “jump”, all edit operations are permitted except for *Insert*, which cannot take place until at least one

<sup>2</sup>The edit distance algorithm described in Cormen et al. (2001) can only handle adjacent word swapping (transposition), but not long-distance swapping.

<sup>3</sup>Recall that we transform *ref* into *sys*, and thus on the *sys* side, we can only insert but not delete. The argument applies equally to the case where the jump was made on the other side.

substitution has been made. When the edit sequence advances to position  $J_{landing}$ , the only operation allowed at that point is another “jump” forward operation to position  $J_{end}$ , at which point we also clear all memory about jump positions and reset.

An intuitive explanation is that when pPDA makes the first forward jump, a gap is left in *sys* that has not been edited yet. It remembers where it left off, and comes back to it after some substitutions have been made to complete the edit sequence. The second row in Figure 1 (starting with pPDA) illustrates an edit sequence in a pPDA model that involves three “jump” operations, which are annotated and indexed by number 1-3 in the example. “Jump 1” creates an un-edited gap between word *43* and *western*, after two substitutions, the model makes “jump 2” to go back and edit the gap. The only edit permitted immediately after “jump 2” is deleting the comma in *ref*, since inserting the word *43* in *sys* before any substitution is disallowed. Once the gap is completed, the model resumes at position  $J_{end}$  by making “jump 3”, and completes the jump sequence. The “jumps” allowed the model to align words such as *western India*, in addition to the alignments of *43 people* found by the pFSM.

In a general pPDA model without the limited distance and non-nestedness jump constraints, there could be recursive jump structures, which violates the finite state property that we are looking for. The constraints we introduced upper-bounds possible reordering, and the resulting model is finite state. In practice, we found that our extension gives a big boost to model performance (cf. Section 4.1), with only a modest increase in computation time.<sup>4</sup>

## 2.3 Parameter Estimation

Since the least squares operator preserves convexity, and the inner log-sum-exponential function is convex, the resulting objective function is also convex. For parameter learning, we used the limited memory quasi-newton method (Liu and Nocedal, 1989) to find the optimal feature weights and scaling constant for the objective. We initialized  $\theta = \vec{0}$ ,  $\alpha = 0$ , and  $\lambda = 5$ . We also threw away features occurring fewer than five times in training corpus. Two variants of the

<sup>4</sup>The length of the longest edit sequence with jumps only increased by  $0.5 * \max(|s|, |r|)$  in the worst case, and on the whole swapping is rare in comparison to basic edits.

forward-backward style dynamic programming algorithm were used for computing gradients in the pFSM and pPDA models, similar to other sequence models such as HMMs and CRFs. Details are omitted here for brevity.

### 3 Rich Linguistic Features

In this section we will add new substitution operations beyond those introduced in Section 2, to capture various linguistic phenomena. These new substitution operations correspond to new transition states in the pPDA.

#### 3.1 Synonyms

Our first set of features matches words that have synonym relations according to WordNet (Miller et al., 1990). Synonyms have been found to be very useful in METEOR and TERplus, and can be easily built into our model as a new substitution operation  $S_{syn}$ .

#### 3.2 Paraphrasing

Newer versions of METEOR and TERplus both found that inclusion of phrase-based matching greatly improves model robustness and accuracy (Denkowski and Lavie, 2010; Snover et al., 2009). We add a substitution operator ( $S_{para}$ ) that matches words that are paraphrases. To better take advantage of paraphrase information at the multi-word phrase level, we extended our substitution operations to match longer phrases by adding one-to-many and many-to-many  $n$ -gram block substitutions. In preliminary experiments, we found that most of the gain came from unigrams and bigrams, with little to no additional gains from trigrams. Therefore, we limited our experiments to bigram pFSM and pPDA models, and pruned the paraphrase table adopted from TERplus<sup>5</sup> to unigrams and bigrams, resulting in 2.5 million paraphrase pairs.

#### 3.3 Sentence Structure

A problem that remains largely unaddressed by most popular MT evaluation metrics is the overall goodness of the translated sentence’s structure (Liu et al., 2005; Owczarzak et al., 2008). Translations with

<sup>5</sup>Available from [www.umiacs.umd.edu/~snover/terp](http://www.umiacs.umd.edu/~snover/terp).

good local  $n$ -gram coverage but horrible global syntactic ordering are not unusual in SMT outputs. Such translations usually score well with existing metrics but poorly among human evaluators.

In our model, when we detect consecutive bigram substitutions in the state transition, we examine the head-modifier dependency between the two words on each side of the sentence pair. A feature is triggered if and only if there is a head-modifier relation between the two words on each side, the labeled dependency on the two sides match, and it is one of subject, object or predicative relations. We deliberately left out features that model mismatches of dependency labels, because we found parsing output from translations to be usually very poor. Since parsing results are generally more reliable for more fluent translations, our hope is that by only modeling parse matches, our model will be able to pick them up as positive signals, indicating good translation quality.

### 4 Experiments

The goal of our experiments is to test both the accuracy and robustness of the proposed new models. We then show that modeling word swapping and rich linguistics features further improve our results.

To better situate our work among past research and to draw meaningful comparison, we use exactly the same standard evaluation data sets and metrics as Pado et al. (2009), which is currently the state-of-the-art result for regression-based MT evaluation. We consider four widely used MT metrics (BLEU, NIST, METEOR (v0.7), and TER) as our baselines. Since our models are trained to regress human evaluation scores, to make a direct comparison in the same regression setting, we also train a small linear regression model for each baseline metric in the same way as described in Pado et al. (2009). These regression models are strictly more powerful than the baseline metrics and show higher robustness and better correlation with human judgments.<sup>6</sup> We also compare our models with the state-of-the-art linear regression models reported in Pado et al. (2009) that

<sup>6</sup>The baseline metric (e.g., BLEU) computes its raw score by taking the geometric mean of  $n$ -gram precision scores ( $1 \leq n \leq 4$ ) scaled by a brevity penalty. The regression model learns to combine these fine-grained scores more intelligently, by optimizing their weights to regress human judgments. See Pado et al. (2009) for more discussion.

combine features from multiple MT evaluation metrics (MT), as well as rich linguistic features from a textual entailment system (RTE).

In all of our experiments, each reference and system translation sentence pair is tokenized using the Penn Treebank (Marcus et al., 1993) tokenization script, and lemmatized by the Porter Stemmer (Porter, 1980). For the overall sentence structure experiment, translations are additionally part-of-speech tagged with MXPOST tagger (Ratnaparkhi, 1996), and parsed with MSTParser (McDonald et al., 2005)<sup>7</sup> labeled dependency parser. Statistical significance tests are performed using the paired bootstrap resampling method (Koehn, 2004).

We divide our experiments into two sections, based on two different prediction tasks — predicting absolute scores and predicting pairwise preference.

#### 4.1 Exp. 1: Predicting Absolute Scores

The first task is to evaluate a system translation on a seven point Likert scale against a single reference. Higher scores indicate translations that are closer to the meaning intended by the reference. Human ratings in the form of absolute scores are available for standard evaluation data sets such as NIST OpenMT06,08.<sup>8</sup> Since our model makes predictions at the granularity of a whole sentence, we focus on sentence-level evaluation. A metric’s goodness is judged by how well it correlates with human judgments, and Spearman’s rank correlation ( $\rho$ ) is reported for all experiments in this section.

We used the NIST OpenMT06 corpus for development purposes, and reserved the NIST OpenMT08 corpus for post-development evaluation. The OpenMT06 data set contains 1,992 English translations of Arabic newswire text from 8 MT systems. For development, we used a 2-fold cross-validation scheme with splits at the first 1,000 and last 992 sentences. The OpenMT08 data set contains English translations of newswire text from three languages (Arabic has 2,769 pairs from 13 MT systems; Chinese has 1,815 pairs from 15; and Urdu has 1,519 pairs, from 7). We followed the same experimental setup as Pado et al. (2009), using a “round robin” training/testing scheme, i.e., we train a model on data

from two languages, making predictions for the third. We also show results of models trained on the entire OpenMT08 data set and tested on OpenMT06.

##### 4.1.1 pFSM vs. pPDA

Data Set		pFSM		pPDA			
<i>tr</i>	<i>te</i>	<i>n1</i>	<i>n2</i>	<i>j1</i>	<i>j2</i>	<i>j5</i>	<i>j10</i>
A+C	U	54.6	54.8	<b>55.6</b>	55.0	55.3	55.3
A+U	C	59.9	59.8	58.0	61.4	63.8	<b>64.0</b>
C+U	A	<b>61.2</b>	<b>61.2</b>	60.2	59.9	60.4	60.2

Table 1: pFSM vs. pPDA results for the round-robin approach on OpenMT08 data set over three languages (A=Arabic, C=Chinese, U=Urdu). Numbers in this table are Spearman’s  $\rho$  for correlation between human assessment scores and model predictions; *tr* stands for training set, and *te* stands for test set. *nx* means the model has *x*-gram block edits. *xy* means the model has jump distance limit *y*. The Best result for each test set row is highlighted in bold.

The second and third columns under the pFSM label in Table 1 compares our bigram block edit extension for the pFSM model. Although we do not yet see a significant performance gain (or loss) from adding block edits, they will enable longer paraphrase matches in later experiments.

Columns 5 through 8 in Table 1 show experimental results validating the contribution of our pPDA extension to the pFSM model (*cf.* Section 2.2). We can see that the pPDA extension gave modest improvements on the Urdu test set, but at a small decrease in performance on the Arabic data. However, for Chinese, there is a substantial gain, particularly with jump distances of five or longer. This trend is even more pronounced at the long jump distance of 10, consistent with the observation that Chinese-English translations exhibit much more medium and long distance reordering than languages like Arabic (Birch et al., 2009).

##### 4.1.2 Evaluating Linguistic Features

Experimental results evaluating the benefits of each linguistic feature set are presented in Table 3. The first row is the pPDA model with jump distance limit 5, without other additional features. The next three rows are the results of adding each of the three feature sets described in Section 3.

Overall, we observed that only paraphrase matching features gave a significant boost to performance.

<sup>7</sup>Trained on the entire Penn Treebank.

<sup>8</sup>Available from <http://www.nist.gov>.

Data Set		Our Metrics			Baseline Metrics				Combined Metrics		
train	test	pFSM	pPDA	pPDA+ <i>f</i>	BLEUR	NISTR	TERR	METR	MTR	RTER	MT+RTER
A+C	U	54.6	55.3	<b>57.2</b>	49.9	49.5	50.1	49.1	50.1	54.5	55.6
A+U	C	59.9	63.8	<b>65.8</b>	53.9	53.1	50.3	61.1	57.3	58.0	62.7
C+U	A	<b>61.2</b>	60.4	59.8	52.5	50.4	54.5	60.1	55.2	59.9	<b>61.1</b>
MT08	MT06	<b>65.2</b>	63.4	64.5	57.6	55.1	63.8	62.1	62.6	62.2	<b>65.2</b>

Table 2: Overall Comparison: Results from OpenMT08 and OpenMT06 evaluation data sets. The R (as in BLEUR) refers to the regression model trained for each baseline metric, same as Pado et al. (2009). The first three rows are round-robin train/test results over three languages on OpenMT08 (A=Arabic, C=Chinese, U=Urdu). The last row are results trained on entire OpenMT08 (A+C+U) and tested on OpenMT06. Numbers in this table are Spearman’s rank correlation  $\rho$  between human assessment scores and model predictions. The pPDA column describes our pPDA model with jump distance limit 5. METR is shorthand for METEORR. +*f* means the model includes synonyms, paraphrase and parsing features (*cf.* Section 3). Best results and scores that are not statistically significantly worse are highlighted in bold in each row.

	Urdu	Chinese	Arabic
pPDA	55.3	63.8	60.4
+Synonym	55.6	63.7	<b>60.7</b>
+Tree	55.3	63.8	60.3
+Paraphrase	57.1	65.4	60.0
+Syn+Tree+Para	<b>57.2</b>	<b>65.8</b>	59.8

Table 3: Results for OpenMT08 with linguistic features, using the same round robin scheme as in Table 1. Numbers in this table are Spearman’s rank correlation  $\rho$  between human assessment scores and model predictions. Best results on each test set are highlighted in bold.

The row starting with pPDA+*f* in Figure 1 shows an example where adding paraphrase features allow pPDA+*f* to find more correct alignments and make better predictions than pPDA.

No significant improvements from synonym and dependency tree matching features are evident from the results. An examination of the feature statistics in training data showed that the parse tree features have very low occurrence counts. On the Chinese+Urdu training set, for example, the features for subject, object and predicative labeled dependency matches fired only 55, 784 and 13 times, respectively. As a reference point for the scale of feature counts, the “same word” match feature fired 875,375 times on the same data set. And our qualitative assessment of the labeled dependency parser outputs was that the quality is very poor on system translations. For future work, more elaborate parse feature engineering could be a promising direction, but is outside the scope of our study.

In combination, the joint feature set of synonym,

paraphrase and parse tree features gave modest improvements over the paraphrase feature alone on the Chinese test set.

### 4.1.3 Overall Comparison

Results of our proposed models compared against the baseline models described in Pado et al. (2009) are shown in Table 2. The pPDA+*f* model has access to paraphrase information, which is not available to the baselines, so it should not be directly compared with. But the pFSM and pPDA models do not use any additional information other than words and lemmas, and thus make a fair comparison with the baseline metrics.<sup>9</sup> We can see from the table that pFSM significantly outperforms all baselines on Urdu and Arabic, but trails behind METEORR on Chinese by a small margin (1.2 point in Spearman’s  $\rho$ ). On Chinese data set, the pPDA extension gives results significantly better than the best baseline metrics for Chinese (2.7 better than METEORR). Both the pFSM and pPDA models also significantly outperform the MTR linear regression model that combines the outputs of all four baselines, on all three source languages. This demonstrates that our regression model is more robust and accurate than a state-of-the-art system combination linear-regression model. Both pFSM and pPDA learned to assign a lower negative feature weight for deletion than insertion (i.e., it is bad to insert an unseen word into system trans-

<sup>9</sup>METEORR actually has an unfair advantage in this comparison, since it uses synonym information from WordNet; TERR on the other hand has a disadvantage because it does not use lemmas. Lemma is added later in the TERplus extension (Snover et al., 2009).

lation, but worse if words from reference translation are deleted), which corresponds to the setting in METEOR where recall is given more importance than precision (Banerjee and Lavie, 2005).

The RTER and MT+RTER linear regression models benefit from the rich linguistic features in the textual entailment system’s output. It has access to all the features in pPDA+*f* such as paraphrase and dependency parse relations, and many more (e.g., Norm Bank, part-of-speech, negation, antonyms). However, our pPDA+*f* model rivals the performance of RTER and MT+RTER on Arabic (with no statistically significant difference from RTER), and greatly improve over these two models on Urdu and Chinese. Most noticeably, pPDA+*f* is 7.7 points better than RTER on Chinese.

Consistent with our earlier observation on OpenMT08 data set that the pPDA model performs slightly worse than the pFSM model on Arabic, the same performance decrease is seen in OpenMT06 data set, which is also Arabic-to-English.

As shown earlier in Table 3, the combined set of paraphrase, parsing and synonym features in pPDA+*f* helps for Urdu and Chinese, but not for Arabic. Here we found that even though the pPDA+*f* model is still worse than pFSM on OpenMT06 tests, it did give a decent improvement to pPDA model, closing up the gap with pFSM.

Other than robustness and accuracy, simplicity is also an important trait we seek in good MT metrics. Our models only have a few tens of features (instead of hundreds of features as found in RTER and MT+RTER), which makes interpretation of the model’s prediction relatively easy. On an important practical note, our model is much more lightweight than the RTER or MTR system. It runs at a much faster speed with a smaller memory footprint, hence potentially useable in MERT training.

## 4.2 Exp. 2: Predicting Pairwise Preferences

To further test our model’s robustness, we evaluate it on WMT data sets with a different prediction task in which metrics make pairwise preference judgments between translation systems. The WMT06-08 data sets are much larger in comparison to the OpenMT06 and 08 data. They contain MT outputs of over 40 systems from five different source languages (French, German, Spanish, Czech, and Hungarian).

The WMT06, 07 and 08 sets contains 10,159, 5,472 and 6,856 sentence pairs, respectively. We used portions of WMT 06 and 07 data sets<sup>10</sup> that are annotated with absolute scores on a five point scale for training, and the WMT08 data set annotated with pairwise preference for testing.

To generate pairwise preference predictions, we first predict an absolute score for each system translation, then compare the scores between each system pair, and give preference to the higher score. We adopt the sentence-level evaluation metric used in Pado et al. (2009), which measures the consistency (accuracy) of metric predictions with human preferences. The random baseline for this task on WMT08 data set is 39.8%.<sup>11</sup>

Models	WMT06	WMT07	WMT06+07
pPDA+ <i>f</i>	51.6	<b>52.4</b>	52.0
BLEUR	49.7	49.5	49.6
METEORR	51.4	51.4	51.5
NISTR	50.0	50.3	50.2
TERR	50.9	51.0	51.2
MTR	50.8	51.5	51.5
RTER	51.8	50.7	51.9
MT+RTER	<b>52.3</b>	51.8	<b>52.5</b>

Table 4: Pairwise preference prediction results on WMT08 test set. Each column shows a different training data set. Numbers in this table are model’s consistency with human pairwise preference judgments. Best result on each test set is highlighted in bold.

Results are shown in Table 4. Similar to the results on OpenMT experiments, our model consistently outperformed BLEUR, METEORR, NISTR and TERR. Our model also gives better performance than the MTR ensemble model on all three tests; and ties with RTER in two out of the three tests but performs significantly better on the other test. The MT+RTER ensemble model is better on two tests, but worse on the other. But overall the two systems are quite comparable, with less than 0.6% accuracy difference. The results also show that our method is stable across different training sets, with test accuracy differences less than 0.4%.

<sup>10</sup>Available from <http://www.statmt.org>.

<sup>11</sup>The random baseline is not 50% for two reasons: (1) human judgments include contradictory and tie annotations; (2) transitivity constraints need to be respected in total ordering. For details, see Pado et al. (2009).

### 4.3 Qualitative Analysis

Example (1) shows a system and reference translation pair in the Chinese test portion of OpenMT08.

(1) **REF:** Two Jordanese sentenced<sub>1</sub> for plotting<sub>2</sub>  
an attack<sub>3</sub> on Americans<sub>4</sub>

**SYS:** The name of Jordan plotting<sub>2</sub> attacks<sub>3</sub>  
Americans<sub>4</sub> were sentenced<sub>1</sub> to death

Human annotators give this example a score of 4.0, but TERR and METEORR both assigned erroneously low scores (1.0 and 2.2, respectively). Words with the same subscript index were aligned by pPDA model. This example exhibits a word swapping phenomenon, and our model was able to capture it correctly. TERR clearly suffered from not being able to model word swapping in this case. It also missed out the word pair *attack* and *attacks* due to the lack of lemma support. The reason why METEORR assigned such a low score for this example is because none of the matched words in the reference were adjacent to each other, causing a high fragmentation penalty. The fragmentation penalty term has two parameters that need to be manually tuned, and has a high variance across examples and data sets. This example illustrates models that require ad-hoc tuning tend not to be robust. Our pPDA model (without linguistic feature) was able to make a prediction of 3.7, much closer to human judgment.

### 4.4 MetricsMATR10 and WMT12 Results

An earlier version of the pFSM model that was trained on the OpenMT08 data set was submitted to the single reference sentence level track at MetricsMATR10 (Peterson and Przybocki, 2010) NIST evaluation. Even though our system was not in the most ideal state at the time of the evaluation,<sup>12</sup> and was trained on a small amount of data, the pFSM model still performed competitively against other metrics. Noticeably, we achieved second best results for Human-targeted Translation Edit Rate (HTER) assessment, trailing behind TERplus with no statistically significant difference. On average, our system made 5th place among 15 different sites and 7th place among 25 different metrics, averaged across 9 assessment types.

<sup>12</sup>Unfortunately the version we submitted in 2010 was plagued with a critical bug. More general enhancements have been made to the model since.

We submitted the version of the pPDA+*f* model trained on the WMT07 dataset to the “into English” segment-level track of the WMT 2012 Shared Evaluation Metrics Task (Callison-Burch et al., 2012). Our model achieved the highest score (measured by Kendall’s tau correlation) on all four language pairs (Fr-En, De-En, Es-En and Cs-En), and tied for the first place with METEOR v1.3 on average correlation.

## 5 Related Work

### Features and Representation

One of the findings in our experimentation is that paraphrasing helps boosting model accuracy, and the idea of using paraphrases in MT evaluation was first proposed by Zhou et al. (2006). Several recent studies have introduced metrics over dependency parses (Liu et al., 2005; Owczarzak et al., 2008; He et al., 2010), but their improvements over *n*-gram models at the sentence level are not always consistent (Liu et al., 2005; Peterson and Przybocki, 2010). Other than string-based methods, recent work has explored more alternative representations for MT evaluation, such as network properties (Amancio et al., 2011), semantic role structures (Lo and Wu, 2011), and the quality of word order (Birch and Osborne, 2011).

### Modeling

The idea of using extended edit distance models with block movements was also explored in Leusch et al. (2003). However, their model is largely empirical and not in a probabilistic learning setting. The line of work on probabilistic tree-edit distance models bears a strong connection to this work (McCallum et al., 2005; Bernard et al., 2008; Wang and Manning, 2010; Emms, 2012). In particular, our pFSM model and the log-linear parameterization were inspired by Wang and Manning (2010). Another body of literature that is closely related to this work is FSM models for word alignment (Vogel et al., 1996; Saers et al., 2010; Berg-Kirkpatrick et al., 2010). The stochastic Inversion Transduction Grammar in Saers et al. (2010) for instance, is a pFSM with special constraints. More recently, Saers and Wu (2011) further explored the connection between Linear Transduction Grammars and FSMs. There is a close tie

between our pFSM model and the HMM model in Berg-Kirkpatrick et al. (2010). Both models adopted a log-linear parameterization for the state transition distribution,<sup>13</sup> but in their case the HMM model and the pFSM arc weights are normalized locally, and the objective is non-convex.

## 6 Conclusion

We described a probabilistic finite state machine based on string edits and a novel pushdown automaton extension for the task of machine translation evaluation. The models admit a rich set of linguistic features, and are trained to learn feature weights automatically by optimizing a regression objective. The proposed models achieve state-of-the-art results on a wide range of standard evaluations, and are much more lightweight than previous regression models, making them suitable candidates to be used in MERT training.

# An Empirical Investigation of Statistical Significance in NLP

Taylor Berg-Kirkpatrick    David Burkett    Dan Klein  
Computer Science Division  
University of California at Berkeley  
{tberg, dburkett, klein}@cs.berkeley.edu

## Abstract

We investigate two aspects of the empirical behavior of paired significance tests for NLP systems. First, when one system appears to outperform another, how does significance level relate in practice to the magnitude of the gain, to the size of the test set, to the similarity of the systems, and so on? Is it true that for each task there is a gain which roughly implies significance? We explore these issues across a range of NLP tasks using both large collections of past systems' outputs and variants of single systems. Next, once significance levels are computed, how well does the standard i.i.d. notion of significance hold up in practical settings where future distributions are neither independent nor identically distributed, such as across domains? We explore this question using a range of test set variations for constituency parsing.

## 1 Introduction

It is, or at least should be, nearly universal that NLP evaluations include statistical significance tests to validate metric gains. As important as significance testing is, relatively few papers have empirically investigated its practical properties. Those that do focus on single tasks (Koehn, 2004; Zhang et al., 2004) or on the comparison of alternative hypothesis tests (Gillick and Cox, 1989; Yeh, 2000; Bisani and Ney, 2004; Riezler and Maxwell, 2005).

In this paper, we investigate two aspects of the empirical behavior of paired significance tests for NLP systems. For example, all else equal, larger metric gains will tend to be more significant. However, what does this relationship look like and how reliable is it? What should be made of the conventional wisdom that often springs up that a certain metric gain is roughly the point of significance for a given task (e.g. 0.4 F1 in parsing or 0.5 BLEU

in machine translation)? We show that, with heavy caveats, there are such thresholds, though we also discuss the hazards in their use. In particular, many other factors contribute to the significance level, and we investigate several of them. For example, what is the effect of the similarity between the two systems? Here, we show that more similar systems tend to achieve significance with smaller metric gains, reflecting the fact that their outputs are more correlated. What about the size of the test set? For example, in designing a shared task it is important to know how large the test set must be in order for significance tests to be sensitive to small gains in the performance metric. Here, we show that test size plays the largest role in determining discrimination ability, but that we get diminishing returns. For example, doubling the test size will not obviate the need for significance testing.

In order for our results to be meaningful, we must have access to the outputs of many of NLP systems. Public competitions, such as the well-known CoNLL shared tasks, provide one natural way to obtain a variety of system outputs on the same test set. However, for most NLP tasks, obtaining outputs from a large variety of systems is not feasible. Thus, in the course of our investigations, we propose a very simple method for automatically generating arbitrary numbers of comparable system outputs and we then validate the trends revealed by our synthetic method against data from public competitions. This methodology itself could be of value in, for example, the design of new shared tasks.

Finally, we consider a related and perhaps even more important question that can only be answered empirically: to what extent is statistical significance on a test corpus predictive of performance on other test corpora, in-domain or otherwise? Focusing on constituency parsing, we investigate the relationship between significance levels and actual performance

on data from outside the test set. We show that when the test set is (artificially) drawn i.i.d. from the same distribution that generates new data, then significance levels are remarkably well-calibrated. However, as the domain of the new data diverges from that of the test set, the predictive ability of significance level drops off dramatically.

## 2 Statistical Significance Testing in NLP

First, we review notation and standard practice in significance testing to set up our empirical investigation.

### 2.1 Hypothesis Tests

When comparing a new system  $A$  to a baseline system  $B$ , we want to know if  $A$  is better than  $B$  on some large population of data. Imagine that we sample a small test set  $x = x_1, \dots, x_n$  on which  $A$  beats  $B$  by  $\delta(x)$ . Hypothesis testing guards against the case where  $A$ 's victory over  $B$  was an unlikely event, due merely to chance. We would therefore like to know how likely it would be that a new, independent test set  $x'$  would show a similar victory for  $A$  assuming that  $A$  is no better than  $B$  on the population as a whole; this assumption is the null hypothesis, denoted  $H_0$ .

Hypothesis testing consists of attempting to estimate this likelihood, written  $p(\delta(X) > \delta(x)|H_0)$ , where  $X$  is a random variable over possible test sets of size  $n$  that we could have drawn, and  $\delta(x)$  is a constant, the metric gain we actually observed. Traditionally, if  $p(\delta(X) > \delta(x)|H_0) < 0.05$ , we say that the observed value of  $\delta(x)$  is sufficiently unlikely that we should reject  $H_0$  (i.e. accept that  $A$ 's victory was real and not just a random fluke). We refer to  $p(\delta(X) > \delta(x)|H_0)$  as  $\text{p-value}(x)$ .

In most cases  $\text{p-value}(x)$  is not easily computable and must be approximated. The type of approximation depends on the particular hypothesis testing method. Various methods have been used in the NLP community (Gillick and Cox, 1989; Yeh, 2000; Riezler and Maxwell, 2005). We use the paired bootstrap<sup>1</sup> (Efron and Tibshirani, 1993) because it is one

<sup>1</sup>Riezler and Maxwell (2005) argue the benefits of approximate randomization testing, introduced by Noreen (1989). However, this method is ill-suited to the type of hypothesis we are testing. Our null hypothesis does not condition on the test data, and therefore the bootstrap is a better choice.

Estimate <math>\text{p-value}(x) \approx \frac{s}{b}</math>.</li> </ol> |
|--|

Figure 1: The bootstrap procedure. In all of our experiments we use  $b = 10^6$ , which is more than sufficient for the bootstrap estimate of  $\text{p-value}(x)$  to stabilize.

of the most widely used (Och, 2003; Bisani and Ney, 2004; Zhang et al., 2004; Koehn, 2004), and because it can be easily applied to any performance metric, even complex metrics like F1-measure or BLEU (Papineni et al., 2002). Note that we could perform the experiments described in this paper using another method, such as the paired Student's t-test. To the extent that the assumptions of the t-test are met, it is likely that the results would be very similar to those we present here.

### 2.2 The Bootstrap

The bootstrap estimates  $\text{p-value}(x)$  through a combination of simulation and approximation, drawing many simulated test sets  $x^{(i)}$  and counting how often  $A$  sees an accidental advantage of  $\delta(x)$  or greater. How can we get sample test sets  $x^{(i)}$ ? We lack the ability to actually draw new test sets from the underlying population because all we have is our data  $x$ . The bootstrap therefore draws each  $x^{(i)}$  from  $x$  itself, sampling  $n$  items from  $x$  with replacement; these new test sets are called *bootstrap samples*.

Naively, it might seem like we would then check how often  $A$  beats  $B$  by more than  $\delta(x)$  on  $x^{(i)}$ . However, there's something seriously wrong with these  $x^{(i)}$  as far as the null hypothesis is concerned: the  $x^{(i)}$  were sampled from  $x$ , and so their average  $\delta(x^{(i)})$  won't be zero like the null hypothesis demands; the average will instead be around  $\delta(x)$ . If we ask how many of these  $x^{(i)}$  have  $A$  winning by  $\delta(x)$ , about half of them will. The solution is a re-centering of the mean – we want to know how often  $A$  does *more than*  $\delta(x)$  better than expected. We expect it to beat  $B$  by  $\delta(x)$ . Therefore, we count up how many of the  $x^{(i)}$  have  $A$  beating  $B$  by at least  $2\delta(x)$ .<sup>2</sup> The pseudocode is shown in Figure 1.

<sup>2</sup>Note that many authors have used a variant where the event tallied on the  $x^{(i)}$  is whether  $\delta(x^{(i)}) < 0$ , rather than  $\delta(x^{(i)}) > 2\delta(x)$ . If the mean of  $\delta(x^{(i)})$  is  $\delta(x)$ , and if the distribution of  $\delta(x^{(i)})$  is symmetric, then these two versions will be equivalent.

As mentioned, a major benefit of the bootstrap is that any evaluation metric can be used to compute  $\delta(x)$ .<sup>3</sup> We run the bootstrap using several metrics: F1-measure for constituency parsing, unlabeled dependency accuracy for dependency parsing, alignment error rate (AER) for word alignment, ROUGE score (Lin, 2004) for summarization, and BLEU score for machine translation.<sup>4</sup> We report all metrics as percentages.

### 3 Experiments

Our first goal is to explore the relationship between metric gain,  $\delta(x)$ , and statistical significance,  $p\text{-value}(x)$ , for a range of NLP tasks. In order to say anything meaningful, we will need to see both  $\delta(x)$  and  $p\text{-value}(x)$  for many pairs of systems.

#### 3.1 Natural Comparisons

Ideally, for a given task and test set we could obtain outputs from all systems that have been evaluated in published work. For each pair of these systems we could run a comparison and compute both  $\delta(x)$  and  $p\text{-value}(x)$ . While obtaining such data is not generally feasible, for several tasks there are public competitions to which systems are submitted by many researchers. Some of these competitions make system outputs publicly available. We obtained system outputs from the TAC 2008 workshop on automatic summarization (Dang and Owczarzak, 2008), the CoNLL 2007 shared task on dependency parsing (Nivre et al., 2007), and the WMT 2010 workshop on machine translation (Callison-Burch et al., 2010).

For cases where the metric linearly decomposes over sentences, the mean of  $\delta(x^{(i)})$  is  $\delta(x)$ . By the central limit theorem, the distribution will be symmetric for large test sets; for small test sets it may not.

<sup>3</sup>Note that the bootstrap procedure given only approximates the true significance level, with multiple sources of approximation error. One is the error introduced from using a finite number of bootstrap samples. Another comes from the assumption that the bootstrap samples reflect the underlying population distribution. A third is the assumption that the mean bootstrap gain is the test gain (which could be further corrected for if the metric is sufficiently ill-behaved).

<sup>4</sup>To save time, we can compute  $\delta(x)$  for each bootstrap sample without having to rerun the evaluation metric. For our metrics, sufficient statistics can be recorded for each sentence and then sampled along with the sentences when constructing each  $x^{(i)}$  (e.g. size of gold, size of guess, and number correct are sufficient for F1). This makes the bootstrap very fast in practice.

Figure 2: **TAC 2008 Summarization:** Confidence vs. ROUGE improvement on TAC 2008 test set for comparisons between all pairs of the 58 participating systems at TAC 2008. Comparisons between systems entered by the same research group and comparisons between systems entered by different research groups are shown separately.

#### 3.1.1 TAC 2008 Summarization

In our first experiment, we use the outputs of the 58 systems that participated in the TAC 2008 workshop on automatic summarization. For each possible pairing, we compute  $\delta(x)$  and  $p\text{-value}(x)$  on the non-update portion of the TAC 2008 test set (we order each pair so that the gain,  $\delta(x)$ , is always positive).<sup>5</sup> For this task, test instances correspond to document collections. The test set consists of 48 document collections, each with a human produced summary. Figure 2 plots the ROUGE gain against  $1 - p\text{-value}$ , which we refer to as *confidence*. Each point on the graph corresponds to an individual pair of systems.

As expected, larger gains in ROUGE correspond to higher confidences. The curved shape of the plot is interesting. It suggests that relatively quickly we reach ROUGE gains for which, in practice, significance tests will most likely be positive. We might expect that systems whose outputs are highly correlated will achieve higher confidence at lower metric gains. To test this hypothesis, in Figure 2 we

<sup>5</sup>In order to run bootstraps between all pairs of systems quickly, we reuse a random sample counts matrix between bootstrap runs. As a result, we no longer need to perform quadratically many corpus resamplings. The speed-up from this approach is enormous, but one undesirable effect is that the bootstrap estimation noise between different runs is correlated. As a remedy, we set  $b$  so large that the correlated noise is not visible in plots.

Figure 3: **CoNLL 2007 Dependency parsing:** Confidence vs. unlabeled dependency accuracy improvement on the Chinese CoNLL 2007 test set for comparisons between all pairs of the 21 participating systems in CoNLL 2007 shared task. Comparisons between systems entered by the same research group and comparisons between systems entered by different research groups are shown separately.

separately show the comparisons between systems entered by the same research group and comparisons between systems entered by different research groups, with the expectation that systems entered by the same group are likely to have more correlated outputs. Many of the comparisons between systems submitted by the same group are offset from the main curve. It appears that they do achieve higher confidences at lower metric gains.

Given the huge number of system comparisons in Figure 2, one obvious question to ask is whether we can take the results of all these statistical significance tests and estimate a ROUGE improvement threshold that predicts when future statistical significance tests will probably be significant at the  $p\text{-value}(x) < 0.05$  level. For example, let's say we take all the comparisons with  $p\text{-value}$  between 0.04 and 0.06 (47 comparisons in all in this case). Each of these comparisons has an associated metric gain, and by taking, say, the 95th percentile of these metric gains, we get a potentially useful threshold. In this case, the computed threshold is 1.10 ROUGE.

What does this threshold mean? Well, based on the way we computed it, it suggests that if somebody reports a ROUGE increase of around 1.10 *on the exact same test set*, there is a pretty good chance that a statistical significance test would show significance at the  $p\text{-value}(x) < 0.05$  level. After all, 95% of

the borderline significant differences that we've already seen showed an increase of even less than 1.10 ROUGE. If we're evaluating past work, or are in some other setting where system outputs just aren't available, the threshold could guide our interpretation of reports containing only summary scores.

That being said, it is important that we don't over-interpret the meaning of the 1.10 ROUGE threshold. We have already seen that pairs of systems submitted by the same research group and by different research groups follow different trends, and we will soon see more evidence demonstrating the importance of system correlation in determining the relationship between metric gain and confidence. Additionally, in Section 4, we will see that properties of the test corpus have a large effect on the trend. There are many factors at work, and so, of course, metric gain alone will not fully determine the outcome of a paired significance test.

### 3.1.2 CoNLL 2007 Dependency Parsing

Next, we run an experiment for dependency parsing. We use the outputs of the 21 systems that participated in the CoNLL 2007 shared task on dependency parsing. In Figure 3, we plot, for all pairs, the gain in unlabeled dependency accuracy against confidence on the CoNLL 2007 Chinese test set, which consists of 690 sentences and parses. We again separate comparisons between systems submitted by the same research group and those submitted by different groups, although for this task there were fewer cases of multiple submission. The results resemble the plot for summarization; we again see a curve-shaped trend, and comparisons between systems from the same group (few that they are) achieve higher confidences at lower metric gains.

### 3.1.3 WMT 2010 Machine Translation

Our final task for which system outputs are publicly available is machine translation. We run an experiment using the outputs of the 31 systems participating in WMT 2010 on the system combination portion of the German-English WMT 2010 news test set, which consists of 2,034 German sentences and English translations. We again run comparisons for pairs of participating systems. We plot gain in test BLEU score against confidence in Figure 4. In this experiment there is an additional class of compar-

Figure 4: **WMT 2010 Machine translation:** Confidence vs. BLEU improvement on the system combination portion of the German-English WMT 2010 news test set for comparisons between pairs of the 31 participating systems at WMT 2010. Comparisons between systems entered by the same research group, comparisons between systems entered by different research groups, and comparisons between system combination entries are shown separately.

isons that are likely to have specially correlated systems: 13 of the submitted systems are system combinations, and each take into account the same set of proposed translations. We separate comparisons into three sets: comparisons between non-combined systems entered by different research groups, comparisons between non-combined systems entered by the same research group, and comparisons between system-combinations.

We see the same curve-shaped trend we saw for summarization and dependency parsing. Different group comparisons, same group comparisons, and system combination comparisons form distinct curves. This indicates, again, that comparisons between systems that are expected to be specially correlated achieve high confidence at lower metric gain levels.

## 3.2 Synthetic Comparisons

So far, we have seen a clear empirical effect, but, because of the limited availability of system outputs, we have only considered a few tasks. We now propose a simple method that captures the shape of the effect, and use it to extend our analysis.

### 3.2.1 Training Set Resampling

Another way of obtaining many different systems' outputs is to obtain implementations of a

handful of systems, and then vary some aspect of the training procedure in order to produce many different systems from each implementation. Koehn (2004) uses this sort of amplification; he uses a single machine translation implementation, and then trains it from different source languages. We take a slightly different approach. For each task we pick some fixed training set. Then we generate resampled training sets by sampling sentences with replacement from the original. In this way, we can generate as many new training sets as we like, each of which is similar to the original, but with some variation. For each base implementation, we train a new system on each resampled training set. This results in slightly tweaked trained systems, and is intended to very roughly approximate the variance introduced by incremental system changes during research. We validate this method by comparing plots obtained by the synthetic approach with plots obtained from natural comparisons.

We expect that each new system will be different, but that systems originating from the same base model will be highly correlated. This provides a useful division of comparisons: those between systems built with the same model, and those between systems built with different models. The first class can be used to approximate comparisons of systems that are expected to be specially correlated, and the latter for comparisons of systems that are not.

### 3.2.2 Dependency Parsing

We use three base models for dependency parsing: MST parser (McDonald et al., 2005), Maltparser (Nivre et al., 2006), and the ensemble parser of Surdeanu and Manning (2010). We use the CoNLL 2007 Chinese training set, which consists of 57K sentences. We resample 5 training sets of 57K sentences, 10 training sets of 28K sentences, and 10 training sets of 14K sentences. Together, this yields a total of 75 system outputs on the CoNLL 2007 Chinese test set, 25 systems for each base model type. The score ranges of all the base models overlap. This ensures that for each pair of model types we will be able to see comparisons where the metric gains are small. The results of the pairwise comparisons of all 75 system outputs are shown in Figure 5, along with the results of the CoNLL 2007 shared task system comparisons from Figure 3.

Figure 5: **Dependency parsing:** Confidence vs. unlabeled dependency accuracy improvement on the Chinese CoNLL 2007 test set for comparisons between all pairs of systems generated by using resampled training sets to train either MST parser, Maltparser, or the ensemble parser. Comparisons between systems generated using the same base model type and comparisons between systems generated using different base model types are shown separately. The CoNLL 2007 shared task comparisons from Figure 3 are also shown.

The overlay of the natural comparisons suggests that the synthetic approach reasonably models the relationship between metric gain and confidence. Additionally, the different model type and same model type comparisons exhibit the behavior we would expect, matching the curves corresponding to comparisons between specially correlated systems and standard comparisons respectively.

Since our synthetic approach yields a large number of system outputs, we can use the procedure described in Section 3.1.1 to compute the threshold above which the metric gain is probably significant. For comparisons between systems of the same model type, the threshold is 1.20 unlabeled dependency accuracy. For comparisons between systems of different model types, the threshold is 1.51 unlabeled dependency accuracy. These results indicate that the similarity of the systems being compared is an important factor. As mentioned, rules-of-thumb derived from such thresholds cannot be applied blindly, but, in special cases where two systems are known to be correlated, the former threshold should be preferred over the latter. For example, during development most comparisons are made between incremental variants of the same system. If adding a feature to a supervised parser increases un-

Figure 6: **Machine translation:** Confidence vs. BLEU improvement on the system combination portion of the German-English WMT 2010 news test set for comparisons between all pairs of systems generated by using resampled training sets to train either Moses or Joshua. Comparisons between systems generated using the same base model type and comparisons between systems generated using different base model types are shown separately. The WMT 2010 workshop comparisons from Figure 4 are also shown.

labeled accuracy by 1.3, it is useful to be able to quickly estimate that the improvement is probably significant. This still isn't the full story; we will soon see that properties of the test set also play a major role. But first, we carry our analysis to several more tasks.

### 3.2.3 Machine Translation

Our two base models for machine translation are Moses (Koehn et al., 2007) and Joshua (Li et al., 2009). We use 1.4M sentence pairs from the German-English portion of the WMT-provided Europarl (Koehn, 2005) and news commentary corpora as the original training set. We resample 75 training sets, 20 of 1.4M sentence pairs, 29 of 350K sentence pairs, and 26 of 88K sentence pairs. This yields a total of 150 system outputs on the system combination portion of the German-English WMT 2010 news test set. The results of the pairwise comparisons of all 150 system outputs are shown in Figure 6, along with the results of the WMT 2010 workshop system comparisons from Figure 4.

The natural comparisons from the WMT 2010 workshop align well with the comparisons between synthetically varied models. Again, the different model type and same model type comparisons form distinct curves. For comparisons between systems

Figure 7: **Word alignment:** Confidence vs. AER improvement on the Hansard test set for comparisons between all pairs of systems generated by using resampled training sets to train either the ITG aligner, the joint HMM aligner, or GIZA++. Comparisons between systems generated using the same base model type and comparisons between systems generated using different base model types are shown separately.

of the same model type the computed p-value  $< 0.05$  threshold is 0.28 BLEU. For comparisons between systems of different model types the threshold is 0.37 BLEU.

### 3.2.4 Word Alignment

Now that we have validated our simple model of system variation on two tasks, we go on to generate plots for tasks that do not have competitions with publicly available system outputs. The first task is English-French word alignment, where we use three base models: the ITG aligner of Haghighi et al. (2009), the joint HMM aligner of Liang et al. (2006), and GIZA++ (Och and Ney, 2003). The last two aligners are unsupervised, while the first is supervised. We train the unsupervised word aligners using the 1.1M sentence pair Hansard training corpus, resampling 20 training sets of the same size.<sup>6</sup> Following Haghighi et al. (2009), we train the supervised ITG aligner using the first 337 sentence pairs of the hand-aligned Hansard test set; again, we resample 20 training sets of the same size as the original data. We test on the remaining 100 hand-aligned sentence pairs from the Hansard test set.

Unlike previous plots, the points corresponding to comparisons between systems with different base

<sup>6</sup>GIZA++ failed to produce reasonable output when trained with some of these training sets, so there are fewer than 20 GIZA++ systems in our comparisons.

Figure 8: **Constituency parsing:** Confidence vs. F1 improvement on section 23 of the WSJ corpus for comparisons between all pairs of systems generated by using resampled training sets to train either the Berkeley parser, the Stanford parser, or the Collins parser. Comparisons between systems generated using the same base model type and comparisons between systems generated using different base model types are shown separately.

model types form two distinct curves. It turns out that the upper curve consists only of comparisons between ITG and HMM aligners. This is likely due to the fact that the ITG aligner uses posteriors from the HMM aligner for some of its features, so the two models are particularly correlated. Overall, the spread of this plot is larger than previous ones. This may be due to the small size of the test set, or possibly some additional variance introduced by unsupervised training. For comparisons between systems of the same model type the p-value  $< 0.05$  threshold is 0.50 AER. For comparisons between systems of different model types the threshold is 1.12 AER.

### 3.2.5 Constituency Parsing

Finally, before we move on to further types of analysis, we run an experiment for the task of constituency parsing. We use three base models: the Berkeley parser (Petrov et al., 2006), the Stanford parser (Klein and Manning, 2003), and Dan Bikel’s implementation (Bikel, 2004) of the Collins parser (Collins, 1999). We use sections 2-21 of the WSJ corpus (Marcus et al., 1993), which consists of 38K sentences and parses, as a training set. We resample 10 training sets of size 38K, 10 of size 19K, and 10 of size 9K, and use these to train systems. We test on section 23. The results are shown in Figure 8.

For comparisons between systems of the same

model type, the  $p$ -value  $< 0.05$  threshold is 0.47 F1. For comparisons between systems of different model types the threshold is 0.57 F1.

## 4 Properties of the Test Corpus

For five tasks, we have seen a trend relating metric gain and confidence, and we have seen that the level of correlation between the systems being compared affects the location of the curve. Next, we look at how the size and domain of the test set play a role, and, finally, how significance level predicts performance on held out data. In this section, we carry out experiments for both machine translation and constituency parsing, but mainly focus on the latter because of the availability of large test corpora that span more than one domain: the Brown corpus and the held out portions of the WSJ corpus.

### 4.1 Varying the Size

Figure 9 plots comparisons for machine translation on variously sized initial segments of the WMT 2010 news test set. Similarly, Figure 10 plots comparisons for constituency parsing on initial segments of the Brown corpus. As might be expected, the size of the test corpus has a large effect. For both machine translation and constituency parsing, the larger the corpus size, the lower the threshold for  $p$ -value  $< 0.05$  and the smaller the spread of the plot. At one extreme, the entire Brown corpus, which consists of approximately 24K sentences, has a threshold of 0.22 F1, while at the other extreme, the first 100 sentences of the Brown corpus have a threshold of 3.00 F1. Notice that we see diminishing returns as we increase the size of the test set. This phenomenon follows the general shape of the central limit theorem, which predicts that variances of observed metric gains will shrink according to the square root of the test size. Even using the entire Brown corpus as a test set there is a small range where the result of a paired significance test was not completely determined by metric gain.

It is interesting to note that for a fixed test size, the domain has only a small effect on the shape of the curve. Figure 11 plots comparisons for a fixed test size, but with various test corpora.

Figure 9: **Machine translation; varying test size:** Confidence vs. BLEU improvement on portions of the German-English WMT 2010 news test set.

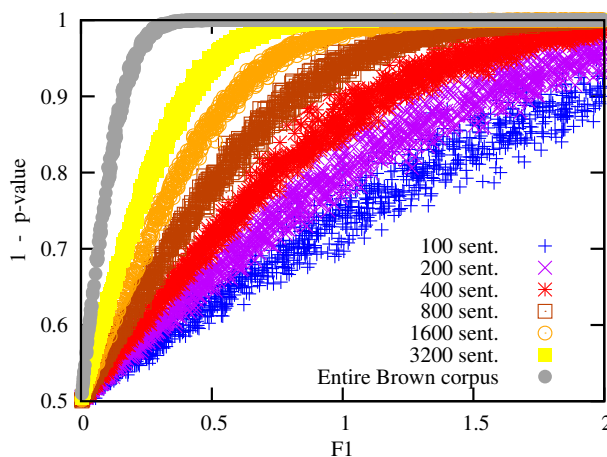

Figure 10: **Constituency parsing; varying test size:** Confidence vs. F1 improvement on portions of the Brown corpus.

Figure 11: **Constituency parsing; varying domain:** Confidence vs. F1 improvement on the first 1,600 sentences of sections 22, 23, and 24 of the WSJ corpus, and the Brown corpus.

## 4.2 Empirical Calibration across Domains

Now that we have a way of generating outputs for thousands of pairs of systems, we can check empirically the practical reliability of significance testing. Recall that the bootstrap p-value( $x$ ) is an approximation to  $p(\delta(X) > \delta(x)|H_0)$ . However, we often really want to determine the probability that the new system is better than the baseline on the underlying test distribution or even the distribution from another domain. There is no reason a priori to expect these numbers to coincide.

In our next experiment, we treat the entire Brown corpus, which consists of 24K sentences, as the true population of English sentences. For each system generated in the way described in Section 3.2.5 we compute F1 on *all* of Brown. Since we are treating the Brown corpus as the actual population of English sentences, for each pair of parsers we can say that the sign of the F1 difference indicates which is the truly better system. Now, we repeatedly resample small test sets from Brown, each consisting of 1,600 sentences, drawn by sampling sentences with replacement. For each pair of systems, and for each resampled test set, we compute p-value( $x$ ) using the bootstrap. Out of the 4K bootstraps computed in this way, 942 had p-value between 0.04 and 0.06, 869 of which agreed with the sign of the F1 difference we saw on the entire Brown corpus. Thus, 92% of the significance tests with p-value in a tight range around 0.05 correctly identified the better system.

This result is encouraging. It suggests that statistical significance computed using the bootstrap is reasonably well calibrated. However, test sets are almost never drawn i.i.d. from the distribution of instances the system will encounter in practical use. Thus, we also wish to compute how calibration degrades as the domain of the test set changes. In another experiment, we look at how significance near p-value = 0.05 on section 23 of the WSJ corpus predicts performance on sections 22 and 24 and the Brown corpus. This time, for each pair of generated systems we run a bootstrap on section 23. Out of all these bootstraps, 58 system pairs had p-value between 0.04 and 0.06. Of these, only 83% had the same sign of F1 difference on section 23 as they did on section 22, 71% the had the same sign on section 23 as on section 24, and 48% the same sign on

Sec. 23 p-value	% Sys. A > Sys. B		
	Sec. 22	Sec. 24	Brown
0.00125 - 0.0025	97%	95%	73%
0.0025 - 0.005	92%	92%	60%
0.005 - 0.01	92%	85%	56%
0.01 - 0.02	88%	92%	54%
0.02 - 0.04	87%	78%	51%
0.04 - 0.08	83%	74%	48%

Table 1: **Empirical calibration:** p-value on section 23 of the WSJ corpus vs. fraction of comparisons where system A beats system B on section 22, section 24, and the Brown corpus. Note that system pairs are ordered so that A always outperforms B on section 23.

section 23 as on the Brown corpus. This indicates that reliability degrades as we switch the domain. In the extreme, achieving a p-value near 0.05 on section 23 provides no information about performance on the Brown corpus.

If we intend to use our system on out-of-domain data, these results are somewhat discouraging. How low does p-value( $x$ ) have to get before we start getting good information about out-of-domain performance? We try to answer this question for this particular parsing task by running the same domain calibration experiment for several different ranges of p-value. The results are shown in Table 1. From these results, it appears that for constituency parsing, when testing on section 23, a p-value level below 0.00125 is required to reasonably predict performance on the Brown corpus.

It should be considered a good practice to include statistical significance testing results with empirical evaluations. The bootstrap in particular is easy to run and makes relatively few assumptions about the task or evaluation metric. However, we have demonstrated some limitations of statistical significance testing for NLP. In particular, while statistical significance is usually a minimum necessary condition to demonstrate that a performance difference is real, it's also important to consider the relationship between test set performance and the actual goals of the systems being tested, especially if the system will eventually be used on data from a different domain than the test set used for evaluation.

## 5 Conclusion

We have demonstrated trends relating several important factors to significance level, which include

both properties of the systems being compared and properties of the test corpus, and have presented a simple approach to approximating the response of these factors for tasks where large numbers of system outputs are not available. Our results reveal that the relationship between metric gain and statistical significance is complex, and therefore simple thresholds are not a replacement for significance tests. Indeed, we strongly advocate the use of statistical significance testing to validate metric gains in NLP, but also note that informal rules-of-thumb do arise in popular discussion and that, for some settings when previous systems are unavailable, these empirical results can supplement less sensitive unpaired tests (e.g. bar-overlaps-point test) in evaluation of progress. Finally, even formal testing has its limits. We provide cautionary evidence to this effect, showing that the information provided by a test quickly degrades as the target corpus shifts domain.

# Employing Compositional Semantics and Discourse Consistency in Chinese Event Extraction

Peifeng Li, Guodong Zhou, Qiaoming Zhu, Libin Hou

School of Computer Science & Technology  
Soochow University, Suzhou, 215006, China  
{pfli, gdzhou, qmzhu, 20094227021}@suda.edu.cn

## Abstract

Current Chinese event extraction systems suffer much from two problems in trigger identification: unknown triggers and word segmentation errors to known triggers. To resolve these problems, this paper proposes two novel inference mechanisms to explore special characteristics in Chinese via compositional semantics inside Chinese triggers and discourse consistency between Chinese trigger mentions. Evaluation on the ACE 2005 Chinese corpus justifies the effectiveness of our approach over a strong baseline.

## 1 Introduction

Event extraction, a classic information extraction task, is to identify instances of a predefined event type and can be typically divided into four subtasks: trigger identification, trigger type determination, argument identification and argument role determination. In the literature, most studies focus on English event extraction and have achieved certain success (e.g. Grishman et al., 2005; Ahn, 2006; Hardy et al., 2006; Maslennikov and Chua, 2007; Finkel et al., 2005; Ji and Grishman, 2008; Patwardhan and Riloff, 2009, 2011; Liao and Grishman 2010; Hong et al., 2011).

In comparison, there are few successful stories regarding Chinese event extraction due to special characteristics in Chinese trigger identification. In particular, there are two major reasons for the low performance: unknown triggers<sup>1</sup> and word segmentation errors to known triggers. Table 1 gives the statistics of unknown triggers and word segmentation errors to known triggers in both the

ACE 2005 Chinese and English corpora<sup>2</sup> using 10-fold cross-validation. In each validation, we leave 10% trigger mentions as the test set and the remaining ones as the training set. If a mention in the test set doesn't occurred in the training set, we regard it as an unknown trigger. It shows that these two cases cover almost 30% of Chinese trigger mentions while this figure reduces to only about 9% in English. It also shows that given the same number of event mentions, there are 30% more different triggers in Chinese than that in English. This justifies the low performance (specifically, the recall) of a Chinese event extraction system, which normally extracts those known triggers occurring in the training data as candidate instances and uses a classifier to distinguish correct triggers from wrong ones.

Language	Chinese	English
% unknown triggers	33.7%	18.5%
% unknown trigger mentions	20.9%	8.9%
% word segmentation errors to known trigger mentions	8.7%	0%
#triggers	763	586

Table 1. Statistics: a comparison between Chinese and English event extraction with regard to unknown triggers and word segmentation errors to known triggers. Note that word segmentation only applies to Chinese.

In this paper, we propose two novel inference mechanisms to Chinese trigger identification by employing compositional semantics inside Chinese triggers and discourse consistency between Chinese trigger mentions.

The first mechanism is motivated by the compositional nature of Chinese words, whose semantics can be often determined by the component characters. Hence, it is natural to infer

<sup>1</sup> In this paper, a trigger word/phrase occurring in the training data is called a known trigger and otherwise, an unknown trigger.

<sup>2</sup> The whole Chinese ACE corpus has about 3300 event mentions. For the sake of fair comparison, we choose the same number of event mentions from the English corpus as the cross-validation data.

unknown triggers by employing compositional semantics inside Chinese triggers.

The second mechanism is enlightened by the wide use of discourse consistency in natural languages, particularly for Chinese, due to its discourse-driven nature (Zhu, 1980). Very often, distinguishing true trigger mentions from pseudo ones is only possible with contextual information.

The rest of this paper is organized as follows. Section 2 overviews the related work. Section 3 introduces a state-of-the-art baseline system for Chinese event extraction. Sections 4 and 5 describe two novel inference mechanisms to Chinese trigger identification by employing compositional semantics inside Chinese triggers and discourse consistency between Chinese trigger mentions. Section 6 presents the experimental results. Section 7 concludes the paper and points out future work.

## 2 Related Work

Almost all the existing studies on event extraction concern English. While earlier studies focus on sentence-level extraction (Grishman et al., 2005; Ahn, 2006; Hardy et al., 2006), later ones turn to employ high-level information, such as document (Maslennikov and Chua, 2007; Finkel et al., 2005; Patwardhan and Riloff, 2009), cross-document (Ji and Grishman, 2008), cross-event (Liao and Grishman, 2010; Gupta and Ji, 2009) and cross-entity (Hong et al., 2011) information.

### 2.1 Chinese Event Extraction

Compared with tremendous efforts in English event extraction, there are only a few studies on Chinese event extraction.

Tan et al. (2008) modeled event extraction as a pipeline of classification tasks. Specially, they used a local feature selection approach to ensure the performance of trigger classification (trigger identification + trigger type determination) and applied multiple levels of patterns to improve the coverage of patterns in argument classification (argument identification + argument role determination). Chen and Ji (2009a) proposed a bootstrapping framework, which exploited extra information captured by an English event extraction system. Chen and Ji (2009b) applied various kinds of lexical, syntactic and semantic features to address the specific issues in Chinese. They also constructed a global errata table to

record the inconsistency in the training set and used it to correct the inconsistency in the test set. Ji (2009) extracted cross-lingual predicate clusters using bilingual parallel corpora and a cross-lingual information extraction system, and then used the derived clusters to improve the performance of Chinese event extraction.

### 2.2 Compositional Semantics

Almost all the related studies on compositional semantics focus on how to combine words together to convey complex meanings, such as semantic parser (Zettlemoyer and Collins, 2007; Wong and Mooney, 2007; Liang et al., 2011). However, the compositional semantics mentioned in this paper is more fined-grained and focuses on how to construct Chinese characters into a word and mine the semantics of words from the word structures, especially of verbs as event triggers.

To our knowledge, there is only one paper associated with compositional semantics inside Chinese words. Li (2011) discussed the internal structures inside Chinese nouns and used it in word segmentation.

### 2.3 Discourse Consistency

Discourse consistency is an important hypothesis in natural languages and has been applied to many natural language processing applications, such as named entity recognition and coreference resolution. Specially, several studies have successfully incorporated trigger or entity consistency constraint into event extraction.

Yarowsky (1995) and Yangarber et al. (Yangarber and Jokipii, 2005; Yangarber et al., 2007) applied cross-document inference to refine local extraction results for disease name, location and start/end time. Mann (2007) proposed some specific inference rules to improve extraction of personal information. Ji and Grishman (2008) employed a rule-based approach to propagate consistent triggers and arguments across topic-related documents. Gupta and Ji (2009) used a similar approach to recover implicit time information for events. Liao and Grishman (2011) also used a similar approach and a self-training strategy to extract events. Liao and Grishman (2010) employed cross-event consistency information to improve sentence-level event extraction. Hong et al. (2011) regarded entity type

consistency as a key feature to predict event mentions and adopted this inference method to improve the traditional event extraction system.

### 3 Baseline

As a baseline, we re-implement a state-of-the-art system, which consists of four typical components (trigger identification, trigger type determination, argument identification and argument role determination), in a pipeline way and employ the same set of features as described in Chen and Ji (2009b).

Besides, the Maximum-Entropy (ME) model is employed to train individual component classifiers for the above four components. During testing, each word in the test set is first scanned for instances of known triggers from the training set. When an instance is found, the trigger identifier is applied to distinguish true trigger mentions from pseudo ones. If true, the trigger type determiner is then applied to recognize its event type. For any entity mentions in the sentence, the argument identifier is employed to assign possible arguments to them afterwards. Finally, the argument role determiner is introduced to assign a role to each argument.

One problem with Chen and Ji's system is its ignoring effective long-distance features. In order to resolve this problem and provide a stronger baseline, we introduce more refined and dependency features in four components:

- **Trigger Identification and Trigger Type Determination:** 1) syntactic features: path to the root of the governing clause, 2) nearest entity information: entity type of left syntactically/physically nearest entity to the trigger + entity, entity type of right syntactically/physically nearest entity to the trigger mention in the sentence + entity; 3) dependency features: the subject and the object of the trigger when they are entities.
- **Argument Identification and Argument Role Determination:** 1) basic features: POS of trigger; 2) neighboring words: left neighboring word of the entity + its POS, right neighbor word of the entity + its POS, left neighbor word of the trigger + its POS, right neighbor word of the trigger + its POS; 3) dependency feature: dependency path from the entity to the trigger; 4) semantic role features: Arg0 and Arg1 which

tagged by semantic role labeling tool (Li, et al., 2010).

### 3.1 Experimental Setting

The ACE 2005 Chinese corpus (only the training data is available) is used in all our experiments. The corpus contains 633 Chinese documents annotated with 8 predefined event types and 33 predefined subtypes. Similar to previous studies, we treat these subtypes simply as 33 separate event types and do not consider the hierarchical structure among them.

Following Chen and Ji (2009b), we randomly select 567 documents as the training set and the remaining 66 documents as the test set. Besides, we reserve 33 documents in the training set as the development set, and follow the setting of ACE diagnostic tasks and use the ground truth entities, times and values for our training and testing.

For evaluation, we follow the standards as defined in Ji (2009):

- A trigger is *correctly* identified if its position in the document matches a reference trigger;
- A trigger type is *correctly* determined if its event type and position in the document match a reference trigger;
- An argument is *correctly* identified if its involved event type and position in the document match any of the reference argument mentions;
- An argument role is *correctly* determined if its involved event type, position in the document, and role match any of the reference argument mentions.

Finally, all sentences in the corpus are divided into words using a word segmentation tool ICTCLAS<sup>3</sup> with all entities annotated in the corpus kept. Besides, we use Stanford Parser (Levy and Manning, 2003, Chang, et al., 2009) to create the constituent and dependency parse trees and employ the ME model to train individual component classifiers.

### 3.2 Experimental Results

Table 2 and 3 show the Precision (P), Recall (R) and F1-Measure (F) on the held-out test set. It shows that our baseline system outperforms Chen and Ji (2009b) by 1.8, 2.2, 3.9 and 2.3 in F1-measure on trigger identification, trigger type

---

<sup>3</sup> <http://ictclas.org/>

determination, argument identification and argument role determination, respectively, with both gains in precision and recall. This is simply due to contribution of the newly-added refined and dependency features.

Performance \ System	Trigger Identification			Trigger Type Determination		
	P(%)	R(%)	F	P(%)	R(%)	F
Chen and Ji (2009b)	71.5	51.2	59.7	66.5	47.7	55.6
Our Baseline	75.2	52.0	61.5	70.3	49.0	57.8

Table 2. Performance of trigger identification and trigger type determination

Performance \ System	Argument Identification			Argument Role Determination		
	P(%)	R(%)	F	P(%)	R(%)	F
Chen and Ji (2009b)	56.1	38.2	45.4	53.1	36.2	43.1
Our Baseline	58.4	42.7	49.3	55.2	38.6	45.4

Table 3. Performance of argument identification and argument role determination

For our baseline system, given the small performance gaps between trigger identification and trigger type determination (3.7 in F1-measure: 61.5 vs. 57.8) and between argument identification and argument role determination (3.9 in F1-measure: 49.3 vs. 45.4), the performance bottlenecks of our baseline system mainly exist in trigger identification and argument identification, particularly for the former one. While argument identification has the performance gap of 8.5 in F1-measure compared to trigger type determination (49.3 vs. 57.8), the former one, trigger identification, can only achieve the performance of 61.5 in F1-measure (in particular the recall with only 52.0). In this paper, we will focus on trigger identification to improve its performance, particularly for the recall, via compositional semantics inside Chinese triggers and discourse consistency between Chinese trigger mentions.

#### 4 Employing Compositional Semantics inside Chinese Triggers

Language is perhaps the only communicative system in nature, which compositionally builds structured meanings from smaller pieces, and this compositionality is the cognitive mechanism that

allows for what Humboldt called language’s “infinite use of finite means.” As usual, the lexical semantics is the smallest piece in most Chinese language processing applications. In this section, we introduce a more fine-grained semantics - the compositional semantics in Chinese verb structure - and unveil its effect and usage in Chinese language processing by employing it into Chinese event extraction.

#### 4.1 Compositional Semantics inside Chinese Triggers

In English, a component character is just the basic unit to form a word instead of a semantics unit. In comparison, almost all Chinese characters have their own meanings and can be formed as SCWs (Single Character Words) themselves. If a Chinese word contains more than one character, its meaning can be often inferred from the meanings of its component characters (Yuan, 1998). Actually, it is the normal way of understanding a new Chinese word in everyday life of a Chinese native speaker. A general method to this problem is to systematically explore the morphological structures in Chinese words. In this paper, compositional semantics provides a simple but effective compromise to the general method and we leave the general method in the future work. Table 4 shows samples of such compositional semantics in Chinese words. For example, “会见” is composed of two characters: “会” and “见” which have their own semantics and the semantics of “会见” comes from that of its component characters “会” and “见”.

Words	Characters
会见 (interview <sup>4</sup> )	会 (meet) 见 (meet)
击毙 (shoot and kill)	击 (shoot) 毙 (kill)
来到 (come)	来 (come) 到 (to)
私信 (private letter)	私 (private) 信 (letter)

Table 4. Examples of compositional semantics in Chinese words

Therefore, it is natural to infer unknown triggers by employing compositional semantics inside Chinese triggers. Take following two sentences as examples:

- (1) 4 名学生被玻璃划伤。(Known trigger)

<sup>4</sup> Most Chinese words have more than one sense. Here, we just give the one when it acts as a trigger.

(Four students were scratched by the glass.)

(2) 1名乘客被刺伤。(Unknown trigger)

(A passenger was stabbed.)

where “划伤” is a known trigger and “刺伤” is an unknown one.

In above examples, the semantics of “划伤” (injure by scratching) can be largely determined from those of its component characters “划” (scratch) and “伤” (injure) while the semantics of “刺伤” (injure by stabbing) from those of its component characters “刺” (stab) and “伤” (injure). Since these two triggers have similar internal structures, we can easily infer that “刺伤” is a trigger of *injure* event if “划伤” is known as a trigger of *injure* event. Similarly, we can infer more triggers for *injure* event, such as “灼伤” (injure by burning), “撞伤” (injure by hitting), “压伤” (injure by pressing), all with component character “伤” (injure) as the head and the other component character as the way of causing injury.

Since most triggers in Chinese event extraction are verbs<sup>5</sup>, we focus on the compositional semantics in the verb structure. Statistics on the training set shows that 3.3% triggers (e.g. “公开信” (open letter), “事件” (event), “病情” (patient's condition), etc.) don't contain a BV and all of them are nouns. Normally, almost all verbs contain one or more single-character verbs as the basic element to construct a verb (we call it basic verb, shorted as BV) and the semantics of such a verb thus can be inferred from its BV. There are some studies on the Chinese verb structure in linguistics. However, their structures are much more complex and there are no annotated corpora available. We define following six main structures from our empirical observations:

- (1) BV (e.g. “看” (see), “杀” (kill))
- (2) BV + verb (e.g. “会见” (meet))
- (3) verb + BV (e.g. “解雇” (fire) )
- (4) BV + complementation (e.g. “杀了” (kill) )
- (5) BV + noun/adj. (e.g. “回家” (go to home))
- (6) noun/adj. +BV (e.g. “枪击” (shoot using gun)).

<sup>5</sup> Actually, in the ACE 2005 Chinese (training) corpus, more than 90% of triggers are either verbs or verbal nouns (those verbs which act as nouns). For simplicity, we don't differentiate these two types in this paper.

From above structures, a BV plays an important role in the verb structure and most of semantics of a verb can be inferred from its contained BV and two words normally have very similar semantics if they have the same BV (e.g. “会见” (meet) and “会晤” (meet)). Actually, sometime the verb can be shortened to its contained BV (e.g. “我见王教授” and “我会见王教授” have the same semantics.).

## 4.2 Inferring via Compositional Semantics inside Chinese Triggers

Here a simple rule is employed to infer triggers via compositional semantics inside Chinese triggers: **a verb is a trigger if it contains a BV which occurs as a known trigger or is contained in a known trigger**. Table 5 shows the distribution of the set of triggers (contains the same BV<sup>6</sup>) classified by number of triggers.

From Table 5, we can find out that 85.3% of BVs occur in more than one trigger and 56.2% of them in more than 4 triggers. As for trigger mentions, these percentages become 89.1% and 65.2% respectively. A extreme example is that 85.2% (75/88) of triggers of *Trial-Hearing* event mentions contain “审” (trial) and 85.4% (117/138) of triggers of *injure* event mentions contains “伤” (injure).

Number	Distribution over Triggers	Distribution over Trigger Mentions
1	14.7%	10.9%
2~4	29.1%	23.9%
5~9	28.1%	32.9%
>=10	28.1%	32.3%

Table 5. Distribution of BVs in the number of triggers/trigger mentions

In this paper, the inference is done as follows:

- Add all single-character triggers into the BV set if it's a verb;
- Split all other triggers in the training set into a set of single characters and include all single characters into the BV set if it's a verb;
- For each word in the test set, it is identified as a trigger if it contains a BV.

It is worthwhile to note that such inference works for unknown triggers and word

<sup>6</sup> We didn't tag BVs in the training set and regards all single-character verbs contained in triggers as BVs.

segmentation errors to known triggers since in both cases, their BVs will always exist as either a SCW or a component of a word.

### 4.3 Noise Filtering

One problem with above inference is that while it is able to recover some true triggers and increase the recall, it may introduce many pseudo ones and harm the precision. To filter out those pseudo triggers, we propose following rules according to our intuition and statistics over the training set.

#### Non-trigger Filtering

**A Chinese word will not be a trigger if it appears in the training set but never trigger an event.** Statistics on the training set shows that this rule applies at 99.7% of cases.

#### POS filtering

**A Chinese word will not be a trigger if it has a different POS from that of the same known trigger or similar known triggers<sup>7</sup> in the training set.** In Chinese, a single-character verb has very high probability of composing words (e.g. “到” (come), “为” (act as), “并” (combine), etc) with different POS from the single-character verb itself, such as preposition (e.g. “为了” (for)), conjunction (e.g. “并且” (and)), etc. Statistics on the training set shows that this rule applies at 97.3% of cases.

#### Verb structure filtering

**A Chinese word will not be a trigger if its verb structure is different from that of the same known trigger or similar known triggers in the training set.** Figure 1 shows different distributions of three BVs over six verb structures as described in subsection 4.1. For example, we can find that all triggers including “解” (unbind) (e.g. “解聘” (fire), “解雇” (fire), “解散” (disband)) just have one verb structure (BV + verb) and those of “杀” (kill) have 4 structures. Obviously, we can use such distribution information to filter out pseudo triggers. For example, although both word “劝解” (console) and “分解” (decompose) are constructed from verb “解”, their verb structure (verb + BV) does not appear in the training set. Therefore, they will be filtered out via verb structure filtering.

<sup>7</sup> Similar triggers are those ones which have the same BV and verb structure.

Statistics on the training set shows that this rule applies at 95.5% of cases.

Figure 1. Distribution of three BVs (“解” (unbind), “审” (trial) and “杀” (kill)) over six verb structures in constructing triggers

## 5 Employing Discourse Consistency between Chinese Trigger Mentions

Chinese event extraction may suffer much from the errors propagated from upstream processing such as part-of-speech tagging and parsing, especially word segmentation. To alleviate word segmentation errors to known triggers, Chen and Ji (2009b) constructed a global errata table to record the inconsistency in the training set and proved its effectiveness. In this paper, a merge and split method is applied to recover those known triggers. In this way, word segmentation errors can be alleviated to certain extent.

For unknown triggers, we can merge two or more neighboring short words or single characters as a trigger candidate. In this paper, for each single-character verb in a document after word segmentation, this single-character verb can be merged with either previous SCW or next SCW to form a trigger candidate if this single-character verb has occurred in the training set with the same verb structure.

Given above recovered triggers for both known and unknown triggers, the key issue here is how to distinguish true triggers from pseudo ones. In this paper, we employ discourse consistency between Chinese trigger mentions for Chinese event extraction. Previous studies on English event extraction have proved the effectiveness of both cross-entity and cross-document consistency.

### 5.1 Discourse Consistency between Chinese Trigger Mentions

As a discourse-driven language, the syntax of

Chinese is not as strict as English and sometime we must infer from the discourse-level information to understand the meaning of a sentence. Kim (2000) compared the use of overt subjects in English and Chinese and he found that overt subjects occupy over 96% in English, while this percentage drops to only 64% in Chinese. Similarly, argument missing is another issue in Chinese event extraction and almost 55% of arguments are missing in the ACE 2005 Chinese corpus. Normally, using a feature-based approach to distinguish true triggers from pseudo ones is very difficult from the sentence level if some of related arguments are missing from the trigger-occurring sentence. Take following two contingent sentences as examples:

(3) 美国与北韩3号在吉隆坡结束飞弹会谈。

(The United States and the Democratic People's Republic of Korea finished missile **talks** in Kuala Lumpur.)

(4) 会谈的气氛严肃。

(The **talks** are serious.)

While it is relatively easy to determine that mention “会谈” in sentence (3) indicates a *meet* event from the contained information in itself (there are many entities, such as agents, time and place in the sentence) and difficult to determine that mention “会谈” in sentence (4) is a *meet* event from the contained information in itself, we can easily infer from sentence (3) that sentence (4) also indicates a *meet* event, using discourse consistency: if one instance of a word is a trigger mention, other instances in the same discourse will be a trigger mention with high probability.

Language	Discourse-based	Instance-based
English	70.2%	87.5%
Chinese	90.5%	95.4%

Table 6. Comparison of discourse consistency between Chinese and English trigger mentions

Table 6 compares the probabilities of discourse consistency between Chinese and English trigger mentions in the ACE 2005 Chinese and English corpora. A trigger may appear many times in a discourse. It's considered discourse-consistent when all the appearances of a trigger have the same event type while instance-based consistency refers to pair-wired cases. It shows that within the discourse, there is a strong consistency in both Chinese and English between trigger mentions: if

one instance of a word is a trigger, other instances in the same discourse will be a trigger of the same event type with very high probability.

Figure 2. Probabilities of discourse-level consistency of top 10 frequent triggers

It also shows that discourse consistency in Chinese triggers holds much more likely than the English counterpart. Figure 2 give the probabilities of discourse-level consistency of top 10 frequent triggers, which occupy 18% of event mentions in the ACE 2005 Chinese corpus.

## 5.2 Inference via Discourse Consistency between Chinese Trigger Mentions

Given a discourse and different mentions of a trigger returned by the trigger identifier, we can simply accept those mentions with high probability as true mentions of the trigger and discard those with low probability<sup>8</sup>. However, for those mentions in-between, an additional discourse-level trigger identifier is further employed to determine whether a trigger mention is true or not from the discourse level by augmenting the normal trigger identifier with several features to explore the consistency information between trigger mentions in the discourse (first three features) and the related information returned from the trigger type identifier (last two features).

- Probability of the discourse consistency of the candidate trigger mention in the training set. If it doesn't exist in the training set, we infer its probability from that of all of its similar triggers
- Number of candidate trigger mentions being a trigger in the same discourse via trigger identification
- Number of candidate trigger mentions being a non-trigger in the same discourse via trigger identification

<sup>8</sup> The high and low probability thresholds are fine-tuned to 95% and 5% respectively, using the development set.

- Event type of candidate trigger mention via trigger type determination
- Confidence of trigger type determination

## 6 Experiments

In this section, we evaluate our two inference mechanisms in Chinese trigger identification and its application to overall Chinese event extraction, using the same experimental settings as described in Subsection 3.1.

### 6.1 Chinese Trigger Identification

Table 7 shows the impact of compositional semantics in trigger identification. Here, the baseline just extracts those triggers occurring in the training data. It justifies the effectiveness of our compositional semantics-based inference mechanism in recovering true triggers and its three filtering rules in removing pseudo triggers.

Approaches	Numbers	Triggers	Non-triggers
Baseline		266	629
+Compositional semantics without filtering		334	1885
+ Non-trigger filtering		328	1062
+ POS filtering		325	974
+ Verb structure filtering		302	444
Gold		367	-

Table 7. Impact of compositional semantics in trigger identification

To reduce those pseudo triggers after above inference process, three rules are introduced.

The first rule, the non-trigger filtering rule, filters out those pseudo ones in the test set which do not frequently occur as trigger mentions in the training set. In particular, to keep true triggers in our candidate set as many as possible, we just filter out those candidates which occur as non-triggers more than 5 times in the training set according to our validation on the development set. Table 7 shows that 43.7% (823) of pseudo triggers are filtered out while only 1.8% (6) of true ones is wrongly filtered out.

The second rule, the POS filtering rule, just filters out 8.3% (88) of pseudo triggers, due to POS errors in word segmentation and constituent parsing (e.g. 9.4% of candidate triggers have wrong POS tags in the development set.). Manual inspection shows that if we correct those wrong

POS tags, that percentage will be increased to 14.5%.

The third rule, the verb structure filtering rule, is deployed in following steps: 1) keeping all candidates if they act as a trigger in the training set; 2) if the candidate is a SCW, removing it when it does not occur as a BV in any triggers in the training set; 3) if the candidate is not a SCW, calculating the condition probability of its similar trigger words as triggers in the training set<sup>9</sup> and then deleting all candidates whose conditional probabilities are less than a threshold  $\theta$ , which is fine-tuned to 0.5. Figure 3 shows the effect on precision, recall and F1-measure of varying the threshold  $\theta$  on the development set.

Figure 3. Effect of threshold  $\theta$  on the development set

System	Performance	Trigger Identification		
		P(%)	R(%)	F
Baseline		75.2	52.0	61.5
+Compositional semantics without filtering		34.8	66.8	45.8
+ Non-trigger filtering		49.4	66.5	56.7
+ POS filtering		50.2	65.9	57.0
+ Verb structure filtering		73.5	62.1	67.4
+Discourse consistency		<b>79.3</b>	<b>63.5</b>	<b>70.5</b>

Table 8. Contribution to Chinese triggers identification (incremental)

Table 8 shows the contribution of employing compositional semantics and discourse consistency to trigger identification on the held-out test set. We can find out that our approach dramatically enhances F1-measure by 9.0 units, largely due to a dramatic increase of 11.5% in recall, benefiting from both compositional semantics and discourse consistency mechanisms. We expect that the precision will also increase since our filtering approach successfully filters out almost 30% more

<sup>9</sup> If there are more than one BV in a candidate, we calculate the average one.

non-triggers and the number of non-trigger mentions is less than that of the baseline. Unfortunately, the resulting set of 444 non-trigger mentions (after all filtering) is not a subset of original 629 non-trigger ones. Our observation shows that our compositional semantics inference adds almost 10% new non-triggers into candidates which are very hard to distinguish.

Table 8 also justifies the impact of the discourse consistency between trigger mentions in trigger identification and the effect of the additional discourse-level trigger identifier, with a big gain of 5.8% in precision and a small gain of 1.4% in recall.

## 6.2 Chinese Event Extraction

Table 9 shows the contribution of trigger

identification with compositional semantics and discourse consistency to overall event extraction on the held-out test set. In addition, we also report the performance of two human annotators (The human annotator 1 is a first year postgraduate student with no background to Chinese event extraction while the human annotator 2 is a third year postgraduate student working on Chinese event extraction) on 33 texts (a subset of the held-out test set). From the results presented in Table 9, we can find that our approach can improve the F1-measure for trigger identification by 9.0 units, trigger type determination by 9.1 units, argument identification by 6.0 units and argument role determination (i.e. overall event extraction) by 5.4 units, largely due to the dramatic increase in recall of 11.5%, 11.2%, 7.5% and 7.2%.

Performance \ System/Human	Trigger Identification			Trigger Type Determination			Argument Identification			Argument Role Determination		
	P(%)	R(%)	F	P(%)	R(%)	F	P(%)	R(%)	F	P(%)	R(%)	F
Our Baseline	75.2	52.0	61.5	70.3	49.0	57.8	58.4	42.7	49.3	55.2	38.6	45.4
+Compositional semantics	73.5	62.1	67.4	70.2	59.1	64.2	58.0	48.9	53.0	54.7	44.5	49.1
+Discourse consistency	<b>79.3</b>	<b>63.5</b>	<b>70.5</b>	<b>75.2</b>	<b>60.2</b>	<b>66.9</b>	<b>61.6</b>	<b>50.2</b>	<b>55.3</b>	<b>56.9</b>	<b>45.8</b>	<b>50.8</b>
Human annotator1(blind)	63.3	62.9	63.1	61.7	59.5	60.6	64.6	54.1	58.9	60.9	48.2	53.8
Human annotator2(familiar)	72.6	74.3	73.4	69.1	70.2	69.6	71.5	65.9	68.6	66.4	54.6	59.9
Inter-Annotator Agreement	45.8	42.9	44.3	45.3	42.5	43.8	60.4	49.7	54.5	55.1	45.9	50.1

Table 9: Overall contribution to Chinese event extraction

In addition, the results of two annotators show that Chinese event extraction is really challenging even for a well-educated human being. As shown in Table 9, the inter-annotator agreement on trigger identification and trigger type determination is even less than 45%. Although this figure is very low, it is not surprising: the results on the English ACE 2005 corpus show that the inter-annotator agreement on trigger identification is only about 40% (Ji and Grishman, 2008). Detailed analysis shows that a human annotator tends to make more mistakes in trigger identification for two reasons. The first reason is that a human annotator always misses some event mentions when a sentence contains more than one event mention. The second reason is that it is hard to identify an event mention due to the failure of following specified annotation guidelines, as mentioned in Ji and Grishman (2008). Table 9 also shows the performance gaps of human annotators between trigger identification and trigger type determination is very small (2.5% and 3.8% in F1-measure). It ensures that trigger

identification is the most important step in Chinese event extraction for a human being. For human annotators, it's much easier to determine the event type of a trigger, identify its arguments and determine the role of each argument, all with more than 90% in accuracy, once a trigger is identified correctly.

## 6.3 Discussion

Compared with English, the word structures in Chinese are much more complex and diverse, causing a lot of troubles in Chinese language processing. We ensure that compositional semantics in Chinese words is very useful for many Chinese language processing applications, such as machine translation, semantic parser, etc. For example, many actions (e.g. “砍” (hack), “咬” (bite), “踢” (kick), etc) can combine with “伤” (injure) to form words and most of those words have similar semantics. The results in table 8 show its contribution in Chinese event extraction. Although our approach is simple, the result is

promising enough for further efforts in this direction.

This paper shows that the compositional semantics in the verb structure provides an ideal way to expand the coverage of triggers. As a discourse-driven language, ellipsis is very common in Chinese, causing inference from the discourse-level information is a fundamental requirement to understand the meaning of a clause, sentence or discourse.

## 7 Conclusion

In this paper we propose two novel inference mechanisms to Chinese trigger identification. In particular, compositional semantics inside Chinese triggers and discourse consistency between Chinese trigger mentions are used to resolve two critical issues in Chinese trigger identification: unknown triggers and word segmentation errors to known triggers. We give good reasons why this should be done, and present effective methods how this could be done. It shows that such novel inference mechanisms for Chinese event extraction are linguistically justified and pragmatically beneficial to real world applications.

In future work, we will focus on how to introduce the discourse information into the individual classifiers to capture those long-distance features and joint learning of subtasks in Chinese event extraction.

## Abstract

We study how to extend a large knowledge base (Freebase) by reading relational information from a large Web text corpus. Previous studies on extracting relational knowledge from text show the potential of syntactic patterns for extraction, but they do not exploit background knowledge of other relations in the knowledge base. We describe a distributed, Web-scale implementation of a path-constrained random walk model that learns syntactic-semantic inference rules for binary relations from a graph representation of the parsed text and the knowledge base. Experiments show significant accuracy improvements in binary relation prediction over methods that consider only text, or only the existing knowledge base.

## 1 Introduction

Manually-created knowledge bases (KBs) often lack basic information about some entities and their relationships, either because the information was missing in the initial sources used to create the KB, or because human curators were not confident about the status of some putative fact, and so they excluded it from the KB. For instance, as we will see in more detail later, many person entries in Freebase (Bollacker et al., 2008) lack nationality information. To fill those KB gaps, we might use general rules, ideally automatically learned, such as “if *person* was born in *town* and *town* is in *country*

then the *person* is a national of the *country*.” Of course, rules like this may be defeasible, in this case for example because of naturalization or political changes. Nevertheless, many such imperfect rules can be learned and combined to yield useful KB completions, as demonstrated in particular with the *Path-Ranking Algorithm* (PRA) (Lao and Cohen, 2010; Lao et al., 2011), which learns such rules on heterogeneous graphs for link prediction tasks.

Alternatively, we may attempt to fill KB gaps by applying relation extraction rules to free text. For instance, Snow et al. (2005) and Suchanek et al. (2006) showed the value of syntactic patterns in extracting specific relations. In those approaches, KB tuples of the relation to be extracted serve as positive training examples to the extraction rule induction algorithm. However, the KB contains much more knowledge about other relations that could potentially be helpful in improving relation extraction accuracy and coverage, but that is not used in such purely text-based approaches.

In this work, we use PRA to learn weighted rules (represented as graph path patterns) that combine both semantic (KB) and syntactic information encoded respectively as edges in a graph-structured KB, and as syntactic dependency edges in dependency-parsed Web text. Our approach can easily incorporate existing knowledge in extraction tasks, and its distributed implementation scales to the whole of the Freebase KB and 60 million parsed documents. To the best of our knowledge, this is the first successful attempt to apply relational learning methods to heterogeneous data with this scale.

\*This research was carried out during an internship at Google Research

## 1.1 Terminology and Notation

In this study, we use a simplified KB consisting of a set  $C$  of concepts and a set  $R$  of labels. Each label  $r$  denotes some binary relation partially represented in the KB. The concrete KB is a directed, edge-labeled graph  $G = (C, T)$  where  $T \subseteq C \times R \times C$  is the set of labeled edges (also known as *triples*)  $(c, r, c')$ . Each triple represents an instance  $r(c, c')$  of the relation  $r \in R$ . The KB may be incomplete, that is,  $r(c, c')$  holds in the real world but  $(c, r, c') \notin T$ . Our method will attempt to learn rules to infer such missing relation instances by combining the KB with parsed text.

We denote by  $r^{-1}$  the inverse relation of  $r$ :  $r(c, c') \Leftrightarrow r^{-1}(c', c)$ . For instance  $Parent^{-1}$  is equivalent to  $Children$ . It is convenient to take  $G$  as containing triple  $(c', r^{-1}, c)$  whenever it contains triple  $(c, r, c')$ .

A *path type* in  $G$  is a sequence  $\pi = \langle r_1, \dots, r_m \rangle$ . An *instance* of the path type is a sequence of nodes  $c_0, \dots, c_m$  such that  $r_i(c_{i-1}, c_i)$ . For instance, “the persons who were born in the same town as the query person”, and “the nationalities of persons who were born in the same town as the query person” can be reached respectively through paths matching the following types

$$\begin{aligned} \pi_1 &: \langle BornIn, BornIn^{-1} \rangle \\ \pi_2 &: \langle BornIn, BornIn^{-1}, Nationality \rangle \end{aligned}$$

## 1.2 Learning Syntactic-Semantic Rules with Path-Constrained Random Walks

Given a query concept  $s \in C$  and a relation  $r \in R$ , PRA begins by enumerating a large set of bounded-length path types. These path types are treated as ranking “experts,” each generating some random instance of the path type starting from  $s$ , and ranking end nodes  $t$  by their weights in the resulting distribution. Finally, PRA combines the weights contributed by different “experts” by using logistic regression to predict the probability that the relation  $r(s, t)$  holds.

In this study, we test the hypothesis that PRA can be used to find useful “syntactic-semantic patterns” – that is, patterns that exploit both semantic and syntactic relationships, thereby using semantic knowledge as background in interpreting syntactic

Figure 1: Knowledge base and parsed text as a labeled graph. For clarity, some word nodes are omitted.

relationships. As shown in Figure 1, we extend the KB graph  $G$  with nodes and edges from text that has been syntactically analyzed with a dependency parser<sup>1</sup> and where pronouns and other anaphoric referring expressions have been clustered with their antecedents. The text nodes are word/phrase instances, and the edges are syntactic dependencies labeled by the corresponding dependency type. Mentions of entities in the text are linked to KB concepts by mention edges created by an entity resolution process.

Given for instance the query  $Profession(CharlotteBronte, ?)$ , PRA produces a ranked list of answers that may have the relation  $Profession$  with the query node  $CharlotteBronte$ . The features used to score answers are the random walk probabilities of reaching a certain profession node from the query node by paths with particular path types. PRA can learn path types that combine background knowledge in the database with syntactic patterns in the text corpus. We now exemplify some path types involving relations described in Table 3. Type  $\langle M, conj, M^{-1}, Profession \rangle$  is *active* (matches paths) for professions of persons who are mentioned in conjunction with the query person as in “collaboration between McDougall and Simon

<sup>1</sup>Stanford dependencies (de Marneffe and Manning, 2008).

Philips”. For a somewhat subtler example, type  $\langle M, TW, CW^{-1}, Profession^{-1}, Profession \rangle$  is active for persons who are mentioned by their titles as in “President Barack Obama”. The type subsequence  $\langle Profession^{-1}, Profession \rangle$  ensures that only profession concepts are activated. The features generated from these path types combine syntactic dependency relations (*conj*) and textual information relations (*TW* and *CW*) with semantic relations in the KB (*Profession*).

Experiments on three Freebase relations (profession, nationality and parents) show that exploiting existing background knowledge as path features can significantly improve the quality of extraction compared with using either Freebase or the text corpus alone.

### 1.3 Related Work

Information extraction from varied unstructured and structured sources involves both complex relational structure and uncertainty at all levels of the extraction process. Statistical Relational Learning (SRL) seeks to combine statistical and relational learning methods to address such tasks. However, most SRL approaches (Friedman et al., 1999; Richardson and Domingos, 2006) suffer the complexity of inference and learning when applied to large scale problems. Recently, Lao and Cohen (2010) introduced Path Ranking algorithm, which is applicable to larger scale problems such as literature recommendation (Lao and Cohen, 2010) and inference on a large knowledge base (Lao et al., 2011).

Much of the previous work on automatic relation extraction was based on certain lexico-syntactic patterns. Hearst (1992) first noticed that patterns such as “NP and other NP” and “NP such as NP” often imply hyponym relations (NP here refers to a noun phrase). However, such approaches to relation extraction are limited by the availability of domain knowledge. Later systems for extracting arbitrary relations from text mostly use shallow surface text patterns (Etzioni et al., 2004; Agichtein and Gravano, 2000; Ravichandran and Hovy, 2002). The idea of using sequences of dependency edges as features for relation extraction was explored by Snow et al. (2005) and Suchanek et al. (2006). They define features to be shortest paths on dependency trees which connect pairs of NP candidates.

This study is most closely related to work of Mintz et al. (2009), who also study the problem of extending Freebase with extraction from parsed text. As in our work, they use a logistic regression model with path features. However, their approach does not exploit existing knowledge in the KB. Furthermore, their path patterns are used as binary-values features. We show experimentally that fractional-valued features generated by random walks provide much higher accuracy than binary-valued ones.

Culotta et al. (2006)’s work is similar to our approach in the sense of relation extraction by discovering relational patterns. However while they focus on identifying relation mentions in text (microreading), this work attempts to infer new tuples by gathering path evidence over the whole corpus (macroreading). In addition, their work involves a few thousand examples, while we aim for Web-scale extraction.

Do and Roth (2010) use a KB (YAGO) to aid the generation of features from free text. However their method is designed specifically for extracting hierarchical taxonomic structures, while our algorithm can be used to discover relations for general general graph-based KBs.

In this paper we extend the PRA algorithm along two dimensions: combining syntactic and semantic cues in text with existing knowledge in the KB; and a distributed implementation of the learning and inference algorithms that works at Web scale.

## 2 Path Ranking Algorithm

We briefly review the Path Ranking algorithm (PRA), described in more detail by Lao and Cohen (2010). Each path type  $\pi = \langle r_1, r_2, \dots, r_\ell \rangle$  specifies a real-valued *feature*. For a given query-answer node pair  $(s, t)$ , the value of the feature  $\pi$  is  $P(s \rightarrow t; \pi)$ , the probability of reaching  $t$  from  $s$  by a random walk that instantiates the type. More specifically, suppose that the random walk has just reached  $v_i$  by traversing edges labeled  $r_1, \dots, r_i$  with  $s=v_0$ . Then  $v_{i+1}$  is drawn at random from all nodes reachable from  $v_i$  by edges labeled  $r_{i+1}$ . A path type  $\pi$  is *active* for pair  $(s, t)$  if  $P(s \rightarrow t; \pi) > 0$ .

Let  $B = \{\perp, \pi_1, \dots, \pi_n\}$  be the set of all path types of length no greater than  $\ell$  that occur in the graph together with the dummy type  $\perp$ , which

represents the bias feature. For convenience, we set  $P(s \rightarrow t; \perp) = 1$  for any nodes  $s, t$ . The score for whether query node  $s$  is related to another node  $t$  by relation  $r$  is given by

$$\text{score}(s, t) = \sum_{\pi \in B} P(s \rightarrow t; \pi) \theta_{\pi} \quad ,$$

where  $\theta_{\pi}$  is the weight of feature  $\pi$ . The model parameters to be learned are the vector  $\boldsymbol{\theta} = \langle \theta_{\pi} \rangle_{\pi \in B}$ . The procedures used to discover  $B$  and estimate  $\boldsymbol{\theta}$  are described in the following. Finally, note that we train a *separate* PRA model for each relation  $r$ .

**Path Discovery:** Given a graph and a target relation  $r$ , the total number of path types is an exponential function of the maximum path length  $\ell$  and considering all possible paths would be computationally very expensive. As a result,  $B$  is constructed using only path types that satisfy the following two constraints:

1. the path type is active for more than  $K$  training query nodes, and
2. the probability of reaching any correct target node  $t$  is larger than a threshold  $\alpha$  on average for the training query nodes  $s$ .

We will discuss how  $K$ ,  $\alpha$  and the training queries are chosen in Section 5. In addition to making the training more efficient, these constraints are also helpful in removing low quality path types.

**Training Examples:** For each relation  $r$  of interest, we start with a set of node pairs  $S_r = \{(s_i, t_i)\}$ . From  $S_r$ , we create the training set  $D_r = \{(\mathbf{x}_i, y_i)\}$ , where  $\mathbf{x}_i = \langle P(s_i \rightarrow t_i; \pi) \rangle_{\pi \in B}$  is the vector of path feature values for the pair  $(s_i, t_i)$ , and  $y_i$  indicates whether  $r(s_i, t_i)$  holds.

Following previous work (Lao and Cohen, 2010; Mintz et al., 2009), node pairs that are in  $r$  in the KB are legitimate positive training examples<sup>2</sup>. One can generate negative training examples by considering all possible pairs of concepts whose type is compatible with  $r$  (as given by the schema) and are not present in the KB. However this

<sup>2</sup>In our experiments we subsample the positive examples. See section 3.2 for more details.

procedure leads to a very large number of negative examples (e.g., for the parents relation, any pair of person concepts which are related by this relation would be valid negative examples) which not only makes training very expensive but also introduces an incorrect bias in the training set. Following Lao and Cohen (2010) we use a simple biased sampling procedure to generate negative examples: first, the path types discovered in the previous (path discovery) step are used to construct an initial PRA model (all feature weights are set to 1.0); then, for each query node  $s_i$ , this model is used to retrieve candidate answer nodes, which are then sorted in descending order by their scores; finally, nodes at the  $k(k+1)/2$ -th positions are selected as negative samples, where  $k = 0, 1, 2, \dots$

**Logistic Regression Training:** Given a training set  $D$ , we estimate parameters  $\boldsymbol{\theta}$  by maximizing the following objective

$$\mathcal{F}(\boldsymbol{\theta}) = \frac{1}{|D|} \sum_{(\mathbf{x}, y) \in D} f(\mathbf{x}, y; \boldsymbol{\theta}) - \lambda_1 \|\boldsymbol{\theta}\|_1 - \lambda_2 \|\boldsymbol{\theta}\|_2^2$$

where  $\lambda_1$  and  $\lambda_2$  control the strength of the  $L_1$ -regularization which helps with structure selection and  $L_2^2$ -regularization which prevents overfitting. The log-likelihood  $f(\mathbf{x}, y; \boldsymbol{\theta})$  of example  $(\mathbf{x}, y)$  is given by

$$f(\mathbf{x}, y, \boldsymbol{\theta}) = y \ln p(\mathbf{x}, \boldsymbol{\theta}) + (1 - y) \ln(1 - p(\mathbf{x}, \boldsymbol{\theta}))$$

$$p(\mathbf{x}, \boldsymbol{\theta}) = \frac{\exp(\boldsymbol{\theta}^T \mathbf{x})}{1 + \exp(\boldsymbol{\theta}^T \mathbf{x})} \quad .$$

**Inference:** After a model is trained for a relation  $r$  in the knowledge base, it can be used to produce new instances of  $r$ . We first generate unlabeled queries  $s$  which belong to the domain of  $r$ . Queries which appear in the training set are excluded. For each unlabeled query node  $s$ , we apply the trained PRA model to generate a list of candidate  $t$  nodes together with their scores. We then sort all the predictions  $(s, t)$  by their scores in descending order, and evaluate the top ones.

### 3 Extending PRA

As described in the previous section, the PRA model is trained on positive and negative queries generated from the KB. As Freebase contains millions of

concepts and edges, training on all the generated queries is computationally challenging. Further, we extend the Freebase graph with parse paths of mentions of concepts in Freebase in millions of Web pages. Yet another issue is that the training queries generated using Freebase are inherently biased towards the distribution of concepts in Freebase and may not reflect the distribution of mentions of these concepts in text data. As one of the goals of our approach is to learn relation instances that are missing in Freebase, training on such a set biased towards the distribution of concepts in Freebase may not lead to good performance. In this section we explain how we modified the PRA algorithm to address those issues.

### 3.1 Scaling Up

Most relations in Freebase have a large set of existing triples. For example, for the *profession* relation, there are around 2 million persons in Freebase, and about 0.3 million of them have known professions. This results in more than 0.3 million training queries (persons), each with one or more positive answers (professions), and many negative answers, which make training computationally challenging. Generating all the paths for millions of queries over a graph with millions of concepts and edges further complicates the computational issues. Incorporating the parse path features from the text only exacerbates the matter. Finally once we have trained a PRA model for a given relation, say *profession*, we would like to infer the professions for all the 1.7 million persons whose professions are not known to Freebase (and possibly predict changes to the profession information of the 0.3 million people whose professions were given).

We use distributed computing to deal with the large number of training and prediction queries over a large graph. A key observation is that the different stages of the PRA algorithm are based on independent computations involving individual queries. Therefore, we can use the MapReduce framework to distribute the computation (Dean and Ghemawat, 2008). For path discovery, we modify Lao et al.’s path finding (2011) approach to decouple the queries: instead of using one depth-first search that involves all the queries, we first find all paths up to certain length for each query node in the

map stage, and then collect statistics for each path from all the query nodes in the reduce stage. We used a 500-machine, 8GB/machine cluster for these computations.

Another challenge associated with applying PRA to a graph constructed using a large amounts of text is that we cannot load the entire graph on a single machine. To circumvent this problem, we first index all parsed sentences by the concepts that they mention. Therefore, to perform a random walk for a query concept  $s$ , we only load the sentences which mention  $s$ .

### 3.2 Sampling Training Data

Using the  $r$ -edges in the KB as positive examples distorts the training set. For example, for the *profession* relation, there are 0.3 million persons for whom Freebase has profession information, and amongst these 0.24 million are either politicians or actors. This may not reflect the distribution of professions of persons mentioned in Web data. Using all of these as training queries will most certainly bias the trained model towards these professions as PRA is trained discriminatively. In other words, training directly with this data would lead to a model that is more likely to predict professions that are popular in Freebase. To avoid this distortion, we use stratified sampling. For each relation  $r$  and concept  $t \in C$ , we count the number of  $r$  edges pointing to  $t$

$$N_{r,t} = |\{(s, r, t) \in T\}| \quad .$$

Given a training query  $(s, r, t)$  we sample it according to

$$P_{r,t} = \min \left( 1, \frac{\sqrt{m + N_{r,t}}}{N_{r,t}} \right)$$

We fix  $m = 100$  in our experiments. If we take the profession relation as an example, the above implies that for popular professions, we only sample about  $\sqrt{N_{r,t}}$  out of the  $N_{r,t}$  possible queries that end in  $t$ , whereas for the less popular professions we would accept all the training queries.

### 3.3 Text Graph Construction

As we are processing Web text data (see following section for more detail), the number of mentions

of a concept follows a somewhat heavy-tailed distribution: there are a small number of very popular concepts (head) and a large number of not so popular concepts (tail). For instance the concept *BarackObama* is mentioned about 8.9 million times in our text corpus. To prevent the text graph from being dominated by the head concepts, for each sentence that mentions concept  $c \in C$ , we accept it as part of the text graph with probability:

$$P_c = \min \left( 1, \frac{\sqrt{k + S_c}}{S_c} \right)$$

where  $S_c$  is the number of sentences in which  $c$  is mentioned in the whole corpus. In our experiments we use  $k = 10^5$ . This means that if  $S_c \gg k$ , then we only sample about  $\sqrt{S_c}$  of the sentences that contain a mention of the concept, while if  $S_c \ll k$ , then all mentions of that concept will likely be included.

## 4 Datasets

We use Freebase as our knowledge base. Freebase data is harvested from many sources, including Wikipedia, AMG, and IMDB.<sup>3</sup> As of this writing, it contains more than 21 million concepts and 70 million labeled edges. For a large majority of concepts that appear both in Freebase and Wikipedia, Freebase maintains a link to the Wikipedia page of that concept.

We also collect a large Web corpus and identify 60 million pages that mention concepts relevant to this study. The free text on those pages are POS-tagged and dependency parsed with an accuracy comparable to that of the current Stanford dependency parser (Klein and Manning, 2003). The parser produces a dependency tree for each sentence with each edge labeled with a standard dependency tag (see Figure 1).

In each of the parsed documents, we use POS tags and dependency edges to identify potential referring noun phrases (NPs). We then use a within-document coreference resolver comparable to that of Haghighi and Klein (2009) to group referring NPs into co-referring clusters. For each cluster that contains a proper-name mention, we find the Freebase concept or concepts, if any, with a name or alias that matches

Table 1: Size of training and test sets for each relation.

Task	Training Set	Test Set
Profession	22,829	15,219
Nationality	14,431	9,620
Parents	21,232	14,155

the mention. If a cluster has multiple possible matching Freebase concepts, we choose a single sense based on the following simple model. For each Freebase concept  $c \in C$ , we compute  $N(c, m)$ , the number of times the concept  $c$  is referred by mention  $m$  by using both the alias information in Freebase and the anchors of the corresponding Wikipedia page for that concept. Based on  $N(c, m)$  we can calculate the empirical probability  $p(c|m) = N(c, m) / \sum_{c'} N(c', m)$ . If  $u$  is a cluster with mention set  $M(u)$  in the document, and  $C(m)$  the set of concepts in KB with name or alias  $m$ , we assign  $u$  to concept  $c^* = \operatorname{argmax}_{c \in C(m), m \in M(u)} p(c|m)$ ,

provided that there exists at least one  $c \in C(m)$  and  $m \in M(u)$  such that  $p(c|m) > 0$ . Note that  $M(c)$  only contains the proper-name mentions in cluster  $c$ .

## 5 Results

We use three relations *profession*, *nationality* and *parents* for our experiments. For each relation, we select its current set of triples in Freebase, and apply the stratified sampling (Section 3.2) to each of the three triple sets. The resulting triple sets are then randomly split into training (60% of the triples) and test (the remaining triples). However, the *parents* relation yields 350k triples after stratified sampling, so to reduce experimental effort we further randomly sub-sample 10% of that as input to the train-test split. Table 1 shows the sizes of the training and test sets for each relation.

To encourage PRA to find paths involving the text corpus, we do not count relation  $M$  (which connects concepts to their mentions) or  $M^{-1}$  when calculating path lengths. We use  $L_1/L_2^2$ -regularized logistic regression to learn feature weights. The PRA hyperparameters ( $\alpha$  and  $K$  as defined in Section 2) and regularizer hyperparameters are tuned by threefold cross validation (CV) on the training set. We average the models across all the folds and choose the model that gives the best

Table 2: Mean Reciprocal Rank (MRR) for different approaches under closed-world assumption. Here KB, Text and KB+Text columns represent results obtained by training a PRA model with only the KB, only text, and both KB and text. KB+Text[b] is the binarized PRA approach trained on both KB and text. The best performing system (results shown in bold font) is significant at 0.0001 level over its nearest competitor according to a difference of proportions significance test.

Task	KB	Text	KB+Text	KB+Text[b]
Profession	0.532	0.516	<b>0.583</b>	0.453
Nationality	0.734	0.729	<b>0.812</b>	0.693
Parents	0.329	0.332	<b>0.392</b>	0.319

performance on the training set for each relation.

We report results of two evaluations. First, we evaluate the performance of the PRA algorithm when trained on a subset of existing Freebase facts and tested on the rest. Second, we had human annotators verify facts proposed by PRA that are not in Freebase.

### 5.1 Evaluation with Existing Knowledge

Previous work in relation extraction from parsed text (Mintz et al., 2009) has mostly used binary features to indicate whether a pattern is present in the sentences where two concepts are mentioned. To investigate the benefit of having fractional valued features generated by random walks (as in PRA), we also evaluate a *binarized PRA* approach, for which we use the same syntactic-semantic pattern features as PRA does, but binarize the feature values from PRA: if the original fractional feature value was zero, the feature value is set to zero (equivalent to not having the feature in that example), otherwise it is set to 1.

Table 2 shows a comparison of the results obtained using the PRA algorithm trained using only Freebase (**KB**), using only the text corpus graph (**Text**), trained with both Freebase and the text corpus (**KB+Text**) and the binarized PRA algorithm using both Freebase and the text corpus (**KB+Text[b]**). We report Mean Reciprocal Rank (MRR) where, given a set of queries  $Q$ ,

$$\text{MRR} = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{\text{rank of } q\text{'s first correct answer}}$$

Comparing the results of first three columns we see that combining Freebase and text achieves significantly better results than using either Freebase or text alone. Further comparing the results of last

two columns we also observe a significant drop in MRR for the binarized version of PRA. This clearly shows the importance of using the random walk probabilities. It can also be seen that the MRR for the parents relation is lower than those for other relations. This is mainly because there are larger number of potential answers for each query node of *Parent* relation than for each query node of the other two relations – all persons in Freebase versus all professions or nationalities. Finally, it is important to point out that our evaluations are actually *lower bounds* of actual performance, because, for instance, a person might have a profession besides the ones in Freebase and in such cases, this evaluation does not give any credit for predicting those professions — they are treated as errors. We try to address this issue with the manual evaluations in the next section.

Table 2 only reports results for the maximum path length  $\ell = 4$  case. We found that shorter maximum path lengths give worse results: for instance, with  $\ell = 3$  for the profession relation, MRR drops to 0.542, from 0.583 for  $\ell = 4$  when using both Freebase and text. This difference is significant at the 0.0001 level according to a difference of proportions test. Further we find that using longer path length takes much longer time to train and test, but does not lead to significant improvements over the  $\ell = 4$  case. For example, for profession,  $\ell = 5$  gives a MRR of 0.589.

Table 3 shows the top weighted features that involve text edges for PRA models trained on both Freebase and the text corpus. To make them easier to understand, we group them based on their functionality. For the profession and nationality tasks, the conjunction dependency relation (in group 1,4) plays an important role: these features first find persons mentioned in conjunction with the query

Table 3: Top weighted path types involving text edges for each task grouped according to functionality.  $M$  relations connect each concept in knowledge base to its mentions in the corpus.  $TW$  relations connect each token in a sentence to the words in the text representation of this token.  $CW$  relations connect each concept in knowledge base to the words in the text representation of this concept. We use lower case names to denote dependency edges, word capitalized names to denote KB edges, and “ $^{-1}$ ” to denote the inverse of a relation.

Profession	Top Weighted Features	Comments
1	$\langle M, conj, M^{-1}, Profession \rangle$ $\langle M, conj^{-1}, M^{-1}, Profession \rangle$	Professions of persons mentioned in conjunction with the query person: “ <i>McDougall and Simon Phillips collaborated ...</i> ”
2	$\langle M, TW, CW^{-1}, Profession^{-1}, Profession \rangle$	Active if a person is mentioned by his profession: “ <i>The president said ...</i> ”
3	$\langle M, TW, TW^{-1}, M^{-1}, Children, Profession \rangle$ $\langle M, TW, TW^{-1}, M^{-1}, Parents, Profession \rangle$ $\langle M, TW, TW^{-1}, M^{-1}, Advisors, Profession \rangle$	First find persons with similar names or mentioned in similar ways, then aggregate the professions of their children/parents/advisors: starting from the concept <i>BarackObama</i> , words such as “ <i>Obama</i> ”, “ <i>leader</i> ”, “ <i>president</i> ”, and “ <i>he</i> ” are reachable through path $\langle M, TW \rangle$
Nationality	Top Weighted Features	Comments
4	$\langle M, conj, TW, CW^{-1}, Nationality \rangle$ $\langle M, conj^{-1}, TW, CW^{-1}, Nationality \rangle$	The nationalities of persons mentioned in conjunction with the query person: “ <i>McDougall and Simon Phillips collaborated ...</i> ”
5	$\langle M, nc^{-1}, TW, CW^{-1}, Nationality \rangle$ $\langle M, tmod^{-1}, TW, CW^{-1}, Nationality \rangle$ $\langle M, nn, TW, CW^{-1}, Nationality \rangle$	The nationalities of persons mentioned close to the query person through other dependency relations.
6	$\langle M, poss, poss^{-1}, M^{-1}, PlaceOfBirth, ContainedBy \rangle$ $\langle M, title, title^{-1}, M^{-1}, PlaceOfDeath, ContainedBy \rangle$	The birth/death places of the query person with restrictions to different syntactic constructions.
Parents	Top Weighted Features	Comments
7	$\langle M, TW, CW^{-1}, Parents \rangle$	The parents of persons with similar names or mentioned in similar ways: starting from the concept <i>CharlotteBronte</i> words such as “ <i>Bronte</i> ”, “ <i>Charlotte</i> ”, “ <i>Patrick</i> ”, and “ <i>she</i> ” are reachable through path $\langle M, TW \rangle$ .
8	$\langle M, nsubj, nsubj^{-1}, TW, CW^{-1} \rangle$ $\langle M, nsubj, nsubj^{-1}, M^{-1}, CW, CW^{-1} \rangle$ $\langle M, nc^{-1}, nc, TW, CW^{-1} \rangle$ $\langle M, TW, CW^{-1} \rangle$ $\langle M, TW, TW^{-1}, TW, CW^{-1} \rangle$	Persons with similar names or mentioned in similar ways to the query person with various restrictions or expansions. $\langle nsubj, nsubj^{-1} \rangle$ and $\langle nc^{-1}, nc \rangle$ require the query to be subject and noun compound respectively. $\langle TW^{-1}, TW \rangle$ expands further by word similarities.

person, and then find their professions or nationalities. The features in group 2 capture the fact that sometimes people are mentioned by their professions. The subpath  $\langle Profession^{-1}, Profession \rangle$  ensures that only profession related concepts are activated. Features in group 3 first find persons with similar names or mentioned in similar ways to the query person, and then aggregate the professions of their children, parents, or advisors. Features in group 6 can be seen as special versions of feature  $\langle PlaceOfBirth, ContainedBy \rangle$  and  $\langle PlaceOfDeath, ContainedBy \rangle$ . The subpaths  $\langle M, poss, poss^{-1}, M^{-1} \rangle$  and  $\langle M, title, title^{-1}, M^{-1} \rangle$  return the random walks back to the query node only if the mentions of the query node have *poss* (stands for *possessive modifier*, e.g. “Bill’s clothes”) or *title* (stands for *person’s title*, e.g. “President Obama”) edges in text; otherwise these features are inactive. Therefore, these features are active only for specific subsets of queries. Features in group 8 generally find persons with similar names or mentioned in similar ways to the query person. However, they further expand or restrict this person set in various ways.

Typically, each trained model includes hundreds of paths with non-zero weights, so the bulk of classifications are not based on a few high-precision-recall patterns, but rather on the combination of a large number of lower-precision high-recall or high-precision lower-recall rules.

## 5.2 Manual Evaluation

We performed two sets of manual evaluations. In each case, an annotator is presented with the triples predicted by PRA, and asked if they are correct. The annotator has access to the Freebase and Wikipedia pages for the concepts (and is able to issue search queries about the concepts).

In the first evaluation, we compared the performance of two PRA models, one trained using the stratified sampled queries and another trained using a randomly sampled set of queries for the profession relation. For each model, we randomly sample 100 predictions from the top 1000 predictions (sorted by the scores returned by the model). We found that the PRA model trained with stratified sampled queries has 0.92 precision, while the other model has only 0.84 precision (significant at the 0.02 level). This shows that stratified sampling leads to improved

Table 4: Human judgement for predicted new beliefs.

Task	p@100	p@1k	p@10k
Profession	0.97	0.92	0.84
Nationality	0.98	0.97	0.90
Parents	0.86	0.81	0.79

performance.

We also evaluated the new beliefs proposed by the models trained for all the three relations using stratified sampled queries. We estimated precision for the top 100 predictions and randomly sampled 100 predictions each from the top 1,000 and 10,000 predictions. Here we use the PRA model trained using both KB and text. The results of this evaluation are shown in Table 4. It can be seen that the PRA model is able to produce very high precision predications even when one considers the top 10,000 predictions.

Finally, note that our model is inductive. For instance, for the profession relation, we are able to predict professions for the around 2 million persons in Freebase. The top 1000 profession facts extracted by our system involve 970 distinct people, the top 10,000 facts involve 8,726 distinct people, and the top 100,000 facts involve 79,885 people.

## 6 Conclusion

We have shown that path constrained random walk models can effectively infer new beliefs from a large scale parsed text corpus with background knowledge. Evaluation by human annotators shows that by combining syntactic patterns in parsed text with semantic patterns in the background knowledge, our model can propose new beliefs with high accuracy. Thus, the proposed random walk model can be an effective way to automate knowledge acquisition from the web.

There are several interesting directions to continue this line of work. First, bidirectional search from both query and target nodes can be an efficient way to discover long paths. This would especially useful for parsed text. Second, relation paths that contain constant nodes (lexicalized features) and conjunction of random walk features are potentially very useful for extraction tasks.

## Abstract

Discovering significant types of relations from the web is challenging because of its open nature. Unsupervised algorithms are developed to extract relations from a corpus without knowing the relations in advance, but most of them rely on tagging arguments of predefined types. Recently, a new algorithm was proposed to jointly extract relations and their argument semantic classes, taking a set of relation instances extracted by an open IE algorithm as input. However, it cannot handle polysemy of relation phrases and fails to group many similar (“synonymous”) relation instances because of the sparseness of features. In this paper, we present a novel unsupervised algorithm that provides a more general treatment of the polysemy and synonymy problems. The algorithm incorporates various knowledge sources which we will show to be very effective for unsupervised extraction. Moreover, it explicitly disambiguates polysemous relation phrases and groups synonymous ones. While maintaining approximately the same precision, the algorithm achieves significant improvement on recall compared to the previous method. It is also very efficient. Experiments on a real-world dataset show that it can handle 14.7 million relation instances and extract a very large set of relations from the web.

## 1 Introduction

Relation extraction aims at discovering semantic relations between entities. It is an important task

that has many applications in answering factoid questions, building knowledge bases and improving search engine relevance. The web has become a massive potential source of such relations. However, its open nature brings an open-ended set of relation types. To extract these relations, a system should not assume a fixed set of relation types, nor rely on a fixed set of relation argument types.

The past decade has seen some promising solutions, unsupervised relation extraction (URE) algorithms that extract relations from a corpus without knowing the relations in advance. However, most algorithms (Hasegawa et al., 2004, Shinyama and Sekine, 2006, Chen et. al, 2005) rely on tagging predefined types of entities as relation arguments, and thus are not well-suited for the open domain.

Recently, Kok and Domingos (2008) proposed Semantic Network Extractor (SNE), which generates argument semantic classes and sets of synonymous relation phrases at the same time, thus avoiding the requirement of tagging relation arguments of predefined types. However, SNE has 2 limitations: 1) Following previous URE algorithms, it only uses features from the set of input relation instances for clustering. Empirically we found that it fails to group many relevant relation instances. These features, such as the surface forms of arguments and lexical sequences in between, are very sparse in practice. In contrast, there exist several well-known corpus-level semantic resources that can be automatically derived from a source corpus and are shown to be useful for generating the key elements of a relation: its 2 argument semantic classes and a set of synonymous phrases. For example, semantic classes can be derived from a source corpus with contextual distributional similarity and web table co-occurrences. The “*synonymy*”<sup>1</sup> problem for clustering relation instances

---

\*Work done during an internship at Microsoft Research Asia

could potentially be better solved by adding these resources. 2) SNE assumes that each entity or relation phrase belongs to exactly one cluster, thus is not able to effectively handle *polysemy* of relation phrases<sup>2</sup>. An example of a polysemous phrase is *be the currency of* as in 2 triples  $\langle \textit{Euro}, \textit{be the currency of}, \textit{Germany} \rangle$  and  $\langle \textit{authorship}, \textit{be the currency of}, \textit{science} \rangle$ . As the target corpus expands from mostly news to the open web, polysemy becomes more important as input covers a wider range of domains. In practice, around 22% (section 3) of relation phrases are polysemous. Failure to handle these cases significantly limits its effectiveness.

To move towards a more general treatment of the *polysemy* and *synonymy* problems, we present a novel algorithm WEBRE for open-domain large-scale unsupervised relation extraction without predefined relation or argument types. The contributions are:

- WEBRE incorporates a wide range of corpus-level semantic resources for improving relation extraction. The effectiveness of each knowledge source and their combination are studied and compared. To the best of our knowledge, it is the first to combine and compare them for unsupervised relation extraction.

- WEBRE explicitly disambiguates polysemous relation phrases and groups synonymous phrases, thus fundamentally it avoids the limitation of previous methods.

- Experiments on the Clueweb09 dataset ([lemurproject.org/clueweb09.php](http://lemurproject.org/clueweb09.php)) show that WEBRE is effective and efficient. We present a large-scale evaluation and show that WEBRE can extract a very large set of high-quality relations. Compared to the closest prior work, WEBRE significantly improves recall while maintaining the same level of precision. WEBRE is efficient. To the best of our knowledge, it handles the largest triple set to date (7-fold larger than largest previous effort). Taking 14.7 million triples as input, a complete run with one CPU core takes about a day.

## 2 Related Work

Unsupervised relation extraction (URE) algorithms (Hasegawa et al., 2004; Chen et al., 2005; Shinyama and Sekine, 2006) collect pairs of co-occurring entities as relation instances, extract features for instances and then apply unsupervised clustering techniques to find the major relations of a corpus. These UREs rely on tagging a predefined set of argument types, such as Person, Organization, and Location, in advance. Yao et al. 2011 learns fine-grained argument classes with generative models, but they share the similar requirement of tagging coarse-grained argument types. Most UREs use a quadratic clustering algorithm such as Hierarchical Agglomerate Clustering (Hasegawa et al., 2004, Shinyama and Sekine, 2006), K-Means (Chen et al., 2005), or both (Rosenfeld and Feldman, 2007); thus they are not scalable to very large corpora.

As the target domain shifts to the web, new methods are proposed without requiring predefined entity types. Resolver (Yates and Etzioni, 2007) resolves objects and relation synonyms. Kok and Domingos (2008) proposed Semantic Network Extractor (SNE) to extract concepts and relations. Based on second-order Markov logic, SNE used a bottom-up agglomerative clustering algorithm to jointly cluster relation phrases and argument entities. However, both Resolver and SNE require each entity and relation phrase to belong to exactly one cluster. This limits their ability to handle polysemous relation phrases. Moreover, SNE only uses features in the input set of relation instances for clustering, thus it fails to group many relevant instances. Resolver has the same sparseness problem but it is not affected as much as SNE because of its different goal (synonym resolution).

As the preprocessing instance-detection step for the problem studied in this paper, open IE extracts relation instances (in the form of triples) from the open domain (Etzioni et al., 2004; Banko et al., 2007; Fader et al., 2011; Wang et al. 2011). For efficiency, they only use shallow features. Reverb (Fader et al., 2011) is a state-of-the-art open domain extractor that targets verb-centric relations, which have been shown in Banko and Etzioni (2008) to cover over 70% of open domain relations. Taking their output as input, algorithms have been proposed to resolve objects and relation synonyms (Resolver), extract semantic networks

---

<sup>1</sup> We use the term *synonymy* broadly as defined in Section 3.

<sup>2</sup> A cluster of relation phrases can, however, act as a whole as the phrase cluster for 2 different relations in SNE. However, this only accounts for 4.8% of the polysemous cases.

(SNE), and map extracted relations into an existing ontology (Soderland and Mandhani, 2007).

Recent work shows that it is possible to construct semantic classes and sets of similar phrases automatically with data-driven approaches. For generating semantic classes, previous work applies distributional similarity (Pasca, 2007; Pantel et al., 2009), uses a few linguistic patterns (Pasca 2004; Sarmiento et al., 2007), makes use of structure in webpages (Wang and Cohen 2007, 2009), or combines all of them (Shi et al., 2010). Pennacchiotti and Pantel (2009) combines several sources and features. To find similar phrases, there are 2 closely related tasks: paraphrase discovery and recognizing textual entailment. Data-driven paraphrase discovery methods (Lin and Pantel, 2001; Pasca and Dienes, 2005; Wu and Zhou, 2003; Sekine, 2005) extends the idea of distributional similarity to phrases. The Recognizing Textual Entailment algorithms (Berant et al. 2011) can also be used to find related phrases since they find pairs of phrases in which one entails the other.

To efficiently cluster high-dimensional datasets, canopy clustering (McCallum et al., 2000) uses a cheap, approximate distance measure to divide data into smaller subsets, and then cluster each subset using an exact distance measure. It has been applied to reference matching. The second phase of WEBRE applies the similar high-level idea of partition-then-cluster for speeding up relation clustering. We design a graph-based partitioning subroutine that uses various types of evidence, such as shared hypernyms.

### 3 Problem Analysis

The basic input is a collection of relation instances (triples) of the form  $\langle ent_1, ctx, ent_2 \rangle$ . For each triple,  $ctx$  is a relational phrase expressing the relation between the first argument  $ent_1$  and the second argument  $ent_2$ . An example triple is  $\langle Obama, win\ in, NY \rangle$ . The triples can be generated by an open IE extractor such as TextRunner or Reverb. Our goal is to automatically build a list of relations  $R = \{ \langle ent_1, ctx, ent_2 \rangle \} \approx^3 \langle C_1, P, C_2 \rangle$  where  $P$  is the set of relation phrases, and  $C_1$  and  $C_2$  are two argument classes. Examples of triples and relations  $R$  (as Type B) are shown in Figure 1.

<sup>3</sup> This approximately equal sign connects 2 possible representations of a relation: as a set of triple instances or a triple with 2 entity classes and a relation phrase class.

The first problem is the *polysemy* of relation phrases, which means that a relation phrase  $ctx$  can express different relations in different triples. For example, the meaning of *be the currency of* in the following two triples is quite different:  $\langle Euro, be\ the\ currency\ of, Germany \rangle$  and  $\langle authorship, be\ the\ currency\ of, science \rangle$ . It is more appropriate to assign these 2 triples to 2 relations “a currency is the currency of a country” and “a factor is important in an area” than to merge them into one. Formally, a relation phrase  $ctx$  is *polysemous* if there exist 2 different relations  $\langle C_1, P, C_2 \rangle$  and  $\langle C'_1, P', C'_2 \rangle$  where  $ctx \in P \cap P'$ . In the previous example, *be the currency of* is polysemous because it appears in 2 different relations.

Polysemy of relation phrases is not uncommon. We generate clusters from a large sample of triples with the assistance of a soft clustering algorithm, and found that around 22% of relation phrases can be put into at least 2 disjoint clusters that represent different relations. More importantly, manual inspection reveals that some common phrases are polysemous. For example, *be part of* can be put into a relation “a city is located in a country” when connecting *Cities* to *Countries*, and another relation “a company is a subsidiary of a parent company” when connecting *Companies* to *Companies*. Failure to handle polysemous relation phrases fundamentally limits the effectiveness of an algorithm. The WEBRE algorithm described later explicitly handles polysemy and synonymy of relation phrases in its first and second phase respectively.

The second problem is the “*synonymy*” of relation instances. We use the term *synonymy* broadly and we say 2 relation instances are synonymous if they express the same semantic relation between the same pair of semantic classes. For example, both  $\langle Euro, be\ the\ currency\ used\ in, Germany \rangle$  and  $\langle Dinar, be\ legal\ tender\ in, Iraq \rangle$  express the relation  $\langle Currencies, be\ currency\ of, Countries \rangle$ . Solving this problem requires grouping synonymous relation phrases and identifying argument semantic classes for the relation.

Various knowledge sources can be derived from the source corpus for this purpose. In this paper we pay special attention to incorporating various semantic resources for relation extraction. We will show that these semantic sources can significantly improve the coverage of extracted relations and the

Figure 1. Overview of the WEBRE algorithm (Illustrated with examples sampled from experiment results). The tables and rectangles with a database sign show knowledge sources, shaded rectangles show the 2 phases, and the dotted shapes show the system output, a set of Type A relations and a set of Type B relations. The orange arrows denote resources used in phase 1 and the green arrows show the resources used in phase 2.

best performance is achieved when various resources are combined together.

## 4 Mining Relations from the Web

We first describe relevant knowledge sources, and then introduce the WEBRE algorithm, followed by a briefly analysis on its computational complexity.

### 4.1 Knowledge Sources

**Entity similarity graph** We build two similarity graphs for entities: a distributional similarity (DS) graph and a pattern-similarity (PS) graph. The DS graph is based on the distributional hypothesis (Harris, 1985), saying that terms sharing similar contexts tend to be similar. We use a text window of size 4 as the context of a term, use Pointwise Mutual Information (PMI) to weight context features, and use Jaccard similarity to measure the similarity of term vectors. The PS graph is generated by adopting both sentence lexical patterns and HTML tag patterns (Hearst, 1992; Kozareva et al., 2008; Zhang et al., 2009; Shi et al., 2010). Two terms ( $T$ ) tend to be semantically similar if they co-occur in multiple patterns. One example of sentence lexical patterns is *(such as | including) T{,T}\* (and|,|.)*. HTML tag patterns include tables, dropdown boxes, etc. In these two graphs, nodes are entities and the edge weights indicate entity similarity. In all there are about 29.6 million nodes and 1.16 billion edges.

**Hyponymy graph** Hyponymy relations are very useful for finding semantically similar term pairs. For example, we observed that a small city in UK and another small city in Germany share common hypernyms such as *city*, *location*, and *place*. Therefore the similarity between the two cities is large according to the hypernymy graph, while their similarity in the DS graph and the PS graph may be very small. Following existing work (Hearst, 1992, Pantel & Ravichandran 2004; Snow et al., 2005; Talukdar et al., 2008; Zhang et al., 2011), we adopt a list of lexical patterns to extract hypernyms. The patterns include *NP {,} (such as) {NP,}\* {and/or} NP*, *NP (is/are/was/were/being) (a/an/the) NP*, etc. The hypernymy graph is a bipartite graph with two types of nodes: entity nodes and label (hypernym) nodes. There is an edge ( $T, L$ ) with weight  $w$  if  $L$  is a hypernym of entity  $T$  with probability  $w$ . There are about 8.2 million nodes and 42.4 million edges in the hypernymy graph. In this paper, we use the terms *hypernym* and *label* interchangeably.

**Relation phrase similarity:** To generate the pairwise similarity graph for relation phrases with regard to the probability of expressing the same relation, we apply a variant of the DIRT algorithm (Lin and Pantel, 2001). Like DIRT, the paraphrase discovery relies on the distributional hypothesis, but there are a few differences: 1) we use stemmed lexical sequences (relation phrases) instead of dependency paths as phrase candidates because of the very large scale of the corpus. 2) We used ordered

pairs of arguments as features of phrases while DIRT uses them as independent features. We empirically tested both feature schemes and found that using ordered pairs results in likely paraphrases but using independent features the result contains general inference rules<sup>4</sup>.

## 4.2 WEBRE for Relation Extraction

WEBRE consists of two phases. In the first phase, a set of semantic classes are discovered and used as argument classes for each relation phrase. This results in a large collection of relations whose arguments are pairs of semantic classes and which have exactly one relation phrase. We call these relations the *Type A* relations. An example *Type A* relation is  $\langle \{New\ York, London\dots\}, be\ locate\ in, \{USA, England, \dots\} \rangle$ . During this phase, polysemous relation phrases are disambiguated and placed into multiple *Type A* relations. The second phase is an efficient algorithm which groups similar *Type A* relations together. This step enriches the argument semantic classes and groups synonymous relation phrases to form relations with multiple expressions, which we called *Type B* relations. Both *Type A* and *Type B* relations are system outputs since both are valuable resources for downstream applications such as QA and Web Search. An overview of the algorithm is shown in Figure 1. Here we first briefly describe a clustering subroutine that is used in both phases, and then describe the algorithm in detail.

To handle polysemy of objects (e.g., entities or relations) during the clustering procedure, a key building block is an effective Multi-Membership Clustering algorithm (*MMClustering*). For simplicity and effectiveness, we use a variant of Hierarchical Agglomerative Clustering (HAC), in which we first cluster objects with HAC, and then reassign each object to additional clusters when its similarities with these clusters exceed a certain threshold<sup>5</sup>. In the remainder of this paper, we use  $\{C\} = MMClustering(\{object\}, SimFunc, \alpha)$  to represent running *MMClustering* over a set of objects,

<sup>4</sup> For example, *be part of* has ordered argument pairs  $\langle A, B \rangle$  and  $\langle C, D \rangle$ , and *be not part of* has ordered argument pairs  $\langle A, D \rangle$  and  $\langle B, C \rangle$ . If arguments are used as independent features, these two phrases shared the same set of features  $\{A, B, C, D\}$ . However, they are inferential (complement relationship) rather than being similar phrases.

<sup>5</sup> This threshold should be slightly greater than the clustering threshold for HAC to avoid generating duplicated clusters.

with threshold  $\alpha$  to generate a list of clusters  $\{C\}$  of the objects, given the pairwise object similarity function *SimFunc*. Our implementation uses HAC with average linkage since empirically it performs well.

**Discovering Type A Relations** The first phase of the relation extraction algorithm generates *Type A* relations, which have exactly one relation phrase and two argument entity semantic classes. For each relation phrase, we apply a clustering algorithm on each of its two argument sets to generate argument semantic classes. The *Phase 1* algorithm processes relation phrases one by one. For each relation phrase *ctx*, step 4 clusters the set  $\{ent_1\}$  using *MMClustering* to find left-hand-side argument semantic classes  $\{C_1\}$ . Then for each cluster  $C$  in  $\{C_1\}$ , it gathers the right-hand-side arguments which appeared in some triple whose left hand-side argument is in  $C$ , and puts them into  $\{ent_2'\}$ . Following this, it clusters  $\{ent_2'\}$  to find right-hand-side argument semantic classes. This results in pairs of semantic classes which are arguments of *ctx*. Each relation phrase can appear in multiple non-overlapping *Type A* relations. For example,  $\langle Cities, be\ part\ of, Countries \rangle$  and  $\langle Companies, be\ part\ of, Companies \rangle$  are different *Type A* relations which share the same relation phrase *be part of*. In the pseudo code, *SimEntFunc* is encoded in the entity similarity graphs.

---

### Algorithm *Phase 1: Discovering Type A relations*

---

Input: set of triples  $T = \{ \langle ent_1, ctx, ent_2 \rangle \}$   
entity similarity function *SimEntFunc*  
Similarity threshold  $\alpha$

Output: list of *Type A* relations  $\{ \langle C_1, ctx, C_2 \rangle \}$

Steps:

01. For each relation phrase *ctx*
02.  $\{ent_1, ctx, ent_2\} =$  set of triples sharing *ctx*
03.  $\{ent_1\} =$  set of  $ent_1$  in  $\{ent_1, ctx, ent_2\}$
04.  $\{C_1\} = MMClustering(\{ent_1\}, SimEntFunc, \alpha)$
05. For each  $C$  in  $\{C_1\}$
06.  $\{ent_2'\} =$  set of  $ent_2$  s.t.  $\exists \langle ent_1, ctx, ent_2 \rangle \in T \wedge ent_1 \in C_1$
07.  $\{C_2\} = MMClustering(\{ent_2'\}, SimEntFunc, \alpha)$
08. For each  $C_2$  in  $\{C_2\}$
09. Add  $\langle C_1, ctx, C_2 \rangle$  into  $\{ \langle C_1, ctx, C_2 \rangle \}$
10. Return  $\{ \langle C_1, ctx, C_2 \rangle \}$

---

**Discovering Type B Relations** The goal of *phase 2* is to merge similar *Type A* relations, such as  $\langle Cities, be\ locate\ in, Countries \rangle$  and  $\langle Cities, be\ city\ of, Countries \rangle$ , to produce *Type B* relations, which have a set of synonymous relation phrases and more complete argument entity classes. The challenge for this phase is to cluster a very large

set of Type A relations, on which it is infeasible to run a clustering algorithm that does pairwise all pair comparison. Therefore, we designed an evidence-based partition-then-cluster algorithm.

The basic idea is to heuristically partition the large set of Type A relations into small subsets, and run clustering algorithms on each subset. It is based on the observation that most pairs of Type A relations are not similar because of the sparseness in the entity class and the relation semantic space. If there is little or no evidence showing that two Type A relations are similar, they can be put into different partitions. Once partitioned, the clustering algorithm only has to be run on each much smaller subset, thus computation complexity is reduced.

The 2 types of evidence we used are shared members and shared hypernyms of relation arguments. For example, 2 Type A relations  $r_1 = \langle \text{Cities, be city of, Countries} \rangle$  and  $r_2 = \langle \text{Cities, be locate in, Countries} \rangle$  share a pair of arguments  $\langle \text{Tokyo, Japan} \rangle$ , and a pair of hypernyms  $\langle \text{"city", "country"} \rangle$ . These pieces of evidence give us hints that they are likely to be similar. As shown in the pseudo code, shared arguments and hypernyms are used as independent evidence to reduce sparseness.

---

**Algorithm Phase 2: Discovering Type B relations**

---

Input: Set of Type A relations  $\{r\} = \langle C_1, ctx, C_2 \rangle$   
Relation similarity function  $SimRelationFunc$   
Map from entities to their hypernyms:  $M_{entity2label}$   
Similarity threshold  $\alpha$   
Edge weight threshold  $\mu$

Variables  $G(V, E) =$  weighted graph in which  $V = \{r\}$

Output: Set of Type B relations  $\langle C_1, P, C_2 \rangle$

Steps:

01.  $\langle ent, \{r'\} \rangle =$  build inverted index from argument  $ent$  to set of Type A relations  $\{r'\}$  on  $\langle C_1, ctx, C_2 \rangle$
02.  $\langle l, \{r'\} \rangle =$  build inverted index from hypernym  $l$  of arguments to set of Type A relations  $\{r'\}$  on  $\langle C_1, ctx, C_2 \rangle$  with map  $M_{entity2label}$
03. For each  $ent$  in  $\langle ent, \{r'\} \rangle$
04. For each pair of  $r_1$  and  $r_2$  s.t.  $r_1 \in \{r'\} \wedge r_2 \in \{r'\}$
05.  $weight\_edge(\langle r_1, r_2 \rangle) += weight(ent)$
06. For each  $l$  in  $\langle l, \{r'\} \rangle$
07. For each pair of  $r_1$  and  $r_2$  s.t.  $r_1 \in \{r'\} \wedge r_2 \in \{r'\}$
08.  $weight\_edge(\langle r_1, r_2 \rangle) += weight(l)$
09. For each edge  $\langle r_1, r_2 \rangle$  in  $G$
10. If  $weight\_edge(\langle r_1, r_2 \rangle) < \mu$
11. Remove edge  $\langle r_1, r_2 \rangle$  from  $G$
12.  $\{CC\} = DFS(G)$
13. For each connected component  $CC$  in  $\{CC\}$
14.  $\langle C_1, ctx, C_2 \rangle =$  vertices in  $CC$
15.  $\langle C_1', P', C_2' \rangle = MMClustering(\langle C_1, ctx, C_2 \rangle, SimRelationFunc, \alpha)$
16. Add  $\langle C_1', P', C_2' \rangle$  into  $\langle C_1, P, C_2 \rangle$
17. Return  $\langle C_1, P, C_2 \rangle$

---

Steps 1 and 2 build an inverted index from evidence to sets of Type A relations. On the graph  $G$  whose vertices are Type A relations, steps 3 to 8 set the value of edge weights based on the strength of evidence that shows the end-points are related. The weight of evidence  $E$  is calculated as follows:

$$weight(E) = \frac{\# \text{ shared tuples in which } E \text{ appears in}}{\max(\# \text{ classes } E \text{ appears in})}$$

The idea behind this weighting scheme is similar to that of TF-IDF in that the weight of evidence is higher if it appears more frequently and is less ambiguous (appeared in fewer semantic classes during clustering of phase 1). The weighting scheme is applied to both shared arguments and labels.

After collecting evidence, we prune (steps 9 to 11) the edges with a weight less than a threshold  $\mu$  to remove noise. Then a Depth-First Search (DFS) is called on  $G$  to find all Connected Components  $CC$  of the graph. These  $CC$ s are the partitions of likely-similar Type A relations. We run  $MMClustering$  on each  $CC$  in  $\{CC\}$  and generate Type B relations (step 13 to step 16). The similarity of 2 relations ( $SimRelationFunc$ ) is defined as follows:

$$\begin{aligned} & sim(\langle C_1, P, C_2 \rangle, \langle C_1', P', C_2' \rangle) \\ &= \begin{cases} 0, & \text{if } sim(P, P') < \sigma \\ \min(sim(C_1, C_1'), sim(C_2, C_2')), & \text{else} \end{cases} \end{aligned}$$

### 4.3 Computational Complexity

WEBRE is very efficient since both phases decompose the large-clustering task into much smaller clustering tasks over partitions. Given  $n$  objects for clustering, a hierarchical agglomerative clustering algorithm requires  $O(n^2)$  pairwise comparisons. Assuming the clustering task is split into subtasks of size  $n_1, n_2, \dots, n_k$ , thus the computational complexity is reduced to  $O(\sum_1^k n_i^2)$ . Ideally each subtask has an equal size of  $n/k$ , so the computational complexity is reduced to  $O(n^2/k)$ , a factor of  $k$  speed up. In practice, the sizes of partitions are not equal. Taking the partition sizes observed in the experiment with 0.2 million Type A relations as input, the phase 2 algorithm achieves around a 100-fold reduction in pairwise comparisons compared to the agglomerative clustering algorithm. The combination of phase 1 and phase 2 achieves more than a 1000-fold reduction in pairwise comparison, compared to running an agglomerative clustering algorithm directly on 14.7 million triples. This reduction of computational

complexity makes the unsupervised extraction of relations on a large dataset a reality. In the experiments with 14.7 million triples as input, phase 1 finished in 22 hours, and the phase 2 algorithm finished in 4 hours with one CPU core.

Furthermore, both phases can be run in parallel in a distributed computing environment because data is partitioned. Therefore it is scalable and efficient for clustering a very large number of relation instances from a large-scale corpus like the web.

## 5 Experiment

**Data preparation** We tested WEBRE on resources extracted from the English subset of the Clueweb09 Dataset, which contains 503 million webpages. For building knowledge resources, all webpages are cleaned and then POS tagged and chunked with in-house tools. We implemented the algorithms described in section 4.1 to generate the knowledge sources, including a hypernym graph, two entity similarity graphs and a relation phrase similarity graph.

We used Reverb Clueweb09 Extractions 1.1 (downloaded from *reverb.cs.washington.edu*) as the triple store (relation instances). It is the complete extraction of Reverb over Clueweb09 after filtering low confidence and low frequency triples. It contains 14.7 million distinct triples with 3.3 million entities and 1.3 million relation phrases. We choose it because 1) it is extracted by a state-of-the-art open IE extractor from the open-domain, and 2) to the best of our knowledge, it contains the largest number of distinct triples extracted from the open-domain and which is publicly available.

**Evaluation setup** The evaluations are organized as follows: we evaluate Type A relation extraction and Type B relation extraction separately, and then we compare WEBRE to its closest prior work SNE. Since both phases are essentially clustering algorithms, we compare the output clusters with human labeled gold standards and report performance measures, following most previous work such as Kok and Domingos (2008) and Hasegawa et al. (2004). Three gold standards are created for evaluating Type A relations, Type B relations and the comparison to SNE, respectively. In the experiments, we set  $\alpha=0.6$ ,  $\mu=0.1$  and  $\sigma=0.02$  based on trial runs on a small development set of 10k relation instances. We filtered out the Type A relations and Type B relations which only contain 1 or 2

triples since most of these relations are not different from a single relation instance and are not very interesting. Overall, 0.2 million Type A relations and 84,000 Type B relations are extracted.

**Evaluating Type A relations** To understand the effectiveness of knowledge sources, we run *Phase 1* multiple times taking entity similarity graphs (matrices) constructed with resources listed below:

- **TS:** Distributional similarity based on the triple store. For each triple  $\langle ent_1, ctx, ent_2 \rangle$ , features of  $ent_1$  are  $\{ctx\}$  and  $\{ctx\ ent_2\}$ ; features of  $ent_2$  are  $\{ctx\}$  and  $\{ent_1\ ctx\}$ . Features are weighted with PMI. Cosine is used as similarity measure.
- **LABEL:** The similarity between two entities is computed according to the percentage of top hypernyms they share.
- **SIM:** The similarity between two entities is the linear combination of their similarity scores in the distributional similarity graph and in the pattern similarity graph.
- **SIM+LABEL** SIM and LABEL are combined. Observing that SIM generates high quality but overly fine-grained semantic classes, we modify the entity clustering procedure to cluster argument entities based on SIM first, and then further clustering the results based on LABEL.

The outputs of these runs are pooled and mixed for labeling. We randomly sampled 60 relation phrases. For each phrase, we select the 5 most frequent Type A relations from each run ( $4 \times 5 = 20^6$  Type A relations in all). For each relation phrase, we ask a human labeler to label the mixed pool of Type A relations that share the phrase: 1) The labelers<sup>7</sup> are asked to first determine the major semantic relation of each Type A relation, and then label the triples as *good*, *fair* or *bad* based on whether they express the major relation. 2) The labeler also reads all Type A relations and manually merges the ones that express the same relation. These 2 steps are repeated for each phrase. After labeling, we create a gold standard *GSI*, which contains roughly 10,000 triples for 60 relation phrases. On average, close to 200 triples are manu-

---

<sup>6</sup> Here 4 means the 4 methods (the bullet items above) of computing similarity.

<sup>7</sup> 4 human labelers perform the task. A portion of the judgments were independently dual annotated; inter-annotator agreement is 79%. Moreover, each judgment is cross-checked by at least one more annotator, further improving quality.

ally labeled and clustered for each phrase. This creates a large data set for evaluation.

We report micro-average of precision, recall and F1 on the 60 relation phrases for each method. Precision (P) and Recall (R) of a given relation phrase is defined as follows. Here  $R_A$  and  $R'_A$  represents a Type A relation in the algorithm output and *GS1*, respectively. We use  $t$  for triples and  $s(t)$  to represent the score of the labeled triple  $t$ .  $s(t)$  is set to 1.0, 0.5 or 0 for  $t$  labeled as good, fair and bad, respectively.

$$P = \frac{\sum_{R_A} \sum_{t \in R_A} s(t)}{\sum_{R_A} |R_A|}, R = \frac{\sum_{R_A} \sum_{t \in R_A} s(t)}{\sum_{R'_A} \sum_{t' \in R'_A} s(t')}$$

The results are in table 1. Overall, LABEL performs 53% better than TS in F-measure, and SIM+LABEL performs the best, 8% better than LABEL. Applying a simple sign test shows both differences are clearly significant ( $p < 0.001$ ). Surprisingly, SIM, which uses the similarity matrix extracted from full text, has a F1 of 0.277, which is lower than TS. We also tried combining TS and LABEL but did not find encouraging performance compared to SIM+LABEL.

Algorithm	Precision	Recall	F1
TS	0.842 (0.886)	0.266	0.388
LABEL	0.855 (0.870)	0.481	0.596
SIM	0.755 ( <b>0.964</b> )	0.178	0.277
SIM+LABEL	0.843 (0.872)	<b>0.540</b>	<b>0.643</b>

Table 1. Phase 1 performance (averaged on multiple runs) of the 4 methods. The highest performance numbers are in bold. (The number in parenthesis is the micro-average when empty-result relation phrases are not considered for the method).

Among the 4 methods, SIM has the highest precision (0.964) when relation phrases for which it fails to generate any Type A relations are excluded, but its recall is low. Manual checking shows that SIM tends to generate overly fine-grained argument classes. If fine-grained argument classes or extremely high-precision Type A relations are preferred, SIM is a good choice. LABEL performs significantly better than TS, which shows that hypernymy information is very useful for finding argument semantic classes. However, it has coverage problems in that the hypernym finding algorithm failed to find any hypernym from the corpus for some entities. Following up, we found that SIM+LABEL has similar precision and the highest recall. This shows that the combination of semantic spaces is very helpful. The significant recall improvement from TS to SIM+LABEL shows that the corpus-based knowledge resources significant-

ly reduce the data sparseness, compared to using features extracted from the triple store only. The result of the phase 1 algorithm with SIM+LABEL is used as input for phase 2.

**Evaluating Type B relations** The goal is 2-fold: 1) to evaluate the phase 2 algorithm. This involves comparing system output to a gold standard constructed by hand, and reporting performance; 2) to evaluate the quality of Type B relations. For this, we will also report triple-level precision.

We construct a gold standard *GS2*<sup>8</sup> for evaluating Type B relations as follows: We randomly sampled 178 Type B relations, which contain 1547 Type A relations and more than 100,000 triples. Since the number of triples is very large, it is infeasible for labelers to manually cluster triples to construct a gold standard. To report precision, we asked the labelers to label each Type A relation contained in this Type B relation as good, fair or bad based on whether it expresses the same relation. For recall evaluation, we need to know how many Type A relations are missing from each Type B relation. We provide the full data set of Type A relations along with three additional resources: 1) a tool which, given a Type A relation, returns a ranked list of similar Type A relations based on the pairwise relation similarity metric in section 4, 2) DIRT paraphrase collection, 3) WordNet (Fellbaum, 1998) synsets. The labelers are asked to find similar phrases by checking phrases which contain synonyms of the tokens in the query phrase. Given a Type B relation, ideally we expect the labelers to find all missing Type A relations using these resources. We report precision (P) and recall (R) as follows. Here  $R_B$  and  $R'_B$  represent Type B relations in the algorithm output and *GS2*, respectively.  $R_A$  and  $R'_A$  represent Type A relations.  $s(R_A)$  denotes the score of  $R_A$ . It is set to 1.0, 0.5 and 0 for good, fair or bad respectively.

$$P = \frac{\sum_{R_B} \sum_{R_A \in R_B} |R_A| \cdot s(R_A)}{\sum_{R_B} \sum_{R_A \in R_B} |R_A|}, R = \frac{\sum_{R_B} \sum_{R_A \in R_B} |R_A| \cdot s(R_A)}{\sum_{R'_B} \sum_{R'_A \in R'_B} |R'_A|}$$

We also ask the labeler to label at most 50 randomly sampled triples from each Type B relation, and calculate triple-level precision as the ratio of the sum of scores of triples over the number of

<sup>8</sup> 3 human labelers performed the task. A portion of the judgments were independently dual annotated; inter-annotator agreement is 73%. Similar to labeling Type A relations, each judgment is cross-checked by at least one more annotator, further improving quality.

Argument 1	Relation phrase	Argument 2
<i>marijuana, caffeine, nicotine...</i>	<i>result in, be risk factor for, be major cause of...</i>	<i>insomnia, emphysema, breast cancer,...</i>
<i>C# 2.0, php5, java, c++, ...</i>	<i>allow the use of, also use, introduce the concept of...</i>	<i>destructors, interfaces, template,...</i>
<i>clinton, obama, mccain, ...</i>	<i>win, win in, take, be lead in,...</i>	<i>ca, dc, fl, nh, pa, va, ga, il, nc,...</i>

Table 3. Sample Type B relations extracted.

sampled triples. We use  $P_{ins}$  to represent the precision calculated based on labeled triples. Moreover, as we are interested in how many phrases are found by our algorithm, we also include  $R_{phrase}$ , which is the recall of synonymous phrases. Results are shown in Table 2.

Interval	$P$	$R(R_{phrase})$	$FI$	$P_{ins}$	count
[3, 5)	0.913	0.426 (0.026)	0.581	0.872	52149
[5, 10)	0.834	0.514 (0.074)	0.636	0.863	21981
[10, 20)	0.854	0.569 (0.066)	0.683	0.883	6277
[20, 50)	0.899	0.675 (0.406)	0.771	0.894	2630
[50, $+\infty$ )	0.922	0.825 (0.594)	0.871	0.929	1089
Overall	0.897	0.684 (0.324)	0.776	0.898	84126

Table 2. Performance for Type B relation extraction. The first column shows the range of the maximum sizes of Type A relations in the Type B relation. The last column shows the number of Type B relations that are in this range. The number in parenthesis in the third column is the recall of phrases.

The result shows that WEBRE can extract Type B relations at high precision (both  $P$  and  $P_{ins}$ ). The overall recall is 0.684. Table 2 also shows a trend that if the maximum number of Type A relation in the target Type B relation is larger, the recall is better. This shows that the recall of Type B relations depends on the amount of data available for that relation. Some examples of Type B relations extracted are shown in Table 3.

**Comparison with SNE** We compare WEBRE’s extracted Type B relations to the relations extracted by its closest prior work SNE<sup>9</sup>. We found SNE is not able to handle the 14.7 million triples in a foreseeable amount of time, so we randomly sampled 1 million (1M) triples<sup>10</sup> and test both algorithms on this set. We also filtered out result clusters which have only 1 or 2 triples from both system outputs. For comparison purposes, we constructed a gold standard *GS3* as follows: randomly select 30 clusters from both system outputs, and then find similar clusters from the other system output, followed by manually refining the clusters

<sup>9</sup> Obtained from [alchemy.cs.washington.edu/papers/kok08](http://alchemy.cs.washington.edu/papers/kok08)

<sup>10</sup> We found that SNE’s runtime on 1M triples varies from several hours to over a week, depending on the parameters. The best performance is achieved with runtime of approximately 3 days. We also tried SNE with 2M triples, on which many runs take several days and show no sign of convergence. For fairness, the comparison was done on 1M triples.

by merging similar ones and splitting non-coherent clusters. *GS3* contains 742 triples and 135 clusters. We report triple-level pairwise precision, recall and F1 for both algorithms against *GS3*, and report results in Table 4. We fine-tuned SNE (using grid search, internal cross-validation, and coarse-to-fine parameter tuning), and report its best performance.

Algorithm	Precision	Recall	F1
WEBRE	0.848	0.734	0.787
SNE	0.850	0.080	0.146

Table 4. Pairwise precision/recall/F1 of WEBRE and SNE.

Table 4 shows that WEBRE outperforms SNE significantly in pairwise recall while having similar precision. There are two reasons. First, WEBRE makes use of several corpus-level semantic sources extracted from the corpus for clustering entities and phrases while SNE uses only features in the triple store. These semantic resources significantly reduced data sparseness. Examination of the output shows that SNE is unable to group many triples from the same generally-recognized fine-grained relations. For example, SNE placed relation instances *<Barbara, grow up in, Santa Fe>* and *<John, be raised mostly in, Santa Barbara>* into 2 different clusters because the arguments and phrases do not share features nor could be grouped by SNE’s mutual clustering. In contrast, WEBRE groups them together. Second, SNE assumes a relation phrase to be in exactly one cluster. For example, SNE placed *be part of* in the phrase cluster *be city of* and failed to place it in another cluster *be subsidiary of*. This limits SNE’s ability to placing relation instances with polysemous phrases into correct relation clusters.

It should be emphasized that we use pairwise precision and recall in table 4 to be consistent with the original SNE paper. Pairwise metrics are much more sensitive than instance-level metrics, and penalize recall exponentially in the worst case<sup>11</sup> if an algorithm incorrectly splits a coherent cluster; therefore the absolute pairwise recall difference

<sup>11</sup> Pairwise precision and recall are calculated on all pairs that are in the same cluster, thus are very sensitive. For example, if an algorithm incorrectly split a cluster of size  $N$  to a smaller main cluster of size  $N/2$  and some constant-size clusters, pairwise recall could drop to as much as  $1/4$  of its original value.

should not be interpreted as the same as the instance-level recall reported in previous experiments. On 1 million triples, WEBRE generates 12179 triple clusters with an average size<sup>12</sup> of 13 while SNE generate 53270 clusters with an average size 5.1. In consequence, pairwise recall drops significantly. Nonetheless, at above 80% pairwise precision, it demonstrates that WEBRE can group more related triples by adding rich semantics harvested from the web and employing a more general treatment of polysemous relation phrases. On 1M triples, WEBRE finished in 40 minutes, while the run time of SNE varies from 3 hours to a few days.

## 6 Conclusion

We present a fully unsupervised algorithm WEBRE for large-scale open-domain relation extraction. WEBRE explicitly handles polysemy relations and achieves a significant improvement on recall by incorporating rich corpus-based semantic resources. Experiments on a large data set show that it can extract a very large set of high-quality relations.

# Forest Reranking through Subtree Ranking

Richárd Farkas, Helmut Schmid

Institute for Natural Language Processing

University of Stuttgart

{farkas, schmid}@ims.uni-stuttgart.de

## Abstract

We propose the *subtree ranking* approach to *parse forest reranking* which is a generalization of current perceptron-based reranking methods. For the training of the reranker, we extract competing local subtrees, hence the training instances (candidate subtree sets) are very similar to those used during beam-search parsing. This leads to better parameter optimization. Another chief advantage of the framework is that arbitrary learning to rank methods can be applied. We evaluated our reranking approach on German and English phrase structure parsing tasks and compared it to various state-of-the-art reranking approaches such as the perceptron-based forest reranker. The subtree ranking approach with a Maximum Entropy model significantly outperformed the other approaches.

## 1 Introduction

**Reranking** has become a popular technique for solving various structured prediction tasks, such as phrase-structure (Collins, 2000) and dependency parsing (Hall, 2007), semantic role labeling (Toutanova et al., 2008) and machine translation (Shen et al., 2004). The idea is to (re)rank candidates extracted by a base system exploiting a rich feature set and operating at a global (usually sentence) level. Reranking achieved significant gains over the base system in many tasks because it has access to information/features which are not computable in the base system. Reranking also outperforms discriminative approaches which try to handle the entire candidate universe (cf. Turian et al.

(2006)) because the base system effectively and efficiently filters out many bad candidates and makes the problem tractable.

The standard approach for reranking is the  $n$ -best list ranking procedure, where the base system extracts its top  $n$  global-level candidates with associated goodness scores that define an initial ranking. Then the task is to rerank these candidates by using a rich feature set. The bottleneck of this approach is the small number of candidates considered. Compared to  $n$ -best lists, packed parse forests encode more candidates in a compact way. **Forest reranking** methods have been proposed, which can exploit the richer set of candidates and they have been successfully applied for phrase-structure (Huang, 2008), dependency (Hayashi et al., 2011) parsing and machine translation (Li and Khudanpur, 2009) as well.

Huang (2008) introduced the **perceptron-based forest reranking** approach. The core of the algorithm is a beam-search based decoder operating on the packed forest in a bottom-up manner. It follows the assumption that the feature values of the whole structure are the sum of the feature values of the local elements and they are designed to the usage of the perceptron update. Under these assumptions a 1-best Viterbi or beam-search decoder can be efficiently employed at parsing and training time. During training, it decodes the 1-best complete parse then it makes the perceptron update against the oracle parse, i.e. the perceptron is trained at the global (sentence) level.

We propose here a **subtree ranker** approach which can be regarded as a generalization of this for-

est reranking procedure. In contrast to updating on a single (sub)tree per sentence using only the 1-best parse (perceptron-based forest reranking), the subtree ranker exploits subtrees of all sizes from a sentence and trains a (re)ranker utilising several derivations of the constituent in question. During parsing we conduct a beam-search extraction by asking the ranker to select the  $k$  best subtrees among the possible candidates of each forest node. The chief motivation for this approach is that in this way, training and prediction are carried out on similar local candidate lists which we expect to be favorable to the learning mechanism. We empirically prove that the trained discriminative rankers benefit from having access to a larger amount of subtree candidates. Moreover, in this framework any kind of learning to rank methods can be chosen as ranker, including pair-wise and list-wise classifiers (Li, 2011).

The contributions of this paper are the following:

- We extend the perceptron-based forest rerankers to the subtree ranker forest reranking framework which allows to replace the perceptron update by any kind of learning to rank procedure.
- We report experimental results on German and English phrase-structure parsing comparing subtree rerankers to various other rerankers showing a significant improvement over the perceptron-based forest reranker approach.

## 2 Related Work

Our method is closely related to the work of Huang (2008), who introduced forest-based reranking for phrase structure parsing. The proposed framework can be regarded as an extension of this approach. It has several advantages compared with the perceptron-based forest reranker. In this paper we focus on the most important one – and briefly discuss two others in Section 5 – which is enabling the use of any kind of learning to rank approaches. While the perceptron is fast to train, other machine learning approaches usually outperform it. Most of the existing learning to rank approaches are built on linear models and evaluate the candidates independently of each other (such as MaxEnt (Charniak and Johnson, 2005), SVMRank (Joachims, 2002), SoftRank (Guiver and Snelson, 2008)). Thus the choice

of the learning method does not influence parsing time. We believe that the real bottleneck of parsing applications is parsing time and not training time. On the other hand, they can learn a better model (at the cost of higher training time) than the Perceptron. In theory, we can imagine learning to rank approaches which can not be reduced to the individual scoring of candidates at prediction time, for instance a decision tree-based pairwise ranker. Although such methods would also fit into the general subtree framework, they are not employed in practice (Li, 2011).

The subtree ranking approach is a generalization of the perceptron-based approach. If the ranking algorithm is the Averaged Perceptron, the parsing algorithm reduces to perceptron-based forest parsing. If the “selection strategy” utilizes the base system ranking and training starts with a filtering step which keeps only candidate sets from the root node of the forest we get the offline version of the training procedure of the perceptron-based forest reranker of Huang (2008).

As our approach is based on local ranking (local update in the online learning literature), it is highly related to early update which looks for the first local decision point where the oracle parse falls out from the beam. Early update was introduced by Collins and Roark (2004) for incremental parsing and adopted to forest reranking by Wang and Zong (2011).

Besides phrase structure parsing, the forest reranking approach was successfully applied for dependency parsing as well. Hayashi et al. (2011) introduced a procedure where the interpolation of a generative and a forest-based discriminative parser is exploited.

From the algorithmic point of view, our approach is probably most closely related to Searn (Daumé et al., 2009) and Magerman (1995) as we also employ a particular machine learned model for a sequence of local decisions. The topological order of the parse forest nodes can form the “sequence of choices” of Searn. The biggest differences between our approach and Searn are that we propose an approach employing beam search and the “policy” is a ranker in our framework instead of a multiclass classifier as there are no “actions” here, instead we have to choose from candidate sets in the forest reranking

framework. In a wider sense, our approach can be regarded – like Searn – as an Inverse Reinforcement Learning approach where “one is given an environment and a set of trajectories and the problem is to find a reward function such that an agent acting optimally with respect to the reward function would follow trajectories that match those in the training set” (Neu and Szepesvári, 2009). Neu and Szepesvári (2009) introduced the top-down parsing Markov Decision Processes and experiment with several inverse reinforcement learning methods. The forest reranking approaches are bottom-up parsers which would require a new (non-straightforward) definition of a corresponding Markov Decision Process.

### 3 Subtree Ranking-based Forest Reranking

A **packed parse forest** is a compact representation of possible parses for a given sentence. A forest has the structure of a hypergraph, whose nodes  $V$  are the elementary units of the underlying structured prediction problem and the hyperedges  $E$  are the possible deductive steps from the nodes. In this paper we experimented with phrase-structure parse reranking. In this framework *nodes* correspond to constituents spanning a certain scope of the input sentence and a *hyperedge*  $e$  links a parent node  $head(e)$  to its children  $tails(e)$  (i.e. a hyperedge is a CFG rule in context).

The forest is extracted from the chart of a base PCFG parser, usually employing a heavy pruning strategy. Then the goal of a forest reranker is to find the best parse of the input sentence exploiting a feature representation of (sub)trees.

We sketch the **parsing** procedure of the subtree ranker in Algorithm 1. It is a bottom-up beam-search parser operating on the hypergraph. At each node  $v$  we store the  $k$  best subtrees  $S(v)$  headed by the node. The  $S(v)$  lists contain the  $k$  top-ranked subtrees by the ranker  $R$  among the candidates in the beam. The set of candidate subtrees at a node is the union of the candidates at the different hyperedges. The set of candidate subtrees at a certain hyperedge, in turn, is formed by the Cartesian product  $\otimes S(v_i)$  of the  $k$ -best subtrees stored at the child nodes  $v_i$ . The final output of forest ranking is the 1-best subtree headed by the goal node  $S_1(v_{goal})$ .

---

#### Algorithm 1 Subtree Ranking

---

**Require:**  $\langle V, E \rangle$  forest,  $R$  ranker  
**for all**  $v \in V$  in bottom-up topological order **do**  
     $C \leftarrow \emptyset$   
    **for all**  $e \in E, head(e) = v$  **do**  
         $C \leftarrow C \cup (\otimes S(v_i)), v_i \in tails(e)$   
    **end for**  
     $S(v) \leftarrow R_k(C)$   
**end for**  
**return**  $S_1(v_{goal})$

---

For **training** the ranker we propose to extract local candidate lists from the forests which share the characteristics of the candidates at parsing time. Algorithm 2 depicts the training procedure of the subtree ranker.

As forests sometimes do not contain the gold standard tree, we extract an oracle tree instead, which is the closest derivable tree in the forest to the gold standard tree (Collins, 2000). Then we optimize the parser for ranking the oracle tree at the top. This procedure is beneficial to training since the objective is a reachable state. In Algorithm 2, we extract the oracle tree from the parses encoded in the forest  $\langle V, E \rangle_i$  for the  $i$ th training sentence, which is the tree with the highest F-score when compared to the gold standard tree  $y_i$ . For each of the training sentences we calculate the oracle subtrees for each node  $\{O_v\}$  of the corresponding parse forest. We follow the dynamic programming approach of Huang (2008) for the extraction of the forest oracle. The goal of this algorithm is to extract the full oracle tree, but as a side product it calculates the best possible subtree for all nodes including the nodes outside of the full oracle tree as well.

After computing the oracle subtrees, we crawl the forests bottom-up and extract a training instance  $\langle C, O_v \rangle$  at each node  $v$  which consists of the candidate set  $C$  and the oracle  $O_v$  at that node. The creation of candidate lists is exactly the same as it was at parsing time. Then we create training instances from each of the candidate lists and form the set of subtrees  $S(v)$  which is stored for candidate extraction at the higher levels of the forest (later steps in the training instance extraction).

A crucial design question is how to form the  $S(v)$  sets during training, which is the task of the *selection*

---

**Algorithm 2** Subtree Ranker Training

---

**Require:**  $\{\langle V, E \rangle_i, y_i\}_1^N$ ,  $SS$  selection strategy  
 $T \leftarrow \emptyset$   
**for all**  $i \leftarrow 1 \dots N$  **do**  
     $O \leftarrow$  oracle extractor( $\langle V, E \rangle_i, y_i$ )  
    **for all**  $v \in V_i$  in bottom-up topological order **do**  
         $C \leftarrow \emptyset$   
        **for all**  $e \in E, \text{head}(e) = v$  **do**  
             $C \leftarrow C \cup (\otimes S(v_j)), v_j \in \text{tails}(e)$   
        **end for**  
         $T \leftarrow T \cup \langle C, O_v \rangle$   
         $S(v) \leftarrow SS(C, O_v)$   
    **end for**  
**end for**  
 $R \leftarrow$  train reranker( $T$ )  
**return**  $R$

---

*strategy SS.* One possible solution is to keep the  $k$  best oracle subtrees, i.e. the  $k$  subtrees closest to the gold standard parse, which is analogous to using the gold standard labels in Maximum Entropy Markov Models for sequence labeling problems (we refer this selection strategy as ‘oracle subtree’ later on). The problem with this solution is that if the rankers have been trained on the oracle subtrees potentially leads to a suboptimal performance as the outputs of the ranker at prediction time are noisy. Note that this approach is not a classical beam-based decoding anymore as the “beam” is maintained according to the oracle parses and there is no model which influences that. An alternative solution – beam-based decoding – is to use a ranker model to extract the  $S(v)$  set in training time as well. In the general reranking approach, we assume that the ranking of the base parser is reliable. So we store the  $k$  best subtrees according to the base system in  $S(v)$  (the ‘base system ranking’ selection strategy). Note that the general framework keeps this question open and lets the implementations define a selection strategy  $SS$ .

After extracting the training instances  $T$  we can train an arbitrary ranker  $R$  offline. Note that the extraction of candidate lists is exactly the same in Algorithm 1 and 2 while the creation of  $S_v$  can be different.

## 4 Experiments

We carried out experiments on English and German phrase-structure reranking. As evaluation metric, we used the standard `evalb` implementation of PARSEVAL on every sentence without length limitation and we start from raw sentences without gold standard POS tagging. As the grammatical functions of constituents are important from a downstream application point of view – especially in German – we also report PARSEVAL scores on the conflation of constituent labels and grammatical functions. These scores are shown in brackets in Table 2.

### 4.1 Datasets

We used the Wall Street Journal subcorpus of the Ontonotes v4.0 corpus (Weischedel et al., 2011)<sup>1</sup> for English. As usual sections 2-21, 23 and 24 served as training set (30,060 sentences), test set (1,640 sentences), and development set (1,336 sentences), respectively. Using the Ontonotes version enables us to assess parser robustness. To this end, we evaluated our models also on the weblog subcorpus of the Ontonotes v4.0 corpus which consists of 15,103 sentences.

For German we used the Tiger treebank (Brants et al., 2002). We take the first 40,474 sentences of the Tiger treebank as training data, the next 5,000 sentences as development data, and the last 5,000 sentences as test data.

### 4.2 Implementation of the Generic Framework

We investigate the Averaged Perceptron and a Maximum Entropy ranker as the reranker  $R$  in the subtree ranking framework. The Maximum Entropy ranker model is optimized with a loss function which is the negative log conditional likelihood of the oracle trees relative to the candidate sets. In the case of multiple oracles we optimize for the sum of the oracle trees’ posterior probabilities (Charniak and Johnson, 2005).

In our setup the parsing algorithm is identical to the perceptron-based forest reranker of Huang (2008) because both the Averaged Perceptron and the Maximum Entropy rankers score the local subtree candidates independently of each other using

---

<sup>1</sup>Note that it contains less sentences and a slightly modified annotation schema than the Penn Treebank.

a linear model. There is no need to compute the global normalization constant of the Maximum Entropy model because we only need the ranking and not the probabilities. Hence the difference is in how to train the ranker model.

We experimented with both the 'oracle subtree' and the 'base system ranking' selection strategies (see Section 3).

### 4.3 Five Methods for Forest-based Reranking

We conducted comparative experiments employing the proposed subtree ranking approach and state-of-the-art methods for forest reranking. Note that they are equivalent in parsing time as each of them uses beam-search with a linear classifier, on the other hand they are radically different in their training.

- The original perceptron-based forest reranker of Huang (2008) ('perceptron with global training').
- The same method employing the early-update updating mechanism instead of the global update. Wang and Zong (2011) reported a significant gain using this update over the standard global update ('perceptron with early update').
- Similar to learning a perceptron at the global level and then applying it at local decisions, we can train a Maximum Entropy ranker at the global level utilizing the  $n$ -best full parse candidates of the base parser, then use this model for local decision making. So we train the standard  $n$ -best rerankers (Charniak and Johnson, 2005) and then apply them in the beam-search-based Viterbi parser (' $n$ -best list training'). Applying the feature weights adjusted in this approach in the forest-based decoding outperforms the standard  $n$ -best list decoding by an F-score of 0.3 on the German dataset.
- The subtree ranker method using the Averaged Perceptron reranker. This is different from the 'perceptron with global training' as we conduct updates at every local decision point and we do offline training ('subtree ranking by AvgPer').
- The subtree ranker method using Maximum Entropy training ('subtree ranking by MaxEnt').

We (re)implemented these methods and used the same forests and the same feature sets for the comparative experiments.

### 4.4 Implementation Details

We used the first-stage **PCFG parser** of Charniak and Johnson (2005) for English and BitPar (Schmid, 2004) for German. BitPar employs a grammar engineered for German (for details please refer to Farkas et al. (2011)). These two parsers are state-of-the-art PCFG parsers for English and German, respectively. For German the base parser and the reranker operate on the conflation of constituent labels and grammatical functions. For English, we used the forest extraction and pruning code of Huang (2008). The pruning removes hyperedges where the difference between the cost of the best derivation using this hyperedge and the cost of the globally best derivation is above some threshold. For German, we used the pruned parse forest of Bitpar (Schmid, 2004). After computing the posterior probability of each hyperedge given the input sentence, Bitpar prunes the parse forest by deleting hyperedges whose posterior probability is below some threshold. (We used the threshold 0.01).

We employed an Averaged Perceptron (for 'perceptron with global training', 'perceptron with early update' and 'subtree ranking by AvgPer') and a Maximum Entropy **reranker** (for 'subtree ranking by MaxEnt' and ' $n$ -best list training'). For the perceptron reranker, we used the Joshua implementation<sup>2</sup>. The optimal number of iterations was determined on the development set. For the Maximum Entropy reranker we used the RankMaxEnt implementation of the Mallet package (McCallum, 2002) modified to use the objective function of Charniak and Johnson (2005) and we optimized the L2 regularizer coefficient on the development set.

The beam-size were set to 15 (the value suggested by Huang (2008)) during parsing and the training of the 'perceptron with global training' and 'perceptron with early update' models. We used  $k = 3$  for training the 'subtree ranking by AvgPer' and 'subtree ranking by MaxEnt' rankers (see Section 5 for a discussion on this).

In the English experiments, we followed (Huang,

---

<sup>2</sup><http://joshua.sourceforge.net/Joshua/>

	Tiger test	WSJ dev	WSJ test	WB
base system (1-best)	76.84 (65.91)	89.29	88.63	81.86
oracle tree	90.66 (80.38)	97.31	97.30	94.18

Table 1: The lower and upper bounds for rerankers on the four evaluation datasets. The numbers in brackets refers to evaluation with grammatical function labels on the German dataset.

	Tiger test	WSJ dev	WSJ test	WB
perceptron with global training	78.39 (67.79)	90.58	89.60	82.87
perceptron with early update	78.83 (68.05)	90.81 <sup>†</sup>	90.01	83.03 <sup>†</sup>
<i>n</i> -best list training	78.75 (68.04)	90.89	90.11	83.55
subtree ranking by AvgPer	78.54 <sup>†</sup> (67.97 <sup>†</sup> )	90.65 <sup>†</sup>	89.97	83.04 <sup>†</sup>
subtree ranking by MaxEnt	79.36 (68.72)	91.14	90.32	83.83

Table 2: The results achieved by various forest rerankers. The difference between the scores marked by <sup>†</sup> and the 'perceptron with global training' were not statistically significant with  $p < 0.005$  according to the McNemar test. All other results are statistically different from this baseline.

2008) and selectively re-implemented **feature templates** from (Collins, 2000) and Charniak and Johnson (2005). For German we re-implemented the feature templates of Versley and Rehbein (2009) which is the state-of-the-art feature set for German. It consists of features constructed from the lexicalized parse tree and its typed dependencies along with features based on external statistical information (such as the clustering of unknown words according to their context of occurrence and PP attachment statistics gathered from the automatically POS tagged DE-WaC corpus, a 1.7G words sample of the German-language WWW). We filtered out rare features which occurred in less than 10 forests (we used the same non-tuned threshold for the English and German training sets as well).

We also re-implemented the oracle extraction procedure of Huang (2008) and extended its convolution and translation operators for using the base system score as tie breaker.

## 4.5 Results

Table 1 shows the results of the 1-best parse of the base system and the oracle scores – i.e. the **lower and upper bounds** for the rerankers – for the four evaluation datasets used in our experiments. The German and the weblog datasets are more difficult for the parsers.

The following table summarizes the characteristics of the subtree ranker’s training sample of the

German and English datasets by employing the 'oracle subtree' selection strategy:

	Tiger train	WSJ train
#candidate lists	266,808	1,431,058
avg. size of cand. lists	3.2	5.7
#features before filtering	2,683,552	22,164,931
#features after filtering	94,164	858,610

Table 3: The sizes of the subtree ranker training datasets at  $k = 3$ .

Using this selection strategy the training dataset is smaller than the training dataset of the *n*-best list rankers – where offline trainers are employed as well – as the total number of candidates is similar (and even less in the Tiger corpus) while there are fewer firing features at the subtrees than at full trees.

Table 2 summarizes the results achieved by various forest rerankers. Both subtree rankers used the oracle subtrees as the selection strategy of Algorithm 2. The 'subtree ranking by MaxEnt' method significantly outperformed the perceptron-based forest reranking algorithms at each of the datasets and seems to be more robust as its advantage on the out-domain data 'WB' is higher compared with the in-domain 'WSJ' datasets. The early update improves the perceptron based forest rerankers which is in line with the results reported by Wang and Zong (2011). The '*n*-best list training' method works surprisingly well. It outperforms both perceptron-based forest

rerankers on the English datasets (while achieving a smaller F-score than the perceptron with early update on the Tiger corpus) which demonstrates the potential of utilizing larger candidate lists for discriminative training of rerankers. The comparison of the 'subtree ranking by AvgPer' row and the 'subtree ranking by MaxEnt' row shows a clear advantage of the Maximum Entropy training mechanism over the Averaged Perceptron.

Besides the 'oracle subtree' **selection strategy** we also experimented with the 'base system ranking' selection strategy with subtree Maximum Entropy ranker. Table 4 compares the accuracies of the two strategies. The difference between the two strategies varies among datasets. In the German dataset, they are competitive and the prediction of grammatical functions benefits from the 'base system ranking' strategy, while it performs considerably worse at the English datasets.

	Tiger test	WSJ test	WB
oracle SS	79.36 (68.72)	90.32	83.83
base sys SS	79.34 (68.84)	89.97	83.34

Table 4: The results of the two selection strategies. Using the oracle trees proved to be better on each of the datasets.

Extracting candidate lists from each of the local decision points might seem to be redundant. To gain some insight into this question, we investigated the effect of training instance filtering strategies on the Tiger treebank. We removed the training instances from the training sample  $T$  where the F-score of the oracle (sub)tree against the gold standard tree is less than a certain threshold (this data selection procedure was inspired by Li and Khudanpur (2008)). The idea behind this **data selection** is to eliminate bad training examples which might push the learner into the wrong direction. Figure 1 depicts the results on the Tiger treebank as a function of this data selection threshold.

With this data selection strategy we could further gain 0.22 F-score percentage points achieving 79.58 (68.87) and we can conclude that omitting candidate sets far from the gold-standard tree helps training. Figure 1 also shows that too strict filtering hurts the performance. The result with threshold=90 is worse than the result without filtering. We should note that similar data selection methods can be applied

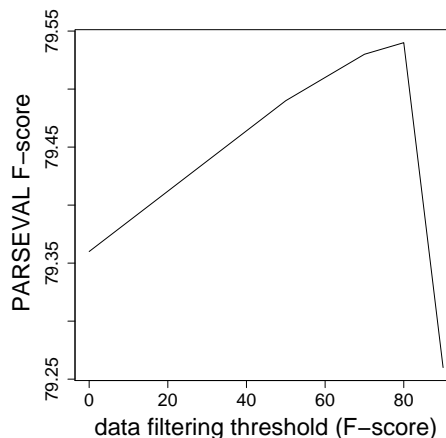

Figure 1: The effect of data selection on the Tiger test set.

to each of the baseline systems and the comparison to them would be fair with conducting that. Thus we consider our results without data selection to be final.

## 5 Discussion

We experimentally showed in the previous section that the subtree forest reranking approach with Maximum Entropy models significantly outperforms the perceptron-based forest reranking approach. This improvement must be the result of differences in the training algorithms because there is no difference between the two approaches at parse time, as we discussed in Section 4.2.

There are two sources of these improvements. (i) We use local subtrees as training instances instead of using the global parses exclusively. The most important difference between the training of the perceptron-based forest reranker and the subtree forest reranker is that we train on subtrees (extract candidate sets) outside of the Viterbi parses as well, i.e. our intuition is that the training of the discriminative model can benefit from seeing good and bad subtrees far from the best parses as well. (ii) The subtree ranker framework enables us to employ the Maximum Entropy ranker on multiple candidates, which usually outperforms the Averaged Perceptron.

The results of Table 2 can be considered as two paths from the 'perceptron with global training' to the 'subtree ranking by MaxEnt' applying these

sources of improvements. If we use (i) and stay with the Averaged Perceptron as learning algorithm we get 'subtree ranking by AvgPer'. If we additionally replace the Averaged Perceptron by Maximum Entropy – i.e. follow (ii) – we arrive at 'subtree ranking by MaxEnt'. On the other hand, the '*n*-best training' uses global trees and Maximum Entropy for training, so the reason of the difference between 'perceptron with global training' and '*n*-best training' is (ii). Then we arrive at 'subtree ranking by MaxEnt' by (i). This line of thoughts and the figures of Table 2 indicate that the added value of (i) and (ii) are similar in magnitude.

## 5.1 Error Analysis

For understanding the added value of the proposed subtree ranking method, we manually investigated sentences from the German development set and compared the parses of the 'perceptron with global training' with the 'subtree ranking by MaxEnt'. We could not find any linguistic phenomena which was handled clearly better by the subtree ranker<sup>3</sup>, but it made considerably more fixes than errors in the following cases:

- the attachment of adverbs,
- the unary branching verbal phrases and
- extremely short sentences which does not contain any verb (fragments).

## 5.2 Novel Opportunities with the Subtree Ranking Framework

A generalization issue of the subtree ranking approach is that it allows to use **any kind of feature representation and arbitrary aggregation** of local features. The basic assumption of training on the global (sentence) level in the perceptron reranking framework is that the feature vector of a subtree is the sum of the feature vectors of the children and the features extracted from the root of the subtree in question. This decomposability assumption provides a fine framework in the case of binary features which fire if a certain linguistic phenomenon occurs. On the other hand, this is not straightforward in the

<sup>3</sup>We believe that this might be the case only if we would introduce new information (e.g. features) for the system.

presence of real valued features. For example, Verley and Rehbein (2009) introduce real-valued features for supporting German PP-attachment recognition – the mutual information of noun and preposition co-occurrence estimated from a huge unlabeled corpus – and this single feature template (about 80 features) could achieve a gain of 1 point in phrase structure parsing accuracy while the same improvement can be achieved by several feature templates and millions of binary features. The aggregation of such feature values can be different from summing, for instance the semantics of the feature can demand averaging, minimum, maximum or introducing new features etc. Another opportunity for extending current approaches is to employ utility functions on top of the sum of the binary feature values. Each of these extensions fits into the proposed framework.

The subtree ranking framework also enables the usage of **different models at different kinds of nodes**. For example, different models can be trained for ranking subtrees headed by noun phrases and for verb phrases. This is not feasible in the perceptron-based forest ranker which sums up features and updates feature weights at the sentence level while the ranker *R* in Algorithm 2 can refer to several models because we handle local decisions separately. This approach would not hurt parsing speed as one particular model is asked at each node, but it multiplies memory requirements. This is an approach which the subtree ranking framework allows, but which would not fit to the global level updates of the perceptron forest rerankers.

As a first step in this direction of research we experimented with training three different Maximum Entropy models using the same feature representation, the first only on candidate lists extracted from noun phrase nodes, the second on verb phrase nodes and the third on all nodes (i.e. the third model is equivalent to the 'subtree MaxEnt' model). Then at prediction time, we ask that model (out of the three) which is responsible for ranking the candidates of the current type of node. This approach performed worse than the single model approach achieving an F-scores of 79.24 (68.46) on the Tiger test dataset. This negative results – compared with 79.36 (68.72) achieved by a single model – is probably due to data sparsity problems. The amount of training samples for noun phrases is 6% of the full training sample

and it seems that a better model can be learned from a much bigger but more heterogeneous dataset.

### 5.3 On the Efficiency of Subtree Ranking

In subtree ranking, we extract a larger number of training instances (candidate lists) than the perceptron-based approach which extracts exactly one instance from a sentence. Moreover, the candidate lists are longer than the perceptron-based approach (where 2 “candidates” are compared against each other). Training on this larger set (refer Table 3 for concrete figures) consumes more space and time.

In our implementation, we keep the whole training dataset in the memory. With this implementation the whole training process (feature extraction, candidate extraction and training the Maximum Entropy ranker) takes 3 hours and uses 10GB of memory at  $k = 1$  and it takes 20 hours and uses 60GB of memory at  $k = 3$  ((Huang, 2008) reported 5.3 and 27.3 hours at beam-sizes of 1 and 15 respectively but it used only 1.2GB of memory). The in-depth investigation of the effect of  $k$  is among our future plans.

## 6 Conclusions

We presented a subtree ranking approach to parse forest reranking, which is a generalization of current reranking methods. The main advantages of our approach are: (i) The candidate lists used during training are very similar to those used during parsing, which leads to better parameter optimization. (ii) Arbitrary ranking methods can be applied in our approach. (iii) The reranking models need not to be decomposable.

We evaluated our parse reranking approach on German and English phrase structure parsing tasks and compared it to various state-of-the-art reranking approaches such as the perceptron-based forest reranker (Huang, 2008). The subtree reranking approach with a Maximum Entropy model significantly outperformed the other approaches.

We conjecture two reasons for this result: (i) By training on all subtrees instead of Viterbi parses or  $n$ -best parses only, we use the available training data more effectively. (ii) The subtree ranker framework allows us to use a standard Maximum Entropy learner in parse-forest training instead of the Perceptron, which is usually superior.

## Acknowledgements

We thank Liang Huang to provide us the modified version of the Charniak parser, which output a packed forest for each sentence along with his forest pruning code.

This work was funded by the Deutsche Forschungsgemeinschaft grant SFB 732, project D4.

## Abstract

Constituency parser performance is primarily interpreted through a single metric, F-score on WSJ section 23, that conveys no linguistic information regarding the remaining errors. We classify errors within a set of linguistically meaningful types using tree transformations that repair groups of errors together. We use this analysis to answer a range of questions about parser behaviour, including what linguistic constructions are difficult for state-of-the-art parsers, what types of errors are being resolved by rerankers, and what types are introduced when parsing out-of-domain text.

## 1 Introduction

Parsing has been a major area of research within computational linguistics for decades, and constituent parser F-scores on WSJ section 23 have exceeded 90% (Petrov and Klein, 2007), and 92% when using self-training and reranking (McClosky et al., 2006; Charniak and Johnson, 2005). While these results give a useful measure of overall performance, they provide no information about the nature, or relative importance, of the remaining errors.

Broad investigations of parser errors beyond the PARSEVAL metric (Abney et al., 1991) have either focused on specific parsers, e.g. Collins (2003), or have involved conversion to dependencies (Carroll et al., 1998; King et al., 2003). In all of these cases, the analysis has not taken into consideration how a set of errors can have a common cause, e.g. a single mis-attachment can create multiple node errors.

We propose a new method of error classification using tree transformations. Errors in the parse

tree are repaired using subtree movement, node creation, and node deletion. Each step in the process is then associated with a linguistically meaningful error type, based on factors such as the node that is moved, its siblings, and parents.

Using our method we analyse the output of thirteen constituency parsers on newswire. Some of the frequent error types that we identify are widely recognised as challenging, such as prepositional phrase (PP) attachment. However, other significant types have not received as much attention, such as clause attachment and modifier attachment.

Our method also enables us to investigate where reranking and self-training improve parsing. Previously, these developments were analysed only in terms of their impact on F-score. Similarly, the challenge of out-of-domain parsing has only been expressed in terms of this single objective. We are able to decompose the drop in performance and show that a disproportionate number of the extra errors are due to coordination and clause attachment.

This work presents a comprehensive investigation of parser behaviour in terms of linguistically meaningful errors. By applying our method to multiple parsers and domains we are able to answer questions about parser behaviour that were previously only approachable through approximate measures, such as counts of node errors. We show which errors have been reduced over the past fifteen years of parsing research; where rerankers are making their gains and where they are not exploiting the full potential of k-best lists; and what types of errors arise when moving out-of-domain. We have released our system<sup>1</sup> to enable future work to apply our methodology.

## 2 Background

Most attempts to understand the behaviour of constituency parsers have focused on overall evaluation metrics. The three main methods are intrinsic evaluation with PARSEVAL, evaluation on dependencies extracted from the constituency parse, and evaluation on downstream tasks that rely on parsing.

Intrinsic evaluation with PARSEVAL, which calculates precision and recall over labeled tree nodes, is a useful indicator of overall performance, but does not pinpoint which structures the parser has most difficulty with. Even when the breakdown for particular node types is presented (e.g. Collins, 2003), the interaction between node errors is not taken into account. For example, a VP node could be missing because of incorrect PP attachment, a coordination error, or a unary production mistake. There has been some work that addresses these issues by analysing the output of constituency parsers on linguistically motivated error types, but only by hand on sets of around 100 sentences (Hara et al., 2007; Yu et al., 2011). By automatically classifying parse errors we are able to consider the output of multiple parsers on thousands of sentences.

The second major parser evaluation method involves extraction of grammatical relations (King et al., 2003; Briscoe and Carroll, 2006) or dependencies (Lin, 1998; Briscoe et al., 2002). These metrics have been argued to be more informative and generally applicable (Carroll et al., 1998), and have the advantage that the breakdown over dependency types is more informative than over node types. There have been comparisons of multiple parsers (Foster and van Genabith, 2008; Nivre et al., 2010; Cer et al., 2010), as well as work on finding relations between errors (Hara et al., 2009), and breaking down errors by a range of factors (McDonald and Nivre, 2007). However, one challenge is that results for constituency parsers are strongly influenced by the dependency scheme being used and how easy it is to extract the dependencies from a given parser’s output (Clark and Hockenmaier, 2002). Our approach does not have this disadvantage, as we analyse parser output directly.

The third major approach involves extrinsic evaluation, where the parser’s output is used in a downstream task, such as machine translation (Quirk

and Corston-Oliver, 2006), information extraction (Miyao et al., 2008), textual entailment (Yuret et al., 2010), or semantic dependencies (Dridan and Oepen, 2011). While some of these approaches give a better sense of the impact of parse errors, they require integration into a larger system, making it less clear where a given error originates.

The work we present here differs from existing approaches by directly and automatically classifying errors into meaningful types. This enables the first very broad, yet detailed, study of parser behaviour, evaluating the output of thirteen parsers over thousands of sentences.

## 3 Parsers

Our evaluation is over a wide range of PTB constituency parsers and their variants from the past fifteen years. For all parsers we used the publicly available version, with the standard parameter settings.

**Berkeley** (Petrov et al., 2006; Petrov and Klein, 2007). An unlexicalised parser with a grammar constructed with automatic state splitting.

**Bikel** (2004) implementation of Collins (1997).

**BUBS** (Dunlop et al., 2011; Bodenstab et al., 2011). A ‘grammar-agnostic constituent parser,’ which uses a Berkeley Parser grammar, but parses with various pruning techniques to improve speed, at the cost of accuracy.

**Charniak** (2000). A generative parser with a maximum entropy-inspired model. We also use the reranker (Charniak and Johnson, 2005), and the self-trained model (McClosky et al., 2006).

**Collins** (1997). A generative lexicalised parser, with three models, a base model, a model that uses subcategorisation frames for head words, and a model that takes into account traces.

**SSN** (Henderson, 2003; Henderson, 2004). A statistical left-corner parser, with probabilities estimated by a neural network.

**Stanford** (Klein and Manning, 2003a; Klein and Manning, 2003b). We consider both the unlexicalised PCFG parser (-U) and the factored parser (-F), which combines the PCFG parser with a lexicalised dependency parser.

System	F	P	R	Exact	Speed
ENHANCED TRAINING / SYSTEMS					
Charniak-SR	92.07	92.44	91.70	44.87	1.8
Charniak-R	91.41	91.78	91.04	44.04	1.8

Collins-1	87.09	87.29	86.90	30.35	3.3
Stanford-L	86.42	86.35	86.49	27.65	0.7
Stanford-U	85.78	86.48	85.09	28.35	2.7

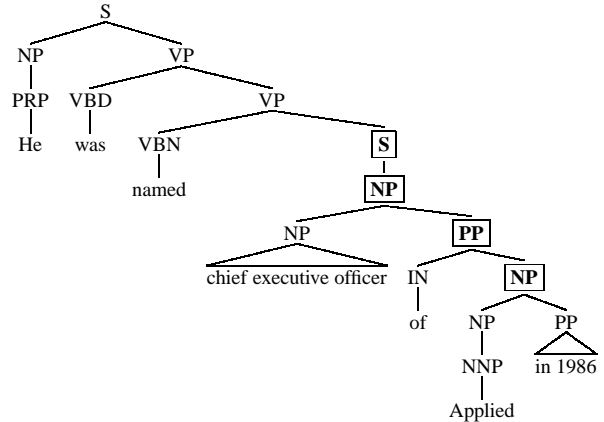

Table 1: PARSEVAL results on WSJ section 23 for the parsers we consider. The columns are F-score, precision, recall, exact sentence match, and speed (sents/sec). Coverage was left out as it was above 99.8% for all parsers. In the ENHANCED TRAINING / SYSTEMS section we include the Charniak parser with reranking (R), with a self-trained model (S), and both (SR).

Table 1 shows the standard performance metrics, measured on section 23 of the WSJ, using all sentences. Speeds were measured using a Quad-Core Xeon CPU (2.33GHz 4MB L2 cache) with 16GB of RAM. These results clearly show the variation in parsing performance, but they do not show which constructions are the source of those variations.

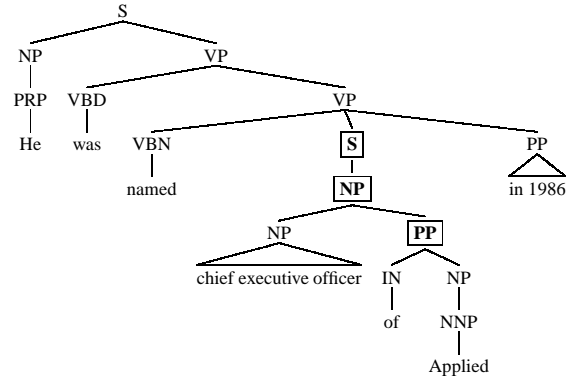

#### 4 Error Classification

While the statistics in Table 1 give a sense of overall parser performance they do not provide linguistically meaningful intuition for the source of remaining errors. Breaking down the remaining errors by node type is not particularly informative, as a single attachment error can cause multiple node errors, many of which are for unrelated node types. For example, in Figure 1 there is a PP attachment error that causes seven bracket errors (extra S, NP, PP, and NP, missing S, NP, and PP). Determining that these correspond to a PP attachment error from just the labels of the missing and extra nodes is difficult. In contrast, the approach we describe below takes into consideration the relations between errors, grouping them into linguistically meaningful sets.

We classify node errors in two phases. First, we

(a) Parser output

(b) Gold tree

Figure 1: Grouping errors by node type is of limited usefulness. In this figure and those that follow the top tree is the incorrect parse and the bottom tree is the correct parse. Bold, boxed nodes are either extra (marked in the incorrect tree) or missing (marked in the correct tree). This is an example of **PP Attachment** (*in 1986* is too low), but that is not at all clear from the set of incorrect nodes (extra S, NP, PP, and NP, missing S, NP, and PP).

find a set of tree transformations that convert the output tree into the gold tree. Second, the transformations are classified into error types such as PP attachment and coordination. Pseudocode for our method is shown in Algorithm 1. The tree transformation stage corresponds to the main loop, while the second stage corresponds to the final loop.

#### 4.1 Tree Transformation

The core of our transformation process is a set of operations that move subtrees, create nodes, and delete nodes. Searching for the shortest path to transform one tree into another is prohibitively slow.<sup>2</sup> We find

<sup>2</sup>We implemented various search procedures and found similar results on the sentences that could be processed in a reason-

---

**Algorithm 1** Tree transformation error classification

---

$U$  = initial set of node errors  
Sort  $U$  by the depth of the error in the tree, deepest first  
 $G = \emptyset$   
**repeat**  
  **for all** errors  $e \in U$  **do**  
    **if**  $e$  fits an environment template  $t$  **then**  
       $g$  = new error group  
      Correct  $e$  as specified by  $t$   
      **for all** errors  $f$  that  $t$  corrects **do**  
        Remove  $f$  from  $U$   
        Insert  $f$  into  $g$   
      **end for**  
      Add  $g$  to  $G$   
    **end if**  
  **end for**  
**until** unable to correct any further errors  
**for all** remaining errors  $e \in U$  **do**  
  Insert a group into  $G$  containing  $e$   
**end for**  
**for all** groups  $g \in G$  **do**  
  Classify  $g$  based on properties of the group  
**end for**

---

a path by applying a greedy bottom-up approach, iterating through the errors in order of tree depth.

We match each error with a template based on nearby tree structure and errors. For example, in Figure 1 there are four extra nodes that all cover spans ending at *Applied in 1986*: S, NP, PP, NP. There are also three missing nodes with spans ending between *Applied* and *in*: PP, NP, and S. Figure 2 depicts these errors as spans, showing that this case fits three criteria: (1) there are a set of extra spans all ending at the same point, (2) there are a set of missing spans all ending at the same point, and (3) the extra spans cross the missing spans, extending beyond their end-point. This indicates that the node starting after *Applied* is attaching too low and should be moved up, outside all of the extra nodes. Together, the criteria and transformation form a template.

Once a suitable template is identified we correct the error by moving subtrees, adding nodes and removing nodes. In the example this is done by moving the node spanning *in 1986* up in the tree until it is outside of all the extra spans. Since moving the PP leaves a unary production from an NP to an NP, we also collapse that level. In total this corrects seven

able amount of time.

Figure 2: Templates are defined in terms of extra and missing spans, shown here with unbroken lines above and dashed lines below, respectively. This is an example of a set of extra spans that cross a set of missing spans (which in both cases all end at the same position). If the last two words are moved, two of the extra spans will match the two missing spans. The other extra span is deleted during the move as it creates an NP→NP unary production.

errors, as there are three cases in which an extra node is present that matches a missing node once the PP is moved. All of these errors are placed in a single group and information about the nearby tree structure before and after the transformation is recorded.

We continue to make passes through the list until no errors are corrected on a pass. For each remaining node error an individual error group is created.

The templates were constructed by hand based on manual analysis of parser output. They cover a range of combinations of extra and missing spans, with further variation for whether crossing is occurring and if so whether the crossing bracket starts or ends in the middle of the correct bracket. Errors that do not match any of our templates are left uncorrected.

## 4.2 Transformation Classification

We began with a large set of node errors, in the first stage they were placed into groups, one group per tree transformation used to get from the test tree to the gold tree. Next we classify each group as one of the error types below.

**PP Attachment** Any case in which the transformation involved moving a Prepositional Phrase, or the incorrect bracket is over a PP, e.g.

*He was (VP named chief executive officer of (NP Applied (PP in 1986)))*

where (PP *in 1986*) should modify the entire VP, rather than just *Applied*.

**NP Attachment** Several cases in which NPs had to be moved, particularly for mistakes in appositive constructions and incorrect attachments within a verb phrase, e.g.

*The bonds (VP go (PP on sale (NP Oct. 19)))*  
where *Oct. 19* should be an argument of *go*.

(a) Parser output

(b) Gold tree

Figure 3: **NP Attachment:** *today* is too high, it should be the argument of *appearing*, rather than *wrote*. This causes three node errors (extra NP, missing NP and VP).

(a) Parser output

(b) Gold tree

Figure 4: **Modifier Attachment:** *ahead of time* is too high, it should modify *think*, not *had*. This causes six node errors (extra S, VP, and VP, missing S, VP, and VP).

**Modifier Attachment** Cases involving incorrectly placed adjectives and adverbs, including errors corrected by subtree movement and errors requiring only creation of a node, e.g. (NP (ADVP *even more*) *severe setbacks*) where there should be an extra ADVP node over *even more severe*.

**Clause Attachment** Any group that involves movement of some form of S node.

(a) Parser output

(b) Gold tree

Figure 5: **Clause Attachment:** *unless the agency receives specific congressional authorization* is attaching too low. This causes six node errors (extra S, VP, and VP, missing S, VP and VP).

(a) Parser output

(b) Gold tree

(c) Gold tree with traces and function tags

Figure 6: Two **Unary** errors, a missing S and a missing NP. The third tree is the PTB tree before traces and function tags are removed. Note that the missing NP is over another NP, a production that does occur widely in the treebank, particularly over the word *it*.

(a) Parser output

(b) Gold tree

Figure 7: **Coordination:** *and Dresdner AG's 10% decline* is too low. This causes four node errors (extra PP and NP, missing NP and PP).

**Unary** Mistakes involving unary productions that are not linked to a nearby error such as a matching extra or missing node. We do not include a breakdown by unary type, though we did find that clause labeling (S, SINV, etc) accounted for a large proportion of the errors.

**Coordination** Cases in which a conjunction is an immediate sibling of the nodes being moved, or is the leftmost or rightmost node being moved.

**NP Internal Structure** While most NP structure is not annotated in the PTB, there is some use of ADJP, NX, NAC and QP nodes. We form a single group for each NP that has one or more errors involving these types of nodes.

**Different label** In many cases a node is present in the tree that spans the correct set of words, but has the wrong label, in which case we group the two node errors, (one extra, one missing), as a single error.

**Single word phrase** A range of node errors that span a single word, with checks to ensure this is not linked to another error (e.g. one part of a set of internal noun phrase errors).

**Other** There is a long tail of other errors. Some could be placed within the categories above, but would require far more specific rules.

For many of these error types it would be difficult to extract a meaningful understanding from only

(a) Parser output

(b) Gold tree

Figure 8: **NP Internal Structure:** *Baker* is too low, causing four errors (extra PP and NP, missing PP and NP).

the list of node errors involved. Even for error types that can be measured by counting node errors or rule production errors, our approach has the advantage that we identify groups of errors with a single cause. For example, a missing unary production may correspond to an extra bracket that contains a subtree that attached incorrectly.

### 4.3 Methodology

We used sections 00 and 24 as development data while constructing the tree transformation and error group classification methods. All of our examples in text come from these sections as well, but for all tables of results we ran our system on section 23. We chose to run our analysis on section 23 as it is the only section we are sure was not used in the development of any of the parsers, either for tuning or feature development. Our evaluation is entirely focused on the errors of the parsers, so unless there is a particular construction that is unusually prevalent in section 23, we are not revealing any information about the test set that could bias future work.

## 5 Results

Our system enables us to answer questions about parser behaviour that could previously only be probed indirectly. We demonstrate its usefulness by applying it to a range of parsers (here), to reranked K-best lists of various lengths, and to output for out-of-domain parsing (following sections).

In Table 2 we consider the breakdown of parser

Parser	F-score	PP	Clause	Diff	Mod	NP	1-Word		NP		
		Attach	Attach	Label	Attach	Attach	Co-ord	Span	Unary	Int.	Other
Best		0.60	0.38	0.31	0.25	0.25	0.23	0.20	0.14	0.14	0.50

VP Attachment	64	159	2.5
Parenthetical Attachment	31	74	2.4
Missing Parenthetical	12	17	1.4
Unclassified	655	734	1.1

Table 3: Breakdown of errors on section 23 for the Charniak parser with self-trained model and reranker. Errors are sorted by the number of times they occur. Ratio is the average number of node errors caused by each error we identify (i.e. Nodes Involved / Occurrences).

errors on WSJ section 23. The shaded area of each bar indicates the frequency of parse errors (i.e. empty means fewest errors). The area filled in is determined by the expected number of node errors per sentence that are attributed to that type of error. The average number of node errors per sentence for a completely full bar is indicated by the Worst row, and the value for a completely empty bar is indicated by the Best row. Exact error counts are available at

<http://code.google.com/p/berkeley-parser-analyser/>.

We use counts of node errors to make the contributions of each type of error more interpretable. As Table 3 shows, some errors typically cause only a single node error, where as others, such as coordination, generally cause several. This means that considering counts of error groups would over-emphasise some error types, e.g. single word phrase errors are second most important by number of groups (in Table 3), but seventh by total number of node errors (in Table 2).

As expected, PP attachment is the largest contributor to errors, across all parsers. Interestingly, coordination is sixth on the list, though that is partly due to the fact that there are fewer coordination decisions to be made in the treebank.<sup>3</sup>

By looking at the performance of the Collins parser we can see the development over the past fifteen years. There has been improvement across the board, but in some cases, e.g. clause attachment errors and different label errors, the change has been more limited (24% and 29% reductions respectively). We investigated the breakdown of the different label errors by label, but no particular cases of la-

<sup>3</sup>This is indicated by the frequency of CCs and PPs in sections 02–21 of the treebank, 16,844 and 95,581 respectively. These counts are only an indicator of the number of decisions as the nodes can be used in ways that do not involve a decision, such as sentences that start with a conjunction.

System	K	F-score	PP Attach	Clause Attach	Diff Label	Mod Attach	NP Attach	Co-ord	1-Word Span	Unary	NP Int.	Other
Best			0.08	0.04	0.08	0.05	0.06	0.04	0.08	0.04	0.04	0.11

	20	92.05										
	10	92.16										
	5	91.94										
	2	91.56										
1	91.02											
Worst			0.66	0.43	0.33	0.26	0.28	0.26	0.23	0.16	0.19	0.60

Table 4: Average number of bracket errors per sentence for a range of K-best list lengths using the Charniak parser with reranking and the self-trained model. The oracle results are determined by taking the parse in each K-best list with the highest F-score.

bel confusion stand out, and we found that the most common cases remained the same between Collins and the top results.

It is also interesting to compare pairs of parsers that share aspects of their architecture. One such pair is the Stanford parser, where the factored parser combines the unlexicalised parser with a lexicalised dependency parser. The main sources of the 0.64 gain in F-score are PP attachment and coordination.

Another interesting pair is the Berkeley parser and the BUBS parser, which uses a Berkeley grammar, but improves speed by pruning. The pruning methods used in BUBS are particularly damaging for PP attachment errors and unary errors.

Various comparisons can be made between Charniak parser variants. We discuss the reranker below. For the self-trained model McClosky et al. (2006) performed some error analysis, considering variations in F-score depending on the frequency of tags such as PP, IN and CC in sentences. Here we see gains on all error types, though particularly for clause attachment, modifier attachment and coordination, which fits with their observations.

## 5.1 Reranking

The standard dynamic programming approach to parsing limits the range of features that can be em-

ployed. One way to deal with this issue is to modify the parser to produce the top  $K$  parses, rather than just the 1-best, then use a model with more sophisticated features to choose the best parse from this list (Collins, 2000). While re-ranking has led to gains in performance (Charniak and Johnson, 2005), there has been limited analysis of how effectively rerankers are using the set of available options. Recent work has explored this question in more depth, but focusing on how variation in the parameters impacts performance on standard metrics (Huang, 2008; Ng et al., 2010; Auli and Lopez, 2011; Ng and Curran, 2012).

In Table 4 we present a breakdown over error types for the Charniak parser, using the self-trained model and reranker. The oracle results use the parse in each K-best list with the highest F-score. While this may not give the true oracle result, as F-score does not factor over sentences, it gives a close approximation. The table has the same columns as Table 2, but the ranges on the bars now reflect the min and max for these sets.

While there is improvement on all errors when using the reranker, there is very little additional gain beyond the first 5-10 parses. Even for the oracle results, most of the improvement occurs within the first 5-10 parses. The limited utility of extra parses

Corpus	F-score	PP	Clause	Diff	Mod	NP	1-Word		NP		
		Attach	Attach	Label	Attach	Attach	Co-ord	Span	Unary	Int.	Other

Table 5: Average number of node errors per word for a range of domains using the Charniak parser with reranking and the self-trained model. We use per word error rates here rather than per sentence as there is great variation in average sentence length across the domains, skewing the per sentence results.

for the reranker may be due to the importance of the base parser output probability feature (which, by definition, decreases within the K-best list).

Interestingly, the oracle performance improves across all error types, even at the 2-best level. This indicates that the base parser model is not particularly biased against a single error. Focusing on the rows for  $K = 2$  we can also see two interesting outliers. The PP attachment improvement of the oracle is considerably higher than that of the reranker, particularly compared to the differences for other errors, suggesting that the reranker lacks the features necessary to make the decision better than the parser. The other interesting outlier is NP internal structure, which continues to make improvements for longer lists, unlike the other error types.

## 5.2 Out-of-Domain

Parsing performance drops considerably when shifting outside of the domain a parser was trained on (Gildea, 2001). Clegg and Shepherd (2005) evaluated parsers qualitatively on node types and rule productions. Bender et al. (2011) designed a Wikipedia test set to evaluate parsers on dependencies representing ten specific linguistic phenomena.

To provide a deeper understanding of the errors arising when parsing outside of the newswire domain, we analyse performance of the Charniak parser with reranker and self-trained model on the eight parts of the Brown corpus (Marcus et al.,

Corpus	Description	Sentences	Av. Length
WSJ 23	Newswire	2416	23.5
Brown F	Popular	3164	23.4
Brown G	Biographies	3279	25.5
Brown K	General	3881	17.2
Brown L	Mystery	3714	15.7
Brown M	Science	881	16.6

Brown R	Humour	967	22.7
G-Web Blogs	Blogs	1016	23.6
G-Web Email	E-mail	2450	11.9

Table 6: Variation in size and contents of the domains we consider. The variation in average sentence lengths skews the results for errors per sentences, and so in Table 5 we consider errors per word.

1993), and two parts of the Google Web corpus (Petrov and McDonald, 2012). Table 6 shows statistics for the corpora. The variation in average sentence lengths skew the results for errors per sentence. To handle this we divide by the number of words to determine the results in Table 5, rather than by the number of sentences, as in previous figures.

There are several interesting features in the table. First, on the Brown datasets, while the general trend is towards worse performance on all errors, NP internal structure is a notable exception and in some cases PP attachment and unaries are as well.

In the other errors we see similar patterns across the corpora, except humour (Brown R), on which the parser is particularly bad at coordination and clause

attachment. This makes sense, as the colloquial nature of the text includes more unusual uses of conjunctions, for example:

*She was a living doll and no mistake – the ...*

Comparing the Brown corpora and the Google Web corpora, there are much larger divergences. We see a particularly large decrease in NP internal structure. Looking at some of the instances of this error, it appears to be largely caused by incorrect handling of structures such as URLs and phone numbers, which do not appear in the PTB. There are also some more difficult cases, for example:

*... going up for sale in the next month or do .*

where *or do* is a QP. This typographical error is extremely difficult to handle for a parser trained only on well-formed text.

For e-mail there is a substantial drop on single word phrases. Breaking the errors down by label we found that the majority of the new errors are missing or extra NPs over single words. Here the main problem appears to be temporal expressions, though there also appear to be a substantial number of errors that are also at the POS level, such as when NNP is assigned to *ta* in this case:

*... let you know that I 'm out ta here !*

Some of these issues, such as URL handling, could be resolved with suitable training data. Other issues, such as ungrammatical language and unconventional use of words, pose a greater challenge.

## 6 Conclusion

The single F-score objective over brackets or dependencies obscures important differences between statistical parsers. For instance, a single attachment error can lead to one or many mismatched brackets.

We have created a novel tree-transformation methodology for evaluating parsers that categorises errors into linguistically meaningful types. Using this approach, we presented the first detailed examination of the errors produced by a wide range of constituency parsers for English. We found that PP attachment and clause attachment are the most challenging constructions, while coordination turns out to be less problematic than previously thought. We

also noted interesting variations in error types for parsers variants.

We investigated the errors resolved in reranking, and introduced by changing domains. We found that the Charniak rerankers improved most error types, but made little headway on improving PP attachment. Changing domain has an impact on all error types, except NP internal structure.

We have released our system so that future constituent parsers can be evaluated using our methodology. Our analysis provides new insight into the development of parsers over the past fifteen years, and the challenges that remain.

## Abstract

This paper proposes the utilization of lexical cohesion to facilitate evaluation of machine translation at the document level. As a linguistic means to achieve text coherence, lexical cohesion ties sentences together into a meaningfully interwoven structure through words with the same or related meaning. A comparison between machine and human translation is conducted to illustrate one of their critical distinctions that human translators tend to use more cohesion devices than machine. Various ways to apply this feature to evaluate machine-translated documents are presented, including one without reliance on reference translation. Experimental results show that incorporating this feature into sentence-level evaluation metrics can enhance their correlation with human judgements.

## 1 Introduction

Machine translation (MT) has benefited a lot from the advancement of automatic evaluation in the past decade. To a certain degree, its progress is also confined to the limitations of evaluation metrics in use. Most efforts devoted to evaluate the quality of MT output so far have still focused on the sentence level without sufficient attention to how a larger text is structured. This is notably reflected in the representative MT evaluation metrics, such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and TER (Snover et al., 2006), that adopt a sentence-by-sentence fashion to score MT outputs. The evaluation result for a document by any of them is usually a simple average of its sentence scores. A

drawback of this kind of sentence-based evaluation is the neglect of document structure. There is no guarantee for the coherence of a text if it is produced by simply putting together stand-alone sentences, no matter how well-translated, without adequate inter-sentential connection. As a consequence, MT system optimized this way to any of these metrics can only have a very dim chance of producing translated document that reads as natural as human writing.

The accuracy of MT output at the document level is particularly important to MT users, for they care about the overall meaning of a text in question more than the grammatical correctness of each sentence (Visser and Fuji, 1996). Post-editors particularly need to ensure the quality of a whole document of MT output when revising its sentences. The connectivity of sentences is surely a significant factor contributing to the understandability of a text as a whole.

This paper studies the inter-sentential linguistic features of cohesion and coherence and presents plausible ways to incorporate them into the sentence-based metrics to support MT evaluation at the document level. In the Framework for MT Evaluation in the International Standards of Language Engineering (FEMTI) (King et al., 2003), coherence is defined as “the degree to which the reader can describe the role of each individual sentence (or group of sentences) with respect to the text as a whole”. The measurement of coherence has to rely on cohesion, referring to the “relations of meaning that exist within the text” (Halliday and Hasan, 1976). Cohesion is realized via the interlinkage of grammatical and lexical elements across sentences. *Grammatical*

cohesion refers to the syntactic links between text items, while *lexical* cohesion is achieved through the word choices in a text. This paper focuses on the latter. A quantitative comparison of lexical cohesion devices between MT output and human translation is first conducted, to examine the weakness of current MT systems in handling this feature. Different ways of exploiting lexical cohesion devices for MT evaluation at the document level are then illustrated.

## 2 Related Works

Cohesion and coherence are both necessary monolingual features in a target text. They can hardly be evaluated in isolation and have to be conjoined with other quality criteria such as adequacy and fluency. A survey of MT post-editing (Vasconcellos, 1989) suggests that cohesion and coherence serve as higher level quality criteria beyond many others such as syntactic well-formedness. Post-editors tend to correct syntactic errors first before any amendment for improving the cohesion and coherence of an MT output. Also, as Wilks (1978)<sup>1</sup> noted, it is rather unlikely for a sufficiently large sample of translations to be coherent and totally wrong at the same time. Cohesion and coherence are appropriate to serve as criteria for the overall quality of MT output.

Previous researches in MT predominantly focus on specific types of cohesion devices. For grammatical cohesion, a series of works, including Nakaiwa and Ikehara (1992), Nakaiwa et al. (1995), and Nakaiwa and Shirai (1996), present approaches to resolving Japanese zero pronouns and to integrating them into a Japanese-English transferred-based MT system. Peral et al. (1999) propose an interlingual mechanism for pronominal anaphora generation by exploiting a rich set of lexical, syntactic, morphologic and semantic information. Murata and Nagao (1993) and Murata et al. (2001) develop a rule base to identify the referential properties of Japanese noun phrases, so as to facilitate anaphora resolution for Japanese and article generation for English during translation. A recent COMTIS project (Cartoni et al., 2011) begins to exploit inter-sentential information for statistical MT. A phase of its work is to have grammatical devices,

<sup>1</sup>As cited in van Slype (1979).

such as verbal tense/aspect/mode, discourse connectives and pronouns, manually annotated in multilingual corpora, in hopes of laying a foundation for the development of automatic labelers for them that can be integrated into an MT model.

For lexical cohesion, it has been only partially and indirectly addressed in terms of translation consistency in MT output. Different approaches to maintaining consistency in target word choices are proposed (Itagaki et al., 2007; Gong et al., 2011; Xiao et al., 2011). Carpuat (2009) also observes a general tendency in human translation that a given sense is usually lexicalized in a consistent manner throughout the whole translation.

Nevertheless there are only a few evaluation methods explicitly targeting on the quality of a document. Miller and Vanni (2001) devise a human evaluation approach to measure the comprehensibility of a text as a whole, based on the Rhetorical Structure Theory (Mann and Thompson, 1988), a theory of text organization specifying coherence relations in an authentic text. Snover et al. (2006) proposes HTER to assess post-editing effort through human annotation. Its automatic versions TER and TERp (Snover et al., 2009), however, remain sentence-based metrics. Comelles et al. (2010) present a family of automatic MT evaluation measures, based on the Discourse Representation Theory (Kamp and Reyle, 1993), that generate semantic trees to put together different text entities for the same referent according to their contexts and grammatical connections. Apart from MT evaluation, automated essay scoring programs such as E-rater (Burstein, 2003) also employ a rich set of discourse features for assessment. However, the parsing process needed for these linguistic-heavy approaches may suffer seriously from grammatical errors, which are unavoidable in MT output. Hence their accuracy and reliability inevitably fluctuate in accord with different evaluation data.

Lexical cohesion has far been neglected in both MT and MT evaluation, even though it is the single most important form of cohesion devices, accounting for nearly half of the cohesion devices in English (Halliday and Hasan, 1976). It is also a significant feature contributing to translation equivalence of texts by preserving their texture (Lotfipour-Saedi, 1997). The lexical cohesion devices in a text can be

represented as lexical chains conjoining related entities. There are many methods of computing lexical chains for various purposes, e.g., Morris and Hirst (1991), Barzilay and Elhadad (1997), Chan (2004), Li et al. (2007), among many others. Contrary to grammatical cohesion highly depending on syntactic well-formedness of a text, lexical cohesion is less affected by grammatical errors. Its computation has to rely on a thesaurus, which is usually available for almost every language. In this research, a number of formulations of lexical cohesion, with or without reliance on external language resource, will be explored for the purpose of MT evaluation.

### 3 Lexical Cohesion in Machine and Human Translation

This section presents a comparative study of MT and human translation (HT) in terms of the use of lexical cohesion devices. It is an intuition that more cohesion devices are used by humans than machines in translation, as part of the superior quality of HT. Two different datasets are used to ensure the reliability and generality of the comparison. The results confirm the incapability of MT in handling this feature and the necessity of using lexical cohesion in MT evaluation.

#### 3.1 Data

The MetricsMATR 2008 development set (Przybocki et al., 2009) and the Multiple-Translation Chinese (MTC) part 4 (Ma, 2006) are used for this study. They consist of MT outputs of different source languages in company with reference translations. The data of MetricsMATR is selected from the NIST Open MT 2006 evaluation, while MTC4 is from the TIDES 2003 MT evaluation. Both datasets include human assessments of MT output, from which the part of adequacy assessment is selected for this study. Table 1 provides overall statistics of the datasets.

#### 3.2 Identification of Lexical Cohesion Devices

Lexical cohesion is achieved through word choices of two major types: reiteration and collocation. Reiteration can be realized in a continuum or a cline of specificity, with repetition of the same lexical item at one end and the use of a general noun to point to the

same referent at the other. In between the two ends is to use a synonym (or near-synonym) and superordinate. Collocation refers to those lexical items that share the same or similar semantic relations, including complementarity, antonym, converse, coordinate term, meronym, troponym, and so on.

In this study, lexical cohesion devices are defined as content words (i.e., tokens after stopword having been removed) that reiterate once or more times in a document, including synonym, near-synonym and superordinate, besides those repetition and collocation. Repetition refers to the same words or stems in a document. Stems are identified with the aid of Porter stemmer (1980).

To classify the semantic relationships of words, WordNet (Fellbaum, 1998) is used as a lexical resource, which clusters words of the same sense (i.e., synonyms) into a semantic group, namely a synset. Synsets are interlinked in WordNet according to their semantic relationships. Superordinate and collocation are formed by words in a proximate semantic relationship, such as *bicycle* and *vehicle* (hypernym), *bicycle* and *wheel* (meronym), *bicycle* and *car* (coordinate term), and so on. They are defined as synset pairs with a distance of 1 in WordNet. The measure of semantic distance (Wu and Palmer, 1994) is also applied to identify near-synonyms, i.e., words that are synonyms in a broad sense but not grouped in the same synset. It quantifies the semantic similarity of word pairs as a real number in between 0 and 1 (the higher the more similar) as

$$sim(c_1, c_2) = \frac{2 d(lcs(c_1, c_2))}{d(c_1) + d(c_2)}$$

where  $c_1$  and  $c_2$  are the concepts (synsets) that the two words in question belong to,  $d$  is the distance in terms of the shortest path from a concept to the

global root node in WordNet, and  $lcs$  is the least common subsumer (i.e., the most specific ancestor concept) of  $c_1$  and  $c_2$ . A threshold is set to 0.96 for words to be considered near-synonyms of each other, based on the empirical observation in a previous study (Wong, 2010).

### 3.3 Results

The difference between MT and HT (reference translation) in terms of the frequencies of lexical cohesion devices in MetricsMATR and MTC4 datasets is presented in Table 2. The frequencies are averaged by the number of MT/HT versions. A further categorization breaks down content words into lexical cohesion devices and those that are not. The count of each type of lexical cohesion device is also provided. In general the two datasets provide highly similar statistics. There are 4.7–5.1% more content words in HT than in MT. The numbers of ordinary content words (i.e., not lexical cohesion devices) are close in MT and HT. The difference of content words

in HT and MT is mostly due to that of lexical cohesion devices, which are mostly repetition. 8.9–11.4% more lexical cohesion devices are found in HT than in MT in the datasets.

A further analysis is carried out to investigate into the use of lexical cohesion devices in each version of MT and HT in terms of the following two ratios,

$$LC = \text{lexical cohesion devices} / \text{content words},$$

$$RC = \text{repetition} / \text{content words}.$$

A higher  $LC$  or  $RC$  ratio means that a greater proportion of content words are used as lexical cohesion devices.

Figure 1 illustrates the  $RC$  and  $LC$  ratios in the two datasets. The ratios of different MT systems are presented in an ascending order in each graph from left to right, according to their human assessment results. The distributions of these values show a strong similarity between the two datasets. First, most of the  $RC$  and  $LC$  ratios are within an observable range, i.e., 0.25–0.35 for the former and 0.40–0.50 for the latter, except a particularly low  $LC$  for

one MT system. Second, the ratios in those different HT versions are very stable in comparison with those of MT. Especially, all four HT versions in the MetricsMATR dataset share the same *RC* ratio 0.31. This shows a typical level of the use of lexical cohesion device. Third, the ratios in MT are lower than or at most equal to those in HT, suggesting their correlation with translation quality: the closer their *RC* and *LC* ratios to those in HT, the better the MT. These results verify our assumption that lexical cohesion can serve as an effective proxy of the level of translation quality.

#### 4 MT Evaluation at Document Level

As a feature at the discourse level, lexical cohesion is a good complement to current evaluation metrics focusing on features at the sentence level. Table 3 illustrates an example selected from the MetricsMATR dataset, consisting two versions of MT output for a short document of two segments only. The n-grams matched with the reference are under-

lined, while the lexical cohesion devices are italicized. The two MT outputs have a similar number of matched n-grams and hence receive similar BLEU scores. These scores, however, do not reflect their real difference in quality: the second version is better, according to human assessment of adequacy. Instead, their *LC* ratios seem to represent such a variation more accurately. The theme of the second output is also highlighted through the lexical chains, including *main/important*, *technology/technologies* and *achieve/achieving*, which create a tight texture between the two sentences, a crucial factor of text quality.

To perform MT evaluation at the document level, the *LC* and *RC* ratios can be used alone or integrated into a sentence-level metric. The former way has an advantage that it does not have to rely on any reference translation. *LC* mainly requires a thesaurus for computing semantic relation, while *RC* only needs a morphological processor such as stemmer, both of which are available for most lan-

guages. Its drawback, however, lies in the risk of relying on a single discourse feature. Although lexical cohesion gives a strong indication of text coherence, it is not indispensable, because a text can be coherent without any surface cohesive clue. Furthermore, the quality of a document is also reflected in that of its sentences. A coherent translation may be mistranslated, and on the other hand, a text containing lots of sentence-level errors would make it difficult to determine its document-level quality. A previous study comparing MT evaluation at the sentence versus document level (Wong et al., 2011) reports a poor consistency in the evaluation results at these two levels when the sentence-level scores of MT output are low. In regard of these, how to integrate these two levels of MT evaluation is particularly worth studying.

## 5 Experiments

We examine, through experiments, the effectiveness of using  $LC$  and  $RC$  ratios alone and integrating them into other evaluation metrics for MT evaluation at the document and system levels. Three evaluation metrics, namely BLEU, TER and METEOR,<sup>2</sup> are selected for testing. They represent three distinctive types of evaluation metrics: n-gram, edit-distance, and unigram with external language resources, respectively. These metrics are evaluated in terms of their correlation with human assessments, using Pearson’s  $r$  correlation coefficient. The MetricsMATR and MTC4 datasets and their adequacy assessments are used as evaluation data. Note that the adequacy assessment is in fact an evaluation method for the sentence level. We have to rely on an assumption that this evaluation data may emulate document-level quality, since its MT outputs were assessed sentence by sentence in sequence as in a document. All experiments are performed under a setting of multiple reference translations.

The integration of the two ratios into an evaluation metric follows a simple weighted average approach. A hybrid metric  $H$  is formulated as

$$H = \alpha m_{doc} + (1 - \alpha) m_{seg}$$

where  $m_{doc}$  refers to the document-level feature in

<sup>2</sup>METEOR 1.0 with default parameters optimized over the adequacy assessments.

use (i.e.,  $LC$  or  $RC$ ),  $m_{seg}$  to a sentence-level metric, and  $\alpha$  to a weight controlling their proportion. The MetricsMATR dataset is used as training data to optimize the values of  $\alpha$  for different metrics, while the MTC4 is used as evaluation data. Table 4 shows the optimized weights for the metrics for evaluation at the document level.

Metrics	$RC$	$LC$
BLEU	0.28	0.29
TER	0.40	0.38
METEOR	0.19	0.18

Table 4: Optimized weights for the integration of discourse feature into sentence-level metrics

Table 5 presents the correlation rates of evaluation metrics obtained in our experiments under different settings, with their 95% confidence intervals (CI) provided. The  $LC$  and  $RC$  ratios are found to have strong correlations with human assessments at the system level even when used alone, highly comparable to BLEU and TER. At the document level, however, they are not as good as the others. They show their advantages when integrated into other metrics, especially BLEU and TER.  $LC$  raises the correlation of BLEU from 0.447 to 0.472 and from 0.861 to 0.905 at the document and system levels, respectively. It improves TER even more significantly, in that the correlation rates are boosted up from -0.326 to -0.390 at the document level, and even from -0.601 to -0.763 at the system level. Since there are only six systems in the MTC4 data, such a dramatic change may not be as meaningful as the smooth improvement at the document level. METEOR is a special case in this experiment. Its correlation cannot be improved by integrating  $LC$  or  $RC$ , and is even slightly dropped at the document level. The cause for this is yet to be identified. Nevertheless, these results confirm the close relationship of an MT system’s capability to appropriately generate lexical cohesion devices with the quality of its output.

Table 6 presents the Pearson correlations between evaluation results at the document level using different evaluation metrics in the MTC4 data. It illustrates the homogeneity/heterogeneity of different metrics and helps explain the performance change

Metrics	Document		System	
	Correlation	95% CI	Correlation	95% CI
<i>RC</i>	0.243	(0.167, 0.316)	0.873	(0.211, 0.985)

<i>RC</i>	0.287	-0.204	0.405	1	
<i>LC</i>	0.263	-0.097	0.437	0.736	1
	BLEU	TER	METEOR	<i>RC</i>	<i>LC</i>

Table 6: Correlation between the evaluation results of different metrics

by combining sentence- and document-level metrics. The table shows that the two ratios *LC* and *RC* highly correlate with each other, as if they are two variants of quantifying lexical cohesion devices. The three sentence-level metrics, BLEU, TER and METEOR, also show strong correlations with each other, especially between BLEU and METEOR. The correlations are generally weaker between sentence- and document-level metrics, for instance, 0.263 between BLEU and *LC* and only -0.097 between TER and *LC*, showing that they are quite heterogeneous in nature. This accounts for the significant performance gain from their combination: their difference allows them to complement each other. It is also worth noting that between METEOR and *LC* the correlation of 0.437 is mildly strong, explaining the negative result of their integration. On the one hand, lexical cohesion is word choice oriented, which is only sensitive to the reiteration and semantic relatedness of words in MT output. On the other hand, METEOR is strong in unigram matching, with multiple strategies to maximize the matching rate be-

tween MT output and reference translation. In this sense they are homogeneous to a certain extent, explaining the null effect of their combination.

## 6 Discussion and Conclusion

In this study we have attempted to address the problem that most existing MT evaluation metrics disregard the connectivity of sentences in a document. By focusing on a typical type of cohesion, i.e., lexical cohesion, we have shown that its use frequency is a significant factor to differentiate HT from MT and MT outputs of different quality from each other. The high correlation rate of its use with translation adequacy also suggests that the more lexical cohesion devices in use, the better the quality of MT output. Accordingly we have used two ratios, *LC* and *RC*, to capture such correlativity. Our experimental results have confirmed the effectiveness of this feature in accounting for the document-level quality of MT output. The performance of two evaluation metrics, BLEU and TER, is highly improved through incorporating this document-level feature, in terms of the

change of their correlation with human assessments.

This finding is positive and sheds light on a region of MT research that is still severely under-explored. Our approach to extending the granularity of MT evaluation from sentence to document through lexical cohesion is highly applicable to different languages. It has a relatively weak demand for language resource in comparison with the processing of other discourse features like grammatical cohesion. It is also much unaffected by grammatical problems or errors commonly seen in natural languages and, in particular, MT outputs.

Our future work will continue to explore the relationship of lexical cohesion to translation quality, so as to identify, apart from its use frequency, other significant aspects for MT evaluation at the document level. A frequent use of cohesion devices in a text is not necessarily appropriate, because an excess of them may decrease the quality and readability of a text. Human writers can strategically change the ways of expression to achieve appropriate coherence and also avoid overuse of the same lexical item. To a certain extent, this is one of the causes for the unnaturalness of MT output: it may contain a large number of lexical cohesion devices which are simply direct translation of those in a source text that do not fit in the target context. How to use lexical cohesion devices appropriately instead of frequently is thus an important issue to tackle before we can adopt them in MT and MT evaluation by a suitable means.

## Abstract

Many natural language processing problems involve constructing large nearest-neighbor graphs. We propose a system called **FLAG** to construct such graphs approximately from large data sets. To handle the large amount of data, our algorithm maintains approximate counts based on sketching algorithms. To find the approximate nearest neighbors, our algorithm pairs a new distributed online-PMI algorithm with novel fast approximate nearest neighbor search algorithms (variants of PLEB). These algorithms return the approximate nearest neighbors quickly. We show our system's efficiency in both intrinsic and extrinsic experiments. We further evaluate our fast search algorithms both quantitatively and qualitatively on two NLP applications.

## 1 Introduction

Many natural language processing (NLP) problems involve graph construction. Examples include constructing polarity lexicons based on lexical graphs from WordNet (Rao and Ravichandran, 2009), constructing polarity lexicons from web data (Velikovich et al., 2010) and unsupervised part-of-speech tagging using label propagation (Das and Petrov, 2011). The later two approaches construct nearest-neighbor graphs between word pairs by computing nearest neighbors between word pairs from large corpora. These nearest neighbors form the edges of the graph, with weights given by the distributional similarity (Turney and Pantel, 2010) between terms. Unfortunately, computing the distributional similarity between all words in a large vocabulary is computationally and memory intensive

when working with large amounts of data (Pantel et al., 2009). This bottleneck is typically addressed by means of commodity clusters. For example, Pantel et al. (2009) compute distributional similarity between 500 million terms over a 200 billion words in 50 hours using 100 quad-core nodes, explicitly storing a similarity matrix between 500 million terms.

In this work, we propose Fast Large-Scale Approximate Graph (**FLAG**) construction, a system that constructs a fast large-scale approximate nearest-neighbor graph from a large text corpus. To build this system, we exploit recent developments in the area of approximation, randomization and streaming for large-scale NLP problems (Ravichandran et al., 2005; Goyal et al., 2009; Levenberg et al., 2010). More specifically we exploit work on Locality Sensitive Hashing (LSH) (Charikar, 2002) for computing word-pair similarities from large text collections (Ravichandran et al., 2005; Van Durme and Lall, 2010). However, Ravichandran et al. (2005) approach stored an enormous matrix of all unique words and their contexts in main memory, which is infeasible for very large data sets. A more efficient online framework to locality sensitive hashing (Van Durme and Lall, 2010; Van Durme and Lall, 2011) computes distributional similarity in a streaming setting. Unfortunately, their approach can handle only additive features like raw-counts, and not non-linear association scores like pointwise mutual information (PMI), which generates better context vectors for distributional similarity (Ravichandran et al., 2005; Pantel et al., 2009; Turney and Pantel, 2010).

In **FLAG**, we first propose a *novel* distributed online-PMI algorithm (Section 3.1). It is a streaming method that processes large data sets in one pass while distributing the data over commodity clusters

and returns context vectors weighted by pointwise mutual information (PMI) for all the words. Our distributed online-PMI algorithm makes use of the Count-Min (CM) sketch algorithm (Cormode and Muthukrishnan, 2004) (previously shown effective for computing distributional similarity in our earlier work (Goyal and Daumé III, 2011)) to store the counts of all words, contexts and word-context pairs using only *8GB* of main memory. The main motivation for using the CM sketch comes from its linearity property (see last paragraph of Section 2) which makes CM sketch to be implemented in distributed setting for large data sets. In our implementation, **FLAG** scaled up to 110 GB of web data with 866 million sentences in less than 2 days using 100 quad-core nodes. Our intrinsic and extrinsic experiments demonstrate the effectiveness of distributed online-PMI.

After generating context vectors from distributed online-PMI algorithm, our goal is to use them to find fast approximate nearest neighbors for all words. To achieve this goal, we exploit recent developments in the area of existing randomized algorithms for random projections (Achlioptas, 2003; Li et al., 2006), Locality Sensitive Hashing (LSH) (Charikar, 2002) and improve on previous work done on PLEB (Point Location in Equal Balls) (Indyk and Motwani, 1998; Charikar, 2002). We propose novel variants of PLEB to address the issue of reducing the pre-processing time for PLEB. One of the variants of PLEB (FAST-PLEB) with considerably *less* pre-processing time has effectiveness comparable to PLEB. We evaluate these variants of PLEB both quantitatively and qualitatively on large data sets. Finally, we show the applicability of large-scale graphs built from **FLAG** on two applications: the Google-Sets problem (Ghahramani and Heller, 2005), and learning concrete and abstract words (Turney et al., 2011).

## 2 Count-Min sketch

The Count-Min (CM) sketch (Cormode and Muthukrishnan, 2004) belongs to a class of ‘sketch’ algorithms that represents a large data set with a compact summary, typically much smaller than the full size of the input by processing the data in one pass. The following surveys comprehensively review the streaming literature (Rusu and Dobra,

2007; Cormode and Hadjieleftheriou, 2008) and sketch techniques (Charikar et al., 2004; Li et al., 2008; Cormode and Muthukrishnan, 2004; Rusu and Dobra, 2007). In our another recent paper (Goyal et al., 2012), we conducted a systematic study and compare many sketch techniques which answer point queries with focus on large-scale NLP tasks. In that paper, we empirically demonstrated that CM sketch performs the best among all the sketches on three large-scale NLP tasks.

CM sketch uses hashing to store the approximate frequencies of all items from the large data set onto a small sketch vector that can be updated and queried in constant time. CM has two parameters  $\epsilon$  and  $\delta$ :  $\epsilon$  controls the amount of tolerable error in the returned count and  $\delta$  controls the probability with which the error exceeds the bound  $\epsilon$ .

CM sketch with parameters  $(\epsilon, \delta)$  is represented as a two-dimensional array with width  $w$  and depth  $d$ ; where  $w$  and  $d$  depends on  $\epsilon$  and  $\delta$  respectively. We set  $w = \frac{2}{\epsilon}$  and  $d = \log(\frac{1}{\delta})$ . The depth  $d$  denotes the number of pairwise-independent hash functions employed by the CM sketch; and the width  $w$  denotes the range of the hash functions. Given an input stream of items of length  $N$  ( $x_1, x_2 \dots x_N$ ), each of the hash functions  $h_k: \{x_1, x_2 \dots x_N\} \rightarrow \{1 \dots w\}, \forall 1 \leq k \leq d$ , takes an item from the input stream and maps it into a position indexed by the corresponding hash function.

UPDATE: For each new item “ $x$ ” with count  $c$ , the sketch is updated as:

$$\text{sketch}[k, h_k(x)] \leftarrow \text{sketch}[k, h_k(x)] + c, \forall 1 \leq k \leq d.$$

QUERY: Since multiple items can be hashed to the same index for each row of the array, hence the stored frequency in each row is guaranteed to *overestimate* the true count, which makes it a biased estimator. Therefore, to answer the point query (QUERY( $x$ )), CM returns the minimum over all the  $d$  positions indexed by the hash functions.

$$\hat{c}(x) = \min_k \text{sketch}[k, h_k(x)], \forall 1 \leq k \leq d.$$

All reported frequencies by CM exceed the true frequencies by at most  $\epsilon N$  with probability of at least  $1 - \delta$ . The space used by the algorithm is  $O(\frac{1}{\epsilon} \log \frac{1}{\delta})$ . Constant time of  $O(\log(\frac{1}{\delta}))$  per each update and query operation.

CM sketch has a linearity property which states that: Given two sketches  $s_1$  and  $s_2$  computed (us-

ing the same parameters  $w$  and  $d$ , and the same set of  $d$  hash functions) over different input streams; the sketch of the combined data stream can be easily obtained by adding the individual sketches in  $O(d \times w)$  time which is independent of the stream size. This property enables sketches to be implemented in distributed setting, where each machine computes the sketch over a small portion of the corpus and makes it *scalable* to large datasets.

The idea of conservative update (Estan and Varghese, 2002) is to only increase counts in the sketch by the minimum amount needed to ensure that the estimate remains accurate. We (Goyal and Daumé III, 2011) used CM sketch with conservative update (CM-CU sketch) to show that the update reduces the amount of over-estimation error by a factor of at least 1.5 on NLP data and showed the effectiveness of CM-CU on three important NLP tasks. The QUERY procedure for CM-CU is identical to Count-Min. However, to UPDATE an item “x” with frequency  $c$ , first we compute the frequency  $\hat{c}(x)$  of this item from the existing data structure:

$$(\forall 1 \leq k \leq d, \hat{c}(x) = \min_k \text{sketch}[k, h_k(x)])$$

and the counts are updated according to:

$$\text{sketch}[k, h_k(x)] \leftarrow \max\{\text{sketch}[k, h_k(x)], \hat{c}(x) + c\}.$$

The intuition is that, since the point query returns the minimum of all the  $d$  values, we will update a counter only if it is necessary as indicated by the above equation. This heuristic avoids the unnecessary updating of counter values to reduce the over-estimation error.

### 3 FLAG: Fast Large-Scale Approximate Graph Construction

We describe a system, **FLAG**, for generating a nearest neighbor graph from a large corpus. For every node (word), our system returns top  $l$  approximate nearest neighbors, which implicitly defines the graph. Our system operates in four steps. First, for every word “z”, our system generates a sparse context vector  $((c_1, v_1); (c_2, v_2) \dots; (c_d, v_d))$  of size  $d$  where  $c_d$  denotes the context and  $v_d$  denotes the PMI (strength of association) between the context  $c_d$  and the word “z”. The context can be lexical, semantic, syntactic, and/or dependency units that co-occur with the word “z”. We compute this ef-

ficiently using a new distributed online Pointwise Mutual Information algorithm (Section 3.1). Second, we project all the words with context vector size  $d$  onto  $k$  random vectors and then binarize these random projection vectors (Section 3.2). Third, we propose novel variants of PLEB (Section 3.3) with less pre-processing time to represent data for fast query retrieval. Fourth, using the output of variants of PLEB, we generate a small set of potential nearest neighbors for every word “z” (Section 3.4). From this small set, we can compute the Hamming distance between every word “z” and its potential nearest neighbors to return the  $l$  nearest-neighbors for all unique words.

#### 3.1 Distributed online-PMI

We propose a *new* distributed online Pointwise Mutual Information (PMI) algorithm motivated by the online-PMI algorithm (Van Durme and Lall, 2009b) (page 5). This is a streaming algorithm which processes the input corpus in one pass. After one pass over the data set, it returns the context vectors for all query words. The original online-PMI algorithm was used to find the top- $d$  verbs for a query verb using the highest approximate online-PMI values using a Talbot-Osborne-Morris-Bloom<sup>1</sup> (TOMB) Counter (Van Durme and Lall, 2009a). Unfortunately, this algorithm is prohibitively slow when computing contexts for *all* words, rather than just a small query set. This motivates us to propose a distributed variant that enables us to scale to large data and large vocabularies.<sup>2</sup>

We make three modifications to the original online-PMI algorithm and refer to it as the “modified online-PMI algorithm” shown in Algorithm 1. First, we use Count-Min with conservative update (CM-CU) sketch (Goyal and Daumé III, 2011) instead of TOMB. We prefer CM because it enables distribution due to its linearity property (Section 2) and footnote #1. Distribution using TOMB is not known in literature and we will like to explore that direction in future. Second, we store the counts of words (“z”), contexts (“y”) and word-context pairs all together in

<sup>1</sup>TOMB is a variant of CM sketch which focuses on reducing the bit size of each counter (in addition to the number of counters) at the cost of incurring more error in the counts.

<sup>2</sup>The serialized online-PMI algorithm took a week to generate context vectors for all the words from **GW** (Section 4.1).

---

**Algorithm 1** Modified online-PMI

---

**Require:** Data set  $D$ , buffer size  $B$ **Ensure:** context vectors  $V$ , mapping word  $z$  to  $d$ -best contexts in priority queue  $\langle y, \text{PMI}(z, y) \rangle$ 

```
1: initialize CM-CU sketch to store approximate counts
   of words, context and word-context pairs
2: for each buffer  $B$  in the data set  $D$  do
3:   initialize  $S$  to store  $\langle z, y \rangle$  observed in  $B$ 
4:   for  $\langle z, y \rangle$  in  $B$  do
5:     set  $S(\langle z, y \rangle) = 1$ 
6:     insert  $z, y$  and pair  $\langle z, y \rangle$  in sketch
7:   end for
8:   for  $x$  in set  $S$  do
9:     recompute vectors  $V(x)$  using current contexts
       in priority queue and  $\{y | S(\langle z, y \rangle) = 1\}$ 
10:  end for
11: end for
12: return context vectors  $V$ 
```

---

the CM-CU sketch (in the original online-PMI algorithm, exact counts of words and contexts were stored in a hash table; only the pairs were stored in the TOMB data structure). Third, in the original algorithm, for each “ $z$ ” a vector of top- $d$  contexts are modified at the end of each buffer (refer Algorithm 1). However, in our algorithm, we only modify the list of those “ $z$ ”s which appeared in the recent buffer rather than modifying for all the “ $z$ ”s (Note, if “ $z$ ” does not appear in the recent buffer, then its top- $d$  contexts cannot be changed. Hence, we only modify those “ $z$ ”s which appear in the recent buffer).

In our distributed online-PMI algorithm, first we split the data into chunks of 10 million sentences. Second, we run the modified online-PMI algorithm on each chunk in distributed setting. This stores counts of all words (“ $z$ ”), contexts (“ $y$ ”) and word-context pairs in the CM-CU sketch, and store top- $d$  contexts for each word in priority queues. In third step, we merge all the sketches using linearity property to sum the counts of the words, contexts and word-context pairs. Additionally we merge the lists of top- $d$  contexts for each word. In the last step, we use the single merged sketch and merged top- $d$  contexts list to generate the final distributed online-PMI top- $d$  contexts list.

It takes around one day to compute context vectors for all the words from a chunk of 10 million sentences using first step of distributed online-PMI. We generated context vectors for all the 87 chunks

(110 GB data with 866 million sentences: see Table 1) in one day by running one process per chunk over a cluster. The first step of the algorithm involves traversing the data set and is the most time intensive step. For the second step, the merging of sketches is fast, since sketches are two dimensional array data structures (we used the sketch of size 2 billion counters with 3 hash functions). Merging the lists of top- $d$  contexts for each word is embarrassingly parallel and fast. The last step to generate the final top- $d$  contexts list is again embarrassingly parallel and fast and takes couple of hours to generate the top- $d$  contexts for all the words from all the chunks. If implemented serially the “modified online-PMI algorithm” on 110 GB data with 866 million sentences would take approximately 3 months.

The downside of the distributed online-PMI is that it splits the data into small chunks and loses information about the global best contexts for a word over all the chunks. The algorithm locally computes the best contexts for each chunk, that can be bad if the algorithm misses out globally *good* contexts and that can affect the accuracy of downstream application. We will demonstrate in our experiments (Section 4.2) by using distributed online-PMI, we do not lose any significant information about global contexts and perform comparable to offline-PMI over an intrinsic and extrinsic evaluation.

### 3.2 Dimensionality Reduction from $\mathbb{R}^D$ to $\mathbb{R}^k$

We are given context vectors for  $Z$  words, our goal is to use  $k$  random projections to project the context vectors from  $\mathbb{R}^D$  to  $\mathbb{R}^k$ . There are total  $D$  unique contexts ( $D \gg k$ ) for all  $Z$  words. Let  $((c_1, v_1); (c_2, v_2) \dots; (c_d, v_d))$  be sparse context vectors of size  $d$  for  $Z$  words. For each word, we use hashing to project the context vectors onto  $k$  directions. We use  $k$  pairwise independent hash functions that maps each of the  $d$  context ( $c_d$ ) dimensions onto  $\beta_{d,k} \in \{-1, +1\}$ ; and compute inner product between  $\beta_{d,k}$  and  $v_d$ . Next,  $\forall k, \sum_d \beta_{d,k} \cdot v_d$  returns the  $k$  random projections for each word “ $z$ ”. We store the  $k$  random projections for all words (mapped to integers) as a matrix  $A$  of size of  $k \times Z$ .

The mechanism described above generates random projections by implicitly creating a random projection matrix from a set of  $\{-1, +1\}$ . This idea of creating implicit random projection matrix

Figure 1: First matrix pairs the words  $1 \dots Z$  and their random projection values. Second matrix sorts each row by the random projection values from smallest to largest. Third matrix throws away the projection values leaving only the words. Fourth matrix maps the words  $1 \dots Z$  to their sorted position in the third matrix for each  $k$ . This allows constant query time for all the words.

is motivated by the work on stable random projections (Li et al., 2006; Li et al., 2008), Count sketch (Charikar et al., 2004), feature hashing (Weinberger et al., 2009) and online Locality Sensitive Hashing (LSH) (Van Durme and Lall, 2010). The idea of generating random projections from the set  $\{-1, +1\}$  was originally proposed by Achlioptas (2003).

Next we create a binary matrix  $B$  using matrix  $A$  by taking sign of each of the entries of the matrix  $A$ . If  $A(i, j) \geq 0$ , then  $B(i, j) = 1$ ; else  $B(i, j) = 0$ . This binarization creates Locality Sensitive Hash (LSH) function that preserves the cosine similarity between every pair of word vectors. This idea was first proposed by Charikar (2002) and used in NLP for large-scale noun clustering (Ravichandran et al., 2005). However, in large-scale noun clustering work, their approach had to store the random projection matrix of size  $D \times k$ ; where  $D$  denotes the number of all unique contexts (which is generally large and  $D \gg Z$ ) and in this paper, we do not explicitly require storing a random projection matrix.

### 3.3 Representation for Fast-Search

We describe three approaches to represent the data (matrix  $A$  and  $B$  from Section 3.2) in such a manner that finding nearest neighbors is fast. These three approaches differ in amount of pre-processing time. First, we propose a naive baseline approach using random projections independently with the best pre-processing time. Second, we describe PLEB (Point Location in Equal Balls) (Indyk and Motwani, 1998; Charikar, 2002) with the worst pre-processing time. Third, we propose a variant of PLEB to reduce its pre-processing time.

#### 3.3.1 Independent Random Projections (IRP)

Here, we describe a naive baseline approach to arrange nearest neighbors next to each other by us-

ing Independent Random Projections (IRP). In this approach, we pre-process the matrix  $A$ . First for matrix  $A$ , we pair the words  $z_1 \dots z_Z$  and their random projection values as shown in Fig. 1(a). Second, we sort the elements of each row of matrix  $A$  by their random projection values from smallest to largest (shown in Fig. 1(b)). The sorting step takes  $O(Z \log Z)$  time (We can assume  $k$  to be a constant). The sorting operation puts all the nearest neighbor words (for each  $k$  independent projections) next to each other. After sorting the matrix  $A$ , we throw away the projection values leaving only the words (see Fig. 1(c)). To search for a word in matrix  $A$  in constant time, we create another matrix  $C$  of size  $(k \times Z)$  (see Fig. 1(d)). Matrix  $C$  maps the words  $z_1 \dots z_Z$  to their sorted position in the matrix  $A$  (see Fig. 1(c)) for each  $k$ .

#### 3.3.2 PLEB

PLEB (Point Location in Equal Balls) was first proposed by Indyk and Motwani (1998) and further improved by Charikar (2002). The improved PLEB algorithm puts in operation *all*  $k$  random projections together. It randomly permutes the ordering of  $k$  binary LSH bits (stored in matrix  $B$ ) for all the words  $p$  times. For each permutation it sorts all the words lexicographically based on their permuted LSH representation of size  $k$ . The sorting operation puts all the nearest neighbor words (using  $k$  projections together) next to each other for all the permutations. In practice  $p$  is generally large, Ravichandran et al. (2005) used  $p = 1000$  in their work.

In our implementation of PLEB, we have a matrix  $A$  of size  $(p \times Z)$  similar to the first matrix in Fig. 1(a). The main difference to the first matrix in Fig. 1(a) is that bit vectors of size  $k$  are used for sorting rather than using scalar projection values. Similar to Fig. 1(c) after sorting, bit vectors are discarded and

a matrix  $C$  of size  $(p \times Z)$  is used to map the words  $1 \dots Z$  to their sorted position in the matrix  $A$ . Note, in IRP approach, the size of  $A$  and  $C$  matrix is  $(k \times Z)$ . In PLEB generating random permutations and sorting the bit vectors of size  $k$  involves worse pre-processing time than using IRP. However, spending more time in pre-processing leads to finding better approximate nearest neighbors.

### 3.3.3 FAST-PLEB

To reduce the pre-processing time for PLEB, we propose a variant of PLEB (FAST-PLEB). In PLEB, while generating random permutations, it uses all the  $k$  bits. In this variant, for each random permutation we randomly sample without replacement  $q$  ( $q \ll k$ ) bits out of  $k$ . We use  $q$  bits to represent each permutation and sort based on these  $q$  bits. This makes pre-processing *faster* for PLEB. Section 4.3 shows that FAST-PLEB only needs  $q = 10$  to perform comparable to PLEB with  $q = 3000$  (that makes FAST-PLEB 300 times faster than PLEB). Here, again we store matrices  $A$  and  $C$  of size  $(p \times Z)$ .

### 3.4 Finding Approximate Nearest Neighbors

The goal here is to exploit three representations discussed in Section 3.3 to find approximate nearest neighbors quickly. For all the three methods (IRP, PLEB, FAST-PLEB), we can use the same fast approximate search which is simple and fast. To search a word “z”, first, we can look up matrix  $C$  to locate the  $k$  positions where “z” is stored in matrix  $A$ . This can be done in constant time (Again assuming  $k$  (for IRP) and  $p$  (for PLEB and FAST-PLEB) to be a constant.). Once, we find “z” in each row, we can select  $b$  (beam parameter) neighbors ( $b/2$  neighbors from left and  $b/2$  neighbors from right of the query word.) for all the  $k$  or  $p$  rows. This can be done in constant time (Assuming  $k$ ,  $p$  and  $b$  to be constants.). This search procedure produces a set of  $bk$  (IRP) or  $bp$  (PLEB and FAST-PLEB) potential nearest neighbors for a query word “z”. Next, we compute Hamming distance between query word “z” and the set of potential nearest neighbors from matrix  $B$  to return  $l$  closest nearest neighbors. For computing hamming distance, all the approaches discussed in Section 3.3 require all  $k$  random projection bits.

## 4 Experiments

We evaluate our system **FLAG** for fast large-scale approximate graph construction. First, we show that using distributed online-PMI algorithm is as effective as offline-PMI. Second, we compare the approximate nearest neighbors lists generated by **FLAG** against the exact nearest neighbor lists. Finally, we show the quality of our approximate similarity lists generated by **FLAG** from the web corpus.

### 4.1 Experimental Setup

**Data sets:** We use two data sets: Gigaword (Graff, 2003) and a copy of news web (Ravichandran et al., 2005). For both the corpora, we split the text into sentences, tokenize and convert into lower-case. To evaluate our approximate graph construction, we evaluate on three data sets: Gigaword (**GW**), Gigaword + 50% of web data (**GWB50**) and Gigaword + 100% (**GWB100**) of web data. Corpus statistics are shown in Table 1. We define the context for a given word “z” as the surrounding words appearing in a window of 2 words to the left and 2 words to the right. The context words are concatenated along with their positions -2, -1, +1, and +2.

Corpus	GW	GWB50	GWB100
<i>Unzipped Size (GB)</i>	12	60	110
<i># of sentences (Million)</i>	57	463	866
<i># of tokens (Billion)</i>	2.1	10.9	20.0

Table 1: Corpus Description

### 4.2 Evaluating Distributed online-PMI

**Experimental Setup:** First we do an intrinsic evaluation to quantitatively evaluate the distributed online-PMI vectors against the offline-PMI vectors computed from Gigaword (**GW**). Offline-PMI computed from the sketches have been shown as effective as exact PMI by Goyal and Daumé III (2011). To compute offline-PMI vectors, we do two passes over the corpus. In the first pass, we store the counts of words, contexts and word-context pairs computed from **GW** in the Count-Min with conservative update (CM-CU) sketch. We use the CM-CU sketch of size 2 billion counters (bounded 8 GB memory)

with 3 hash functions. In second pass, using the aggregated counts from the sketch, we generate the offline-PMI vectors of size  $d = 1000$  for every word. For rest of this paper for distributed online-PMI, we set  $d = 1000$  and the size of the buffer=10,000 and we split the data sets into small chunks of 10 million sentences.

**Intrinsic Evaluation:** We use four kinds of measures: precision (P), recall (R), f-measure (F1) and Pearson’s correlation ( $\rho$ ) to measure the overlap in the context vectors obtained using online and offline PMI.  $\rho$  is computed between contexts that are found in offline and online context vectors. We do this evaluation on 447 words selected from the concatenation of four test-sets mentioned in the next paragraph. On these 447 words, we achieve an average P of .97, average R of .96 and average F1 of .97 and a perfect average  $\rho$  of 1. This evaluation show that the vectors obtained using online-PMI are as effective as offline-PMI.

**Extrinsic Evaluation:** We also compare online-PMI effectiveness on four test sets which consist of word pairs, and their corresponding human rankings. We generate the word pair rankings using online-PMI and offline-PMI strategies. We report the Pearson’s correlation ( $\rho$ ) between the human and system generated similarity rankings. The four test sets are: **WS-353** (Finkelstein et al., 2002) is a set of 353 word pairs. **WS-203:** A subset of WS-353 with 203 word pairs (Agirre et al., 2009). **RG-65:** (Rubenstein and Goodenough, 1965) has 65 word pairs. **MC-30:** A subset of RG-65 dataset with 30 word pairs (Miller and Charles, 1991).

The results in Table 2 shows that by using distributed online-PMI (by making a single pass over the corpus) is comparable to offline-PMI (which is computed by making two passes over the corpus).

For generating context vectors from **GW**, for both offline-PMI and online-PMI, we use a frequency cutoff of 5 for word-context pairs to throw away the rare terms as they are sensitive to PMI (Church and Hanks, 1989). Next, **FLAG** generates online-PMI vectors from **GWB50** and **GWB100** and uses frequency cutoffs of 15 and 25. The higher frequency cutoffs are selected based on the intuition that, with more data, we get more noise, and hence not considering word-context pairs with frequency less than 25 will be better for the system. As **FLAG** is go-

ing to use the context vectors to find nearest neighbors, we also throw away all those words which have  $\leq 50$  contexts associated with them. This generates context vectors for 57,930 words from **GW**; 95,626 from **GWB50** and 106,733 from **GWB100**.

Test Set	WS-353	WS-203	RG-65	MC-30

### 4.3 Evaluating Approximate Nearest Neighbor

**Experimental Setup:** To evaluate approximate nearest neighbor similarity lists generated by **FLAG**, we conduct three experiments. We evaluate all the three experiments on 447 words (test set) as used in Section 4.2. For each word, both exact and approximate methods return  $l = 100$  nearest neighbors. The exact similarity lists for 447 test words is computed by calculating cosine similarity between 447 test words with respect to all other words. We also compare the LSH (computed using Hamming distance between all words and test set.) approximate nearest neighbor similarity lists against the exact similarity lists. LSH provides an upper bound on the performance of our approximate search representations (IRP, PLEB, and FAST-PLEB) for fast-search from Section 3.3). We set the number of projections  $k = 3000$  for all three methods and for PLEB and FAST-PLEB, we set number of permutations  $p = 1000$  as used in large-scale noun clustering work (Ravichandran et al., 2005).

**Evaluation Metric:** We use two kinds of measures, recall and Pearson’s correlation to measure the overlap in the approximate and exact similarity lists. Intuitively, recall (R) captures the number of

	IRP								PLEB								FAST-PLEB

PLEB	.54	.58	.50	.59	.46	.56	.43	.54	.46	.58	.42	.56	.38	.53	.36	.51	.44	.57	.40	.56	.36	.52	.33	.49
FAST-PLEB	.53	.58	.49	.56	.45	.55	.42	.53	.46	.56	.41	.56	.37	.54	.35	.51	.43	.57	.38	.55	.35	.52	.32	.50

Table 5: Evaluation results on comparing LSH, IRP, PLEB, and FAST-PLEB with  $k = 3000$ ,  $b = 40$ ,  $p = 1000$  and  $q = 10$  with exact nearest neighbors across three different data sets: **GW**, **GWB50**, and **GWB100**. We report results on recall (R) and  $\rho$  metric. The gray color row is the system that we use for further evaluations.

nearest neighbors that are found in both the lists and then Pearson’s ( $\rho$ ) correlation captures if the relative order of these lists is preserved in both the similarity lists. We also compute R and  $\rho$  at various  $l = \{10, 25, 50, 100\}$ .

**Results:** For the first experiment, we evaluate IRP, PLEB, and FAST-PLEB against the exact nearest neighbor similarity lists. For IRP, we sample first  $p$  rows and only use  $p$  rather than  $k$ , this ensures that all the three methods (IRP, PLEB, and FAST-PLEB) take the same query time. We vary the approximate nearest neighbor beam parameter  $b = \{20, 30, 40, 50, 100\}$  that controls the number of closest neighbors for a word with respect to each independent random projection. Note, with increasing  $b$ , our algorithm approaches towards LSH (computing Hamming distance with respect to all the words). For FAST-PLEB, we set  $q = 10$  ( $q \ll k$ ) that is the number of random bits selected out of  $k$  to generate  $p$  permuted bit vectors of size  $q$ . The results are reported in Table 3, where the first row compares the LSH approach against the exact similarity list for test set words. Across three columns we compare IRP, PLEB, and FAST-PLEB. For all methods, increasing  $b$  means better recall. If we move down the table, with  $b = 100$ , IRP, PLEB, and FAST-

PLEB get results comparable to LSH (reaches an upper bound). However, using large  $b$  implies generating a long potential nearest neighbor list close to the size of the unique context vectors. If we focus on the gray color row with  $b = 40$  (This will have comparatively *small* potential list and return nearest neighbors in *less* time), IRP has worse recall with best pre-processing time. FAST-PLEB ( $q = 10$ ) is comparable to PLEB (using all bits  $q = 3000$ ) with pre-processing time 300 times faster than PLEB. For rest of this work, **FLAG** will use FAST-PLEB as it has best recall and pre-processing time with fixed  $b = 40$ .

For the second experiment, we vary parameter  $q = \{1, 5, 10, 100, 3000\}$  for FAST-PLEB in Table 4. Table 4 demonstrates using  $q = \{1, 5\}$  result in worse recall, however using  $q = 5$  for FAST-PLEB is better than IRP.  $q = 10$  has comparable recall to  $q = \{100, 3000\}$ . For rest of this work, we fix  $q = 10$  as it has best recall and pre-processing time.

For the third experiment, we increase the size of the data set across the Table 5. With the increase in size of the data set, LSH, IRP, PLEB, and FAST-PLEB ( $q = 10$ ) have worse recall. The reason for such a behavior is that the number of unique context vectors is greater for big data sets. Across all the

Table 6: Sample Top 10 similarity lists returned by FAST-PLEB with  $k = 3000$ ,  $p = 1000$ ,  $b = 40$  and  $q = 10$  from **GWB100**.

three data sets, FAST-PLEB has recall comparable to PLEB with best pre-processing time. Hence, for the next evaluation to show the quality of final lists we use FAST-PLEB with  $q = 10$  for **GWB100** data set.

In Table 6, we list the top 10 most similar words for some words found by our system **FLAG** using **GWB100** data set. Even though **FLAG**'s approximate nearest neighbor algorithm has less recall with respect to exact but still the quality of these nearest neighbor lists is excellent.

For the final experiment, we demonstrate the pre-processing and query time results comparing LSH, IRP, PLEB, and FAST-PLEB with  $k = 3000$ ,  $p = 1000$ ,  $b = 40$  and  $q = 10$  parameter settings. For pre-processing timing results, we perform all the experiments (averaged over 5 runs) on **GWB100** data set with 106, 733 words. The second pre-processing step of the system **FLAG** (Section 3.2) that is dimensionality reduction from  $\mathbb{R}^D$  to  $\mathbb{R}^k$  took 8.8 hours. The pre-processing time differences among IRP, PLEB, and FAST-PLEB from third step (Section 3.3) are shown in second column of Table 7. Experimental results show that the naive baseline IRP is the fastest and FAST-PLEB has 120 times *faster pre-processing time* compared to PLEB.

For comparing query time among several methods, we evaluate over 447 words (Section 4.2). We report average timing results (averaged over 10 runs and 447 words) to find top 100 nearest neighbors for single query word. The results are shown in third column of Table 7. Comparing first and second rows show that LSH is 87 times faster than computing exact top-100 (cosine similarity) nearest neighbors. Comparing second, third, fourth and fifth rows of the table demonstrate that IRP, PLEB and FAST-PLEB

Methods	Preprocessing	Query (seconds)
<i>Exact</i>	n/a	87
LSH	8.8 hours	0.59
IRP	7.5 minutes	0.28
PLEB	1.8 days	0.28
FAST-PLEB	22 minutes	0.26

methods are twice as fast as LSH.

## 5 Applications

We use the graph constructed by **FLAG** from **GWB100** data set (110 GB) by applying FAST-PLEB with parameters  $k = 3000$ ,  $p = 1000$ ,  $q = 10$  and  $b = 40$ . The graph has 106, 733 nodes (words), with each node having 100 edges that denote the top  $l = 100$  approximate nearest neighbors associated with each node. However, **FLAG** applied FAST-PLEB (approximate search) to find these neighbors. Therefore many of these edges can be noisy for our applications. Hence for each node, we only consider top 10 edges. In general for graph-based NLP problems; for example, constructing web-derived polarity lexicons (Velikovich et al., 2010), top 25 edges were used, and for unsupervised part-of-speech tagging using label propagation (Das and Petrov, 2011), top 5 edges were used.

### 5.1 Google Sets Problem

Google Sets problem (Ghahramani and Heller, 2005) can be defined as: given a set of query words, return top  $t$  similar words with respect to query words. To evaluate the quality of our approximate large-scale graph, we return top 25 words which have best aggregated similarity scores with respect to query words. We take 5 classes and their query terms (McIntosh and Curran, 2008) shown in Table 8 and our goal is to learn 25 *new* words which are similar with these 5 query words.

<b>Language:</b> german, french, estonian, hungarian, bulgarian
<b>Place:</b> scandinavia, mongolia, mozambique, zambia, namibia
<b>Nationality:</b> german, hungarian, estonian, latvian, lithuanian
<b>Date:</b> september, february, august, july, november
<b>Organization:</b> looksmart, hotbot, lycos, webcrawler, alltheweb

Table 9: Learned terms for Google Sets Problem

<b>Concrete seeds</b>	car, house, tree, horse, animal man, table, bottle, woman, computer
<b>Abstract seeds</b>	idea, bravery, deceit, trust, dedication anger, humour, luck, inflation, honesty

Table 10: Example seeds for bootstrapping.

We conduct a manual evaluation to directly measure the quality of returned words. We recruited 1 annotator and developed annotation guidelines that instructed each recruiter to judge whether learned values are similar to query words or not. Overall the annotator found almost all the learned words to be similar to the query words. However, the algorithm can not differentiate between different senses of the word. For example, “French” can be a language and a nationality. Table 9 shows the top ranked words with respect to query words.

## 5.2 Learning Concrete and Abstract Words

Our goal is to automatically learn concrete and abstract words (Turney et al., 2011). We apply bootstrapping (Kozareva et al., 2008) on the word graphs by manually selecting 10 seeds for concrete and abstract words (see Table 10). We use in-degree (sum of weights of incoming edges) to compute the score for each node which has connections with known (seeds) or automatically labeled nodes, previously exploited to learn hyponymy relations from the web (Kozareva et al., 2008). We learn concrete and abstract words together (known as mutual exclusion principle in bootstrapping (Thelen and Riloff, 2002; McIntosh and Curran, 2008)), and each word is assigned to only one class. Moreover, after each iteration, we harmonically decrease the weight of the in-degree associated with instances learned in later iterations. We add 25 new instances at each iteration and ran 100 iterations of bootstrapping, yielding 2506 concrete nouns and 2498 abstract nouns. To evaluate our learned words, we searched in WordNet whether they had ‘abstraction’ or ‘physical’ as their hypernym. Out of 2506 learned concrete nouns,

<b>Concrete:</b> girl, person, bottles, wife, gentleman, microcomputer, neighbor, boy, foreigner, housewives, texan, granny, bartender, tables, policeman, chubby, mature, trees, mainframe, backbone, truck
--

<b>Abstract:</b> perseverance, tenacity, sincerity, professionalism, generosity, heroism, compassion, commitment, openness, resentment, treachery, deception, notion, jealousy, loathing, hurry, valour
---

Table 11: Learned concrete/abstract words.

1655 were found in WordNet. According to WordNet, 74% of those are *concrete* and 26% are *abstract*. Out of 2498 learned abstract nouns, 942 were found in WordNet. According to WordNet, 5% of those are *concrete* and 95% are *abstract*. Table 11 shows the top ranked concrete and abstract words.

## 6 Conclusion

We proposed a system, **FLAG** which constructs fast large-scale approximate graphs from large data sets. To build this system we proposed a distributed online-PMI algorithm that scaled up to 110 GB of web data with 866 million sentences in less than 2 days using 100 quad-core nodes. Our both intrinsic and extrinsic experiments demonstrated that online-PMI algorithm not at all loses globally good contexts and perform comparable to offline-PMI. Next, we proposed FAST-PLEB (a variant of PLEB) and empirically demonstrated that it has recall comparable to PLEB with 120 *times faster* pre-processing time. Finally, we show the applicability of **FLAG** on two applications: Google-Sets problem and learning concrete and abstract words.

In future, we will apply **FLAG** to construct graphs using several kinds of contexts like lexical, semantic, syntactic and dependency relations or a combination of them. Moreover, we will apply graph theoretic models on graphs constructed using **FLAG** for solving a large variety of NLP applications.

## Abstract

Short listings such as classified ads or product listings abound on the web. If a computer can reliably extract information from them, it will greatly benefit a variety of applications. Short listings are, however, challenging to process due to their informal styles. In this paper, we present an unsupervised information extraction system for short listings. Given a corpus of listings, the system builds a semantic model that represents typical objects and their attributes in the domain of the corpus, and then uses the model to extract information. Two key features in the system are a semantic parser that extracts objects and their attributes and a listing-focused clustering module that helps group together extracted tokens of same type. Our evaluation shows that the semantic model learned by these two modules is effective across multiple domains.

## 1 Introduction

Short listings such as classified ads or product listings are prevalent on the web. These texts are generally concise – around 10 words in length. Fig. 1 shows some example listings. Due to the recent explosive growth of such listings, extracting information from them becomes crucial for tasks such as faceted search and reasoning. For example, consider an online shopping site on which information about merchandises for sale is posted. Detecting brands/styles/features that are frequently mentioned in the postings would allow a company to design a better marketing strategy.

Most Information Extraction (IE) techniques developed for formal texts, however, would be inapplicable to listings because of their informal and idiosyncratic styles. For example, typos, abbreviations and synonyms often appear and should be resolved (e.g., *apartment/lapt*, *bikel/bicycle*). Symbols could have the special meanings (e.g.,  $\times$  in  $2\times 2$  in Fig. 1 indicates number of bedrooms and bathrooms). Tokenization based only on space is insufficient (e.g., *RawlingBaseball* in Fig. 1). Multiwords such as *granite top* should also be detected. Applying off-the-shelf parsers is infeasible because of unusual phrasal forms in most listings, such as a long sequence of nouns/adjectives (e.g., “*New Paint Wood Floors New Windows Gated Complex*”)

To address these challenges, several approaches have applied machine learning algorithms (Ghani et al., 2006) (Putthividhya and Hu, 2011) or an external knowledge base (Michelson and Knoblock, 2005). These approaches, however, commonly require human supervision to produce training data or to build a knowledge base. This is expensive, requiring repeated manual effort whenever a new domain or a new set of information to be extracted is introduced.

In this paper, we present an unsupervised IE system for listings. The system extracts tokens from a corpus of listings and then clusters tokens of the same types, where each resulting cluster corresponds to an information type (e.g., size, brand, etc.). For formal texts, contexts (e.g., surrounding words) have been a major feature for word clustering (Turney and Pantel, 2010). This feature alone, however, is insufficient for short listings because of lack of contextual clues in short listings.

<i>2x2 Charming Condo – 1515 Martin Avenue near Downtown (from Craigslist)</i>	HousingType: <i>Condo</i> , BedroomNum: 2, BathroomNum: 2, Location: <i>1515 Martin Avenue</i> , Neighborhood: <i>Downtown</i>
<i>RawlingsBaseball Gloves Pro Preferred Black 12” (from EBay)</i>	ProductType: <i>Gloves</i> , Brand: <i>Rawlings</i> , Sport: <i>Baseball</i> , Color: <i>Black</i> , Size: <i>12”</i> , SeriesName: <i>Pro Preferred</i>
<i>LG 32” 1080p LCD TV – \$329 @ BestBuy (from FatWallet)</i>	Product Type: <i>TV</i> , Brand: <i>Panasonic</i> , Size: <i>32”</i> , Resolution : <i>1080P</i> , DisplayTechnology: <i>LCD</i> , Price <i>329\$</i> , Seller: <i>Best Buy</i>

Figure 1: Example short listings and the information extracted from them.

To address this limitation of context-based clustering, we first identify common types of information (main objects and their attributes) represented in listings and apply customized clustering for these types. Specifically, we define a semantic model to explicitly represent these information types, and based on the semantic model, develop two components to improve clustering – a shallow semantic parser and listing-focused clustering module. The semantic parser specifically focuses on extracting main objects and the listing-focused clustering module helps group together extracted tokens of the same type.

Our evaluation shows that our two main contributions (shallow semantic parser and listing-focused clustering) significantly improve performance across three different domains – Craigslist, EBay, and FatWallet. Our system achieves .50~.65 F1-score for the EBay and the FatWallet datasets based on gold standards constructed by human annotators. For the Craigslist dataset, which is more difficult than the other two, F1-score is .35.

## 2 Related Work

**IE on Listings.** (Ghani et al., 2006) (Putthividhya and Hu, 2011) propose semi-supervised approaches to extract product types and their attributes from product listings. (Ghani et al., 2006) applies the EM (Expectation-Maximization) algorithm to incorporate unlabelled data. (Putthividhya and Hu, 2011) uses unlabelled data to build dictionaries of values to be extracted (e.g., brand or model names), which are then used as a feature for a machine learning system. (Michelson and Knoblock, 2005) uses a manually-crafted knowledge base called *reference set* to define standard forms of values to be extracted. Using a string edit function, the system then identifies tokens in listings that have a low distance score with

the values defined in the reference set. They also propose a semi-supervised method to building reference sets (Michelson and Knoblock, 2009). Unlike these systems, our approach is unsupervised.

**Unsupervised Information Extraction.** Most unsupervised IE systems produce clusters for tokens of same type extracted from a corpus of unlabelled texts. (Chambers and Jurafsky, 2011) (Poon and Domingos, 2010) (Chen et al., 2011) focus on extracting frame-like structures (Baker et al., 1998) by defining two types of clusters, event clusters and role clusters. Event clusters define an event (a situation or a frame) such as BOMBING by clustering verbs/nominalized verbs such as  $\{kill, explosion\}$ . Role clusters define the semantic roles of the event (e.g.,  $\{terrorist, gunman\}$  for the Perpetrator role in BOMBING). Similarly, our system defines two types of clusters – the main concept clusters (e.g., TV or book) and the attribute clusters (e.g., size, color). (Chambers and Jurafsky, 2011) is similar to our approach in that it learns a semantic model, called *template*, from unlabelled news articles and then uses the template to extract information.

Our system is different because it focuses on informal listings, which the components (such as a parser) used by these systems cannot handle.

**Field Segmentation (Sequence Modelling).** This task focuses on segmenting a short text, such as bibliographies or listings. (Grenager et al., 2005) presents an unsupervised HMM based on the observation that the segmented fields tend to be of multiple words length. (Haghighi and Klein, 2006) exploits prototype words (e.g., *close*, *near*, *shopping* for the NEIGHBORHOOD attribute) in an unsupervised setting. (Chang et al., 2007) incorporates domain specific constraints in semi-supervised learning. Our task is different than these systems because we focus on extracting information to enable a variety of automated applications such as business

intelligence reporting, faceted search or automated reasoning, rather than segmenting the text. The segmented fields are often a long unstructured text (e.g., *2 bath 1 bed* for `size` rather than 2 for `BathroomNum` and 1 for `BedroomNum`).

**IE on Informal Texts.** IE on informal texts is getting much attention because of the recent explosive growth of these texts. The informal texts that are attempted for IE include online forums (Gruhl et al., 2009), SMS (Beaufort et al., 2010), twitter messages (Liu et al., 2011).

### 3 Our Approach

Given a corpus of listings for a domain of interest, our system constructs a semantic model that represents the types of information and their values to be extracted. Our system then uses the resulting model to extract both the type and value from the corpus<sup>1</sup>.

We first describe the semantic model and then the two key steps for creating this model – shallow semantic parsing and listing-focused clustering. Fig. 3 illustrates these two steps with example listings.

#### 3.1 Semantic Model

Our semantic model captures two important pieces of information – the main concept and its attributes. This representation is based on the observation that most listings (e.g. rentals, products) describe the attributes of a single object (i.e. the main concept in our model). Our system takes advantage of this observation by applying customized clustering for each type of information in the model, which results in better performance compared to a *one-size-fits-all* algorithm. Moreover, this model is general enough to be applicable across a wide range of domains. We quantitatively show both benefits in our evaluation.

Fig. 2 illustrates our model along with an instantiation for rental listings. The main concept is a cluster containing tokens referencing the main object in the listing. For example, in the rental listing, the main concept cluster includes tokens such as *house*, *condo*, and *townhouse*.

Each attribute of the main concept (e.g. `Address`, `BedroomNum`, etc.) is also a cluster, and two types

<sup>1</sup>To handle string variations (e.g., typos) during extraction, our system uses a string edit distance function, Jaro-Winkler distance (Winkler, 1990) with a threshold, 0.9.

Figure 2: Semantic model and its instantiation for rental listings. + indicates multiple clusters can be created.

of attributes are defined in our model – quantitative attributes and qualitative ones. Quantitative attributes capture numeric values (e.g. *1 bedroom*, *150 Hz*, and *70 kg*), and are generally a number followed by a token indicating the attribute (e.g., unit of measurement). Hence, clusters for quantitative attributes include these indicator tokens (see Fig. 2).

Qualitative attributes capture descriptions about the main concept (e.g., address, shipping information, condition). The values of these attributes generally appear in listings without explicitly mentioning the names of these attributes. Hence, the clusters for qualitative attributes include tokens corresponding to the values themselves (e.g. *washer hookup*).

#### 3.2 Shallow Semantic Parser

Our Shallow Semantic Parser (SSP) analyzes an input corpus to produce a partial semantic model. SSP first performs preprocessing and multiword detection. SSP then identifies which resulting tokens are the main concepts and which are their attributes.

##### 3.2.1 Preprocessing and Multiword Detection

SSP preprocesses the corpus through three steps. (1) SSP cleans the corpus by removing duplicate listings and HTML expressions/tags. (2) SSP tokenizes each listing based on spaces along with custom heuristics – e.g., handling alpha-numeric tokens starting with numbers (e.g., *3bedroom* to *3 bedroom*) and mixed case tokens (e.g., *NikeShoes* to *Nike Shoes*). (3) SSP performs POS tagging using an off-the-shelf tagger (Tsuruoka and Tsujii, 2005). To improve accuracy, SSP assigns to a token the most frequent POS across all occurrences of that token. This heuristic works well because most tokens in focused domains, like listings, have only one POS.

SSP then detects multiword tokens based on the following rules:

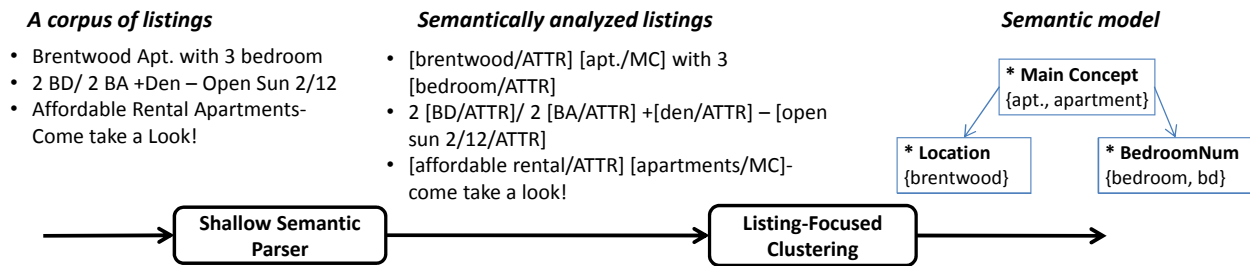

Figure 3: Steps of our system: The parser tokenizes listings (multiword detection) and then identifies main concepts and attributes (marked as MC and ATTR). The clustering module then clusters tokens of the same type. The tags (such as Location, BedroomNum) are included to help understand the figure. They are not produced by the system.

1. If a bigram (e.g., *top floor*) in a listing frequently appears as either a single or dashed token (e.g., *TopFloor* or *top-floor*) in other listings, then the bigram is regarded as a multiword.

2. For each bigram,  $w_1 w_2$  (excluding symbols and numbers), if the conditional probability of the bigram given either  $w_1$  or  $w_2$  (i.e.,  $p(w_1 w_2 \mid w_1 \text{ (or } w_2))$ ) is high (over 0.75 in our system), the bigram is considered as a candidate multiword. This rule tests the tendency of two tokens appearing together when either one appears.

However, this test alone is insufficient, as it often generates coarse-grained results – e.g., *baseball glove*, *softball glove*, and *Hi-Def TV*<sup>2</sup>. To prevent this problem, for each  $w_2$ , we measure the entropy over the distribution of the tokens in the  $w_1$  position. Our intuition is that high variability in the  $w_1$  position (i.e., high entropy) indicates that the multiword is likely a breakable phrase. Hence, those candidates with high entropy are removed.

SPP repeatedly applies the above rules to acquire multiwords of arbitrary length. In our implementation, we limit multiword detection up to four-gram.

### 3.2.2 Main Concept Identification

SSP then identifies the main concepts (*mc\_words*) and their attributes (*attrs*) to produce a partial semantic model. This process is guided by the observation that main concepts tend to appear as head nouns in a listing and attributes as the modifiers of these head nouns (see the examples in Fig. 3).

<sup>2</sup>Even though these examples are legitimate multiwords, they overlook useful information such as baseball and softball are types of gloves and Hi-Def is an attribute of TV.

Algorithm 1 describes the discovery process of *mc\_words* and *attrs*. First, SSP initializes *attrs* with tokens that are likely to be a modifier (line 2), by choosing tokens that frequently appear as the object of a preposition within the corpus – e.g., *for rent*, *with washer and dryer*, *for baseball*.

SSP then iteratively performs two steps – PARSE and EXPANDMODEL (lines 3 ~ 6) – in a bootstrap manner (see Fig. 4). PARSE tags the noun tokens in each listing as either head nouns or modifiers. Specifically, PARSE first assesses if a listing is “hard” to parse (line 10) based on two criteria – (1) the listing contains a long sequence of nouns (seven words or longer in our system) without any prepositions (e.g., *worth shutout series 12” womens fast-pitch softball fielders glove s0120 lefty*); and (2) the majority of these nouns do not appear in *mc\_words* and *attrs* (e.g., over 70% in our system). The listings meeting these criteria are generally difficult to recognize the head noun without any semantic knowledge. PARSE will revisit these listings in the next round as more *mc\_words* and *attrs* are identified.

If a listing does not meet these criteria, PARSE tags nouns appearing in *mc\_words* and *attrs* as head nouns and modifiers respectively (line 11). If this step fails to recognize a head noun, a heuristic is used to identify the head noun – it identifies the first noun phrase by finding a sequence of nouns/adjectives/numbers, and then tags as the head noun the last noun in the phrase that is not tagged as a modifier (line 13). For example, in the first listing of Fig. 3, *brentwood apts.* is the first noun phrase that meets the condition above; and hence *apt.* is tagged as the head noun. The remaining untagged nouns in the listing are tagged as modifiers (line 15).

---

**Algorithm 1** Extracting main concepts

---

```
1: Input: POS-tagged corpus, corp
2: Initialize attrs
3: repeat
4:   (hn,mod) = Parse(corp, mc_words, attrs)
5:   (mc_words,attrs) = ExpandModel(hn,mod)
6: until mc_words, attrs not changed
7:
8: function PARSE(mc_words, attrs)
9:   for all each listing do
10:    if parsible then
11:      Parse with mc_words, attrs
12:      if headnoun is not tagged then
13:        Tag the last noun in the first noun
        phrase that are not a modifier as hn
14:      end if
15:      Tag the other nouns as mod
16:    end if
17:  end for
18: end function
19:
20: function EXPANDMODEL(corp)
21:   For each token, calculate a ratio of as a head
   noun to as a modifier
22:   Add tokens with high ratio to mc_words
23:   Add tokens with low ratio to attrs
24: end function
```

---

EXPANDMODEL assigns tokens to either *mc\_words* or *attrs* based on the tags generated by PARSE. For each token, EXPANDMODEL counts the frequency of the token being tagged as a head noun and as a modifier. If a token is predominately tagged as a head noun (or a modifier), the token is added to *mc\_words* (or *attrs*)<sup>3</sup>.

This bootstrap method is advantageous<sup>4</sup> because SSP can initially focus on easy cases – i.e., *mc\_words* and *attrs* that can be detected with high confidence, such as *condo(mc\_words)* and *bedroom(attrs)*, which often appear as a head noun and a modifier in the easy-to-parse listings. These results can help the system to parse more difficult

<sup>3</sup>In our system, if the ratio of the frequency of the head noun to the frequency of the modifier is over .55, the token is added to *mc\_words*. If less than .35, it is added to *attrs*.

<sup>4</sup>The bootstrapping cycle generally ends within 3~4 iterations.

Figure 4: Bootstrapped PARSE and EXPANDMODEL

listings. For example, identifying *condo(mc\_words)* helps parsing the following more difficult listing, “2 bedroom 1 bathroom condo large patio washer dryer available” – *condo* would be tagged as a head noun and the rest of the nouns as modifiers.

The result of this step is a partial semantic model that contains a cluster for the main concept and a list of candidate attribute tokens.

### 3.3 Listing-Focused Clustering

Listing-Focused Clustering (LFC) further expands the partial semantic model (constructed by SSP) by grouping the remaining candidate attribute tokens into attribute clusters – i.e. one cluster for each attribute of the main concept. LFC may also add a token to the main concept cluster if appropriate.

For formal texts, distributional similarity is widely used for clustering words because the contextual clues in these texts are sufficiently discriminative (Lin and Pantel, 2001). This feature alone, however, is insufficient for listings because they lack discriminative contexts due to the short length. Hence, our approach augments context-based similarity with the following rules (presented in order of precedence), based on general properties we observed from listing data across various domains.

- Two quantitative attribute tokens cannot be placed into the same cluster if they frequently appear together in a listing. For example, *bed* and *bath* should not be clustered because they frequently appear together (e.g. *2 bed / 2bath*). This rule is based on the observation that a quantitative attribute is likely to appear only once in a listing. To enforce this restriction, for all pairs of tokens,  $t_1$  and  $t_2$ , LFC measures the conditional probability of the pair appearing together in a listing given the appearance of either

$t_1$  and  $t_2$ . If any of these conditional probabilities are high,  $t_1$  and  $t_2$  are not clustered.

- Attribute types are strongly enforced by never clustering together a quantitative attribute token and a qualitative attribute token. The type of a token is determined by analyzing the immediate preceding tokens throughout the corpus. If the preceding tokens are generally numbers, then LFC regards the token as a quantitative attribute. Otherwise, the token is regarded as a qualitative attribute.
- Two tokens are similar if the characters in one token appear in the other, preserving the order (e.g., *bdrm* and *bedroom*)

If the above rules fail to determine the similarity between two tokens, LFC reverts to context-based similarity. For each token, LFC creates a context vector containing frequencies of the context words around the token with a window size of two. For example, in the first sentence in Fig. 3, the context words around *apts.* are *l-start* (beginning of the sentence), *l-brentwood*, *r-with*, and *r-3*<sup>5</sup>. The frequencies in these vectors are also weighted using PMI scores (pointwise mutual information) between a token and its context words, as suggested by (Turney and Pantel, 2010). The intuition is that a high PMI indicates a context word is strongly associated with a token and hence has high discriminative power. We also apply a smoothing function suggested in (Turney and Pantel, 2010) to mitigate PMI’s bias towards infrequent events. The similarity score is based on a cosine similarity between the two weighted vectors.

Based on this similarity function, LFC applies agglomerative clustering (with average linkage) to produce attribute clusters (or to expand the main concept cluster). However, calculating similarity scores for all pairs of tokens is expensive. To address this problem, LFC performs clustering in two steps. First, LFC performs agglomerative clustering on all pairs of tokens with high frequency<sup>6</sup>. LFC then calculates the similarity between each low-frequency token and the clusters resulting from the previous step. If the similarity score is over a user-specified

<sup>5</sup> $l$  and  $r$  indicates the left or right window.

<sup>6</sup>The threshold for stopping clustering is determined with the development dataset.

Dataset	Dev	Test	Avg word
Rent Ad	8,950	9,400	9.44
Glove	8,600	9,500	10.56
TV Deal	-	900	15.60

Table 1: **Dev/Test** indicates the number of listings used for development/testing. **Avg word** indicates the average number of words in a listing. The development dataset is used to tune the parameters.

threshold, then LFC adds the token to the cluster. If the score is less than the threshold but the token still appears relatively frequently, then LFC creates a new cluster for the token.

## 4 Evaluation

We perform two evaluations to assess the performance of our approach. First, we evaluate how well our approach extracts the correct type (e.g., *BedroomNum*) and value (e.g., *2*) across multiple domains. Next, we evaluate the contribution of each main component in our approach – i.e., shallow semantic parsing and listing-focused clustering – through an ablation study. We also provide an in-depth error analysis along with how our system’s performance is affected by the corpus size.

### 4.1 Evaluation Setup

We first assemble three different listing datasets for our evaluation – housing rental advertisements from Craigslist (*Rent Ad*), auction listings of baseball gloves from EBay (*Glove*), and hot deal postings of TV/Projector from FatWallet (*TV Deal*)<sup>7</sup>. Table 1 shows the size of each dataset, and example listings are shown in Fig. 1<sup>8</sup>. We also include example extractions for each domain in Table. 3.

We then construct a gold standard by employing two independent human annotators. To do this, we first define the information types (i.e. main concept and attribute) for each dataset (and hence the targets for extraction). We use attributes from EBay

<sup>7</sup>The datasets are available at <https://sites.google.com/site/2soonk/>

<sup>8</sup>The parameters were tuned by the development set. Our system is sensitive to the similarity score threshold in agglomerative clustering but less sensitive to the other parameters. Hence, we tuned the similarity threshold for each domain while fixing the values for the other parameters across different domains.

Rent Ad	housing_type (.70/.93), num_bedroom (.94/.99), num_bathroom (.97/1), location (-.64/.82), neighborhood (.55/.79), others(14 types)
Glove	product_type (.71/1.00), brand (.58/.98), sport (.71/1.00), size (.87/.99), series_name (.51/.77), others(10 types)
TV Deal	product_type (.98/1.00), size (.85/1.00), display_technology (.93/1.00), resolution (.89/.99), seller (.73/1.00), others(14 types)

Table 2: Information types for each domain. See Fig. 1 for the examples of each type. Due to space limitation, we show only top five types in terms of the number of extractions made by the annotators. The parentheses indicate inter-annotator agreement based on exact match between two annotators (first number) and partial match (second number). Exact agreement for qualitative attributes (e.g., location, neighborhood, series\_name) is found to be difficult.

Rent Ad	housing_type	studio, townhome, condo, townhouse, cottage,
	num_bedroom	bd, bed, br, bedroom, bdrm, bedrooms
	neighborhood	downtown, San Francisco, china town
Glove	product_type	mitt, base mitt, glove, glove mitt
	size	”, inch, in
	brand	rawlings, louisville slugger, mizuno, wilson
TV Deal	product_type	hdtv, wall mount, monitor
	size	”, inch
	seller	walmart, amazon, newegg, best buy

Table 3: Examples of positive extractions for the main concept attributes (e.g., housing\_type, product\_type), the qualitative attributes (e.g., num\_bedroom, size) and the quantitative attributes (e.g., neighborhood, brand, seller) used in the experiment

as the starting point for *Glove* and *TV Deal*; and attributes from Rent.com<sup>9</sup> for *Rent Ad*. We review these attributes with two independent Subject Matter Experts (SMEs) to identify (and include) additional, missing attributes that are useful for analytics and reporting. In total, 19 types (*Rent Ad*), 15 types (*Glove*) and 19 types (*TV Deal*) are defined. For each dataset, we randomly select 100 listings from the *Test* listings, and instruct each annotator to extract values from these listings, based on the information types for the dataset. Table 2 shows the defined attributes of each data set and the inter-annotator agreement across the attributes<sup>10</sup>.

Finally, we apply our system to the *Test* listings in each dataset; and evaluate the extraction results

against the gold standards using the metrics of precision (P), recall (R), and F1-score (a harmonic mean of precision and recall). Each extraction result is a tuple  $(T_i, v_i)$  where  $T_i$  is the information type (e.g., BedroomNum) and  $v_i$  is the value (e.g. 2).

$$P = \frac{\# \text{ correct extractions by our system}}{\text{Total \# extractions by our system}}$$

$$R = \frac{\# \text{ correct extractions by our system}}{\text{Total \# extractions by an annotator}}$$

We say that an extraction result is correct if  $v_i$  matches exactly the value extracted by the annotator and  $T_i$  matches the information type assigned to  $v_i$  by the annotator. To enforce this criteria, we match the attribute clusters produced by our system to the information types. This matching step is needed because our approach is unsupervised and hence the clusters are unlabelled. We use two methods for this matching step – many-to-one mapping and one-to-one mapping. For many-to-one mapping (as used in (Chen et al., 2011)), we match an attribute cluster to the information type whose values (as extracted by the annotator) have the highest overlap with the

<sup>9</sup><http://www.rent.com>

<sup>10</sup>We use Cohen’s kappa,  $\frac{P(a)-P(e)}{1-P(e)}$ .  $P(a)$ , the agreement probability, is calculated by the number of listings in which the two annotators agree divided by 100.  $P(e)$ , the chance agreement probability, is calculated by  $\sum_{(T_i, v_i)} P_1((T_i, v_i)) * P_2((T_i, v_i))$  in which  $P_j((T_i, v_i))$  denotes a probability of extracting  $v_i$  of the type  $T_i$  by the annotator  $j$ .  $P((T_i, v_i))$  is calculated by the frequency of  $(T_i, v_i)$  extracted divided by the frequency of  $T_i$  extracted.

values of the cluster. Hence, many attribute clusters can map to the same information type. This method, however, has one major disadvantage: high performance can be easily achieved by creating small-sized clusters – e.g., singleton clusters in the extreme case. To mitigate this problem, we also use a one-to-one mapping method – i.e. at most one attribute cluster (i.e. the one with the best overlap) can be mapped to one information type.

We report results for both methods. We also report results for partial matches using the same metrics above. We say that an extraction result is partially correct if  $v_i$  partially matches the value extracted by the annotator (*hardwood vs. hardwood floors*) and  $T_i$  matches the information type assigned to  $v_i$  by the annotator.<sup>11</sup>

## 4.2 Performance Across Multiple Domains

Table 4 shows the system performance result across the domains. Considering our approach is unsupervised, the result is encouraging. For the baseball glove and the TV dataset, F-score is .51 and .66 (in one-to-one mapping). For the rent ad, which is more difficult, F-score is .39. We hypothesize that the low F1-score in the rent ad dataset is the result of poor extraction due to spurious tokens (e.g., *our community, this weather*). To test this hypothesis, we measure the performance of our system only on the extraction task (i.e., excluding the information type assignment task). Table 5 shows that the performance on extraction for the rent ad dataset is the lowest, confirming our hypothesis.

We also measure the performance per each information type. Fig. 5 shows the result, revealing several facts. First, the main concept clusters (housing\_type and product\_type) achieve a high F1-score, showing the benefit of our semantic parser. Sec-

<sup>11</sup>We could not compare our system to other systems for several reasons. First, to the best of our knowledge, no unsupervised IE system has been built specifically for short listings. Second, semi-supervised systems such as (Putthividhya and Hu, 2011) (Michelson and Knoblock, 2005) require domain-specific dictionaries, which are expensive to build and scale. Third, even developing a supervised IE system is non-trivial. In our preliminary evaluation with the (linear chain) conditional random field (170/30 training/testing listings) using basic features (the lexemes and POS of the current word and words in the two left/right windows), precision/recall/F1-score are .5/.33/.4. This result is no better than our system. More training data and/or better features seem to be required.

	Full			Full(Par)		
	P	R	F	P	R	F
Rent Ad	0.3	0.41	0.35	0.43	0.55	0.48
(302/219)	0.34	0.46	0.39	0.65	0.69	0.67
Glove	0.54	0.48	0.51	0.72	0.58	0.64
(563/631)	0.57	0.51	0.54	0.81	0.65	0.72
TV Deal	0.7	0.63	0.66	0.81	0.7	0.75
(765/851)	0.74	0.67	0.7	0.86	0.74	0.79

Table 4: Performance based on one-to-one (first row) and many-to-one mappings (second row) combined across both annotators. Full indicates exact match between system’s extraction and annotators’ extraction. (Par) indicates partial match. The parentheses indicate the total number of extraction made by our system and the annotators (averaged) respectively.

	Full	Full(Par)	Ext	Ext(Par)
Rent Ad	0.35	0.48	0.42	0.58
Glove	0.51	0.64	0.62	0.69
TV Deal	0.66	0.75	0.75	0.77

Table 5: F1-score when considering only extraction task (Ext and Ext(Par)). Ext(Par) is based on partial match.

ond, the quantitative attributes (e.g., num\_bedroom, glove\_size, screen\_size) generally have a higher F1 than the qualitative attributes (e.g., location, neighborhood, series\_name). These qualitative attributes, in fact, have a low inter-annotator agreement (e.g., -.64, .55 for location and neighborhood in Rent Ad and .51 for series\_name in Glove), indicating the difficulty of exactly predicting the extractions made by the annotators. If we consider the partial match or the extraction only match (Ext) for those qualitative attributes, their F1-scores are significantly higher than the exact match in the Full task.

## 4.3 Ablation Study

To evaluate our semantic parser and listing-focused clustering module, we ablate these two components to create four versions of our system for comparison – Baseline, Baseline+LFC, Baseline+SSP and Full System. Baseline performs a space-based tokenization followed by clustering based only on the context feature. Baseline+LFC and Baseline+SSP add listing-focused clustering and shallow semantic parser features respectively. The Full system uses both features.

Figure 5: F1-score across the attribute types shown in Table 2. The parentheses indicate the number of extractions made by our system and the annotators respectively.

		Rent Ad			Glove			TV Deal		
		P	R	F	P	R	F	P	R	F
Full	Baseline	0.10	0.27	0.14	0.26	0.34	0.29	0.42	0.51	0.46
	Baseline+LFC	0.11	0.30	0.16	<b>0.30</b> <sup>†</sup>	<b>0.39</b> <sup>†</sup>	0.34	0.42	0.51	0.46
	Baseline+SSP	<b>0.21</b> *	<b>0.37</b> *	0.26	<b>0.46</b> *	<b>0.47</b> *	0.46	<b>0.65</b> *	<b>0.59</b> *	0.62
	Full System	<b>0.30</b> *	<b>0.41</b> *	0.35	<b>0.54</b> *	<b>0.48</b> *	0.51	<b>0.70</b> *	<b>0.63</b> *	0.66
Full(Par)	Baseline	0.15	0.40	0.22	0.37	0.50	0.42	0.59	0.69	0.63
	Baseline+SSP	0.15	0.43	0.22	<b>0.44</b> *	<b>0.56</b> *	0.49	0.59	0.69	0.63
	Baseline+LFC	<b>0.39</b> *	<b>0.55</b> *	0.46	0.37	0.34	0.35	<b>0.79</b> *	0.69	0.73
	Full System	<b>0.43</b> *	<b>0.55</b> *	0.48	<b>0.72</b> *	<b>0.58</b> *	0.64	<b>0.81</b> *	0.70	0.75

Table 6: Based on one-to-one mapping. \* indicates two-tail statistically significant difference ( $p < 0.05$ ) against Baseline in Fisher’s test. † indicates one-tail difference. The Fisher’s test is inapplicable to F1-scores.

Rent Ad		Glove		TV Deal	
NOT IN MAPPING	0.42	NOT IN MAPPING	0.27	NOT_IN_MAPPING	0.33
WRONG EXT	0.25	WRONG EXT	0.16	WRONG EXT	0.20
TK-neighborhood	0.05	WRONG TYPE	0.15	TK-display_technology	0.13
TK-housing_type	0.05	TK-series_name	0.13	TK-shipping_info	0.07
TK-location	0.03	TK-dexterity	0.12	WRONG TYPE	0.07

Table 7: The top five errors based on the one-to-one mapping.

The results shown in Table 6 lead to the following observations. First, the use of SSP (Baseline+SSP) makes an improvement for all categories except Full(Par) in the glove dataset. This is because SSP identifies main concepts accurately. Second, while LFC by itself (Bseline+LFC) is effective only in the glove dataset, it has the best F1-score in all three domains when combined with SSP (Full System). The result also shows that the simple space-based tokenization and the context-based clustering (Baseline) is insufficient for handling short listings.

#### 4.4 Error Analysis and Corpus Size Effect

We analyze the error types for the wrong extraction made by our system. Specifically, for each error, we assign it to one (or more) of the following causes: (1) a cluster (and hence attribute type) was excluded due to the 1-to-1 mapping methodology described above (NOT IN MAPPING); (2) the value extracted by the system was not extracted by any of the annotators (WRONG EXT); (3) wrong information type – i.e., the token belonged to a wrong cluster (WRONG TYPE); (4) incorrect tokenization for an information type (TK-<type name>).

Table 7 shows the result. In all three domains, NOT IN MAPPING is a major source of error, indicating the system’s clusters are too fine-grained as compared to the gold standard. WRONG EXT is another source of error (especially in the housing rental), indicating the system should extract more informative tokens. Tokenization on the qualitative attributes (neighborhood, series name, display technology in Table 7) should be improved also.

Finally, we measure the effect of the corpus size on the system performance. Fig. 6 shows how the F1-score varies with the corpus size<sup>12</sup>. It shows that a small corpus size is sufficient for achieving good performance. We hypothesize that, for focused domains such as our dataset, only a couple of hundred listings are sufficient to acquire meaningful statistics.

## 5 Conclusion and Future Work

We presented an unsupervised IE system on short listings. The key features in our system are a shal-

<sup>12</sup>Due to the space limitation, we include only the rent domain result. However, all three datasets follow a similar pattern.

Figure 6: F1-score of our system over varying corpus size for the rent domain

low semantic parser and a listing-focused clustering module. Our evaluation shows the benefits of the two features across multiple domains. To improve our system further, we plan the following works.

First, we plan to compare our system with supervised systems to identify the gap between the two systems. Second, as in (Poon and Domingos, 2010), we plan to explore a joint learning method to combine the tasks of tokenization, forming the main concept cluster and forming the attribute clusters; these tasks depend on the outputs of one another. Finally, we plan to explore that external knowledge resources such as DBPedia (Auer et al., 2007) and FreeBase (Bollacker et al., 2008) can be used to further improve performance.

## 6 Acknowledgements

We would like to thank Colin Puri and Rey Vasquez for their contribution to this work. We also thank the anonymous reviewers for their helpful comments and suggestions for improving the paper.

## Abstract

Many NLP tasks rely on accurate statistics from large corpora. Tracking complete statistics is memory intensive, so recent work has proposed using compact approximate “sketches” of frequency distributions. We describe 10 sketch methods, including existing and novel variants. We compare and study the errors (over-estimation and under-estimation) made by the sketches. We evaluate several sketches on three important NLP problems. Our experiments show that *one* sketch performs best for all the three tasks.

## 1 Introduction

Since the emergence of the World Wide Web, social media and mobile devices, we have ever larger and richer examples of text data. Such vast corpora have led to leaps in the performance of many language-based tasks: the concept is that simple models trained on big data can outperform more complex models with fewer examples. However, this new view comes with its own challenges: principally, how to effectively represent such large data sets so that model parameters can be efficiently extracted? One answer is to adopt compact summaries of corpora in the form of probabilistic “sketches”.

In recent years, the field of Natural Language Processing (NLP) has seen tremendous growth and interest in the use of approximation, randomization, and streaming techniques for large-scale problems (Brants et al., 2007; Turney, 2008). Much of this work relies on tracking very many statistics. For example, storing approximate counts (Talbot and Osborne, 2007; Van Durme and Lall, 2009a; Goyal and Daumé III, 2011a), computing approximate as-

sociation scores like Pointwise Mutual Information (Li et al., 2008; Van Durme and Lall, 2009b; Goyal and Daumé III, 2011a), finding frequent items (like  $n$ -grams) (Goyal et al., 2009), building streaming language models (Talbot and Brants, 2008; Levenberg and Osborne, 2009), and distributional similarity (Ravichandran et al., 2005; Van Durme and Lall, 2010). All these problems ultimately depend on approximate counts of items (such as  $n$ -grams, word pairs and word-context pairs). Thus we focus on solving this central problem in the context of NLP applications.

Sketch algorithms (Charikar et al., 2004; Cormode, 2011) are a memory- and time-efficient solution to answering point queries. Recently in NLP, we (Goyal and Daumé III, 2011a) demonstrated that a version of the Count-Min sketch (Cormode and Muthukrishnan, 2004) accurately solves three large-scale NLP problems using small bounded memory footprint. However, there are several other sketch algorithms, and it is not clear why this instance should be preferred amongst these. In this work, we conduct a systematic study and compare many sketch techniques which answer point queries with focus on large-scale NLP tasks. While sketches have been evaluated within the database community for finding frequent items (Cormode and Hadjieleftheriou, 2008) and join-size estimation (Rusu and Dobra, 2007), this is the *first* comparative study for NLP problems.

Our work includes three contributions: (1) We propose novel variants of existing sketches by extending the idea of *conservative update* to them. We propose Count sketch (Charikar et al., 2004) with conservative update (COUNT-CU) and Count-mean-min sketch with conservative update

(CMM-CU). The motivation behind proposing new sketches is inspired by the success of Count-Min sketch with conservative update in our earlier work (Goyal and Daumé III, 2011a). (2) We empirically compare and study the errors in approximate counts for several sketches. Errors can be over-estimation, under-estimation, or a combination of the two. We also evaluate their performance via Pointwise Mutual Information and LogLikelihood Ratio. (3) We use sketches to solve three important NLP problems. Our experiments show that sketches can be very effective for these tasks, and that the best results are obtained using the “conservative update” technique. Across all the three tasks, *one* sketch (CM-CU) performs best.

## 2 Sketches

In this section, we review existing sketch algorithms from the literature, and propose novel variants based on the idea of conservative update (Estan and Varghese, 2002). The term ‘sketch’ refers to a class of algorithm that represents a large data set with a compact summary, typically much smaller than the full size of the input. Given an input of  $N$  items  $(x_1, x_2 \dots x_N)$ , each item  $x$  (where  $x$  is drawn from some domain  $U$ ) is mapped via hash functions into a small sketch vector that records frequency information. Thus, the sketch does not store the items explicitly, but only information about the frequency distribution. Sketches support fundamental queries on their input such as point, range and inner product queries to be quickly answered approximately. In this paper, we focus on point queries, which ask for the (approximate) count of a given item.

The algorithms we consider are *randomized* and *approximate*. They have two user-chosen parameters  $\epsilon$  and  $\delta$ .  $\epsilon$  controls the amount of tolerable error in the returned count and  $\delta$  controls the probability with which the error exceeds the bound  $\epsilon$ . These values of  $\epsilon$  and  $\delta$  determine respectively the width  $w$  and depth  $d$  of a two-dimensional array  $\text{sk}[\cdot, \cdot]$  of count information. The depth  $d$  denotes the number of hash functions employed by the sketch algorithms.

**Sketch Operations.** Every sketch has two operations: UPDATE and QUERY to update and estimate the count of an item. They all guarantee essentially

*constant time* operation (technically, this grows as  $O(\log(\frac{1}{\delta}))$ ) but in practice this is set to a constant per UPDATE and QUERY. Moreover, sketches can be combined: given two sketches  $s_1$  and  $s_2$  computed (using the same parameters  $w$  and  $d$ , and same set of  $d$  hash functions) over different inputs, a sketch of the combined input is obtained by adding the individual sketches, entry-wise. The time to perform the COMBINE operation on sketches is  $O(d \times w)$ , independent of the data size. This property enables sketches to be implemented in distributed setting, where each machine computes the sketch over a small portion of the corpus and makes it *scalable* to large datasets.

### 2.1 Existing sketch algorithms

This section describes sketches from the literature:

**Count-Min sketch (CM):** The CM (Cormode and Muthukrishnan, 2004) sketch has been used effectively for many large scale problems across several areas, such as Security (Schechter et al., 2010), Machine Learning (Shi et al., 2009; Aggarwal and Yu, 2010), Privacy (Dwork et al., 2010), and NLP (Goyal and Daumé III, 2011a). The sketch stores an array of size  $d \times w$  counters, along with  $d$  hash functions (drawn from a pairwise-independent family), one for each row of the array. Given an input of  $N$  items  $(x_1, x_2 \dots x_N)$ , each of the hash functions  $h_k: U \rightarrow \{1 \dots w\}, \forall 1 \leq k \leq d$ , takes an item from the input and maps it into a counter indexed by the corresponding hash function.

UPDATE: For each new item “ $x$ ” with count  $c$ , the sketch is updated as:

$$\text{sk}[k, h_k(x)] \leftarrow \text{sk}[k, h_k(x)] + c, \forall 1 \leq k \leq d.$$

QUERY: Since multiple items are hashed to the same index for each array row, the stored frequency in each row is guaranteed to *overestimate* the true count, making it a biased estimator. Therefore, to answer the point query (QUERY( $x$ )), CM returns the minimum over all the  $d$  positions  $x$  is stored.

$$\hat{c}(x) = \min_k \text{sk}[k, h_k(x)], \forall 1 \leq k \leq d.$$

Setting  $w = \frac{2}{\epsilon}$  and  $d = \log(\frac{1}{\delta})$  ensures all reported frequencies by CM exceed the true frequencies by at most  $\epsilon N$  with probability of at least  $1 - \delta$ . This makes the space used by the algorithm  $O(\frac{1}{\epsilon} \log \frac{1}{\delta})$ .

**Spectral Bloom Filters (SBF):** Cohen and Matias (2003) proposed SBF, an extension to Bloom Filters (Bloom, 1970) to answer point queries. The

UPDATE and QUERY procedures for SBF are the same as Count-Min (CM) sketch, except that the range of all the hash functions for SBF are the full array:  $h_k: U \rightarrow \{1 \dots w \times d\}, \forall 1 \leq k \leq d$ . While CM and SBF are very similar, only CM provides guarantees on the query error.

**Count-mean-min (CMM)** (Deng and Rafiei, 2007) sketch is to provide an unbiased estimator for Count-Min (CM) sketch. The construction of CMM sketch is identical to the CM sketch, while the QUERY procedure differs. Instead of returning the minimum value over the  $d$  counters (indexed by  $d$  hash functions), CMM deducts the value of estimated noise from each of the  $d$  counters, and return the median of the  $d$  residues. The noise is estimated as  $(N - \text{sk}[k, h_k(x)]) / (w - 1)$ . Nevertheless, the median estimate ( $\hat{f}_1$ ) over the  $d$  residues can overestimate more than the original CM sketch min estimate ( $\hat{f}_2$ ), so we return  $\min(\hat{f}_1, \hat{f}_2)$  as the final estimate for CMM sketch. CMM gives the same theoretical guarantees as Count sketch (below).

**Count sketch (COUNT)** (Charikar et al., 2004): COUNT (aka Fast-AGMS) keeps two hash functions for each row,  $h_k$  maps items onto  $[1, w]$ , and  $g_k$  maps items onto  $\{-1, +1\}$ . UPDATE: For each new item “x” with count  $c$ :  $\text{sk}[k, h_k(x)] \leftarrow \text{sk}[k, h_k(x)] + c \cdot g_k(x), \forall 1 \leq k \leq d$ . QUERY: the median over the  $d$  rows is an unbiased estimator of the point query:

$$c(\hat{x}) = \text{median}_k \text{sk}[k, h_k(x)] \cdot g_k(x), \forall 1 \leq k \leq d.$$

Setting  $w = \frac{2}{\epsilon^2}$  and  $d = \log(\frac{4}{\delta})$  ensures that all reported frequencies have error at most  $\epsilon(\sum_{i=1}^N f_i^2)^{1/2} \leq \epsilon N$  with probability at least  $1 - \delta$ . The space used by the algorithm is  $O(\frac{1}{\epsilon^2} \log \frac{1}{\delta})$ .

## 2.2 Conservative Update sketch algorithms

In this section, we propose novel variants of existing sketches (see Section 2) by combining them with the conservative update process (Estan and Varghese, 2002). The idea of conservative update (also known as Minimal Increase (Cohen and Matias, 2003)) is to only increase counts in the sketch by the minimum amount needed to ensure the estimate remains accurate. It can easily be applied to Count-Min (CM) sketch and Spectral Bloom Filters (SBF) to further improve the estimate of a point query. Goyal and Daumé III (2011a) showed that CM sketch with

conservative update reduces the amount of over-estimation error by a factor of at least 1.5, and also improves performance on three NLP tasks.

Note that while conservative update for CM and SBF never increases the error, there is no guaranteed improvement. The method relies on seeing multiple updates in sequence. When a large corpus is being summarized in a distributed setting, we can apply conservative update on each sketch independently before combining the sketches together (see “Sketch Operations” in Section 2).

### Count-Min sketch with conservative update

**Count-Min sketch with conservative update (CM-CU)**: The QUERY procedure for CM-CU (Cormode, 2009; Goyal and Daumé III, 2011a) is identical to Count-Min. However, to UPDATE an item “x” with frequency  $c$ , we first compute the frequency  $\hat{c}(x)$  of this item from the existing data structure ( $\forall 1 \leq k \leq d, \hat{c}(x) = \min_k \text{sk}[k, h_k(x)]$ ) and the counts are updated according to:

$$\text{sk}[k, h_k(x)] \leftarrow \max\{\text{sk}[k, h_k(x)], \hat{c}(x) + c\} \quad (*).$$

The intuition is that, since the point query returns the minimum of all the  $d$  values, we update a counter only if it is necessary as indicated by (\*). This heuristic avoids unnecessarily updating counter values to reduce the over-estimation error.

### Spectral Bloom Filters with conservative update

**Spectral Bloom Filters with conservative update (SBF-CU)**: The QUERY procedure for SBF-CU (Cohen and Matias, 2003) is identical to SBF. SBF-CU UPDATE procedure is similar to CM-CU, with the difference that all  $d$  hash functions have the common range  $d \times w$ .

### Count-mean-min with conservative update

**Count-mean-min with conservative update (CMM-CU)**: We propose a *new* variant to reduce the over-estimation error for CMM sketch. The construction of CMM-CU is identical to CM-CU. However, due to conservative update, each row of the sketch is not updated for every update, hence the sum of counts over each row ( $\sum_i \text{sk}[k, i], \forall 1 \leq k \leq d$ ) is not equal to input size  $N$ . Hence, the estimated noise to be subtracted here is  $(\sum_i \text{sk}[k, i] - \text{sk}[k, h_k(x)]) / (w - 1)$ . CMM-CU deducts the value of estimated noise from each of the  $d$  counters, and returns the median of the  $d$  residues as the point query.

### Count sketch with conservative update

**Count sketch with conservative update (COUNT-CU)**: We propose a *new* variant to reduce over-estimation error for the COUNT sketch. The QUERY procedure for COUNT-CU is the same as

COUNT. The UPDATE procedure follows the same outline as CM-CU, but uses the current estimate  $\hat{c}(x)$  from the COUNT sketch, i.e.

$$\hat{c}(x) = \text{median}_k \text{sk}[k, h_k(x)] \cdot g_k(x), \forall 1 \leq k \leq d.$$

Note, this heuristic is not as strong as for CM-CU and SBF-CU because COUNT can have both over-estimate and under-estimate errors.

**Lossy counting with conservative update (LCU-WS):** LCU-WS (Goyal and Daumé III, 2011b) was proposed to reduce the amount of over-estimation error for CM-CU sketch, without incurring too much under-estimation error. This scheme is inspired by lossy counting (Manku and Motwani, 2002). In this approach, the input sequence is conceptually divided into *windows*, each containing  $1/\gamma$  items. The size of each window is equal to size of the sketch i.e.  $d \times w$ . Note that there are  $\gamma N$  windows; let  $t$  denote the index of current window. At window boundaries,  $\forall 1 \leq i \leq d, 1 \leq j \leq w$ , if  $(\text{sk}[i, j] > 0 \text{ and } \text{sk}[i, j] \leq t)$ , then  $\text{sk}[i, j] \leftarrow \text{sk}[i, j] - 1$ . The idea is to remove the contribution of small items colliding in the same entry, while not altering the count of frequent items. The current window index is used to draw this distinction. Here, all reported frequencies  $\hat{f}$  have both under and over estimation error:  $f - \gamma N \leq \hat{f} \leq f + \epsilon N$ .

**Lossy counting with conservative update II (LCU-SWS):** This is a variant of the previous scheme, where the counts of the sketch are decreased more conservatively. Hence, this scheme has worse over-estimation error compared to LCU-WS, with better under-estimation. Here, only those counts are decremented which are at most the square root of current window index,  $t$ . At window boundaries,  $\forall 1 \leq i \leq d, 1 \leq j \leq w$ , if  $(\text{sk}[i, j] > 0 \text{ and } \text{sk}[i, j] \leq \lceil \sqrt{t} \rceil)$ , then  $\text{sk}[i, j] \leftarrow \text{sk}[i, j] - 1$ . LCU-SWS has similar analytical bounds to LCU-WS.

### 3 Intrinsic Evaluations

We empirically compare and study the errors in approximate counts for all 10 sketches. Errors can be over-estimation, under-estimation, or a combination of the two. We also study the behavior of approximate Pointwise Mutual Information and Log Likelihood Ratio for the sketches.

### 3.1 Experimental Setup

**DATA:** We took 50 million random sentences from Gigaword (Graff, 2003). We split this data in 10 chunks of 5 million sentences each. Since all sketches have probabilistic bounds, we report average results over these 10 chunks. For each chunk, we generate counts of all word pairs within a window size 7. This results in an average stream size of 194 million word pair tokens and 33.5 million word pair types per chunk.

To compare error in various sketch counts, first we compute the exact counts of all the word pairs. Second, we store the counts of all the word pairs in all the sketches. Third, we query sketches to generate *approximate* counts of all the word pairs. Recall, we do not store the word pairs explicitly in sketches but only a compact summary of the associated counts.

We fix the size of each sketch to be  $w = \frac{20 \times 10^6}{3}$  and  $d = 3$ . We keep the size of sketches equal to allow fair comparison among them. Prior work (Deng and Rafiei, 2007; Goyal and Daumé III, 2011a) showed with *fixed sketch size*, a small number of hash functions ( $d$ =number of hash functions) with large  $w$  (or range) give rise to small error over counts. Next, we group all word pairs with the same true frequency into a single bucket. We then compute the Mean Relative Error (MRE) in each of these buckets. Because different sketches have different accuracy behavior on low, mid, and high frequency counts, making this distinction based on frequency lets us determine the regions in which different sketches perform best. Mean Relative Error (MRE) is defined as the average of absolute difference between the predicted and the exact value divided by the exact value over all the word pairs in each bucket.

### 3.2 Studying the Error in Counts

We study the errors produced by all 10 sketches. Since various sketches result in different errors on low, mid, and high frequency counts, we plot the results with a linear error scale (Fig. 1(a)) to highlight the performance for low frequency counts, and with a log error scale (Fig. 1(b)) for mid and high frequency counts.

We make several observations on low frequency counts from Fig. 1(a). (1) Count-Min (CM) and

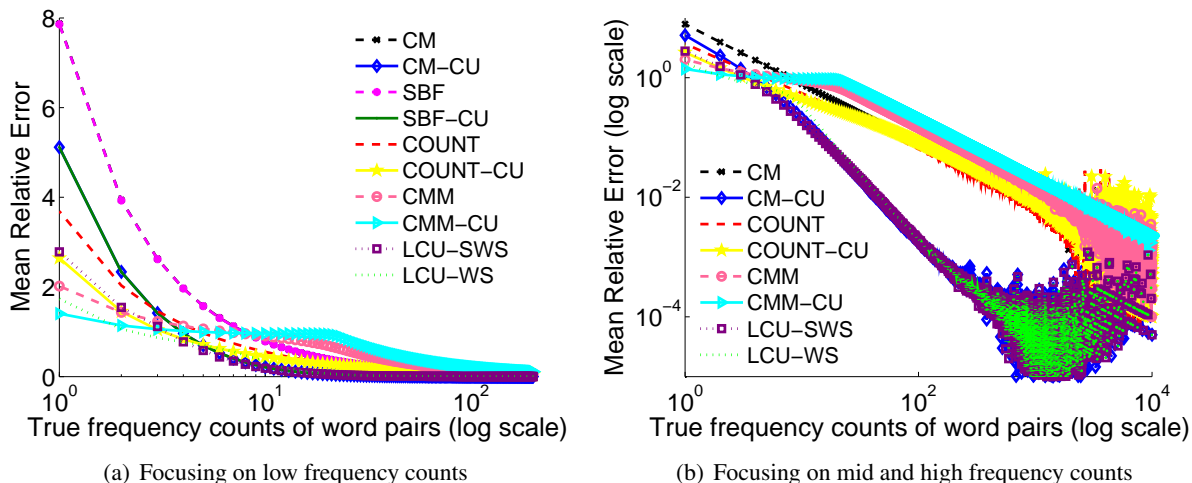

Figure 1: Comparing several sketches for input size of 75 million word pairs. Size of each sketch:  $w = \frac{20 \times 10^6}{3}$  and  $d = 3$ . All items with same exact count are put in one bucket and we plot Mean Relative Error on the y-axis with exact counts on the x-axis.

Spectral Bloom Filters (SBF) have identical MRE for word pairs. Using conservative update with CM (CM-CU) and SBF (SBF-CU) reduces the MRE by a factor of 1.5. MRE for CM-CU and SBF-CU is also identical. (2) COUNT has better MRE than CM-CU and using conservative update with COUNT (COUNT-CU) further reduces the MRE. (3) CMM has better MRE than COUNT and using conservative update with CMM (CMM-CU) further reduces the MRE. (4) Lossy counting with conservative update variants (LCU-SWS, LCU-WS) have comparable MRE to COUNT-CU and CMM-CU respectively.

In Fig. 1(b), we do not plot the SBF variants as SBF and CM variants had identical MRE in Fig. 1(a). From Figure 1(b), we observe that, CM, COUNT, COUNT-CU, CMM, CMM-CU sketches have worse MRE than CM-CU, LCU-SWS, and LCU-WS for mid and high frequency counts. CM-CU, LCU-SWS, and LCU-WS have zero MRE for all the counts  $> 1000$ .

To summarize the above observations, for those NLP problems where we cannot afford to make errors on mid and high frequency counts, we should employ CM-CU, LCU-SWS, and LCU-WS sketches. If we want to reduce the error on low frequency counts, LCU-WS generates least error. For NLP tasks where we can allow error on mid and high frequency counts but not on low frequency

Figure 2: Compare several sketches on over-estimation and under-estimation errors with respect to exact counts.

counts, CMM-CU sketch is best.

### 3.3 Examining OE and UE errors

In many NLP applications, we are willing to tolerate either over-estimation or under-estimation errors. Hence we breakdown the error into over-estimation (OE) and under-estimation (UE) errors for the six best-performing sketches (COUNT, COUNT-CU, CMM, CMM-CU, LCU-SWS, and LCU-WS). To accomplish that, rather than using absolute error values, we divide the values into over-estimation (positive), and under-estimation (negative) error buck-

Figure 3: Evaluate the approximate PMI and LLR rankings (obtained using various sketches) with the exact rankings.

ets. Hence, to compute the over-estimation MRE, we take the average of positive values over all the items in each bucket. For under-estimation, we take the average over the negative values. We can make several interesting observations from Figure 2: (1) Comparing COUNT-CU and LCU-SWS, we learn that both have the same over-estimation errors. However, LCU-SWS has less under-estimation error than COUNT-CU. Therefore, LCU-SWS is always better than COUNT-CU. (2) LCU-WS has less over-estimation than LCU-SWS but with more under-estimation error on mid frequency counts. LCU-WS has less under-estimation error than COUNT-CU. (3) CMM-CU has the least over-estimation error and most under-estimation error among all the compared sketches.

From the above experiments, we conclude that tasks sensitive to under-estimation should use the CM-CU sketch, which guarantees over-estimation. However, if we are willing to make some under-estimation error with less over-estimation error, then LCU-WS and LCU-SWS are recommended. Lastly, to have minimal over-estimation error with willingness to accept large under-estimation error, CMM-CU is recommended.

### 3.4 Evaluating association scores ranking

Last, in many NLP problems, we are interested in association rankings obtained using Pointwise Mutual Information (PMI) and Log Likelihood Ratio (LLR). In this experiment, we compare the word pairs association rankings obtained using PMI and LLR from several sketches and exact word pair counts. We use

recall to measure the number of top- $K$  sorted word pairs that are found in both the rankings.

In Figure 3(a), we compute the recall for CM-CU, COUNT-CU, CMM-CU, LCU-SWS, and LCU-WS sketches at several top- $K$  thresholds of word pairs for approximate PMI ranking. We can make several observations from Figure 3(a). COUNT-CU has the worst recall for almost all the top- $K$  settings. For top- $K$  values less than 750, all sketches except COUNT-CU have comparable recall. Meanwhile, for  $K$  greater than 750, LCU-WS has the best recall. This is because PMI is sensitive to low frequency counts (Church and Hanks, 1989), over-estimation of the counts of low frequency word pairs can make their approximate PMI scores worse.

In Figure 3(b), we compare the LLR rankings. For top- $K$  values less than 1000, all the sketches have comparable recall. For top- $K$  values greater than 1000, CM-CU, LCU-SWS, and LCU-WS perform better. The reason for such a behavior is due to LLR favoring high frequency word pairs, and COUNT-CU and CMM-CU making under-estimation error on high frequency word pairs.

To summarize, to maintain top- $K$  PMI rankings making over-estimation error is *not* desirable. Hence, LCU-WS is recommended for PMI rankings. For LLR, producing under-estimation error is *not* preferable and therefore, CM-CU, LCU-WS, and LCU-SWS are recommended.

Test Set	Random			Buckets			Neighbor

## 4 Extrinsic Evaluation

### 4.1 Experimental Setup

We study three important NLP applications, and compare the three best-performing sketches: Count-Min sketch with conservative update (CM-CU), Count-mean-min with conservative update (CMM-CU), and Lossy counting with conservative update (LCU-WS). The above mentioned 3 sketches are selected from 10 sketches (see Section 2) considering these sketches make errors on different ranges of the counts: low, mid and, high frequency counts as seen in our intrinsic evaluations in Section 3. The goal of this experiment is to show the effectiveness of sketches on large-scale language processing tasks.

These adhere to the premise that simple methods using large data can dominate more complex models. We purposefully select simple methods as they use approximate counts and associations directly to solve these tasks. This allows us to have a fair comparison among different sketches, and to more directly see the impact of different choices of sketch on the task outcome. Of course, sketches are still broadly applicable to many NLP problems where we want to count (many) items or compute associations: e.g. language models, Statistical Machine Translation, paraphrasing, bootstrapping and label propagation for automatically creating a knowledge base and finding interesting patterns in social media.

**Data:** We use **Gigaword** (Graff, 2003) and a 50% portion of a copy of news web (**GWB50**) crawled by (Ravichandran et al., 2005). The raw size of **Gigaword** (**GW**) and **GWB50** is 9.8 GB and 49 GB with 56.78 million and 462.60 sentences respectively. For both the corpora, we split the text into sentences, tokenize and convert into lower-case.

### 4.2 Pseudo-Words Evaluation

In NLP, it is difficult and time consuming to create annotated test sets. This problem has motivated the use of pseudo-words to automatically create the test sets without human annotation. The pseudo-words are a common way to evaluate selectional preferences models (Erk, 2007; Bergsma et al., 2008) that measure the strength of association between a predicate and its argument filler, e.g., that the noun “song” is likely to be the object of the verb “sing”.

A pseudo-word is the conflation of two words (e.g. song/dance). One word is the original in a sentence, and the second is the confounder. For example, in our task of selectional preferences, the system has to decide for the verb “sing” which is the correct object between “song”/“dance”. Recently, Chambers and Jurafsky (2010) proposed a simple baseline based on co-occurrence counts of words, which has state-of-the-art performance on pseudo-words evaluation for selectional preferences.

We use a simple approach (without any typed dependency data) similar to Chambers and Jurafsky (2010), where we count all word pairs (except word pairs involving stop words) that appear within a window of size 3 from **Gigaword** (9.8 GB). That generates 970 million word pair tokens (stream size) and 94 million word pair types. Counts of all the 94 million unique word pairs are stored in CM-CU, CMM-CU, and LCU-WS. For a target verb, we return that noun which has higher co-occurrence count with it, as the correct selectional preference. We evaluate on Chambers and Jurafsky’s three test sets<sup>1</sup> (excluding instances involving stop words) that are based on different strategies in selecting confounders: *Random* (4081 instances), *Buckets* (4028

<sup>1</sup><http://www.usna.edu/Users/cs/nchamber/data/pseudowords/>

Figure 4: Determining the proportion of low, mid and high frequency test word pairs in **Gigaword (GW)**.

instances), and *Neighbor* (3881 instances). To evaluate against the exact counts, we compute exact counts for only those word pairs that are present in the test sets. Accuracy is used for evaluation and is defined as the percentage of number of correctly identified pseudo words.

In Fig. 4, we plot the cumulative proportion of true frequency counts of all word pairs (from the three tests) in **Gigaword (GW)**. To include unseen word pairs from test set in **GW** on log-scale in Fig. 4, we increment the true counts of all the word pairs by 1. This plot demonstrates that 45% of word-pairs are unseen in **GW**, and 67% of word pairs have counts less than 10. Hence, to perform better on this task, it is essential to *accurately maintain counts of rare word pairs*.

In Table 1, we vary the size of all sketches (50 million ( $M$ ),  $100M$ ,  $200M$ ,  $500M$  and 1 billion ( $1B$ ) counters) with 3 hash functions to compare them against the exact counts. It takes 1.8 GB uncompressed space to maintain the exact counts on the disk. Table 1 shows that with sketches of size  $> 200M$  on all the three test sets, CM-CU and LCU-WS are comparable to exact. However, the CMM-CU sketch performs less well. We conjecture the reason for such a behavior is due to loss of recall (information about low frequency word pairs) by under-estimation error. For this task CM-CU and LCU-WS scales to storing  $94M$  unique word pairs using  $200M$  integer (4 bytes each) counters (using  $800\text{ MB}$ )  $< 1.8\text{ GB}$  to maintain exact counts. Moreover, these results are comparable to Chambers and Jurafsky’s state-of-the-art framework.

Data	Exact	CM-CU	CMM-CU	LCU-WS
<b>GW</b>	74.2	<i>74.0</i>	65.3	72.9
<b>GWB50</b>	<b>81.2</b>	<b>80.9</b>	74.9	78.3

Table 2: Evaluating Semantic Orientation on accuracy metric using several sketches of 2 billion counters against exact. Bold and italic numbers denote no statistically significant difference.

### 4.3 Finding Semantic Orientation of a word

Given a word, the task of finding its Semantic Orientation (SO) (Turney and Littman, 2003) is to determine if the word is more probable to be used in positive or negative connotation. We use Turney and Littman’s (2003) state-of-the-art framework to compute the SO of a word. We use same seven positive words (good, nice, excellent, positive, fortunate, correct, and superior) and same seven negative words (bad, nasty, poor, negative, unfortunate, wrong, and inferior) from their framework as seeds. The SO of a given word is computed based on the strength of its association with the seven positive words and the seven negative words. Association scores are computed via Pointwise Mutual Information (PMI). We compute the SO of a word “w” as:

$$SO(w) = \sum_{p \in \text{Pos}} PMI(p, w) - \sum_{n \in \text{Neg}} PMI(n, w)$$

where, Pos and Neg denote the seven positive and negative seeds respectively. If this score is negative, we predict the word as negative; otherwise, we predict it as positive. We use the General Inquirer lexicon<sup>2</sup> (Stone et al., 1966) as a benchmark to evaluate the semantic orientation similar to Turney and Littman’s (2003) work. Our test set consists of 1611 positive and 1987 negative words. Accuracy is used for evaluation and is defined as the percentage of number of correctly identified SO words.

We evaluate SO of words on two different sized corpora (see Section 4.1): **Gigaword (GW)** (9.8GB), and **GW** with 50% news web corpus (**GWB50**) (49GB). We fix the size of all sketches to 2 billion ( $2B$ ) counters with 5 hash functions. We store exact counts of all words in a hash table for both **GW** and **GWB50**. We count all word pairs (except word pairs involving stop words) that appear within a window of size 7 from **GW** and **GWB50**. This yields 2.67 billion( $B$ ) tokens and  $.19B$  types

<sup>2</sup>The General Inquirer lexicon is freely available at <http://www.wjh.harvard.edu/~inquirer/>

Test Set		WS-203			MC-30		
Model		CM-CU	CMM-CU	LCU-WS	CM-CU	CMM-CU	LCU-WS
PMI	10M	<b>.58</b>	.25	.28	<b>.67</b>	.20	.16
	50M	<b>.44</b>	.23	.41	<b>.61</b>	.22	.31
	200M	<b>.53</b>	<b>.44</b>	<b>.47</b>	<b>.57</b>	.28	<b>.43</b>

from **GW** and 13.20*B* tokens and 0.8*B* types from **GWB50**. Next, we compare the sketches against the exact counts over two different size corpora.

Table 2 shows that increasing the amount of data improves the accuracy of identifying the SO of a word. We get an absolute increase of 7 percentage points (with exact counts) in accuracy (The 95% statistical significance boundary for accuracy is about  $\pm 1.5$ .), when we add 50% web data (**GWB50**). CM-CU results are equivalent to exact counts for all the corpus sizes. These results are also comparable to Turney’s (2003) accuracy of 82.84%. However, CMM-CU results are worse by absolute 8.7 points and 6 points on **GW** and **GWB50** respectively with respect to CM-CU. LCU-WS is better than CMM-CU but worse than CM-CU. Using 2*B* integer (4 bytes each) counters (bounded memory footprint of 8 GB), CM-CU scales to 0.8*B* word pair types (It takes 16 GB uncompressed disk space to store *exact* counts of all the unique word pair types.).

Figure 4 has similar frequency distribution of word pairs<sup>3</sup> in SO test set as pseudo-words evaluation test sets word pairs. Hence, CMM-CU again has substantially worse results than CM-CU due to loss of recall (information about low frequency word pairs) by under-estimation error. We can conclude that for this task CM-CU is best.

#### 4.4 Distributional Similarity

Distributional similarity is based on the distributional hypothesis that similar terms appear in simi-

<sup>3</sup>Consider only those pairs in which one word appears in the seed list and the other word appears in the test set.

lar contexts (Firth, 1968; Harris, 1954). The context vector for each term is represented by the strength of association between the term and each of the lexical, semantic, syntactic, and/or dependency units that co-occur with it. For this work, we define context for a given term as the surrounding words appearing in a window of 2 words to the left and 2 words to the right. The context words are concatenated along with their positions -2, -1, +1, and +2. We use PMI and LLR to compute the association score (AS) between the term and each of the context to generate the context vector. We use the cosine similarity measure to find the distributional similarity between the context vectors for each of the terms.

We use two test sets which consist of word pairs, and their corresponding human rankings. We generate the word pair rankings using distributional similarity. We report the Spearman’s rank correlation coefficient ( $\rho$ ) between the human and distributional similarity rankings. We report results on two test sets: **WS-203**: A set of 203 word pairs marked according to similarity (Agirre et al., 2009). **MC-30**: A set of 30 noun pairs (Miller and Charles, 1991).

We evaluate distributional similarity on **Giga-word (GW)** (9.8GB) (see Section 4.1). First, we store exact counts of all words and contexts in a hash table from **GW**. Next, we count all the word-context pairs and store them in CM-CU, CMM-CU, and LCU-WS sketches. That generates a stream of size 3.35 billion (3.35*B*) word-context pair tokens and 215 million unique word-context pair types (It takes 4.6 GB uncompressed disk space to store *exact* counts of all these unique word-context pair types.). For every target word in the test set, we maintain top-1000 approximate AS scores contexts using a priority queue, by passing over the corpus a second time. Finally, we use cosine similarity with these approximate top-*K* context vectors to compute distributional similarity.

In Table 3, we vary the size of all sketches across 10 million (*M*), 50*M*, and 200*M* counters with 3 hash functions. The results using PMI shows that CM-CU has best  $\rho$  on both **WS-203** and **MC-30** test sets. The results for LLR in Table 3 show similar trends with CM-CU having best results on small size sketches. Thus, CM-CU scales using 10*M* counters (using fixed memory of 40 MB versus 4.6 GB to store exact counts). These results are compa-

rable against the state-of-the-art results for distributional similarity (Agirre et al., 2009).

On this task CM-CU is best as it avoids loss of recall (information about low frequency word pairs) due to under-estimation error. For a target word that has low frequency, using CMM-CU will not generate any contexts for it, as it will have large under-estimation error for word-context pairs counts. This phenomenon is demonstrated in Table 3, where CMM-CU and LCU-WS have worse result with small size sketches.

## 5 Conclusion

In this work, we systematically studied the problem of estimating point queries using different sketch algorithms. As far as we know, this represents the *first* comparative study to demonstrate the relative behavior of sketches in the context of NLP applications. We proposed two novel sketch variants: Count sketch (Charikar et al., 2004) with conservative update (COUNT-CU) and Count-mean-min sketch with conservative update (CMM-CU). We empirically showed that CMM-CU has under-estimation error with small over-estimation error, CM-CU has only over-estimation error, and LCU-WS has more under-estimation error than over-estimation error. Finally, we demonstrated CM-CU has better results on all three tasks: pseudo-words evaluation for selectional preferences, finding semantic orientation task, and distributional similarity. This shows that maintaining information about low frequency items (even with over-estimation error) is better than throwing away information (under-estimation error) about rare items.

Future work is to reduce the bit size of each counter (instead of the number of counters), as has been tried for other summaries (Talbot and Osborne, 2007; Talbot, 2009; Van Durme and Lall, 2009a) in NLP. However, it may be challenging to combine this with conservative update.

## Abstract

Conditional random fields and other graphical models have achieved state of the art results in a variety of tasks such as coreference, relation extraction, data integration, and parsing. Increasingly, practitioners are using models with more complex structure—higher tree-width, larger fan-out, more features, and more data—rendering even approximate inference methods such as MCMC inefficient. In this paper we propose an alternative MCMC sampling scheme in which transition probabilities are approximated by sampling from the set of relevant factors. We demonstrate that our method converges more quickly than a traditional MCMC sampler for both marginal and MAP inference. In an author coreference task with over 5 million mentions, we achieve a 13 times speedup over regular MCMC inference.

## 1 Introduction

Conditional random fields and other graphical models are at the forefront of many natural language processing (NLP) and information extraction (IE) tasks because they provide a framework for discriminative modeling while succinctly representing dependencies among many related output variables. Previously, most applications of graphical models were limited to structures where exact inference is possible, for example linear-chain CRFs (Lafferty et al., 2001). More recently, there has been a desire to include more factors, longer range dependencies, and more sophisticated features; these include skip-chain CRFs for named entity recognition (Sutton and McCallum, 2004), probabilistic

DBs (Wick et al., 2010), higher-order models for dependency parsing (Carreras, 2007), entity-wise models for coreference (Culotta et al., 2007; Wick et al., 2009), and global models of relations (Hoffmann et al., 2011). The increasing sophistication of these individual NLP components compounded with the community’s desire to model these tasks jointly across cross-document considerations has resulted in graphical models for which inference is computationally intractable. Even popular approximate inference techniques such as loopy belief propagation and Markov chain Monte Carlo (MCMC) may be prohibitively slow.

MCMC algorithms such as Metropolis-Hastings are usually efficient for graphical models because the only factors needed to score a proposal are those touching the changed variables. However, MCMC is slowed in situations where a) the model exhibits variables that have a high-degree (neighbor many factors), b) proposals modify a substantial subset of the variables to satisfy domain constraints (such as transitivity in coreference), or c) evaluating a single factor is expensive, for example when features are based on string-similarity. For example, the seemingly innocuous proposal changing the entity type of a single entity requires examining all its mentions, i.e. scoring a linear number of factors (in the number of mentions of that entity). Similarly, evaluating coreference of a mention to an entity also requires scoring factors to all the mentions of the entity. Often, however, the factors are somewhat *redundant*, for example, not all mentions of the “USA” entity need to be examined to confidently conclude that it is a COUNTRY, or that it is coreferent with “United

States of America”.

In this paper we propose an approximate MCMC framework that facilitates efficient inference in high-degree graphical models. In particular, we approximate the acceptance ratio in the Metropolis Hastings algorithm by replacing the exact model score with a stochastic approximation that samples from the set of relevant factors. We explore two sampling strategies, a fixed proportion approach that samples the factors uniformly, and a dynamic alternative that samples factors until the method is confident about its estimate of the model score.

We evaluate our method empirically on both synthetic and real-world data. On synthetic classification data, our approximate MCMC procedure obtains the true marginals faster than a traditional MCMC sampler. On real-world tasks, our method achieves 7 times speedup on citation matching, and 13 times speedup on large-scale author disambiguation.

## 2 Background

### 2.1 Graphical Models

Factor graphs (Kschischang et al., 2001) succinctly represent the joint distribution over random variables by a product of factors that make the dependencies between the random variables explicit. A factor graph is a bipartite graph between the variables and factors, where each (log) factor  $f \in \mathcal{F}$  is a function that maps an assignment of its neighboring variables to a real number. For example, in a linear-chain model of part-of-speech tagging, transition factors score compatibilities between consecutive labels, while emission factors score compatibilities between a label and its observed token.

The probability distribution expressed by the factor graph is given as a normalized product of the factors, which we rewrite as an exponentiated sum:

$$p(\mathbf{y}) = \frac{\exp \psi(\mathbf{y})}{Z} \quad (1)$$

$$\psi(\mathbf{y}) = \sum_{f \in \mathcal{F}} f(\mathbf{y}_f) \quad (2)$$

$$Z = \sum_{\mathbf{y} \in \mathcal{Y}} \exp \psi(\mathbf{y}) \quad (3)$$

Intuitively, the model favors assignments to the random variables that yield higher factor scores and will

assign higher probabilities to such configurations.

The two common inference problems for graphical models in NLP are *maximum a posterior* (MAP) and marginal inference. For models without latent variables, the MAP estimate is the setting to the variables that has the highest probability under the model:

$$\mathbf{y}_{\text{MAP}} = \operatorname{argmax}_{\mathbf{y}} p(\mathbf{y}) \quad (4)$$

Marginal inference is the problem of finding marginal distributions over subsets of the variables, used primarily in maximum likelihood gradients and for max marginal inference.

### 2.2 Markov chain Monte Carlo (MCMC)

Often, computing marginal estimates of a model is computationally intractable due to the normalization constant  $Z$ , while maximum a posteriori (MAP) is prohibitive due to the search space of possible configurations. Markov chain Monte Carlo (MCMC) is important tool for performing sample- and search-based inference in these models. A particularly successful MCMC method for graphical model inference is Metropolis-Hastings (MH). Since sampling from the true model  $p(\mathbf{y})$  is intractable, MH instead uses a simpler distribution  $q(\mathbf{y}'|\mathbf{y})$  that conditions on a current state  $\mathbf{y}$  and proposes a new state  $\mathbf{y}'$  by modifying a few variables. This new assignment is then accepted with probability  $\alpha$ :

$$\alpha = \min \left( 1, \frac{p(\mathbf{y}') q(\mathbf{y}|\mathbf{y}')}{p(\mathbf{y}) q(\mathbf{y}'|\mathbf{y})} \right) \quad (5)$$

Computing this acceptance probability is often highly efficient because the partition function cancels, as do all the factors in the model that do not neighbor the modified variables. MH can be used for both MAP and marginal inference.

#### 2.2.1 Marginal Inference

To compute marginals with MH, the variables are initialized to an arbitrary assignment (i.e., randomly or with some heuristic), and sampling is run until the samples  $\{\mathbf{y}_i | i = 0, \dots, n\}$  become independent of the initial assignment. The ergodic theorem provides the MCMC analog to the law-of-large-numbers, justifying the use of the generated samples to compute the desired statistics (such as feature expectations or variable marginals).

### 2.2.2 MAP Inference

Since MCMC can efficiently explore the high density regions for a given distribution, the distribution  $p$  can be modified such that the high-density region of the new distribution represents the MAP configuration of  $p$ . This is achieved by adding a temperature term  $\tau$  to the distribution  $p$ , resulting in the following MH acceptance probability:

$$\alpha = \min \left( 1, \left( \frac{p(\mathbf{y}')}{p(\mathbf{y})} \right)^{\frac{1}{\tau}} \right) \quad (6)$$

Note that as  $\tau \rightarrow 0$ , MH will sample closer to the MAP configuration. If a cooling schedule is implemented for  $\tau$  then the MH sampler for MAP inference can be seen as an instance of simulated annealing (Bertsimas and Tsitsiklis, 1993).

## 3 Monte Carlo MCMC

In this section we introduce our approach for approximating the acceptance ratio of Metropolis-Hastings that samples the factors, and describe two sampling strategies.

### 3.1 Stochastic Proposal Evaluation

Although one of the benefits of MCMC lies in its ability to leverage the locality of the proposal, for some information extraction tasks this can become a crucial bottleneck. In particular, evaluation of each sample requires computing the score of all the factors that are *involved* in the change, i.e. all factors that neighbor any variable in the set that has changed. This evaluation becomes a bottleneck for tasks in which a large number of variables is involved in each proposal, or in which the model contains a number of high-degree variables, resulting in a large number of factors, or in which computing the factor score involves an expensive computation, such as string similarity between mention text.

Instead of evaluating the log-score  $\psi$  of the model exactly, this paper proposes a Monte-Carlo estimation of the log-score. In particular, if the set of factors for a given proposal  $\mathbf{y} \rightarrow \mathbf{y}'$  is  $\mathcal{F}(\mathbf{y}, \mathbf{y}')$ , we use a sampled subset of the factors  $\mathcal{S} \subseteq \mathcal{F}(\mathbf{y}, \mathbf{y}')$  as an approximation of the model score. In the following

we use  $\mathcal{F}$  as an abbreviation for  $\mathcal{F}(\mathbf{y}, \mathbf{y}')$ . Formally,

$$\begin{aligned} \psi(\mathbf{y}) &= \sum_{f \in \mathcal{F}} f(\mathbf{y}_f) = |\mathcal{F}| \cdot \mathbb{E}_{\mathcal{F}} [f(\mathbf{y}_f)] \\ \psi_{\mathcal{S}}(\mathbf{y}) &= |\mathcal{S}| \cdot \mathbb{E}_{\mathcal{S}} [f(\mathbf{y}_f)] \end{aligned} \quad (7)$$

We use the sample log-score ( $\psi_{\mathcal{S}}$ ) in the acceptance probability  $\alpha$  to evaluate the samples. Since we are using a stochastic approximation to the model score, in general we need to take more MCMC samples before we converge, however, since evaluating each sample will be *much* faster ( $O(|\mathcal{S}|)$ ) as opposed to  $O(|\mathcal{F}|)$ , we expect overall sampling to be faster.

In the next sections we describe several alternative strategies for sampling the set of factors  $\mathcal{S}$ . The primary restriction on the set of samples  $\mathcal{S}$  is that their mean should be an unbiased estimator of  $\mathbb{E}_{\mathcal{F}}[f]$ . Further, time taken to obtain the set of samples should be negligible when compared to scoring all the factors in  $\mathcal{F}$ . Note that there is an implicit minimum of 1 to the number of the sampled factors.

### 3.2 Uniform Sampling

The most direct approach for subsampling the set of  $\mathcal{F}$  is to perform uniform sampling. In particular, given a proportion parameter  $0 < p \leq 1$ , we select a random subset  $\mathcal{S}_p \subseteq \mathcal{F}$  such that  $|\mathcal{S}_p| = p \cdot |\mathcal{F}|$ . Since this approach is agnostic as to the actual factors scores,  $\mathbb{E}_{\mathcal{S}}[f] \equiv \mathbb{E}_{\mathcal{F}}[f]$ . A low  $p$  leads to fast evaluation, however it may require a large number of samples due to the substantial approximation. On the other hand, although a higher  $p$  will converge with fewer samples, evaluating each sample is slower.

### 3.3 Confidence-Based Sampling

Selecting the best value for  $p$  is difficult, requiring analysis of the graph structure, and statistics on the distribution of the factors scores; often a difficult task in real-world applications. Further, the same value for  $p$  can result in different levels of approximation for different proposals, either unnecessarily accurate or problematically noisy. We would prefer a strategy that adapts to the distribution of the scores in  $\mathcal{F}$ .

Instead of sampling a fixed proportion of factors, we can sample until we are confident that the current set of samples  $\mathcal{S}_c$  is an accurate estimate of the true mean of  $\mathcal{F}$ . In particular, we maintain a running count of the sample mean  $\mathbb{E}_{\mathcal{S}_c}[f]$  and variance

$\sigma_{\mathcal{S}_c}$ , using them to compute a confidence interval  $I_{\mathcal{S}}$  around our estimate of the mean. Since the number of sampled factors  $\mathcal{S}$  could be a substantial fraction of the set of factors  $\mathcal{F}$ ,<sup>1</sup> we also incorporate *finite population control (fpc)* in our sample variance computation. We compute the confidence interval as follows:

$$\sigma_{\mathcal{S}}^2 = \frac{1}{|\mathcal{S}|-1} \sum_{f \in \mathcal{S}} (f - \mathbb{E}_{\mathcal{S}}[f])^2 \quad (8)$$

$$I_{\mathcal{S}} = 2z \frac{\sigma_{\mathcal{S}}}{\sqrt{|\mathcal{S}|}} \sqrt{\frac{|\mathcal{F}| - |\mathcal{S}|}{|\mathcal{F}| - 1}} \quad (9)$$

where we set the  $z$  to 1.96, i.e. the 95% confidence interval. This approach starts with an empty set of samples,  $\mathcal{S} = \{\}$ , and iteratively samples factors without replacement to add to  $\mathcal{S}$ , until the confidence interval around the estimated mean falls below a user specified maximum interval width threshold  $i$ . As a result, for proposals that contain high-variance factors, this strategy examines a large number of factors, while proposals that involve similar factors will result in fewer samples. Note that this user-specified threshold is agnostic to the graph structure and the number of factors, and instead directly reflects the score distribution of the relevant factors.

## 4 Experiments

In this section we evaluate our approach for both marginal and MAP inference.

### 4.1 Marginal Inference on Synthetic Data

Consider the task of classifying entities into a set of types, for example, POLITICIAN, VEHICLE, CITY, GOVERNMENT-ORG, etc. For knowledge base construction, this prediction often takes place on the entity-level, as opposed to the mention-level common in traditional NLP. To evaluate the type at the entity-level, the scored factors examine features of all the entity mentions of the entity, along with the labels of all relation mentions for which it is an argument. See Yao et al. (2010) and Hoffmann et al. (2011) for examples of such models. Since a subset of the mentions can be sufficiently informative for the model, we expect our stochastic MCMC approach to work well.

<sup>1</sup>Specifically, the fraction may be higher than  $> 5\%$

(a) Binary Classification (b) Distribution of Factor scores Model ( $n = 100$ )

Figure 1: Synthetic Model for Classification

Figure 2: Marginal Inference Error for Classification on Synthetic Data

We use synthetic data for such a model to evaluate the quality of marginals returned by the Gibbs sampling form of MCMC. Since the Gibbs algorithm samples each variable using a fixed assignment of its neighborhood, we represent generating a single sample as classification. We create star-shaped models with a single unobserved variable (entity type) that neighbors many unary factors, each representing a single entity- or a relation-mention factor (See Figure 1a for an example). We generate a synthetic dataset for this model, creating 100 variables consisting of 100 factors each. The scores of the factors are generated from gaussians,  $\mathcal{N}(0.5, 1)$  for the positive label, and  $\mathcal{N}(-0.5, 1)$  for the negative label (note the overlap between the weights in Figure 1b). Although each structure contains only a single variable, and no cycles, it is a valid benchmark to test our sampling approach since the effects of the setting of burn-in period and the thinning samples are not a concern.

We perform standard Gibbs sampling, and com-

pare the marginals obtained during sampling with the true marginals, computed exactly. We evaluate the previously described uniform sampling and confidence-based sampling, with several parameter values, and plot the  $L_1$  error to the true marginals as more factors are examined. Note that here, and in the rest of the evaluation, we shall use the number of factors scored as a proxy for running time, since the effects of the rest of the steps of sampling are relatively negligible. The error in comparison to regular MCMC ( $p = 1$ ) is shown in Figure 2, with standard error bars averaging over 100 models. Initially, as the sampling approach is made more stochastic (lowering  $p$  or increasing  $i$ ), we see a steady improvement in the running time needed to obtain the same error tolerance. However, the amount of relative improvements slows as stochasticity is increased further; in fact for extreme values ( $i = 0.05, p = 0.1$ ) the chains perform worse than regular MCMC.

## 4.2 Entity Resolution in Citation Data

To evaluate our approach on a real world dataset, we apply stochastic MCMC for MAP inference on the task of citation matching. Given a large number of citations (that appear at the end of research papers, for example), the task is to group together the citations that refer to the same paper. The citation matching problem is an instance of entity resolution, in which observed mentions need to be partitioned such that mentions in a set refer to the same underlying entity. Note that neither the identities, or the number of underlying entities is known.

In this paper, the graphical model of entity resolution consists of observed mentions ( $m_i$ ), and pairwise binary variables between all pairs of mentions ( $y_{ij}$ ) which represent whether the corresponding observed mentions are coreferent. There is a local factor for each coreference variable  $y_{ij}$  that has a high score if the underlying mentions  $m_i$  and  $m_j$  are similar. For the sake of efficiency, we only instantiate and incorporate the variables and factors when the variable is true, i.e. if  $y_{ij} = 1$ . Thus,  $\psi(\mathbf{y}) = \sum_e \sum_{m_i, m_j \in e} f(y_{ij})$ . The set of possible worlds consists of all settings of the  $\mathbf{y}$  variables that are consistent with transitivity, i.e. the binary variables directly represent a valid clustering over the mentions. An example of the model defined over 5

Figure 3: **Graphical Model for Entity Resolution:** defined over 5 mentions, with the setting of the variables resulting in 2 entities. For the sake of brevity, we’ve only included variables set to 1; binary variables between mentions that are not coreferent have been omitted.

mentions is given in Figure 3. This representation is equivalent to Model 2 as introduced in McCallum and Wellner (2004). As opposed to belief propagation and other approximate inference techniques, MCMC is especially appropriate for the task as it can directly enforce transitivity.

When performing MCMC, each sample is a setting to all the  $\mathbf{y}$  variables that is consistent with transitivity. To maintain transitivity during sampling, Metropolis Hastings is used to change the binary variables in a way that is consistent with moving individual mentions. Our proposal function selects a random mention, and moves it to a random entity, changing all the pairwise variables with mentions in its old entity, and the pairwise variables with mentions in its new entity. Thus, evaluation of such a proposal function requires scoring a number of factors linear in the size of the entities, which, for large datasets, can be a significant bottleneck. In practice, however, these set of factors are often highly redundant, as many of the mentions that refer to the same entity contain redundant information and features, and entity membership may be efficiently determined by observing a subset of its mentions.

We evaluate on the Cora dataset (McCallum et al., 1999), used previously to evaluate a number of information extraction approaches (Pasula et al., 2003), including MCMC based inference (Poon and Domingos, 2007; Singh et al., 2009). The dataset

Figure 4: Citation Resolution Accuracy Plot for uniform and variance-based sampling compared to regular MCMC ( $p = 1$ )

consists of 1295 mentions, that refer to 134 true underlying entities. We use the same features for our model as (Poon and Domingos, 2007), using true *author*, *title*, and *venue* segmentation for features. Since our focus is on evaluating scalability of inference, we combine all the three folds of the data, and train the model using Samplerank (Wick et al., 2011).

We run MCMC on the entity resolution model using the proposal function described above, running our approach with different parameter values. Since we are interested in the MAP configuration, we use a temperature term for annealing. As inference progresses, we compute  $BCubed^2$  F1 of the current sample, and plot it against the number of scored factors in Figure 4. We observe consistent speed improvements as stochasticity is improved, with uniform sampling and confidence-based sampling performing competitively. To compute the speedup, we measure the number of factors scored to obtain a desired level of accuracy (90% F1), shown for a diverse set of parameters in Table 1. With a very large confidence interval threshold ( $i = 20$ ) and small proportion ( $p = 0.1$ ), we obtain up to 7 times speedup over regular MCMC. Since the average entity size in this data set is  $< 10$ , using a small proportion (and a wide interval) is equivalent to picking a single mention to compare against.

<sup>2</sup> $B^3$  is a coreference evaluation metric, introduced by Bagga and Baldwin (1998)

Method	Factors Examined	Speedup
Baseline	57,292,700	1x
Uniform Sampling		
$p = 0.75$	34,803,972	1.64x
$p = 0.5$	28,143,323	2.04x
$p = 0.3$	17,778,891	3.22x
$p = 0.2$	12,892,079	4.44x
$p = 0.1$	7,855,686	7.29x
Variance-Based Sampling		
$i = 0.001$	52,522,728	1.09x
$i = 0.01$	51,547,000	1.11x
$i = 0.1$	47,165,038	1.21x
$i = 0.5$	32,828,823	1.74x
$i = 1$	18,938,791	3.02x
$i = 2$	11,134,267	5.14x
$i = 5$	9,827,498	5.83x
$i = 10$	8,675,833	6.60x
$i = 20$	8,295,587	6.90x

Table 1: Speedups on Cora to obtain 90%  $B^3$  F1

### 4.3 Large-Scale Author Coreference

As the body of published scientific work continues to grow, author coreference, the problem of clustering mentions of research paper authors into the real-world authors to which they refer, is becoming an increasingly important step for performing meaningful bibliometric analysis. However, scaling typical pairwise models of coreference (e.g., McCallum and Wellner (2004)) is difficult because the number of factors in the model grows quadratically with the number of mentions (research papers) and the number of factors evaluated for every MCMC proposal scales linearly in the size of the clusters. For author coreference, the number of author mentions and the number of references to an author entity can often be in the millions, making the evaluation of the MCMC proposals computationally expensive.

We use the publicly available DBLP dataset<sup>3</sup> of BibTex entries as our unlabeled set of mentions, which contains nearly 5 million authors. For evaluation of accuracy, we also include author mentions from the Rexa corpus<sup>4</sup> that contains 2, 833 mentions

<sup>3</sup><http://www.informatik.uni-trier.de/~ley/db/>

(a) Accuracy versus Number of Factors scored

(b) Accuracy versus Number of Samples

Figure 5: Performance of Different Sampling Strategies and Parameters for coreference over 5 million mentions. Plot with  $p$  refer to uniform sampling with proportion  $p$  of factors picked, while plots with  $i$  sample till confidence intervals are narrower than  $i$ .

labeled for coreference.

We use the same Metropolis-Hastings scheme that we employ in the problem of citation matching. As before, we initialize to the singleton configuration and run the experiments for a fixed number of samples, plotting accuracy versus the number of factors evaluated (Figure 5a) as well as accuracy versus the number of samples generated (Figure 5b). We also tabulate the relative speedups to obtain the desired accuracy level in Table 2. Our proposed method achieves substantial savings on this task: speedups of 13.16 using the variance sampler and speedups of 9.78 using the uniform sampler. As expected, when we compare the performance using the number of generated samples, the approximate MCMC chains appear to converge more slowly; however, the overall convergence for our approach is substantially faster because evaluation of each sample is significantly cheaper. We also present results on using extreme approximations (for example,  $p = 0.01$ ), resulting in convergence to a low accuracy.

## 5 Discussion and Related Work

MCMC is a popular method for inference amongst researchers that work with large and dense graphical models (Richardson and Domingos, 2006; Poon and Domingos, 2006; Poon et al., 2008; Singh et al., 2009; Wick et al., 2009). Some of the probabilistic

Method	Factors Examined	Speedup
Baseline	1,395,330,603	1x
Uniform		
$p = 0.5$	689,254,134	2.02x
$p = 0.2$	327,616,794	4.26x
$p = 0.1$	206,157,705	6.77x
$p = 0.05$	152,069,987	9.17x
$p = 0.02$	142,689,770	9.78x
Variance		
$i = 0.00001$	1,442,091,344	0.96x
$i = 0.0001$	1,419,110,724	0.98x
$i = 0.001$	1,374,667,077	1.01x
$i = 0.1$	1,012,321,830	1.38x
$i = 1$	265,327,983	5.26x
$i = 10$	179,701,896	7.76x
$i = 100$	106,850,725	13.16x

Table 2: Speedups on DBLP to reach 80%  $B^3$  F1

programming packages popular amongst NLP practitioners also rely on MCMC for inference and learning (Richardson and Domingos, 2006; McCallum et al., 2009). Although most of these methods apply MCMC directly, the rate of convergence of MCMC has become a concern as larger and more densely-factored models are being considered, motivating the need for more efficient sampling that uses parallelism (Singh et al., 2011; Gonzalez et al., 2011)

and domain knowledge for blocking (Singh et al., 2010). Thus we feel providing a method to speed up MCMC inference can have a significant impact.

There has also been recent work in designing scalable approximate inference techniques. Belief propagation has, in particular, has gained some recent interest. Similar to our approach, a number of researchers propose modifications to BP that perform inference without visiting all the factors. Recent work introduces dynamic schedules to prioritize amongst the factors (Coughlan and Shen, 2007; Sutton and McCallum, 2007) that has been used to only visit a small fraction of the factors (Riedel and Smith, 2010). Gonzalez et al. (2009) utilize these schedules to facilitate parallelization.

A number of existing approaches in statistics are also related to our contribution. Leskovec and Faloutsos (2006) propose techniques to sample a graph to compute certain graph statistics with associated confidence. Christen and Fox (2005) also propose an approach to efficiently evaluate a proposal, however, once accepted, they score all the factors. Murray and Ghahramani (2004) propose an approximate MCMC technique for Bayesian models that estimates the partition function instead of computing it exactly.

Related work has also applied such ideas for robust learning, for example Kok and Domingos (2005), based on earlier work by Hulten and Domingos (2002), uniformly sample the groundings of an MLN to estimate the likelihood.

## 6 Conclusions and Future Work

Motivated by the need for an efficient inference technique that can scale to large, densely-factored models, this paper considers a simple extension to the Markov chain Monte Carlo algorithm. By observing that many graphical models contain substantial redundancy among the factors, we propose *stochastic* evaluation of proposals that subsamples the factors to be scored. Using two proposed sampling strategies, we demonstrate improved convergence for marginal inference on synthetic data. Further, we evaluate our approach on two real-world entity resolution datasets, obtaining a 13 times speedup on a dataset containing 5 million mentions.

Based on the ideas presented in the paper, we will

consider additional sampling strategies. In particular, we will explore *dynamic* sampling, in which we sample fewer factors during the initial, burn-in phase, but sample more factors as we get close to convergence. Motivated by our positive results, we will also study the application of this approach to other approximate inference techniques, such as belief propagation and variational inference. Since training is often a huge bottleneck for information extraction, we will also explore its applications to parameter estimation.

## Abstract

This paper deals with the problem of predicting structures in the context of NLP. Typically, in structured prediction, an inference procedure is applied to each example independently of the others. In this paper, we seek to optimize the time complexity of inference over entire datasets, rather than individual examples. By considering the general inference representation provided by integer linear programs, we propose three exact inference theorems which allow us to re-use earlier solutions for certain instances, thereby completely avoiding possibly expensive calls to the inference procedure. We also identify several approximation schemes which can provide further speedup. We instantiate these ideas to the structured prediction task of semantic role labeling and show that we can achieve a speedup of over 2.5 using our approach while retaining the guarantees of exactness and a further speedup of over 3 using approximations that do not degrade performance.

## 1 Introduction

Typically, in structured prediction applications, every example is treated independently and an inference algorithm is applied to each one of them. For example, consider a dependency parser that uses the maximum spanning tree algorithm (McDonald et al., 2005) or its integer linear program variants (Riedel and Clarke, 2006; Martins et al., 2009) to make predictions. Given a trained model, the parser addresses

each sentence separately and runs the inference algorithm to predict the parse tree. Thus, the time complexity of inference over the test set is linear in the size of the corpus.

In this paper, we ask the following question: *For a given task, since the inference procedure predicts structures from the same family of structures (dependency trees, semantic role structures, etc.), can the fact that we are running inference for a large number of examples help us improve the time complexity of inference?* In the dependency parsing example, this question translates to asking whether, having parsed many sentences, we can decrease the parsing time for the next sentence.

Since any combinatorial optimization problem can be phrased as an integer linear program (ILP), we frame inference problems as ILPs for the purpose of analysis. By analyzing the objective functions of integer linear programs, we identify conditions when two ILPs have the same solution. This allows us to reuse solutions of previously solved problems and theoretically guarantee the optimality of the solution. Furthermore, in some cases, even when the conditions are not satisfied, we can reuse previous solutions with high probability of being correct.

Given the extensive use of integer linear programs for structured prediction in Natural Language Processing over the last few years, these ideas can be applied broadly to NLP problems. We instantiate our improved inference approaches in the structured prediction task of semantic role labeling, where we use an existing implementation and a previous trained model that is based on the approach of (Punyakanok et al., 2008). We merely modify the inference pro-

---

\* These authors contributed equally to this work.

cess to show that we can realize the theoretical gains by making fewer calls to the underlying ILP solver.

Algorithm	Speedup
Theorem 1	2.44
Theorem 2	2.18
Theorem 3	2.50

Table 1: The speedup for semantic role labeling corresponding to the three theorems described in this paper. These theorems guarantee the optimality of the solution, thus ensuring that the speedup is not accompanied by any loss in performance.

Table 1 presents a preview of our results, which are discussed in Section 4. All three approaches in this table improve running time, while guaranteeing optimum solutions. Allowing small violations to the conditions of the theorems provide an even higher improvement in speedup (over 3), without loss of performance.

The primary contributions of this paper are:

1. We pose the problem of optimizing inference costs over entire datasets rather than individual examples. Our approach is agnostic to the underlying models and allows us to use pre-trained scoring functions.
2. We identify equivalence classes of ILP problems and use this notion to prove exact conditions under which no inference is required. These conditions lead to algorithms that can speed up inference problem without losing the exactness guarantees. We also use these conditions to develop approximate inference algorithms that can provide a further speedup.
3. We apply our approach to the structured prediction task of semantic role labeling. By not having to perform inference on some of the instances, those that are equivalent to previously seen instances, we show significant speed up in terms of the number of times inference needs to be performed. These gains are also realized in terms of wall-clock times.

The rest of this paper is organized as follows: In section 2, we formulate the problem of amortized inference and provide motivation for why amortized

gains can be possible. This leads to the theoretical discussion in section 3, where we present the meta-algorithm for amortized inference along with several exact and approximate inference schemes. We instantiate these schemes for the task of semantic role labeling (Section 4). Section 5 discusses related work and future research directions.

## 2 Motivation

Many NLP tasks can be phrased as structured prediction problems, where the goal is to jointly assign values to many inference variables while accounting for possible dependencies among them. This decision task is a combinatorial optimization problem and can be solved using a dynamic programming approach if the structure permits. In general, the inference problem can be formulated and solved as integer linear programs (ILPs).

Following (Roth and Yih, 2004) Integer linear programs have been used broadly in NLP. For example, (Riedel and Clarke, 2006) and (Martins et al., 2009) addressed the problem of dependency parsing and (Punyakanok et al., 2005; Punyakanok et al., 2008) dealt with semantic role labeling with this technique.

In this section, we will use the ILP formulation of dependency parsing to introduce notation. The standard approach to framing dependency parsing as an integer linear program was introduced by (Riedel and Clarke, 2006), who converted the MST parser of (McDonald et al., 2005) to use ILP for inference. The key idea is to build a complete graph consisting of tokens of the sentence where each edge is weighted by a learned scoring function. The goal of inference is to select the maximum spanning tree of this weighted graph.

### 2.1 Problem Formulation

In this work, we consider the general inference problem of solving a 0-1 integer linear program. To perform inference, we assume that we have a model that assigns scores to the ILP decision variables. Thus, our work is applicable not only in cases where inference is done after a separate learning phase, as in (Roth and Yih, 2004; Clarke and Lapata, 2006; Roth and Yih, 2007) and others, but also when inference is done during the training phase, for algorithms like

the structured perceptron of (Collins, 2002), structured SVM (Tsochantaridis et al., 2005) or the constraints driven learning approach of (Chang et al., 2007).

Since structured prediction assigns values to a collection of inter-related binary decisions, we denote the  $i^{\text{th}}$  binary decision by  $y_i \in \{0, 1\}$  and the entire structure as  $\mathbf{y}$ , the vector composed of all the binary decisions. In our running example, each edge in the weighted graph generates a single decision variable (for unlabeled dependency parsing). For each  $y_i$ , let  $c_i \in \mathfrak{R}$  denote the weight associated with it. We denote the entire collection of weights by the vector  $\mathbf{c}$ , forming the *objective* for this ILP.

Not all assignments to these variables are valid. Without loss of generality, these constraints can be expressed using linear inequalities over the inference variables, which we write as  $\mathbf{M}^T \mathbf{y} \leq \mathbf{b}$  for a real valued matrix  $\mathbf{M}$  and a vector  $\mathbf{b}$ . In dependency parsing, for example, these constraints ensure that the final output is a spanning tree.

Now, the overall goal of inference is to find the highest scoring structure. Thus, we can frame inference as an optimization problem  $\mathbf{p}$  with  $n$  inference variables as follows:

$$\arg \max_{\mathbf{y} \in \{0,1\}^n} \mathbf{c}^T \mathbf{y} \quad (1)$$

$$\text{subject to } \mathbf{M}^T \mathbf{y} \leq \mathbf{b}. \quad (2)$$

For brevity, we denote the space of feasible solutions that satisfy the constraints for the ILP problem  $\mathbf{p}$  as  $K_{\mathbf{p}} = \{\mathbf{y} \in \{0, 1\}^n | \mathbf{M}^T \mathbf{y} \leq \mathbf{b}\}$ . Thus, the goal of inference is to find

$$\arg \max_{\mathbf{y} \in K_{\mathbf{p}}} \mathbf{c}^T \mathbf{y}.$$

We refer to  $K_{\mathbf{p}}$  as the feasible set for the inference problem  $\mathbf{p}$  and  $\mathbf{y}_{\mathbf{p}}$  as its solution.

In the worst case, integer linear programs are known to be NP-hard. Hence, solving large problems, (that is, problems with a large number of constraints and/or variables) can be infeasible.

For structured prediction problems seen in NLP, we typically solve many instances of inference problems. In this paper, we investigate whether an inference algorithm can use previous predictions to speed up inference time, thus giving us an *amortized gain*

in inference time over the lifetime of the program. We refer to inference algorithms that have this capability as **amortized inference algorithms**.

In our running example, each sentence corresponds to a separate ILP. Over the lifetime of the dependency parser, we create one inference instance (that is, one ILP) per sentence and solve it. An amortized inference algorithm becomes *faster* at parsing as it parses more and more sentences.

## 2.2 Why can inference costs be amortized over datasets?

In the rest of this section, we will argue that the time cost of inference can be amortized because of the nature of inference in NLP tasks. Our argument is based on two observations, which are summarized in Figure (1): (1) Though the space of possible structures may be large, only a very small fraction of these occur. (2) The distribution of observed structures is heavily skewed towards a small number of them.

Figure 1: For a structured prediction task, the inference problem  $\mathbf{p}$  for an example  $\mathbf{x}$  needs to be formulated before solving it to get the structure  $\mathbf{y}$ . In structured prediction problems seen in NLP, while an exponential number of structures is possible for a given instance, in practice, only a small fraction of these ever occur. This figure illustrates the empirical observation that there are fewer inference problems  $\mathbf{p}$ 's than the number of examples and the number of observed structures  $\mathbf{y}$ 's is even lesser.

As an illustration, consider the problem of part-of-speech tagging. With the standard Penn Treebank tag set, each token can be assigned one of 45 labels. Thus, for a sentence of size  $n$ , we could have  $45^n$  structures out of which the inference process needs to choose one. However, a majority of these structures never occur. For example, we cannot have a

Figure 2: Number of inference instances for different input sizes (red solid lines) and the number of unique structures for each size (blue dotted lines). The x-axis indicates the size of the input (number of tokens for part of speech and dependency, and number of argument candidates for SRL.) Note that the number of instances is not the number of unique examples of a given length, but the number of times an inference procedure is called for an input of a given size.

Figure 3: These plots show the log-frequencies of occurrences of part-of-speech sequences for sentences with five, ten and fifteen tokens. The x-axes list different unique part-of-speech tag sequences for the entire sentence. These plots show that for sentences of a given length, most structures (solutions) that are possible never occur, or occur very infrequently; only a few of the possible structures (solutions) actually occur frequently.

sentence where all the tokens are determiners.

Furthermore, many sentences of the same size share the same part-of-speech tag sequence. To quantify the redundancy of structures, we part-of-speech tagged the English Gigaword corpus (Graff and Cieri, 2003). Figure (2a) shows the number of sentences in the corpus for different sentence lengths. In addition, it also shows the number of unique part-of-speech tag sequences (over the entire sentence) for each size. We see that the number of structures is much fewer than the number of instances for any sentence size. Note that  $45^n$  quickly outgrows the number of sentences as  $n$  increases. The figures (2b) and (2c) show similar statistics for unlabeled dependency parsing and semantic role labeling. In the former case, the size of the instance is

the number of tokens in a sentence, while in the latter, the size is the number of argument candidates that need to be labeled for a given predicate. In both cases, we see that the number of empirically observed structures is far fewer than the number of instances to be labeled.

Thus, for any given input size, the number of instances of that size (over the lifetime of the program) far exceeds the number of observed structures for that size. Moreover, the number of observed structures is significantly smaller than the number of theoretically possible structures. Thus, we have a small number of structures that form optimum structures for many inference instances of the same size.

Our second observation deals with the distribution of structures for a given input size. Figure (3)

shows the log frequencies of part-of-speech tagging sequences for sentences of lengths five, ten and fifteen. In all cases, we see that a few structures are most frequent. We observed similar distributions of structures for all input sizes for dependency parsing and semantic role labeling as well.

Since the number of structures for a given example size is small, many examples  $\mathbf{x}$ 's, and hence many inference problems  $\mathbf{p}$ 's, are associated with the same structure  $\mathbf{y}$ . These observations suggest the possibility of getting an amortized gain in inference time by characterizing the set of inference problems that produce the same structure. Then, for a new inference problem, if we can identify that it belongs to a known set, that is, will yield a solution that we have already seen, we do not have to run inference at all. The second observation also suggests that this characterization of sets of problems that have the same solution can be done in a data-driven way because characterizing a small number of structures can give us high coverage.

### 3 Amortizing inference costs

In this section, we present different schemes for amortized inference leading up to an inference meta-algorithm. The meta-algorithm is both agnostic to the underlying inference algorithm that is used by the problem and maintains the exactness properties of the underlying inference scheme. That is, if we have an exact/approximate inference algorithm with a certain guarantees, the meta-algorithm will have the same guarantees, but with a speedup.

#### 3.1 Notation

For an integer linear program  $\mathbf{p}$  with  $n_{\mathbf{p}}$  variables, we denote its objective coefficients by  $\mathbf{c}_{\mathbf{p}}$  and its feasible set by  $K_{\mathbf{p}}$ . We denote its solution as  $\mathbf{y}_{\mathbf{p}}$ . We represent vectors by boldfaced symbols and their  $i^{\text{th}}$  component using subscripts.

We consider many instantiations of the inference problem and use superscripts to denote each individual instance. Thus, we have a large collection of inference instances  $P = \{\mathbf{p}^1, \mathbf{p}^2, \dots\}$  along with their respective solutions  $\{\mathbf{y}_{\mathbf{p}^1}^1, \mathbf{y}_{\mathbf{p}^2}^2, \dots\}$ .

**Definition 1** (Equivalence classes of ILPs). *Two integer linear programs are said to be in the same equivalence class if they have the same number of*

*inference variables and the same feasible set.*

We square brackets to denote equivalence classes. If  $[P]$  is an equivalence class of ILPs, we use the notation  $K_{[P]}$  to denote its feasible set and  $n_{[P]}$  to denote the number of variables. Also, for a program  $\mathbf{p}$ , we use the notation  $\mathbf{p} \sim [P]$  to indicate that it belongs to the equivalence class  $[P]$ .

#### 3.2 Exact theorems

Our goal is to characterize the set of objective functions which will have the same solution for a given equivalence class of problems.

Suppose we have solved an ILP  $\mathbf{p}$  to get a solution  $\mathbf{y}_{\mathbf{p}}$ . For every inference variable that is active in the solution (i.e., whose value is 1), increasing the corresponding objective value will not change the optimal assignment to the variables. Similarly, for all other variables (whose value in the solution is 0), decreasing the objective value will not change the optimal solution. This intuition gives us our first theorem for checking whether two ILPs have the same solution by looking at the difference between their objective coefficients.

**Theorem 1.** *Let  $\mathbf{p}$  denote an inference problem posed as an integer linear program belonging to an equivalence class  $[P]$ . Let  $\mathbf{q} \sim [P]$  be another inference instance in the same equivalence class. Define  $\delta\mathbf{c} = \mathbf{c}_{\mathbf{q}} - \mathbf{c}_{\mathbf{p}}$  to be the difference of the objective coefficients of the ILPs. Then,  $\mathbf{y}_{\mathbf{p}}$  is the solution of the problem  $\mathbf{q}$  if for each  $i \in \{1, \dots, n_{\mathbf{p}}\}$ , we have*

$$(2\mathbf{y}_{\mathbf{p},i} - 1)\delta\mathbf{c}_i \geq 0 \quad (3)$$

The condition in the theorem, that is, inequality (3), requires that the objective coefficients corresponding to values  $\mathbf{y}_{\mathbf{p},i}$  that are set to 1 in  $\mathbf{p}$  increase, and those that correspond to values of  $\mathbf{y}_{\mathbf{p},i}$  set to 0, decrease. Under these conditions, if  $\mathbf{y}_{\mathbf{p}}$  is the maximizer of the original objective, then it maximizes the new objective too.

Theorem 1 identifies perturbations of an ILP's objective coefficients that will not change the optimal assignment. Next, we will characterize the sets of objective values that will have the same solution using a criterion that is independent of the actual solution. Suppose we have two ILPs  $\mathbf{p}$  and  $\mathbf{q}$  in an equivalence class  $[P]$  whose objective values are  $\mathbf{c}_{\mathbf{p}}$  and  $\mathbf{c}_{\mathbf{q}}$  respectively. Suppose  $\mathbf{y}^*$  is the solution to

both these programs. That is, for every  $\mathbf{y} \in K_{[P]}$ , we have  $\mathbf{c}_p^T \mathbf{y} \leq \mathbf{c}_p^T \mathbf{y}^*$  and  $\mathbf{c}_q^T \mathbf{y} \leq \mathbf{c}_q^T \mathbf{y}^*$ . Multiplying these inequalities by any two positive real numbers  $x_1$  and  $x_2$  and adding them shows us that  $\mathbf{y}^*$  is also the solution for the ILP in  $[P]$  which has the objective coefficients  $x_1 \mathbf{c}_p + x_2 \mathbf{c}_q$ . Extending this to an arbitrary number of inference problems gives us our next theorem.

**Theorem 2.** *Let  $P$  denote a collection  $\{\mathbf{p}^1, \mathbf{p}^2, \dots, \mathbf{p}^m\}$  of  $m$  inference problems in the same equivalence class  $[P]$  and suppose that all the problems have the same solution,  $\mathbf{y}_p$ . Let  $\mathbf{q} \sim [P]$  be a new inference program whose optimal solution is  $\mathbf{y}$ . Then  $\mathbf{y} = \mathbf{y}_p$  if there is some  $\mathbf{x} \in \mathbb{R}^m$  such that  $\mathbf{x} \geq \mathbf{0}$  and*

$$\mathbf{c}_q = \sum_j \mathbf{x}_j \mathbf{c}_p^j. \quad (4)$$

From the geometric perspective, the pre-condition of this theorem implies that if the new coefficients lie in the cone formed by the coefficients of the programs that have the same solution, then the new program shares the solution.

Theorems 1 and 2 suggest two different approaches for identifying whether a new ILP can use the solution of previously solved inference instances. These theorems can be combined to get a single criterion that uses the objective coefficients of previously solved inference problems *and* their common solution to determine whether a new inference problem will have the same solution. Given a collection of solved ILPs that have the same solution, from theorem 2, we know that an ILP with the objective coefficients  $\mathbf{c} = \sum_j \mathbf{x}_j \mathbf{c}_p^j$  will share the solution. Considering an ILP whose objective vector is  $\mathbf{c}$  and applying theorem 1 to it gives us the next theorem.

**Theorem 3.** *Let  $P$  denote a collection  $\{\mathbf{p}^1, \mathbf{p}^2, \dots, \mathbf{p}^m\}$  of  $m$  inference problems belonging to the same equivalence class  $[P]$ . Furthermore, suppose all the programs have the same solution  $\mathbf{y}_p$ . Let  $\mathbf{q} \sim [P]$  be a new inference program in the equivalence class. For any  $\mathbf{x} \in \mathbb{R}^m$ , define  $\Delta \mathbf{c}(\mathbf{x}) = \mathbf{c}_q - \sum_j \mathbf{x}_j \mathbf{c}_p^j$ . The assignment  $\mathbf{y}_p$  is the optimal solution of the problem  $\mathbf{q}$  if there is some  $\mathbf{x} \in \mathbb{R}^m$  such that  $\mathbf{x} \geq \mathbf{0}$  and for each  $i \in \{1, n_p\}$ , we have*

$$(2\mathbf{y}_{p,i} - 1)\Delta \mathbf{c}_i \geq 0 \quad (5)$$

Theorem	Condition
Theorem 1	$\forall i \in \{1, \dots, n_p\},$ $(2\mathbf{y}_{p,i} - 1)\delta \mathbf{c}_i \geq 0; \forall i.$
Theorem 2	$\exists \mathbf{x} \in \mathbb{R}^m$ , such that $\mathbf{x} \geq \mathbf{0}$ and $\mathbf{c}_q = \sum_j \mathbf{x}_j \mathbf{c}_p^j$
Theorem 3	$\exists \mathbf{x} \in \mathbb{R}^m$ , such that $\mathbf{x} \geq \mathbf{0}$ and $(2\mathbf{y}_{p,i} - 1)\Delta \mathbf{c}_i \geq 0; \forall i.$

Table 2: Conditions for checking whether  $\mathbf{y}_p$  is the solution for an inference problem  $\mathbf{q} \sim [P]$  according to theorems 1, 2 and 3. Please refer to the statements of the theorems for details about the notation.

### 3.3 Implementation

Theorems 1, 2 and 3 each specify a condition that checks whether a pre-existing solution is the optimal assignment for a new inference problem. These conditions are summarized in Table 2. In all cases, if the condition matches, the theorems guarantee that the two solutions will be the same. That is, applying the theorems will not change the performance of the underlying inference procedure. Only the number of inference calls will be decreased.

In our implementation of the conditions, we used a database<sup>1</sup> to cache ILPs and implemented the retrieval of equivalence classes and solutions as queries to the database. To implement theorem 1, we iterate over all ILPs in the equivalence class and check if the condition is satisfied for one of them. The conditions of theorems 2 and 3 check whether a collection of linear (in)equalities has a feasible solution using a linear program solver.

We optimize the wall-clock time of theorems 2 and 3 by making two observations. First, we do not need to solve linear programs for all possible observed structures. Given an objective vector, we only need consider the highest scoring structures within an equivalence class. (All other structures cannot be the solution to the ILP.) Second, since theorem 2 checks whether an ILP lies within a cone, we can optimize the cache for theorem 2 by only storing the ILPs that form on the boundary of the cone. A similar optimization can be performed for theorem 3 as well. Our implementation uses the following weaker version of this optimization: while caching ILPs, we

<sup>1</sup>We used the H2 database engine, which can be downloaded from <http://h2database.com>, for all caching.

do not add an instance to the cache if it already satisfies the theorem. This optimization reduces the size of the linear programs used to check feasibility.

### 3.4 Approximation schemes

So far, in the above three theorems, we retain the guarantees (in terms of exactness and performance) of the underlying inference procedure. Now, we will look at schemes for approximate inference. Unlike the three theorems listed above, with the following amortized inference schemes, we are not guaranteed an optimal solution.

#### 3.4.1 Most frequent solution

The first scheme for approximation uses the observation that the most frequent solution occurs an overwhelmingly large number of times, compared to the others. (See the discussion in section 2.2 and figures 3a, 3b and 3c for part-of-speech tagging.) Under this approximation scheme, given an ILP problem, we simply pick the most frequent solution for that equivalence class as the solution, provided this solution has been seen a sufficient number of times. If the support available in the cache is insufficient, we call the underlying inference procedure.

#### 3.4.2 Top-K approximation

The previous scheme for approximate amortized inference is agnostic to the objective coefficients of integer linear program to be solved and uses only its equivalence class to find a candidate structure. The top- $K$  approach extends this by scoring the  $K$  most frequent solutions using the objective coefficients and selecting the highest scoring one as the solution to the ILP problem. As with the previous scheme, we only consider solutions that have sufficient support.

#### 3.4.3 Approximations to theorems 1 and 3

The next approximate inference schemes relaxes the conditions in theorems 1 and 3 by allowing the inequalities to be violated by  $\epsilon$ . That is, the inequality (3) from Theorem 1 now becomes

$$(2\mathbf{y}_{\mathbf{p},i} - 1)\delta\mathbf{c}_i + \epsilon \geq 0. \quad (6)$$

The inequality (5) from Theorem 3 is similarly relaxed as follows:

$$(2\mathbf{y}_{\mathbf{p},i} - 1)\Delta\mathbf{c}_i + \epsilon \geq 0 \quad (7)$$

### 3.5 Amortized inference algorithm

Each exact and approximate inference approach described above specifies a condition to check whether an inference procedure should be called for a new problem. This gives us the following meta-algorithm for amortized inference, parameterized by the actual scheme used: If the given input instance  $\mathbf{p}$  satisfies the condition specified by the scheme, then use the cached solution. Otherwise, call the inference procedure and cache the solution for future use.

## 4 Experiments

In this section, we apply the theory from Section 3 to the structure prediction problem of semantic role labeling. Since the inference schemes presented above are independent of the learning aspects, we use an off-the-shelf implementation and merely modify the inference as discussed in Section 3.5.

The goal of the experiments is to show that using an amortized inference algorithm, we can make fewer calls to the underlying inference procedure. For the exact inference algorithms, doing so will not change the performance as compared to the underlying system. For the approximations, we can make a trade-off between the inference time and performance.

### 4.1 Experimental setup

Our goal is to simulate a long-running NLP process that can use a cache of already solved problems to improve inference time. Given a new input problem, our theorems require us to find all elements in the equivalence class of that problem along with their solutions. Intuitively, we expect a higher probability of finding members of an arbitrary equivalence class if the size of the cache is large. Hence, we processed sentences from the Gigaword corpus and cached the inference problems for our task.

The wall-clock time is strongly dependent on such specific implementation of the components, which are independent of the main contributions of this work. Also, in most interesting applications, the computation time for each step will be typically dominated by the number of inference steps, especially with efficient implementations of caching and retrieval. Hence, the number of calls to the underlying procedure is the appropriate complexity param-

eter. Let  $N_{Base}$  be the number of times we would need to call the underlying inference procedure had we not used an amortized algorithm. (This is the same as the number of inference problems.) Let  $N_A$  be the number of times the underlying inference procedure is actually called using an amortized algorithm  $A$ . We define the *speedup* of  $A$  as

$$Speedup(A) = \frac{N_{Base}}{N_A}. \quad (8)$$

We also report the *clock speedup* of our implementation for all algorithms, which is the ratio of the wall-clock time taken by the baseline algorithm to that of the amortized algorithm. For measuring time, we only measure the time for inference as the other aspects (feature extraction, scoring, etc.) are not changed.

## 4.2 Semantic Role Labeling

The goal of Semantic Role Labeling (SRL) (Palmer et al., 2010) is to identify and assign semantic roles to arguments of verb predicates in a sentence. For example, consider the sentence *John gave the ball to Mary*. The verb *give* takes three arguments, *John*, *the ball* and *to Mary*, which are labeled A0, A1 and A2 respectively.

We used the system of (Punyakanok et al., 2008) as our base SRL system. It consists of two classifiers trained on the Propbank corpus. The first one, called the argument identifier, filters argument candidates which are generated using a syntactic parse-based heuristic. The second model scores each candidate that has not been filtered for all possible argument labels. The scores for all candidates of a predicate are combined via inference. As in the system of (Punyakanok et al., 2008), the softmax function is applied to the raw classifier scores to ensure that they are in the same numeric range.

Inference mandates that certain structural and linguistic constraints hold over the full predicate-argument structure for a verb. (Punyakanok et al., 2008) modeled inference via an integer linear program instance, where each assignment of labels to candidates corresponds to one decision variable. Given a set of argument candidates, the feasible set of decisions is dependent of the number of argument candidates and the verb predicate. Thus, in terms of the notation used in this paper, the equivalence

classes are defined by the pair (*predicate*, *number of argument candidates*).

We ran the semantic role labeler on 225,000 verb predicates from the Gigaword corpus and cached the equivalence classes, objective coefficients and solutions generated by the SRL system. We report speedup for the various amortized inference schemes on the standard Penn Treebank test set. On this data, the unaltered baseline system, processes 5127 integer linear programs and achieves an F1 of 75.85%.

Table 3 shows the speedup and performance for the various inference schemes. The most frequent and top-K systems are both naive solutions that take advantage of the cache of stored problems. In spite of their simplicity, they attain F1 scores of 62% and 70.06% because few structures occur most frequently, as described in section 2.2. We see that all the exact theorems attain a speedup higher than two without losing performance. (The variation in F1 between them is because of the existence of different equivalent solutions in terms of the objective value.) This shows us that we can achieve an amortized gain in inference. Note that a speedup of 2.5 indicates that the solver is called only for 40% of the examples. The approximate versions of theorems 1 and 3 (with  $\epsilon = 0.3$  in both cases, which was not tuned) attain an even higher gain in speedup over the baseline than the base versions of the theorems. Interestingly, the SRL performance in both cases does not decline much even though the conditions of the theorems may be violated.

## 5 Related work and Future directions

In recent years, we have seen several approaches to speeding up inference using ideas like using the cutting plane approach (Riedel, 2009), dual decomposition and Lagrangian relaxation (Rush et al., 2010; Chang and Collins, 2011). The key difference between these and the work in this paper is that all these approaches solve one instance at a time. Since we can use any inference procedure as a underlying system, the speedup reported in this paper is applicable to all these algorithms.

**Decomposed amortized inference** In this paper, we have taken advantage of redundancy of structures that can lead to the re-use of solutions. In the

Type	Algorithm	# instances	# solver calls	Speedup	Clock speedup	F1
Exact	Baseline	5127	5217	1.0	1.0	75.85
Exact	Theorem 1	5127	2134	2.44	1.54	75.90
Exact	Theorem 2	5127	2390	2.18	1.14	75.79
Exact	Theorem 3	5127	2089	2.50	1.36	75.77
Approx.	Most frequent (Support = 50)	5127	2812	1.86	1.57	62.00
Approx.	Top-10 solutions (Support = 50)	5127	2812	1.86	1.58	70.06
Approx.	Theorem 1 (approx, $\epsilon = 0.3$ )	5127	1634	3.19	1.81	75.76
Approx.	Theorem 3 (approx, $\epsilon = 0.3$ )	5127	1607	3.25	1.50	75.46

Table 3: Speedup and performance for various inference methods for the task of Semantic Role Labeling. All the exact inference algorithms get a speedup higher than two. The speedup of the approximate version of the theorems is even higher without loss of performance. The clock speedup is defined as the ratio of the inference times of the baseline and the given algorithm. All numbers are averaged over ten trials.

part of speech example, we showed redundancy of structures at the sentence level (Figure 2a). However, for part-of-speech tagging, the decisions are rarely, if at all, dependent on a very large context. One direction of future work is to take advantage of the fact that the inference problem can be split into smaller sub-problems. To support this hypothesis, we counted the number of occurrences of ngrams of tokens (including overlapping and repeated mentions) for  $n \leq 10$  and compared this to the number of unique part-of-speech ngrams of this length. Figure 4 shows these two counts. Following the argument in Section 2.2, this promises a large amortized gain in inference time. We believe that such decomposition can also be applied to other, more complex structured prediction tasks.

**The value of approximate inference** From the experiments, we see that the first two approximate inference schemes (most frequent solution and the top-K scheme) can speed up inference with the only computational cost being the check for preconditions of the exact theorems. Effectively, these algorithms have parameters (i.e., the support parameter) that allow us to choose between the inference time and performance. Figure 5 shows the performance of the most frequent and top-K baselines for different values of the support parameter, which indicates how often a structure must occur for it to be considered. We see that for lower values of support, we can get a very high speedup but pay with poorer performance.

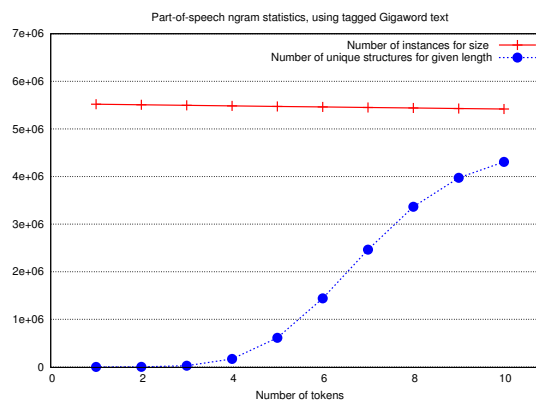

Figure 4: The red line shows the number of ngrams of tokens (including overlapping and repeated occurrences) in the Gigaword corpus and the blue line shows the number of unique POS tag sequences.

However, the prediction of the approximate algorithms can be used to warm-start any solver that can accept an external initialization. Warm-starting a solver can give a way to get the exact solution and yet take advantage of the frequency of structures that have been observed.

**Lifted inference** The idea of amortizing inference time over the dataset is conceptually related to the idea of lifted inference (de Salvo Braz et al., 2005). We abstract many instances into equivalence classes and deal with the inference problem with respect to the equivalence classes in the same way as done in lifted inference algorithms.

Figure 5: Most frequent solutions and top-K: Speedup and SRL performance (F1) for different values of the support parameter, using the most-frequent solutions (dashed blue line) and the top-K scheme (thick gray line). Support indicates how many times a structure should be seen for it to be considered. Note that the speedup values for both schemes are identical (red line).

## 6 Conclusion

In this paper, we addressed structured prediction in the context of NLP and proposed an approach to improve inference costs over an entire dataset, rather than individual instances. By treating inference problems as instances of integer linear programs, we proposed three exact theorems which identify examples for which the inference procedure need not be called at all and previous solutions can be re-used with the guarantee of optimality. In addition, we also proposed several approximate algorithms. We applied our algorithms, which are agnostic to the actual tasks, to the problem semantic role labeling, showing significant decrease in the number of inference calls without any loss in performance. While the approach suggested in this paper is evaluated in semantic role labeling, it is generally applicable to any NLP task that deals with structured prediction.

## Abstract

We present a method for exact optimization and sampling from high order Hidden Markov Models (HMMs), which are generally handled by approximation techniques. Motivated by adaptive rejection sampling and heuristic search, we propose a strategy based on sequentially refining a lower-order language model that is an upper bound on the true model we wish to decode and sample from. This allows us to build tractable variable-order HMMs. The ARPA format for language models is extended to enable an efficient use of the *max-backoff* quantities required to compute the upper bound. We evaluate our approach on two problems: a SMS-retrieval task and a POS tagging experiment using 5-gram models. Results show that the same approach can be used for exact optimization and sampling, while explicitly constructing only a fraction of the total implicit state-space.

## 1 Introduction

In NLP, sampling is important for many real tasks, such as: (i) diversity in language generation or machine translation (proposing multiple alternatives which are not clustered around a single maximum); (ii) Bayes error minimization, for instance in Statistical Machine Translation (Kumar and Byrne, 2004); (iii) learning of parametric and non-parametric Bayesian models (Teh, 2006).

However, most practical sampling algorithms are based on MCMC, i.e. they are based on local moves

starting from an initial valid configuration. Often, these algorithms are stuck in local minima, i.e. in a basin of attraction close to the initialization, and the method does not really sample the whole state space. This is a problem when there are ambiguities in the distribution we want to sample from: by having a local approach such as MCMC, we might only explore states that are close to a given configuration.

The necessity of exact sampling can be questioned in practice. Approximate sampling techniques have been developed over the last century and seem sufficient for most purposes. However, the cases where one actually knows the quality of a sampling algorithm are very rare, and it is common practice to forget about the approximation and simply treat the result of a sampler as a set of i.i.d. data. Exact sampling provides a de-facto guarantee that the samples are truly independent. This is particularly relevant when one uses a cascade of algorithms in complex NLP processing chains, as shown by (Finkel et al., 2006) in their work on linguistic annotation pipelines.

In this paper, we present an approach for exact decoding and sampling with an HMM whose hidden layer is a high-order language model (LM), which innovates on existing techniques in the following ways. First, it is a *joint* approach to sampling and optimization (i.e. decoding), which is based on introducing a simplified, “optimistic”, version  $q(x)$  of the underlying language model  $p(x)$ , for which it is tractable to use standard dynamic programming techniques both for sampling and optimization. We then formulate the problem of sampling/optimization with the original model  $p(x)$  in

---

\*This work was conducted during an internship at XRCE.

terms of a novel algorithm which can be viewed as a form of *adaptive rejection sampling* (Gilks and Wild, 1992; Gorur and Teh, 2008), in which a low acceptance rate (in sampling) or a low ratio  $p(x^*)/q(x^*)$  (in optimization, with  $x^*$  the argmax of  $q$ ) leads to a refinement of  $q$ , i.e., a slightly more complex and less optimistic  $q$  but with a higher acceptance rate or ratio.

Second, it is the first technique that we are aware of which is able to perform *exact sampling* with such models. Known techniques for sampling in such situations have to rely on approximation techniques such as Gibbs or Beam sampling (see e.g. (Teh et al., 2006; Van Gael et al., 2008)). By contrast, our technique produces exact samples from the start, although in principle, the first sample may be obtained only after a long series of rejections (and therefore refinements). In practice, our experiments indicate that a good acceptance rate is obtained after a relatively small number of refinements. It should be noted that, in the case of exact optimization, a similar technique to ours has been proposed in an image processing context (Kam and Kopec, 1996), but without any connection to sampling. That paper, written in the context of image processing, appears to be little known in the NLP community.

Overall, our method is of particular interest because it allows for exact decoding and sampling from HMMs where the applications of existing dynamic programming algorithms such as Viterbi decoding (Rabiner, 1989) or Forward-Backward sampling (Scott, 2002) are not feasible, due to a large state space.

In Section 2, we present our approach and describe our joint algorithm for HMM sampling/optimization, giving details about our extension of the ARPA format and refinement procedure. In Section 3 we define our two experimental tasks, SMS-retrieval and POS tagging, for which we present the results of our joint algorithm. We finally discuss perspectives and conclude in Section 4.

## 2 Adaptive rejection sampling and heuristic search for high-order HMMs

**Notation** Let  $x = \{x_1, x_2, \dots, x_\ell\}$  be a given hidden state sequence (e.g. each  $x_i$  is an English word) which takes values in  $\mathcal{X} = \{1, \dots, N\}^\ell$  where  $\ell$

is the length of the sequence and  $N$  is the number of latent symbols. Subsequences  $(x_a, x_{a+1}, \dots, x_b)$  are denoted by  $x_a^b$ , where  $1 \leq a \leq b \leq \ell$ . Let  $o = \{o_1, o_2, \dots, o_\ell\}$  be the set of observations associated to these words (e.g.  $o_i$  is an acoustic realization of  $x_i$ ). The notations  $p$ ,  $q$  and  $q'$  refer to unnormalized densities, i.e. non-negative measures on  $\mathcal{X}$ . Since only discrete spaces are considered, we use for short  $p(x) = p(\{x\})$ . When the context is not ambiguous, sampling according to  $p$  means sampling according to the distribution with density  $\bar{p}(x) = \frac{p(x)}{p(\mathcal{X})}$ , where  $p(\mathcal{X}) = \int_{\mathcal{X}} p(x) dx$  is the total mass of the unnormalized distribution  $p$ .

**Sampling** The objective is to sample a sequence with density  $\bar{p}(x)$  proportional to  $p(x) = p_{\text{lm}}(x)p_{\text{obs}}(o|x)$  where  $p_{\text{lm}}$  is the probability of the sequence  $x$  under a  $n$ -gram model and  $p_{\text{obs}}(o|x)$  is the probability of observing the noisy sequence  $o$  given that the correct/latent sequence is  $x$ . Assuming the observations depend only on the current state, this probability becomes

$$p(x) = \prod_{i=1}^{\ell} p_{\text{lm}}(x_i | x_{i-n+1}^{i-1}) p_{\text{obs}}(o_i | x_i) . \quad (1)$$

To find the most likely sequence given an observation, or to sample sequences from Equation 1, standard dynamic programming techniques are used (Rabiner, 1989; Scott, 2002) by expanding the state space at each position. However, as the transition order  $n$  increases, or the number of latent tokens  $N$  that can emit to each observation  $o_i$  increases, the dynamic programming approach becomes intractable, as the number of operations increases exponentially in the order of  $\mathcal{O}(\ell N^n)$ .

If one can find a proposal distribution  $q$  which is an upper bound of  $p$  — i.e such that  $q(x) \geq p(x)$  for all sequences  $x \in \mathcal{X}$  — and which it is easy to sample from, the standard *rejection sampling* algorithm can be used:

1. Sample  $x \sim q/q(\mathcal{X})$ , with  $q(\mathcal{X}) = \int_{\mathcal{X}} q(x) dx$ ;
2. Accept  $x$  with probability  $p(x)/q(x)$ , otherwise reject  $x$ ;

To obtain multiple samples, the algorithm is repeated several times. However, for simple bounds,

Figure 1: An example of an initial  $q$ -automaton (a), and the refined  $q$ -automaton (b) Each state corresponds to a context (only state 6 has a non-empty context) and each edge represents the emission of a symbol. Thick edges are representing the path for the sampling/decoding of two dog(s) barked, thin edges corresponding to alternative symbols. By construction,  $w_1(\text{dog}) \geq w_2(\text{dog}|\text{two})$  so that the total weight of (b) is smaller than the total weight of (a).

the average acceptance rate — which is equal to  $p(\mathcal{X})/q(\mathcal{X})$  — can be so large that rejection sampling is not practical. In *adaptive rejection sampling* (ARS), the initial bound  $q$  is incrementally improved based on the values of the rejected elements. While often based on log-concave distributions which are easy to bound, ARS is valid for any type of bound, and in particular can be applied to the upper bounds on  $n$ -gram models introduced by (Kam and Kopec, 1996) in the context of optimization. When a sample is rejected, our algorithm assumes that a small set of refined proposals is available, say  $q'_1, \dots, q'_m$ , where  $m$  is a small integer value. These refinements are *improved* versions of the current proposal  $q$  in the sense that they still upper-bound the target distribution  $p$ , but their mass is strictly smaller than the mass of  $q$ , i.e.  $q'(\mathcal{X}) < q(\mathcal{X})$ . Thus, each such refinement  $q'$ , while still being optimistic relative to the target distribution  $p$ , has higher average acceptance rate than the previous upper bound  $q$ . A bound on the  $n$ -gram LM will be presented in Section 2.1.

**Optimization** In the case of optimization, the objective is to find the sequence maximizing  $p(x)$ . Viterbi on high-order HMMs is intractable but we have access to an upper bound  $q$ , for which Viterbi is tractable. Sampling from  $q$  is then replaced by finding the maximum point  $x$  of  $q$ , looking at the ratio  $r(x) = p(x)/q(x)$ , and accepting  $x$  if this ratio is equal to 1, otherwise refining  $q$  into  $q'$  exactly as in the sampling case. This technique is able to find the exact maximum of  $p$ , similarly to standard heuristic search algorithms based on optimistic bounds. We stop the process when  $q$  and  $p$  agree at the value maximizing  $q$  which implies that we have found the global maximum.

## 2.1 Upper bounds for $n$ -gram models

To apply ARS on the target density given by Equation 1 we need to define a random sequence of proposal distributions  $\{q^{(t)}\}_{t=1}^{\infty}$  such that  $q^{(t)}(x) \geq p(x), \forall x \in \mathcal{X}, \forall t \in \{0, 1, \dots\}$ . Each  $n$ -gram  $x_{i-n+1}, \dots, x_i$  in the hidden layer contributes an  $n$ -th order factor  $w_n(x_i|x_{i-n+1}^{i-1}) \equiv p_{\text{lm}}(x_i|x_{i-n+1}^{i-1})p_{\text{obs}}(o_i|x_i)$ . The key idea is that these  $n$ -th order factors can be upper bounded by factors of order  $n - k$  by maximizing over the head (i.e. prefix) of the context, as if part of the context was “forgotten”. Formally, we define the *max-backoff weights* as:

$$w_{n-k}(x_i|x_{i-n+1+k}^{i-1}) \equiv \max_{x_{i-n+1}^{i-n+k}} w_n(x_i|x_{i-n+1}^{i-1}), \quad (2)$$

By construction, the max-backoff weights  $w_{n-k}$  are factors of order  $n - k$  and can be used as surrogates to the original  $n$ -th order factors of Equation (1), leading to a nested sequence of upper bounds until reaching binary or unary factors:

$$p(x) = \prod_{i=1}^{\ell} w_n(x_i|x_{i-n+1}^{i-1}) \quad (3)$$

$$\leq \prod_{i=1}^{\ell} w_{n-1}(x_i|x_{i-n+2}^{i-1}) \quad (4)$$

...

$$\leq \prod_{i=1}^{\ell} w_2(x_i|x_{i-1}) \quad (5)$$

$$\leq \prod_{i=1}^{\ell} w_1(x_i) := q^{(0)}(x) . \quad (6)$$

Now, one can see that the loosest bound (6) based on unigrams corresponds to a completely factorized distribution which is straightforward to sample and optimize. The bigram bound (5) corresponds to a standard HMM probability that can be efficiently decoded (using Viterbi algorithm) and sampled (using backward filtering-forward sampling).<sup>1</sup> In the context of ARS, our initial proposal  $q^{(0)}(x)$  is set to

<sup>1</sup>Backward filtering-forward sampling (Scott, 2002) refers to the process of running the Forward algorithm (Rabiner,

the unigram bound (6). The bound is then incrementally improved by adaptively refining the max-backoff weights based on the values of the rejected samples. Here, a refinement refers to the increase of the order of *some* of the max-backoff weights in the current proposal (thus most refinements consist of  $n$ -grams with heterogeneous max-backoff orders, not only those shown in equations (3)-(6)). This operation tends to tighten the bound and therefore increase the acceptance probability of the rejection sampler, at the price of a higher sampling complexity. There are several possible ways of choosing the weights to refine; in Section 2.2 different refinement strategies will be discussed, but the main technical difficulty remains in the efficient exact optimization and sampling of a HMM with  $n$ -grams of variable orders. The construction of the refinement sequence  $\{q^{(t)}\}_{t \geq 0}$  can be easily explained and implemented through a Weighted Finite State Automaton (WFSA) referred as a  $q$ -automaton, as illustrated in the following example.

**Example** We give now a high-level description of the refinement process to give a better intuition of our method. In Fig. 1(a), we show a WFSA representing the initial proposal  $q^{(0)}$  corresponding to an example with an acoustic realization of the sequence of words (the, two, dogs, barked). The weights on edges of this  $q$ -automaton correspond to the unigram max-backoffs, so that the total weight corresponds to Equation (6). Considering sampling, we suppose that the first sample from  $q^{(0)}$  produces  $x_1 = (\text{the}, \text{two}, \text{dog}, \text{barked})$ , marked with bold edges in the drawing. Now, computing the ratio  $p(x_1)/q^{(0)}(x_1)$  gives a result much below 1, because from the viewpoint of the full model  $p$ , the trigram (the two dog) is very unlikely; in other words the ratio  $w_3(\text{dog}|\text{the two})/w_1(\text{dog})$  (and, in fact, already the ratio  $w_2(\text{dog}|\text{two})/w_1(\text{dog})$ ) is very low. Thus, with high probability,  $x_1$  is rejected. When this is the case, we produce a refined proposal  $q^{(1)}$ , represented by the WFSA in Fig. 1(b), which takes into account the more real-

istic weight  $w_2(\text{dog}|\text{two})$  by adding a node (node 6) for the context `two`. We then perform a sampling trial with  $q^{(1)}$ , which this time tends to avoid producing `dog` in the context of `two`; if the new sample is rejected, the refinement process continues until we start observing that the acceptance rate reaches a fixed threshold value. The case of optimization is similar. Suppose that with  $q^{(0)}$  the maximum is  $x_1$ , then we observe that  $p(x_1)$  is lower than  $q^{(0)}(x_1)$ , reject suboptimal  $x_1$  and refine  $q^{(0)}$  into  $q^{(1)}$ .

istic weight  $w_2(\text{dog}|\text{two})$  by adding a node (node 6) for the context `two`. We then perform a sampling trial with  $q^{(1)}$ , which this time tends to avoid producing `dog` in the context of `two`; if the new sample is rejected, the refinement process continues until we start observing that the acceptance rate reaches a fixed threshold value. The case of optimization is similar. Suppose that with  $q^{(0)}$  the maximum is  $x_1$ , then we observe that  $p(x_1)$  is lower than  $q^{(0)}(x_1)$ , reject suboptimal  $x_1$  and refine  $q^{(0)}$  into  $q^{(1)}$ .

## 2.2 Algorithm

We describe in detail the algorithm and procedure for updating a  $q$ -automaton with a max-backoff of longer context.

Algorithm 1 gives the pseudo-code of the sam-

pling/optimization strategy. On line 1,  $h$  represents the history of all trials so far, where the stopping criterion for decoding is whether the last trial in the history has been accepted, and for sampling whether the ratio of accepted trials relative to all trials exceeds a certain threshold. The WFSA is initialized so that all transitions only take into account the  $w_1(x_i)$  max-backoffs, i.e. the initial optimistic-bound ignores all contexts. Then depending on whether we are sampling or decoding, in lines 2-5, we draw an event from our automaton using either the Viterbi algorithm or Forward-Backward sampling. If the sequence is rejected at line 7, then the  $q$ -automaton is updated in lines 10 and 11. This is done by expanding all the factors involved in the sampling/decoding of the rejected sequence  $x$  to a higher order. That is, while sampling or decoding the automaton using the current proposal  $q^{(t)}$ , the contexts used in the path of the rejected sequence are replaced with higher order contexts in the new refined proposal  $q^{t+1}(x)$ .

The update process of the  $q$ -automaton represented as a WFSA is described in Algorithm 2. This procedure guarantees that a lower, more realistic weight is used in *all* paths containing the  $n$ -gram  $x_{i-n+1}^i$  while decoding/sampling the  $q$ -automaton, where  $n$  is the order at which  $x_{i-n+1}^i$  has been expanded so far. The algorithm takes as input a max-backoff function, and refines the WFSA such that any paths that include this  $n$ -gram have a smaller weight thanks to the fact that higher-order max-backoff have automatically smaller weights.

The algorithm requires the following functions:

- $\text{ORDER}_i(x)$  returns the order at which the  $n$ -gram has been expanded so far at position  $i$ .
- $S_i$  returns the states at a position  $i$ .
- $T_i(s)$  returns end states, labels and weights of all edges that originate from this state.
- $\text{SUF}_i(x)$  returns the states at  $i$  which have a suffix matching the given context  $x$ . For empty contexts, all states at  $i$  are returned.
- $\text{EDGE}(s, l)$  returns the edge which originates from  $s$  and has label  $l$ . Deterministic WFSA, such as those used here, can only have a single transition with a label  $l$  leaving from a state  $s$ .

- $\text{CREATE-STATE}(s, i)$  creates a state with name  $s$  at position  $i$ ,  $\text{CREATE-EDGE}(s_1, s_2, l, \omega)$  creates an edge  $(s_1, s_2)$  between  $s_1$  and  $s_2$  with weight  $\omega$  and label  $l$ , and  $\text{MOVE-EDGE-END}(e, s)$  sets the end of edge  $e$  to be the state  $s$ , keeping the same starting state, weight and label.

At line 1, the expansion of the current  $n$ -gram is increased by one so that we only need to expand contexts of size  $n - 2$ . Line 2 checks whether the context state exists. If it doesn't it is created at lines 3-10. Finally, the weight of the edges that could be involved in the decoding of this  $n$ -gram are updated to a smaller value given by a higher-order max-backoff weight.

The creation of a new state in lines 3-10 is straightforward: At lines 5-7, incoming edges are moved from states at position  $i - 2$  with a matching context to the newly created edge. At lines 9-10 edges heading out of the context state are created. They are simply copied over from all edges that originate from the suffix of the context state, as we know these will be legitimate transitions (i.e we will always transition to a state of the same order or lower).

Note that we can derive many other variants of Algorithm 2 which also guarantee a smaller total weight for the  $q$ -automaton. We chose to present this version because it is relatively simple to implement, and numerical experiments comparing different refinement approaches (including replacing the max-backoffs with the highest-possible context, or picking a single ‘‘culprit’’ to refine) showed that this approach gives a good trade-off between model complexity and running time.

### 2.3 Computing Max-Backoff Factors

An interesting property of the max-backoff weights is that they can be computed recursively; taking a 3-gram LM as an example, we have:

$$\begin{aligned} w_1(x_i) &= \max_{x_{i-1}} w_2(x_i | x_{i-1}) \\ w_2(x_i | x_{i-1}) &= \max_{x_{i-2}} w_3(x_i | x_{i-2}^{i-1}) \\ w_3(x_i | x_{i-2}^{i-1}) &= p(x_i | x_{i-2}^{i-1}) p(o_i | x_i). \end{aligned}$$

The final  $w_3(x_i | x_{i-2}^{i-1})$  upper bound function is simply equal to the true probability (multiplied by the

conditional probability of the observation), as any extra context is discarded by the 3-gram language model. It's easy to see that as we refine  $q^{(t)}$  by replacing existing max-backoff weights with more specific contexts, the  $q^{(t)}$  tends to  $p$  as  $t$  tends to infinity.

In the HMM formulation, we need to be able to efficiently compute at run-time the max-backoffs  $w_1(\text{the})$ ,  $w_2(\text{dog}|\text{the})$ ,  $\dots$ , taking into account smoothing. To do so, we present a novel method for converting language models in the standard ARPA format used by common toolkits such as (Stolcke, 2002) into a format that we can use. The ARPA file format is a table  $T$  composed of three columns: (1) an  $n$ -gram which has been observed in the training corpus, (2) the log of the conditional probability of the last word in the  $n$ -gram given the previous words ( $\log f(\cdot)$ ), and (3) a backoff weight ( $\text{bow}(\cdot)$ ) used when unseen  $n$ -grams 'backoff' to this  $n$ -gram.<sup>2</sup>

The probability of any  $n$ -gram  $x_{i-n}^i$  (in the previous sense, i.e. writing  $p(x_{i-n}^i)$  for  $p(x_i|x_{i-n}^{i-1})$ ) is then computed recursively as:

$$p(x_{i-n}^i) = \begin{cases} f(x_{i-n}^i) & \text{if } x_{i-n}^i \in T \\ \text{bow}(x_{i-n}^{i-1}) p(x_{i-n+1}^i) & \text{otherwise.} \end{cases} \quad (7)$$

Here, it is understood that if  $x_{i-n}^{i-1}$  is in  $T$ , then its  $\text{bow}(\cdot)$  is read from the table, otherwise it is taken to be 1.

Different smoothing techniques will lead to different calculations of  $f(x_{i-n}^i)$  and  $\text{bow}(x_{i-n}^{i-1})$ , however both backoff and linear-interpolation methods can be formulated using the above equation.

Starting from the ARPA format, we pre-compute a new table MAX-ARPA, which has the same lines as ARPA, each corresponding to an  $n$ -gram  $x_{i-n}^i$  observed in the corpus, and the same  $f$  and  $\text{bow}$ , but with two additional columns: (4) a max log probability ( $\log \text{mf}(x_{i-n}^i)$ ), which is equal to the maximum log probability over all the  $n$ -grams extending the context of  $x_{i-n}^i$ , i.e. which have  $x_{i-n}^i$  as a suffix; (5) a "max backoff" weight ( $\text{mbow}(x_{i-n}^i)$ ), which is a number used for computing the max log probability of an  $n$ -gram not listed in the table. From the MAX-ARPA table, the max probability  $w$  of any  $n$ -

<sup>2</sup>See [www.speech.sri.com/projects/srilm/manpages/ngram-format.5.html](http://www.speech.sri.com/projects/srilm/manpages/ngram-format.5.html), last accessed at 1/3/2012, for further details.

gram  $x_{i-n}^i$ , i.e the maximum of  $p(x_{i-n-k}^i)$  over all  $n$ -grams extending the context of  $x_{i-n}^i$ , can then be computed recursively (again very quickly) as:

$$w(x_{i-n}^i) = \begin{cases} \text{mf}(x_{i-n}^i) & \text{if } x_{i-n}^i \in T \\ \text{mbow}(x_{i-n}^{i-1}) p(x_{i-n}^i) & \text{otherwise.} \end{cases} \quad (8)$$

Here, if  $x_{i-n}^{i-1}$  is in  $T$ , then its  $\text{mbow}(\cdot)$  is read from the table, otherwise it is taken to be 1. Also note that the procedure calls  $p$ , which is computed as described in Equation 7.<sup>3</sup>

### 3 Experiments

In this section we empirically evaluate our joint, exact decoder and sampler on two tasks; SMS-retrieval (Section 3.1), and supervised POS tagging (Section 3.2).

#### 3.1 SMS-Retrieval

We evaluate our approach on an SMS-message retrieval task. A latent variable  $x \in \{1, \dots, N\}^\ell$  represents a sentence represented as a sequence of words:  $N$  is the number of possible words in the vocabulary and  $\ell$  is the number of words in the sentence. Each word is converted into a sequence of numbers based on a mobile phone numeric keypad. The standard character-to-numeric function  $\text{num} : \{a, b, \dots, z, ., \dots, ?\} \rightarrow \{1, 2, \dots, 9, 0\}$  is used. For example, the words `dog` and `fog` are represented by the sequence (3, 6, 4) because  $\text{num}(d)=\text{num}(f)=3$ ,  $\text{num}(o)=6$  and  $\text{num}(g)=4$ . Hence, observed sequences are sequences of numeric strings separated by white spaces. To take into account typing errors, we assume we observe a noisy version of the correct numeric sequence  $(\text{num}(x_{i1}), \dots, \text{num}(x_{i|x_i|}))$  that encodes the word  $x_i$  at the  $i$ -th position of the sentence  $x$ . The noise model is:

$$p(o_i|x_i) \propto \prod_{t=1}^{|x_i|} \frac{1}{k * d(o_{it}, \text{num}(x_{it})) + 1}, \quad (9)$$

where  $d(a, b)$  is the physical distance between the numeric keys  $a$  and  $b$  and  $k$  is a user provided con-

<sup>3</sup>In this discussion of the MAX-ARPA table we have ignored the contribution of the observation  $p(o_i|x_i)$ , which is a constant factor over the different max-backoffs for the same  $x_i$  and does not impact the computation of the table.

Figure 2: On the left we report the average # of iterations taken to decode given different LMs over input sentences of different lengths, and on the right we show the average # of states in the final  $q$ -automaton once decoding is completed.

stant that controls the ambiguity in the distribution; we use 64 to obtain moderately noisy sequences.

We used the English side of the Europarl corpus (Koehn, 2005). The language model was trained using SRILM (Stolcke, 2002) on 90% of the sentences. On the remaining 10%, we randomly selected 100 sequences for lengths 1 to 10 to obtain 1000 sequences from which we removed the ones containing numbers, obtaining a test set of size 926.

**Decoding** Algorithm 1 was run in the optimization mode. In the left plot of Fig. 2, we show the number of iterations (running Viterbi then updating  $q$ ) that the different  $n$ -gram models of size 3, 4 and 5 take to do exact decoding of the test-set. For a fixed sentence length, we can see that decoding with larger  $n$ -gram models leads to a sub-linear increase w.r.t.  $n$  in the number of iterations taken. In the right plot of Fig. 2, we show the average number of states in our variable-order HMMs.

To demonstrate the reduced nature of our  $q$ -automaton, we show in Tab. 1 the distribution of  $n$ -grams in our final model for a specific input sentence of length 10. The number of  $n$ -grams in the full model is  $\sim 3.0 \times 10^{15}$ . Exact decoding here is not tractable using existing techniques. Our HMM has only 9008  $n$ -grams in total, including 118 5-grams.

n:	1	2	3	4	5
q:	7868	615	231	176	118

Table 1: # of  $n$ -grams in our variable-order HMM.

Finally, we show in Tab. 2 an example run of our algorithm in the optimization setting for a given

input. Note that the weight according to our  $q$ -automaton for the first path returned by the Viterbi algorithm is high in comparison to the true log probability according to  $p$ .

**Sampling** For the sampling experiments, we limit the number of latent tokens to 100. We refine our  $q$ -automaton until we reach a certain fixed cumulative acceptance rate (AR). We also compute a rate based only on the last 100 trials (AR-100), as this tends to better reflect the current acceptance rate.

In Fig. 3a, we plot a running average of the ratio at each iteration over the last 10 trials, for a single sampling run using a 5-gram model for an example input. The ratios start off at  $10^{-20}$ , but gradually increase as we refine our HMM. After  $\sim 500$  trials, we start accepting samples from  $p$ . In Fig. 3b, we show the respective ARs (bottom and top curves respectively), and the cumulative # of accepts (middle curve), for the same input. Because the cumulative accept ratio takes into account all trials, the final AR of 17.7% is an underestimate of the true accept ratio at the final iteration; this final accept ratio can be better estimated on the basis of the last 100 trials, for which we read AR-100 to be at around 60%.

We note that there is a trade-off between the time needed to construct the forward probability lattice needed for sampling, and the time it takes to adapt the variable-order HMM. To resolve this, we propose to use batch-updates: making  $B$  trials from the same  $q$ -automaton, and then updating our model in one step. By doing this, we noted significant speed-ups in sampling times. In Tab. 3, we show various

<i>input:</i>		3637	843	66639	39478 *
<i>oracle:</i>		does the money exist ?			
<i>best:</i>		does the money exist .			
<i>Viterbi paths</i>		log q(x)	log p(x)		
$q^1$	does the money exist )	-0.11	-17.42

$q^{100}$	<b>ends</b> the money exist .	-12.76	-17.09		
$q^{150}$	does <b>vis</b> money exist .	-13.45	-23.74		
$q^{170}$	does the money exist .	-13.70	-13.70		

Table 2: Viterbi paths given different  $q^t$ . Here, for the given input, it took 170 iterations to find the best sequence according to  $p$ , so we only show every 50th path.

Figure 3: In 3a, we plot the running average over the last 10 trials of the ratio. In 3b, we plot the cumulative # of accepts (middle curve), the accept rate (bottom curve), and the accept rate based on the last 100 samples (top curve). In 3c, we plot the average number of iterations needed to sample up to an AR of 20% for sentences of different lengths in our test set, and in 3d, we show the average number of states in our HMMs for the same experiment.

B:	1	10	20	30	40	50	100
time:	97.5	19.9	15.0	13.9	12.8	12.5	11.4
iter:	453	456	480	516	536	568	700

Table 3: In this table we show the average amount of time in seconds and the average number of iterations (iter) taken to sample sentences of length 10 given different values of  $B$ .

statistics for sampling up to  $AR-100 = 20$  given different values for  $B$ . We ran this experiment using the set of sentences of length 10. A value of 1 means that we refine our automaton after each rejected trial, a value of 10 means we wait until rejecting 10 trials before updating our automaton in one step. We can see that while higher values of  $B$  lead to more iterations, as we do not need to re-compute the forward trellis needed for sampling, the time needed to reach the specific AR threshold actually decreases, from 97.5 seconds to 11.4 seconds, an 8.5% speedup. Unless explicitly stated otherwise, further experiments use a  $B = 100$ .

We now present the full sampling results on our test-set in Fig. 3c and 3d, where we show the average number of iterations and states in the final models once refinements are finished ( $AR-100=20\%$ ) for different orders  $n$  over different lengths. We note a sub-linear increase in the average number of trials and states when moving to higher  $n$ ; thus, for length=10, and for  $n = 3, 4, 5$ , # trials: 3-658.16, 4-683.3, 5-700.9, and # states: 3-1139.5, 4-1494.0, 5-1718.3.

Finally, we show in Tab. 4, the ranked samples drawn from an input sentence, according to a 5-gram LM. After refining our model up to  $AR-100 = 20\%$ ,

<i>input:</i>	3637 843 66639 39478 *		
<i>oracle:</i>	does the money exist ?		
<i>best:</i>	does the money exist .

does the money exist !	72	-15.49	-15.49
does the <b>moody</b> exist .	45	-15.70	-15.70
does the money exist :	25	-16.73	-16.73

Table 4: Top-5 ranked samples for an example input. We highlight in bold the words which are different to the Viterbi best of the model. The oracle and best are not the same for this input.

we continued drawing samples until we had 1000 exact samples from  $p$  (out of  $\sim 4.7k$  trials). We show the count of each sequence in the 1000 samples, and the log probability according to  $p$  for that event. We only present the top-five samples, though in total there were 90 unique sequences sampled, 50 of which were only sampled once.

### 3.2 POS-tagging

Our HMM is the same as that used in (Brants, 2001); the emission probability of a word given a POS tag  $x_i$  is calculated using maximum likelihood techniques. That is,  $p(o_i|x_i) = \frac{c(o_i,x_i)}{c(x_i)}$ . Unseen words are handled by interpolating longer suffixes with shorter, more general suffixes. To train our language model, we use the SRILM toolkit (Stolcke, 2002) We build LMs of up to size 9. We present results on the WSJ Penn Treebank corpus (Marcus et al., 1993). We use sections 0-18 to train our emission and transitions probabilities, and report results on

Figure 4: In 4a, we report the accuracy results given different  $n$ -gram models on the WSJ test-set. In 4b, we show the time taken (seconds) to decode the WSJ test-set given our method (ARS), and compare this to the full model (F). In 4c, the average number of iterations needed to sample the test-set given different  $n$ -gram language models is given, and 4d shows the average number of states in the variable-order HMMs.

sections 22-24.

We first present results for our decoding experiments. In Fig. 4a we show the accuracy results of our different models on the WSJ test-set. We see that the best result is achieved with the 5-gram LM giving an accuracy of 95.94%. After that, results start to drop, most likely due to over-fitting of the LM during training and an inability for the smoothing technique to correctly handle this.

In Fig. 4b, we compare the time it takes in seconds to decode the test-set with the full model at each  $n$ -gram size; that is a WFSA with all context states and weights representing the true language model log probabilities. We can see that while increasing the  $n$ -gram model size, our method (ARS) exhibits a linear increase in decoding time, in contrast to the exponential factor exhibited when running the Viterbi algorithm over the full WFSA (F). Note for  $n$ -gram models of order 7 and higher, we could not decode the entire test set as creating the full WFSA was taking too long.

Finally in both Figs 4c and 4d, we show the average number of iterations taken to sample from the entire test-test, and the average number of states in our variable-order HMMs, with AR-100=60%. Again we note a linear increase in both Fig., in contrast to the exponential nature of standard techniques applied to the full HMM.

## 4 Conclusion and Perspectives

We have presented a dual-purpose algorithm that can be used for performing exact decoding and sampling on high-order HMMs. We demonstrated the validity of our method on SMS-retrieval and POS examples, showing that the “proposals” that we obtain re-

quire only a fraction of the space that would result from explicitly representing the HMM. We believe that this ability to support exact inference (both approximation and sampling) at a reasonable cost has important applications, in particular when moving from inference to learning tasks, which we see as a natural extension of this work.

By proposing a common framework for sampling and optimization our approach has the advantage that we do not need separate skills or expertise to solve the two problems. In several situations, we might be interested not only in the most probable sequence, but also in the distribution of the sequences, especially when diversity is important or in the presence of underlying ambiguities.

The interplay between optimization and sampling is a fruitful area of research that can lead to state-of-the-art performances on inference and decoding tasks in the special case of high-order HMM decoding, but the method is generic enough to be generalized to many others models of interest for NLP applications. One family of models is provided by agreement-based models, for example HMM+PCFG, where distribution  $p$  takes the form of a product:  $p(x) = p_{\text{HMM}}(x)p_{\text{PCFG}}(x)$ . Even if the factors  $p_{\text{HMM}}(x)$  and  $p_{\text{PCFG}}(x)$  can be decoded and sampled efficiently, the product of them is intractable. Dual decomposition is a generic method that has been proposed for handling decoding (i.e. optimization) with such models, by decoupling the problem into two alternating steps that can each be handled by dynamic programming or other polynomial-time algorithms (Rush et al., 2010), an approach that has been applied to Statistical Machine Translation (phrase-based (Chang and Collins,

2011) and hierarchical (Rush and Collins, 2011)) among others. However, sampling such distributions remains a difficult problem. We are currently extending the approach described in this paper to handle such applications. Again, using ARS on a sequence of upper bounds to the target distribution, our idea is to express one of the two models as a context free grammar and incrementally compute the intersection with the second model, maintaining a good trade-off between computational tractability of the refinement and a reasonable acceptance rate.

# PATTY: A Taxonomy of Relational Patterns with Semantic Types

Ndapandula Nakashole, Gerhard Weikum, Fabian Suchanek

Max Planck Institute for Informatics

Saarbrücken, Germany

{nnakasho,weikum,suchanek}@mpi-inf.mpg.de

## Abstract

This paper presents PATTY: a large resource for textual patterns that denote binary relations between entities. The patterns are semantically typed and organized into a subsumption taxonomy. The PATTY system is based on efficient algorithms for frequent itemset mining and can process Web-scale corpora. It harnesses the rich type system and entity population of large knowledge bases. The PATTY taxonomy comprises 350,569 pattern synsets. Random-sampling-based evaluation shows a pattern accuracy of 84.7%. PATTY has 8,162 subsumptions, with a random-sampling-based precision of 75%. The PATTY resource is freely available for interactive access and download.

## 1 Introduction

**Motivation.** WordNet (Fellbaum 1998) is one of the most widely used lexical resources in computer science. It groups nouns, verbs, and adjectives into sets of synonyms, and arranges these synonyms in a taxonomy of hypernyms. WordNet is limited to single words. It does not contain entire *phrases* or *patterns*. For example, WordNet does not contain the pattern *X is romantically involved with Y*. Just like words, patterns can be synonymous, and they can subsume each other. The pattern *X is romantically involved with Y* is synonymous with the pattern *X is dating Y*. Both are subsumed by *X knows Y*. Patterns for relations are a vital ingredient for many applications, including information extraction and question answering. If a large-scale resource of relational patterns were available, this could boost progress in NLP and AI tasks.

Yet, existing large-scale knowledge bases are mostly limited to abstract binary relationships between entities, such as “bornIn” (Auer 2007; Bollacker 2008; Nastase 2010; Suchanek 2007). These do not correspond to real text phrases. Only the Re-Verb system (Fader 2011) yields a larger number of relational textual patterns. However, no attempt is made to organize these patterns into synonymous patterns, let alone into a taxonomy. Thus, the patterns themselves do not exhibit semantics.

**Goal.** Our goal in this paper is to systematically compile relational patterns from a corpus, and to impose a semantically typed structure on them. The result we aim at is a WordNet-style taxonomy of binary relations. In particular, we aim at patterns that contain *semantic types*, such as  $\langle \text{singer} \rangle \text{ sings } \langle \text{song} \rangle$ . We also want to automatically generalize syntactic variations such as  $\text{sings her } \langle \text{song} \rangle$  and  $\text{sings his } \langle \text{song} \rangle$ , into a more general pattern  $\text{sings } [\text{prp}] \langle \text{song} \rangle$  with POS tag [prp]. Analogously but more demanding, we want to automatically infer that the above patterns are semantically subsumed by the pattern  $\langle \text{musician} \rangle \text{ performs on } \langle \text{musical composition} \rangle$  with more general types for the entity arguments in the pattern.

Compiling and organizing such patterns is challenging for the following reasons. 1) The number of possible patterns increases exponentially with the length of the patterns. For example, the string “Amy sings ‘Rehab’” can give rise to the patterns  $\langle \text{singer} \rangle \text{ sings } \langle \text{song} \rangle$ ,  $\langle \text{person} \rangle \text{ sings } \langle \text{artifact} \rangle$ ,  $\langle \text{person} \rangle [\text{vbz}] \langle \text{entity} \rangle$ , etc. If wildcards for multiple words are allowed (such as in  $\langle \text{person} \rangle \text{ sings } * \langle \text{song} \rangle$ ), the number of possible patterns explodes. 2) A pattern

can be semantically more general than another pattern (when one relation is implied by the other relation), and it can also be syntactically more general than another pattern (by the use of placeholders such as [vzb]). These two subsumption orders have a non-obvious interplay, and none can be analyzed without the other. 3) We have to handle pattern sparseness and coincidental matches. If the corpus is small, e.g., the patterns  $\langle singer \rangle$  later disliked her song  $\langle song \rangle$  and  $\langle singer \rangle$  sang  $\langle song \rangle$ , may apply to the same set of entity pairs in the corpus. Still, the patterns are not synonymous. 4) Computing mutual subsumptions on a large set of patterns may be prohibitively slow. Moreover, due to noise and vague semantics, patterns may even not form a crisp taxonomy, but require a hierarchy in which subsumption relations have to be weighted by statistical confidence measures.

**Contributions.** In this paper, we present PATTY, a large resource of relational patterns that are arranged in a semantically meaningful taxonomy, along with entity-pair instances. More precisely, our contributions are as follows:

1) *SOL patterns*: We define an expressive family of relational patterns, which combines syntactic features (S), ontological type signatures (O), and lexical features (L). The crucial novelty is the addition of the ontological, semantic dimension to patterns. When compared to a state-of-the-art pattern language, we found that SOL patterns yield higher recall while achieving similar precision.

2) *Mining algorithms*: We present efficient and scalable algorithms that can infer SOL patterns and subsumptions at scale, based on instance-level overlaps and an ontological type hierarchy.

3) A large *Lexical resource*: On the Wikipedia corpus, we obtained 350,569 pattern synsets with 84.7% precision. We make our pattern taxonomy available for further research at [www.mpi-inf.mpg.de/yago-naga/patty/](http://www.mpi-inf.mpg.de/yago-naga/patty/).

The paper is structured as follows. Section 2 discusses related work. Section 3 outlines the basic machinery for pattern extraction. Section 4 introduces our SOL pattern model. Sections 5 and 6 present the syntactic and semantic generalization of patterns. Section 7 explains how to arrange the pat-

terns into a taxonomy. Section 8 reports our experimental findings.

## 2 Related Work

A wealth of taxonomic knowledge bases (KBs) about entities and their semantic classes have become available. These are very rich in terms of unary predicates (semantic classes) and their entity instances. However, the number of *binary relations* (i.e., relation types, not instances) in these KBs is usually small: Freebase (Bollacker 2008) has a few thousand hand-crafted relations. WikiNet (Nastase 2010) has automatically extracted ca. 500 relations from Wikipedia category names. DBpedia (Auer 2007) has automatically compiled ca. 8000 names of properties from Wikipedia infoboxes, but these include many involuntary semantic duplicates such as *surname* and *lastname*. In all of these projects, the resource contains the *relation names*, but not the *natural language patterns* for them. The same is true for other projects along these lines (Navigli 2010; Philpot 2008; Ponzetto 2007; Suchanek 2007).

In contrast, knowledge base projects that automatically populate relations from Web pages also learn *surface patterns* for the relations: examples are TextRunner/ReVerb (Banko 2007; Fader 2011), NELL (Carlson 2010; Mohamed11), Probase (Wu 2011), the dynamic lexicon approach by (Hoffmann 2010; Wu 2008), the LDA-style clustering approach by (Yao 2011), and projects on Web tables (Limaye 2010; Venetis 2011). Of these, only TextRunner/ReVerb and NELL have made large pattern collections publicly available.

*ReVerb* (Fader 2011) constrains patterns to verbs or verb phrases that end with prepositions, while PATTY can learn arbitrary patterns. More importantly, all methods in the TextRunner/ReVerb family are blind to the ontological dimension of the entities in the patterns. Therefore, there is no notion of semantic typing for relation phrases as in PATTY.

*NELL* (Carlson 2010) is based on a fixed set of prespecified relations with type signatures, (e.g., *personHasCitizenship*:  $\langle person \rangle \times \langle country \rangle$ ), and learns to extract suitable noun-phrase pairs from a large Web corpus. In contrast, PATTY discovers patterns for relations that are a priori unknown.

In *OntExt* (Mohamed11), the NELL architecture was extended to automatically compute new relation types (beyond the prespecified ones) for a given type signature of arguments, based on a clustering technique. For example, the relation *musicianPlaysInstrument* is found by clustering pattern co-occurrences for the noun-phrase pairs that fall into the specific type signature  $\langle \textit{musician} \rangle \times \langle \textit{musicinstrument} \rangle$ . This technique works for one type signature at a time, and does not scale up to mining a large corpus. Also, the technique is not suitable for inferring semantic subsumptions. In contrast, PATTY efficiently acquires patterns from large-scale corpora and organizes them into a subsumption hierarchy.

Class-based *attribute discovery* is a special case of mining relational patterns (e.g., (Alfonseca 2010; Pasca 2007; Pasca 2008; Reisinger 2009)). Given a semantic class, such as *movies* or *musicians*, the task is to determine relevant attributes, such as *cast* and *budget* for movies, or *albums* and *biography* for musicians, along with their instances. Unlike PATTY's patterns, the attributes are not typed. They come with a prespecified type for the domain, but without any type for the range of the underlying relation.

There are further *relation-centric tasks in NLP and text mining* that have commonalities with our endeavor, but differ in fundamental ways. The SemEval-2010 task on classification of semantic relations between noun-phrase pairs (Hendrickx 2010) aimed at predicting the relation for a given sentence and pair of nominals, but used a fixed set of prespecified relations. Another task in this research avenue is to characterize and predict the argument types for a given relation or pattern (Kozareva 2010; Nakov 2008). This is closer to KB population and less related to our task of discovering relational patterns and systematically organizing them.

From a *linguistic perspective*, there is ample work on patterns for unary predicates of the form *class(entity)*. This includes work on entailment of classes, i.e., on *is-a* and *subclassOf* relationships. Entailment among binary predicates of the form *relation(entity1, entity2)* has received less attention (Lin 2001; Chklovski 2004; Hashimoto 2009; Berant 2011). These works focus solely on verbs, while

PATTY learns arbitrary phrases for patterns.

Several lexical resources capture verb categories and entailment: WordNet 3.0 (Fellbaum 1998) contains about 13,000 verb senses, with troponymy and entailment relations; VerbNet (Kipper 2008) is a hierarchical lexicon with more than 5,000 verb senses in ca. 300 classes, including selectional preferences. Again, all of these resources focus solely on verbs.

ConceptNet 5.0 (Havasi 2007) is a thesaurus of commonsense knowledge built as a crowdsourcing endeavor. PATTY, in contrast, is constructed fully automatically from large corpora. Automatic learning of paraphrases and textual entailment has received much attention (see the survey of (Androutsopoulos 2010)), but does not consider fine-grained typing for binary relations, as PATTY does.

### 3 Pattern Extraction

This section explains how we obtain basic textual patterns from the input corpus. We first apply the Stanford Parser (Marneffe 2006) to the individual sentences of the corpus to obtain dependency paths. The dependency paths form a directed graph, with words being nodes and dependencies being edges. For example, the sentence "*Winehouse effortlessly performed her song Rehab.*" yields the following dependency paths:

```
nsubj(performed-3, Winehouse-1)
advmod(performed-3, effortlessly-2)
poss(Rehab-6, her-4)
nn(Rehab-6, song-5)
dobj(performed-3, Rehab-6)
```

While our method also works with patterns obtained from shallow features such as POS tags, we found that dependency paths improve pattern extraction precision especially on long sentences.

We then detect mentions of named entities in the parsed corpus. For this purpose, we use a dictionary of entities. This can be any resource that contains named entities with their surface names and semantic types (Auer 2007; Suchanek 2007; Hoffart 2011; Bollacker 2008). In our experiments, we used the YAGO2 knowledge base (Hoffart 2011). We match noun phrases that contain at least one proper noun against the dictionary. For disambiguation, we

use a simple context-similarity prior, as described in (Suchanek 2009). We empirically found that this technique has accuracy well above 80% (and higher for prominent and thus frequently occurring entities). In our example, the entity detection yields the entities *Amy Winehouse* and *Rehab (song)*.

Whenever two named entities appear in the same sentence, we extract a textual pattern. For this purpose, we traverse the dependency graph to get the shortest path that connects the two entities. In the example, the shortest path between “Winehouse” and “Rehab” is: Winehouse *nsubj* performed *dobj* Rehab. In order to capture only relations that refer to subject-relation-object triples, we only consider shortest paths that start with subject-like dependencies, such as *nsubj*, *rmod* and *partmod*. To reflect the full meaning of the patterns, we expand the shortest path with adverbial and adjectival modifiers, for example the *advmod* dependency. The sequence of words on the expanded shortest path becomes our final textual pattern. In the example, the textual pattern is *Amy Winehouse effortlessly performed Rehab (song)*.

#### 4 SOL Pattern Model

Textual patterns are tied to the particular surface form of the text. Therefore, we transform the textual patterns into a new type of patterns, called syntactic-ontologic-lexical patterns (SOL patterns). SOL patterns extend lexico-syntactic patterns by ontological type signatures for entities. The SOL pattern language is expressive enough to capture fine-grained relational patterns, yet simple enough to be dealt with by efficient mining algorithms at Web scale.

A SOL pattern is an abstraction of a textual pattern that connects two entities of interest. It is a sequence of words, POS-tags, wildcards, and ontological types. A POS-tag stands for a word of the part-of-speech class. We introduce the special POS-tag [word], which stands for any word of any POS class. A wildcard, denoted \*, stands for any (possibly empty) sequence of words. Wildcards are essential to avoid overfitting of patterns to the corpus. An ontological type is a semantic class name (such as *<singer>*) that stands for an instance of that class. Every pattern contains at least two types, and these

are designated as *entity placeholders*.

A string and a pattern *match*, if there is an order-preserving bijection from sequences of words in the string to items in the pattern, so that each item can stand for the respective sequence of words. For example, the pattern *<person>*'s *[adj]* voice \* *<song>* matches the strings “Amy Winehouse’s soft voice in ‘Rehab’” and “Elvis Presley’s solid voice in his song ‘All shook up’”. The *type signature* of a pattern is the pair of the entity placeholders. In the example, the type signature is *person* × *song*. The *support set* of a pattern is the set of pairs of entities that appear in the place of the entity placeholders in all strings in the corpus that match the pattern. In the example, the support set of the pattern could be  $\{(Amy, Rehab), (Elvis, AllShookUp)\}$ . Each pair is called a *support pair* of the pattern.

Pattern *B* is *syntactically more general* than pattern *A* if every string that matches *A* also matches *B*. Pattern *B* is *semantically more general* than *A* if the support set of *B* is a superset of the support set of *A*. If *A* is semantically more general than *B* and *B* is semantically more general than *A*, the patterns are called *synonymous*. A set of synonymous patterns is called a *pattern synset*. Two patterns, of which neither is semantically more general than the other, are called *semantically different*.

To generate SOL patterns from the textual patterns, we decompose the textual patterns into n-grams (n consecutive words). A SOL pattern contains only the n-grams that appear frequently in the corpus and the remaining word sequences are replaced by wildcards. For example, in the sentence “was the first female to run for the governor of” might give rise to the pattern \* *the first female* \* *governor of*, if “the first female” and “governor of” are frequent in the corpus.

To find the frequent n-grams efficiently, we apply the technique of frequent itemset mining (Agrawal 1993; Srikant 1996): each sentence is viewed as a “shopping transaction” with a “purchase” of several n-grams, and the mining algorithm computes the n-gram combinations with large co-occurrence support<sup>1</sup>. These n-grams allow us to break down a sen-

<sup>1</sup>Our implementation restricts n-grams to length 3 and uses up to 4 n-grams per sentence

tence into wildcard-separated subsequences, which yields an SOL pattern. We generate multiple patterns with different types, one for each combination of types that the detected entities have in the underlying ontology.

We quantify the *statistical strength* of a pattern by means of its support set. For a given pattern  $p$  with type signature  $t1 \times t2$ , the *support* of  $p$  is the size of its support set. For confidence, we compare the support-set sizes of  $p$  and an untyped variant  $p^u$  of  $p$ , in which the types  $\langle t1 \rangle$  and  $\langle t2 \rangle$  are replaced by the generic type  $\langle entity \rangle$ . We define the *confidence* of  $p$  as the ratio of the support-set sizes of  $p$  and  $p^u$ .

## 5 Syntactic Pattern Generalization

Almost every pattern can be generalized into a syntactically more general pattern in several ways: by replacing words by POS-tags, by introducing wildcards (combining more n-grams), or by generalizing the types in the pattern. It is not obvious which generalizations will be reasonable and useful. We observe, however, that generalizing a pattern may create a pattern that subsumes two semantically different patterns. For example, the generalization  $\langle person \rangle [vb] \langle person \rangle$  subsumes the two semantically different patterns  $\langle person \rangle loves \langle person \rangle$  and  $\langle person \rangle hates \langle person \rangle$ . This means that the pattern is semantically meaningless.

Therefore, we proceed as follows. For every pattern, we generate all possible generalizations. If a generalization subsumes multiple patterns with disjoint support sets, we abandon the generalized pattern. Otherwise, we add it to our set of patterns.

## 6 Semantic Pattern Generalization

The main difficulty in generating semantic subsumptions is that the support sets may contain spurious pairs or be incomplete, thus destroying crisp set inclusions. To overcome this problem, we designed a notion of a *soft set inclusion*, in which one set  $S$  can be a subset of another set  $B$  to a certain degree. One possible measure for this degree is the confidence, i.e., the ratio of elements in  $S$  that are in  $B$ ,  $deg(S \subseteq B) = |S \cap B|/|S|$ . However, if a support set  $S$  has only few elements due to sparsity, it may become a subset of another support set  $B$ , even if the

two patterns are semantically different. Therefore, one has to take into account also the *support*, i.e., the size of the set  $S$ . Traditionally, this is done through a weighted trade-off between confidence and support.

To avoid the weight tuning, we instead devised a probabilistic model. We interpret  $S$  as a *random sample* from the “true” support set  $S'$  that the pattern would have on an infinitely large corpus. We want to estimate the ratio of elements of  $S'$  that are in  $B$ . This ratio is a Bernoulli parameter that can be estimated from the ratio of elements of the sample  $S$  that are in  $B$ . We compute the Wilson score interval  $[c - d, c + d]$  (Brown 2001) for the sample. This interval guarantees that with a given probability (set a priori, usually to  $\alpha = 95\%$ ), the true ratio falls into the interval  $[c - d, c + d]$ . If the sample is small,  $d$  is large and  $c$  is close to 0.5. If the sample is large,  $d$  decreases and  $c$  approaches the naive estimation  $|S \cap B|/|S|$ . Thereby, the Wilson interval center naturally balances the trade-off between confidence and the support. Hence we define  $deg(S \subset B) = c$ . This estimator may degrade when the sample size is too small. We can alternatively use a conservative estimator  $deg(S \subset B) = c - d$ , i.e., the lower bound of the Wilson score interval. This gives a low score to the case where  $S \subset B$  if we have few samples ( $S$  is small).

## 7 Taxonomy Construction

We now have to arrange the patterns in a semantic taxonomy. A baseline solution would compare every pattern support set to every other pattern support set in order to determine inclusion, mutual inclusion, or independence. This would be prohibitively slow. For this reason, we make use of a prefix-tree for frequent patterns (Han 2005). The prefix-tree stores support sets of patterns. We then developed an algorithm for obtaining set intersections from the prefix-tree.

### 7.1 Prefix-Tree Construction

Suppose we have pattern synsets and their support sets as shown in Table 1. An entity pair in a support set is denoted by a letter. For example, in the support set for the pattern  $\langle Politician \rangle was\ governor\ of\ \langle State \rangle$ , the entry  $\langle A, 80 \rangle$  may denote the entity

ID	Pattern Synset & Support Sets
$P_1$	$\langle \text{Politician} \rangle$ was governor of $\langle \text{State} \rangle$ A,80 B,75 C,70
$P_2$	$\langle \text{Politician} \rangle$ politician from $\langle \text{State} \rangle$ A,80 B,75 C,70 D,66 E,64
$P_3$	$\langle \text{Person} \rangle$ daughter of $\langle \text{Person} \rangle$ F,78 G,75 H,66
$P_4$	$\langle \text{Person} \rangle$ child of $\langle \text{Person} \rangle$ I,88 J,87 F,78 G,75 K,64

Table 1: Pattern Synsets and their Support Sets

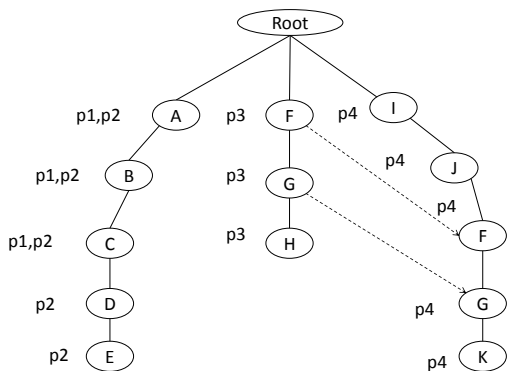

Figure 1: Prefix-Tree for the Synsets in Table 1.

pair *Arnold Schwarzenegger, California*, with an occurrence frequency 80. The contents of the support sets are used to construct a prefix-tree, where nodes are entity pairs. If synsets have entity pairs in common, they share a common prefix; thus the shared parts can be represented by one prefix-path in the tree. This enables subsumptions to be directly “read off” from the tree, while representing the tree in a compact manner. To increase the chance of shared prefixes, entity pairs are inserted into the tree in decreasing order of occurrence frequency.

The prefix-tree of support sets is a prefix-tree augmented with synset information stored at the nodes. Each node (entity pair) stores the identifiers of the pattern synsets whose support sets contain that entity pair. In addition, each node stores a link to the next node with the same entity pair.

Figure 1 shows the tree for the pattern synsets in Table 1. The left-most path contains synsets  $P_1$  and  $P_2$ . The two patterns have a prefix in common,

thus they share the same path. This is reflected by the synsets stored in the nodes in the path. Synsets  $P_2$  and  $P_3$  belong to two different paths due to dissimilar prefixes although they have common nodes. Instead, their common nodes are connected by the same-entity-pair links shown as dotted lines in Figure 1. These links are created whenever the entity pair already exists in the tree but with a prefix different from the prefix of the synset being added to the tree. The size of the tree is at most the total number of entity pairs making up the supports sets of the synsets. The height of the tree is at most the size of the the largest support set.

## 7.2 Mining Subsumptions from the Prefix-Tree

To efficiently mine subsumptions from the prefix-tree, we have to avoid comparing every path to every other path as this introduces the same inefficiencies that the baseline approach suffers from.

From the construction of the tree it follows that for any node  $N_i$  in the tree, all paths containing  $N_i$  can be found by following node  $N_i$ 's links including the same-entity-pair links. By traversing the entire path of a synset  $P_i$ , we can reach all the pattern synsets sharing common nodes with  $P_i$ . This leads to our main insight: if we start traversing the tree bottom up, starting at the last node in  $P_i$ 's support set, we can determine exactly which paths are subsumed by  $P_i$ . Traversing the tree this way for all patterns gives us the sizes of the support set intersection. The determined intersection sizes can then be used in the Wilson estimator to determine the degree of semantic subsumption and semantic equivalence of patterns.

## 7.3 DAG Construction

Once we have generated subsumptions between relational patterns, there might be cycles in the graph we generate. We ideally want to remove the minimal total number of subsumptions whose removal results in an a directed acyclic graph (DAG). This task is related to the minimum feedback-arc-set problem: given a directed graph, we want to remove the smallest set of edges whose removal makes the remaining graph acyclic. This is a well known NP-hard problem (Kann 1992). We use a greedy algorithm for

removing cycles and eliminating redundancy in the subsumptions, thus effectively constructing a DAG. Starting with a list of subsumption edges ordered by decreasing weights, we construct the DAG bottom-up by adding the highest-weight subsumption edge. This step is repeated for all subsumptions, where we add a subsumption to the DAG only if it does not introduce cycles or redundancy. Redundancy occurs when there already exists a path, by transitivity of subsumptions, between pattern synsets linked by the subsumption. This process finally yields a DAG of pattern synsets – the PATTY taxonomy.

## 8 Experimental Evaluation

### 8.1 Setup

The PATTY extraction and mining algorithms were run on two different input corpora: the New York Times archive (*NYT*) which includes about 1.8 Million newspaper articles from the years 1987 to 2007, and the English edition of Wikipedia (*WKP*), which contains about 3.8 Million articles (as of June 21, 2011). Experiments were carried out, for each corpus, with two different type systems: a) the type system of YAGO2, which consists of about 350,000 semantic classes from WordNet and the Wikipedia category system, and b) the two-level domain/type hierarchy of Freebase which consists of 85 domains and a total of about 2000 types within these domains.

All relational patterns and their respective entity pairs are stored in a MongoDB database. We evaluated PATTY along four dimensions: quality of patterns, quality of subsumptions, coverage, and design alternatives. These dimensions are discussed in the following four subsections. We also performed an extrinsic study to demonstrate the usefulness of PATTY for paraphrasing the relations of DBpedia and YAGO2. In terms of runtimes, the most expensive part is the pattern extraction, where we identify pattern candidates through dependency parsing and perform entity recognition on the entire corpus. This phase runs about a day for Wikipedia a cluster. All other phases of the PATTY system take less than an hour. All experimental data is available on our Web site at [www.mpi-inf.mpg.de/yago-naga/patty/](http://www.mpi-inf.mpg.de/yago-naga/patty/).

### 8.2 Precision of Relational Patterns

To assess the precision of the automatically mined patterns (patterns in this section always mean pattern synsets), we sampled the PATTY taxonomy for each combination of input corpus and type system. We ranked the patterns by their statistical strength (Section 4), and evaluated the precision of the *top 100* pattern synsets. Several human judges were shown a sampled pattern synset, its type signature, and a few example instances, and then stated whether the pattern synset indicates a valid relation or not. Evaluators checked the correctness of the type signature, whether the majority of patterns in the synset is reasonable, and whether the instances seem plausible. If so, the synset was flagged as meaningful. The results of this evaluation are shown in column four of Table 2, with a 0.9-confidence Wilson score interval (Brown 2001). In addition, the same assessment procedure was applied to *randomly sampled* synsets, to evaluate the quality in the long tail of patterns. The results are shown in column five of Table 2. For the top 100 patterns, we achieve above 90% precision for Wikipedia, and above 80% for 100 random samples.

Corpus	Types	Patterns	Top 100	Random
NYT	YAGO2	86,982	0.89±0.06	0.72±0.09
	Freebase	809,091	0.87 ±0.06	0.71±0.09
WKP	YAGO2	350,569	0.95±0.04	<b>0.85±0.07</b>
	Freebase	1,631,531	0.93±0.05	0.80±0.08

Table 2: Precision of Relational Patterns

From the results we make two observations. First, Wikipedia patterns have higher precision than those from the New York Times corpus. This is because some the language in the news corpus does not express relational information; especially the news on stock markets produced noisy patterns picked up by PATTY. However, we still manage to have a precision of close to 90% for the top 100 patterns and around 72% for random sample on the NYT corpus. The second observation is that the YAGO2 type system generally led to higher precision than the Freebase type system. This is because YAGO2 has finer grained, ontologically clean types, whereas Freebase has broader categories with a more liberal

assignment of entities to categories.

### 8.3 Precision of Subsumptions

We evaluated the quality of the subsumptions by assessing 100 top-ranked as well as 100 randomly selected subsumptions. As shown in Table 3, a large number of the subsumptions are correct. The Wikipedia-based PATTY taxonomy has a random-sampling-based precision of 75%.

Corpus	Types	# Edges	Top 100	Random
NYT	YAGO2	12,601	0.86±0.07	0.68±0.09
	Freebase	80,296	0.89±0.06	0.41±0.09
WKP	YAGO2	<b>8,162</b>	0.83±0.07	<b>0.75±0.07</b>
	Freebase	20,339	0.85±0.07	0.62±0.09

Table 3: Quality of Subsumptions

Example subsumptions from Wikipedia are:

- $\langle person \rangle$  *nominated for*  $\langle award \rangle$   $\sqsubset$   
 $\langle person \rangle$  *winner of*  $\langle award \rangle$
- $\langle person \rangle$  *'s wife*  $\langle person \rangle$   $\sqsubset$   
 $\langle person \rangle$  *'s widow*  $\langle person \rangle$

### 8.4 Coverage

To evaluate the coverage of PATTY, we would need a complete ground-truth resource that contains all possible binary relations between entities. Unfortunately, there is no such resource<sup>2</sup>. We tried to approximate such a resource by manually compiling all binary relations between entities that appear in Wikipedia articles of a certain domain. We chose the domain of popular music, because it offers a plethora of non-trivial relations (such as *addictedTo(person,drug)*, *coveredBy(musician,musician)*, *dedicatedSongTo(musician,entity)*). We considered the Wikipedia articles of five musicians (Amy Winehouse, Bob Dylan, Neil Young, John Coltrane, Nina Simone). For each page, two annotators hand-extracted all relationship types that they would spot in the respective articles. The annotators limited themselves to relations where at least one argument type is  $\langle musician \rangle$ . Then we formed the intersection of the two annotators' outputs (i.e., their agreement)

<sup>2</sup>Lexical resources such as WordNet contain only verbs, but not binary relations such as *is the president of*. Other resources are likely incomplete.

as a reasonable gold standard for relations identifiable by skilled humans. In total, the gold-standard set contains 163 relations.

We then compared our relational patterns to the relations included in four major knowledge bases, namely, YAGO2, DBpedia (DBP), Freebase (FB), and NELL, limited to the specific domain of music. Table 4 shows the absolute number of relations covered by each resource. For PATTY, the patterns were derived from the Wikipedia corpus with the YAGO2 type system.

gold standard	PATTY	YAGO2	DBP	FB	NELL
163	<b>126</b>	31	39	69	13

Table 4: Coverage of Music Relations

PATTY covered 126 of the 163 gold-standard relations. This is more than what can be found in large semi-curated knowledge bases such as Freebase, and twice as much as Wikipedia-infobox-based resources such as DBpedia or YAGO offer. Some PATTY examples that do not appear in the other resources at all are:

- $\langle musician \rangle$  *PRP idol*  $\langle musician \rangle$  for the relation *hasMusicalIdol*
- $\langle person \rangle$  *criticized by*  $\langle organization \rangle$  for *criticizedByMedia*
- $\langle person \rangle$  *headliner*  $\langle artifact \rangle$  for *headlinerAt*
- $\langle person \rangle$  *successfully sued*  $\langle person \rangle$  for *suedBy*
- $\langle musician \rangle$  *wrote hits for*  $\langle musician \rangle$  for *wroteHitsFor*,

This shows (albeit anecdotally) that PATTY's patterns contribute added value beyond today's knowledge bases.

### 8.5 Pattern Language Alternatives

We also investigated various design alternatives to the PATTY pattern language. We looked at three main alternatives: the first is verb-phrase-centric patterns advocated by ReVerb (Fader 2011), the second is the PATTY language without type signatures (just using sets of n-grams with syntactic generalizations), and the third one is the full PATTY language. The results for the Wikipedia corpus and the

	Reverb-style patterns	PATTY without types	PATTY full
# Patterns	5,996	184,629	<b>350,569</b>
Patterns Precision	0.96±0.03	0.74±0.08	<b>0.95±0.04</b>
# Subsumptions	74	15,347	<b>8,162</b>
Subsumptions Precision	0.79 ±0.09	0.58±0.09	<b>0.83±0.07</b>
# Facts	192,144	6,384,684	<b>3,890,075</b>
Facts Precision.	0.86 ±0.07	0.64±0.09	<b>0.88 ±0.06</b>

Table 6: Sample Results for Relation Paraphrasing

YAGO2 type system are shown in Table 5; precision figures are based on the respective top 100 patterns or subsumption edges. We observe from these results that the type signatures are crucial for precision. Moreover, the number of patterns, subsumptions and facts found by verb-phrase-centric patterns (ReVerb (Fader 2011)), are limited in recall. General pattern synsets with type signatures, as newly pursued in this paper, substantially outperform the verb-phrase-centric alternative in terms of pattern and subsumption recall while yielding high precision.

## 8.6 Extrinsic Study: Relation Paraphrasing

To further evaluate the usefulness of PATTY, we performed a study on relation paraphrasing: given a relation from a knowledge base, identify patterns that can be used to express that relation. Paraphrasing relations with high-quality patterns is important for populating knowledge bases and counters the problem of semantic drifting caused by ambiguous and noisy patterns.

We considered relations from two knowledge bases, DBpedia and YAGO2, focusing on relations that hold between entities and do not include literals. PATTY paraphrased 225 DBpedia relations with a

total of 127,811 patterns, and 25 YAGO2 relations with a total of 43,124 patterns. Among these we evaluated a random sample of 1,000 relation paraphrases. Table 6 shows precision figures for some selected relations, along anecdotic example patterns.

Some relations are hard to capture precisely. For *DBPedia/doctoralAdvisor*, e.g., PATTY picked up patterns like “worked with” as paraphrases. These are not entirely wrong, but we evaluated them as false because they are too general to indicate the more specific doctoral advisor relation.

Overall, however, the paraphrasing precision is high. Our evaluation showed an average precision of **0.76±0.03** across all relations.

## 9 Conclusion and Future Directions

This paper presented PATTY, a large resource of text patterns. Different from existing resources, PATTY organizes patterns into synsets and a taxonomy, similar in spirit to WordNet. Our evaluation shows that PATTY’s patterns are semantically meaningful, and that they cover large parts of the relations of other knowledge bases. The Wikipedia-based version of PATTY contains 350,569 pattern synsets at a precision of 84.7%, with 8,162 subsumptions, at a precision of 75%. The PATTY resource is

freely available for interactive access and download at [www.mpi-inf.mpg.de/yago-naga/patty/](http://www.mpi-inf.mpg.de/yago-naga/patty/).

Our approach harnesses existing knowledge bases for entity-type information. However, PATTY is not tied to a particular choice for this purpose. In fact, it would be straightforward to adjust PATTY to using surface-form noun phrases rather than disambiguated entities, as long as we have means to infer at least coarse-grained types (e.g., person, organization, location). An interesting future direction is to study this generalized setting. We would also like to investigate the enhanced interplay of information extraction and pattern extraction, and possible applications for question answering.

# Training Factored PCFGs with Expectation Propagation

David Hall and Dan Klein  
Computer Science Division  
University of California, Berkeley  
{dlwh, klein}@cs.berkeley.edu

## Abstract

PCFGs can grow exponentially as additional annotations are added to an initially simple base grammar. We present an approach where multiple annotations coexist, but in a factored manner that avoids this combinatorial explosion. Our method works with linguistically-motivated annotations, induced latent structure, lexicalization, or any mix of the three. We use a structured expectation propagation algorithm that makes use of the factored structure in two ways. First, by partitioning the factors, it speeds up parsing exponentially over the unfactored approach. Second, it minimizes the redundancy of the factors during training, improving accuracy over an independent approach. Using purely latent variable annotations, we can efficiently train and parse with up to 8 latent bits per symbol, achieving F1 scores up to 88.4 on the Penn Treebank while using two orders of magnitudes fewer parameters compared to the naïve approach. Combining latent, lexicalized, and unlexicalized annotations, our best parser gets 89.4 F1 on all sentences from section 23 of the Penn Treebank.

## 1 Introduction

Many high-performance PCFG parsers take an initially simple base grammar over treebank labels like NP and enrich it with deeper syntactic features to improve accuracy. This broad characterization includes lexicalized parsers (Collins, 1997), unlexicalized parsers (Klein and Manning, 2003), and latent variable parsers (Matsuzaki et al., 2005). Figures 1(a), 1(b), and 1(c) show small examples of context-free trees that have been annotated in these ways.

When multi-part annotations are used in the same grammar, systems have generally multiplied these annotations together, in the sense that an NP that

was definite, possessive, and VP-dominated would have a single unstructured PCFG symbol that encoded all three facts. In addition, modulo backoff or smoothing, that unstructured symbol would often have rewrite parameters entirely distinct from, say, the indefinite but otherwise similar variant of the symbol (Klein and Manning, 2003). Therefore, when designing a grammar, one would have to carefully weigh new contextual annotations. Should a definiteness annotation be included, doubling the number of NPs in the grammar and perhaps overly fragmenting statistics? Or should it be excluded, thereby losing important distinctions? Klein and Manning (2003) discuss exactly such trade-offs and omit annotations that were helpful on their own because they were not worth the combinatorial or statistical cost when combined with other annotations.

In this paper, we argue for grammars with *factored annotations*, that is, grammars with annotations that have structured component parts that are partially decoupled. Our annotated grammars can include both latent and explicit annotations, as illustrated in Figure 1(d), and we demonstrate that these factored grammars outperform parsers with unstructured annotations.

After discussing the factored representation, we describe a method for parsing with factored annotations, using an approximate inference technique called expectation propagation (Minka, 2001). Our algorithm has runtime linear in the number of annotation factors in the grammar, improving on the naïve algorithm, which has runtime exponential in the number of annotations. Our method, the Expectation Propagation for Inferring Constituency (*EPIC*) parser, jointly trains a model over factored annotations, where each factor naturally leverages information from other annotation factors and improves on their mistakes.

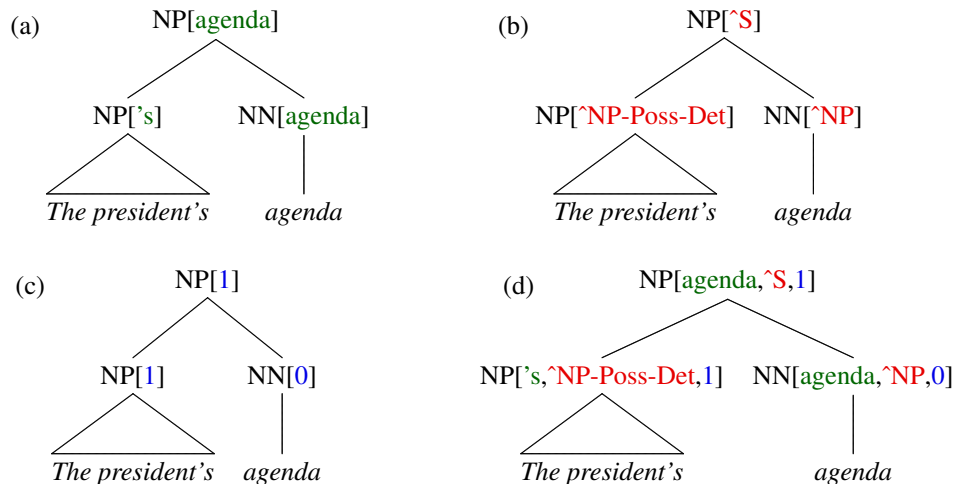

Figure 1: Parse trees using four different annotation schemes: (a) Lexicalized annotation like that in Collins (1997); (b) Unlexicalized annotation like that in Klein and Manning (2003); (c) Latent annotation like that in Matsuzaki et al. (2005); and (d) the factored, mixed annotations we argue for in our paper.

We demonstrate the empirical effectiveness of our approach in two ways. First, we efficiently train a latent-variable grammar with 8 disjoint one-bit latent annotation factors, with scores as high as 89.7 F1 on length  $\leq 40$  sentences from the Penn Treebank (Marcus et al., 1993). This latent variable parser outscores the best of Petrov and Klein (2008a)’s comparable parsers while using two orders of magnitude fewer parameters. Second, we combine our latent variable factors with lexicalized and unlexicalized annotations, resulting in our best F1 score of 89.4 on all sentences.

## 2 Intuitions

Modern theories of grammar such as HPSG (Pollard and Sag, 1994) and Minimalism (Chomsky, 1992) do not ascribe unstructured conjunctions of annotations to phrasal categories. Rather, phrasal categories are associated with sequences of metadata that control their function. For instance, an NP might have annotations to the effect that it is singular, masculine, and nominative, with perhaps further information about its animacy or other aspects of the head noun. Thus, it is appealing for a grammar to be able to model these (somewhat) orthogonal notions, but most models have no mechanism to encourage this. As a notable exception, Dreyer and Eisner (2006) tried to capture this kind of insight by allowing factored annotations to pass unchanged from parent label to child label, though they were not

able to demonstrate substantial gains in accuracy.

Moreover, there has been to our knowledge no attempt to employ both latent and non-latent annotations at the same time. There is good reason for this: lexicalized or highly annotated grammars like those of Collins (1997) or Klein and Manning (2003) have a very large number of states and an even larger number of rules. Further annotating these rules with latent annotations would produce an infeasibly large grammar. Nevertheless, it is a shame to sacrifice expert annotation just to get latent annotations. Thus, it makes sense to combine these annotation methods in a way that does not lead to an explosion of the state space or a fragmentation of statistics.

## 3 Parsing with Annotations

Suppose we have a raw (binarized) treebank grammar, with productions of the form  $A \rightarrow B C$ . The typical process is to then annotate these rules with additional information, giving rules of the form  $A[x] \rightarrow B[y] C[z]$ . In the case of explicit annotations, an  $x$  might include information about the parent category, or a head word, or a combination of things. In the case of latent annotations,  $x$  will be an integer that may or may not correspond to some linguistic notion. We are interested in the specific case where each  $x$  is actually factored into  $M$  disjoint parts:  $A[x_1, x_2, \dots, x_M]$ . (See Figure 1(d).) We call each component of  $x$  an *annotation factor* or an *annotation component*.

### 3.1 Annotation Classes

In this paper, we consider three kinds of annotation models, representing three of the major traditions in constituency parsing. Individually, none of our models are state-of-the-art, instead achieving F1 scores in the mid-80’s on the Penn Treebank.

The first model is a relatively simple lexicalized parser. We are not aware of a prior discriminative lexicalized constituency parser, and it is quite different from the generative models of Collins (1997). Broadly, it considers features over a binary rule annotated with head words:  $A[h] \rightarrow B[h] C[d]$  and  $A[h] \rightarrow B[d] C[h]$ , focusing on monolexical rule features and bilexical dependency features. It is our best individual model, scoring 87.3 F1 on the development set.

The second is similar to the unlexicalized model of Klein and Manning (2003). This parser starts from a grammar with labels annotated with sibling and parent information, and then adds specific annotations, such as whether an NP is possessive or whether a symbol rewrites as a unary. This parser gets 86.3, tying the original generative version of Klein and Manning (2003).

Finally, we use a straightforward *discriminative* latent variable model much like that of Petrov and Klein (2008a). Here, each symbol is given a latent annotation, referred to as a substate. Typically, these substates correlate at least loosely with linguistic phenomena. For instance, NP-1 might be associated with possessive NPs, while NP-3 might be for adjuncts. Often, these latent integers are considered as bit strings, with each bit indicating one latent annotation. Prior work in this area has considered the effect of splitting and merging these states (Petrov et al., 2006; Petrov and Klein, 2007), as well as “multiscale” grammars (Petrov and Klein, 2008b). With two states (or one bit of annotation), our version of this parser gets 81.7 F1, edging out the comparable parser of Petrov and Klein (2008a). On the other hand, our parser gets 83.2 with four states (two bits), short of the performance of prior work.<sup>1</sup>

<sup>1</sup>Much of the difference stems from the different binarization scheme we employ. We use head-outward binarization, rather than the left-branching binarization they employed. This change was to enable integrating lexicalization with our other models.

### 3.2 Model Representation

We employ a general exponential family representation of our grammar. This representation is fairly general, and—in its generic form—by no means new, save for the focus on annotation components.

Formally, we begin with a parse tree  $T$  over base symbols for some sentence  $\mathbf{w}$ , and we decorate the tree with annotations  $X$ , giving a parse tree  $T[X]$ . We focus on the case when  $X$  partitions into disjoint components  $X = [X_1, X_2, \dots, X_M]$ . These components are decoupled in the sense that, conditioned on the coarse tree  $T$ , each column of the annotation is independent of every other column. However, they are crucially not independent conditioned only on the sentence  $\mathbf{w}$ . This model is represented schematically in Figure 2(a).

The conditional probability  $P(T[X]|\mathbf{w}, \theta)$  of an annotated tree given words is:

$$\begin{aligned} P(T[X]|\mathbf{w}, \theta) &= \frac{\prod_m f_m(T[X_m]; \mathbf{w}, \theta_m)}{\sum_{T', X'} \prod_m f_m(T'[X'_m]; \mathbf{w}, \theta_m)} \quad (1) \\ &= \frac{1}{Z(\mathbf{w}, \theta)} \prod_m f_m(T[X_m]; \mathbf{w}, \theta_m) \end{aligned}$$

where the factors  $f_m$  for each model take the form:

$$f_m(T[X_m]; \mathbf{w}, \theta_m) = \exp(\theta_m^T \varphi_m(T, X_m, \mathbf{w}))$$

Here,  $X_m$  is the annotation associated with a particular model  $m$ .  $\varphi$  is a feature function that projects the raw tree, annotations, and words into a feature vector. The features  $\varphi$  need to decompose into features for each factor  $f_m$ ; we do not allow features that take into account the annotation from two different components.

We further add a pruning filter that assigns zero weight to any tree with a constituent that a baseline unannotated grammar finds sufficiently unlikely, and a weight of one to any other tree. This filter is similar to that used in Petrov and Klein (2008a) and allows for much more efficient training and inference.

Because our model is discriminative, training takes the form of maximizing the probability of the training trees given the words. This objective is convex for deterministic annotations, but non-convex for latent annotations. We (locally) optimize the

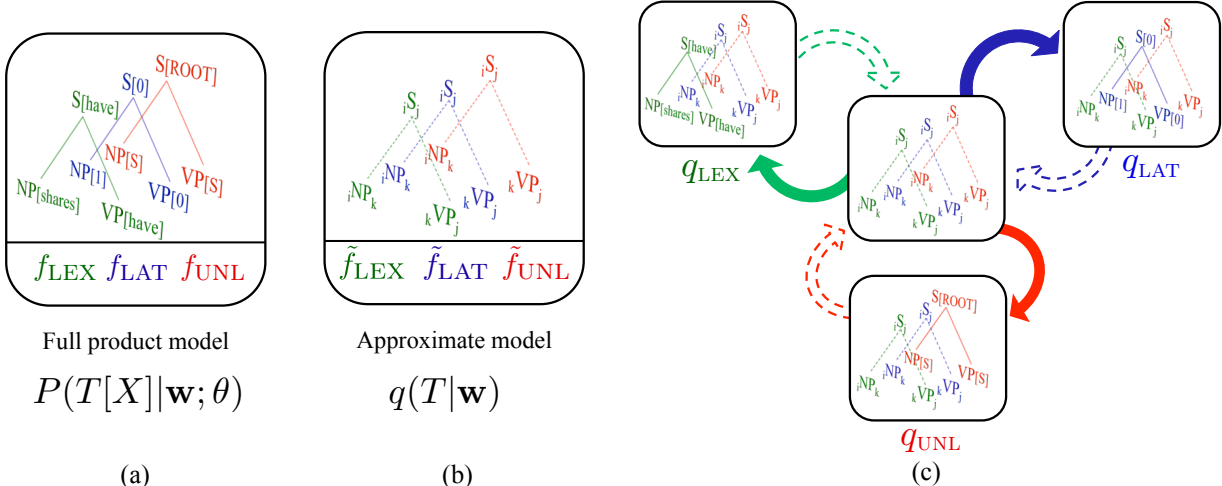

Figure 2: Schematic representation of our model, its approximation, and expectation propagation. (a) The full joint distribution consists of a product of three grammars with different annotations, here lexicalized, latent, and unlexicalized. This model is described in Section 3.2. (b) The core approximation is an anchored PCFG with one factor corresponding to each annotation component, described in Section 5.1. (c) Fitting the approximation with expectation propagation, as described in Section 5.3. At the center is the core approximation. During each step, an “augmented” distribution  $q_m$  is created by taking one annotation factor from the full grammar and the rest from the approximate grammar. For instance, in upper left hand corner the full  $f_{\text{LEX}}$  is substituted for  $\tilde{f}_{\text{LEX}}$ . This new augmented distribution is projected back to the core approximation. This process is repeated for each factor until convergence.

(non-convex) log conditional likelihood of the observed training data  $(T^{(d)}, \mathbf{w}^{(d)})$ :

$$\begin{aligned} \ell(\theta) &= \sum_d \log P(T^{(d)}|\mathbf{w}^{(d)}, \theta) \\ &= \sum_d \log \sum_X P(T^{(d)}[X]|\mathbf{w}^{(d)}, \theta) \end{aligned} \quad (2)$$

Using standard results, the derivative takes the form:

$$\begin{aligned} \nabla \ell(\theta) &= \sum_d E[\varphi(T, X, \mathbf{w})|T^{(d)}, \mathbf{w}^{(d)}] \\ &\quad - \sum_d E[\varphi(T, X, \mathbf{w})|\mathbf{w}^{(d)}] \end{aligned} \quad (3)$$

The first half of this derivative can be obtained by the forward/backward-like computation defined by Matsuzaki et al. (2005), while the second half requires an inside/outside computation (Petrov and Klein, 2008a). The partition function  $Z(\mathbf{w}, \theta)$  is computed as a byproduct of the latter computation. Finally, this objective is regularized, using the L2 norm of  $\theta$  as a penalty.

We note that we omit from our parser one major feature class found in other discriminative parsers,

namely those that use features over the words in the span (Finkel et al., 2008; Petrov and Klein, 2008b). These features might condition on words on either side of the split point of a binary rule or take into account the length of the span. While such features have proven useful in previous work, they are not the focus of our current work and so we omit them.

## 4 The Complexity of Annotated Grammars

Note that the first term of Equation 3—which is conditioned on the coarse tree  $T$ —factors into  $M$  pieces, one for each of the annotation components. However, the second term does not factor because it is conditioned on just the words  $\mathbf{w}$ . Indeed, naïvely computing this term requires parsing with the fully articulated grammar, meaning that inference would be no more efficient than parsing with non-factored annotations.

Standard algorithms for parsing run in time  $O(G|\mathbf{w}|^3)$ , where  $|\mathbf{w}|$  is the length of the sentence, and  $G$  is the size of the grammar, measured in the number of (binary) rules. Let  $G_0$  be the number of binary rules in the unannotated “base” grammar.

Suppose that we have  $M$  annotation components. Each annotation component can have up to  $A$  primitive annotations per rule. For instance, a latent variable grammar will have  $A = 8^b$  where  $b$  is the number of bits of annotation. If we compile all annotation components into unstructured annotations, we can end up with a total grammar size of  $O(A^M G_0)$ , and so in general parsing time scales exponentially with the number of annotation components. Thus, if we use latent annotations and the hierarchical splitting approach of Petrov et al. (2006), then the grammar has size  $O(8^S G_0)$ , where  $S$  is the number of times the grammar was split in two. Therefore, the size of annotated grammars can reach intractable levels very quickly, particularly in the case of latent annotations, where all combinations of annotations are possible.

Petrov (2010) considered an approach to slowing this growth down by using a set of  $M$  independently trained parsers  $P_m$ , and parsed using the product of the scores from each parser as the score for the tree. This approach worked largely because training was intractable: if the training algorithm could reach the global optimum, then this approach might have yielded no gain. However, because the optimization technique is local, the same algorithm produced multiple grammars.

In what follows, we propose another solution that exploits the factored structure of our grammar with expectation propagation. Crucially, we are able to jointly train and parse with all annotation factors, minimizing redundancy across the models. While not exact, we will see that expectation propagation is indeed effective.

## 5 Factored Inference

The key insight behind the approximate inference methods we consider here is that the full model is a product of complex factors that interact in complicated ways, and we will approximate it with a product of corresponding simple factors that interact in simple ways. Since each annotation factor is a reasonable model in both power and complexity on its own, we can consider them one at a time, replacing all others with their approximations, as shown in Figure 2(c).

The way we will build these approximations is

with *expectation propagation* (Minka, 2001). Expectation propagation (EP) is a general method for approximate inference that generalizes belief propagation. We describe it here, but we first try to provide an intuition for how it functions in our system. We also describe a simplified version of EP, called *assumed density filtering* (Boyen and Koller, 1998), which is somewhat easier to understand and rhetorically convenient. For a more detailed introduction to EP in general, we direct the reader to either Minka (2001) or Wainwright and Jordan (2008). Our treatment most resembles the former.

### 5.1 Factored Approximations

Our goal is to build an approximation that takes information from all components into account. To begin, we note that each of these components captures different phenomena: an unlexicalized grammar is good at capturing structural relationships in a parse tree (e.g. subject noun phrases have different distributions than object noun phrases), while a lexicalized grammar captures preferred attachments for different verbs. At the same time, each of these component grammars can be thought of as a refinement of the raw unannotated treebank grammar. By itself, each of these grammars induces a different posterior distribution over *unannotated* trees for each sentence. If we can approximate each model’s contribution by using only unannotated symbols, we can define an algorithm that avoids the exponential overhead of parsing with the full grammar, and instead works with each factor in turn.

To do so, we define a sentence specific *core approximation* over unannotated trees  $q(T|\mathbf{w}) = \prod_m \tilde{f}_m(T, \mathbf{w})$ . Figure 2(b) illustrates this approximation. Here,  $q(T)$  is a product of  $M$  structurally identical factors, one for each of the annotated components. We will approximate each model  $f_m$  by its corresponding  $\tilde{f}_m$ . Thus, there is one color-coordinated approximate factor for each component of the model in Figure 2(a).

There are multiple choices for the structure of these factors, but we focus on *anchored PCFGs*. Anchored PCFGs have productions of the form  ${}_i A_j \rightarrow {}_i B_k {}_k C_j$ , where  $i$ ,  $k$ , and  $j$  are indexes into the sentence. Here,  ${}_i A_j$  is a symbol representing building the base symbol  $A$  over the span  $[i, j]$ .

Billott and Lang (1989) introduced anchored

CFGs as “shared forests,” and Matsuzaki et al. (2005) have previously used these grammars for finding an approximate one-best tree in a latent variable parser. Note that, even though an anchored grammar is unannotated, because it is sentence specific it can represent many complex properties of the full grammar’s posterior distribution for a given sentence. For example, it might express a preference for whether a PP token attaches to a particular verb or to that verb’s object noun phrase in a particular sentence.

Before continuing, note that a pointwise product of anchored grammars is still an anchored grammar. The complexity of parsing with a product of these grammars is therefore no more expensive than parsing with just one. Indeed, anchoring adds no inferential cost at all over parsing with an unannotated grammar: the anchored indices  $i, j, k$  have to be computed just to parse the sentence at all. This property is crucial to EP’s efficiency in our setting.

## 5.2 Assumed Density Filtering

We now describe a simplified version of EP: parsing with assumed density filtering (Boyer and Koller, 1998). We would like to train a sequence of  $M$  models, where each model is trained with knowledge of the posterior distribution induced by the previous models. Much as boosting algorithms (Freund and Schapire, 1995) work by focusing learning on as-yet-unexplained data points, this approach will encourage each model to improve on earlier models, albeit in a different formal way.

At a high level, assumed density filtering (ADF) proceeds as follows. First, we have an initially uninformative  $q$ : it assigns the same probability to all unpruned trees for a given sentence. Then, we factor in one of the annotated grammars and parse with this new augmented grammar. This gives us a new posterior distribution for this sentence over trees annotated with just that annotation component. Then, we can marginalize out the annotations, giving us a new  $q$  that approximates the annotated grammar as closely as possible without using any annotations. Once we have incorporated the current model’s component, we move on to the next annotated grammar, augmenting it with the new  $q$ , and repeating. In this way, information from all grammars is incorporated into a final posterior distribution over trees

using only unannotated symbols. The algorithm is then as follows:

- Initialize  $q(T)$  uniformly.
- For each  $m$  in sequence:
  1. Create the augmented distribution  $q_m(\mathbf{T}[X_m]) \propto q(\mathbf{T}) \cdot f_m(\mathbf{T}[X_m])$  and compute inside and outside scores.
  2. Minimize  $D_{\text{KL}}(q_m(T) || \tilde{f}_m(T)q(T))$  by fitting an anchored grammar  $\tilde{f}_m$ .
  3. Set  $q(T) = \prod_{m'=1}^m \tilde{f}_{m'}(T)$ .

Step 1 of the inner loop forms an approximate posterior distribution using  $f_m$ , which is the parsing model associated with component  $m$ , and  $q$ , which is the anchored core approximation to the posterior induced by the first  $m - 1$  models. Then, the marginals are computed, and the new posterior distribution is projected to an anchored grammar, creating  $\tilde{f}_m$ . More intuitively, we create an anchored PCFG that makes the approximation “as close as possible” to the augmented grammar. (We describe this procedure more precisely in Section 5.4.) Thus, each term  $f_m$  is approximated in the context of the terms that come before it. This contextual approximation is essential: without it, ADF would approximate the terms independently, meaning that no information would be shared between the models. This method would be, in effect, a simple method for parser combination, not all that dissimilar to the method proposed by Petrov (2010). Finally, note that the same inside and outside scores computed in the loop can be used to compute the expected counts needed in Equation 3.

Now we consider the runtime complexity of this algorithm. If the maximum number of annotations per rule for any factor is  $A$ , ADF has complexity  $O(MAG_0|\mathbf{w}|^3)$  when using  $M$  factors. In contrast, parsing with the fully annotated grammar would have complexity  $O(A^M G_0|\mathbf{w}|^3)$ . Critically, for a latent variable parser with  $M$  annotation bits, the exact algorithm takes time exponential in  $M$ , while this approximate algorithm takes time linear in  $M$ .

It is worth pausing to consider what this algorithm does during training. At each step, we have

in  $q$  an approximation to what the posterior distribution looks like with the first  $m - 1$  models. In some places,  $q$  will assign high probabilities to spans in the gold tree, and in some places it will not be so accurate.  $\theta_m$  will be particularly motivated to correct the latter, because they are less like the gold tree. On the other hand,  $\theta_m$  will ignore the other “correct” segments, because  $q$  has already sufficiently captured them.

### 5.3 Expectation Propagation

While this sequential algorithm gives us a way to efficiently combine many kinds of annotations, it is not a fully joint algorithm: there is no backward propagation of information from later models to earlier models. Ideally, no model should be privileged over any other. To correct that, we use EP, which is essentially the iterative generalization of ADF.

Intuitively, EP cycles among the models, updating the approximation for that model in turn so that it closely resembles the predictions made by  $f_m$  in the context of all other approximations, as in Figure 2(c). Thus, each approximate term  $\tilde{f}_m$  is created using information from all other  $\tilde{f}_{m'}$ , meaning that the different annotation factors can still “talk” to each other. The product of these approximations  $q$  will therefore come to act as an approximation to the true posterior: it takes into account joint information about all annotation components, all within one tractable anchored grammar.

With that intuition in mind, EP is defined as follows:

- Initialize contributions  $\tilde{f}_m$  to the approximate posterior  $q$ .
- At each step, choose  $m$ .
  1. Include approximations to all factors other than  $m$ :  $q^{\setminus m}(T) = \prod_{m' \neq m} \tilde{f}_{m'}(T)$ .
  2. Create the augmented distribution by including the actual factor for component  $m$   $q_m(T[X_m]) \propto f_m(T[X_m])q^{\setminus m}(T)$  and compute inside and outside scores.
  3. Create a new  $\tilde{f}_m(T)$  that minimizes  $D_{\text{KL}}(q_m(T) || \tilde{f}_m(T)q^{\setminus m}(T))$ .
- Finally, set  $q(T) \propto \prod_m \tilde{f}_m(T)$ .

Step 2 creates the augmented distribution  $q_m$ , which includes  $f_m$  along with the approximate factors for all models except the current model. Step 3 creates a new anchored  $\tilde{f}_m$  that has the same marginal distribution as the true model  $f_m$  in the context of the other approximations, just as we did in ADF.

In practice, it is usually better to not recompute the product of all  $\tilde{f}_m$  each time, but instead to maintain the full product  $q(T) \propto \prod_m \tilde{f}_m$  and to remove the appropriate  $\tilde{f}_m$  by division. This optimization is analogous to belief propagation, where messages are removed from beliefs by division, instead of recomputing beliefs on the fly by multiplying all messages.

Schematically, the whole process is illustrated in Figure 2(c). At each step, one piece of the core approximation is replaced with the corresponding component from the full model. This augmented model is then reapproximated by a new core approximation  $q$  after updating the corresponding  $\tilde{f}_m$ . This process repeats until convergence.

### 5.4 EPIC Parsing

In our parser, EP is implemented as follows.  $q$  and each of the  $\tilde{f}_m$  are anchored grammars that assign weights to unannotated rules. The product of anchored grammars with the annotated factor  $f_m$  need not be carried out explicitly. Instead, note that an anchored grammar is just a function  $q(A \rightarrow B C, i, k, j) \in \mathbb{R}^+$  that returns a score for every anchored binary rule. This function can be easily integrated into the CKY algorithm for a single annotated grammar by simply multiplying in the value of  $q$  whenever computing the score of the respective production over some span. The modified inside recurrence takes the form:

$$\begin{aligned}
& \text{INSIDE}(A[x], i, j) \\
&= \sum_{B, y, C, z} \theta^T \varphi(A[x] \rightarrow B[y] C[z], \mathbf{w}) \\
&\quad \cdot \sum_{i < k < j} \text{INSIDE}(B[y], i, k) \cdot \text{INSIDE}(C[z], k, j) \\
&\quad \cdot q(A \rightarrow B C, i, k, j)
\end{aligned} \tag{4}$$

Thus, parsing with a pointwise product of an anchored grammar and an annotated grammar has no increased combinatorial cost over parsing with just the annotated grammar.

To actually perform the projection in step 3 of EP, we create an anchored grammar from inside and outside probabilities. First, we compute the expected number of times the rule  $iA_j \rightarrow iB_k kC_j$  occurs, and then we locally normalize for each symbol  $iA_j$ . This actually creates the new  $q$  distribution, and so we have to divide out  $q^m$ . This process minimizes KL divergence subject to the local normalization constraints.

All in all, this gives an algorithm that takes time  $O\left(IMG_0|\mathbf{w}|^3\right)$ , where  $I$  is the maximum number of iterations,  $M$  is the number of models, and  $A$  is the maximum number of annotations for any given rule.

## 5.5 Other Inference Algorithms

To our knowledge, expectation propagation has been used only once in the NLP community; Daumé III and Marcu (2006) employed an unstructured version in a Bayesian model of extractive summarization. Therefore, it is worth describing how EP differs from more familiar techniques.

EP can be thought of as a more flexible generalization of belief propagation, which has been used several times in NLP (Smith and Eisner, 2008; Niehues and Vogel, 2008; Cromières and Kurohashi, 2009; Burkett and Klein, 2012). In particular, EP allows for the arbitrary choice of messages (the  $\tilde{f}_m$ ), meaning that we can use structured messages like anchored PCFGs.

Mean field (Saul and Jordan, 1996) is another approximate inference technique that allows for structured approximations (Xing et al., 2003; Burkett et al., 2010), but here the natural version of mean field for our model would still be intractable. However, it is possible to adapt mean field into allowing for tractable updates that are similar to the ones we proposed. We do not pursue that approach here.

Dual decomposition (Dantzig and Wolfe, 1960; Komodakis et al., 2007) has recently become popular in the community (Rush et al., 2010; Koo et al., 2010). In fact, EP can be seen as a particular kind of dual decomposition of the log normalization constant  $\log Z(\mathbf{w}, \theta)$  that is optimized with message passing rather than (sub-)gradient descent or LP relaxations. Indeed, Minka (2001) argues that the EP objective is more efficiently optimized with message

passing than with gradient updates. This assertion should be examined for the structured models common in NLP, but that is beyond the scope of this paper.

Finally, note that EP, like belief propagation but unlike mean field, is not guaranteed to converge, though in practice it usually seems to. In our experiments, typically three or four iterations are enough for almost all sentences to reach convergence, and we found no loss in cutting off the number of iterations to four.

## 6 Experiments

In what follows, we describe three experiments. First, in a small experiment, we examine how effective the different inference algorithms are for both training and testing. Second, we scale up our latent variable model into successively larger products. Finally, we present a selection of the many possible model combinations, showing that combining latent and expert annotation can be quite effective.

### 6.1 Experimental Setup

For our experiments, we trained and tested on the Penn Treebank using the standard splits: sections 2-21 were training, 22 development, and 23 testing. In preliminary experiments, we report development set F1 on sentences up to length 40. For our final test set experiment, we report F1 on sentences from section 23 up to length 40, as well as all sentences from that section. Scores reported are computed using EVALB (Sekine and Collins, 1997). We binarize trees using Collins’ head rules (Collins, 1997).

Each discriminative parser was trained using the Adaptive Gradient variant of Stochastic Gradient Descent (Duchi et al., 2010). Smaller models were seeded from larger models. That is, before training a grammar of 5 models with 1 latent bit each, we started with weights from a parser with 4 factored bits. Initial experiments suggested this step did not affect final performance, but greatly decreased total training time, especially for the latent variable parsers. For extracting a one-best tree, we use a version of the Max-Recall algorithm of Goodman (1996). When using EP or ADF, we initialized the core approximation  $q$  to the uniform distribution over unpruned trees.

Training	Parsing			
	ADF	EP	Exact	Petrov
ADF	84.3	84.5	84.5	82.5
EP	84.1	84.6	84.5	78.7
Exact	83.8	84.5	<b>84.9</b>	81.5
Indep.	82.3	82.1	82.2	82.6

Table 1: The effect of algorithm choice for training and parsing on a product of two 2-state parsers on F1. Petrov is the product parser of Petrov (2010), and Indep. refers to independently trained models. For comparison, a four-state parser achieves a score of 83.2.

When counting parameters, we consider the number of parameters per binary rule. Hence, a single four-state latent model would have 64 ( $= 4^3$ ) parameters per rule, while a product of 5 two-state models would have just 40 ( $= 5 \cdot 2^3$ ).

## 6.2 Comparison of Inference Algorithms

In our first experiment, we test the relative performance of the various approximate inference methods at both train and test time. In order to include exact inference, we necessarily need to look at a smaller scale example for which exact inference is still feasible. We examined development performance for training and inference on a small product of two parsers, each with two latent states per symbol.

During training, we have several options. We can use exact training by parsing with the fully articulated product of both grammars, or, we can instead use EP, ADF, or independent training. At test time, we can parse using the full product of both grammars, or, we can instead use EP, ADF, or we can use the method of Petrov (2010) wherein we multiply the parsers together in an *ad hoc* fashion.

The results are in Table 1. The best reported score, unsurprisingly, is for using exact training and parsing, but using EP for training and parsing results in a relatively small loss of 0.3 F1. ADF, however, suffers a loss of 0.6 F1 over Exact when used for training and parsing. Otherwise, Exact and EP seem to perform fairly similarly at parse time for all training conditions.

In general, there seems to be a gain for using the same method for training and testing. Each testing method performs at its best when using models trained with the same method. Moreover, except for ADF, the converse holds true: the grammars trained

Figure 3: Development F1 plotted against the number  $M$  of one-bit latent annotation components. The best grammar has 6 one-bit annotations, with 89.7 F1.

with a given parsing method are best decoded using the same method.

Oddly, using Petrov (2010)’s method does not seem to work well at all for jointly trained models, except for ADF. Similarly, joint parsing underperforms Petrov (2010)’s method when using independently trained models. Likely, the joint parsing algorithms are miscalibrating the redundant information present in the two independently-trained models, while the two jointly-trained components come to depend on each other. In fact, the F1 scores for the two separate models of the EP parser are in the 60’s.

As expected, ADF does not perform as well as EP. Therefore, we exclude it from our subsequent experiments, focusing exclusively on EP.

## 6.3 Latent Variable Experiments

Most of the previous work in latent variable parsing has focused on splitting smaller unstructured annotations into larger unstructured annotations. Here, we consider training a joint model consisting of a large number of disjoint one-bit (i.e. two-state) latent variable annotations. Specifically, we consider the performance of products of up to 8 one-bit annotations.

In Figure 3, we show development F1 as a function of the number of latent bits. Improvement is roughly linear up to 3 components. Performance levels off afterwards, with the top performing system scoring 89.7 F1. Nevertheless, these parsers outperform the comparable parsers of Petrov and Klein (2008a) (89.3), even though our six-bit parser has many fewer effective parameters per binary rule:

Models	F1, $\leq 40$	F1, All
Lexicalized	87.3	86.5
Unlexicalized	86.3	85.4
3xLatent	88.6	87.6
Lex+Unlex	90.2	89.5
Lex+Lat	90.0	89.4
Unlex+Lat	90.0	89.4
Lex+Unlex+Lat	90.2	89.7

Table 2: Development F1 score for various model combinations for sentences less than length 40 and all sentences. 3xLatent refers to a latent annotation model with 3 factored latent bits.

48 instead of the 4096 in their best parser. We also ran our best system on Section 23, where it gets 89.1 and 88.4 on sentences less than length 40 and on all sentences, respectively. This result compares favorably to the 88.8/88.3 of Petrov and Klein (2008a).

#### 6.4 Heterogeneous Models

We now consider factored models with different kinds of annotations. Specifically, we tested grammars comprising all subsets of {Lexicalized, Unlexicalized, Latent}. We used a model with 3 factored bits as our representative of the latent variable class, because it was closest in performance to the other models. Of course, other smaller and larger combinations are possible, but we found this selection to be representative.

The development results are in Table 2. Unsurprisingly, adding more kinds of annotations helps for the most part, though the combination of all three components is not much better than a combination of just the lexicalized and unlexicalized models. Indeed, our best systems involved combining the lexicalized model with some other model. This is probably because the lexicalized model can represent very different syntactic relationships than the latent and unlexicalized models, meaning there is more diversity in the joint model’s capacity when using combinations involving the lexicalized annotations.

Finally, we ran our best system (the fully combined one) on Section 23 of the Penn Treebank. It scored 90.1/89.4 F1 on length 40 and all sentences respectively, slightly edging out the 90.0/89.3 F1 of Petrov and Klein (2008a). However, it is not quite as good at exact match: 37.7/35.3 vs 40.1/37.7. Note, though, that their parser makes use of span features, which deliver a gain of +0.3/0.2F1 respec-

tively, while ours does not. We suspect that similar gains could be had by incorporating these features, but we leave that for future work.

## 7 Conclusion

Factored representations capture a fundamental linguistic insight: grammatical categories are not monolithic, unanalyzable entities. Instead, they are composed of numerous facets that together govern how categories combine into parse trees.

We have developed a new model for grammars with factored annotations and presented two methods for parsing with these grammars. Our experiments have demonstrated that our approach produces higher performance parsers with many fewer parameters. Moreover, our model works with both latent and explicit annotations, allowing us to combine linguistic knowledge with machine learning. Finally, our source code is available at <http://nlp.cs.berkeley.edu/Software.shtml>.

## Abstract

We introduce a model of coherence which captures the intentional discourse structure in text. Our work is based on the hypothesis that syntax provides a proxy for the communicative goal of a sentence and therefore the sequence of sentences in a coherent discourse should exhibit detectable structural patterns. Results show that our method has high discriminating power for separating out coherent and incoherent news articles reaching accuracies of up to 90%. We also show that our syntactic patterns are correlated with manual annotations of intentional structure for academic conference articles and can successfully predict the coherence of abstract, introduction and related work sections of these articles.

## 1 Introduction

Recent studies have introduced successful automatic methods to predict the structure and coherence of texts. They include entity approaches for local coherence which track the repetition and syntactic realization of entities in adjacent sentences (Barzilay and Lapata, 2008; Elsner and Charniak, 2008) and content approaches for global coherence which view texts as a sequence of topics, each characterized by a particular distribution of lexical items (Barzilay and Lee, 2004; Fung and Ngai, 2006). Other work has shown that co-occurrence of words (Lapata, 2003; Soricut and Marcu, 2006) and discourse relations (Pitler and Nenkova, 2008; Lin et al., 2011) also predict coherence.

Early theories (Grosz and Sidner, 1986) posited that there are three factors which collectively con-

tribute to coherence: intentional structure (purpose of discourse), attentional structure (what items are discussed) and the organization of discourse segments. The highly successful entity approaches capture attentional structure and content approaches are related to topic segments but intentional structure has largely been neglected. Every discourse has a purpose: explaining a concept, narrating an event, critiquing an idea and so on. As a result each sentence in the article has a communicative goal and the sequence of goals helps the author achieve the discourse purpose. In this work, we introduce a model to capture coherence from the intentional structure dimension. Our key proposal is that syntactic patterns are a useful proxy for intentional structure.

This idea is motivated from the fact that certain sentence types such as questions and definitions have distinguishable and unique syntactic structure. For example, consider the opening sentences of two descriptive articles<sup>1</sup> shown in Table 1. Sentences (1a) and (2a) are typical instances of definition sentences. Definitions are written with the concept to be defined expressed as a noun phrase followed by a copular verb (is/are). The predicate contains two parts: the first is a noun phrase reporting the concept as part of a larger class (eg. an aqueduct is a water supply), the second component is a relative clause listing unique properties of the concept. These are examples of syntactic patterns related to the communicative goals of individual sentences. Similarly, sentences (1b) and (2b) which provide further details about the concept also have some distinguish-

<sup>1</sup>Wikipedia articles on “Aqueduct” and “Cytokine Receptors”

- 1a) An aqueduct is a water supply or navigable channel constructed to convey water.
- b) In modern engineering, the term is used for any system of pipes, canals, tunnels, and other structures used for this purpose.
- 
- 2a) Cytokine receptors are receptors that binds cytokines.
- b) In recent years, the cytokine receptors have come to demand more attention because their deficiency has now been directly linked to certain debilitating immunodeficiency states.

Table 1: The first two sentences of two descriptive articles

ing syntactic features such as the presence of a topicalized phrase providing the focus of the sentence. The two sets of sentences have similar sequence of communicative goals and so we can expect the syntax of adjacent sentences to also be related.

We aim to characterize this relationship on a broad scale using a coherence model based entirely on syntax. The model relies on two assumptions which summarize our intuitions about syntax and intentional structure:

1. Sentences with similar syntax are likely to have the same communicative goal.
2. Regularities in intentional structure will be manifested in syntactic regularities between adjacent sentences.

There is also evidence from recent work that supports these assumptions. Cheung and Penn (2010) find that a better syntactic parse of a sentence can be derived when the syntax of adjacent sentences is also taken into account. Lin et al. (2009) report that the syntactic productions in adjacent sentences are powerful features for predicting which discourse relation (cause, contrast, etc.) holds between them. Cocco et al. (2011) show that significant associations exist between certain part of speech tags and sentence types such as explanation, dialog and argumentation.

In our model, syntax is represented either as parse tree productions or a sequence of phrasal nodes augmented with part of speech tags. Our best performing method uses a Hidden Markov Model to learn the patterns in these syntactic items. Sections 3 and 5 discuss the representations and their specific implementations and relative advantages. Results show that syntax models can distinguish coherent and incoherent news articles from two domains with 75-90% accuracies over a 50% baseline. In addition,

the syntax coherence scores turn out complementary to scores given by lexical and entity models.

We also study our models' predictions on academic articles, a genre where intentional structure is widely studied. Sections in these articles have well-defined purposes and we find recurring sentence types such as motivation, citations, description, and speculations. There is a large body of work (Swales, 1990; Teufel et al., 1999; Liakata et al., 2010) concerned with defining and annotating these sentence types (called zones) in conference articles. In Section 6, we describe how indeed some patterns captured by the syntax-based models are correlated with zone categories that were proposed in prior literature. We also present results on coherence prediction: our model can distinguish the introduction section of conference papers from its perturbed versions with over 70% accuracy. Further, our model is able to identify conference from workshop papers with good accuracies, given that we can expect these articles to vary in purpose.

## 2 Evidence for syntactic coherence

We first present a pilot study that confirms that adjacent sentences in discourse exhibit stable patterns of syntactic co-occurrence. This study validates our second assumption relating the syntax of adjacent sentences. Later in Section 6, we examine syntactic patterns in individual sentences (assumption 1) using a corpus of academic articles where sentences were manually annotated with communicative goals.

Prior work has reported that certain grammatical productions are repeated in adjacent sentences more often than would be expected by chance (Reitter et al., 2006; Cheung and Penn, 2010). We analyze all co-occurrence patterns rather than just repetitions.

We use the gold standard parse trees from the Penn Treebank (Marcus et al., 1994). Our unit of analysis is a pair of adjacent sentences  $(S_1, S_2)$  and we choose to use Section 0 of the corpus which has 99 documents and 1727 sentence pairs. We enumerate all productions that appear in the syntactic parse of any sentence and exclude those that appear less than 25 times, resulting in a list of 197 unique productions. Then all ordered pairs<sup>2</sup>  $(p_1, p_2)$  of productions are formed. For each pair, we compute

<sup>2</sup> $(p_1, p_2)$  and  $(p_2, p_1)$  are considered as different pairs.

$p_1, p_2$	Sentence 1	Sentence 2
NP → NP NP-ADV QP → CD CD	The two concerns said they entered into a definitive merger agreement under which Ratners will begin a tender offer for all of Weisfield’s common shares for [\$57.50 each] <sub>NP</sub> .	Also on the takeover front, Jaguar’s ADRs rose 1/4 to 13 7/8 on turnover of [4.4 million] <sub>QP</sub> .
VP → VB VP NP-SBJ → NNP NNP	“The refund pool may not [be held hostage through another” round of appeals] <sub>VP</sub> ,” Judge Curry said.	[Commonwealth Edison] <sub>NP-SBJ</sub> said it is already appealing the underlying commission order and is considering appealing Judge Curry’s order.
NP-LOC → NNP S-TPC-1 → NP-SBJ VP	“It has to be considered as an additional risk for the investor,” said Gary P. Smaby of Smaby Group Inc., [Minneapolis] <sub>NP-LOC</sub> .	[“Cray Computer will be a concept” “stock,”] <sub>S-TPC-1</sub> he said.

Table 2: Example sentences for preferred production sequences. The span of the LHS of the corresponding production is indicated by [] braces.

the following:  $c(p_1 p_2)$  = number of sentence pairs where  $p_1 \in S_1$  and  $p_2 \in S_2$ ;  $c(p_1 \neg p_2)$  = number of pairs where  $p_1 \in S_1$  and  $p_2 \notin S_2$ ;  $c(\neg p_1 p_2)$  and  $c(\neg p_1 \neg p_2)$  are computed similarly. Then we perform a chi-square test to understand if the observed count  $c(p_1 p_2)$  is significantly (95% confidence level) greater or lesser than the expected value if occurrences of  $p_1$  and  $p_2$  were independent.

Of the 38,809 production pairs, we found that 1,168 pairs occurred in consecutive sentences significantly more often than chance and 172 appeared significantly fewer times than expected. In Table 2 we list, grouped in three simple categories, the 25 pairs of the first kind with most significant p-values.

Some of the preferred pairs are indeed repetitions as pointed out by prior work. But they form only a small fraction (5%) of the total preferred production pairs indicating that there are several other classes of syntactic regularities beyond priming. Some of these other sequences can be explained by the fact that these articles come from the finance domain: they involve productions containing numbers and quantities. An example for this type is shown in Table 2. Finally, there is also a class that is not repetitions or readily observed as domain-specific. The most frequent one reflects a pattern where the first sentence introduces a subject and predicate and the subject in the second sentence is pronominalized. Examples for two other patterns are given in Table 2. For the sequence (VP → VB VP | NP-SBJ → NNP NNP), a bare verb is present in  $S_1$  and is often associated with modals. In the corpus, these statements often present hypothesis or speculation. The following sentence  $S_2$  has an entity, a person or organization, giving an explanation or opinion on the statement. This pattern roughly corresponds to a SPECULATE followed by ENDORSE sequence of intentions.

$p_1$	$p_2$	$c(p_1 p_2)$
	— Repetition —	
VP → VBD SBAR	VP → VBD SBAR	83
QP → \$ CD CD	QP → \$ CD CD	18
NP → \$ CD -NONE-	NP → \$ CD -NONE-	16

NP-LOC → NNP	S-TPC-1 → NP-SBJ VP	6

Table 3: Top patterns in productions from WSJ

Similarly, in all the six adjacent sentence pairs from our corpus containing the items (NP-LOC → NNP | S-TPC-1 → NP-SBJ VP),  $p_1$  introduces a location name, and is often associated with the title of a person or organization. The next sentence has a quote from that person, where the quotation forms the topicalized clause in  $p_2$ . Here the intentional structure is INTRODUCE X / STATEMENT BY X.

In the remainder of the paper we formalize our representation of syntax and the derived model of coherence and test its efficacy in three domains.

### 3 Coherence models using syntax

We first describe the two representations of sentence structure we adopted for our analysis.<sup>3</sup> Next, we

<sup>3</sup>Our representations are similar to features used for reranking in parsing. Our first representation corresponds to “rules” features (Charniak and Johnson, 2005; Collins and Koo, 2005), and our second representation is related to “spines” (Carreras et al., 2008) and edge annotation (Huang, 2008).

present two coherence models: a local model which captures the co-occurrence of structural features in adjacent sentences and a global one which learns from clusters of sentences with similar syntax.

### 3.1 Representing syntax

Our models rely exclusively on syntactic cues. We derive representations from constituent parses of the sentences, and terminals (words) are removed from the parse tree before any processing is done. The leaf nodes in our parse trees are part of speech tags.

**Productions:** In this representation we view each sentence as the set of grammatical productions, LHS  $\rightarrow$  RHS, which appear in the parse of the sentence. As we already pointed out, the right-hand side (RHS) contains only non-terminal nodes. This representation is straightforward, however, some productions can be rather specific with long right hand sides. Another apparent drawback of this representation is that it contains sequence information only about nodes that belong to the same constituent.

**$d$ -sequence:** In this representation we aim to preserve more sequence information about adjacent constituents in the sentence. The simplest approach would be to represent the sentence as the sequence of part of speech (POS) tags but then we lose all the abstraction provided by higher level nodes in tree. Instead, we introduce a more general representation,  $d$ -sequence where the level of abstraction can be controlled using a parameter  $d$ . The parse tree is truncated to depth at most  $d$ , and the leaves of the resulting tree listed left to right form the  $d$ -sequence representation. For example, in Figure 1, the line depicts the cutoff at depth 2.

Next the representation is further augmented; all *phrasal* nodes in the  $d$ -sequence are annotated (concatenated) with the left-most leaf that they dominate in the full non-lexicalized parse tree. This is shown as suffixes on the S, NP and VP nodes in the figure. Such annotation conveys richer information about the structure of the subtree below nodes in the  $d$ -sequence. For example, “the chairs”, “his chairs”, “comfortable chairs” will be represented as NP<sub>DT</sub>, NP<sub>PRP\$</sub> and NP<sub>JJ</sub>. In the resulting representations, sentences are viewed as sequences of *syntactic words* ( $w_1, w_2, \dots, w_k$ ),  $k \leq p$ , where  $p$  is the length of the full POS sequence and each  $w_i$  is either POS tag or a phrasal node+POS tag combination.

depth-2 sequence = " S<sub>DT</sub> , " NP<sub>NNP</sub> VP<sub>VBD</sub> .  
depth-3 sequence = " NP<sub>DT</sub> VP<sub>VBZ</sub> , " NNP NNP VBD .

Figure 1: Example for  $d$ -sequence representation

In our example, at depth-2, the quotation sentence gets the representation ( $w_1=“$ ,  $w_2=S_{DT}$ ,  $w_3=,$ ,  $w_4=“$ ,  $w_5=NP_{NNP}$ ,  $w_6=VP_{VBD}$ ,  $w_7=.$ ) where the actual quote is omitted. Sentences that contain attributions are likely to appear more similar to each other when compared using this representation in contrast to representations derived from word or POS sequence. The depth-3 sequence is also indicated in the figure.

The main verb of a sentence is central to its structure, so the parameter  $d$  is always set to be greater than that of the main verb and is tuned to optimize performance for coherence prediction.

### 3.2 Implementing the model

We adapt two models of coherence to operate over the two syntactic representations.

#### 3.2.1 Local co-occurrence model

This model is a direct extension from our pilot study. It allows us to test the assumption that coherent discourse is characterized by syntactic regularities in adjacent sentences. We estimate the probabilities of pairs of syntactic items from adjacent sentences in the training data and use these probabilities to compute the coherence of new texts.

The coherence of a text  $T$  containing  $n$  sentences ( $S_1 \dots S_n$ ) is computed as:

$$P(T) = \prod_{i=2}^n \prod_{j=1}^{|S_i|} \frac{1}{|S_{i-1}|} \sum_{k=1}^{|S_{i-1}|} p(S_i^j | S_{i-1}^k)$$

where  $S_x^y$  indicates the  $y^{\text{th}}$  item of  $S_x$ . Items are either productions or syntactic word unigrams depending on the representation. The conditional probabilities are computed with smoothing:

### Cluster a

ADJP → JJ PP | VP → VBZ ADJP

[1] This method VP-[is ADJP-[capable of sequence-specific detection of DNA with high accuracy]-ADJP]-VP .

[2] The same VP-[is ADJP-[true for synthetic polyamines such as polyallylamine]-ADJP]-VP .

### Cluster b

VP → VB VP | VP → MD VP

[1] Our results for the difference in reactivity VP-[can VP-[be linked to experimental observations]-VP]-VP .

[2] These phenomena taken together VP-[can VP-[be considered as the signature of the gelation process]-VP]-VP .

Table 4: Example syntactic similarity clusters. The top two descriptive productions for each cluster are also listed.

$$p(w_j|w_i) = \frac{c(w_i, w_j) + \delta_C}{c(w_i) + \delta_C * |V|}$$

where  $w_i$  and  $w_j$  are syntactic items and  $c(w_i, w_j)$  is the number of sentences that contain the item  $w_i$  immediately followed by a sentence that contains  $w_j$ .  $|V|$  is the vocabulary size for syntactic items.

### 3.2.2 Global structure

Now we turn to a global coherence approach that implements the assumption that sentences with similar syntax have the same communicative goal as well as captures the patterns in communicative goals in the discourse. This approach uses a Hidden Markov Model (HMM) which has been a popular implementation for modeling coherence (Barzilay and Lee, 2004; Fung and Ngai, 2006; Elsner et al., 2007). The hidden states in our model depict communicative goals by encoding a probability distribution over syntactic items. This distribution gives higher weight to syntactic items that are more likely for that communicative goal. Transitions between states record the common patterns in intentional structure for the domain.

In this syntax-HMM, states  $h_k$  are created by clustering the sentences from the documents in the training set by *syntactic similarity*. For the productions representation of syntax, the features for clustering are the number of times a given production appeared in the parse of the sentence. For the  $d$ -sequence approach, the features are  $n$ -grams of size one to four of syntactic words from the sequence. Clustering was done by optimizing for average cosine similarity and was implemented using the CLUTO toolkit (Zhao et al., 2005).  $C$  clusters are formed and taken as the states of the model. Table 4 shows sentences from two clusters formed on the abstracts of journal articles using the productions representation. One of them, cluster (a), appears

to capture descriptive sentences and cluster (b) involves mostly speculation type sentences.

The emission probabilities for each state are modeled as a (syntactic) language model derived from the sentences in it. For productions representation, this is the unigram distribution of productions from the sentences in  $h_k$ . For  $d$ -sequences, the distribution is computed for bigrams of syntactic words. These language models use Lidstone smoothing with constant  $\delta_E$ . The probability for a sentence  $S_l$  to be generated from state  $h_k$ ,  $p_E(S_l|h_k)$  is computed using these syntactic language models.

The transition probability  $p_M$  from a state  $h_i$  to state  $h_j$  is computed as:

$$p_M(h_j|h_i) = \frac{d(h_i, h_j) + \delta_M}{d(h_i) + \delta_M * C}$$

where  $d(h_i)$  is the number of documents whose sentences appear in  $h_i$  and  $d(h_i, h_j)$  is the number of documents which have a sentence in  $h_i$  which is immediately followed by a sentence in  $h_j$ . In addition to the  $C$  states, we add one initial  $h_S$  and one final  $h_F$  state to capture document beginning and end. Transitions from  $h_S$  to any state  $h_k$  records how likely it is for  $h_k$  to be the starting state for documents of that domain.  $\delta_M$  is a smoothing constant.

The likelihood of a text with  $n$  sentences is given by  $P(T) = \sum_{h_1 \dots h_n} \prod_{t=1}^n p_M(h_t|h_{t-1})p_E(S_t|h_t)$ .

All model parameters—the number of clusters  $C$ , smoothing constants  $\delta_C$ ,  $\delta_E$ ,  $\delta_M$  and  $d$  for  $d$ -sequences—are tuned to optimize how well the model can distinguish coherent from incoherent articles. We describe these settings in Section 5.1.

## 4 Content and entity grid models

We compare the syntax model with content model and entity grid methods. These approaches are the most popular ones from prior work and also allow us to test the complementary nature of syntax with

lexical statistics and entity structure. This section explains how we implemented these approaches.

Content models introduced by Barzilay and Lee (2004) and Fung and Ngai (2006) use lexically driven HMMs to capture coherence. The hidden states represent the topics of the domain and encode a probability distribution over words. Transitions between states record the probable succession of topics. We built a content model using our HMM implementation. Clusters are created using word bigram features after replacing numbers and proper names with tags NUM and PROP. The emissions are given by a bigram language model on words from the clustered sentences. Barzilay and Lee (2004) also employ an iterative clustering procedure before finalizing the states of the HMM but our method only uses one-step clustering. Despite the difference, the content model accuracies for our implementation are quite close to that from the original.

For the entity grid model, we follow the generative approach proposed by Lapata and Barzilay (2005). A text is converted into a matrix, where rows correspond to sentences, in the order in which they appear in the article. Columns are created one for each entity appearing in the text. Each cell  $(i, j)$  is filled with the grammatical role  $r_{i,j}$  of the entity  $j$  in sentence  $i$ . We computed the entity grids using the Brown Coherence Toolkit<sup>4</sup>. The probability of the text ( $T$ ) is defined using the likely sequence of grammatical role transitions.

$$P(T) = \prod_{j=1}^m \prod_{i=1}^n p(r_{i,j} | r_{i-1,j} \dots r_{i-h,j})$$

for  $m$  entities and  $n$  sentences. Parameter  $h$  controls the history size for transitions and is tuned during development. When  $h = 1$ , for example, only the grammatical role for the entity in the previous sentence is considered and earlier roles are ignored.

## 5 Evaluating syntactic coherence

We follow the common approach from prior work and use pairs of articles, where one has the original document order and the other is a random permutation of the sentences from the same document. Since the original article is always more coherent than a random permutation, a model can be evaluated using

<sup>4</sup><http://www.cs.brown.edu/~melsner/manual.html>

the accuracy with which it can identify the original article in the pair, i.e. it assigns higher probability to the original article. This setting is not ideal but has become the de facto standard for evaluation of coherence models (Barzilay and Lee, 2004; Elsner et al., 2007; Barzilay and Lapata, 2008; Karamanis et al., 2009; Lin et al., 2011; Elsner and Charniak, 2011). It is however based on a reasonable assumption as recent work (Lin et al., 2011) shows that people identify the original article as more coherent than its permutations with over 90% accuracy and assessors also have high agreement. Later, we present an experiment distinguishing conference from workshop articles as a more realistic evaluation.

We use two corpora that are widely employed for coherence prediction (Barzilay and Lee, 2004; Elsner et al., 2007; Barzilay and Lapata, 2008; Lin et al., 2011). One contains reports on airplane accidents from the National Transportation Safety Board and the other has reports about earthquakes from the Associated Press. These articles are about 10 sentences long. These corpora were chosen since within each dataset, the articles have the same intentional structure. Further, these corpora are also standard ones used in prior work on lexical, entity and discourse relation based coherence models. Later in Section 6, we show that the models perform well on the academic genre and longer articles too.

For each of the two corpora, we have 100 articles for training and 100 (accidents) and 99 (earthquakes) for testing. A maximum of 20 random permutations were generated for each test article to create the pairwise data (total of 1986 test pairs for the accident corpus and 1956 for earthquakes).<sup>5</sup> The baseline accuracy for random prediction is 50%. The articles were parsed using the Stanford parser (Klein and Manning, 2003).

### 5.1 Accuracy of the syntax model

For each model, the relevant parameters were tuned using 10-fold cross validation on the training data. In each fold, 90 documents were used for training and evaluation was done on permutations from the remaining articles. After tuning, the final model was trained on all 100 articles in the training set.

<sup>5</sup>We downloaded the permutations from <http://people.csail.mit.edu/regina/coherence/CLsubmission/>

Table 5 shows the results on the test set. The best number of clusters and depth for  $d$ -sequences are also indicated. Overall, the syntax models work quite well, with accuracies at least 15% or more absolute improvement over the baseline.

In the local co-occurrence approach, both productions and  $d$ -sequences provide 72% accuracy for the accidents corpus. For the earthquake corpus, the accuracies are lower and the  $d$ -sequence method works better. The best depth setting for  $d$ -sequence is rather small: depth of main verb (MVP) + 2 (or 1), and indicates that a fairly abstract level of nodes is preferred for the patterns. For comparison, we also provide results using just the POS tags in the model and this is worse than the  $d$ -sequence approach.

The global HMM model is better than the local model for each representation type giving 2 to 38% better accuracies. Here we see a different trend for the  $d$ -sequence representation, with better results for greater depths. At such depths (8 and 9) below the main verb, the nodes are mostly POS tags.

Overall both productions and  $d$ -sequence work competitively and give the best accuracies when implemented with the global approach.

## 5.2 Comparison with other approaches

For our implementations of the content and entity grid models, the best accuracies are 71% on the accidents corpus and 85% on the earthquakes one, similar to the syntactic models.

Ideally, we would like to combine models but we do not have separate training data. So we perform the following classification experiment which combines the predictions made by different models on the *test set*. Each test pair (article and permutation) forms one example and is given a class value of 0 or 1 depending on whether the first article in the pair is the original one or the second one. The example is represented as an  $n$ -dimensional vector, where  $n$  is the number of models we wish to combine. For instance, to combine content models and entity grid, two features are created: one of these records the difference in log probabilities for the two articles from the content model, the other feature indicates the difference in probabilities from the entity grid.

A logistic regression classifier is trained to predict the class using these features. The test pairs are created such that an equal number of examples have

Model	Accidents		Earthquake	
	Parameter	Acc	Parameter	Acc
A. Local co-occurrence				
Prodns		72.8		55.0
$d$ -seq	dep. MVP+2	71.8	dep. MVP+1	65.1
POS		61.3		42.6
B. HMM-syntax				
Prodns	clus. 37	74.6	clus. 5	93.8
$d$ -seq	dep. MVP+8	82.2	dep. MVP+9	86.5
	clus. 8		clus. 45	
C. Other approaches				
Egrid	history 1	67.6	history 1	82.2
Content	clus. 48	71.4	clus. 23	84.5

Table 5: Accuracies on accident and earthquake corpora

Model	Accid.	Earthq.
Content + Egrid	<b>76.8</b>	<b>90.7</b>
Content + HMM-prodn	74.2	<b>95.3</b>
Content + HMM- $d$ -seq	82.1	<b>90.3</b>
Egrid + HMM-prodn	<b>79.6</b>	93.9
Egrid + HMM- $d$ -seq	<b>84.2</b>	<b>91.1</b>
Egrid + Content + HMM-prodn	79.5	95.0
Egrid + Content + HMM- $d$ -seq	84.1	92.3
Egrid + Content + HMM-prodn + HMM- $d$ -seq	83.6	95.7

Table 6: Accuracies for combined approaches

class 0 and 1, so the baseline accuracy is 50%. We run this experiment using 10-fold cross validation on the test set after first obtaining the log probabilities from individual models. In each fold, the training is done using the pairs from 90 articles and tested on permutations from the remaining 10 articles. These accuracies are reported in Table 6. When the accuracy of a combination is better than that using any of its smaller subsets, the value is bolded.

We find that syntax supplements both content and entity grid methods. While on the airplane corpus syntax only combines well with the entity grid, on the earthquake corpus, both entity and content approaches give better accuracies when combined with syntax. However, adding all three approaches does not outperform combinations of any two of them. This result can be due to the simple approach that we tested for combination. In prior work, content and entity grid methods have been combined generatively (Elsner et al., 2007) and using discriminative training with different objectives (Soricut and

Marcu, 2006). Such approaches might bring out the complementary strengths of the different aspects better and we leave such analysis for future work.

## 6 Predictions on academic articles

The distinctive intentional structure of academic articles has motivated several proposals to define and annotate the communicative purpose (argumentative zone) of each sentence (Swales, 1990; Teufel et al., 1999; Liakata et al., 2010). Supervised classifiers were also built to identify these zones (Teufel and Moens, 2000; Guo et al., 2011). So we expect that these articles form a good testbed for our models. In the remainder of the paper, we examine how unsupervised patterns discovered by our approach relate to zones and how well our models predict coherence for articles from this genre.

We employ two corpora of scientific articles.

**ART Corpus:** contains a set of 225 Chemistry journal articles that were manually annotated for intentional structure (Liakata and Soldatova, 2008). Each sentence was assigned one of 11 zone labels: *Result*, *Conclusion*, *Objective*, *Method*, *Goal*, *Background*, *Observation*, *Experiment*, *Motivation*, *Model*, *Hypothesis*. For our study, we use the annotation of the introduction and the abstract sections. We divide the data into training, development and test sets. For abstracts, we have 75, 50 and 100 for these sets respectively. For introductions, this split is 75, 31, 82.<sup>6</sup>

**ACL Anthology Network (AAN) Corpus:** Radev et al. (2009) provides the full text of publications from ACL venues. These articles do not have any zone annotations. The AAN corpus is produced from OCR analysis and no section marking is available. To recreate these, we use the Parscit tagger<sup>7</sup> (Councill et al., 2008). We use articles from years 1999 to 2011. For training, we randomly choose 70 articles from ACL and NAACL main conferences. Similarly, we obtain a development corpus of 36 ACL-NAACL articles. We create two test sets: one has 500 ACL-NAACL conference articles and another has 500 articles from ACL-sponsored workshops. We only choose articles in which all three sections—abstract, introduction and related work—

<sup>6</sup>Some articles did not have labelled ‘introduction’ sections resulting in fewer examples for this setup.

<sup>7</sup><http://aye.comp.nus.edu.sg/parsCit/>

could be successfully identified using Parscit.<sup>8</sup>

This data was sentence-segmented using MxTerminator (Reynar and Ratnaparkhi, 1997) and parsed with the Stanford Parser (Klein and Manning, 2003).

For each corpus and each section, we train all our syntactic models: the two local coherence models using the production and  $d$ -sequence representations and the HMM models with the two representations. These models are tuned on the respective development data, on the task of differentiating the original from a permuted section. For this purpose, we created a maximum of 30 permutations per article.

### 6.1 Comparison with ART Corpus zones

We perform this analysis using the ART corpus. The zone annotations present in this corpus allow us to directly test our first assumption in this work, that sentences with similar syntax have the same communicative goal.

For this analysis, we use the the HMM-prod model for abstracts and the HMM- $d$ -seq model for introductions. These models were chosen because they gave the best performance on the ART corpus development sets.<sup>9</sup> We examine the clusters created by these models on the training data and check whether there are clusters which strongly involve sentences from some particular annotated zone.

For each possible pair of cluster and zone ( $C_i$ ,  $Z_j$ ), we compute  $c(C_i, Z_j)$ : the number of sentences in  $C_i$  that are annotated as zone  $Z_j$ . Then we use a chi-square test to identify pairs for which  $c(C_i, Z_j)$  is significantly greater than expected (there is a “positive” association between  $C_i$  and  $Z_j$ ) and pairs where  $c(C_i, Z_j)$  is significantly less than chance ( $C_i$  is not associated with  $Z_j$ ). A 95% confidence level was used to determine significance.

The HMM-prod model for abstracts has 9 clusters (named Clus0 to 8) and the HMM- $d$ -seq model for introductions has 6 clusters (Clus0 to 5). The pairings of these clusters with zones which turned out to be significant are reported in Table 7. We also report for each positively associated cluster-zone pair, the following numbers: matches  $c(C_i, Z_j)$ , precision  $c(C_i, Z_j)/|C_i|$  and recall  $c(C_i, Z_j)/|Z_j|$ .

<sup>8</sup>We also exclude introduction and related work sections longer than 50 sentences and those shorter than 4 sentences since they often have inaccurate section boundaries.

<sup>9</sup>Their test accuracies are reported in the next section.

<b>Abstracts (HMM-prod 9 clusters)</b>			
<b>Positive associations</b>	<b>matches</b>	<b>prec.</b>	<b>recall</b>

<b>Not associated:</b> Clus1 - Motivation, Clus2 - Goal, Clus4 - Background, Clus 5 - Model			

Table 7: Cluster-Zone mappings on the ART Corpus

The presence of significant associations validate our intuitions that syntax provides clues about communicative goals. Some clusters overwhelmingly contain the same zone, indicated by high precision, for example 64% of sentences in Clus2 from introduction sections are background sentences. Other clusters have high recall of a zone, 55% of all goal sentences from the abstracts training data is captured by Clus7. It is particularly interesting to see that Clus7 of abstracts captures both objective and goal zone sentences and for introductions, Clus4 is a mix of hypothesis and goal sentences which intuitively are closely related categories.

## 6.2 Original versus permuted sections

We also explore the accuracy of the syntax models for predicting coherence of articles from the test set of ART corpus and the 500 test articles from ACL-NAACL conferences. We use the same experimental setup as before and create pairs of original and permuted versions of the test articles. We created a maximum of 20 permutations for each article. The baseline accuracy is 50% as before.

For the ART corpus, we also built an oracle model of annotated zones. We train a first order Markov Chain to record the sequence of zones in the training articles. For testing, we assume that the oracle zone is provided for each sentence and use the model to predict the likelihood of the zone sequence. Results from this model represent an upper bound because

an accurate hypothesis of the communicative goal is available for each sentence.

The accuracies are presented in Table 8. Overall, the HMM-*d*-seq model provides the best accuracies. The highest results are obtained for ACL introduction sections (74%). These results are lower than that obtained on the earthquake/accident corpus but the task here is much harder: the articles are longer and the ACL corpus also has OCR errors which affect sentence segmentation and parsing accuracies. When the oracle zones are known, the accuracies are much higher on the ART corpus indicating that the intentional structure of academic articles is very predictive of their coherence.

## 6.3 Conference versus workshop papers

Finally, we test whether the syntax-based model can distinguish the structure of conference from workshop articles. Conferences publish more complete and tested work and workshops often present preliminary studies. Workshops are also venues to discuss a focused and specialized topic. So the way information is conveyed in the abstracts and introductions would vary in these articles.

We perform this analysis on the ACL corpus and no permutations are used, only the original text of the 500 articles each in the conference and workshop test sets. While permutation examples provide cheap training/test data, they have a few unrealistic properties. For example, both original and permuted articles have the same length. Further some permutations could result in an outstandingly incoherent sample which is easily distinguished from the original articles. So we use the conference versus workshop task as another evaluation of our model.

We designed a classification experiment for this task which combines features from the different syntax models that were trained on the ACL conference training set. We include four features indicating the perplexity of an article under each model (Local-prod, Local-*d*-seq, HMM-prod, HMM-*d*-seq). We use perplexity rather than probability because the length of the articles vary widely in contrast to the previous permutation-based tests, where both permutation and original article have the same length. We compute perplexity as  $P(T)^{-1/n}$ , where  $n$  is the number of words in the article. We also obtain the most likely state sequence for the article under

Data	Section	Test pairs	Local-prod	Local- <i>d</i> -seq	HMM-prod	HMM- <i>d</i> -seq	Oracle zones
ART Corpus	Abstract	1633	57.0	52.9	<b>64.1</b>	55.0	80.8
	Intro	1640	44.5	54.6	58.1	<b>64.6</b>	94.0
ACL Conference	Abstract	8815	44.0	47.2	58.2	<b>63.7</b>	
	Intro	9966	54.5	53.0	64.4	<b>74.0</b>	
	Rel. wk.	10,000	54.6	54.4	57.3	<b>67.3</b>	

Table 8: Accuracy in differentiating permutation from original sections on ACL and ART test sets.

HMM-prod and HMM-*d*-seq models using Viterbi decoding. Then the proportion of sentences from each state of the two models are added as features.

We also add some fine-grained features from the local model. We represent sentences in the training set as either productions or *d*-sequence items and compute pairs of associated items  $(x_i, x_j)$  from adjacent sentences using the same chi-square test as in our pilot study. The most significant (lowest *p*-values) 30 pairs (each for production and *d*-seq) are taken as features.<sup>10</sup> For a test article, we compute features that represent how often each pair is present in the article such that  $x_i$  is in  $S_m$  and  $x_j$  is in  $S_{m+1}$ .

We perform this experiment for each section and there are about 90 to 140 features for the different sections. We cast the problem as a binary classification task: conference articles belong to one class and workshop to the other. Each class has 500 articles and so the baseline random accuracy is 50%. We perform 10-fold cross validation using logistic regression. Our results were 59.3% accuracy for distinguishing abstracts of conference versus workshop, 50.3% for introductions and 55.4% for related work. For abstracts and related work, these accuracies are significantly better than baseline (95% confidence level from a two-sided paired *t*-test comparing the accuracies from the 10 folds). It is possible that introductions in either case, talk in general about the field and importance of the problem addressed and hence have similar structure.

Our accuracies are not as high as on permutations examples because the task is clearly harder. It may also be the case that the prediction is more difficult for certain papers than for others. So we also analyze our results by the confidence provided by the classifier for the predicted class. We consider only the examples predicted above a certain confidence level and compute the accuracy on these predictions.

<sup>10</sup>A cutoff is applied such that the pair was seen at least 25 times in the training data.

Conf.	Abstract	Intro	Rel wk
$\geq 0.5$	59.3 (100.0)	50.3 (100.0)	55.4 (100.0)
$\geq 0.6$	63.8 (67.2)	50.8 (71.1)	58.6 (75.9)
$\geq 0.7$	67.2 (32.0)	54.4 (38.6)	63.3 (52.8)
$\geq 0.8$	74.0 (10.0)	51.6 (22.0)	63.0 (25.7)
$\geq 0.9$	91.7 (2.0)	30.6 (5.0)	68.1 (7.2)

Table 9: Accuracy (% examples) above each confidence level for the conference versus workshop task.

These results are shown in Table 9. The proportion of examples under each setting is also indicated.

When only examples above 0.6 confidence are examined, the classifier has a higher accuracy of 63.8% for abstracts and covers close to 70% of the examples. Similarly, when a cutoff of 0.7 is applied to the confidence for predicting related work sections, we achieve 63.3% accuracy for 53% of examples. So we can consider that 30 to 47% of the examples in the two sections respectively are harder to tell apart. Interestingly however even high confidence predictions on introductions remain incorrect.

These results show that our model can successfully distinguish the structure of articles beyond just clearly incoherent permutation examples.

## 7 Conclusion

Our work is the first to develop an unsupervised model for intentional structure and to show that it has good accuracy for coherence prediction and also complements entity and lexical structure of discourse. This result raises interesting questions about how patterns captured by these different coherence metrics vary and how they can be combined usefully for predicting coherence. We plan to explore these ideas in future work. We also want to analyze genre differences to understand if the strength of these coherence dimensions varies with genre.

## Abstract

Approximate search algorithms, such as cube pruning in syntactic machine translation, rely on the language model to estimate probabilities of sentence fragments. We contribute two changes that trade between accuracy of these estimates and memory, holding sentence-level scores constant. Common practice uses lower-order entries in an  $N$ -gram model to score the first few words of a fragment; this violates assumptions made by common smoothing strategies, including Kneser-Ney. Instead, we use a unigram model to score the first word, a bigram for the second, etc. This improves search at the expense of memory. Conversely, we show how to save memory by collapsing probability and backoff into a single value without changing sentence-level scores, at the expense of less accurate estimates for sentence fragments. These changes can be stacked, achieving better estimates with unchanged memory usage. In order to interpret changes in search accuracy, we adjust the pop limit so that accuracy is unchanged and report the change in CPU time. In a German-English Moses system with target-side syntax, improved estimates yielded a 63% reduction in CPU time; for a Hiero-style version, the reduction is 21%. The compressed language model uses 26% less RAM while equivalent search quality takes 27% more CPU. Source code is released as part of KenLM.

## 1 Introduction

Language model storage is typically evaluated in terms of speed, space, and accuracy. We introduce

a fourth dimension, rest cost quality, that captures how well the model scores sentence fragments for purposes of approximate search. Rest cost quality is distinct from accuracy in the sense that the score of a complete sentence is held constant. We first show how to improve rest cost quality over standard practice by using additional space. Then, conversely, we show how to compress the language model by making a pessimistic rest cost assumption<sup>1</sup>.

Language models are designed to assign probability to sentences. However, approximate search algorithms use estimates for sentence fragments. If the language model has order  $N$  (an  $N$ -gram model), then the first  $N - 1$  words of the fragment have incomplete context and the last  $N - 1$  words have not been completely used as context. Our baseline is common practice (Koehn et al., 2007; Dyer et al., 2010; Li et al., 2009) that uses lower-order entries from the language model for the first words in the fragment and no rest cost adjustment for the last few words. Formally, the baseline estimate for sentence fragment  $w_1^k$  is

$$\left( \prod_{n=1}^{N-1} p_N(w_n | w_1^{n-1}) \right) \left( \prod_{n=N}^k p_N(w_n | w_{n-N+1}^{n-1}) \right)$$

where each  $w_n$  is a word and  $p_N$  is an  $N$ -gram language model.

The problem with the baseline estimate lies in lower order entries  $p_N(w_n | w_1^{n-1})$ . Commonly used Kneser-Ney (Kneser and Ney, 1995) smoothing,

<sup>1</sup>Here, the term rest cost means an adjustment to the score of a sentence fragment but not to whole sentences. The adjustment may be good or bad for approximate search.

including the modified version (Chen and Goodman, 1998), assumes that a lower-order entry will only be used because a longer match could not be found<sup>2</sup>. Formally, these entries actually evaluate  $p_N(w_n|w_1^{n-1})$ , did not find  $w_0^n$ . For purposes of scoring sentence fragments, additional context is simply indeterminate, and the assumption may not hold.

As an example, we built 5-gram and unigram language models with Kneser-Ney smoothing on the same data. Sentence fragments frequently begin with “the”. Using a lower-order entry from the 5-gram model,  $\log_{10} p_5(\text{the}) = -2.49417$ . The unigram model does not condition on backing off, assigning  $\log_{10} p_1(\text{the}) = -1.28504$ . Intuitively, the 5-gram model is surprised, by more than an order of magnitude, to see “the” without matching words that precede it.

To remedy the situation, we train  $N$  language models on the same data. Each model  $p_n$  is an  $n$ -gram model (it has order  $n$ ). We then use  $p_n$  to score the  $n$ th word of a sentence fragment. Thus, a unigram model scores the first word of a sentence fragment, a bigram model scores the second word, and so on until either the  $n$ -gram is not present in the model or the first  $N - 1$  words have been scored. Storing probabilities from these models requires one additional value per  $n$ -gram in the model, except for  $N$ -grams where this probability is already stored.

Conversely, we can lower memory consumption relative to the baseline at the expense of poorer rest costs. Baseline models store two entries per  $n$ -gram: probability and backoff. We will show that the probability and backoff values in a language model can be collapsed into a single value for each  $n$ -gram without changing sentence probability. This transformation saves memory by halving the number of values stored per entry, but it makes rest cost estimates worse. Specifically, the rest cost pessimistically assumes that the model will back off to unigrams immediately following the sentence fragment.

The two modifications can be used independently or simultaneously. To measure the impact of their different rest costs, we experiment with cube pruning (Chiang, 2007) in syntactic machine transla-

tion. Cube pruning’s goal is to find high-scoring sentence fragments for the root non-terminal in the parse tree. It does so by going bottom-up in the parse tree, searching for high-scoring sentence fragments for each non-terminal. Within each non-terminal, it generates a fixed number of high-scoring sentence fragments; this is known as the *pop limit*. Increasing the pop limit therefore makes search more accurate but costs more time. By moderating the pop limit, improved accuracy can be interpreted as a reduction in CPU time and vice-versa.

## 2 Related Work

Vilar and Ney (2011) study several modifications to cube pruning and cube growing (Huang and Chiang, 2007). Most relevant is their use of a class-based language model for the first of two decoding passes. This first pass is cheaper because translation alternatives are likely to fall into the same class. Entries are scored with the maximum probability over class members (thereby making them no longer normalized). Thus, paths that score highly in this first pass may contain high-scoring paths under the lexicalized language model, so the second pass more fully explores these options. The rest cost estimates we describe here could be applied in both passes, so our work is largely orthogonal.

Zens and Ney (2008) present rest costs for phrase-based translation. These rest costs are based on factors external to the sentence fragment, namely output that the decoder may generate in the future. Our rest costs examine words internal to the sentence fragment, namely the first and last few words. We also differ by focusing on syntactic translation.

A wide variety of work has been done on language model compression. While data structure compression (Raj and Whittaker, 2003; Heafield, 2011) and randomized data structures (Talbot and Osborne, 2007; Guthrie and Hepple, 2010) are useful, here we are concerned solely with the values stored by these data structures. Quantization (Whittaker and Raj, 2001; Federico and Bertoldi, 2006) uses less bits to store each numerical value at the expense of model quality, including scores of full sentences, and is compatible with our approach. In fact, the lower-order probabilities might be quantized further than normal since these are used solely for rest cost

<sup>2</sup>Other smoothing techniques, including Witten-Bell (Witten and Bell, 1991), do not make this assumption.

purposes. Our compression technique reduces storage from two values, probability and backoff, to one value, theoretically halving the bits per value (except  $N$ -grams which all have backoff 1). This makes the storage requirement for higher-quality modified Kneser-Ney smoothing comparable to stupid backoff (Brants et al., 2007). Whether to use one smoothing technique or the other then becomes largely an issue of training costs and quality after quantization.

### 3 Contribution

#### 3.1 Better Rest Costs

As alluded to in the introduction, the first few words of a sentence fragment are typically scored using lower-order entries from an  $N$ -gram language model. However, Kneser-Ney smoothing (Kneser and Ney, 1995) conditions lower-order probabilities on backing off. Specifically, lower-order counts are adjusted to represent the number of unique extensions an  $n$ -gram has:

$$a(w_1^n) = \begin{cases} |\{w_0 : c(w_0^n) > 0\}| & \text{if } n < N \\ c(w_1^n) & \text{if } n = N \end{cases}$$

where  $c(w_1^n)$  is the number of times  $w_1^n$  appears in the training data<sup>3</sup>. This adjustment is also performed for modified Kneser-Ney smoothing. The intuition is based on the fact that the language model will base its probability on the longest possible match. If an  $N$ -gram was seen in the training data, the model will match it fully and use the smoothed count. Otherwise, the full  $N$ -gram was not seen in the training data and the model resorts to a shorter  $n$ -gram match. Probability of this shorter match is based on how often the  $n$ -gram is seen in different contexts. Thus, these shorter  $n$ -gram probabilities are not representative of cases where context is short simply because additional context is unknown at the time of scoring.

In some cases, we are able to determine that the model will back off and therefore the lower-order probability makes the appropriate assumption. Specifically, if  $vw_1^n$  does not appear in the model for any word  $v$ , then computing  $p(w_n|vw_1^{n-1})$  will al-

<sup>3</sup>Counts are not modified for  $n$ -grams bound to the beginning of sentence, namely those with  $w_1 = \langle s \rangle$ .

ways back off to  $w_1^{n-1}$  or fewer words<sup>4</sup>. This criterion is the same as used to minimize the length of left language model state (Li and Khudanpur, 2008) and can be retrieved for each  $n$ -gram without using additional memory in common data structures (Heafield et al., 2011).

Where it is unknown if the model will back off, we use a language model of the same order to produce a rest cost. Specifically, there are  $N$  language models, one of each order from 1 to  $N$ . The models are trained on the same corpus with the same smoothing parameters to the extent that they apply. We then compile these into one data structure where each  $n$ -gram record has three values:

1. Probability  $p_n$  from the  $n$ -gram language model
2. Probability  $p_N$  from the  $N$ -gram language model
3. Backoff  $b$  from the  $N$ -gram language model

For  $N$ -grams, the two probabilities are the same and backoff is always 1, so only one value is stored. Without pruning, the  $n$ -gram model contains the same  $n$ -grams as the  $N$ -gram model. With pruning, the two sets may be different, so we query the  $n$ -gram model in the normal way to score every  $n$ -gram in the  $N$ -gram model. The idea is that  $p_n$  is the average conditional probability that will be encountered once additional context becomes known. We also tried more complicated estimates by additionally interpolating upper bound, lower bound, and  $p_N$  with weights trained on cube pruning logs; none of these improved results in any meaningful way.

Formalizing the above, let  $w_1^k$  be a sentence fragment. Choose the largest  $s$  so that  $vw_1^s$  appears in the model for some  $v$ ; equivalently  $w_1^s$  is the left state described in Li and Khudanpur (2008). The

<sup>4</sup>Usually, this happens because  $w_1^n$  does not appear, though it can also happen that  $w_1^n$  appears but all  $vw_1^n$  were removed by pruning or filtering.

baseline estimate is

$$p_b(w_1^k) = \left( \prod_{n=1}^s p_N(w_n|w_1^{n-1}) \right) \cdot \left( \prod_{n=s+1}^{N+1} p_N(w_n|w_1^{n-1}) \right) \cdot \left( \prod_{n=N}^k p_N(w_n|w_{n-N+1}^{n-1}) \right). \quad (1)$$

while our improved estimate is

$$p_r(w_1^k) = \left( \prod_{n=1}^s p_n(w_n|w_1^{n-1}) \right) \cdot \left( \prod_{n=s+1}^{N+1} p_N(w_n|w_1^{n-1}) \right) \cdot \left( \prod_{n=N}^k p_N(w_n|w_{n-N+1}^{n-1}) \right). \quad (2)$$

The difference between these equations is that  $p_n$  is used for words in the left state i.e.  $1 \leq n \leq s$ . We have also abused notation by using  $p_N$  to denote both probabilities stored explicitly in the model and the model's backoff-smoothed probabilities when not present. It is not necessary to store backoffs for  $p_n$  because  $s$  was chosen such that all queried  $n$ -grams appear in the model.

This modification to the language model improves rest costs (and therefore quality or CPU time) at the expense of using more memory to store  $p_n$ . In the next section, we do the opposite: make rest costs worse to reduce storage size.

### 3.2 Less Memory

Many language model smoothing strategies, including modified Kneser-Ney smoothing, use the backoff algorithm shown in Figure 1. Given an  $n$ -gram  $w_1^n$ , the backoff algorithm bases probability on as much context as possible. Equivalently, it finds the minimum  $f$  so that  $w_f^n$  is in the model then uses  $p(w_n|w_f^{n-1})$  as a basis. Backoff penalties  $b$  are charged because a longer match was not found, forming the product

$$p(w_n|w_1^{n-1}) = p(w_n|w_f^{n-1}) \prod_{j=1}^{f-1} b(w_j^{n-1}) \quad (3)$$

Notably, the backoff penalties  $\{b(w_j^{n-1})\}_{j=1}^{n-1}$  are independent of  $w_n$ , though which backoff penalties are charged depends on  $f$  and therefore  $w_n$ .

```

backoff ← 1
for  $f = 1 \rightarrow n$  do
  if  $w_f^n$  is in the model then
    return  $p(w_n|w_f^{n-1}) \cdot \text{backoff}$ 
  else
    if  $w_f^{n-1}$  is in the model then
      backoff ← backoff ·  $b(w_f^{n-1})$ 
    end if
  end if
end for

```

Figure 1: The baseline backoff algorithm to compute  $p(w_n|w_1^{n-1})$ . It always terminates with a probability because even unknown words are treated as a unigram.

```

for  $f = 1 \rightarrow n$  do
  if  $w_f^n$  is in the model then
    return  $q(w_n|w_f^{n-1})$ 
  end if
end for

```

Figure 2: The run-time pessimistic backoff algorithm to find  $q(w_n|w_1^{n-1})$ . It assumes that  $q$  has been computed at model building time.

In order to save memory, we propose to account for backoff in a different way, defining  $q$

$$q(w_n|w_1^{n-1}) = \frac{p(w_n|w_f^{n-1}) \prod_{j=f}^n b(w_j^n)}{\prod_{j=f}^{n-1} b(w_j^{n-1})}$$

where again  $w_f^n$  is the longest matching entry in the model. The idea is that  $q$  is a term in the telescoping series that scores a sentence fragment, shown in equation (1) or (2). The numerator pessimistically charges all backoff penalties, as if the next word  $w_{n+1}$  will only match a unigram. When  $w_{n+1}$  is scored, the denominator of  $q(w_{n+1}|w_1^n)$  cancels out backoff terms that were wrongly charged. Once these terms are canceled, all that is left is  $p$ , the correct backoff penalties, and terms on the edge of the series.

**Proposition 1.** *The terms of  $q$  telescope. Formally, let  $w_1^k$  be a sentence fragment and  $f$  take the minimum value so that  $w_f^k$  is in the model. Then,*

$$q(w_1^k) = p(w_1^k) \prod_{j=f}^k b(w_j^k)$$

*Proof.* By induction on  $k$ . When  $k = 1$ ,  $f = 1$  since the word  $w_1$  is either in the vocabulary or mapped to  $\langle \text{unk} \rangle$  and treated like a unigram.

$$q(w_1) = \frac{p(w_1) \prod_{j=1}^1 b(w_j^1)}{\prod_{j=1}^0 b(w_j^0)} = p(w_1) b(w_1)$$

For  $k > 1$ ,

$$\begin{aligned} q(w_1^k) &= q(w_1^{k-1}) q(w_k | w_1^{k-1}) \\ &= \frac{q(w_1^{k-1}) p(w_k | w_f^{k-1}) \prod_{j=f}^k b(w_j^k)}{\prod_{j=f}^{k-1} b(w_j^{k-1})} \end{aligned}$$

where  $f$  has the lowest value such that  $w_f^k$  is in the model. Applying the inductive hypothesis to expand  $q(w_1^{k-1})$ , we obtain

$$\frac{p(w_1^{k-1}) \left( \prod_{j=e}^{k-1} b(w_j^{k-1}) \right) p(w_k | w_f^{k-1}) \prod_{j=f}^k b(w_j^k)}{\prod_{j=f}^{k-1} b(w_j^{k-1})}$$

where  $e$  has the lowest value such that  $w_e^{k-1}$  is in the model. The backoff terms cancel to yield

$$p(w_1^{k-1}) \left( \prod_{j=e}^{f-1} b(w_j^{k-1}) \right) p(w_k | w_f^{k-1}) \prod_{j=f}^k b(w_j^k)$$

By construction of  $e$ ,  $w_j^{k-1}$  is not in the model for all  $j < e$ . Hence,  $b(w_j^{k-1}) = 1$  implicitly for all  $j < e$ . Multiplying by 1,

$$p(w_1^{k-1}) \left( \prod_{j=1}^{f-1} b(w_j^{k-1}) \right) p(w_k | w_f^{k-1}) \prod_{j=f}^k b(w_j^k)$$

Recognizing the backoff equation (3) to simplify,

$$p(w_1^{k-1}) p(w_k | w_1^{k-1}) \prod_{j=f}^k b(w_j^k)$$

Finally, the conditional probability folds as desired

$$q(w_1^k) = p(w_1^k) \prod_{j=f}^k b(w_j^k)$$

□

We note that entries ending in  $\langle /s \rangle$  have back-off 1, so it follows from Proposition 1 that sentence-level scores are unchanged.

$$q(\langle s \rangle w_1^k \langle /s \rangle) = p(\langle s \rangle w_1^k \langle /s \rangle)$$

Proposition 1 characterizes  $q$  as a pessimistic rest cost on sentence fragments that scores sentences in exactly the same way as the baseline using  $p$  and  $b$ . To save memory, we simply store  $q$  in lieu of  $p$  and  $b$ . Compared with the baseline, this halves number of values from two to one float per  $n$ -gram, except  $N$ -grams that already have one value. The impact of this reduction is substantial, as seen in Section 4.3. Run-time scoring is also simplified as shown in Figure 2 since the language model locates the longest match  $w_f^n$  then returns the value  $q(w_n | w_1^{n-1}) = q(w_n | w_f^{n-1})$  without any calculation or additional lookup. Baseline language models either retrieve backoffs values with additional lookups (Stolcke, 2002; Federico et al., 2008) or modify the decoder to annotate sentence fragments with backoff information (Heafield, 2011); we have effectively moved this step to preprocessing. The disadvantage is that  $q$  is not a proper probability and it produces worse rest costs than does the baseline.

Language models are actually applied at two points in syntactic machine translation: scoring lexical items in grammar rules and during cube pruning. Grammar scoring is an offline and embarrassingly parallel process where memory is not as tight (since the phrase table is streamed) and fewer queries are made, so slow non-lossy compression and even network-based sharding can be used. We therefore use an ordinary language model for grammar scoring and only apply the compressed model during cube pruning. Grammar scoring impacts grammar pruning (by selecting only top-scoring grammar rules) and the order in which rules are tried during cube pruning.

### 3.3 Combined Scheme

Our two language model modifications can be trivially combined by using lower-order probabilities on the left of a fragment and by charging all backoff penalties on the right of a fragment. The net result is a language model that uses the same memory as the baseline but has better rest cost estimates.

## 4 Experiments

To measure the impact of different rest costs, we use the Moses chart decoder (Koehn et al., 2007) for the WMT 2011 German-English translation task (Callison-Burch et al., 2011). Using the Moses pipeline, we trained two syntactic German-English systems, one with target-side syntax and the other hierarchical with unlabeled grammar rules (Chiang, 2007). Grammar rules were extracted from Europarl (Koehn, 2005) using the Collins parser (Collins, 1999) for syntax on the English side. The language model interpolates, on the WMT 2010 test set, separate models built on Europarl, news commentary, and the WMT news data for each year. Models were built and interpolated using SRILM (Stolcke, 2002) with modified Kneser-Ney smoothing (Kneser and Ney, 1995; Chen and Goodman, 1998) and the default pruning settings. In all scenarios, the primary language model has order 5. For lower-order rest costs, we also built models with orders 1 through 4 then used the  $n$ -gram model to score  $n$ -grams in the 5-gram model. Feature weights were trained with MERT (Och, 2003) on the baseline using a pop limit of 1000 and 100-best output. Since final feature values are unchanged, we did not re-run MERT in each condition. Measurements were collected by running the decoder on the 3003-sentence test set.

### 4.1 Rest Costs as Prediction

Scoring the first few words of a sentence fragment is a prediction task. The goal is to predict what the probability will be when more context becomes known. In order to measure performance on this task, we ran the decoder on the hierarchical system with a pop limit of 1000. Every time more context became known, we logged<sup>5</sup> the prediction error (estimated log probability minus updated log probabili-

<sup>5</sup>Logging was only enabled for this experiment.

$n$	Mean	Lower			Baseline		
		Bias	MSE	Var	Bias	MSE	Var
1	-3.21	.10	.84	.83	-.12	.87	.86
2	-2.27	.04	.18	.17	-.14	.23	.24
3	-1.80	.02	.07	.07	-.09	.10	.09
4	-1.29	.01	.04	.04	-.10	.09	.08

Table 1: Bias (mean error), mean squared error, and variance (of the error) for the lower-order rest cost and the baseline. Error is the estimated log probability minus the final probability. Statistics were computed separately for the first word of a fragment ( $n = 1$ ), the second word ( $n = 2$ ), etc. The lower-order estimates are better across the board, reducing error in cube pruning. All numbers are in log base ten, as is standard for ARPA-format language models. Statistics were only collected for words with incomplete context.

ity) for both lower-order rest costs and the baseline. Table 1 shows the results.

Cube pruning uses relative scores, so bias matters less, though positive bias will favor rules with more arity. Variance matters the most because lower variance means cube pruning’s relative rankings are more accurate. Our lower-order rest costs are better across the board in terms of absolute bias, mean squared error, and variance.

### 4.2 Pop Limit Trade-Offs

The cube pruning pop limit is a trade-off between search accuracy and CPU time. Here, we measure how our rest costs improve (or degrade) that trade-off. Search accuracy is measured by the average model score of single-best translations. Model scores are scale-invariant and include a large constant factor; higher is better. We also measure overall performance with uncased BLEU (Papineni et al., 2002). CPU time is the sum of user and system time used by Moses divided by the number of sentences (3003). Timing includes time to load, though files were forced into the disk cache in advance. Our test machine has 64 GB of RAM and 32 cores. Results are shown in Figures 3 and 4.

Lower-order rest costs perform better in both systems, reaching plateau model scores and BLEU with less CPU time. The gain is much larger for tar-

Pop	Baseline			Lower Order			Pessimistic			Combined		
	CPU	Model	BLEU	CPU	Model	BLEU	CPU	Model	BLEU	CPU	Model	BLEU
2	3.29	-105.56	20.45	3.68	-105.44	20.79	3.74	-105.62	20.01	3.18	-105.49	20.43
10	5.21	-104.74	21.13	5.50	-104.72	21.26	5.43	-104.77	20.85	5.67	-104.75	21.10
50	23.30	-104.31	21.36	23.51	-104.24	21.38	23.68	-104.33	21.25	24.29	-104.22	21.34
500	54.61	-104.25	21.33	55.92	-104.15	21.38	54.23	-104.26	21.31	55.74	-104.15	21.40
700	64.08	-104.25	21.34	87.02	-104.14	21.42	68.74	-104.25	21.29	78.84	-104.15	21.41

(b) Model and BLEU scores near the plateau.

Figure 3: Target-syntax performance. CPU time and model score are averaged over 3003 sentences.

get syntax, where a pop limit of 50 outperforms the baseline with pop limit 700. CPU time per sentence is reduced to 23.5 seconds from 64.0 seconds, a 63.3% reduction. The combined setting, using the same memory as the baseline, shows a similar 62.1% reduction in CPU time. We attribute this difference to improved grammar rule scoring that impacts pruning and sorting. In the target syntax model, the grammar is not saturated (i.e. less pruning will still improve scores) but we nonetheless prune for tractability reasons. The lower-order rest costs are particularly useful for grammar pruning because lexical items are typically less than five words long (and frequently only word).

The hierarchical grammar is nearly saturated with respect to grammar pruning, so improvement there is due mostly to better search. In the hierarchical system, peak BLEU 22.34 is achieved under the lower-order condition with pop limits 50 and 200, while

other scenarios are still climbing to the plateau. With a pop limit of 1000, the baseline’s average model score is -101.3867. Better average models scores are obtained from the lower-order model with pop limit 690 using 79% of baseline CPU, the combined model with pop limit 900 using 97% CPU, and the pessimistic model with pop limit 1350 using 127% CPU.

Pessimistic compression does worsen search, requiring 27% more CPU in the hierarchical system to achieve the same quality. This is worthwhile to fit large-scale language models in memory, especially if the alternative is a remote language model.

### 4.3 Memory Usage

Our rest costs add a value (for lower-order probabilities) or remove a value (pessimistic compression) for each  $n$ -gram except those of highest order ( $n = N$ ). The combined condition adds one value

Pop	Baseline			Lower Order			Pessimistic			Combined		
	CPU	Model	BLEU	CPU	Model	BLEU	CPU	Model	BLEU	CPU	Model	BLEU
2	2.96	-101.85	21.19	2.44	-101.80	21.63	2.71	-101.90	20.85	3.05	-101.84	21.37
10	2.80	-101.60	21.90	2.42	-101.58	22.20	2.95	-101.63	21.74	2.69	-101.60	21.98
50	3.02	-101.47	22.18	3.11	-101.46	22.34	3.46	-101.48	22.08	2.67	-101.47	22.14
690	10.83	-101.39	22.28	11.45	-101.39	22.25	10.88	-101.40	22.25	11.19	-101.39	22.23
900	13.41	-101.39	22.27	14.00	-101.38	22.24	13.38	-101.39	22.25	14.09	-101.39	22.22
1000	14.50	-101.39	22.27	15.17	-101.38	22.25	15.09	-101.39	22.26	15.23	-101.39	22.23
1350	18.52	-101.38	22.27	19.16	-101.38	22.23	18.46	-101.39	22.25	18.61	-101.38	22.23
5000	59.67	-101.38	22.24	61.41	-101.38	22.22	59.76	-101.38	22.27	61.38	-101.38	22.22

(a) Numerical results for select pop limits.

(b) Model and BLEU scores near the plateau.

Figure 4: Hierarchical system performance. All values are averaged over 3003 sentences.

and removes another, so it uses the same memory as the baseline. The memory footprint of adding or removing a value depends on the number of such  $n$ -grams, the underlying data structure, and the extent of quantization. Our test language model has 135 million  $n$ -grams for  $n < 5$  and 56 million 5-grams. Memory usage was measured for KenLM data structures (Heafield, 2011) and minimal perfect hashing (Guthrie and Hepple, 2010). For minimal perfect hashing, we assume the Compress, Hash and Displace algorithm (Belazzougui et al., 2008) with 8-bit signatures and 8-bit quantization. Table 2 shows the results. Storage size of the smallest model is reduced by 26%, bringing higher-quality smoothed models in line with stupid backoff models that also store one value per  $n$ -gram.

Structure	Baseline	Change	%
Probing	4,072	517	13%
Trie	2,647	506	19%
8-bit quantized trie	1,236	140	11%
8-bit minimal perfect hash	540	140	26%

Table 2: Size in megabytes of our language model, excluding operating system overhead. Change is the cost of adding an additional value to store lower-order probabilities. Equivalently, it is the savings from pessimistic compression.

## 5 Conclusion

Our techniques reach plateau-level BLEU scores with less time or less memory. Efficiently storing lower-order probabilities and using them as rest costs improves both cube pruning (21% CPU reduction in a hierarchical system) and model filtering (net 63% CPU time reduction with target syntax) at the expense of 13-26% more RAM for the language model. This model filtering improvement is surprising both in the impact relative to changing the pop limit and simplicity of implementation, since it can be done offline. Compressing the language model to halve the number of values per  $n$ -gram (except  $N$ -grams) results in a 13-26% reduction in RAM with 26% over the smallest model, costing 27% more CPU and leaving overall sentence scores unchanged. This compression technique is likely to have more general application outside of machine translation, especially where only sentence-level scores are required. Source code is being released<sup>6</sup> under the LGPL as part of KenLM (Heafield, 2011).

## Abstract

Independence between sentences is an assumption deeply entrenched in the models and algorithms used for statistical machine translation (SMT), particularly in the popular dynamic programming beam search decoding algorithm. This restriction is an obstacle to research on more sophisticated discourse-level models for SMT. We propose a stochastic local search decoding method for phrase-based SMT, which permits free document-wide dependencies in the models. We explore the stability and the search parameters of this method and demonstrate that it can be successfully used to optimise a document-level semantic language model.

## 1 Motivation

In the field of translation studies, it is undisputed that discourse-wide context must be considered carefully for good translation results (Hatim and Mason, 1990). By contrast, the state of the art in statistical machine translation (SMT), despite significant advances in the last twenty years, still assumes that texts can be translated sentence by sentence under strict independence assumptions, even though it is well known that certain linguistic phenomena such as pronominal anaphora cannot be translated correctly without referring to extra-sentential context. This is true both for the phrase-based and the syntax-based approach to SMT. In the rest of this paper, we shall concentrate on phrase-based SMT.

One reason why it is difficult to experiment with document-wide models for phrase-based SMT is that the dynamic programming (DP) algorithm

which has been used almost exclusively for decoding SMT models in the recent literature has very strong assumptions of locality built into it. DP beam search for phrase-based SMT was described by Koehn et al. (2003), extending earlier work on word-based SMT (Tillmann et al., 1997; Och et al., 2001; Tillmann and Ney, 2003). This algorithm constructs output sentences by starting with an empty hypothesis and adding output words at the end until translations for all source words have been generated. The core models of phrase-based SMT, in particular the n-gram language model (LM), only depend on a constant number of output words to the left of the word being generated. This fact is exploited by the search algorithm with a DP technique called *hypothesis recombination* (Och et al., 2001), which permits the elimination of hypotheses from the search space if they coincide in a certain number of final words with a better hypothesis and no future expansion can possibly invert the relative ranking of the two hypotheses under the given models. Hypothesis recombination achieves a substantial reduction of the search space without affecting search optimality and makes it possible to use aggressive pruning techniques for fast search while still obtaining good results.

The downside of this otherwise excellent approach is that it only works well with models that have a local dependency structure similar to that of an n-gram language model, so they only depend on a small context window for each target word. Sentence-local models with longer dependencies can be added, but doing so greatly increases the risk for search errors by inhibiting hypothesis recombination. Cross-sentence dependencies cannot be directly integrated into DP SMT decoding in

any obvious way, especially if joint optimisation of a number of interdependent decisions over an entire document is required. Research into models with a more varied, non-local dependency structure is to some extent stifled by the difficulty of decoding such models effectively, as can be seen by the problems some researchers encountered when they attempted to solve discourse-level problems. Consider, for instance, the work on cache-based language models by Tiedemann (2010) and Gong et al. (2011), where error propagation was a serious issue, or the works on pronominal anaphora by Le Nagard and Koehn (2010), who implemented cross-sentence dependencies with an ad-hoc two-pass decoding strategy, and Hardmeier and Federico (2010) with the use of an external decoder driver to manage backward-only dependencies between sentences.

In this paper, we present a method for decoding complete documents in phrase-based SMT. Our decoder uses a local search approach whose state consists of a complete translation of an entire document at any time. The initial state is improved by the application of a series of operations using a hill climbing strategy to find a (local) maximum of the score function. This setup gives us complete freedom to define scoring functions over the entire document. Moreover, by optionally initialising the state with the output of a traditional DP decoder, we can ensure that the final hypothesis is no worse than what would have been found by DP search alone. We start by describing the decoding algorithm and the state operations used by our decoder, then we present empirical results demonstrating the effectiveness of our approach and its usability with a document-level semantic language model, and finally we discuss some related work.

## 2 SMT Decoding by Hill Climbing

In this section, we formally describe the phrase-based SMT model implemented by our decoder as well as the decoding algorithm we use.

### 2.1 SMT Model

Our decoder is based on local search, so its state at any time is a representation of a complete translation of the entire document. Even though the decoder operates at the document level, it is important to keep

track of sentence boundaries, and the individual operations that are applied to the state are still confined to sentence scope, so it is useful to decompose the state of a document into the state of its sentences, and we define the overall state  $S$  as a sequence of sentence states:

$$S = S_1 S_2 \dots S_N, \quad (1)$$

where  $N$  is the number of sentences. This implies that we constrain the decoder to emit exactly one output sentence per input sentence.

Let  $i$  be the number of a sentence and  $m_i$  the number of input tokens of this sentence,  $p$  and  $q$  (with  $1 \leq p \leq q \leq m_i$ ) be positions in the input sentence and  $[p; q]$  denote the set of positions from  $p$  up to and including  $q$ . We say that  $[p; q]$  precedes  $[p'; q']$ , or  $[p; q] \prec [p'; q']$ , if  $q < p'$ . Let  $\Phi_i([p; q])$  be the set of translations for the source phrase covering positions  $[p; q]$  in the input sentence  $i$  as given by the phrase table. We call  $A = \langle [p; q], \phi \rangle$  an *anchored phrase pair* with coverage  $C(A) = [p; q]$  if  $\phi \in \Phi_i([p; q])$  is a target phrase translating the source words at positions  $[p; q]$ . Then a sequence of  $n_i$  anchored phrase pairs

$$S_i = A_1 A_2 \dots A_{n_i} \quad (2)$$

is a valid sentence state for sentence  $i$  if the following two conditions hold:

1. The coverage sets  $C(A_j)$  for  $j$  in  $1, \dots, n_i$  are mutually disjoint, and
2. the anchored phrase pairs jointly cover the complete input sentence, or

$$\bigcup_{j=1}^{n_i} C(A_j) = [1; m_i]. \quad (3)$$

Let  $f(S)$  be a scoring function mapping a state  $S$  to a real number. As usual in SMT, it is assumed that the scoring function can be decomposed into a linear combination of  $K$  feature functions  $h_k(S)$ , each with a constant weight  $\lambda_k$ , so

$$f(S) = \sum_{k=1}^K \lambda_k h_k(S). \quad (4)$$

The problem addressed by the decoder is the search for the state  $\hat{S}$  with maximal score, such that

$$\hat{S} = \arg \max_S f(S). \quad (5)$$

The feature functions implemented in our baseline system are identical to the ones found in the popular Moses SMT system (Koehn et al., 2007). In particular, our decoder has the following feature functions:

1. phrase translation scores provided by the phrase table including forward and backward conditional probabilities, lexical weights and a phrase penalty (Koehn et al., 2003),
2. n-gram language model scores implemented with the KenLM toolkit (Heafield, 2011),
3. a word penalty score,
4. a distortion model with geometric decay (Koehn et al., 2003), and
5. a feature indicating the number of times a given distortion limit is exceeded in the current state.

In our experiments, the last feature is used with a fixed weight of negative infinity in order to limit the gaps between the coverage sets of adjacent anchored phrase pairs to a maximum value. In DP search, the distortion limit is usually enforced directly by the search algorithm and is not added as a feature. In our decoder, however, this restriction is not required to limit complexity, so we decided to add it among the scoring models.

## 2.2 Decoding Algorithm

The decoding algorithm we use (algorithm 1) is very simple. It starts with a given initial document state. In the main loop, which extends from line 3 to line 12, it generates a successor state  $S'$  for the current state  $S$  by calling the function `Neighbour`, which non-deterministically applies one of the operations described in section 3 of this paper to  $S$ . The score of the new state is compared to that of the previous one. If it meets a given acceptance criterion,  $S'$  becomes the current state, else search continues from the previous state  $S$ . For the experiments in this paper, we use the *hill climbing acceptance criterion*, which simply accepts a new state if its score is higher than that of the current state. Other acceptance criteria are possible and could be used to endow the search algorithm with stochastic behaviour.

The main loop is repeated until a maximum number of steps (*step limit*) is reached or until a maximum number of moves are rejected in a row (*rejection limit*).

---

### Algorithm 1 Decoding algorithm

---

**Input:** an initial document state  $S$ ;  
search parameters  $maxsteps$  and  $maxrejected$   
**Output:** a modified document state

```

1:  $nsteps \leftarrow 0$ 
2:  $nrejected \leftarrow 0$ 
3: while  $nsteps < maxsteps$  and
    $nrejected < maxrejected$  do
4:    $S' \leftarrow \text{Neighbour}(S)$ 
5:   if  $\text{Accept}(f(S'), f(S))$  then
6:      $S \leftarrow S'$ 
7:      $nrejected \leftarrow 0$ 
8:   else
9:      $nrejected \leftarrow nrejected + 1$ 
10:  end if
11:   $nsteps \leftarrow nsteps + 1$ 
12: end while
13: return  $S$ 

```

---

A notable difference between this algorithm and other hill climbing algorithms that have been used for SMT decoding (Germann et al., 2004; Langlais et al., 2007) is its non-determinism. Previous work for sentence-level decoding employed a *steepest ascent* strategy which amounts to enumerating the complete neighbourhood of the current state as defined by the state operations and selecting the next state to be the best state found in the neighbourhood of the current one. Enumerating all neighbours of a given state, costly as it is, has the advantage that it makes it easy to prove local optimality of a state by recognising that all possible successor states have lower scores. It can be rather inefficient, since at every step only one modification will be adopted; many of the modifications that are discarded will very likely be generated anew in the next iteration.

As we extend the decoder to the document level, the size of the neighbourhood that would have to be explored in this way increases considerably. Moreover, the inefficiency of the steepest ascent approach potentially increases as well. Very likely, a promising move in one sentence will remain promising after a modification has been applied to another sen-

tence, even though this is not guaranteed to be true in the presence of cross-sentence models. We therefore adopt a *first-choice hill climbing* strategy that non-deterministically generates successor states and accepts the first one that meets the acceptance criterion. This frees us from the necessity of generating the full set of successors for each state. On the downside, if the full successor set is not known, it is no longer possible to prove local optimality of a state, so we are forced to use a different condition for halting the search. We use a combination of two limits: The step limit is a hard limit on the resources the user is willing to expend on the search problem. The value of the rejection limit determines how much of the neighbourhood is searched for better successors before a state is accepted as a solution; it is related to the probability that a state returned as a solution is in fact locally optimal.

To simplify notations in the description of the individual state operations, we write

$$S_i \longrightarrow S'_i \quad (6)$$

to signify that a state operation, when presented with a document state as in equation 1 and acting on sentence  $i$ , returns a new document state of

$$S' = S_1 \dots S_{i-1} S'_i S_{i+1} \dots S_N. \quad (7)$$

Similarly,

$$S_i : A_j \dots A_{j+h-1} \longrightarrow A'_1 \dots A'_{h'} \quad (8)$$

is equivalent to

$$S_i \longrightarrow A_1 \dots A_{j-1} A'_1 \dots A'_{h'} A_{j+h} \dots A_{n_i} \quad (9)$$

and indicates that the operation returns a state in which a sequence of  $h$  consecutive anchored phrase pairs has been replaced by another sequence of  $h'$  anchored phrase pairs.

### 2.3 Efficiency Considerations

When implementing the feature functions for the decoder, we have to exercise some care to avoid re-computing scores for the whole document at every iteration. To achieve this, the scores are computed completely only once, at the beginning of the decoding run. In subsequent iterations, scoring functions are presented with the scores of the previous

iteration and a list of modifications produced by the state operation, a set of tuples  $\langle i, r, s, A'_1 \dots A'_{h'} \rangle$ , each indicating that the document should be modified as described by

$$S_i : A_r \dots A_s \longrightarrow A'_1 \dots A'_{h'}. \quad (10)$$

If a feature function is decomposable in some way, as all the standard features developed under the constraints of DP search are, it can then update the state simply by subtracting and adding score components pertaining to the modified parts of the document. Feature functions have the possibility to store their own state information along with the document state to make sure the required information is available. Thus, the framework makes it possible to exploit decomposability for efficient scoring without imposing any particular decomposition on the features as beam search does.

To make scoring even more efficient, scores are computed in two passes: First, every feature function is asked to provide an upper bound on the score that will be obtained for the new state. In some cases, it is possible to calculate reasonable upper bounds much more efficiently than computing the exact feature value. If the upper bound fails to meet the acceptance criterion, the new state is discarded right away; if not, the full score is computed and the acceptance criterion is tested again.

Among the basic SMT models, this two-pass strategy is only used for the n-gram LM, which requires fairly expensive parameter lookups for scoring. The scores of all the other baseline models are fully computed during the first scoring pass. The n-gram model is more complex. In its state information, it keeps track of the LM score and LM library state for each word. The first scoring pass then identifies the words whose LM scores are affected by the current search step. This includes the words changed by the search operation as well as the words whose LM history is modified. The range of the history dependencies can be determined precisely by considering the “valid state length” information provided by the KenLM library. In the first pass, the LM scores of the affected words are subtracted from the total score. The model only looks up the new LM scores for the affected words and updates the total score if the new search state passes the first acceptance check. This two-pass scoring approach allows us

to avoid LM lookups altogether for states that will be rejected anyhow because of low scores from the other models, e. g. because the distortion limit is violated.

Model score updates become more complex and slower as the number of dependencies of a model increases. While our decoding algorithm does not impose any formal restrictions on the number or type of dependencies that can be handled, there will be practical limits beyond which decoding becomes unacceptably slow or the scoring code becomes very difficult to maintain. These limits are however fairly independent of the types of dependencies handled by a model, which permits the exploration of more varied model types than those handled by DP search.

## 2.4 State Initialisation

Before the hill climbing decoding algorithm can be run, an initial state must be generated. The closer the initial state is to an optimum, the less work remains to be done for the algorithm. If the algorithm is to be self-contained, initialisation must be relatively uninformed and can only rely on some general prior assumptions about what might be a good initial guess. On the other hand, if optimal results are sought after, it pays off to invest some effort into a good starting point. One way to do this is to run DP search first.

For uninformed initialisation, we chose to implement a very simple procedure based only on the observation that, at least for language pairs involving the major European languages, it is usually a good guess to keep the word order of the output very similar to that of the input. We therefore create the initial state by selecting, for each sentence in the document, a sequence of anchored phrase pairs covering the input sentence in monotonic order, that is, such that for all pairs of adjacent anchored phrase pairs  $A_j$  and  $A_{j+1}$ , we have that  $C(A_j) \prec C(A_{j+1})$ .

For initialisation with DP search, we first run the Moses decoder (Koehn et al., 2007) with default search parameters and the same models as those used by our decoder. Then we extract the best output hypothesis from the search graph of the decoder and map it into a sequence of anchored phrase pairs in the obvious way. When the document-level decoder is used with models that are incompatible with beam search, Moses can be run with a subset of the models in order to find an approximation of the solution

which is then refined with the complete feature set.

## 3 State Operations

Given a document state  $S$ , the decoder uses a neighbourhood function `Neighbour` to simulate a move in the state space. The neighbourhood function non-deterministically selects a type of state operation and a location in the document to apply it to and returns the resulting new state. We use a set of three operations that has the property that every possible document state can be reached from every other state in a sequence of moves.

Designing operations for state transitions in local search for phrase-based SMT is a problem that has been addressed in the literature (Langlais et al., 2007; Arun et al., 2010). Our decoder’s first-choice hill climbing strategy never enumerates the full neighbourhood of a state. We therefore place less emphasis than previous work on defining a compact neighbourhood, but allow the decoder to make quite extensive changes to a state in a single step with a certain probability. Otherwise our operations are similar to those used by Arun et al. (2010).

All of the operations described in this paper make changes to a single sentence only. Each time it is called, the `Neighbour` function selects a sentence in the document with a probability proportional to the number of input tokens in each sentence to ensure a fair distribution of the decoder’s attention over the words in the document regardless of varying sentence lengths.

### 3.1 Changing Phrase Translations

The `change-phrase-translation` operation replaces the translation of a single phrase with a random translation with the same coverage taken from the phrase table. Formally, the operation selects an anchored phrase pair  $A_j$  by drawing uniformly from the elements of  $S_i$  and then draws a new translation  $\phi'$  uniformly from the set  $\Phi_i(C(A_j))$ . The new state is given by

$$S_i : A_j \longrightarrow \langle C(A_j), \phi' \rangle. \quad (11)$$

### 3.2 Changing Word Order

The `swap-phrases` operation affects the output word order without changing the phrase translations.

It exchanges two anchored phrase pairs  $A_j$  and  $A_{j+h}$ , resulting in an output state of

$$S_i : A_j \dots A_{j+h} \longrightarrow A_{j+h} A_{j+1} \dots A_{j+h-1} A_j. \quad (12)$$

The start location  $j$  is drawn uniformly from the eligible sentence positions; the swap range  $h$  comes from a geometric distribution with configurable decay. Other word-order changes such as a one-way move operation that does not require another movement in exchange or more advanced permutations can easily be defined.

### 3.3 Resegmentation

The most complex operation is *resegment*, which allows the decoder to modify the segmentation of the source phrase. It takes a number of anchored phrase pairs that form a contiguous block both in the input and in the output and replaces them with a new set of phrase pairs covering the same span of the input sentence. Formally,

$$S_i : A_j \dots A_{j+h-1} \longrightarrow A'_1 \dots A'_{h'} \quad (13)$$

such that

$$\bigcup_{j'=j}^{j+h-1} C(A_{j'}) = \bigcup_{j'=1}^{h'} C(A'_{j'}) = [p; q] \quad (14)$$

for some  $p$  and  $q$ , where, for  $j' = 1, \dots, h'$ , we have that  $A'_{j'} = \langle [p_{j'}; q_{j'}], \phi_{j'} \rangle$ , all  $[p_{j'}; q_{j'}]$  are mutually disjoint and each  $\phi_{j'}$  is randomly drawn from  $\Phi_i([p_{j'}; q_{j'}])$ .

Regardless of the ordering of  $A_j \dots A_{j+h-1}$ , the *resegment* operation always generates a sequence of anchored phrase pairs in linear order, such that  $C(A'_{j'}) \prec C(A'_{j'+1})$  for  $j' = 1, \dots, h' - 1$ .

As for the other operations,  $j$  is generated uniformly and  $h$  is drawn from a geometric distribution with a decay parameter. The new segmentation is generated by extending the sequence of anchored phrase pairs with random elements starting at the next free position, proceeding from left to right until the whole range  $[p; q]$  is covered.

## 4 Experimental Results

In this section, we present the results of a series of experiments with our document decoder. The

goal of our experiments is to demonstrate the behaviour of the decoder and characterise its response to changes in the fundamental search parameters.

The SMT models for our experiments were created with a subset of the training data for the English-French shared task at the WMT 2011 workshop (Callison-Burch et al., 2011). The phrase table was trained on Europarl, news-commentary and UN data. To reduce the training data to a manageable size, singleton phrase pairs were removed before the phrase scoring step. Significance-based filtering (Johnson et al., 2007) was applied to the resulting phrase table. The language model was a 5-gram model with Kneser-Ney smoothing trained on the monolingual News corpus with IRSTLM (Federico et al., 2008). Feature weights were trained with Minimum Error-Rate Training (MERT) (Och, 2003) on the news-test2008 development set using the DP beam search decoder and the MERT implementation of the Moses toolkit (Koehn et al., 2007). Experimental results are reported for the newstest2009 test set, a corpus of 111 newswire documents totalling 2,525 sentences or 65,595 English input tokens.

### 4.1 Stability

An important difference between our decoder and the classical DP decoder as well as previous work in SMT decoding with local search is that our decoder is inherently non-deterministic. This implies that repeated runs of the decoder with the same search parameters, input and models will not, in general, find the same local maximum of the score space. The first empirical question we ask is therefore how different the results are under repeated runs. The results in this and the next section were obtained with random state initialisation, i. e. without running the DP beam search decoder.

Figure 1 shows the results of 7 decoder runs with the models described above, translating the news-test2009 test set, with a step limit of  $2^{27}$  and a rejection limit of 100,000. The  $x$ -axis of both plots shows the number of decoding steps on a logarithmic scale, so the number of steps is doubled between two adjacent points on the same curve. In the left plot, the  $y$ -axis indicates the model score optimised by the decoder summed over all 2525 sentences of the document. In the right plot, the case-sensitive BLEU score (Papineni et al., 2002) of the current decoder

Figure 1: Score stability in repeated decoder runs

state against a reference translation is displayed.

We note, as expected, that the decoder achieves a considerable improvement of the initial state with diminishing returns as decoding continues. Between  $2^8$  and  $2^{14}$  steps, the score increases at a roughly logarithmic pace, then the curve flattens out, which is partly due to the fact that decoding for some documents effectively stopped when the maximum number of rejections was reached. The BLEU score curve shows a similar increase, from an initial score below 5% to a maximum of around 21.5%. This is below the score of 22.45% achieved by the beam search decoder with the same models, which is not surprising considering that our decoder approximates a more difficult search problem, from which a number of strong independence assumptions have been lifted, without, at the moment, having any stronger models at its disposal to exploit this additional freedom for better translation.

In terms of stability, there are no dramatic differences between the decoder runs. Indeed, the small differences that exist are hardly discernible in the plots. The model scores at the end of the decoding run range between  $-158767.9$  and  $-158716.9$ , a relative difference of only about 0.03%. Final BLEU scores range from 21.41% to 21.63%, an interval that is not negligible, but comparable to the variance observed when, e. g., feature weights from repeated MERT runs are used with one and the same SMT system. Note that these results were obtained with random state initialisation. With DP initialisation, score differences between repeated runs rarely

exceed 0.02 absolute BLEU percentage points.

Overall, we conclude that the decoding results of our algorithm are reasonably stable despite the non-determinism inherent in the procedure. In our subsequent experiments, the evaluation scores reported are calculated as the mean of three runs for each experiment.

## 4.2 Search Algorithm Parameters

The hill climbing algorithm we use has two parameters which govern the trade-off between decoding time and the accuracy with which a local maximum is identified: The *step limit* stops the search process after a certain number of steps regardless of the search progress made or lack thereof. The *rejection limit* stops the search after a certain number of unsuccessful attempts to make a step, when continued search does not seem to be promising. In most of our experiments, we used a step limit of  $2^{27} \approx 1.3 \cdot 10^8$  and a rejection limit of  $10^5$ . In practice, decoding terminates by reaching the rejection limit for the vast majority of documents. We therefore examined the effect of different rejection limits on the learning curves. The results are shown in figure 2.

The results show that continued search does pay off to a certain extent. Indeed, the curve for rejection limit  $10^7$  seems to indicate that the model score increases roughly logarithmically, albeit to a higher base, even after the curve has started to flatten out at  $2^{14}$  steps. At a certain point, however, the probability of finding a good successor state drops rather sharply by about two orders of magnitude, as

Figure 2: Search performance at different rejection limits

evidenced by the fact that a rejection limit of  $10^6$  does not give a large improvement over one of  $10^5$ , while one of  $10^7$  does. The continued model score improvement also results in an increase in BLEU scores, and with a BLEU score of 22.1 % the system with rejection limit  $10^7$  is fairly close to the score of 22.45 % obtained by DP beam search.

Obviously, more exact search comes at a cost, and in this case, it comes at a considerable cost, which is an explosion of the time required to decode the test set from 4 minutes at rejection limit  $10^3$  to 224 minutes at rejection limit  $10^5$  and 38 hours 45 minutes at limit  $10^7$ . The DP decoder takes 31 minutes for the same task. We conclude that the rejection limit of  $10^5$  selected for our experiments, while technically suboptimal, realises a good trade-off between decoding time and accuracy.

### 4.3 A Semantic Document Language Model

In this section, we present the results of the application of our decoder to an actual SMT model with cross-sentence features. Our model addresses the problem of *lexical cohesion*. In particular, it rewards the use of semantically related words in the translation output by the decoder, where semantic distance is measured with a word space model based on Latent Semantic Analysis (LSA). LSA has been applied to semantic language modelling in previous research with some success (Coccaro and Jurafsky, 1998; Bellegarda, 2000; Wandmacher and Antoine, 2007). In SMT, it has mostly been used for domain adaptation (Kim and Khudanpur, 2004; Tam et al.,

2007), or to measure sentence similarities (Banchs and Costa-jussà, 2011).

The model we use is inspired by Bellegarda (2000). It is a Markov model, similar to a standard n-gram model, and assigns to each content word a score given a history of  $n$  preceding content words, where  $n = 30$  below. Scoring relies on a 30-dimensional LSA word vector space trained with the S-Space software (Jurgens and Stevens, 2010). The score is defined based on the cosine similarity between the word vector of the predicted word and the mean word vector of the words in the history, which is converted to a probability by histogram lookup as suggested by Bellegarda (2000). The model is structurally different from a regular n-gram model in that word vector n-grams are defined over content words occurring in the word vector model only and can cross sentence boundaries. Stop words, identified by an extensive stop word list and amounting to around 60 % of the tokens, are scored by a different mechanism based on their relative frequency (undiscounted unigram probability) in the training corpus. In sum, the score produced by the semantic document LM has the following form:

$$h(w|h) = \begin{cases} p_{\text{unigr}}(w) & \text{if } w \text{ is a stop word, else} \\ \alpha p_{\text{cos}}(w|h) & \text{if } w \text{ is known, else} \\ \varepsilon & \text{if } w \text{ is unknown,} \end{cases} \quad (15)$$

where  $\alpha$  is the proportion of content words in the training corpus and  $\varepsilon$  is a small fixed probability. It is integrated into the decoder as an extra feature function. Since we lack an automatic method for

training the feature weights of document-wide features, its weight was selected by grid search over a number of values, comparing translation performance for the newstest2009 test set.

In these experiments, we used DP beam search to initialise the state of our local search decoder. Three results are presented (table 1): The first table row shows the baseline performance using DP beam search with standard sentence-local features only. The scores in the second row were obtained by running the hill climbing decoder with DP initialisation, but without adding any models. A marginal increase in scores for all three test sets demonstrates that the hill climbing decoder manages to fix some of the search errors made by the DP search. The last row contains the scores obtained by adding in the semantic language model. Scores are presented for three publicly available test sets from recent WMT Machine Translation shared tasks, of which one (newstest2009) was used to monitor progress during development and select the final model.

Adding the semantic language model results in a small increase in NIST scores (Dodgington, 2002) for all three test sets as well as a small BLEU score gain (Papineni et al., 2002) for two out of three corpora. We note that the NIST score turned out to react more sensitively to improvements due to the semantic LM in all our experiments, which is reasonable because the model specifically targets content words, which benefit from the information weighting done by the NIST score. While the results we present do not constitute compelling evidence in favour of our semantic LM in its current form, they do suggest that this model could be improved to realise higher gains from cross-sentence semantic information. They support our claim that cross-sentence models should be examined more closely and that existing methods should be adapted to deal with them, a problem addressed by our main contribution, the local search document decoder.

## 5 Related Work

Even though DP beam search (Koehn et al., 2003) has been the dominant approach to SMT decoding in recent years, methods based on local search have been explored at various times. For word-based SMT, greedy hill-climbing techniques were advo-

cated as a faster replacement for beam search (Germann et al., 2001; Germann, 2003; Germann et al., 2004), and a problem formulation specifically targeting word reordering with an efficient word reordering algorithm has been proposed (Eisner and Tromble, 2006).

A local search decoder has been advanced as a faster alternative to beam search also for phrase-based SMT (Langlais et al., 2007; Langlais et al., 2008). That work anticipates many of the features found in our decoder, including the use of local search to refine an initial hypothesis produced by DP beam search. The possibility of using models that do not fit well into the beam search paradigm is mentioned and illustrated with the example of a reversed n-gram language model, which the authors claim would be difficult to implement in a beam search decoder. Similarly to the work by Germann et al. (2001), their decoder is deterministic and explores the entire neighbourhood of a state in order to identify the most promising step. Our main contribution with respect to the work by Langlais et al. (2007) is the introduction of the possibility of handling document-level models by lifting the assumption of sentence independence. As a consequence, enumerating the entire neighbourhood becomes too expensive, which is why we resort to a “first-choice” strategy that non-deterministically generates states and accepts the first one encountered that meets the acceptance criterion.

More recently, Gibbs sampling was proposed as a way to generate samples from the posterior distribution of a phrase-based SMT decoder (Arun et al., 2009; Arun et al., 2010), a process that resembles local search in its use of a set of state-modifying operators to generate a sequence of decoder states. Where local search seeks for the best state attainable from a given initial state, Gibbs sampling produces a representative sample from the posterior. Like all work on SMT decoding that we know of, the Gibbs sampler presented by Arun et al. (2010) assumes independence of sentences and considers the complete neighbourhood of each state before taking a sample.

## 6 Conclusion

In the last twenty years of SMT research, there has been a strong assumption that sentences in a text

Table 1: Experimental results with a cross-sentence semantic language model

are independent of one another, and discourse context has been largely neglected. Several factors have contributed to this. Developing good discourse-level models is difficult, and considering the modest translation quality that has long been achieved by SMT, there have been more pressing problems to solve and lower hanging fruit to pick. However, we argue that the popular DP beam search algorithm, which delivers excellent decoding performance, but imposes a particular kind of local dependency structure on the feature models, has also had its share in driving researchers away from discourse-level problems.

In this paper, we have presented a decoding procedure for phrase-based SMT that makes it possible to define feature models with cross-sentence dependencies. Our algorithm can be combined with DP beam search to leverage the quality of the traditional approach with increased flexibility for models at the discourse level. We have presented preliminary results on a cross-sentence semantic language model addressing the problem of lexical cohesion to demonstrate that this kind of models is worth exploring further. Besides lexical cohesion, cross-sentence models are relevant for other linguistic phenomena such as pronominal anaphora or verb tense selection. We believe that SMT research has reached a point of maturity where discourse phenomena should not be ignored any longer, and we consider our decoder to be a step towards this goal.

## Abstract

Decoding algorithms for syntax based machine translation suffer from high computational complexity, a consequence of intersecting a language model with a context free grammar. Left-to-right decoding, which generates the target string in order, can improve decoding efficiency by simplifying the language model evaluation. This paper presents a novel left to right decoding algorithm for tree-to-string translation, using a bottom-up parsing strategy and dynamic future cost estimation for each partial translation. Our method outperforms previously published tree-to-string decoders, including a competing left-to-right method.

## 1 Introduction

In recent years there has been rapid progress in the development of tree-to-string models for statistical machine translation. These models use the syntactic parse tree of the source language to inform its translation, which allows the models to capture consistent syntactic transformations between the source and target languages, e.g., from subject-verb-object to subject-object-verb word orderings. Decoding algorithms for grammar-based translation seek to find the best string in the intersection between a weighted context free grammar (the translation mode, given a source string/tree) and a weighted finite state acceptor (an n-gram language model). This intersection

is problematic, as it results in an intractably large grammar, and makes exact search impossible.

Most researchers have resorted to approximate search, typically beam search (Chiang, 2007). The decoder parses the source sentence, recording the target translations for each span.<sup>1</sup> As the partial translation hypothesis grows, its component ngrams are scored and the hypothesis score is updated. This decoding method though is inefficient as it requires recording the language model context ( $n - 1$  words) on the left and right edges of each chart cell. These contexts allow for boundary ngrams to be evaluated when the cell is used in another grammar production. In contrast, if the target string is generated in left-to-right order, then only one language model context is required, and the problem of language model evaluation is vastly simplified.

In this paper, we develop a novel method of left-to-right decoding for tree-to-string translation using a shift-reduce parsing strategy. A central issue in any decoding algorithm is the technique used for pruning the search space. Our left-to-right decoding algorithm groups hypotheses, which cover the same number of source words, into a bin. Pruning requires the evaluation of different hypotheses in the same bin, and eliminating the least promising options. As each hypotheses may cover different sets of tree

<sup>1</sup>The process is analogous for tree-to-string models, except that only rules and spans matching those in the source trees are considered. Typically nodes are visited according to a post-order traversal.

nodes, it is necessary to consider the cost of uncovered nodes, i.e., the *future cost*. We show that a good future cost estimate is essential for accurate and efficient search, leading to high quality translation output.

Other researchers have also considered the left-to-right decoding algorithm for tree-to-string models. Huang and Mi (2010) developed an Earley-style parsing algorithm (Earley, 1970). In their approach, hypotheses covering the same number of tree nodes were binned together. Their method uses a top-down depth-first search, with a mechanism for early elimination of some rules which lead to dead-ends in the search. Huang and Mi (2010)’s method was shown to outperform the traditional post-order-traversal decoding algorithm, considering fewer hypotheses and thus decoding much faster at the same level of performance. However their algorithm used a very rough estimate of future cost, resulting in more search errors than our approach.

Our experiments show that compared with the Earley-style left-to-right decoding (Huang and Mi, 2010) and the traditional post-order-traversal decoding (Liu et al., 2006) algorithms, our algorithm achieves a significant improvement on search capacity and better translation performance at the same level of speed.

## 2 Background

A typical tree-to-string system (Liu et al., 2006; Huang et al., 2006) searches through a 1-best source parse tree for the best derivation. It transduces the source tree into a target-language string using a Synchronous Tree Substitution Grammar (STSG). The grammar rules are extracted from bilingual word alignments using the GHKM algorithm (Galley et al., 2004).

We will briefly review the traditional decoding algorithm (Liu et al., 2006) and the Earley-style top-down decoding algorithm (Huang and Mi, 2010) for the tree-to-string model.

### 2.1 Traditional Decoding

The traditional decoding algorithm processes source tree nodes one by one according to a post-order traversal. For each node, it applies matched STSG rules by substituting each non-terminal with its cor-

	in theory	beam search
traditional	$O(nc V ^{4(g-1)})$	$O(ncb^2)$
top-down	$O((cr)^d V ^{g-1})$	$O(ncb)$
bottom-up	$O((cr)^d V ^{g-1})$	$O(nub)$

Table 1: Time complexity of different algorithms. *traditional* : Liu et al. (2006), *top-down* : Huang and Mi (2010).  $n$  is the source sentence length,  $b$  is the beam width,  $c$  is the number of rules used for each node,  $V$  is the target word vocabulary,  $g$  is the order of the language model,  $d$  is the depth of the source parse tree,  $u$  is the number of viable prefixes for each node and  $r$  is the maximum arity of each rule.

responding translation. For the derivation in Figure 1 (b), the traditional algorithm applies  $r_2$  at node  $NN_2$

$$r_2 : NN_2(jieguo) \rightarrow \text{the result},$$

to obtain “the result” as the translation of  $NN_2$ . Next it applies  $r_4$  at node NP,

$$r_4 : NP(NN_1(toupiao), x_1 : NN_2) \\ \rightarrow x_1 \text{ of the vote}$$

and replaces  $NN_2$  with its translation “the result”, then it gets the translation of NP as “the result of the vote”.

This algorithm needs to contain boundary words at both left and right extremities of the target string for the purpose of LM evaluation, which leads to a high time complexity. The time complexity in theory and with beam search (Huang and Mi, 2010) is shown in Table 1.

### 2.2 Earley-style Top-down Decoding

The Earley-style decoding algorithm performs a top-down depth-first parsing and generates the target translation left to right. It applies Context-Free Grammar (CFG) rules and employs three actions: *predict*, *scan* and *complete* (Section 3.1 describes how to convert STSG rules into CFG rules). We can simulate its translation process using a stack with a dot  $\cdot$  indicating which symbol to process next. For the derivation in Figure 1(b) and CFG rules in Figure 1(c), Figure 2 illustrates the whole translation process.

The time complexity is shown in Table 1 .

### 3 Bottom-Up Left-to-Right Decoding

We propose a novel method of left-to-right decoding for tree-to-string translation using a bottom-up parsing strategy. We use **viable prefixes** (Aho and Johnson, 1974) to indicate all possible target strings the translations of each node should start with. Therefore, given a tree node to expand, our algorithm can drop immediately to target terminals no matter whether there is a **gap** or not. We say that there is a gap between two symbols in a derivation when there are many rules separating them, e.g.  $IP \xrightarrow{r_6} \dots \xrightarrow{r_4} NN_2$ . For the derivation in Figure 1(b), our algorithm starts from the root node IP and applies  $r_2$  first although there is a gap between IP and  $NN_2$ . Then it applies  $r_4$ ,  $r_5$  and  $r_6$  in sequence to generate the translation “the result of the vote was released at night”. Our algorithm takes the gap as a black-box and does not need to fix which partial derivation should be used for the gap at the moment. So it can get target strings as soon as possible and thereby perform more accurate pruning. A valid derivation is generated only when the source tree is completely matched by rules.

Our bottom-up decoding algorithm involves the following steps:

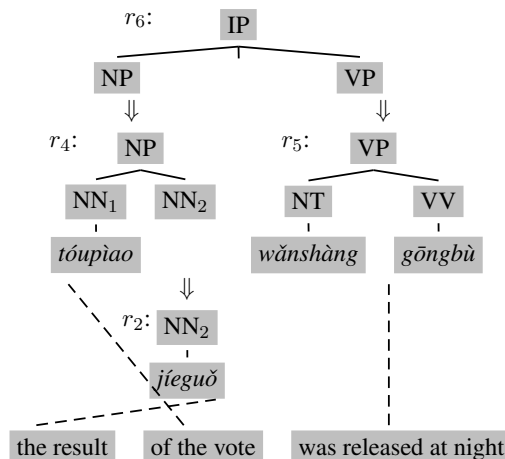

1. Match STSG rules against the source tree.
2. Convert STSG rules to CFG rules.
3. Collect the viable prefix set for each node in a post-order transversal.
4. Search bottom-up for the best derivation.

#### 3.1 From STSG to CFG

After rule matching, each tree node has its applicable STSG rule set. Given a matched STSG rule, our decoding algorithm only needs to consider the tree node the rule can be applied to and the target side, so we follow Huang and Mi (2010) to convert STSG rules to CFG rules. For example, an STSG rule  $NP (NN_1 (toupiao), x_1 : NN_2) \rightarrow x_1 \text{ of the vote}$  can be converted to a CFG rule

$$NP \rightarrow NN_2 \text{ of the vote}$$

The target non-terminals are replaced with corresponding source non-terminals. Figure 1 (c) shows all converted CFG rules for the toy example. Note

$r_1$ :	$NN_1 \rightarrow \text{the vote}$
$r_2$ :	$NN_2 \rightarrow \text{the result}$
$r_3$ :	$NP \rightarrow NN_2 \text{ of } NN_1$
$r_4$ :	$NP \rightarrow NN_2 \text{ of the vote}$
$r_5$ :	$VP \rightarrow \text{was released at night}$
$r_6$ :	$IP \rightarrow NP VP$
$r_7$ :	$IP \rightarrow NN_2 \text{ of the vote } VP$
$r_8$ :	$IP \rightarrow VP NP$

(c) Target-side CFG rule set

Figure 1: A toy example.

that different STSG rules might be converted to the same CFG rule despite having different source tree structures.

#### 3.2 Viable Prefix

During decoding, how do we decide which rules should be used next given a partial derivation, especially when there is a gap? A key observation is that some rules should be excluded. For example, any derivation for Figure 1(a) will never begin with  $r_1$  as there is no translation starting with “the vote”. In order to know which rules can be excluded for each node, we can recursively calculate the starting terminal strings for each node. For example,

NN <sub>1</sub> :	{the vote}	NN <sub>2</sub> :	{the result}
NT:	∅	VV:	∅
NP:	{the result}		
VP:	{was released at night}		
IP:	{the result, was released at night}		

Table 2: The Viable prefix sets for Figure 1 (c)

according to  $r_1$ , the starting terminal string of the translation for NN<sub>1</sub> is “the vote”. According to  $r_2$ , the starting terminal string for NN<sub>2</sub> is “the result”. According to  $r_3$ , the starting terminal string of NP must include that of NN<sub>2</sub>. Table 2 lists the starting terminal strings of all nodes in Figure 1(a). As the translations of node IP should begin with either “the result” or “was released at night”, the first rule must be either  $r_2$  or  $r_5$ . Therefore,  $r_1$  will never be used as the first rule in any derivation.

We refer to starting terminal strings of a node as a **viable prefixes**, a term borrowed from LR parsing (Aho and Johnson, 1974). Viable prefixes are used to decide which rule should be used to ensure efficient left-to-right target generation. Formally, assume that  $V_N$  denotes the set of non-terminals (i.e., source tree node labels),  $V_T$  denotes the set of terminals (i.e., target words),  $v_1, v_2 \in V_N$ ,  $w \in V_T$ ,  $\pi \in \{V_T \cup V_N\}^*$ , we say that  $w$  is a viable prefix of  $v_1$  if and only if:

- $v_1 \rightarrow w$ , or
- $v_1 \rightarrow wv_2\pi$ , or
- $v_1 \rightarrow v_2\pi$ , and  $w$  is a viable prefix of  $v_2$ .

Note that we bundle all successive terminals in one symbol.

### 3.3 Shift-Reduce Parsing

We use a shift-reduce algorithm to search for the best deviation. The algorithm maintains a stack of dotted rules (Earley, 1970). Given the source tree in Figure 1(a), the stack is initialized with a dotted rule for the root node IP:

[. IP].

Then, the algorithm selects one viable prefix of IP and appends it to the stack with the dot at the beginning (*predict*):

[. IP] [. the result]<sup>2</sup>.

Then, a *scan* action is performed to produce a partial translation “the result”:

[. IP] [the result .].

Next, the algorithm searches for the CFG rules starting with “the result” and gets  $r_2$ . Then, it pops the rightmost dotted rule and append the left-hand side (LHS) of  $r_2$  to the stack (*complete*):

[. IP] [NN<sub>2</sub> .].

Next, the algorithm chooses  $r_4$  whose right-hand side “NN<sub>2</sub> of the vote” matches the rightmost dotted rule in the stack<sup>3</sup> and *grows* the rightmost dotted rule:

[. IP] [NN<sub>2</sub> . of the vote].

Figure 3 shows the whole process of derivation generation.

Formally, we define four actions on the rightmost rule in the stack:

- *Predict*. If the symbol after the dot in the rightmost dotted rule is a non-terminal  $v$ , this action chooses a viable prefix  $w$  of  $v$  and generates a new dotted rule for  $w$  with the dot at the beginning. For example:

[. IP]  $\xrightarrow{predict}$  [. IP] [. the result]

- *Scan*. If the symbol after the dot in the rightmost dotted rule is a terminal string  $w$ , this action advances the dot to update the current partial translation. For example:

[. IP] [. the result]  $\xrightarrow{scan}$  [. IP] [the result .]

- *Complete*. If the rightmost dotted rule ends with a dot and it happens to be the right-hand side of a rule, then this action removes the right-most dotted rule. Besides, if the symbol after the dot in the new rightmost rule corresponds to the same tree node as the LHS non-terminal of the rule, this action advance the dot. For example,

[. IP] [NP . VP] [was released at night .]  
 $\xrightarrow{complete}$  [. IP] [NP VP .]

<sup>2</sup>There are another option: “was released at night”

<sup>3</sup>Here there is an alternative:  $r_3$  or  $r_7$

step	action	rule used	stack	hypothesis
0			[. IP]	
1	<i>p</i>	$r_6$	[. IP] [. NP VP]	
2	<i>p</i>	$r_4$	[. IP] [. NP VP] [. NN <sub>2</sub> of the vote]	
3	<i>p</i>	$r_2$	[. IP] [. NP VP] [. NN <sub>2</sub> of the vote] [. the result]	
4	<i>s</i>		[. IP] [. NP VP] [. NN <sub>2</sub> of the vote] [the result .]	the result
5	<i>c</i>		[. IP] [. NP VP] [NN <sub>2</sub> . of the vote]	the result
6	<i>s</i>		[. IP] [. NP VP] [NN <sub>2</sub> of the vote .]	the result of the vote
7	<i>c</i>		[. IP] [NP . VP]	the result of the vote
8	<i>p</i>	$r_5$	[. IP] [NP . VP] [. was released at night]	the result of the vote
9	<i>s</i>		[. IP] [NP . VP] [was released at night .]	the ... vote was ... night
10	<i>c</i>		[. IP] [NP VP .]	the ... vote was ... night
11	<i>c</i>		[IP .]	the ... vote was ... night

Figure 2: Simulation of top-down translation process for the derivation in Figure 1(b). Actions: *p*, predict; *s*, scan; *c*, complete. “the ... vote” and “was ... released” are the abbreviated form of “the result of the vote” and “was released at night”, respectively.

step	action	rule used	stack	number	hypothesis
0			[. IP]	0	
1	<i>p</i>		[. IP] [. the result]	0	
2	<i>s</i>		[. IP] [the result .]	1	the result
3	<i>c</i>	$r_2$	[. IP] [NN <sub>2</sub> .]	1	the result
4	<i>g</i>	$r_4$ or $r_7$	[. IP] [NN <sub>2</sub> . of the vote]	1	the result
5	<i>s</i>		[. IP] [NN <sub>2</sub> of the vote .]	2	the result of the vote
6	<i>c</i>	$r_4$	[. IP] [NP .]	2	the result of the vote
7	<i>g</i>	$r_6$	[. IP] [NP . VP]	2	the result of the vote
8	<i>p</i>		[. IP] [NP . VP] [. was released at night]	2	the result of the vote
9	<i>s</i>		[. IP] [NP . VP] [was released at night .]	4	the ... vote was ... night
10	<i>c</i>	$r_5$	[. IP] [NP VP .]	4	the ... vote was ... night
11	<i>c</i>	$r_6$	[IP .]	4	the ... vote was ... night

Figure 3: Simulation of bottom-up translation process for the derivation in Figure 1(b). Actions: *p*, predict; *s*, scan; *c*, complete; *g*, grow. The column of *number* gives the number of source words the hypothesis covers.

If the string cannot rewrite on the frontier non-terminal, then we add the LHS to the stack with the dot after it. For example:

$$[. IP] [the result .] \xrightarrow{complete} [. IP] [NN_2 .]$$

- *Grow*. If the right-most dotted rule ends with a dot and it happens to be the starting part of a CFG rule, this action appends one symbol of the remainder of that rule to the stack<sup>4</sup>. For example:

$$[. IP] [NN_2 .] \xrightarrow{grow} [. IP] [NN_2 . of the vote]$$

From the above definition, we can find that there may be an ambiguity about whether to use a complete action or a grow action. Similarly, predict actions must select a viable prefix form the set for a node. For example in step 5, although we select to perform complete with  $r_4$  in the example,  $r_7$  is applicable, too. In our implementation, if both  $r_4$  and  $r_7$  are applicable, we apply them both to generate two separate hypotheses. To limit the exponential explosion of hypotheses (Knight, 1999), we use beam search over bins of similar partial hypotheses (Koehn, 2004).

<sup>4</sup>We bundle the successive terminals in one rule into a symbol

Figure 4: The translation forest composed of applicable CFG rules for the partial derivation of step 3 in Figure 3.

### 3.4 Future Cost

Partial derivations covering different tree nodes may be grouped in the same bin for beam pruning<sup>5</sup>. In order to perform more accurate pruning, we take into consideration **future cost**, the cost of the uncovered part. The **merit** of a derivation is the **covered cost** (the cost of the covered part) plus the future cost. We borrow ideas from the Inside-Outside algorithm (Charniak and Johnson, 2005; Huang, 2008; Mi et al., 2008) to compute the merit. In our algorithm, the merit of a derivation is just the Viterbi inside cost  $\beta$  of the root node calculated with the derivations continuing from the current derivation.

Given a partial derivation, we calculate its future cost by searching through the translation forest defined by all applicable CFG rules. Figure 4 shows the translation forest for the derivation of step 3. We calculate the future cost for each node as follows: given a node  $v$ , we define its cost function  $f(v)$  as

$$f(v) = \begin{cases} 1 & v \text{ is completed} \\ lm(v) & v \text{ is a terminal string} \\ \max_{r \in R_v} f(r) \prod_{\pi \in rhs(r)} f(\pi) & \text{otherwise} \end{cases}$$

where  $V_N$  is the non-terminal set,  $V_T$  is the terminal set,  $v, \pi \in V_N \cup V_T^+$ ,  $R_v$  is the set of currently applicable rules for  $v$ ,  $rhs(r)$  is the right-hand symbol set of  $r$ ,  $lm$  is the local language model probability,  $f(r)$  is calculated using a linear model whose features are bidirectional translation probabilities and lexical probabilities of  $r$ . For the translation forest in Figure 4, if we calculate the future cost of NP with

<sup>5</sup>Section 3.7 will describe the binning scheme

$r_4$ , then

$$\begin{aligned} f(NP) &= f(r_4) \cdot f(NN_2) \cdot lm(\text{of the vote}) \\ &= f(r_4) \cdot 1 \cdot lm(\text{of the vote}) \end{aligned}$$

Note that we calculate  $lm(\text{of the vote})$  locally and do not take “the result” derived from  $NN_2$  as the context. The  $lm$  probability of “the result” has been included in the covered cost.

As a partial derivation grows, some CFG rules will conflict with the derivation (i.e. inapplicable) and the translation forest will change accordingly. For example, when we reach step 5 from step 3 (see Figure 4 for its translation forest),  $r_3$  is inapplicable and thereby should be ruled out. Then the nodes on the path from the last covered node (it is “of the vote” in step 5) to the root node should update their future cost, as they may employ  $r_3$  to produce the future cost. In step 5, NP and IP should be updated. In this sense, we say that the future cost is dynamic.

### 3.5 Comparison with Top-Down Decoding

In order to generate the translation “the result” based on the derivation in Figure 1(b), Huang and Mi’s top-down algorithm needs to specify which rules to apply starting from the root node until it yields “the result”. In this derivation, rule  $r_6$  is applied to IP,  $r_4$  to NP,  $r_2$  to  $NN_2$ . That is to say, it needs to represent the partial derivation from IP to  $NN_2$  explicitly. This can be a problem when combined with beam pruning. If the beam size is small, it may discard the intermediate hypotheses and thus never consider the string. In our example with a beam of 1, we must select a rule for IP among  $r_6$ ,  $r_7$  and  $r_8$  although we do not get any information for NP and VP.

Instead, our bottom-up algorithm allows top-down and bottom-up information to be used together with the help of viable prefixes. This allows us to encode more candidate derivations than the purely top-down method. In the above example, our algorithm does not specify the derivation for the gap from IP and “the result”. In fact, all derivations composed of currently applicable rules are allowed. When needed, our algorithm derives the derivation dynamically using applicable rules. So when our algorithm performs pruning at the root node, it has got much more information and consequently introduces fewer pruning errors.

### 3.6 Time Complexity

Assume the depth of the source tree is  $d$ , the maximum number of matched rules for each node is  $c$ , the maximum arity of each rule is  $r$ , the language model order is  $g$  and the target-language vocabulary is  $V$ , then the time complexity of our algorithm is  $O((cr)^d |V|^{g-1})$ . Analysis is as follows:

Our algorithm expands partial paths with terminal strings to generate new hypotheses, so the time complexity depends on the number of partial paths used. We split a path which is from the root node to a leaf node with a node on it (called the end node) and get the segment from the root node to the end node as a partial path, so the length of the partial path is not definite with a maximum of  $d$ . If the length is  $d'$  ( $d' \leq d$ ), then the number of partial paths is  $(cr)^{d'}$ . Besides, we use the rightest  $g - 1$  words to signature each partial path, so we can get  $(cr)^{d'} |V|^{g-1}$  states. For each state, the number of viable prefixes produced by predict operation is  $c^{d-d'}$ , so the total time complexity is  $f = O((cr)^{d'} |V|^{g-1} c^{d-d'}) = O(c^d r^{d'} |V|^{g-1}) = O((cr)^d |V|^{g-1})$ .

### 3.7 Beam Search

To make decoding tractable, we employ beam search (Koehn, 2004) and choose “binning” as follows: hypotheses covering the same number of source words are grouped in a bin. When expanding a hypothesis in a beam (bin), we take series of actions until new terminals are appended to the hypothesis, then add the new hypothesis to the corresponding beam. Figure 3 shows the number of source words each hypothesis covers.

Among the actions, only the scan action changes the number of source words each hypothesis covers. Although the complete action does not change source word number, it changes the covered cost of hypotheses. So in our implementation, we take scan and complete as “closure” actions. That is to say, once there are some complete actions after a scan action, we finish all the complete actions until the next action is grow. The predict and grow actions decide which rules can be used to expand hypotheses next, so we update the applicable rule set during these two actions.

Given a source sentence with  $n$  words, we maintain  $n$  beams, and let each beam hold  $b$  hypotheses

at most. Besides, we prune viable prefixes of each node up to  $u$ , so each hypothesis can expand to  $u$  new hypotheses at most, so the time complexity of beam search is  $O(nub)$ .

## 4 Related Work

Watanabe et al. (2006) present a novel Earley-style top-down decoding algorithm for hierarchical phrase-based model (Chiang, 2005). Their framework extracts Greibach Normal Form rules only, which always has at least one terminal on the left of each rule, and discards other rules.

Dyer and Resnik (2010) describe a translation model that combines the merits of syntax-based models and phrase-based models. Their decoder works in two passes: for first pass, the decoder collects a context-free forest and performs tree-based source reordering without a LM. For the second pass, the decoder adds a LM and performs bottom-up CKY decoding.

Feng et al. (2010) proposed a shift-reduce algorithm to add BTG constraints to phrase-based models. This algorithm constructs a BTG tree in a reduce-eager manner while the algorithm in this paper searches for a best derivation which must be derived from the source tree.

Galley and Manning (2008) use the shift-reduce algorithm to conduct hierarchical phrase reordering so as to capture long-distance reordering. This algorithm shows good performance on phrase-based models, but can not be applied to syntax-based models directly.

## 5 Experiments

In the experiments, we use two baseline systems: our in-house tree-to-string decoder implemented according to Liu et al. (2006) (denoted as *traditional*) and the Earley-style top-down decoder implemented according to Huang and Mi (2010) (denoted as *top-down*), respectively. We compare our bottom-up left-to-right decoder (denoted as *bottom-up*) with the baseline in terms of performance, translation quality and decoding speed with different beam sizes, and search capacity. Lastly, we show the influence of future cost. All systems are implemented in C++.

## 5.1 Data Setup

We used the FBIS corpus consisting of about 250K Chinese-English sentence pairs as the training set. We aligned the sentence pairs using the GIZA++ toolkit (Och and Ney, 2003) and extracted tree-to-string rules according to the GHKM algorithm (Galley et al., 2004). We used the SRILM toolkit (Stolcke, 2002) to train a 4-gram language model on the Xinhua portion of the GIGAWORD corpus.

We used the 2002 NIST MT Chinese-English test set (571 sentences) as the development set and the 2005 NIST MT Chinese-English test set (1082 sentences) as the test set. We evaluated translation quality using BLEU-metric (Papineni et al., 2002) with case-insensitive  $n$ -gram matching up to  $n = 4$ . We used the standard minimum error rate training (Och, 2003) to tune feature weights to maximize BLEU score on the development set.

## 5.2 Performance Comparison

Our bottom-up left-to-right decoder employs the same features as the traditional decoder: rule probability, lexical probability, language model probability, rule count and word count. In order to compare them fairly, we used the same beam size which is 20 and employed cube pruning technique (Huang and Chiang, 2005).

We show the results in Table 3. From the results, we can see that the bottom-up decoder outperforms top-down decoder and traditional decoder by 1.1 and 0.8 BLEU points respectively and the improvements are statistically significant using the *sign-test* of Collins et al. (2005) ( $p < 0.01$ ). The improvement may result from dynamically searching for a whole derivation which leads to more accurate estimation of a partial derivation. The additional time consumption of the bottom-up decoder against the top-down decoder comes from dynamic future cost computation.

Next we compare decoding speed versus translation quality using various beam sizes. The results are shown in Figure 5. We can see that our bottom-up decoder can produce better BLEU score at the same decoding speed. At small beams (decoding time around 0.5 second), the improvement of translation quality is much bigger.

System	BLEU(%)	Time (s)
Traditional	29.8	0.84
Top-down	29.5	0.41
Bottom-up	<b>30.6</b>	0.81

Table 3: Performance comparison.

Figure 5: BLEU score against decoding time with various beam size.

## 5.3 Search Capacity Comparison

We also compare the search capacity of the bottom-up decoder and the traditional decoder. We do this in the following way: we let both decoders use the same weights tuned on the traditional decoder, then we compare their translation scores of the same test sentence.

From the results in Table 4, we can see that for many test sentences, the bottom-up decoder finds target translations with higher score, which have been ruled out by the traditional decoder. This may result from more accurate pruning method. Yet for some sentences, the traditional decoder can attain higher translation score. The reason may be that the traditional decoder can hold more than two nonterminals when cube pruning, while the bottom-up decoder always performs dual-arity pruning.

Next, we check whether higher translation scores bring higher BLEU scores. We compute the BLEU score of both decoders on the test sentence set on which bottom-up decoder gets higher translation scores than the traditional decoder does. We record the results in Figure 6. The result shows that higher score indeed bring higher BLEU score, but the improvement of BLEU score is not large. This is because the features we use don't reflect the real statis-

Figure 6: BLEU score with various beam sizes on the sub test set consisting of sentences on which the bottom-up decoder gets higher translation score than the traditional decoder does.

$b$	$>$		$=$		$<$	
10	728	67%	347	32%	7	1%
20	657	61%	412	38%	13	1%
30	615	57%	446	41%	21	2%
40	526	49%	523	48%	33	3%
50	315	29%	705	65%	62	6%

Table 4: Search capacity comparison. The first column is beam size, the following three columns denote the number of test sentences, on which the translation scores of the bottom-up decoder are greater, equal to, lower than that of the traditional decoder.

System	BLEU(%)	Time (s)
with	30.6	0.81
without	28.8	0.39

Table 5: Influence of future cost. The results of the bottom-up decoder with and without future cost are given in the second and three rows, respectively.

tical distribution of hypotheses well. In addition, the weights are tuned on the traditional decoder, not on the bottom-up decoder. The bottom-up decoder can perform better with weights tuned by itself.

#### 5.4 Influence of Future Cost

Next, we will show the impact of future cost via experiments. We give the results of the bottom-up decoder with and without future cost in Table 5. From the result, we can conclude that future cost plays a significant role in decoding. If the bottom-up decoder does not employ future cost, its performance

will be influenced dramatically. Furthermore, calculating dynamic future cost is time consuming. If the bottom-up decoder does not use future cost, it decodes faster than the top-down decoder. This is because the top-down decoder has  $|T|$  beams, while the bottom-up decoder has  $n$  beams, where  $T$  is the source parse tree and  $n$  is the length of the source sentence.

## 6 Conclusions

In this paper, we describe a bottom-up left-to-right decoding algorithm for tree-to-string model. With the help of viable prefixes, the algorithm generates a translation by constructing a target-side CFG tree according to a post-order traversal. In addition, it takes into consideration a dynamic future cost to estimate hypotheses.

On the 2005 NIST Chinese-English MT translation test set, our decoder outperforms the top-down decoder and the traditional decoder by 1.1 and 0.8 BLEU points respectively and shows more powerful search ability. Experiments also prove that future cost is important for more accurate pruning.

# Semantic Compositionality through Recursive Matrix-Vector Spaces

Richard Socher Brody Huval Christopher D. Manning Andrew Y. Ng  
richard@socher.org, {brodyh,manning,ang}@stanford.edu  
Computer Science Department, Stanford University

## Abstract

Single-word vector space models have been very successful at learning lexical information. However, they cannot capture the compositional meaning of longer phrases, preventing them from a deeper understanding of language. We introduce a recursive neural network (RNN) model that learns compositional vector representations for phrases and sentences of arbitrary syntactic type and length. Our model assigns a vector and a matrix to every node in a parse tree: the vector captures the inherent meaning of the constituent, while the matrix captures how it changes the meaning of neighboring words or phrases. This matrix-vector RNN can learn the meaning of operators in propositional logic and natural language. The model obtains state of the art performance on three different experiments: predicting fine-grained sentiment distributions of adverb-adjective pairs; classifying sentiment labels of movie reviews and classifying semantic relationships such as cause-effect or topic-message between nouns using the syntactic path between them.

## 1 Introduction

Semantic word vector spaces are at the core of many useful natural language applications such as search query expansions (Jones et al., 2006), fact extraction for information retrieval (Paşca et al., 2006) and automatic annotation of text with disambiguated Wikipedia links (Ratinov et al., 2011), among many others (Turney and Pantel, 2010). In these models the meaning of a word is encoded as a vector computed from co-occurrence statistics of a word and its neighboring words. Such vectors have been shown to correlate well with human judgments of word similarity (Griffiths et al., 2007).

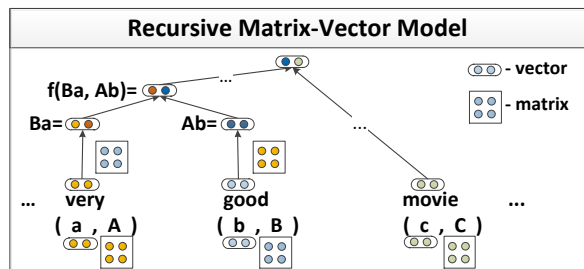

Figure 1: A recursive neural network which learns semantic vector representations of phrases in a tree structure. Each word and phrase is represented by a vector and a matrix, e.g., *very* = (*a*, *A*). The matrix is applied to neighboring vectors. The same function is repeated to combine the phrase *very good* with *movie*.

Despite their success, single word vector models are severely limited since they do not capture *compositionality*, the important quality of natural language that allows speakers to determine the meaning of a longer expression based on the meanings of its words and the rules used to combine them (Frege, 1892). This prevents them from gaining a deeper understanding of the semantics of longer phrases or sentences. Recently, there has been much progress in capturing compositionality in vector spaces, e.g., (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Zanzotto et al., 2010; Yessenalina and Cardie, 2011; Socher et al., 2011c) (see related work). We extend these approaches with a more general and powerful model of semantic composition.

We present a novel recursive neural network model for semantic compositionality. In our context, compositionality is the ability to learn compositional vector representations for various types of phrases and sentences of arbitrary length. Fig. 1 shows an illustration of the model in which each constituent (a word or longer phrase) has a matrix-vector (MV)

representation. The vector captures the meaning of that constituent. The matrix captures how it modifies the meaning of the other word that it combines with. A representation for a longer phrase is computed bottom-up by recursively combining the words according to the syntactic structure of a parse tree. Since the model uses the MV representation with a neural network as the final merging function, we call our model a matrix-vector recursive neural network (MV-RNN).

We show that the ability to capture semantic compositionality in a syntactically plausible way translates into state of the art performance on various tasks. The first experiment demonstrates that our model can learn fine-grained semantic compositionality. The task is to predict a sentiment distribution over movie reviews of adverb-adjective pairs such as *unbelievably sad* or *really awesome*. The MV-RNN is the only model that is able to properly negate sentiment when adjectives are combined with *not*. The MV-RNN outperforms previous state of the art models on full sentence sentiment prediction of movie reviews. The last experiment shows that the MV-RNN can also be used to find relationships between words using the learned phrase vectors. The relationship between words is recursively constructed and composed by words of arbitrary type in the variable length syntactic path between them. On the associated task of classifying relationships between nouns in arbitrary positions of a sentence the model outperforms all previous approaches on the SemEval-2010 Task 8 competition (Hendrickx et al., 2010). It outperforms all but one of the previous approaches without using any hand-designed semantic resources such as WordNet or FrameNet. By adding WordNet hypernyms, POS and NER tags our model outperforms the state of the art that uses significantly more resources. The code for our model is available at [www.socher.org](http://www.socher.org).

## 2 MV-RNN: A Recursive Matrix-Vector Model

The dominant approach for building representations of multi-word units from single word vector representations has been to form a linear combination of the single word representations, such as a sum or weighted average. This happens in information re-

trieval and in various text similarity functions based on lexical similarity. These approaches can work well when the meaning of a text is literally “the sum of its parts”, but fails when words function as operators that modify the meaning of another word: the meaning of “extremely strong” cannot be captured as the sum of word representations for “extremely” and “strong.”

The model of Socher et al. (2011c) provided a new possibility for moving beyond a linear combination, through use of a matrix  $W$  that multiplied the word vectors  $(a, b)$ , and a nonlinearity function  $g$  (such as a sigmoid or tanh). They compute the parent vector  $p$  that describes both words as

$$p = g \left( W \begin{bmatrix} a \\ b \end{bmatrix} \right) \quad (1)$$

and apply this function recursively inside a binarized parse tree so that it can compute vectors for multi-word sequences. Even though the nonlinearity allows to express a wider range of functions, it is almost certainly too much to expect a single fixed  $W$  matrix to be able to capture the meaning combination effects of all natural language operators. After all, inside the function  $g$ , we have the same linear transformation for all possible pairs of word vectors.

Recent work has started to capture the behavior of natural language operators inside semantic vector spaces by modeling them as matrices, which would allow a matrix for “extremely” to appropriately modify vectors for “smelly” or “strong” (Baroni and Zamparelli, 2010; Zanzotto et al., 2010). These approaches are along the right lines but so far have been restricted to capture linear functions of pairs of words whereas we would like nonlinear functions to compute compositional meaning representations for multi-word phrases or full sentences.

The MV-RNN combines the strengths of both of these ideas by (i) assigning a vector and a matrix to *every* word and (ii) learning an input-specific, nonlinear, compositional function for computing vector and matrix representations for multi-word sequences of any syntactic type. Assigning vector-matrix representations to all words instead of only to words of one part of speech category allows for greater flexibility which benefits performance. If a word lacks operator semantics, its matrix can be an identity matrix. However, if a word acts mainly as an operator,

such as “extremely”, its vector can become close to zero, while its matrix gains a clear operator meaning, here magnifying the meaning of the modified word in both positive and negative directions.

In this section we describe the initial word representations, the details of combining two words as well as the multi-word extensions. This is followed by an explanation of our training procedure.

## 2.1 Matrix-Vector Neural Word Representation

We represent a word as both a continuous vector and a matrix of parameters. We initialize all word vectors  $x \in \mathbb{R}^n$  with pre-trained 50-dimensional word vectors from the unsupervised model of Collobert and Weston (2008). Using Wikipedia text, their model learns word vectors by predicting how likely it is for each word to occur in its context. Similar to other local co-occurrence based vector space models, the resulting word vectors capture syntactic and semantic information. Every word is also associated with a matrix  $X$ . In all experiments, we initialize matrices as  $X = I + \epsilon$ , i.e., the identity plus a small amount of Gaussian noise. If the vectors have dimensionality  $n$ , then each word’s matrix has dimensionality  $X \in \mathbb{R}^{n \times n}$ . While the initialization is random, the vectors and matrices will subsequently be modified to enable a sequence of words to compose a vector that can predict a distribution over semantic labels. Henceforth, we represent any phrase or sentence of length  $m$  as an ordered list of vector-matrix pairs  $((a, A), \dots, (m, M))$ , where each pair is retrieved based on the word at that position.

## 2.2 Composition Models for Two Words

We first review composition functions for two words. In order to compute a parent vector  $p$  from two consecutive words and their respective vectors  $a$  and  $b$ , Mitchell and Lapata (2010) give as their most general function:  $p = f(a, b, R, K)$ , where  $R$  is the a-priori known syntactic relation and  $K$  is background knowledge.

There are many possible functions  $f$ . For our models, there is a constraint on  $p$  which is that it has the same dimensionality as each of the input vectors. This way, we can compare  $p$  easily with its children and  $p$  can be the input to a composition with another word. The latter is a requirement that will become clear in the next section. This excludes

tensor products which were outperformed by simpler weighted addition and multiplication methods in (Mitchell and Lapata, 2010).

We will explore methods that do not require any manually designed semantic resources as background knowledge  $K$ . No explicit knowledge about the type of relation  $R$  is used. Instead we want the model to capture this implicitly via the learned matrices. We propose the following combination function which is input dependent:

$$p = f_{A,B}(a, b) = f(Ba, Ab) = g \left( W \begin{bmatrix} Ba \\ Ab \end{bmatrix} \right), \quad (2)$$

where  $A, B$  are matrices for single words, the global  $W \in \mathbb{R}^{n \times 2n}$  is a matrix that maps both transformed words back into the same  $n$ -dimensional space. The element-wise function  $g$  could be simply the identity function but we use instead a nonlinearity such as the sigmoid or hyperbolic tangent  $\tanh$ . Such a nonlinearity will allow us to approximate a wider range of functions beyond purely linear functions. We can also add a bias term before applying  $g$  but omit this for clarity. Rewriting the two transformed vectors as one vector  $z$ , we get  $p = g(Wz)$  which is a single layer neural network. In this model, the word matrices can capture compositional effects specific to each word, whereas  $W$  captures a general composition function.

This function builds upon and generalizes several recent models in the literature. The most related work is that of (Mitchell and Lapata, 2010; Zanzotto et al., 2010) who introduced and explored the composition function  $p = Ba + Ab$  for word pairs. This model is a special case of Eq. 2 when we set  $W = [II]$  (i.e. two concatenated identity matrices) and  $g(x) = x$  (the identity function). Baroni and Zamparelli (2010) computed the parent vector of adjective-noun pairs by  $p = Ab$ , where  $A$  is an adjective matrix and  $b$  is a vector for a noun. This cannot capture nouns modifying other nouns, e.g., *disk drive*. This model too is a special case of the above model with  $B = 0_{n \times n}$ . Lastly, the models of (Socher et al., 2011b; Socher et al., 2011c; Socher et al., 2011a) as described above are also special cases with both  $A$  and  $B$  set to the identity matrix. We will compare to these special cases in our experiments.

Figure 2: Example of how the MV-RNN merges a phrase with another word at a nonterminal node of a parse tree.

### 2.3 Recursive Compositions of Multiple Words and Phrases

This section describes how we extend a word-pair matrix-vector-based compositional model to learn vectors and matrices for longer sequences of words. The main idea is to apply the same function  $f$  to pairs of constituents in a parse tree. For this to work, we need to take as input a binary parse tree of a phrase or sentence and also compute matrices at each nonterminal parent node. The function  $f$  can be readily used for phrase vectors since it is recursively compatible ( $p$  has the same dimensionality as its children). For computing nonterminal phrase matrices, we define the function

$$P = f_M(A, B) = W_M \begin{bmatrix} A \\ B \end{bmatrix}, \quad (3)$$

where  $W_M \in \mathbb{R}^{n \times 2n}$ , so  $P \in \mathbb{R}^{n \times n}$  just like each input matrix.

After two words form a constituent in the parse tree, this constituent can now be merged with another one by applying the same functions  $f$  and  $f_M$ . For instance, to compute the vectors and matrices depicted in Fig. 2, we first merge words  $a$  and  $b$  and their matrices:  $p_1 = f(Ba, Ab)$ ,  $P_1 = f_M(A, B)$ . The resulting vector-matrix pair  $(p_1, P_1)$  can now be used to compute the full phrase when combining it with word  $c$  and computing  $p_2 = f(Cp_1, P_1c)$ ,  $P_2 = f_M(P_1, C)$ . The model computes vectors and matrices in a bottom-up fashion, applying the functions  $f$ ,  $f_M$  to its own previous output (i.e. recursively) until it reaches the top node of the tree which represents the entire sentence.

For experiments with longer sequences we will compare to standard RNNs and the special case of the MV-RNN that computes the parent by  $p = Ab +$

$Ba$ , which we name the *linear Matrix-Vector Recursion* model (linear MVR). Previously, this model had not been trained for multi-word sequences. Sec. 6 talks about alternatives for compositionality.

### 2.4 Objective Functions for Training

One of the advantages of RNN-based models is that each node of a tree has associated with it a distributed vector representation (the parent vector  $p$ ) which can also be seen as features describing that phrase. We train these representations by adding on top of each parent node a simple softmax classifier to predict a class distribution over, e.g., sentiment or relationship classes:  $d(p) = \text{softmax}(W^{label}p)$ . If there are  $K$  labels, then  $d \in \mathbb{R}^K$  is a  $K$ -dimensional multinomial distribution. For the applications below (excluding logic), the corresponding error function  $E(s, t, \theta)$  that we minimize for a sentence  $s$  and its tree  $t$  is the sum of cross-entropy errors at all nodes.

The only other methods that use this type of objective function are (Socher et al., 2011b; Socher et al., 2011c), who also combine it with either a score or reconstruction error. Hence, for comparisons to other related work, we need to merge variations of computing the parent vector  $p$  with this classifier. The main difference is that the MV-RNN has more flexibility since it has an input specific recursive function  $f_{A,B}$  to compute each parent. In the following applications, we will use the softmax classifier to predict both sentiment distributions and noun-noun relationships.

### 2.5 Learning

Let  $\theta = (W, W_M, W^{label}, L, L_M)$  be our model parameters and  $\lambda$  a vector with regularization hyperparameters for all model parameters.  $L$  and  $L_M$  are the sets of all word vectors and word matrices. The gradient of the overall objective function  $J$  becomes:

$$\frac{\partial J}{\partial \theta} = \frac{1}{N} \sum_{(x,t)} \frac{\partial E(x, t; \theta)}{\partial \theta} + \lambda \theta. \quad (4)$$

To compute this gradient, we first compute all tree nodes  $(p_i, P_i)$  from the bottom-up and then take derivatives of the softmax classifiers at each node in the tree from the top down. Derivatives are computed efficiently via backpropagation through structure (Goller and Küchler, 1996). Even though the

objective is not convex, we found that L-BFGS run over the complete training data (batch mode) minimizes the objective well in practice and convergence is smooth. For more information see (Socher et al., 2010).

## 2.6 Low-Rank Matrix Approximations

If every word is represented by an  $n$ -dimensional vector and additionally by an  $n \times n$  matrix, the dimensionality of the whole model may become too large with commonly used vector sizes of  $n = 100$ . In order to reduce the number of parameters, we represent word matrices by the following low-rank plus diagonal approximation:

$$A = UV + \text{diag}(a), \quad (5)$$

where  $U \in \mathbb{R}^{n \times r}$ ,  $V \in \mathbb{R}^{r \times n}$ ,  $a \in \mathbb{R}^n$  and we set the rank for all experiments to  $r = 3$ .

## 2.7 Discussion: Evaluation and Generality

Evaluation of compositional vector spaces is a complex task. Most related work compares similarity judgments of unsupervised models to those of human judgments and aims at high correlation. These evaluations can give important insights. However, even with good correlation the question remains how these models would perform on downstream NLP tasks such as sentiment detection. We experimented with unsupervised learning of general vector-matrix representations by having the MV-RNN predict words in their correct context. Initializing the models with these general representations, did not improve the performance on the tasks we consider. For sentiment analysis, this is not surprising since antonyms often get similar vectors during unsupervised learning from co-occurrences due to high similarity of local syntactic contexts. In our experiments, the high prediction performance came from supervised learning of meaning representations using labeled data. While these representations are task-specific, they could be used across tasks in a multi-task learning setup. However, in order to fairly compare to related work, we use only the supervised data of each task. Before we describe our full-scale experiments, we analyze the model’s expressive powers.

## 3 Model Analysis

This section analyzes the model with two proof-of-concept studies. First, we examine its ability to learn operator semantics for adverb-adjective pairs. If a model cannot correctly capture how an adverb operates on the meaning of adjectives, then there’s little chance it can learn operators for more complex relationships. The second study analyzes whether the MV-RNN can learn simple boolean operators of propositional logic such as conjunctives or negation from truth values. Again, if a model did not have this ability, then there’s little chance it could learn these frequently occurring phenomena from the noisy language of real texts such as movie reviews.

### 3.1 Predicting Sentiment Distributions of Adverb-Adjective Pairs

The first study considers the prediction of fine-grained sentiment distributions of adverb-adjective pairs and analyzes different possibilities for computing the parent vector  $p$ . The results show that the MV-RNN operators are powerful enough to capture the operational meanings of various types of adverbs. For example, *very* is an intensifier, *pretty* is an attenuator, and *not* can negate or strongly attenuate the positivity of an adjective. For instance *not great* is still *pretty good* and not *terrible*; see Potts (2010) for details.

We use a publicly available IMDB dataset of extracted adverb-adjective pairs from movie reviews.<sup>1</sup> The dataset provides the distribution over star ratings: Each consecutive word pair appears a certain number of times in reviews that have also associated with them an overall rating of the movie. After normalizing by the total number of occurrences, one gets a multinomial distribution over ratings. Only word pairs that appear at least 50 times are kept. Of the remaining pairs, we use 4211 randomly sampled ones for training and a separate set of 1804 for testing. We never give the algorithm sentiment distributions for single words, and, while single words overlap between training and testing, the test set consists of never before seen word pairs.

The softmax classifier is trained to minimize the cross entropy error. Hence, an evaluation in terms of KL-divergence is the most reasonable choice. It is

<sup>1</sup><http://compprag.christopherpotts.net/reviews.html>

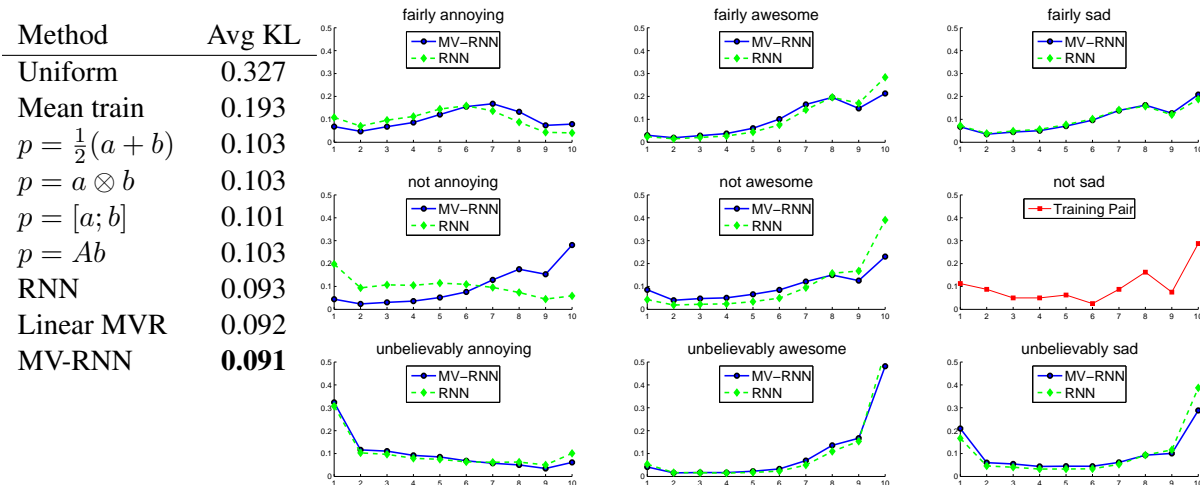

Figure 3: **Left:** Average KL-divergence for predicting sentiment distributions of unseen adverb-adjective pairs of the test set. See text for  $p$  descriptions. Lower is better. The main difference in the KL divergence comes from the few negation pairs in the test set. **Right:** Predicting sentiment distributions (over 1-10 stars on the  $x$ -axis) of adverb-adjective pairs. Each row has the same adverb and each column the same adjective. Many predictions are similar between the two models. The RNN and linear MVR are not able to modify the sentiment correctly: *not awesome* is more positive than *fairly awesome* and *not annoying* has a similar shape as *unbelievably annoying*. Predictions of the linear MVR model are almost identical to the standard RNN for these examples.

defined as  $KL(g||p) = \sum_i g_i \log(g_i/p_i)$ , where  $g$  is the gold distribution and  $p$  is the predicted one.

We compare to several baselines and ablations of the MV-RNN model. An (adverb, adjective) pair is described by its vectors  $(a, b)$  and matrices  $(A, B)$ .

1.  $p = 0.5(a + b)$ , vector average
2.  $p = a \otimes b$ , element-wise vector multiplication
3.  $p = [a; b]$ , vector concatenation
4.  $p = Ab$ , similar to (Baroni and Lenci, 2010)
5.  $p = g(W[a; b])$ , RNN, similar to Socher et al.
6.  $p = Ab + Ba$ , Linear MVR, similar to (Mitchell and Lapata, 2010; Zanzotto et al., 2010)
7.  $p = g(W[Ba; Ab])$ , MV-RNN

The final distribution is always predicted by a softmax classifier whose inputs  $p$  vary for each of the models. This objective function (see Sec. 2.4) is different to all previously published work except that of (Socher et al., 2011c).

We cross-validated all models over regularization parameters for word vectors, the softmax classifier, the RNN parameter  $W$  and the word operators ( $10^{-4}, 10^{-3}$ ) and word vector sizes ( $n = 6, 8, 10, 12, 15, 20$ ). All models performed best at vector sizes of below 12. Hence, it is the model’s power and not the number of parameters that deter-

mines the performance. The table in Fig. 3 shows the average KL-divergence on the test set. It shows that the idea of matrix-vector representations for all words and having a nonlinearity are both important. The MV-RNN which combines these two ideas is best able to learn the various compositional effects. The main difference in KL divergence comes from the few negation cases in the test set. Fig. 3 shows examples of predicted distributions. Many of the predictions are accurate and similar between the top models. However, only the MV-RNN has enough expressive power to allow negation to completely shift the sentiment with respect to an adjective. A negated adjective carrying negative sentiment becomes slightly positive, whereas *not awesome* is correctly attenuated. All three top models correctly capture the U-shape of *unbelievably sad*. This pair peaks at both the negative and positive spectrum because it is ambiguous. When referring to the performance of actors, it is very negative, but, when talking about the plot, many people enjoy sad and thought-provoking movies. The  $p = Ab$  model does not perform well because it cannot model the fact that for an adjective like “sad,” the operator of “unbelievably” behaves differently.

Figure 4: Training trees for the MV-RNN to learn propositional operators. The model learns vectors and operators for  $\wedge$  (*and*) and  $\neg$  (*negation*). The model outputs the exact representations of *false* and *true* respectively at the top node. Hence, the operators can be combined recursively an arbitrary number of times for more complex logical functions.

### 3.2 Logic- and Vector-based Compositionality

Another natural question is whether the MV-RNN can, in general, capture some of the simple boolean logic that is sometimes found in language. In other words, can it learn some of the propositional logic operators such as *and*, *or*, *not* in terms of vectors and matrices from a few examples. Answering this question can also be seen as a first step towards bridging the gap between logic-based, formal semantics (Montague, 1974) and vector space models.

The logic-based view of language accounts nicely for compositionality by directly mapping syntactic constituents to lambda calculus expressions. At the word level, the focus is on function words, and nouns and adjectives are often defined only in terms of the sets of entities they denote in the world. Most words are treated as atomic symbols with no relation to each other. There have been many attempts at automatically parsing natural language to a logical form using recursive compositional rules.

Conversely, vector space models have the attractive property that they can automatically extract knowledge from large corpora without supervision. Unlike logic-based approaches, these models allow us to make fine-grained statements about the semantic similarity of words which correlate well with human judgments (Griffiths et al., 2007). Logic-based approaches are often seen as orthogonal to distributional vector-based approaches. However, Garrette et al. (2011) recently introduced a combination of a vector space model inside a Markov Logic Network.

One open question is whether vector-based models can learn some of the simple logic encountered in language such as negation or conjunctives. To this end, we illustrate in a simple example that our MV-RNN model and its learned word matrices (operators) have the ability to learn propositional logic operators such as  $\wedge$ ,  $\vee$ ,  $\neg$  (*and*, *or*, *not*). This is a necessary (though not sufficient) condition for the ability to pick up these phenomena in real datasets

and tasks such as sentiment detection which we focus on in the subsequent sections.

Our setup is as follows. We train on 6 strictly right-branching trees as in Fig. 4. We consider the 1-dimensional case and fix the representation for *true* to  $(t = 1, T = 1)$  and *false* to  $(f = 0, F = 1)$ . Fixing the operators to the  $1 \times 1$  identity matrix 1 is essentially ignoring them. The objective is then to create a perfect reconstruction of  $(t, T)$  or  $(f, F)$  (depending on the formula), which we achieve by the least squares error between the top vector’s representation and the corresponding truth value, e.g. for  $\neg false$ :  $\min \|p_{top} - t\|^2 + \|P_{top} - T\|^2$ .

As our function  $g$  (see Eq. 2), we use a linear threshold unit:  $g(x) = \max(\min(x, 1), 0)$ . Giving the derivatives computed for the objective function for the examples in Fig. 4 to a standard L-BFGS optimizer quickly yields a training error of 0. Hence, the output of these 6 examples has exactly one of the truth representations, making it recursively compatible with further combinations of operators. Thus, we can combine these operators to construct any propositional logic function of any number of inputs (including xor). Hence, this MV-RNN is complete in terms of propositional logic.

## 4 Predicting Movie Review Ratings

In this section, we analyze the model’s performance on full length sentences. We compare to previous state of the art methods on a standard benchmark dataset of movie reviews (Pang and Lee, 2005; Nakagawa et al., 2010; Socher et al., 2011c). This dataset consists of 10,000 positive and negative single sentences describing movie sentiment. In this and the next experiment we use binarized trees from the Stanford Parser (Klein and Manning, 2003). We use the exact same setup and parameters (regularization, word vector size, etc.) as the published code of Socher et al. (2011c).<sup>2</sup>

<sup>2</sup>[www.socher.org](http://www.socher.org)

Method	Acc.
Tree-CRF (Nakagawa et al., 2010)	77.3
RAE (Socher et al., 2011c)	77.7
Linear MVR	77.1
MV-RNN	<b>79.0</b>

Table 1: Accuracy of classification on full length movie review polarity (MR).

S.	C.	Review sentence
1	✓	The film is bright and flashy in all the right ways.
0	✓	Not always too whimsical for its own good this strange hybrid of crime thriller, quirky character study, third-rate romance and female empowerment fantasy never really finds the tonal or thematic glue it needs.
0	✓	Doesn't come close to justifying the hype that surrounded its debut at the Sundance film festival two years ago.
0	x	Director Hoffman, his writer and Kline's agent should serve detention.
1	x	A bodice-ripper for intellectuals.

Table 2: Hard movie review examples of positive (1) and negative (0) sentiment (S.) that of all methods only the MV-RNN predicted correctly (C: ✓) or could not classify as correct either (C: x).

Table 1 shows comparisons to the system of (Nakagawa et al., 2010), a dependency tree based classification method that uses CRFs with hidden variables. The state of the art recursive autoencoder model of Socher et al. (2011c) obtained 77.7% accuracy. Our new MV-RNN gives the highest performance, outperforming also the linear MVR (Sec. 2.2).

Table 2 shows several hard examples that only the MV-RNN was able to classify correctly. None of the methods correctly classified the last two examples which require more world knowledge.

## 5 Classification of Semantic Relationships

The previous task considered global classification of an entire phrase or sentence. In our last experiment we show that the MV-RNN can also learn how a syntactic context composes an aggregate meaning of the semantic relationships between words. In particular, the task is finding semantic relationships between pairs of nominals. For instance, in the sentence “My [apartment]<sub>e1</sub> has a pretty large [kitchen]<sub>e2</sub>.”, we want to predict that the kitchen and apartment are in a *component-whole* relationship. Predicting such

Figure 5: The MV-RNN learns vectors in the path connecting two words (dotted lines) to determine their semantic relationship. It takes into consideration a variable length sequence of various word types in that path.

semantic relations is useful for information extraction and thesaurus construction applications. Many approaches use features for all words on the path between the two words of interest. We show that by building a single compositional semantics for the minimal constituent including both terms one can achieve a higher performance.

This task requires the ability to deal with sequences of words of arbitrary type and length in between the two nouns in question. Fig. 5 explains our method for classifying nominal relationships. We first find the path in the parse tree between the two words whose relation we want to classify. We then select the highest node of the path and classify the relationship using that node’s vector as features. We apply the same type of MV-RNN model as in sentiment to the subtree spanned by the two words.

We use the dataset and evaluation framework of SemEval-2010 Task 8 (Hendrickx et al., 2010). There are 9 ordered relationships (with two directions) and an undirected *other* class, resulting in 19 classes. Among the relationships are: message-topic, cause-effect, instrument-agency (etc. see Table 3 for list). A pair is counted as correct if the order of the words in the relationship is correct.

Table 4 lists results for several competing methods together with the resources and features used by each method. We compare to the systems of the competition which are described in Hendrickx et al. (2010) as well as the RNN and linear MVR. Most systems used a considerable amount of hand-designed semantic resources. In contrast to these methods, the MV-RNN only needs a parser for the tree structure and learns all semantics from unlabeled corpora and the training data. Only the SemEval training dataset is specific to this task, the re-

Relationship	Sentence with labeled nouns for which to predict relationships
Cause-Effect(e2,e1)	Avian [influenza] <sub>e1</sub> is an infectious disease caused by type a strains of the influenza [virus] <sub>e2</sub> .
Entity-Origin(e1,e2)	The [mother] <sub>e1</sub> left her native [land] <sub>e2</sub> about the same time and they were married in that city.
Message-Topic(e2,e1)	Roadside [attractions] <sub>e1</sub> are frequently advertised with [billboards] <sub>e2</sub> to attract tourists.
Product-Producer(e1,e2)	A child is told a [lie] <sub>e1</sub> for several years by their [parents] <sub>e2</sub> before he/she realizes that ...
Entity-Destination(e1,e2)	The accident has spread [oil] <sub>e1</sub> into the [ocean] <sub>e2</sub> .
Member-Collection(e2,e1)	The siege started, with a [regiment] <sub>e1</sub> of lightly armored [swordsmen] <sub>e2</sub> ramming down the gate.
Instrument-Agency(e2,e1)	The core of the [analyzer] <sub>e1</sub> identifies the paths using the constraint propagation [method] <sub>e2</sub> .
Component-Whole(e2,e1)	The size of a [tree] <sub>e1</sub> [crown] <sub>e2</sub> is strongly correlated with the growth of the tree.
Content-Container(e1,e2)	The hidden [camera] <sub>e1</sub> , found by a security guard, was hidden in a business card-sized [leaflet box] <sub>e2</sub> placed at an unmanned ATM in Tokyo's Minato ward in early September.

Table 3: Examples of correct classifications of ordered, semantic relations between nouns by the MV-RNN. Note that the final classifier is a recursive, compositional function of all the words in the syntactic path between the bracketed words. The paths vary in length and the words vary in type.

Classifier	Feature Sets	F1
SVM	POS, stemming, syntactic patterns	60.1
SVM	word pair, words in between	72.5
SVM	POS, WordNet, stemming, syntactic patterns	74.8
SVM	POS, WordNet, morphological features, thesauri, Google <i>n</i> -grams	77.6
MaxEnt	POS, WordNet, morphological features, noun compound system, thesauri, Google <i>n</i> -grams	77.6
SVM	POS, WordNet, prefixes and other morphological features, POS, dependency parse features, Levin classes, PropBank, FrameNet, NomLex-Plus, Google <i>n</i> -grams, paraphrases, TextRunner	82.2
RNN	-	74.8
Lin.MVR	-	73.0
MV-RNN	-	79.1
RNN	POS,WordNet,NER	77.6
Lin.MVR	POS,WordNet,NER	78.7
MV-RNN	POS,WordNet,NER	<b>82.4</b>

Table 4: Learning methods, their feature sets and F1 results for predicting semantic relations between nouns. The MV-RNN outperforms all but one method without any additional feature sets. By adding three such features, it obtains state of the art performance.

maining inputs and the training setup are the same as in previous sentiment experiments.

The best method on this dataset (Rink and Harabagiu, 2010) obtains 82.2% F1. In order to see whether our system can improve over this system, we added three features to the MV-RNN vector and trained another softmax classifier. The features and their performance increases were POS tags (+0.9); WordNet hypernyms (+1.3) and named en-

tity tags (NER) of the two words (+0.6). Features were computed using the code of Ciaramita and Altun (2006).<sup>3</sup> With these features, the performance improved over the state of the art system. Table 3 shows random correct classification examples.

## 6 Related work

Distributional approaches have become omnipresent for the recognition of semantic similarity between words and the treatment of compositionality has seen much progress in recent years. Hence, we cannot do justice to the large amount of literature. Commonly, single words are represented as vectors of distributional characteristics – e.g., their frequencies in specific syntactic relations or their co-occurrences with given context words (Pado and Lapata, 2007; Baroni and Lenci, 2010; Turney and Pantel, 2010). These representations have proven very effective in sense discrimination and disambiguation (Schütze, 1998), automatic thesaurus extraction (Lin, 1998; Curran, 2004) and selectional preferences.

There are several sophisticated ideas for compositionality in vector spaces. Mitchell and Lapata (2010) present an overview of the most important compositional models, from simple vector addition and component-wise multiplication to tensor products, and convolution (Metcalfe, 1990). They measured the similarity between word pairs such as compound nouns or verb-object pairs and compared these with human similarity judgments. Simple vector averaging or multiplication performed best, hence our focus on related baselines above.

<sup>3</sup>[sourceforge.net/projects/supersensetag/](https://sourceforge.net/projects/supersensetag/)

Other important models are tensor products (Clark and Pulman, 2007), quantum logic (Widdows, 2008), holographic reduced representations (Plate, 1995) and the Compositional Matrix Space model (Rudolph and Giesbrecht, 2010). RNNs are related to autoencoder models such as the recursive autoassociative memory (RAAM) (Pollack, 1990) or recurrent neural networks (Elman, 1991). Bottou (2011) and Hinton (1990) discussed related models such as recursive autoencoders for text understanding.

Our model builds upon and generalizes the models of (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Zanzotto et al., 2010; Socher et al., 2011c) (see Sec. 2.2). We compare to them in our experiments. Yessenalina and Cardie (2011) introduce a sentiment analysis model that describes words as matrices and composition as matrix multiplication. Since matrix multiplication is associative, this cannot capture different scopes of negation or syntactic differences. Their model, is a special case of our encoding model (when you ignore vectors, fix the tree to be strictly branching in one direction and use as the matrix composition function  $P = AB$ ). Since our classifiers are trained on the vectors, we cannot compare to this approach directly. Grefenstette and Sadrzadeh (2011) learn matrices for verbs in a categorical model. The trained matrices improve correlation with human judgments on the task of identifying relatedness of subject-verb-object triplets.

## 7 Conclusion

We introduced a new model towards a complete treatment of compositionality in word vector spaces. Our model builds on a syntactically plausible parse tree and can handle compositional phenomena. The main novelty of our model is the combination of matrix-vector representations with a recursive neural network. It can learn both the meaning vectors of a word and how that word modifies its neighbors (via its matrix). The MV-RNN combines attractive theoretical properties with good performance on large, noisy datasets. It generalizes several models in the literature, can learn propositional logic, accurately predicts sentiment and can be used to classify semantic relationships between nouns in a sentence.

## Abstract

Existing vector space models typically map synonyms and antonyms to similar word vectors, and thus fail to represent antonymy. We introduce a new vector space representation where antonyms lie on opposite sides of a sphere: in the word vector space, synonyms have cosine similarities close to one, while antonyms are close to minus one.

We derive this representation with the aid of a thesaurus and latent semantic analysis (LSA). Each entry in the thesaurus – a word sense along with its synonyms and antonyms – is treated as a “document,” and the resulting document collection is subjected to LSA. The key contribution of this work is to show how to assign signs to the entries in the co-occurrence matrix on which LSA operates, so as to induce a subspace with the desired property.

We evaluate this procedure with the Graduate Record Examination questions of (Mohammed et al., 2008) and find that the method improves on the results of that study. Further improvements result from refining the subspace representation with discriminative training, and augmenting the training data with general newspaper text. Altogether, we improve on the best previous results by 11 points absolute in F measure.

## 1 Introduction

Vector space representations have proven useful across a wide variety of text processing applications ranging from document clustering to search relevance measurement. In these applications, text is

represented as a vector in a multi-dimensional continuous space, and a similarity metric such as cosine similarity can be used to measure the relatedness of different items. Vector space representations have been used both at the document and word levels. At the document level, they are effective for applications including information retrieval (Salton and McGill, 1983; Deerwester et al., 1990), document clustering (Deerwester et al., 1990; Xu et al., 2003), search relevance measurement (Baeza-Yates and Ribiero-Neto, 1999) and cross-lingual document retrieval (Platt et al., 2010). At the word level, vector representations have been used to measure word similarity (Deerwester et al., 1990; Turney and Littman, 2005; Turney, 2006; Turney, 2001; Lin, 1998; Agirre et al., 2009; Reisinger and Mooney, 2010) and for language modeling (Bellegarda, 2000; Coccaro and Jurafsky, 1998). While quite successful, these applications have typically been consistent with a very general notion of similarity in which basic association is measured, and finer shades of meaning need not be distinguished. For example, latent semantic analysis might assign a high degree of similarity to opposites as well as synonyms (Landauer and Laham, 1998; Landauer, 2002).

Independent of vector-space representations, a number of authors have focused on identifying different kinds of relatedness. At the simplest level, we may wish to distinguish between synonyms and antonyms, which can be further differentiated. For example, in synonymy, we may wish to distinguish hyponyms and hypernyms. Moreover, Cruse (1986) notes that numerous kinds of antonymy are possible, for example *antipodal pairs* like “top-bottom” or

*gradable opposites* like “light-heavy.” Work in this area includes (Turney, 2001; Lin et al., 2003; Turney and Littman, 2005; Turney, 2006; Curran and Moens, 2002; van der Plas and Tiedemann, 2006; Mohammed et al., 2008; Mohammed et al., 2011). Despite the existence of a large amount of related work in the literature, distinguishing synonyms and antonyms is still considered as a difficult open problem in general (Poon and Domingos, 2009).

In this paper, we fuse these two strands of research in an attempt to develop a vector space representation in which the synonymy and antonymy are naturally differentiated. We follow Schwab et al. (2002) in requiring a representation in which two lexical items in an antonymy relation should lie at opposite ends of an axis. However, in contrast to the logical axes used previously, we desire that antonyms should lie at the opposite ends of a sphere lying in a continuous and automatically induced vector space. To generate this vector space, we present a novel method for assigning both *negative* and *positive* values to the TF-IDF weights used in latent semantic analysis.

To determine these signed values, we exploit the information present in a thesaurus. The result is a vector space representation in which synonyms cluster together, and the opposites of a word tend to cluster together at the opposite end of a sphere.

This representation provides several advantages over the raw thesaurus. First, by finding the items most and least similar to a word, we are able to discover new synonyms and antonyms. Second, as discussed in Section 5, the representation provides a natural starting point for gradient-descent based optimization. Thirdly, as we discuss in Section 6, it is straightforward to embed *new words* into the derived subspace by using information from a large unsupervised text corpus such as Wikipedia.

The remainder of this paper is organized as follows. Section 2 describes previous work. Section 3 presents the classical LSA approach and analyzes some of its limitations. In Section 4 we present our polarity inducing extension to LSA. Section 5 further extends the approach by optimizing the vector space representation with supervised discriminative training. Section 6 describes the proposed method of embedding new words in the thesaurus-derived subspace. The experimental results of Section 7 indi-

cate that the proposed method outperforms previous approaches on a GRE test of closest-opposites (Mohammed et al., 2008). Finally, Section 8 concludes the paper.

## 2 Related Work

The detection of antonymy has been studied in a number of previous papers. Mohammed et al. (2008) approach the problem by combining information from a published thesaurus with corpus statistics derived from the Google *n*-gram corpus (Brants and Franz, 2006). Their method consists of two main steps: first, detecting contrasting word categories (e.g. “WORK” vs. “ACTIVITY FOR FUN”) and then determining the degree of antonymy. Categories are defined by a thesaurus; contrasting categories are found by using affix rules (e.g., un- & dis-) and WordNet antonymy links. Words belonging to contrasting categories are treated as antonyms and the degree of contrast is determined by distributional similarity. Mohammed et al. (2008) also provides a publicly available dataset for detection of antonymy, which we have adopted. This work has been extended in (Mohammed et al., 2011) to include a study of antonymy based on crowd-sourcing experiments.

Turney (2008) proposes a unified approach to handling analogies, synonyms, antonyms and associations by transforming the last three cases into cases of analogy. A supervised learning method is then used to solve the resulting analogical problems. This is evaluated on a set of 136 ESL questions. Lin et al. (2003) builds on (Lin, 1998) and identifies antonyms as semantically related words which also happen to be found together in a database in pre-identified phrases indicating opposition. Lin et al. (2003) further note that whereas synonyms will tend to translate to the same word in another language, antonyms will not. This observation is used to select antonyms from amongst distributionally similar words. Antonymy is used in (de Simone and Kazakov, 2005) for document clustering and (Harabagiu et al., 2006) to find contradiction.

The automatic detection of synonyms has been more extensively studied. Lin (1998) presents a thorough comparison of word-similarity metrics based on distributional similarity, where this is de-

terminated from co-occurrence statistics in dependency triples extracted by parsing a large dataset. Related studies are described in (Curran and Moens, 2002; van der Plas and Bouma, 2005). Later, van der Plas and Tiedemann (2006) extend the use of multilingual data present in Lin et al. (2003) by measuring distributional similarity based on the contexts that a word occurs in *once translated* into a new language. This is used to improve the precision/recall characteristics on synonym pairs. Structured information can be important in determining relatedness, and thesauri and Wikipedia links have been studied in (Milne and Witten, 2008; Jarmasz and Szpakowicz, 2003). Combinations of approaches are studied in (Turney et al., 2003).

Vector-space models and latent semantic analysis in particular have a long history of use in synonym detection, which in fact was suggested in some of the earliest LSA papers. Deerwester et al. (1990) defines a metric for measuring word similarity based on LSA, and it has been used in (Landauer and Dumais, 1997; Landauer et al., 1998) to answer word similarity questions derived from the Test of English as a Foreign Language (TOEFL). Turney (2001) proposes the use of point-wise mutual information in conjunction with LSA, and again presents results on synonym questions derived from the TOEFL. Variants of vector space models are further analyzed in (Turney and Littman, 2005; Turney, 2006; Turney and Pantel, 2010).

### 3 Latent Semantic Analysis

Latent Semantic Analysis (Deerwester et al., 1990) is a widely used method for representing words and documents in a low dimensional vector space. The method is based on applying singular value decomposition (SVD) to a matrix  $W$  which indicates the occurrence of words in documents. To perform LSA, one proceeds as follows. The input is a collection of  $d$  documents which are expressed in terms of words from a vocabulary of size  $n$ . These documents may be actual documents such as newspaper articles, or simply notional documents such as sentences, or any other collection in which words are grouped together. Next, a  $d \times n$  document-term ma-

trix  $W$  is formed<sup>1</sup>. At its simplest form, the  $ij^{\text{th}}$  entry contains the number of times word  $j$  has occurred in document  $i$  – its *term frequency* or TF value. More conventionally, the entry is weighted by some notion of the importance of word  $j$ , for example the negative logarithm of the fraction of documents that contain it, resulting in a TF-IDF weighting (Salton et al., 1975). The similarity between two documents can be computed using the cosine similarity of their corresponding row vectors:

$$\text{sim}(\mathbf{x}, \mathbf{y}) = \frac{\mathbf{x} \cdot \mathbf{y}}{\|\mathbf{x}\| \|\mathbf{y}\|}$$

Similarly, the cosine similarity of two column vectors can be used to judge the similarity of the corresponding words. Finally, to obtain a subspace representation of dimension  $k$ ,  $W$  is decomposed as

$$W \approx USV^T$$

where  $U$  is  $d \times k$ ,  $V^T$  is  $k \times n$ , and  $S$  is a  $k \times k$  diagonal matrix. In applications,  $k \ll n$  and  $k \ll d$ ; for example one might have a 50,000 word vocabulary and 1,000,000 documents and use a 300 dimensional subspace representation.

An important property of SVD is that the columns of  $SV^T$  – which now represent the words – behave similarly to the original columns of  $W$ , in the sense that the cosine similarity between two columns in  $SV^T$  approximates the cosine similarity between the corresponding columns in  $W$ . This follows from the observation that  $W^T W = V S^2 V^T$ , and the fact that the  $ij^{\text{th}}$  entry of  $W^T W$  is the dot product of the  $i^{\text{th}}$  and  $j^{\text{th}}$  columns (words) in  $W$ . We will use this observation subsequently in the derivation of polarity-inducing LSA. For efficiency, we normalize the columns of  $SV^T$  to unit length, allowing the cosine similarity between two words to be computed with a single dot-product; this also has the property of mapping each word to a point on a multi-dimensional sphere.

A second important property of LSA is that in the word representations which result can be viewed as the result of applying a projection matrix  $U$  to the original vectors as:

$$U^T W = SV^T$$

<sup>1</sup>(Bellegarda, 2000) constructs the transpose of this, but we have found it convenient in data processing for documents to represent rows.

In Section 5, we will view  $U$  simply as a  $d \times k$  matrix learned through gradient descent so as to optimize an objective function.

### 3.1 Limitation of LSA

Word similarity as determined by LSA assigns high values to words which tend to co-occur in documents. However, as noted by (Landauer and Laham, 1998; Landauer, 2002), there is no notion of antonymy; words with low or negative cosine scores are simply unrelated. In comparison, words with high cosine similarity scores are typically *semantically* related, which includes both synonyms and antonyms, as contrasting words often co-occur (Murphy and Andrew, 1993; Mohammed et al., 2008). To illustrate this, we have performed SVD with the aid of the Encarta thesaurus developed by Bloomsbury Publishing Plc. This thesaurus contains approximately 47k word senses and a vocabulary of 50k words and phrases. Each “document” is taken to be the thesaurus entry for a word-sense, including synonyms and antonyms. For example, the word “admirable” induces a document consisting of {admirable, estimable, commendable, venerable, good, splendid, worthy, marvelous, excellent, *unworthy*}. Note that the last word in this set is its antonym. Performing SVD on this set of thesaurus derived “meaning-documents” results in a subspace representation for each word. This form of LSA is similar to the use of Wikipedia in (Gabrilovich and Markovitch, 2007).

Table 1 shows some words, their original thesaurus documents, and the most and least similar words in the LSA subspace. Several properties are apparent:

- The vector-space representation of words is able to identify related words that are not explicitly present in the original thesaurus. For example, “meritorious” for “admirable” – arguably better than any of the words given in the thesaurus itself.
- Similarity is based on co-occurrence, so the co-occurrence of antonyms in the thesaurus-derived documents induces their presence as LSA-similar words. For example, “contemptible” is identified as similar to “admirable.” In the case of “mourning,” opposites

	acrimony	rancor	goodwill	affection
acrimony	1	1	1	1
affection	1	1	1	1

Table 2: The  $W$  matrix for two thesaurus entries in its original form. Rows represent documents; columns words.

	acrimony	rancor	goodwill	affection
acrimony	1	1	-1	-1
affection	-1	-1	1	1

Table 3: The  $W$  matrix for two thesaurus entries in its polarity-inducing form.

such as “joy” and “elation” actually dominate the list of LSA-similar words.

- The LSA-least-similar words have no relationship at all to the word they are least-similar to. For example, the least-similar word to “considered” is “ready-made-meal.”

In the next section, we will present a method for inducing polarity in LSA subspaces, where opposite words will tend to have negative cosine similarities, analogous to the positive similarities of synonyms. Thus, the least-similar words to a given word will be its opposites.

## 4 Polarity Inducing LSA

We modify LSA so that we may exploit a thesaurus to embed meaningful axes in the induced subspace representation. Words with opposite meaning will lie at opposite positions on a sphere. Recall that the cosine similarity between word-vectors in the original matrix  $W$  are preserved in the subspace representation of words. Thus, if we construct the original matrix so that the columns representing antonyms will tend to have negative cosine similarities while columns representing synonyms will tend to have positive similarities, we will achieve the desired behavior.

This can be achieved by negating the TF-IDF entries for the antonyms of a word when constructing  $W$  from the thesaurus, which is illustrated in Tables 2 and 3. The two rows in these tables correspond to thesaurus entries for the sense-categories

Word	Thesaurus Entry	LSA Most-Similar Words	LSA Least-Similar Words
admirable	estimable, commendable, venerable, good, splendid, worthy, marvelous, excellent, <i>unworthy</i>	commendable, creditable, laudable, praiseworthy, worthy, meritorious, scurvy, contemptible, despicable, estimable	easy-on-the-eye, peace-keeper, peace-lover, conscientious-objector, uninviting, dishy, dessert, pudding, seductive
considered	careful, measured, well-thought-out, painstaking, <i>rash</i>	calculated, premeditated, planned, tactical, strategic, thought-through, intentional, fortuitous, purposeful, unpremeditated	ready-made-meal, ready-meal, disposed-to, apt-to, wild-animals, big-game, game-birds, game-fish, rugger, rugby
mourning	grief, bereavement, sorrow, sadness, lamentation, woe, grieving, <i>exultation</i>	sorrowfulness, anguish, exultation, rejoicing, jubilation, glee, heartache, travail, joy, elation	muckiness, turn-the-corner, impassibility, filminess, pellucidity, limpidity, sheerness

Table 1: LSA on a thesaurus. Thesaurus entries include antonyms in italics.

“acrimony,” and “affection.” The thesaurus entries induce two “documents” containing the words and their synonyms and antonyms. The complete set of words is *acrimony, rancor, goodwill, affection*. For simplicity, we assume that all TF-IDF weights are 1. In the original LSA formulation, we have the representation of Table 2. “Rancor” is listed as a synonym of “acrimony,” which has “goodwill” and “affection” as its antonyms. This results in the first row. Note that the cosine similarity between every pair of words (columns) is 1.

Table 3 shows the polarity-inducing representation. Here, the cosine similarity between synonymous words (columns) is 1, and the cosine similarity between antonymous words is -1. Since LSA tends to preserve cosine similarities between words, in the resulting subspace we may expect to find meaningful axes, where opposite senses map to opposite extremes. We refer to this as polarity-inducing LSA or PILSA.

In Table 4, we show the PILSA-similar and PILSA-least-similar words for the same words as in Table 1. We see now that words which are least similar in the sense of having the lowest cosine-similarity are indeed opposites. In this table generally the most similar words have similarities in the range of 0.7 to 1.0 and the least similar in the range of -0.7 to -1.0.

## 5 Discriminative Training

Although the cosine similarity of LSA-derived word vectors are generally very effective in applications such as judging the relevance of words or documents, or detecting antonyms as in our construction, the process of singular value decomposition in LSA does not explicitly try to achieve such goals. In this section, we see that when supervised training data is available, the projection matrix of LSA can be enhanced through a discriminative training technique explicitly designed to create a representation suited to a specific task.

Because LSA is closely related to principle component analysis (PCA), extensions of PCA such as canonical correlation analysis (CCA) and oriented principle component analysis (OPCA) can leverage the labeled data and produce the projection matrix through general eigen-decomposition (Platt et al., 2010). Along this line of work, Yih et al. (2011) proposed a Siamese neural network approach called *S2Net*, which tunes the projection matrix directly through gradient descent, and has shown to outperform other methods in several tasks. Below we describe briefly this technique and explain how we adopt it for the task of antonym detection.

The goal of *S2Net* is to learn a concept vector representation of the original sparse term vectors. Although such transformation can be non-linear in general, its current design chooses the model form to be a linear projection matrix, which is identical to

Word	PILSA-Similar Words	PILSA-Least-Similar Words
admirable	commendable, creditable, laudable, praiseworthy, worthy, meritorious, estimable, deserving, tiptop, valued	scurvy, contemptible, despicable, lamentable, shameful, reprehensible, unworthy, disgraceful, discreditable, undeserving
considered	calculated, premeditated, planned, tactical, strategic, thought-through, intentional, purposeful, intended, psychological	fortuitous, unpremeditated, unconsidered, off-your-own-bat, unintended, undirected, objectiveless, hit-and-miss, unforced, involuntary
mourning	sorrowful, doleful, sad, miserable, wistful, pitiful, wailing, sobbing, heavy-hearted, forlorn	smiley, happy, blissful, wooden, mirthful, joyful, deadpan, fulfilled, straight-faced, content

Table 4: PILSA on a thesaurus. Thesaurus entries are as in Table 1.

that of LSA, PCA, OPCA or CCA. Given a  $d$ -by-1 input vector  $\mathbf{f}$ , the model of S2Net is a  $d$ -by- $k$  matrix  $\mathbf{A} = [a_{ij}]_{d \times k}$ , which maps  $\mathbf{f}$  to a  $k$ -by-1 output vector  $\mathbf{g} = \mathbf{A}^T \mathbf{f}$ . The fact that the transformation can be viewed as a two-layer neural network leads to the method’s name.

What differentiates S2Net from other approaches is its loss function and optimization process. In the “parallel text” setting, the labeled data consists of pairs of *similar* text objects such as documents. The objective of the training process is to assign higher cosine similarities to these pairs compared to others. More specifically, suppose the training set consists of  $m$  pairs of raw input vectors  $\{(\mathbf{f}_{p_1}, \mathbf{f}_{q_1}), (\mathbf{f}_{p_2}, \mathbf{f}_{q_2}), \dots, (\mathbf{f}_{p_m}, \mathbf{f}_{q_m})\}$ . Given a projection matrix  $\mathbf{A}$ , the similarity score of any pair of objects is  $sim_{\mathbf{A}}(\mathbf{f}_{p_i}, \mathbf{f}_{q_j}) = cosine(\mathbf{A}^T \mathbf{f}_{p_i}, \mathbf{A}^T \mathbf{f}_{q_j})$ . Let  $\Delta_{ij} = sim_{\mathbf{A}}(\mathbf{f}_{p_i}, \mathbf{f}_{q_i}) - sim_{\mathbf{A}}(\mathbf{f}_{p_i}, \mathbf{f}_{q_j})$  be the difference of the similarity scores of  $(\mathbf{f}_{p_i}, \mathbf{f}_{q_i})$  and  $(\mathbf{f}_{p_i}, \mathbf{f}_{q_j})$ . The learning procedure tries to increase  $\Delta_{ij}$  by using the following logistic loss:

$$L(\Delta_{ij}; \mathbf{A}) = \log(1 + exp(-\gamma \Delta_{ij})),$$

where  $\gamma$  is a scaling factor that adjusts the loss function<sup>2</sup>. The loss of the whole training set is thus:

$$\frac{1}{m(m-1)} \sum_{1 \leq i, j \leq m, i \neq j} L(\Delta_{ij}; \mathbf{A})$$

Parameter learning (i.e., tuning  $\mathbf{A}$ ) can be done

<sup>2</sup>As suggested in (Yih et al., 2011),  $\gamma$  is set to 10 in our experiments.

by standard gradient-based methods, such as L-BFGS (Nocedal and Wright, 2006).

The original setting of S2Net can be directly applied to finding synonymous words, where the training data consists of pairs of vectors representing two synonyms. It is also easy to modify the loss function to apply it to the antonym detection problem. We first sample pairs of antonyms from the thesaurus to create the training data. The raw input vector  $\mathbf{f}$  of a selected word is its corresponding column vector of the document-term matrix  $W$  (Section 3) after inducing polarity (Section 4). When each pair of vectors in the training data represents two antonyms, we can redefine  $\Delta_{ij}$  by flipping the sign:  $\Delta_{ij} = sim_{\mathbf{A}}(\mathbf{f}_{p_i}, \mathbf{f}_{q_j}) - sim_{\mathbf{A}}(\mathbf{f}_{p_i}, \mathbf{f}_{q_i})$ , and leave others unchanged. As the loss function encourages  $\Delta_{ij}$  to be larger, an antonym pair will tend to have a smaller cosine similarity than other pairs. Because S2Net uses a gradient descent technique and a non-convex objective function, it is sensitive to initialization, and we have found that the PILSA projection matrix  $U$  (Section 3) provides an excellent starting point. As illustrated in Section 7, learning the word vectors with S2Net produces a significant improvement over PILSA alone.

## 6 Extending PILSA to Out-of-thesaurus Words

While PILSA is effective at representing synonym and antonym information, in its pure form, it is limited to the vocabulary of the thesaurus. In order to extend PILSA to operate on out-of-thesaurus words,

we employ a two-stage strategy. We first conduct some lexical analysis and try to match an unknown word to one or more in-thesaurus words in their lemmatized forms. If no such match can be found, we then attempt to find semantically related in-thesaurus words by leveraging co-occurrence statistics from general text data. These two steps are described in detail below.

## 6.1 Matching via Lexical Analysis

When a target word is not included in a thesaurus, it is quite often that some of its morphological variations are covered. For example, although the Encarta thesaurus does not have the word “corruptibility,” it does contain other forms like “corruptible” and “corruption.” Replacing the out-of-thesaurus target word with these morphological variations may alter the part-of-speech but typically does not change the meaning<sup>3</sup>.

Given an out-of-thesaurus target word, we first apply a morphological analyzer for English developed by Minnen et al. (2001), which removes the inflectional affixes and returns the lemma. If the lemma still does not exist in the thesaurus, we then apply Porter’s stemmer (Porter, 1980) and check whether the target word can match any of the in-thesaurus words in their stemmed forms. A simple rule that checks whether removing hyphens from words can lead to a match and whether the target word occurs as part of a compound word in the thesaurus is applied when both morphological analysis and stemming fail to find a match. When there are more than one matched words, the centroid of their PILSA vectors is used to represent the target word. When there is only one matched word, the matched word is treated as the target word.

## 6.2 Leveraging General Text Data

If no words in the thesaurus can be linked to the target word through the simple lexical analysis procedure, we try to find matched words by creating a *context* vector space model from a large document collection, and then mapping from this space to the PILSA space. We use contexts because of the *distributional hypothesis* – words that occur in the same *contexts* tend to have similar meaning (Harris,

<sup>3</sup>The rules we use based on lexical analysis are moderately conservative to avoid mistakes like mapping *hopeless* to *hope*.

1954). When a word is not in the thesaurus but appears in the corpus, we predict its PILSA vector representation from the context vector space model by using its  $k$ -nearest neighbors which are in the thesaurus and *consistent* with each other.

### 6.2.1 Context Vector Space Model

Given a corpus of documents, we construct the raw context vectors as follows. For each target word, we first create a bag of words by collecting all the terms within a window of  $[-10,+10]$  centered at each occurrence of the target word in the corpus. The non-identical terms form a term-vector, where each term is weighted using its TF-IDF value. We then perform LSA on the context-word matrix. The semantic similarity/relatedness of two words can then be determined using the cosine similarity of their corresponding LSA word vectors. In the following text, we refer to this LSA context vector space model as the *corpus* space, in contrast to the PILSA *thesaurus* space.

### 6.2.2 Embedding Out-of-Vocabulary Words

Given the context space model, we may use a linear regression or a  $k$ -nearest neighbors approach to embed out-of-thesaurus words into the thesaurus-space representation. However, as near words in the context space may be synonyms in addition to other semantically related words (including antonyms), such approaches can potentially be noisy. For example, words like “hot” and “cold” may be close to each other in the context space due to their similar usage in text. An affine transform cannot “tear space” and map them to opposite poles in the thesaurus space.

Therefore, we propose a revised  $k$ -nearest neighbors approach. Suppose we are interested in an out-of-thesaurus word  $w$ . We first find  $K$ -nearest in-thesaurus neighbors to  $w$  in the context space. We then select a subset of  $k$  members of these  $K$  words such that the pairwise similarity of each of the  $k$  members with every other member is positive. The thesaurus-space centroid of these  $k$  items is computed as  $w$ ’s representation. This procedure has the property that the  $k$  nearby words used to form the embedding of a non-thesaurus word are selected to be consistent with each other. In practice, we used  $K = 10$  and  $k = 3$ , which requires only around

1000 pairwise computations even done in a brute-force way. To provide a concrete example, if we had the out-of-the-saurus word “sweltering” with in-the-saurus neighbors “hot, cold, burning, scorching, ...” the procedure would return the centroid of “hot, burning, scorching” and exclude “cold.”

## 7 Experimental Validation

In this section, we present our experimental results on applying PILSA and its extensions to answering the closest-opposite GRE questions.

### 7.1 Data Resources

The primary thesaurus we use is the Encarta Thesaurus developed by Bloomsbury Publishing Plc<sup>4</sup>. Our version of this has approximately 47k word senses and a vocabulary of 50k words, and contains 125,724 pairs of antonyms. To experiment with the effect of using a different thesaurus, we used WordNet as an information source. Each *synset* in WordNet maps to a row in the document-term matrix; synonyms in a synset are weighted with positive TFIDF values, and antonyms are weighted negative TFIDF values. Entries corresponding to other words in the vocabulary are 0. WordNet provides significantly greater coverage with approximately 227k synsets involving multiple words, and a vocabulary of about 190k words. However, it is also much sparser, with 5.3 words per sense on average as opposed to 10.3 in the thesaurus, and has only 62,821 pairs of antonyms. As general text data for use in embedding out-of-vocabulary words, we used a Nov-2010 dump of English Wikipedia, which contains approximately 917M words.

### 7.2 Development and Test Data

For testing, we use the closest-opposite questions from GRE tests provided by (Mohammed et al., 2008). Each question contains a target word and five choices, and asks which of the choice words has the most opposite meaning to the target word. Two datasets are made publicly available by Mohammad et al. (2008): the *development set*, which consists of 162 questions, and the *test set*, which has 950 questions<sup>5</sup>. We considered making our own, more exten-

<sup>5</sup><http://www.umiacs.umd.edu/~saif/WebDocs/LC-data/{devset,testset}.txt>

Dimensions	Bloomsbury Prec.	WordNet Prec.
50	0.778	0.475
100	0.850	0.563
200	0.856	0.569
300	<b>0.863</b>	<b>0.625</b>
400	0.843	<b>0.625</b>
500	0.843	0.613
750	0.830	0.613
1000	0.837	0.544
2000	0.784	0.519
3000	0.778	0.494

Table 5: The performance of PILSA vs. the number of dimensions when applied to the closest-opposite questions from the GRE development set. Out of the 162 questions, using the Bloomsbury thesaurus data we are able to answer 153 of them. Using 300 dimensions gives the best precision ( $132/153 = 0.863$ ). This dimension setting is also optimal when using the WordNet data, which answers 100 questions correctly out of the 160 attempts ( $100/160 = 0.625$ ).

sive, test – for example one which would require the use of sentence context to choose between related yet distributionally different antonyms (e.g. “little, small” as antonyms of “big”) but chose to stick to a previously used benchmark. This allows the direct comparison with previously reported methods.

Some of these questions contain very rarely used target or choice words, which are not included in the thesaurus vocabulary. In order to provide a fair comparison to existing methods, we do not try to randomly answer these questions. Instead, when the target word is out of vocabulary, we skip the whole question. When the target word is in vocabulary but one or more choices are unknown words, we ignore those unknown words and pick the word with the lowest cosine similarity from the rest as the answer. The results of our methods are reported in *precision* (the number of questions answered correctly divided by the number of questions attempted), *recall* (the number of questions answered correctly divided by the number of all questions) and  $F_1$  (the harmonic mean of precision and recall)<sup>6</sup>. We now turn to an in-depth evaluation.

<sup>6</sup>Precision/recall/ $F_1$  were used in (Mohammed et al., 2008) as when their system “did not find any evidence of antonymy between the target and any of its alternatives, then it refrained from attempting that question.” We adopt this convention to provide a fair comparison to their system.

	Dev. Set			Test Set		
	Prec	Rec	F <sub>1</sub>	Prec	Rec	F <sub>1</sub>
WordNet lookup	0.40	0.40	0.40	0.42	0.41	0.42
WordNet signed-TFIDF w/o LSA	0.41	0.41	0.41	0.43	0.42	0.43
WordNet PILSA	0.63	0.62	0.62	0.60	0.60	0.60
Bloomsbury lookup	0.65	0.61	0.63	0.61	0.56	0.59
Bloomsbury signed TFIDF w/o LSA	0.68	0.64	0.66	0.63	0.57	0.60
Bloomsbury PILSA	0.86	0.81	0.84	0.81	0.74	0.77
Bloomsbury PILSA + S2Net	<b>0.89</b>	0.84	0.86	<b>0.84</b>	0.77	0.80
Bloomsbury PILSA + S2Net + Embedding	0.88	<b>0.87</b>	<b>0.87</b>	0.81	<b>0.80</b>	<b>0.81</b>
(Mohammed et al., 2008)	0.76	0.66	0.70	0.76	0.64	0.70

Table 6: The overall results. PILSA performs LSA on the signed TF-IDF vectors.

### 7.3 Basic PILSA

When applying PILSA, we need to determine the number of dimensions in the projected space. Evaluated on the GRE development set, Table 5 shows the precision of PILSA, using two different training datasets, Bloomsbury and WordNet, at different dimensions.

The Bloomsbury-based system is able to answer 153 questions, and the best dimension setting is 300, which answers 132 questions correctly and thus archives 0.863 in precision. In contrast, the larger vocabulary in WordNet helps the system answer 160 questions but the quality is not as good. We find dimensions 300 and 400 are equally good, where both answer 100 questions correctly (0.625 in precision)<sup>7</sup>. Because a lower number of dimensions is preferred for saving storage space and computing time, we choose 300 as the number of dimensions in PILSA.

We now compare the proposed methods. All results are summarized in Table 6. When evaluated on the GRE test set, the Bloomsbury thesaurus-based methods (Lines 4–7) attempted 865 questions. The precision, recall and F<sub>1</sub> of the Bloomsbury-based PILSA model (Line 6) are 0.81, 0.74 and 0.77, which are all better than the best reported method in (Mohammed et al., 2008)<sup>8</sup>. In contrast, the WordNet-based methods (Lines 1–3) attempted 936

<sup>7</sup>Note that the number of questions attempted is not a function of the number of dimensions.

<sup>8</sup>We take a conservative approach and assume that skipped questions are answered incorrectly. The difference is statistically significant at 99% confidence level using a binomial test.

questions. However, consistent with what we observed on the development set, the WordNet-based model is inferior. Its precision, recall and F<sub>1</sub> on the test set are 0.60, 0.60 and 0.60 (Line 3). Although the quality of the data source plays an important role, we need to emphasize that performing LSA using our polarity inducing construction is in fact a critical step in enhancing the model performance. For example, directly using the antonym sets in the Bloomsbury thesaurus gives 0.59 in F<sub>1</sub> (Line 4), while using cosine similarity on the signed vectors prior to LSA only reaches 0.60 in F<sub>1</sub> (Line 5).

### 7.4 Improving Precision with Discriminative Training

Building on the success of the unsupervised PILSA model, we refine the projection matrix. As described in Section 5, we take the PILSA projection matrix as the initial model in S2Net and train the model using 20,517 pairs of antonyms sampled from the Bloomsbury thesaurus. A separate sample of 5,000 antonym pairs is used as the validation set for hyperparameter tuning in regularization. Encouragingly, we found that the already strong results of PILSA can indeed be improved, which gives 3 more points in both precision (0.84), recall (0.77) and F<sub>1</sub> (0.80).

### 7.5 Improving Recall with Unsupervised Data

We next evaluate our approach of extending the word coverage with the help of an external text corpus, as well as the lexical analysis procedure. Using the Bloomsbury PILSA-S2Net thesaurus space and the Wikipedia corpus space, our method increases

recall by 3 points on the test set. Compared to the in-vocabulary only setting, it attempted 75 more questions (865  $\rightarrow$  940) and had 33 of them correctly answered.

While the accuracy on these questions is much higher than random, the fact that it is substantially below the precision of the original indicates some room for improvement. We notice that the out-of-thesaurus words are either offensive words excluded in the thesaurus (e.g., *moronic*) or some very rarely used words (e.g., *froward*). When the lexical analysis procedure fails to match the target word to some in-thesaurus words, the context vector embedding approach solves the former case, but has difficulty in handling the latter. The main reason is that such words occur very infrequently in a general corpus, which result in significant uncertainty in their semantic vectors. Other than using a much larger corpus, approaches that leverage character  $n$ -grams may help. We leave this as future work.

## 8 Conclusion

In this paper we have tackled the problem of finding a vector-space representation of words where, by construction, synonyms and antonyms are easy to distinguish. Specifically, we have defined a way of assigning sign to the entries in the co-occurrence matrix on which LSA operates, such that synonyms will tend to have positive cosine similarity, and antonyms will tend to have negative similarities. To the best of our knowledge, our method of inducing polarity to the document-term matrix *before* applying LSA is novel and has shown to effectively preserve and generalize the synonymous/antonymous information in the projected space. With this vector space representation, we were able to bring to bear the machinery of discriminative training in order to further optimize the word representations. Finally, by using the notion of closeness in this space, we were able to embed new out-of-vocabulary words into the space. On a standard test set, the proposed methods improved the F measure by 11 points absolute over previous results.

## Abstract

Adjectival modification, particularly by expressions that have been treated as higher-order modifiers in the formal semantics tradition, raises interesting challenges for semantic composition in distributional semantic models. We contrast three types of adjectival modifiers – intersectively used color terms (as in *white towel*, clearly first-order), subsectively used color terms (*white wine*, which have been modeled as both first- and higher-order), and intensional adjectives (*former bassist*, clearly higher-order) – and test the ability of different composition strategies to model their behavior. In addition to opening up a new empirical domain for research on distributional semantics, our observations concerning the attested vectors for the different types of adjectives, the nouns they modify, and the resulting noun phrases yield insights into modification that have been little evident in the formal semantics literature to date.

## 1 Introduction

One of the most appealing aspects of so-called distributional semantic models (see Turney and Pantel (2010) for a recent overview) is that they afford some hope for a non-trivial, computationally tractable treatment of the context dependence of lexical meaning that might also approximate in interesting ways the psychological representation of that meaning (Andrews et al., 2009). However, in order to have a complete theory of natural language meaning, these models must be supplied with or connected to a compositional semantics; otherwise,

we will have no account of the recursive potential that natural language affords for the construction of novel complex contents.

In the last 4-5 years, researchers have begun to introduce compositional operations on distributional semantic representations, for instance to combine verbs with their arguments or adjectives with nouns (Erk and Padó, 2008; Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Socher et al., 2011)<sup>1</sup>. Although the proposed operations have shown varying degrees of success in a number of tasks such as detecting phrase similarity and paraphrasing, it remains unclear to what extent they can account for the full range of meaning composition phenomena found in natural language. Higher-order modification (that is, modification that cannot obviously be modeled as property intersection, in contrast to first-order modification, which can) presents one such challenge, as we will detail in the next section.

The goal of this paper is twofold. First, we examine how the properties of different types of adjectival modifiers, both in isolation and in combination with nouns, are represented in distributional models. We take as a case study three groups of adjectives: 1) color terms used to ascribe true color properties (referred to here as **intersective** color terms), as prototypical representative of first-order modifiers; 2) color terms used to ascribe properties other than simple color (here, **subjective** color terms), as representatives of expressions that could in principle

<sup>1</sup>In a complementary direction, Garrette et al. (2011) connect distributional representations of lexical semantics to logic-based compositional semantics.

be given a well-motivated first-order or higher-order analysis; and 3) **intensional** adjectives (e.g. *former*), as representative of modifiers that arguably require a higher-order analysis. Formal semantic models tend to group the second and third groups together, despite the existence of some natural language data that questions this grouping. However, our results show that all three types of modifiers behave differently from each other, suggesting that their semantic treatment needs to be differentiated.

Second, we test how five different composition functions that have been proposed in recent literature fare in predicting the attested properties of nominals modified by each type of adjective. The model by Baroni and Zamparelli (2010) emerges as a suitable model of adjectival composition, while multiplication and addition shed mixed results.

The paper is structured as follows. Section 2 provides the necessary background on the semantics of adjectival modification. Section 3 presents the methods used in our study. Section 4 describes the characteristics of the different types of adjectival modification, and Section 5, the results of the composition operations. The paper concludes with a general discussion of the results and prospects for future work.

## 2 The semantics of adjectival modification

Accounting for inference in language is an important concern of semantic theory. Perhaps for this reason, within the formal semantics tradition the most influential classification of adjectives is based on the inferences they license (see (Parsons, 1970) and (Kamp, 1975) for early discussion). We very briefly review this classification here.

First, so called *intersective* adjectives, such as (the literally used) *white* in *white dress*, yield the inference that both the property contributed by the adjective and that contributed by the noun hold of the individual described; in other words, a white dress is white and is a dress. The semantics for such modifiers is easily characterized in terms of the intersection of two first-order properties, that is, properties that can be ascribed to individuals.

On the other extreme, *intensional* adjectives, such as *former* or *alleged* in *former/alleged criminal*, do not license the inference that either of the properties holds of the individual to which the modified nom-

inal is ascribed. Indeed, such adjectives cannot be used as predicates at all:

- (1) ??The criminal was former/alleged.

The infelicity of (1) is generally attributed to the fact that these adjectives do not describe individuals directly but rather effect more complex operations on the meaning of the modified noun. It is for this reason that these adjectives can be considered higher-order modifiers: they behave as properties of properties. Though rather abstract, the higher-order analysis is straightforwardly implementable in formal semantic models and captures a range of linguistic facts successfully.

Finally, *subjective* adjectives such as (the non-literally-used) *white* in *white wine*, constitute an intermediate case: they license the inference that the property denoted by the noun holds of the individual being described, but not the property contributed by the adjective. That is, white wine is not white but rather a color that we would probably call some shade of yellow. This use of color terms, in general, is distinguished primarily by the fact that color serves as a proxy for another property that is related to color (e.g. type of grape), though the color in question may or may not match the color identified by the adjective on the intersective use (see (Gärdenfors, 2000) and (Kennedy and McNally, 2010) for discussion and analysis). The effect of the adjective, rather than to identify a value for an incidental COLOR attribute of an object, is often to characterize a subclass of the class described by the noun (white wine is a kind of wine, brown rice a kind of rice, etc.).

This use of color terms can be modeled by property intersection in formal semantic models only if the term is previously disambiguated or allowed to depend on context for its precise denotation. However, it is easily modeled if the adjective denotes a (higher-order) function from properties (e.g. that denoted by *wine*) to properties (that denoted by *white wine*), since the output of the function denoted by the color term can be made to depend on the input it receives from the noun meaning. Nonetheless, there is ample evidence in natural language that a first-order analysis of the subjective color terms would be preferable, as they share more features with pred-

icative adjectives such as *happy* than they do with adjectives such as *former*.

The trio of intersective color terms, subjective color terms, and intensional adjectives provides fertile ground for exploring the different composition functions that have been proposed for distributional semantic representations. Most of these functions start from the assumption that composition takes pairs of vectors (e.g. a verb vector and a noun vector) and returns another vector (e.g. a vector for the verb with the noun as its complement), usually by some version of vector addition or multiplication (Erk and Padó, 2008; Mitchell and Lapata, 2010; Grefenstette and Sadrzadeh, 2011). Such functions, insofar as they yield representations which strengthen distributional features shared by the component vectors, would be expected to model intersective modification.

Consider the example of *white dress*. We might expect the vector for *dress* to include non-zero frequencies for words such as *wedding* and *funeral*. The vector for *white*, on the other hand, is likely to have higher frequencies for *wedding* than for *funeral*, at least in corpora obtained from the U.S. and the U.K. Combining the two vectors with an additive or multiplicative operation should rightly yield a vector for *white dress* which assigns a higher frequency to *wedding* than to *funeral*.

Additive and multiplicative functions might also be expected to handle subjective modification with some success because these operations provide a natural account for how polysemy is resolved in meaning composition. Thus, the vector that results from adding or multiplying the vector for *white* with that for *dress* should differ in crucial features from the one that results from combining the same vector for *white* with that for *wine*. For example, depending on the details of the algorithm used, we should find the frequencies of words such as *snow* or *milky* weakened and words like *straw* or *yellow* strengthened in combination with *wine*, insofar as the former words are less likely than the latter to occur in contexts where *white* describes wine than in those where it describes dresses. In contrast, it is not immediately obvious how these operations would fare with intensional adjectives such as *former*. In particular, it is not clear what specific distributional features of the adjective would capture the effect that the ad-

jective has on the meaning of the resulting modified nominal.

Interestingly, recent approaches to the semantic composition of adjectives with nouns such as Baroni and Zamparelli (2010) and Guevara (2010) draw on the classical analysis of adjectives within the Montague tradition of formal semantic theory (Montague, 1974), on which they are treated as higher order predicates, and model adjectives as matrices of weights that are applied to noun vectors. On such models, the distributional properties of observed occurrences of adjective-noun pairs are used to induce the effect of adjectives on nouns. Insofar as it is grounded in the intuition that adjective meanings should be modeled as mappings from noun meanings to adjective-noun meanings, the matrix analysis might be expected to perform better than additive or multiplicative models for adjective-noun combinations when there is evidence that the adjective denotes only a higher-order property. There is also no *a priori* reason to think that it would fare more poorly at modeling the intersective and subjective adjectives than would additive or multiplicative analyses, given its generality.

In this paper, we present the first studies that we know of that explore these expectations.

### 3 Method

We built a semantic space and tested the composition functions as specified in what follows.

#### 3.1 Semantic space

The semantic space we used for our experiments consists of a matrix where each row vector represents an adjective, noun or adjective-noun phrase (henceforth, AN). We first introduce the source corpus, then the vocabulary that we represent in the space, and finally the procedure to build the vectors representing the vocabulary items from corpus data.

##### 3.1.1 Source corpus

Our source corpus is the concatenation of the ukWaC corpus<sup>2</sup>, a mid-2009 dump of the English Wikipedia<sup>3</sup> and the British National Corpus<sup>4</sup>. The corpus is tokenized, POS-tagged and lemmatized

<sup>2</sup><http://wacky.sslmit.unibo.it/>

<sup>3</sup><http://en.wikipedia.org>

<sup>4</sup><http://www.natcorp.ox.ac.uk/>

with TreeTagger (Schmid, 1995) and contains about 2.8 billion tokens. We extracted all statistics at the lemma level, ignoring inflectional information.

### 3.1.2 Vocabulary

The core vocabulary of the semantic space consists of the 8K most frequent nouns and the 4K most frequent adjectives from the corpus. By crossing the set of 700 most frequent adjectives (reduced to 663 after removing questionable items like *above*, *less* and *very*) and the 4K most frequent nouns and selecting those ANs that occurred at least 100 times in the corpus, we obtained a set of 179K ANs that we added to the semantic space, for a total of 191K rows. These ANs were used for training the linear models as well as for providing a basis for the analysis of the results.

### 3.1.3 Semantic space parameters

The dimensions (columns) of our semantic space are the top 10K most frequent content words in the corpus (nouns, adjectives, verbs and adverbs), excluding the 300 most frequent words of *all* parts of speech.

For each word or AN, we collected raw co-occurrence counts by recording their sentence-internal co-occurrence with each of words in the dimensions. The counts were then transformed into Local Mutual Information (LMI) scores, an association measure that closely approximates the commonly used Log-Likelihood Ratio but is simpler to compute (Evert, 2005). Specifically, given a row element  $r$ , a column element  $c$  and a counting function  $C(r, c)$ , then

$$LMI = C(r, c) \cdot \log \frac{C(r, c)C(*, *)}{C(r, *)C(*, c)} \quad (1)$$

where  $C(r, c)$  is how many times  $r$  cooccurs with  $c$ ,  $C(r, *)$  is the total count of  $r$ ,  $C(*, c)$  is the total count of  $c$ , and  $C(*, *)$  is the cumulative co-occurrence count of any  $r$  with any  $c$ .

The dimensionality of the space was reduced using Singular Value Decomposition (SVD), as in Latent Semantic Analysis and related distributional semantic methods (Landauer and Dumais, 1997; Rapp, 2003; Schütze, 1997). Both LMI and SVD were used for the core vocabulary, and the AN vectors were computed based on the values for the

core vocabulary. All of the results discussed in the article are based on the SVD-reduced space, because it yielded consistently better results, except for those involving multiplicative composition, which was carried out on the non-reduced model because SVD reduction introduces negative values for the latent dimensions used for the reduced space.

Some of the parameters of the space and composition functions were set based on performance on independent word similarity and AN similarity tasks (Rubenstein and Goodenough, 1965; Mitchell and Lapata, 2010). In addition to LMI, we tested the performance using log-transformed frequencies and found very poor performance in the aforementioned tasks. The number of latent dimensions for the SVD-reduced space was set at 300 after testing the performance using 300, 600 and 900 latent dimensions.

In the discussion, we use the cosine of two vectors as a measure of similarity. This is the most common choice in related work, as it has shown to be robust across different tasks and settings, though other options (in particular, measures that are not symmetric or do not normalize) could be explored (Widdows, 2004).

## 3.2 Composition models

The experiments described below were carried out using five compositional methods that have been explored in recent studies of compositionality in distributional semantic spaces (Mitchell and Lapata, 2010; Guevara, 2010; Baroni and Zamparelli, 2010). For each function, we define  $\mathbf{p}$  as the composition of the adjective vector,  $\mathbf{u}$ , and the noun vector,  $\mathbf{v}$ , a nomenclature that follows Mitchell and Lapata (2010).

**Additive** (*add*) AN vectors were obtained by summing the corresponding adjective and noun vectors. We also explored the effects of the additive model with normalized component adjective and noun vectors (*add<sub>n</sub>*).

$$\mathbf{p} = \mathbf{u} + \mathbf{v} \quad (2)$$

**Multiplicative** (*mult*) AN vectors were obtained by component-wise multiplication of the adjective and noun vectors in the non-reduced semantic space.

$$\mathbf{p} = \mathbf{u} \odot \mathbf{v} \quad (3)$$

**Dilation** (*dl*) AN vectors were obtained by calculating the dot products of  $\mathbf{u} \cdot \mathbf{u}$  and  $\mathbf{u} \cdot \mathbf{v}$  and stretching  $\mathbf{v}$  by a factor  $\lambda$  (in our case, 16.7) in the direction of  $\mathbf{u}$  (Clark et al., 2008; Mitchell and Lapata, 2010). The effect of this operation is to “stretch” the head vector  $\mathbf{v}$  (noun, in our case) in the direction of the modifying vector  $\mathbf{u}$  (adjective).

$$\mathbf{p} = (\mathbf{u} \cdot \mathbf{u})\mathbf{v} + (\lambda - 1)(\mathbf{u} \cdot \mathbf{v}) \quad (4)$$

The factor  $\lambda$  was selected based on the optimal parameters presented in Mitchell and Lapata (2010). We tested both reported values (16.7 and 2.2) and found  $\lambda = 16.7$  to perform better in terms of rank of observed equivalent (see Section 5).

The preceding functions produce an AN vector from the component A and N vectors. The remaining two functions do not use the vector for the adjective, but learn a matrix representation for it. The composed AN vector is obtained by multiplying the matrix by the noun vector. The general equation for the two functions is the following, where  $\mathbf{B}$  is a matrix of weights that is multiplied by the noun vector  $\mathbf{v}$  to produce the AN vector  $\mathbf{p}$ .

$$\mathbf{p} = \mathbf{B}\mathbf{v} \quad (5)$$

In the **linear map** (*lim*) approach proposed by Guevara (2010), one single matrix  $\mathbf{B}$  is learnt that represents all adjectives. An AN vector is obtained by multiplying the weight matrix by the concatenation of the adjective and noun vectors, so that each dimension of the generated AN vector is a linear combination of dimensions of the corresponding adjective and noun vectors. In our implementation,  $\mathbf{B}$  is an 300 x 300 weight matrix representing an adjective, and  $\mathbf{v}$  is a 300-dimension noun vector. Following Guevara (2010), we estimate the coefficients of the equation using (multivariate) partial least squares regression (PLSR) as implemented in the `R` `pls` package (Mevik and Wehrens, 2007), setting the latent dimension parameter of PLSR to 300. This value was chosen after testing values 100, 200 and 300 on the AN similarity tasks (Mitchell and Lapata, 2010). Coefficient matrix estimation is performed by feeding PLSR a set of input-output examples, where the input is given by concatenated adjective and noun vectors, and the output is the vector of the corresponding AN directly extracted from our

semantic space. The matrix is estimated using a random sample of 2.5K adjective-noun-AN tuples.<sup>5</sup>

In the **adjective-specific linear map** (*alm*) model, proposed by Baroni and Zamparelli (2010), a different matrix  $\mathbf{B}$  is learnt for each adjective. The weights of each of the rows of the weight matrix are the coefficients of a linear equation predicting the values of one of the dimensions of the normalized AN vector as a linear combination of the dimensions of the normalized component noun. The linear equation coefficients are estimated again using PLSR, and in the present implementation we use ridge regression generalized cross-validation (GCV) to automatically choose the optimal ridge parameter for each adjective (Golub et al., 1979). This procedure drastically outperforms setting a fixed number of dimensions. The model is trained on all N-AN vector pairs available in the semantic space for each adjective, and range from 100 to over 1K items across the adjectives we tested.

### 3.3 Datasets

We built two datasets of adjective-noun phrases for the present research, one with color terms and one with intensional adjectives.<sup>6</sup>

**Color terms.** This dataset is populated with a randomly selected set of adjective-noun pairs from the space presented above. From the 11 colors in the basic set proposed by Berlin and Kay (1969), we cover 7 (*black, blue, brown, green, red, white, and yellow*), since the remaining (*grey, orange, pink, and purple*) are not in the 700 most frequent set of adjectives in the corpora used. From an original set of 412 ANs, 43 were manually removed because of suspected parsing errors (e.g. *white photograph*, for *black and white photograph*) or because the head noun was semantically transparent (*white variety*). The remaining 369 ANs were tagged independently by the second and fourth authors of this paper, both native English speaker linguists, as **intersective** (e.g. *white towel*), **subsective** (e.g. *white wine*), or **idiomatic**, i.e. compositionally non-transparent (e.g. *black hole*). They were allowed the assignment of at

<sup>5</sup>2.5K ANs is the upper bound of the software package used.

<sup>6</sup>Available at <http://dl.dropbox.com/u/513347/resources/data-emnlp2012.zip>. See Bruni et al. (to appear) for an analysis of the color term dataset from a multi-modal perspective.

most two labels in case of polysemy, for instance for *black staff* for the person vs. physical object senses of the noun or *yellow skin* for the race vs. literally painted interpretations of the AN. In this paper, only the first label (most frequent interpretation, according to the judges) has been used. The  $\kappa$  coefficient of the annotation on the three categories (first interpretation only) was 0.87 (conf. int. 0.82-0.92, according to Fleiss et al. (1969)), observed agreement 0.96.<sup>7</sup> There were too few instances of idioms (17) for a quantitative analysis of the sort presented here, so these are collapsed with the subjective class in what follows.<sup>8</sup> The dataset as used here consists of 239 intersective and 130 subjective ANs.

**Intensional adjectives.** The intensional dataset contains all ANs in the semantic space with a pre-selected list of 10 intensional adjectives, manually pruned by one of the authors of the paper to eliminate erroneous examples and to ensure that the adjective was being intensionally used. Examples of the ANs eliminated on these grounds include *past twelve* (cp. accepted *past president*), *former girl* (probably *former girl friend* or similar), *false rumor* (which is a real rumor that is false, vs. e.g. *false floor*, which is not a real floor), or *theoretical work* (which is real work related to a theory, vs. e.g. *theoretical speed*, which is a speed that should have been reached in theory). Other AN pairs were excluded on the grounds that the noun was excessively vague (e.g. *past one*) or because the AN formed a fixed expression (e.g. *former USSR*). The final dataset contained 1,200 ANs, distributed as follows: *former* (300 examples), *possible* (244), *future* (243), *potential* (183), *past* (87), *false* (44), *apparent* (39), *artificial* (36), *likely* (18), *theoretical* (6).<sup>9</sup>

Table 1 contains examples of each type of AN we are considering.

<sup>7</sup>Code for the computation of inter-annotator agreement by Stefan Evert, available at [http://www.collocations.de/temp/kappa\\_example.zip](http://www.collocations.de/temp/kappa_example.zip).

<sup>8</sup>An alternative would have been to exclude idiomatic ANs from the analysis.

<sup>9</sup>*Alleged*, one of the most prototypical intensional adjectives, is not considered here because it was not among the 700 most frequent adjectives in the space. We will consider it in future work.

<i>Intersective</i>	<i>Subjective</i>	<i>Intensional</i>
white towel	white wine	artificial leg
black sack	black athlete	former bassist
green coat	green politics	likely suspect
red disc	red ant	possible delay
blue square	blue state	theoretical limit

Table 1: Example ANs in the datasets.

## 4 Observed vectors

We began by exploring the empirically **observed vectors** for the adjectives (A), nouns (N), and adjective-noun phrases (AN) in the datasets, as they are represented in the semantic space. Note that we are working with the AN vectors directly harvested from the corpora (that is, based on the co-occurrence of, say, the phrase *white towel* with each of the 10K words in the space dimensions), without doing any composition. AN vectors obtained by composition will be examined in the following section. Though observed AN vectors should not be regarded as a gold standard in the sense of, for instance, Machine Learning approaches, because they are typically sparse<sup>10</sup> and thus the vectors of their component adjective and noun will be richer, they are still useful for exploration and as a comparison point for the composition operations (Baroni and Lenci, 2010; Guevara, 2010).

Figure 1 shows the distribution of the cosines between A, N, and AN vectors with intensional adjectives (I, white box), intersective uses of color terms (IE, lighter gray box), and subjective uses of color terms (S, darker gray box).

In general, the similarity of the A and N vectors is quite low (cosine  $< 0.2$ , left graph of Figure 1), and much lower than the similarities between both the AN and A vectors and the AN and N vectors. This is not surprising, given that adjectives and nouns describe rather different sorts of things.

We find significant differences between the three types of adjectives in the similarity between AN and A vectors (middle graph of Figure 1). The adjective and adjective-noun phrase vectors are nearer for

<sup>10</sup>The frequency of the adjectives in the datasets range from 3.5K to 3.7M, with a median frequency of 109,114. The nouns range from 4.9K to 2.5M, with a median frequency of 148,459. While the frequency of the ANs range from 100 to 18.5K, with a median frequency of 239.

Figure 1: Cosine distance distribution in the different types of AN. We report the cosines between the component adjective and noun vectors ( $\cos(A,N)$ ), between the observed AN and adjective vectors ( $\cos(AN,A)$ ), and between the observed AN and noun vectors ( $\cos(AN,N)$ ). Each chart contains three boxplots with the distribution of the cosine scores (y-axis) for the intensional (I), intersective (IE), and subjective (S) types of ANs. The boxplots represent the value distribution of the cosine between two vectors. The horizontal lines in the rectangles represent the first quartile, median, and third quartile. Larger rectangles correspond to a more spread distribution, and their (a)symmetry mirrors the (a)symmetry of the distribution. The lines above and below the rectangle stretch to the minimum and maximum values, at most 1.5 times the length of the rectangle. Values outside this range (outliers) are represented as points.

intersective uses than for subjective uses of color terms, a pattern that parallels the difference in the distance between component A and N vectors. Since intersective uses correspond to the prototypical use of color terms (a *white dress* is the color white, while *white wine* is not), the greater similarity for the intersective cases is unsurprising – it suggests that in the case of subjective adjectival modifiers, the noun “pulls” the AN further away from the adjective than happens with the cases of intersective modification. This is compatible with the intuition (manifest in the formal semantics tradition in the treatment of subjective adjectives as higher-order rather than first-order, intersective modifiers) that the adjective’s effect on the AN in cases of subjective modification depends heavily on the interpretation of the noun with which the adjective combines, whereas that is less the case when the adjective is used intersectively.

As for intensional adjectives, the middle graph shows that their AN vectors are quite distant from the corresponding A vectors, in sharp contrast to what we find with both intersective and subjective

color terms. We hypothesize that the results for the intensional adjectives are due to the fact that they cannot plausibly be modeled as first order attributes (i.e. being *potential* or *apparent* is not a property in the same sense that being *white* or *yellow* is) and thus typically do not restrict the nominal description *per se*, but rather provide information about whether or when the nominal description applies. The result is that intensional adjectives should be even weaker than subjectively used adjectives, in comparison with the nouns with which they combine, in their ability to “pull” the AN vector in their direction. Note, incidentally, that an alternative explanation, namely that the effect mentioned could be due to the fact that most nouns in the intensional dataset are abstract and that adjectives modifying abstract nouns might tend to be further away from their nouns altogether, is ruled out by the comparison between the A and N vectors: the A-N cosines of the intensional and intersective ANs are similar. We thus conclude that here we see an effect of the *type of modification* involved.

An examination of the average distances among

the nearest neighbors of the intensional and of the color adjectives in the distributional space supports our hypothesized account of their contrasting behaviors. We predict that the nearest neighbors are more dispersed for adjectives that cannot be modeled as first-order properties (i.e., intensional adjectives), than for those that can (here, the color terms). We find that the average cosine distance among the nearest ten neighbors of the intensional adjectives is 0.74 with a standard deviation of 0.13, which is significantly lower ( $t$ -test,  $p < 0.001$ ) than the average similarity among the nearest neighbors of the color adjectives, 0.96 with a standard deviation of 0.04.

Finally, with respect to the distances between the adjective-noun and head noun vectors (right graph of Figure 1), there is no significant difference for the intersective vs. subjective color terms. This can be explained by the fact that both kinds of modifiers are subjective, that is, the fact that a white dress is a dress and that white wine is wine.

In contrast, intensional ANs are closer to their component Ns than are color ANs (the difference is qualitatively quite small, but significant even for the intersective vs. intensional ANs according to a  $t$ -test,  $p$ -value = 0.015). This effect, the inverse of what we find with the AN-A vectors, can similarly be explained by the fact that intensional adjectives do not restrict the descriptive content of the noun they modify, in contrast to both the intersective and subjective color ANs. Restriction of the nominal description may lead to significantly restricted distributions (e.g. the phrase *red button* may appear in distinctively different contexts than does *button*; similarly for *green politics* and *politics*), while we do not expect the contexts in which *former bassist* and *bassist* appear to diverge in a qualitatively different way because the basic nominal descriptions are identical, though further research will be necessary to confirm these explanations.

Finally, note that, contrary to predictions from some approaches in formal semantics, subjective color ANs and intensional ANs do not pattern together: subjective ANs are closer to their component As, and intensional ANs closer to their component Ns. This unexpected behavior underscores the fact highlighted in the previous paragraph: that the distributional properties of modified expressions are more sensitive to whether the modification restricts

the nominal description than to whether the modifier is intersective in the strictest sense of term.

We now discuss the extent to which the different composition functions account for these patterns.

## 5 Composed vectors

Since intersective modification is the point of comparison for both subjective and intensional modification, we first discuss the composed vectors for the intersective vs. subjective uses of color terms, and then turn to intersective vs. intensional modification.

### 5.1 Intersective and subjective modification with color terms

To adequately model the differences between intersective and subjective modification observed in the previous section, a successful composition function should yield a significantly smaller distance between the adjective and AN vectors for intersectively used adjectives, whereas it should yield no significant difference for the distances between the noun and AN vectors.

Table 2 provides a summary of the results with the observed data (*obs*) and the composition functions discussed in Section 3.2. The median rank of observed equivalent (ROE) is provided as a general measure of the quality of the composition function. It is computed by finding the cosine between the composed AN vectors and all rows in the semantic space and then determining the rank in which the observed ANs are found.<sup>11</sup> The remaining columns report the differences in standardized ( $z$ -score) cosines between the vector built with each of the composition functions and the observed AN, A, and N vectors. A positive value means that the cosines for intersective uses are higher, while a negative value means that the cosines for subjective uses are higher. The first row (*obs*) contains a numerical summary of the tendencies for observed ANs explained in the previous section. This is the behavior that we expect to model.

Two composition functions come close to modeling the observed behavior: *alm* and *mult*, though *alm* is better in terms of ROE, consistent with the

<sup>11</sup>The ROE is provided as a general guide; however, recall that the ROE was taken into account to tune the  $\lambda$  parameter in the dilation model, and that the ANs of the color dataset were included when training the matrices for the *alm* model.

<i>model</i>	<i>ROE</i>	$\Delta$ :AN	$\Delta$ :A	$\Delta$ :N
obs	-	-	.54 ***	.10
add	286	.40 ***	.14	.15
add <sub>n</sub>	11	.40 ***	.65 ***	.65 ***
mult	111	.40 ***	.74 ***	.29 *
dl	298	.63 ***	.85 ***	-.66 ***
lim	1,940	.46 ***	.20	.38 **
alm	1	.16	.52 ***	.27 *

Table 2: Intersective vs. subjective uses of color terms. The first column reports the rank of the observed equivalent (ROE), the rest report the differences ( $\Delta$ ) between the intersective and subjective uses of color terms when comparing the composed AN with the observed vectors for: AN, adjective (A), noun (N). See text for details. Significances according to a t-test: \*\*\* for  $p < 0.001$ , \*\*  $< 0.01$ , \*  $< 0.05$ .

results reported in Baroni and Zamparelli (2010). In both cases, we find that these functions yield higher similarities for AN-A for the intersective than for the subjective uses of color terms, and a very slight (though still mildly significant) difference for the distance to the head noun. The *add<sub>n</sub>* function performs very good in terms of ROE (median 11). This suggests that, for adjectival modification, providing a vector that is in the middle of the two component vectors (which is what normalized addition does) is a reasonable approximation of the observed vectors. However, precisely because the resulting vector is in the middle of the two component vectors, this function cannot account for the asymmetries in the distances found in the observed data. The non-normalized version also cannot account for these effects because the adjective vector, being much longer (as color terms are very frequent), totally dominates the AN, which results in no difference across uses when comparing to the adjective or to the noun.

The dilation model shows a strange pattern, as it yields a strongly significant negative difference in the AN-N distance. The *lim* function exhibits the opposite pattern as predicted, yielding no difference for the AN-A similarities and a difference for the AN-N similarities. A possible explanation for the AN-A results is that *lim* learns from such a broad range of AN pairs that the impact of the distance between intersective vs. subjective uses of color terms from their component adjectives is dampened. Moreover,

*lim* is by far the worst function in terms of ROE.

All composition functions except for *alm* find intersective uses easier to model. This is shown in the positive values in column  $\Delta$ :AN, which mean that the similarity between observed and composed AN vectors is greater for intersective than for subjective ANs. This is consistent with expectations. The subjective uses are specific to the nouns with which the color terms combine, and the exact interpretation of the adjective varies across those nouns. In contrast, the interpretation associated with intersective use is consistent across a larger variety of nouns, and in that sense should be predominantly reflected in the adjective’s vector. The exception in this respect is the *alm* function, since the weights for each adjective matrix are estimated in relation to the noun vectors with which the adjective combines, on the one hand, and the related observed AN vectors, on the other; thus, the basic lexical representation of the adjective is inherently reflective of the distributions of the ANs in which it appears in a way that is not the case for the adjective representations used in the other composition models. And indeed, *alm* is the only function that shows no difference in difficulty (distance) between the predicted and observed AN vectors for intersective vs. subjective ANs.

Both *mult* and *alm* seem to account for the observed patterns in color terms. However, an examination of the nearest neighbors of the composed ANs suggest that *alm* captures the semantics of adjective composition in this case to a larger extent than *mult*. For instance, the NN for *blue square* (intersective) are the following according to *mul*: *blue, red, official colour, traditional colour, blue number, yellow*; while *alm* yields the following: *blue square, red square, blue circle, blue triangle, blue pattern, yellow circle*. Similarly, for *green politics* (subjective) *mul* yields: *pleasant land, green business, green politics, green issue, green strategy, green product*, while *alm* yields *green politics, green movement, political agenda, environmental movement, progressive government, political initiative*.

## 5.2 Intensional modification

Table 3 contains the results of the composition functions comparing the behavior of intersective color ANs and intensional ANs. The tendencies in the ROE are as in Table 2, so we will not comment on

<i>model</i>	<i>ROE</i>	$\Delta:AN$	$\Delta:A$	$\Delta:N$
obs	-	-	1.39 ***	-.27 ***
add	198	.66 ***	.71 ***	-.81 ***
add <sub>n</sub>	40	.93 ***	.20 *	.20 *
mult	110	.58 ***	1.09 ***	-.25 ***
dl	354	.97 ***	-.27 **	.47 ***
lim	7,943	.27 ***	.65 ***	-.47 ***
alm	1	.81 ***	1.43 ***	-.59 ***

Table 3: Intersective vs. intensional ANs. Information as in Table 2.

them further (note the very poor performance of *lim*, though). As noted above, we expect more difficulty in modeling intensional modification vs. other kinds of modification, and this is verified in the results (cf. the positive values in second column). The difference with the results in the previous subsection is that in this case the *alm* function does present a higher difficulty in modeling intensional ANs, unlike with the color terms. This points to a qualitative difference between substantive and intensional adjectives that could be evidence for a first-order analysis of substantive color terms.

A good composition function should provide a large positive difference when comparing the AN to the A, and a small negative difference (because the effect is very small in the observed data) when comparing the AN to the N. The functions that best match the observed data are again *alm* and *mult*. *Add* and *lim* show the predicted pattern, but to a much lesser degree (cf. smaller differences in column  $\Delta:A$ ). *Dl* yields the exact opposite effect and *add<sub>n</sub>*, though good in terms of ROE, is subject to the problems discussed in the previous section.

Again, *alm* seems to be capturing relevant semantic aspects of composition with intensional adjectives. For instance, the nearest neighbors of *artificial leg* according to *alm* are *artificial leg*, *artificial limb*, *artificial joint*, *artificial hip*, *scar*, *small wound*.

## 6 Discussion and conclusions

The present research provides some evidence for treating adjectives as matrices or functions, rather than vectors, although simple operations on vectors such as addition (for its excellent approximation to observed vectors) and multiplication (for its ability to reproduce the observed trends in the data) still ac-

count for some aspects of adjectival modification. The dilation model, in contrast, is not suitable for adjectival modification.

Our results also show that *alm* performs better than *lim*, but it is worth observing that it does so at the expense of modeling each adjective as a completely different function. We consider *lim* very attractive in principle because it generalizes across adjectives and is thus more parsimonious. Part of the poor results on *lim* were due to limitations of our implementation, as we trained the matrices on only 2.5K ANs, while our semantic space contains more than 170K ANs. However, the linguistic literature and the present results suggest that it might be useful to try a compromise between *alm* and *lim*, training one matrix for each subclass of adjectives under analysis.

Beyond the new data it offers regarding the comparative ability of the different composition functions to account for different kinds of adjectival modification, the study presented here underscores the complexity of modification as a semantic phenomenon. The role of adjectival modifiers as restrictors of descriptive content is reflected differently in distributional data than is their role in providing information about whether or when a description applies to some individual. Formal semantic models, thanks to their abstractness, are able to handle these two roles with little difficulty, but also with limited insight. Distributional models, in contrast, offer the promise of greater insight into each of these roles, but face serious challenges in handling both of them in a unified manner.

## Acknowledgments

This research was funded by the Spanish MICINN (FFI2010-09464-E, FFI2010-15006, TIN2009-14715-C04-04), the Catalan AGAUR (2010BP-A00070), and the EU (PASCAL2; FP7-ICT-216886). Eva Maria Vecchi was partially funded by ERC Starting Grant 283554. We thank Marco Baroni, Roberto Zamparelli, and six anonymous reviewers for valuable feedback, and Yao-zhong Zhang for the code for the *alm* function.

## Abstract

We explore the interplay of knowledge and structure in co-reference resolution. To inject knowledge, we use a state-of-the-art system which cross-links (or “grounds”) expressions in free text to Wikipedia. We explore ways of using the resulting grounding to boost the performance of a state-of-the-art co-reference resolution system. To maximize the utility of the injected knowledge, we deploy a learning-based multi-sieve approach and develop novel entity-based features. Our end system outperforms the state-of-the-art baseline by 2  $B^3$  F1 points on non-transcript portion of the ACE 2004 dataset.

## 1 Introduction

Co-reference resolution is the task of grouping mentions to entities. For example, consider the text snippet in Fig. 1<sup>1</sup>. The correct output groups the mentions  $\{m_1, m_2, m_5\}$  to one entity while leaving  $m_3$

“After the  $\{[vessel]\}_{m_1}$  suffered a catastrophic torpedo detonation,  $\{[Kursk]\}_{m_2}$  sank in the waters of  $\{[Barents Sea]\}_{m_3}$  with all hands lost. Though rescue attempts were offered by a nearby  $\{Norwegian [ship]\}_{m_4}$ , Russia declined initial rescue offers, and all 118 sailors and officers aboard  $\{[Kursk]\}_{m_5}$  perished.”

Figure 1: Example illustrating the challenges in co-reference resolution.

and  $m_4$  as singletons. Resolving co-reference is fundamental for understanding natural language. For example in Fig. 1, to infer that Kursk has suffered a torpedo detonation, we have to understand that  $\{[vessel]\}_{m_1}$  refers to  $\{[Kursk]\}_{m_2}$ .

This inference is typically trivial for humans, but proves extremely challenging for state-of-the-art co-reference resolution systems. We believe that it is world knowledge that gives people the ability to understand text with such ease. A human reader can infer that since Kursk sank, it must be a vessel and vessels which suffer catastrophic torpedo detonations can sink. Moreover, some readers might *just know* that *Kursk* is a Russian submarine named after the city of Kursk, where the largest tank battle in history took place in 1943. In this work we are using Wikipedia as a source of encyclopedic knowledge. The key contributions of this work are:

(1) Using Wikipedia to assign a set of knowledge attributes to mentions in a context-sensitive way. For example, for the text in Fig. 1, our system assigns to the mention “*Kursk*” the nationalities: *Russian*, *Soviet* and the attributes *ship*, *incident*, *submarine*, *shipwreck* (as opposed to *city* or *battle*). We are using a publicly available system for context-

\* We thank Nicholas Rizzolo and Kai Wei Chang for their invaluable help with modifying the baseline co-reference system. We thank the anonymous EMNLP reviewers for constructive comments. <sup>1</sup> Throughout this paper, curly brackets  $\{\}$  denote the extent and square brackets  $\square$  denote the head.

sensitive disambiguation to Wikipedia. We then extract attributes from the cross-linked Wikipedia pages (described in Sec. 3.1), assign these attributes to the document mentions (Sec. 3.2) and develop knowledge-rich compatibility metric between mentions (Sec. 3.3)<sup>2</sup>.

(2) Integrating the strength of rule-based systems such as (Haghighi and Klein, 2009; Raghunathan et al., 2010) into a machine learning framework. We are using a multi-sieve approach (Raghunathan et al., 2010), which splits pairwise “co-reference” vs. “non-coreference” decisions to different types and attempts to make the easy decisions first (Goldberg and Elhadad, 2010). Our multi-sieve approach is different from (Raghunathan et al., 2010) in several respects: (a) our sieves are machine-learning classifiers, (b) the same pair of mentions can fall into multiple sieves, (c) later sieves can override the decisions made by earlier sieves, allowing to recover from errors as additional evidence becomes available. In our running example, the decision of whether  $\{[vessel]\}_{m_1}$  refers to  $\{[Kursk]\}_{m_2}$  is made before the decision of whether  $\{[vessel]\}_{m_1}$  refers to  $\{Norwegian [ship]\}_{m_4}$  since decisions in the same sentence are believed to be easier than cross-sentence ones. We describe our learning-based multi-sieve approach in Sec. 4.

(3) A novel approach for entity-based features. As sieves of classifiers are applied, our system attempts to model entities and share the attributes between the mentions belonging to the same entity. Once the decision that  $\{[vessel]\}_{m_1}$  and  $\{[Kursk]\}_{m_2}$  co-refer is made, we want the two mentions to share the *Russian* nationality. This allows us to avoid erroneously linking  $\{[vessel]\}_{m_1}$  to  $\{Norwegian [ship]\}_{m_4}$  despite *vessel* and *ship* being synonyms in WordNet. However, in this work we allow the sieves to make conflicting decisions on the same pair of mentions. Hence, obtaining entities and their attributes by straightforward transitive closure of co-reference predictions is impossible. We describe our approach for leveraging possibly contradicting predictions in Sec. 5.

(4) By adding word-knowledge features and us-

Figure 2: High-level system architecture.

ing learning-based multi-sieve approach, we improve the performance of the state-of-the-art system of (Bengtson and Roth, 2008) by 3 MUC, 2  $B^3$  and 2 CEAF F1 points on the non-transcript portion of the ACE 2004 dataset. We report our experimental results in Sec. 6 and conclude with discussion in Sec. 7.

We conclude the introduction by giving a high-level overview of our system in Fig. 2.

## 2 Baseline System

In this work, we are using the state-of-the-art system of (Bengtson and Roth, 2008), which relies on a pairwise scoring function  $pc$  to assign an ordered pair of mentions a probability that they are coreferential. It uses a rich set of features including: string edit distance, gender match, whether the mentions appear in the same sentence, whether the heads are synonyms in WordNet etc. The function  $pc$  is modeled using regularized averaged perceptron for a tuned number of training rounds, learning rate and margin. For the end system, we keep these parameters intact, our only modifications will be adding knowledge-rich features and adding intermediate classification sieves to the training and the inference, which we will discuss in the following sections.

At inference time, given a document  $d$  and a pairwise co-reference scoring function  $pc$ , (Bengtson and Roth, 2008) generate a graph  $G_d$  accord-

ing to the Best-Link decision model (Ng and Cardie, 2002) as follows. For each mention  $m$  in document  $d$ , let  $B_m$  be the set of mentions appearing before  $m$  in  $d$ . Let  $a$  be the highest scoring antecedent:  $a = \operatorname{argmax}_{b \in B_m} (pc(b, m))$ . We will add the edge  $(a, m)$  to  $G_d$  if  $pc(a, m)$  predicts the pair to be co-referent with a confidence exceeding a chosen threshold, then we take the transitive closure<sup>3</sup>.

The properties of the Best-Link inference are illustrated in Fig. 3. At this stage, we ask the reader to ignore the knowledge attributes at the bottom of the figure. Let us assume that the pairwise classifier labeled the mentions  $(m_2, m_5)$  co-referent because they have identical surface form; mentions  $(m_1, m_4)$  are co-referred because the heads are synonyms in WordNet. Let us assume that since  $m_1$  and  $m_2$  appear in the same sentence, the pairwise classifier managed to leverage the dependency parse tree to correctly co-ref the pair  $(m_1, m_2)$ . The transitive closure would correctly link  $(m_1, m_5)$  despite the incorrect prediction of the pairwise classifier on  $(m_1, m_5)$ , and would incorrectly link  $m_4$  with all other mentions because of the incorrect pairwise prediction on  $(m_1, m_4)$  and despite the correct predictions on  $(m_2, m_4)$  and  $(m_4, m_5)$ .

Figure 3: A sample output of a pairwise co-reference classifier. The full edges represent a co-ref prediction and the empty edges represent a non-coref prediction. A set of knowledge attributes for selected mentions is shown as well.

### 3 Wikipedia as Knowledge

In this section we describe our methodology for using Wikipedia as a knowledge resource. In Sec. 3.1 we cover the process of knowledge extraction from

<sup>3</sup>We use Platt Scaling while (Bengtson and Roth, 2008) used the raw output value of  $pc$ .

Wikipedia pages. We describe how to inject this knowledge into mentions in Sec. 3.2. The bottom part of Fig. 3 illustrates the knowledge attributes our system injects to two sample mentions at this stage. Finally, in Sec. 3.3 we describe a compatibility metric our system learns over the injected knowledge.

#### 3.1 Wikipedia Knowledge Attributes

Our goal in this section is to extract from Wikipedia pages a compact and highly-accurate set of **knowledge attributes**, which nevertheless possesses discriminative power for co-reference<sup>4</sup>. We concentrate on three types of knowledge attributes: fine-grained semantic categories, gender information and nationality where applicable.

Each Wikipedia page is assigned a set of categories. There are over 100K categories in Wikipedia, many are extremely fine-grained and contain very few pages. The value of the Wikipedia category structure for knowledge acquisition has long been noticed in several influential works, such as (Suchanek et al., 2007; Nastase and Strube, 2008) to name a few. However, while the recall of the above resources is excellent, we found their precision insufficient for our purposes. We have implemented a simple high-precision low-recall heuristic for extracting the head words of Wikipedia categories as follows.

We noticed that Wikipedia categories have a simple structure of either  $\langle noun-phrase \rangle$  or  $\langle noun-phrase \rangle \langle relation-token \rangle \langle noun-phrase \rangle$ , where in the second case the category information is always on the left. Therefore, we first remove the text succeeding a set of carefully chosen relation tokens<sup>5</sup>. With this heuristic “*Recipients of the Gold Medal of the Royal Astronomical Society*” becomes just “*Recipients*”; “*Populated places in Africa*” becomes “*places*”; however “*Institute for Advanced Study faculty*” becomes “*Institute*” (rather than “*faculty*”). At the second step, we apply the Illinois POS tagger and keep only the tokens labeled as NNS. This step allows us to exclude singular nouns incorrectly identified as heads, such as “*Institute*” above. To further reduce the noise in the category

<sup>4</sup>We justify the reasons for our choice of high-precision low-recall knowledge extraction in Sec. 3.2.

<sup>5</sup>The selected set was: {of, in, with, from, ”, ”, at, who, which, for, and, by}

extraction, we also remove all rare category tokens which appeared in less than 100 titles ending up with 2088 fine-grained entity types. We manually map popular fine-grained categories to coarser-grained ones, more consistent with ACE entity typing. A sample of the mapping is shown in the table below:

Fine-grained	Coarse-grained
departments, organizations, banks, ...	ORG
venues, trails, areas, buildings, ...	LOC
countries, towns, villages, ...	GPE
churches, highways, schools, ...	FACILITY

Manual inspection of the extracted category keywords has led us to believe that this heuristic achieves a higher precision at a considerable loss of recall when compared to the more sophisticated approach of (Nastase and Strube, 2008), which correctly identifies “*faculty*” as the head of “*Institute for Advanced Study faculty*”, but incorrectly identifies “*statistical organizations*” as the head of “*Presidents of statistical organizations*” in about half the titles containing the category<sup>6</sup>.

We assign gender to the titles using the following simple heuristic. The first paragraph of each Wikipedia article provides a very brief summary of the entity in focus. If the first paragraph of a Wikipedia page contains the pronoun “she”, but not “he”, the article is considered to be about a female (and vice-versa). However, when the page is assigned a non-person-related fine-grained NE type (e.g. school) and at the same time is not assigned a person-related fine-grained NE type (e.g. novelist), we mark the page as inanimate regardless of the presence of he/she pronouns. The nationality is assigned by matching the tokens in the original (unprocessed) categories of the Wikipedia page to a list of countries. We assign nationality not only to the Wikipedia titles, but also to single tokens. For each token, we track the list of titles it appears in, and if the union of the nationalities assigned to the titles it appears in is less than 7, we mark the token compatible with these nationalities. This allows us to identify Ivan Lebedev as Russian and Ronen Ben-Zohar as Israeli, even though Wikipedia may not contain pages for these specific people.

<sup>6</sup> (Nastase and Strube, 2008) analyze a set of categories  $S$  assigned to Wikipedia page  $p$  jointly, hence the same category expression can be interpreted differently, depending on  $S$ .

### 3.2 Injecting Knowledge Attributes

Once we have extracted the knowledge attributes of Wikipedia pages, we need to inject them into the mentions. (Rahman and Ng, 2011) used YAGO for similar purposes, but noticed that knowledge injection is often noisy. Therefore they used YAGO only for mention pairs where one mention was an NE of type PER/LOC/ORG and the other was a common noun. This implies that all MISC NEs were discarded, and all NE-NE pairs were discarded as well. We also note that (Rahman and Ng, 2011) reports low utility of FrameNet-based features. In fact, when incrementally added to other features in cluster-ranking model the FrameNet-based features sometimes led to performance drops. This observation has motivated our choice of high-precision low-recall heuristic in Sec. 3.1 and will motivate us to add features conservatively when building attribute compatibility metric in Sec. 3.3.

Additionally, while (Rahman and Ng, 2011) uses the union of all possible meanings a mention may have in Wikipedia, we deploy GLOW (Ratinov et al., 2011)<sup>7</sup>, a context-sensitive system for disambiguation to Wikipedia. Using context-sensitive disambiguation to Wikipedia as well as high-precision set of knowledge attributes allows us to inject the knowledge to more mention pairs when compared to (Rahman and Ng, 2011). Our exact heuristic for injecting knowledge attributes to mentions is as follows:

#### Named Entities with Wikipedia Disambiguation

If the mention head is an NE matched to a Wikipedia page  $p$  by GLOW, we import all the knowledge attributes from  $p$ . GLOW allows us to map “*Ephraim Sneh*” to [http://en.wikipedia.org/wiki/Ephraim\\_Sneh](http://en.wikipedia.org/wiki/Ephraim_Sneh) and to assign it the *Israeli* nationality, *male* gender, and the fine-grained entity types: {*member, politician, person, minister, alumnus, physician, general*}.

#### Head and Extent Keywords

If the mention head is not mapped to Wikipedia by GLOW and the head contains keywords which appear in the list of 2088 fine-grained entity types, then the rightmost such keyword is added to the list of mention knowledge attributes. If the head does

<sup>7</sup>Available at: [http://cogcomp.cs.illinois.edu/page/software\\_view/Wikifier](http://cogcomp.cs.illinois.edu/page/software_view/Wikifier)

not contain any entity-type keywords but the extent does, we add the rightmost such keyword of the extent. In both cases, we apply the heuristic of removing clauses starting with a select set of punctuations, prepositions and pronouns, annotating what is left with POS tagger and restricting to noun tokens only<sup>8</sup>. This allows us to inject knowledge to mentions unmapped to Wikipedia, such as: “{*current Cycle World publisher [Larry Little]*}”, which is assigned the attribute *publisher* but not *world* or *cycle*. Likewise, “{*[Joseph Conrad Parkhurst], who founded the motorcycle magazine Cycle World in 1962* }”, is not assigned the attribute *magazine*, since the text following “*who*” is discarded.

### 3.3 Learning Attributes Compatibility

In the previous section we have assigned knowledge attributes to the mentions. Some of this information, such as gender and coarse-grained entity types are also modeled in the baseline system of (Bengtson and Roth, 2008). Our goal is to build a compatibility metric on top of this redundant, yet often inconsistent information.

The majority of the features we are using are straightforward, such as: (1) whether the two mentions mapped to the same Wikipedia page, (2) gender agreement (both Wikipedia and dictionary-based), (3) nationality agreement (here we measure only whether the sets intersect, since mentions can have multiple nationalities in the real world), (4) coarse-grained entity type match, etc.

The only non-trivial feature is measuring compatibility between sets of fine-grained entity types, which we describe below. Let us assume that mention  $m_1$  was assigned the set of fine-grained entity types  $S_1$  and the mention  $m_2$  was assigned the set of fine-grained entity types  $S_2$ . We record whether  $S_1$  and  $S_2$  share elements. If they do, then, in addition to the Boolean feature, the list of the shared elements also appears as a list of discrete features. We do the same for the most similar and most dissimilar elements of  $S_1$  and  $S_2$  (along with their discretized similarity score) according to a WordNet-based similarity metric of (Do et al., 2009). The reason for explicitly listing the shared, the most similar and dis-

<sup>8</sup>This heuristic is similar to the one we used for extracting Wikipedia category headwords and seems to be a reasonable baseline for parsing noun structures (Vadas and Curran, 2008).

similar elements is that the WordNet similarity does not always correspond to co-reference compatibility. For example, the pair (*company, rival*) has a low similarity score according to WordNet, but characterizes co-referent mentions. On the other hand, the pair (*city, region*) has a high WordNet similarity score, but characterizes non-coreferent mentions. We want to allow our system to “memorize” the discrepancy between the WordNet similarity and co-reference compatibility of specific pairs.

We also note that we generate a set of selected conjunctive features, most notably of fine-grained categories with NER predictions. The reason is that the pair of mentions “(*Microsoft, Google*)” are not co-referent despite the fact that they both have the *company* attribute. On the other hand “(*Microsoft, Redmond-based company*)” is a co-referent pair. To capture this difference, we generate the feature *ORG-ORG&&share\_attribute* for the first pair, and *ORG-O&&share\_attribute* for the second pair<sup>9</sup>. These features are also used in conjunction with string edit distance. Therefore, if our system sees two named entities which share the same fine-grained type but have a large string edit distance, it will label the pair as non-coref.

## 4 Learning-based Multi-Sieve Approach

State-of-the-art machine-learning co-ref systems, e.g. (Bengtson and Roth, 2008; Rahman and Ng, 2011) train a single model for predicting co-reference of all mention pairs. However, rule-based systems, e.g. (Haghighi and Klein, 2009; Raghunathan et al., 2010) characterize mention pairs by discourse structure and linguistic properties and apply rules in a prescribed order (high-precision rules first). Somewhat surprisingly, such hybrid approach of applying rules on top of structures produced by statistical tools (such as dependency parse trees) performs better than pure machine-learning approach<sup>10</sup>.

In this work, we attempt to integrate the strength of linguistically motivated rule-based systems with the robustness of a machine learning approach. We started with a hypothesis that different types of men-

<sup>9</sup>The head of “*Redmond-based company*” is “*company*”, which is not a named entity, and is marked O.

<sup>10</sup>(Raghunathan et al., 2010) recorded the best result on CoNLL 2011 shared task.

tion pairs may require a different co-ref model. For example, consider the text below:

*Queen Rania of Jordan, Egypt's [Suzanne Mubarak]<sub>m1</sub> and others were using their charisma and influence to campaign for equality of the sexes. [Mubarak]<sub>m2</sub>, wife of Egyptian President [Hosni Mubarak]<sub>m3</sub>, and one of the conference organizers, said they must find ways to . . .*

There is a subtle difference between mention pairs  $(m_1, m_2)$  and  $(m_2, m_3)$ . One of the differences is purely structural. The first pair appears in different sentences, while the second pair – in the same sentence. It turns out that string edit distance feature between two named entities has different “semantics” depending on whether the two mentions appear in the same sentence. The reason is that to avoid redundancy, humans refer to the same entity differently within the sentence, preferring titles, nicknames and pronouns. Therefore, when a similar-looking named entities appear in the same sentence, they are actually likely to refer to different entities. On the other hand, in the sentence “*Reggie Jackson, nicknamed Mr. October . . .*” we have to rely heavily on sentence structure rather than string edit distance to make the correct co-ref prediction.

Sieve	Trained on All Data	Sieve-specific Training
AllSentencePairs	61.37	67.46
ClosestNonProDiffSent	60.71	63.33
NonProSameSentence	62.97	63.80
NerMentionsDiffSent	86.44	87.12
SameSentenceOneNer	64.10	68.88
Adjacent	71.00	78.80
SameSenBothNer	75.30	73.75
Nested	76.11	79.00

Table 1: F1 performance on co-referent mention pairs by sieve type when trained with all data versus sieve-specific data only.

Our second intuition is that “easy-first” inference is necessary to effectively leverage knowledge. For example, in Fig. 3, our goal is to link *vessel* to *Kursk* and assign it the *Russian/Soviet* nationality prior to applying the pairwise co-reference classifier on (*vessel*, *Norwegian ship*). Therefore, our goal is to apply the pairwise classifier on pairs in *prescribed order* and to propagate the knowledge across mentions. The ordering should be such that (a) maximum amount of information is injected at early stages (b) the precision at the early stages is as

high as possible (Raghunathan et al., 2010). Hence, we divide the mention pairs as follows:

**Nested:** are pairs such as “ $\{\{[city]_{m1}\} \text{ of } [Jerusalem]_{m2}\}$ ” where the extent of one of the mentions contains the extent of the other. For some mentions, the extent is the entire clause, so we also added a requirement that mention heads are at most 7 tokens apart. Intuitively, it is the easiest case of co-reference. There are 5,804 training samples and 992 testing samples, out of which 208 are co-referent.

**SameSenBothNer:** are pairs of named entities which appear in the same sentence. We already saw an example for this case involving  $[Mubarak]_{m2}$  and  $[Hosni Mubarak]_{m3}$ . There are 13,041 training samples and 1,746 testing samples, out of which 86 are co-referent.

**Adjacent:** are pairs of mentions which appear closest to each other on the dependency tree. We note that most of the nested pairs are also adjacent. There are training 5,872 samples and 895 testing samples, out of which 219 are co-referent.

**SameSentenceOneNer:** are pairs which appear in the same sentence and exactly one of the mentions is a named entity, and the other is not a pronoun. Typical pairs are “*Israel-country*”, as opposed to “*Bill Clinton - reporter*”. This type of pairs is fairly difficult, but our hope is to use encyclopedic knowledge to boost the performance. There are 15,715 training samples and 2,635 testing samples, out of which 207 are co-referent.

**NerMentionsDiffSent:** are pairs of mentions in different sentences, both of which are named entities. There are 189,807 training samples and 24,342 testing samples, out of which 1,628 are co-referent.

**NonProSameSentence:** are pairs in the same sentence, where both mentions are non-pronouns. This sieve includes all the pairs in the SameSentenceOneNer sieve. Typical pairs are “*city-capital*” and “*reporter-celebrity*”. *There are 33,895 training samples and 5,393 testing samples, out of which 336 are co-referent.*

**ClosestNonProDiffSent:** are pairs of mentions in different sentences with no other mentions between the two. 3,707 training samples and 488 testing samples, out of which 38 are co-referent.

**AllSentencePairs:** All mention pairs within same sentence. There are 49,953 training samples and 7,809 testing samples, out of which 846 are co-referent.

**TopSieve:** The set of mention pairs classified by the baseline system. 525,398 training samples and 85,358 testing samples, out of which 1,387 are co-referent.

In Tab. 1 we compare the performance at each sieve in two scenarios<sup>11</sup>. First, we train with the entire 525,398 training samples, and then we train on

<sup>11</sup>The data is described in Sec. 6.1.

whatever training data is available for the specific sieve<sup>12</sup>. We were surprised to see that the F1 on the nested mentions, when trained on the 5,804 sieve-specific samples improves to 79.00 versus 76.11 when trained on the 525,398 top sieve samples.

There are several things to note when interpreting the results in Tab 1. First, the sheer ratio of positive to negative samples fluctuates drastically. For example, 208 out of the 992 testing samples at the nested sieve are positive, while there are only 86 positive samples out of 1,746 testing samples in the Same-SenBothNer sieve. It seems unreasonable to use the same model for inference at both sieves. Second, the data for intermediate sieves is not always a subset of the top sieve. The reason is that top sieve extracts a positive instance only for the closest co-referent mentions, while sieves such as AllSentencePairs extract samples for all co-referent pairs which appear in the same sentence. Third, while our division to sieves may resemble witchcraft, it is motivated by the intuition that mentions appearing close to one another are easier instances of co-ref as well as linguistic insights of (Raghunathan et al., 2010).

## 5 Entity-Based Features

In this section we describe our approach for building entity-based features. Let  $\{C_1, C_2, \dots, C_N\}$  be the set of sieve-specific classifiers. In our case,  $C_1$  is the nested mention pairs classifier,  $C_2$  is the Same-SenBothNer classifier, and  $C_9$  is the top sieve classifier. We design entity-based features so that the subsequent sieves “see” the decisions of the previous sieves and use entity-based features based on the intermediate clustering. However, unlike (Raghunathan et al., 2010), we allow the subsequent sieves to change the decisions made by the lower sieves (since additional information becomes available).

### 5.1 Intermediate Clustering Features (IC)

Let  $R_i(m)$  be the set of all mentions which, when paired with the mention  $m$ , form valid sample pairs for sieve  $i$ . E.g. in our running example of Fig. 1,

<sup>12</sup>We report *pairwise* performance on mention pairs because it is the more natural metric for the intermediate sieves. We report only performance on co-referent pairs, because for many sieves, such as the top sieve, 99% of the mention pairs are non-coreferent, hence the baseline of labeling all samples as non-coreferent would result in 99% accuracy. We are interested in a more challenging baseline, the co-referent pairs.

$R_2([Kursk]_{m_2}) = \{[Barents\ Sea]_{m_3}\}$ , since both  $m_1$  and  $m_2$  are NEs and appear in the same sentence. Let  $R_i^+(m)$  be the set of all mentions which were labeled as co-referent to the mention  $m$  by the classifier  $C_i$  (including  $m$ , which is co-referent to itself). We define  $R_i^-(m)$  similarly. We denote the union of mentions co-refered to  $m$  during inference up to sieve  $i$  as  $E_i^+(m) = \cup_{j=1}^{i-1} R_j^+(m)$ . Similarly,  $E_i^-(m) = \cup_{j=1}^{i-1} R_j^-(m)$ . Using these definitions we can introduce entity-based prediction features which allow subsequent sieves to use information aggregated from previous sieves:

$$IC_i^R(m_j, m_k) = \begin{cases} -1 & m_j \in R_{i-1}^-(m_k) \\ +1 & m_j \in R_{i-1}^+(m_k) \\ 0 & \text{Otherwise} \end{cases}$$

$$IC_i^E(m_j, m_k) = \begin{cases} -1 & m_j \in E_{i-1}^-(m_k) \\ +1 & m_j \in E_{i-1}^+(m_k) \\ 0 & \text{Otherwise} \end{cases}$$

$IC_i^R$  stores the pairwise prediction history, thus when classifying a pair  $(m_j, m_k)$  at sieve  $i$ , a classifier can see the predictions of all the previous sieves applicable on that pair.  $IC_i^E$  stores the transitive closures of the sieve-specific predictions. We note that both  $IC_i^R$  and  $IC_i^E$  can have the values +1 and -1 active at the same time if intermediate sieve classifiers generated conflicting predictions. However, a classifier at sieve  $i$  will use as features both  $IC_1^R, \dots, IC_{i-1}^R$  and  $IC_1^E, \dots, IC_{i-1}^E$ , thus it will know the lowest sieve at which the conflicting evidence occurs. The classifier at sieve  $i$  also uses set identity, set containment, set overlap and other set comparison features between  $E_{i-1}^{+/-}(m_j)$  and  $E_{i-1}^{+/-}(m_k)$ . We check whether the sets have symmetric difference, whether the size of the intersection between the two sets is at least half the size of the smallest set etc. We also generate subtypes of set comparison features when restricting the elements to NE-mentions and non-pronominal mentions (e.g “what percent of named entities do the sets have in common?”).

### 5.2 Surface Form Compatibility (SFC)

The intermediate clustering features do not allow us to generalize predictions from pairs of mentions to pairs of surface strings. For example, if we have three mentions:  $\{[vessel]_{m_1}, [Kursk]_{m_2}, [Kursk]_{m_5}\}$ , then the prediction on the pair  $(m_1, m_2)$  will not be

	(B)aseline	(B)+Knowledge	(B)+Predictions	(B)+Knowledge+Predictions
TopSieve	66.58	69.08	68.77	<b>70.43</b>
AllSentencePairs	67.46	71.79	69.59	<b>73.50</b>
ClosestNonProDiffSent	63.33	65.62	65.57	<b>70.76</b>
NonProSameSentence	63.80	69.62	67.03	<b>71.11</b>
NerMentionsDiffSent	87.12	88.23	88.68	<b>89.07</b>

Table 2: Utility of knowledge and prediction features (F1 on co-referent mention pairs) by inference sieves. Both knowledge and entity-based features significantly and independently improve the performance for all sieves. The goal of entity-based features is to propagate knowledge effectively, thus it is encouraging that the combination of entity-based and knowledge features performed significantly better than any of the approaches individually at the top sieve.

used for the prediction on the pair  $(m_1, m_5)$ , even though in both pairs we are asking whether *Kursk* can be referred to as *vessel*. The surface form compatibility features mirror the intermediate clustering features, but relax mention IDs and replace them by surface forms. Similarly to intermediate clustering features, both +1 and -1 values can be active at the same time. We also generate subtypes of set-comparison features for NE-mentions and optionally stemmed non-pronominal mentions. For example, in a text discussing *President Clinton* and *President Putin*, some instances of the surface from *president* will refer to *Putin* but not *Clinton* and vice-versa. Therefore, both for  $(Putin, president)$  and for  $(Clinton, president)$ , the surface from compatibility will be +1 and -1 simultaneously. This indicates to the system that *Putin* can be referred to as *president*, but *president* can refer to other entities in the document as well.

## 6 Experiments and Results

### 6.1 Data

We use the official ACE 2004 English training data (NIST, 2004). We started with the data split used in (Culotta et al., 2007), which used 336 documents for training and 107 documents for testing. We note that ACE data contains both newswire text and transcripts. In this work, we are using NLP tools such as POS tagger, named entity recognizer, shallow parser, and a disambiguation to Wikipedia system to inject expressive features into a co-reference system.

Unfortunately, current state-of-the-art NLP tools

do not work well on transcribed text. Therefore, we discard all the transcripts. Our criteria was simple. The ACE annotators have marked the named entities both in newswire and in the transcripts. We kept only those documents which contained named entities (according to manual ACE annotation) and at least 1/3 of the named entities started with a capital letter. After this pre-processing step, we were left with 275 out of the original 336 training documents, and 42 out of the 107 testing documents.

For the experiments throughout this paper, following Culotta et al. (Culotta et al., 2007) and much other work, to make experiments more comparable across systems, we assume that perfect mention boundaries and mention type labels are given. However, we do not use the gold named entity types such as person/location/facility etc. available in the data. In all experiments we automatically split words and sentences, and annotate the text with part-of-speech tags, named entities and cross-link concepts from the text to Wikipedia using publicly available tools.

### 6.2 Ablation Study

In Tab. 2 we report the pairwise F1 scores on co-referent mention pairs broken down by sieve and using different components. This allows us to see, for example, that adding only the knowledge attributes improved the performance at *NonProSameSentence* sieve from 63.80 to 69.62. We have ordered the sieves according to our initial intuition of “easy first”. We were surprised to see that co-ref resolution for named entities in the same sentence was harder than cross-sentence (73.75 vs. 87.12 base-

Figure 4: End performance for various systems.

line F1). We were also surprised to see that resolving all mention pairs within sentence when including pronouns was easier than resolving pairs where both mentions were non-pronouns (67.46 vs. 63.80 baseline F1).

We note that conceptually, the nested (B)+Predictions sieve should be identical to the baseline. However, in practice, the surface form compatibility (SFC) features are generated for the nested sieve as well. Given two mentions  $m_1$  and  $m_2$ , the SFC features capture how many surface forms  $E^+(m_1)$  and  $E^+(m_2)$  share. At the nested sieve,  $E^+(m)$  and  $R^+(m)$  are just  $m$ , which is identical to string comparison features already existing in the baseline system. While the SFC features do not add new information, they influence the weight the features get (essentially leading to a different regularization), which in turn leads to slightly different results.

### 6.3 End system performance

Recall that the Best-Link algorithm applies transitive closure on the graph generated by thresholding the pairwise co-reference scoring function  $pc$ . The lower the threshold on the positive prediction, the lower is the precision and the higher is the recall. In Fig. 4 we compare the end clustering quality across a variety of thresholds and for various system flavors using three metrics: MUC (Vilain et al., 1995),  $B^3$  (Bagga and Baldwin, 1998) and CEAF (Luo, 2005)<sup>13</sup>. The purpose of this comparison is to see the impact of the knowledge and the prediction features on the final output and to see whether the performance gains are due to (mis-)tuning of one of the systems or are they consistent across a variety of thresholds.

The end performance of the baseline system on our training/testing split peaks at around 78.39 MUC, 83.03  $B^3$  and 77.52 CEAF, which is higher (e.g. 3  $B^3$  F1 points) than the originally reported result on the entire dataset (which includes the transcripts). This is expected, since well-formed text is easier to process than transcripts. We note that our baseline is a state-of-the-art system which recorded the highest  $B^3$  and BLANC scores at CoNLL 2011 shared task and took the third place overall. Fig. 4 shows a minimum improvement of 3 MUC, 2  $B^3$  and 1.25 CEAF F1 points across all thresholds when comparing the baseline to our end system. Surprisingly, the knowledge features outperformed prediction features on pairwise, MUC and  $B^3$  metrics, but not on the CEAF metric. This shows that pairwise performance is not always indicative of cluster-level performance for all metrics.

## 7 Conclusions and Related Work

To illustrate the strengths of our approach, let us consider the following text:

*Another terminal was made available in {[Jiangxi] $_{m_1}$ }, an {inland [province] $_{m_2}$ }. ... The previous situation whereby large amount of goods for {Jiangxi [province] $_{m_3}$ } had to be re-shipped through Guangzhou and Shanghai will be changed completely.*

The baseline system assigns each mention to a separate cluster. The pairs  $(m_1, m_2)$  and  $(m_1, m_3)$

<sup>13</sup>In the interest of space, we refer the reader to the literature for details about the different metrics.

are misclassified because the baseline classifier does not know that *Jiangxi* is a *province* and the preposition *an* before  $m_2$  is interpreted to mean it is a previously unmentioned entity. The pair  $(m_2, m_3)$  is misclassified because identical heads have different modifiers, as in *(big province, small province)*. Our end system first co-refs  $(m_1, m_2)$  at the *AllSameSentence* sieve due to the knowledge features, and then co-refs  $(m_1, m_3)$  at the top sieve due to surface form compatibility features indicating that *province* was observed to refer to *Jiangxi* in the document. The transitivity of Best-Link takes care of  $(m_2, m_3)$ .

However, our approach has multiple limitations. Entity-based features currently do not propagate knowledge attributes directly, but through aggregating pairwise predictions at knowledge-infused intermediate sieves. We rely on gold mention boundaries and exhaustive gold co-reference annotation. This prevented us from applying our approach to the Ontonotes dataset where singleton clusters and co-referent nested mentions are removed. Therefore the gold annotation for training several sieves of our scheme is missing (e.g. nested mentions). Another limitation is our somewhat preliminary division to sieves. (Vilalta and Rish, 2003) have experimented with approaches for automatic decomposition of data to subclasses and learning multiple models to improve data separability. We hope that similar approach would be useful for co-reference resolution. Ideally, we want to make “simple decisions” first, similarly to what was done in (Goldberg and Elhadad, 2010) for dependency parsing, and model clustering as a structured problem, similarly to (Joachims et al., 2009; Wick et al., 2011). However, our experience with multi-sieve approach with classifiers suggests that a single model would not perform well for both lower sieves with little entity-based information and higher sieves with a lot of entity-based features. Addressing the aforementioned challenges is a subject for future work.

There has been an increasing interest in knowledge-rich co-reference resolution (Ponzetto and Strube, 2006; Haghighi and Klein, 2010; Rahman and Ng, 2011). We use Wikipedia differently from (Ponzetto and Strube, 2006) who focus on using WikiRelate, a Wikipedia-based relatedness metric (Strube and Ponzetto, 2006). (Rahman and Ng, 2011) used the union of all possible inter-

pretations a mention may have in YAGO, which means that *Michael Jordan* could be co-refed both to a *scientist* and *basketball player* in the same document. Additionally, (Rahman and Ng, 2011) use exact word matching, relying on YAGO’s ability to extract a comprehensive set of facts offline<sup>14</sup>. We are the first to use context-sensitive disambiguation to Wikipedia, which received a lot of attention recently (Bunescu and Pasca, 2006; Cucerzan, 2007; Mihalcea and Csomai, 2007; Milne and Witten, 2008; Ratinov et al., 2011). We extract context-sensitive, high-precision knowledge attributes from Wikipedia pages and apply (among other features) WordNet similarity metric on pairs of knowledge attributes to determine attribute compatibility.

We have integrated the strengths of rule-based systems such as (Haghighi and Klein, 2009; Raghunathan et al., 2010) into a multi-sieve machine learning framework. We show that training sieve-specific models significantly increases the performance on most intermediate sieves.

We develop a novel approach for entity-based inference. Unlike (Rahman and Ng, 2011) who construct entities left-to-right, and similarly to (Raghunathan et al., 2010) we resolve easy instances of coref to reduce error propagation in entity-based features. Unlike (Raghunathan et al., 2010), we allow later stages of inference to change the decisions made at lower stages as additional entity-based evidence becomes available.

By adding word-knowledge features and refining the inference, we improve the performance of a state-of-the-art system of (Bengtson and Roth, 2008) by 3 MUC, 2  $B^3$  and 2 CEAF F1 points on the non-transcript portion of the ACE 2004 dataset.

## Abstract

Pairwise coreference resolution models must merge pairwise coreference decisions to generate final outputs. Traditional merging methods adopt different strategies such as the best-first method and enforcing the transitivity constraint, but most of these methods are used independently of the pairwise learning methods as an isolated inference procedure at the end. We propose a joint learning model which combines pairwise classification and mention clustering with Markov logic. Experimental results show that our joint learning system outperforms independent learning systems. Our system gives a better performance than all the learning-based systems from the CoNLL-2011 shared task on the same dataset. Compared with the best system from CoNLL-2011, which employs a rule-based method, our system shows competitive performance.

## 1 Introduction

The task of noun phrase coreference resolution is to determine which mentions in a text refer to the same real-world entity. Many methods have been proposed for this problem. Among them the mention-pair model (McCarthy and Lehnert, 1995) is one of the most influential ones and can achieve the state-of-the-art performance (Bengtson and Roth, 2008). The mention-pair model splits the task into three parts: mention detection, pairwise classification and mention clustering. Mention detection aims to identify anaphoric noun phrases, including proper nouns, common noun phrases and pronouns. Pairwise classification takes a pair of detected anaphoric noun

phrase candidates and determines whether they refer to the same entity. Because these classification decisions are local, they do not guarantee that candidate mentions are partitioned into clusters. Therefore a mention clustering step is needed to resolve conflicts and generate the final mention clusters.

Much work has been done following the mention-pair model (Soon et al., 2001; Ng and Cardie, 2002). In most work, pairwise classification and mention clustering are done sequentially. A major weakness of this approach is that pairwise classification considers only local information, which may not be sufficient to make correct decisions. One way to address this weakness is to jointly learn the pairwise classification model and the mention clustering model. This idea has been explored to some extent by McCallum and Wellner (2005) using conditional undirected graphical models and by Finley and Joachims (2005) using an SVM-based supervised clustering method.

In this paper, we study how to use a different learning framework, Markov logic (Richardson and Domingos, 2006), to learn a joint model for both pairwise classification and mention clustering under the mention-pair model. We choose Markov logic because of its appealing properties. Markov logic is based on first-order logic, which makes the learned models readily interpretable by humans. Moreover, joint learning is natural under the Markov logic framework, with local pairwise classification and global mention clustering both formulated as weighted first-order clauses. In fact, Markov logic has been previously used by Poon and Domingos (2008) for coreference resolution and achieved good

results, but it was used for unsupervised coreference resolution and the method was based on a different model, the entity-mention model.

More specifically, to combine mention clustering with pairwise classification, we adopt the commonly used strategies (such as best-first clustering and transitivity constraint), and formulate them as first-order logic formulas under the Markov logic framework. Best-first clustering has been previously studied by Ng and Cardie (2002) and Bengtson and Roth (2008) and found to be effective. Transitivity constraint has been applied to coreference resolution by Klenner (2007) and Finkel and Manning (2008), and also achieved good performance.

We evaluate Markov logic-based method on the dataset from CoNLL-2011 shared task. Our experiment results demonstrate the advantage of joint learning of pairwise classification and mention clustering over independent learning. We examine best-first clustering and transitivity constraint in our methods, and find that both are very useful for coreference resolution. Compared with the state of the art, our method outperforms a baseline that represents a typical system using the mention-pair model. Our method is also better than all learning systems from the CoNLL-2011 shared task based on the reported performance. Even with the top system from CoNLL-2011, our performance is still competitive.

In the rest of this paper, we first describe a standard pairwise coreference resolution system in Section 2. We then present our Markov logic model for pairwise coreference resolution in Section 3. Experimental results are given in Section 4. Finally we discuss related work in Section 5 and conclude in Section 6.

## 2 Standard Pairwise Coreference Resolution

In this section, we describe standard learning-based framework for pairwise coreference resolution. The major steps include mention detection, pairwise classification and mention clustering.

### 2.1 Mention Detection

For mention detection, traditional methods include learning-based and rule-based methods. Which kind of method to choose depends on specific dataset. In

this paper, we first consider all the noun phrases in the given text as candidate mentions. Without gold standard mention boundaries, we use a well-known preprocessing tool from Stanford’s NLP group<sup>1</sup> to extract noun phrases. After obtaining all the extracted noun phrases, we also use a rule-based method to remove some erroneous candidates based on previous studies (e.g. Lee et al. (2011), Uryupina et al. (2011)). Some examples of these erroneous candidates include stop words (e.g. *uh*, *hmm*), web addresses (e.g. <http://www.google.com>), numbers (e.g. \$9,000) and pleonastic “it” pronouns.

### 2.2 Pairwise Classification

For pairwise classification, traditional learning-based methods usually adopt a classification model such as maximum entropy models and support vector machines. Training instances (i.e. positive and negative mention pairs) are constructed from known coreference chains, and features are defined to represent these instances.

In this paper, we build a baseline system that uses maximum entropy models as the classification algorithm. For generation of training instances, we follow the method of Bengtson and Roth (2008). For each predicted mention  $m$ , we generate a positive mention pair between  $m$  and its closest preceding antecedent, and negative mention pairs by pairing  $m$  with each of its preceding predicted mentions which are not coreferential with  $m$ . To avoid having too many negative instances, we impose a maximum sentence distance between the two mentions when constructing mention pairs. This is based on the intuition that for each anaphoric mention, its preceding antecedent should appear quite near it, and most coreferential mention pairs which have a long sentence distance can be resolved using string matching. During the testing phase, we generate mention pairs for each mention candidate with each of its preceding mention candidates and use the learned model to make coreference decisions for these mention pairs. We also impose the sentence distance constraint and use string matching for mention pairs with a sentence distance exceeding the threshold.

---

<sup>1</sup><http://nlp.stanford.edu/software/corenlp.shtml>

### 2.3 Mention Clustering

After obtaining the coreferential results for all mention pairs, some clustering method should be used to generate the final output. One strategy is the single-link method, which links all the mention pairs that have a prediction probability higher than a threshold value. Two other alternative methods are the best-first clustering method and clustering with the transitivity constraint. Best-first clustering means that for each candidate mention  $m$ , we select the best one from all its preceding candidate mentions based on the prediction probabilities. A threshold value is given to filter out those mention pairs that have a low probability to be coreferential. Transitivity constraint means that if  $a$  and  $b$  are coreferential and  $b$  and  $c$  are coreferential, then  $a$  and  $c$  must also be coreferential. Previous work has found that best-first clustering and transitivity constraint-based clustering are better than the single-link method. Finally we remove all the singleton mentions.

### 3 Markov Logic for Pairwise Coreference Resolution

In this section, we present our method for joint learning of pairwise classification and mention clustering using Markov logic. For mention detection, training instance generation and postprocessing, our method follows the same procedures as described in Section 2. In what follows, we will first describe the basic Markov logic networks (MLN) framework, and then introduce the first-order logic formulas we use in our MLN including local formulas and global formulas which perform pairwise classification and mention clustering respectively. Through this way, these two isolated parts are combined together, and joint learning and inference can be performed in a single framework. Finally we present inference and parameter learning methods.

#### 3.1 Markov Logic Networks

Markov logic networks combine Markov networks with first-order logic (Richardson and Domingos, 2006; Riedel, 2008). A Markov logic network consists of a set of first-order clauses (which we will refer to as *formulas* in the rest of the paper) just like in first-order logic. However, different from first-order logic where a formula represents a hard constraint,

in an MLN, these constraints are softened and they can be violated with some penalty. An MLN  $\mathcal{M}$  is therefore a set of *weighted* formulas  $\{(\phi_i, w_i)\}_i$ , where  $\phi_i$  is a first order formula and  $w_i$  is the penalty (the formula’s weight). These weighted formulas define a probability distribution over sets of ground atoms or so-called possible worlds. Let  $y$  denote a possible world, then we define  $p(y)$  as follows:

$$p(y) = \frac{1}{Z} \exp \left( \sum_{(\phi_i, w_i) \in \mathcal{M}} w_i \sum_{\mathbf{c} \in C^{n_{\phi_i}}} f_{\mathbf{c}}^{\phi_i}(y) \right). \quad (1)$$

Here each  $\mathbf{c}$  is a binding of free variables in  $\phi_i$  to constants. Each  $f_{\mathbf{c}}^{\phi_i}$  represents a binary feature function that returns 1 if the ground formula we get by replacing the free variables in  $\phi_i$  with the constants in  $\mathbf{c}$  under the given possible world  $y$  is true, and 0 otherwise.  $n_{\phi_i}$  denotes the number of free variables of a formula  $\phi_i$ .  $C^{n_{\phi_i}}$  is the set of all bindings for the free variables in  $\phi_i$ .  $Z$  is a normalization constant. This distribution corresponds to a Markov network where nodes represent ground atoms and factors represent ground formulas.

Each formula consists of a set of first-order predicates, logical connectors and variables. Take the following formula as one example:

$$(\phi_i, w_i) : headMatch(a, b) \wedge (a \neq b) \Rightarrow coref(a, b).$$

The formula above indicates that if two different candidate mentions  $a$  and  $b$  have the same head word, then they are coreferential. Here  $a$  and  $b$  are variables which can represent any candidate mention, *headMatch* and *coref* are observed predicate and hidden predicate respectively. An observed predicate is one whose value is known from the observations when its free variables are assigned some constants. A hidden predicate is one whose value is not known from the observations. From this example, we can see that *headMatch* is an observed predicate because we can check whether two candidate mentions have the same head word. *coref* is a hidden predicate because this is something we would like to predict.

#### 3.2 Formulas

We use two kinds of formulas for pairwise classification and mention clustering, respectively. For

<b>describing the attributes of <math>m_i</math></b>	
mentionType(i,t)	$m_i$ has mention type NAM(named entities), NOM(nominal) or PRO(pronouns).
entityType(i,e)	$m_i$ has entity type PERSON, ORG, GPE or UN...
genderType(i,g)	$m_i$ has gender type MALE, FEMALE, NEUTRAL or UN.
numberType(i,n)	$m_i$ has number type SINGULAR, PLURAL or UN.
hasHead(i,h)	$m_i$ has head word h, here h can represent all possible head words.
firstMention(i)	$m_i$ is the first mention in its sentence.
reflexive(i)	$m_i$ is reflexive.
possessive(i)	$m_i$ is possessive.
definite(i)	$m_i$ is definite noun phrase.
indefinite(i)	$m_i$ is indefinite noun phrase.
demonstrative(i)	$m_i$ is demonstrative.
<b>describing the attributes of relations between <math>m_j</math> and <math>m_i</math></b>	
mentionDistance(j,i,m)	Distance between $m_j$ and $m_i$ in mentions.
sentenceDistance(j,i,s)	Distance between $m_j$ and $m_i$ in sentences.
bothMatch(j,i,b)	Gender and number of both $m_j$ and $m_i$ match: AGREE_YES, AGREE_NO and AGREE_UN).
closestMatch(j,i,c)	$m_j$ is the first agreement in number and gender when looking backward from $m_i$ : CAGREE_YES, CAGREE_NO and CAGREE_UN.
exactStrMatch(j,i)	Exact strings match between $m_j$ and $m_i$ .
pronounStrMatch(j,i)	Both are pronouns and their strings match.
nopronounStrMatch(j,i)	Both are not pronouns and their strings match.
properStrMatch(j,i)	Both are proper names and their strings match.
headMatch(j,i)	Head word strings match between $m_j$ and $m_i$ .
subStrMatch(j,i)	Sub-word strings match between $m_j$ and $m_i$ .
animacyMatch(j,i)	Animacy types match between $m_j$ and $m_i$ .
nested(j,i)	$m_j/i$ is included in $m_i/j$ .
c_command(j,i)	$m_j/i$ C-Commands $m_i/j$ .
sameSpeaker(j,i)	$m_j$ and $m_i$ have the same speaker.
entityTypeMatch(j,i)	Entity types match between $m_j$ and $m_i$ .
alias(j,i)	$m_j/i$ is an alias of $m_i/j$ .
srlMatch(j,i)	$m_j$ and $m_i$ have the same semantic role.
verbMatch(j,i)	$m_j$ and $m_i$ have semantic role for the same verb.

Table 1: Observed predicates.

pairwise classification, because the decisions are local, we use a set of *local* formulas. For mention clustering, we use *global* formulas to implement best-first clustering or transitivity constraint. We naturally combine pairwise classification with mention clustering via local and global formulas in the Markov logic framework, which is the essence of “joint learning” in our work.

### 3.2.1 Local Formulas

A local formula relates any observed predicates to exactly one hidden predicate. For our problem, we define a list of observed predicates to describe the properties of individual candidate mentions and the relations between two candidate mentions, shown in Table 1. For our problem, we have only one hidden predicate, i.e. *coref*. Most of our local formulas are

from existing work (e.g. Soon et al. (2001), Ng and Cardie (2002), Sapena et al. (2011)). They are listed in Table 2, where the symbol “+” indicates that for every value of the variable preceding “+” there is a separate weight for the corresponding formula.

### 3.2.2 Global Formulas

Global formulas are designed to add global constraints for hidden predicates. Since in our problem there is only one hidden predicate, i.e. *coref*, our global formulas incorporate correlations among different ground atoms of the *coref* predicates. Next we will show the best-first and transitivity global constraints. Note that we treat them as hard constraints so we do not set any weights for these global formulas.

Table 2: Local Formulas.

### Best-First constraint:

$$\text{coref}(j, i) \Rightarrow \neg \text{coref}(k, i) \quad \forall j, k < i (k \neq j) \quad (2)$$

Here we assume that  $\text{coref}(j, i)$  returns true if candidate mentions  $j$  and  $i$  are coreferential and false otherwise. Therefore for each candidate mention  $i$ , we should only select at most one candidate mention  $j$  to return true for the predicate  $\text{coref}(j, i)$  from all its preceding candidate mentions.

### Transitivity constraint:

$$\text{coref}(j, k) \wedge \text{coref}(k, i) \wedge j < k < i \Rightarrow \text{coref}(j, i) \quad (3)$$

$$\text{coref}(j, k) \wedge \text{coref}(j, i) \wedge j < k < i \Rightarrow \text{coref}(k, i) \quad (4)$$

$$\text{coref}(j, i) \wedge \text{coref}(k, i) \wedge j < k < i \Rightarrow \text{coref}(j, k) \quad (5)$$

With the transitivity constraint, it means for given mentions  $j$ ,  $k$  and  $i$ , if any two pairs of them are coreferential, then the third pair of them should be also coreferential.

We use best-first clustering and transitivity constraint in our joint learning model respectively. Detailed comparisons between them will be shown in Section 4.

### 3.3 Inference

We use MAP inference which is implemented by Integer Linear Programming (ILP). Its objective is to maximize a posteriori probability as follows. Here we use  $x$  to represent all the observed ground atoms and  $y$  to represent the hidden ground atoms. Formally, we have

$$\hat{y} = \arg \max_y p(y|x) \simeq \arg \max_y s(y, x),$$

where

$$s(y, x) = \sum_{(\phi_i, w_i) \in M} w_i \sum_{\mathbf{c} \in C^{n_{\phi_i}}} f_{\mathbf{c}}^{\phi_i}(y, x). \quad (6)$$

Each hidden ground atom can only takes a value of either 0 or 1. And global formulas should be satisfied as hard constraints when inferring the best  $\hat{y}$ . So

the problem can be easily solved using ILP. Detailed introduction about transforming ground Markov networks in Markov logic into an ILP problem can be found in (Riedel, 2008).

### 3.4 Parameter Learning

For parameter learning, we employ the online learner MIRA (Crammer and Singer, 2003), which establishes a large margin between the score of the gold solution and all wrong solutions to learn the weights. This is achieved by solving the quadratic program as follows

$$\begin{aligned} \min \quad & \| \mathbf{w}_t - \mathbf{w}_{t-1} \| . \\ \text{s.t.} \quad & s(y_i, x_i) - s(y', x_i) \geq L(y_i, y') \\ & \forall y' \neq y_i, \quad (y_i, x_i) \in D \end{aligned} \quad (7)$$

Here  $D = \{(y_i, x_i)\}_{i=1}^N$  represents  $N$  training instances (each instance represents one single document in the dataset) and  $t$  represents the number of iterations. In our problem, we adopt 1-best MIRA, which means that in each iteration we try to find  $\mathbf{w}_t$  which can guarantee the difference between the right solution  $y_i$  and the best solution  $y'$  (i.e. the one with the highest score  $s(y', x_i)$ , equivalent to  $\hat{y}$  in Section 3.3) is at least as big as the loss  $L(y_i, y')$ , while changing  $\mathbf{w}_{t-1}$  as little as possible. The number of false ground atoms of *coref* predicate is selected as loss function in our experiments. Hard global constraints (i.e. best-first clustering or transitivity constraint) must be satisfied when inferring the best  $y'$  in each iteration, which can make learned weights more effective.

## 4 Experiments

In this section, we will first describe the dataset and evaluation metrics we use. We will then present the effect of our joint learning method, and finally discuss the comparison with the state of the art.

### 4.1 Data Set

We use the dataset from the CoNLL-2011 shared task, ‘‘Modeling Unrestricted Coreference in OntoNotes’’ (Pradhan et al., 2011)<sup>2</sup>. It uses the English portion of the OntoNotes v4.0 corpus. There are three important differences between OntoNotes

<sup>2</sup><http://conll.cemantix.org/2011/>

and another well-known coreference dataset from ACE. First, OntoNotes does not label any singleton entity cluster, which has only one reference in the text. Second, only identity coreference is tagged in OntoNotes, but not appositives or predicate nominatives. Third, ACE only considers mentions which belong to ACE entity types, whereas OntoNotes considers more entity types. The shared task is to automatically identify both entity coreference and event coreference, although we only focus on entity coreference in this paper. We don’t assume that gold standard mention boundaries are given. So we develop a heuristic method for mention detection. See details in Section 2.1.

The training set consists of 1674 documents from newswire, magazine articles, broadcast news, broadcast conversations and webpages, and the development set consists of 202 documents from the same source. For training set, there are 101264 mentions from 26612 entities. And for development set, there are 14291 mentions from 3752 entities (Pradhan et al., 2011).

### 4.2 Evaluation Metrics

We use the same evaluation metrics as used in CoNLL-2011. Specifically, for mention detection, we use precision, recall and the F-measure. A mention is considered to be correct only if it matches the exact same span of characters in the annotation key. For coreference resolution, MUC (Vilain et al., 1995), B-CUBED (Bagga and Baldwin, 1998) and CEAF-E (Luo, 2005) are used for evaluation. The unweighted average F score of them is used to compare different systems.

### 4.3 The Effect of Joint Learning

To assess the performance of our method, we set up several variations of our system to compare with the joint learning system. The *MLN-Local* system uses only the local formulas described in Table 2 without any global constraints under the MLN framework. By default, the *MLN-Local* system uses the single-link method to generate clustering results. The *MLN-Local+BF* system replaces the single-link method with best-first clustering to infer mention clustering results after learning the weights for all the local formulas. The *MLN-Local+Trans* system replaces the best-first clustering with transitivity

System	Mention Detection			MUC			B-cube			CEAF			Avg
	R	P	F	R	P	F	R	P	F	R	P	F	F
MLN-Local	62.52	74.75	68.09	56.07	65.55	60.44	65.67	72.95	69.12	45.55	37.19	40.95	56.84
MLN-Local+BF	65.74	73.2	69.27	56.79	64.08	60.22	65.71	74.18	69.69	47.29	40.53	43.65	57.85
MLN-Local+Trans	<b>68.49</b>	70.32	69.40	<b>57.16</b>	60.98	59.01	<b>66.97</b>	72.90	69.81	46.96	<b>43.34</b>	<b>45.08</b>	57.97
MLN-Joint(BF)	64.36	75.25	69.38	55.47	66.95	60.67	64.14	77.75	70.29	50.47	39.85	44.53	58.50
MLN-Joint(Trans)	64.46	<b>75.37</b>	<b>69.49</b>	55.48	<b>67.15</b>	<b>60.76</b>	64.00	<b>78.11</b>	<b>70.36</b>	<b>50.63</b>	39.84	44.60	<b>58.57</b>

Table 3: Comparison between different MLN-based systems, using 10-fold cross validation on the training dataset.

constraint. The *MLN-Joint* system is a joint model for both pairwise classification and mention clustering. It can combine either best-first clustering or enforcing transitivity constraint with pairwise classification, and we denote these two variants of *MLN-Joint* as *MLN-Joint(BF)* and *MLN-Joint(Trans)* respectively.

To compare the performance of the various systems above, we use 10-fold cross validation on the training dataset. We empirically find that our method has a fast convergence rate, to learn the MLN model, we set the number of iterations to be 10.

The performance of these compared systems is shown in Table 3. To provide some context for the performance of this task, we report the median average F-score of the official results of CoNLL-2011, which is 50.12 (Pradhan et al., 2011). We can see that *MLN-Local* achieves an average F-score of 56.84, which is well above the median score. When adding best-first or transitivity constraint which is independent of pairwise classification, *MLN-Local+BF* and *MLN-Local+Trans* achieve better results of 57.85 and 57.97. Most of all, we can see that the joint learning model (*MLN-Joint(BF)* or *MLN-Joint(Trans)*) significantly outperforms independent learning model (*MLN-Local+BF* or *MLN-Local+Trans*) no matter whether best-first clustering or transitivity constraint is used (based on a paired 2-tailed t-test with  $p < 0.05$ ) with the score of 58.50 or 58.57, which shows the effectiveness of our proposed joint learning method.

Best-first clustering and transitivity constraint are very useful in Markov logic framework, and both *MLN-Local* and *MLN-Joint* benefit from them. For *MLN-Joint*, these two clustering methods result in similar performance. But actually, transi-

tivity is harder than best-first, because it significantly increases the number of formulas for constraints and slows down the learning process. In our experiments, we find that *MLN-Joint(Trans)*<sup>3</sup> is much slower than *MLN-Joint(BF)*. Overall, *MLN-Joint(BF)* has a good trade-off between effectiveness and efficiency.

#### 4.4 Comparison with the State of the Art

In order to compare our method with the state-of-the-art systems, we consider the following systems. We implemented a traditional pairwise coreference system using Maximum Entropy as the base classifier and best-first clustering to link the results. We used the same set of local features in *MLN-Joint*. We refer to this system as *MaxEnt+BF*. To replace best-first clustering with transitivity constraint, we have another system named as *MaxEnt+Trans*. We also consider the best 3 systems from CoNLL-2011 shared task. Chang’s system uses ILP to perform best-first clustering after training a pairwise coreference model. Sapena’s system uses a relaxation labeling method to iteratively perform function optimization for labeling each mention’s entity after learning the weights for features under a C4.5 learner. Lee’s system is a purely rule-based one. They use a battery of sieves by precision (from highest to lowest) to iteratively choose antecedent for each mention. They obtained the highest score in CoNLL-2011.

Table 4 shows the comparisons of our system with the state-of-the-art systems on the development set of CoNLL-2011. From the results, we can see that our joint learning systems are obviously better than

<sup>3</sup>For *MLN-Joint(Trans)*, not all training instances can be learnt in a reasonable amount of time, so we set up a time out threshold of 100 seconds. If the model cannot response in 100 seconds for some training instance, we remove it from the training set.

System	Mention Detection			MUC			B-cube			CEAF			Avg
	R	P	F	R	P	F	R	P	F	R	P	F	F
MLN-Joint(BF)	67.33	72.94	<b>70.02</b>	<b>58.03</b>	64.05	60.89	67.11	73.88	70.33	47.6	41.92	44.58	58.60

Chang’s System	-	-	64.69	-	-	55.8	-	-	69.29	-	-	43.96	56.35

Table 4: Comparisons with state-of-the-art systems on the development dataset.

*MaxEnt+BF* and *MaxEnt+Trans*. They also outperform the learning-based systems of Sapena et al. (2011) and Chang et al. (2011), and perform competitively with Lee’s system (Lee et al., 2011). Note that Lee’s system is purely rule-based, while our methods are developed in a theoretically sound way, i.e., Markov logic framework.

## 5 Related Work

Supervised noun phrase coreference resolution has been extensively studied. Besides the mention-pair model, two other commonly used models are the entity-mention model (Luo et al., 2004; Yang et al., 2008) and ranking models (Denis and Baldrige, 2008; Rahman and Ng, 2009). Interested readers can refer to the literature review by Ng (2010).

Under the mention-pair model, Klenner (2007) and Finkel and Manning (2008) applied Integer Linear Programming (ILP) to enforce transitivity on the pairwise classification results. Chang et al. (2011) used the same ILP technique to incorporate best-first clustering and generate the mention clusters. In all these studies, however, mention clustering is combined with pairwise classification only at the inference stage but not at the learning stage.

To perform joint learning of pairwise classification and mention clustering, in (McCallum and Wellner, 2005), each mention pair corresponds to a binary variable indicating whether the two mentions are coreferential, and the dependence between these variables is modeled by conditional undirected graphical models. Finley and Joachims (2005) proposed a general SVM-based framework for supervised clustering that learns item-pair similarity measures, and applied the framework to noun phrase

coreference resolution. In our work, we take a different approach and apply Markov logic. As we have shown in Section 3, given the flexibility of Markov logic, it is straightforward to perform joint learning of pairwise classification and mention clustering.

In recent years, Markov logic has been widely used in natural language processing problems (Poon and Domingos, 2009; Yoshikawa et al., 2009; Che and Liu, 2010). For coreference resolution, the most notable one is unsupervised coreference resolution by Poon and Domingos (2008). Poon and Domingos (2008) followed the entity-mention model while we follow the mention-pair model, which are quite different approaches. To seek good performance in an unsupervised way, Poon and Domingos (2008) highly rely on two important strong indicators: appositives and predicate nominatives. However, OntoNotes corpus (state-of-art NLP data collection) on coreference layer for CoNLL-2011 has excluded these two conditions of annotations (appositives and predicate nominatives) from their judging guidelines. Compared with it, our methods are more applicable for real dataset. Huang et al. (2009) used Markov logic to predict coreference probabilities for mention pairs followed by correlation clustering to generate the final results. Although they also perform joint learning, at the inference stage, they still make pairwise coreference decisions and cluster mentions sequentially. Unlike their method, We formulate the two steps into a single framework.

Besides combining pairwise classification and mention clustering, there has also been some work that jointly performs mention detection and coreference resolution. Daumé and Marcu (2005) developed such a model based on the Learning as

Search Optimization (LaSO) framework. Rahman and Ng (2009) proposed to learn a cluster-ranker for discourse-new mention detection jointly with coreference resolution. Denis and Baldridge (2007) adopted an Integer Linear Programming (ILP) formulation for coreference resolution which models anaphoricity and coreference as a joint task.

## 6 Conclusion

In this paper we present a joint learning method with Markov logic which naturally combines pairwise classification and mention clustering. Experimental results show that the joint learning method significantly outperforms baseline methods. Our method is also better than all the learning-based systems in CoNLL-2011 and reaches the same level of performance with the best system.

In the future we will try to design more global constraints and explore deeper relations between training instances generation and mention clustering. We will also attempt to introduce more predicates and transform structure learning techniques for MLN into coreference problems.

## Abstract

We annotate and resolve a particular case of abstract anaphora, namely, *this-issue* anaphora. We propose a candidate ranking model for *this-issue* anaphora resolution that explores different *issue*-specific and general abstract-anaphora features. The model is not restricted to nominal or verbal antecedents; rather, it is able to identify antecedents that are arbitrary spans of text. Our results show that (a) the model outperforms the strong adjacent-sentence baseline; (b) general abstract-anaphora features, as distinguished from *issue*-specific features, play a crucial role in *this-issue* anaphora resolution, suggesting that our approach can be generalized for other NPs such as *this problem* and *this debate*; and (c) it is possible to reduce the search space in order to improve performance.

## 1 Introduction

Anaphora in which the anaphoric expression refers to an abstract object such as a proposition, a property, or a fact is known as *abstract object anaphora*. This is seen in the following examples.

- (1) **[Be careful what you wish... because wishes sometimes come true.]<sub>i</sub> [That]<sub>i</sub>** is what the Semiconductor Industry Association, which represents U.S. manufacturers, has been learning. (from Asher (1993))
- (2) This prospective study suggested **[that oral carvedilol is more effective than oral metoprolol in the prevention of AF after on-pump**

**CABG]<sub>i</sub>**. It is well tolerated when started before and continued after the surgery. However, further prospective studies are needed to clarify **[this issue]<sub>i</sub>**.

- (3) In principle, he said, airlines should be allowed **[to sell standing-room-only tickets for adults]<sub>i</sub>** — as long as **[this decision]<sub>i</sub>** was approved by their marketing departments.

These examples highlight a difficulty not found with nominal anaphora. First, the anaphors refer to abstract concepts that can be expressed with different syntactic shapes which are usually not nominals. The anaphor *That* in (1) refers to the proposition in the previous utterance, whereas the anaphor *this issue* in (2) refers to a clause from the previous text. In (3), the anaphoric expression *this decision* refers to a verb phrase from the same sentence. Second, the antecedents do not always have precisely defined boundaries. In (2), for example, the whole sentence containing the marked clause could also be thought to be the correct antecedent. Third, the actual referents are not always the precise textual antecedents. The actual referent in (2), the issue to be clarified, is *whether oral carvedilol is more effective than oral metoprolol in the prevention of AF after on-pump CABG or not*, a variant of the antecedent text.

Generally, abstract anaphora, as distinguished from *nominal anaphora*, is signalled in English by pronouns *this*, *that*, and *it* (Müller, 2008). But in abstract anaphora, English prefers demonstratives to personal pronouns and definite articles (Pasonneau, 1989; Navarretta, 2011).<sup>1</sup> Demonstrations

<sup>1</sup>This is not to say that personal pronouns and definite articles do not occur in abstract anaphora, but they are not common.

tives can be used in isolation (*That* in (1)) or with *nouns* (e.g., *this issue* in (2)). The latter follows the pattern *demonstrative {modifier}\* noun*. The demonstrative acts as a determiner and the noun following the demonstrative imposes selectional constraints for the antecedent, as in examples (2) and (3). Francis (1994) calls such nouns *label nouns*, which “serve to encapsulate or package a stretch of discourse”. Schmid (2000) refers to them as *shell nouns*, a metaphoric term which reflects different functions of these nouns such as encapsulation, pointing, and signalling.

Demonstrative nouns, along with pronouns like *both* and *either*, are referred to as *sortal anaphors* (Castaño et al., 2002; Lin and Liang, 2004; Torii and Vijay-Shanker, 2007). Castaño et al. observed that sortal anaphors are prevalent in the biomedical literature. They noted that among 100 distinct anaphors derived from a corpus of 70 Medline abstracts, 60% were sortal anaphors. But how often do demonstrative nouns refer to abstract objects? We observed that from a corpus of 74,000 randomly chosen Medline<sup>2</sup> abstracts, of the first 150 most frequently occurring distinct demonstrative nouns (frequency > 30), 51.3% were abstract, 41.3% were concrete, and 7.3% were discourse deictic. This shows that abstract anaphora resolution is an important component of general anaphora resolution in the biomedical domain. However, automatic resolution of this type of anaphora has not attracted much attention and the previous work for this task is limited.

The present work is a step towards resolving abstract anaphora in written text. In particular, we choose the interesting abstract concept *issue* and demonstrate the complexities of resolving *this-issue* anaphora manually as well as automatically in the Medline domain. We present our algorithm, results, and error analysis for *this-issue* anaphora resolution.

The abstract concept *issue* was chosen for the following reasons. First, it occurs frequently in all kinds of text from newspaper articles to novels to scientific articles. There are 13,489 *issue* anaphora instances in the New York Times corpus and 1,116 instances in 65,000 Medline abstracts. Second, it is abstract enough that it can take several syntactic and

semantic forms, which makes the problem interesting and non-trivial. Third, *issue* referents in scientific literature generally lie in the previous sentence or two, which makes the problem tractable. Fourth, *issues* in Medline abstracts are generally associated with clinical problems in the medical domain and spell out the motivation of the research presented in the article. So extraction of this information would be useful in any biomedical information retrieval system.

## 2 Related Work

Anaphora resolution has been extensively studied in computational linguistics (Hirst, 1981; Mitkov, 2002; Poesio et al., 2011). But CL research has mostly focused on nominal anaphora resolution (e.g., resolving multiple ambiguous mentions of a single entity representing a person, a location, or an organization) mainly for two reasons. First, nominal anaphora is the most frequently occurring anaphora in most domains, and second, there is a substantial amount of annotated data available for this kind of anaphora.

Besides pronominal anaphora, some work has been done on complement anaphora (Modjeska, 2003) (e.g., *British and other European steelmakers*). There is also some research on resolving sortal anaphora in the medical domain using domain knowledge (Castaño et al., 2002; Lin and Liang, 2004; Torii and Vijay-Shanker, 2007). But all these approaches focus only on the anaphors with nominal antecedents.

By contrast, the area of abstract object anaphora remains relatively unexplored mainly because the standard anaphora resolution features such as agreement and apposition cannot be applied to abstract anaphora resolution. Asher (1993) built a theoretical framework to resolve abstract anaphora. He divided discourse abstract anaphora into three broad categories: event anaphora, proposition anaphora, and fact anaphora, and discussed how abstract entities can be resolved using discourse representation theory. Chen et al. (2011) focused on a subset of event anaphora and resolved event coreference chains in terms of the representative verbs of the events from the OntoNotes corpus. Our task differs from their work as follows. Chen et al. mainly

<sup>2</sup><http://www.nlm.nih.gov/bsd/pmresources.html>

focus on events and actions and use verbs as a proxy for the non-nominal antecedents. But *this-issue* antecedents cannot usually be represented by a verb. Our work is not restricted to a particular syntactic type of the antecedent; rather we provide the flexibility of marking arbitrary spans of text as antecedents.

There are also some prominent approaches to abstract anaphora resolution in the spoken dialogue domain (Eckert and Strube, 2000; Byron, 2004; Müller, 2008). These approaches go beyond nominal antecedents; however, they are restricted to spoken dialogues in specific domains and need serious adaptation if one wants to apply them to arbitrary text.

In addition to research on resolution, there is also some work on effective annotation of abstract anaphora (Strube and Müller, 2003; Botley, 2006; Poesio and Artstein, 2008; Dipper and Zinsmeister, 2011). However, to the best of our knowledge, there is currently no English corpus annotated for *issue* anaphora antecedents.

### 3 Data and Annotation

To create an initial annotated dataset, we collected 188 *this {modifier} \* issue* instances along with the surrounding context from Medline abstracts.<sup>3</sup> Five instances were discarded as they had an unrelated (publication related) sense. Among the remaining 183 instances, 132 instances were independently annotated by two annotators, a domain expert and a non-expert, and the remaining 51 instances were annotated only by the domain expert. We use the former instances for training and the latter instances (unseen by the developer) for testing. The annotator’s task was to mark arbitrary text segments as antecedents (without concern for their linguistic types). To make the task tractable, we assumed that an antecedent does not span multiple sentences but lies in a single sentence (since we are dealing with singular *this-issue* anaphors) and that it is a continuous span of text.

<sup>3</sup>Although our dataset is rather small, its size is similar to other available abstract anaphora corpora in English: 154 instances in Eckert and Strube (2000), 69 instances in Byron (2003), 462 instances annotated by only one annotator in Botley (2006), and 455 instances restricted to those which have only nominal or clausal antecedents in Poesio and Artstein (2008).

Figure 1: Example of annotated data. Bold segments denote the marked antecedents for the corresponding anaphor *ids*.  $r_{hj}$  is the  $j^{\text{th}}$  section identified by the annotator  $h$ .

#### 3.1 Inter-annotator Agreement

This kind of annotation — identifying and marking arbitrary units of text that are not necessarily constituents — requires a non-trivial variant of the usual inter-annotator agreement measures. We use Krippendorff’s *reliability coefficient for unitizing* ( $\alpha_u$ ) (Krippendorff, 1995) which has not often been used or described in CL. In our context, *unitizing* means marking the spans of the text that serve as the antecedent for the given anaphors within the given text. The coefficient  $\alpha_u$  assumes that the annotated sections do not overlap in a single annotator’s output and our data satisfies this criterion.<sup>4</sup> The general form of coefficient  $\alpha_u$  is:

$$\alpha_u = 1 - \frac{{}_u D_o}{{}_u D_e} \quad (1)$$

where  ${}_u D_o$  and  ${}_u D_e$  are observed and expected disagreements respectively. Both disagreement quantities express the average squared differences between the mismatching pairs of values assigned by annotators to given units of analysis.  $\alpha_u = 1$  indicates perfect reliability and  $\alpha_u = 0$  indicates the absence of reliability. When  $\alpha_u < 0$ , the disagreement is systematic. Annotated data with reliability of  $\alpha_u \geq 0.80$  is considered reliable (Krippendorff, 2004).

Krippendorff’s  $\alpha_u$  is non-trivial, and explaining it in detail would take too much space, but the general idea, in our context, is as follows. The annotators mark the antecedents corresponding to each anaphor in their respective copies of the text, as shown in Figure 1. The marked antecedents are mutually exclusive sections  $r$ ; we denote the  $j^{\text{th}}$  section identified

<sup>4</sup>If antecedents overlap with each other in a single annotator’s output (which is a rare event) we construct data that satisfies the non-overlap criterion by creating different copies of the same text corresponding to each anaphor instance.

Antecedent type	Distribution	Example
clause	37.9%	There is a controversial debate ( <b>SBAR</b> <i>whether back school program might improve quality of life in back pain patients</i> ). This study aimed to address <b>this issue</b> .
sentence	26.5%	( <b>S</b> <i>Reduced serotonin function and abnormalities in the hypothalamic-pituitary-adrenal axis are thought to play a role in the aetiology of major depression.</i> ) We sought to examine <b>this issue</b> in the elderly ...
mixed	18.2%	(S (PP Given these data) (, .) ( <b>NP</b> <i>decreasing HTD to &lt; or = 5 years</i> ) ( <b>VP</b> <i>may have a detrimental effect on patients with locally advanced prostate cancer</i> ) (. .)) Only a randomized trial will conclusively clarify <b>this issue</b> .
nominalization	17.4%	As ( <b>NP</b> <i>the influence of estrogen alone on breast cancer detection</i> ) is not established, we examined <b>this issue</b> in the Women’s Health Initiative trial...

Table 1: Antecedent types. In examples, the antecedent type is in **bold** and the marked antecedent is in *italics*.

by the annotator  $h$  by  $r_{hj}$ . In Figure 1, annotators 1 and 2 have reached different conclusions by identifying 9 and 10 sections respectively in their copies of the text. Annotator 1 has not marked any antecedent for the anaphor with  $id = 1$ , while annotator 2 has marked  $r_{21}$  for the same anaphor. Both annotators have marked exactly the same antecedent for the anaphor with  $id = 4$ . The difference between two annotated sections is defined in terms of the square of the distance between the non-overlapping parts of the sections. The distance is 0 when the sections are unmarked by both annotators or are marked and exactly same, and is the summation of the squares of the unmatched parts if they are different. The coefficient is computed using intersections of the marked sections. In Figure 1, annotators 1 and 2 have a total of 14 intersections. The observed disagreement  ${}_u D_o$  is the weighted sum of the differences between all mismatching intersections of sections marked by the annotators, and the expected disagreement is the summation of all possible differences of pairwise combinations of all sections of all annotators normalized by the length of the text (in terms of the number of tokens) and the number of pairwise combinations of annotators.

For our data, the inter-annotator agreement was  $\alpha_u = 0.86$  ( ${}_u D_o = 0.81$  and  ${}_u D_e = 5.81$ ) despite the fact that the annotators differed in their domain expertise, which suggests that abstract concepts such as *issue* can be annotated reliably.

### 3.2 Corpus Statistics

A gold standard corpus was created by resolving the cases where the annotators disagreed. Among 132 training instances, the annotators could not resolve

6 instances and we broke the tie by writing to the authors of the articles and using their response to resolve the disagreement. In the gold standard corpus, 95.5% of the antecedents were in the current or previous sentence and 99.2% were in the current or previous two sentences. Only one antecedent was found more than two sentences back and it was six sentences back. One instance was a cataphor, but the antecedent occurred in the same sentence as the anaphor. This suggests that for an automatic *this-issue* resolution system, it would be reasonable to consider only the previous two sentences along with the sentence containing the anaphor.

The distribution of the different linguistic forms that an antecedent of *this-issue* can take in our data set is shown in Table 1. The majority of antecedents are clauses or whole sentences. A number of antecedents are noun phrases, but these are generally nominalizations that refer to abstract concepts (e.g., *the influence of estrogen alone on breast cancer detection*). Some antecedents are not even well-defined syntactic constituents<sup>5</sup> but are combinations of several well-defined constituents. We denote the type of such antecedents as *mixed*. In the corpus, 18.2% of the antecedents are of this type, suggesting that it is not sufficient to restrict the antecedent search space to well-defined syntactic constituents.<sup>6</sup>

In our data, we did not find anaphoric chains for any of the *this-issue* anaphor instances, which indicates that the antecedents of *this-issue* anaphors are

<sup>5</sup>We refer to every syntactic constituent identified by the parser as a *well-defined syntactic constituent*.

<sup>6</sup>Indeed, many of mixed type antecedents (nearly three-quarters of them) are the result of parser attachment errors, but many are not.

in the reader’s local memory and not in the global memory. This observation supports the THIS-NPs hypothesis (Gundel et al., 1993; Poesio and Modjeska, 2002) that *this*-NPs are used to refer to entities which are *active* albeit not in *focus*, i.e., they are not the center of the previous utterance.

## 4 Resolution Algorithm

### 4.1 Candidate Extraction

For correct resolution, the set of extracted candidates must contain the correct antecedent in the first place. The problem of candidate extraction is non-trivial in abstract anaphora resolution because the antecedents are of many different types of syntactic constituents such as clauses, sentences, and nominalizations. Drawing on our observation that the mixed type antecedents are generally a combination of different well-defined syntactic constituents, we extract the set of candidate antecedents as follows. First, we create a set of candidate sentences which contains the sentence containing the *this-issue* anaphor and the two preceding sentences. Then, we parse every candidate sentence with the Stanford Parser<sup>7</sup>. Initially, the set of candidate constituents contains a list of well-defined syntactic constituents. We require that the node type of these constituents be in the set {S, SBAR, NP, SQ, SBARQ, S+V}. This set was empirically derived from our data. To each constituent, there is associated a set of mixed type constituents. These are created by concatenating the original constituent with its sister constituents. For example, in (4), the set of well-defined eligible candidate constituents is {NP, NP<sub>1</sub>} and so NP<sub>1</sub> PP<sub>1</sub> is a mixed type candidate.

The set of candidate constituents is updated with the extracted mixed type constituents. Extracting mixed type candidate constituents not only deals with mixed type instances as shown in Table 1, but as a side effect it also corrects some attachment errors made by the parser. Finally, the constituents

<sup>7</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

having a number of leaves (words) less than a threshold<sup>8</sup> are discarded to give the final set of candidate constituents.

### 4.2 Features

We explored the effect of including 43 automatically extracted features (12 feature classes), which are summarized in Table 2. The features can also be broadly divided into two groups: *issue*-specific features and general abstract-anaphora features. *Issue*-specific features are based on our common-sense knowledge of the concept of *issue* and the different semantic forms it can take; e.g., controversy (*X is controversial*), hypothesis (*It has been hypothesized X*), or lack of knowledge (*X is unknown*), where *X* is the issue. In our data, we observed certain syntactic patterns of issues such as *whether X or not* and *that X* and the IP feature class encodes this information. Other *issue*-specific features are IVERB and IHEAD. The feature IVERB checks whether the governing verb of the candidate is an issue verb (e.g., *speculate, hypothesize, argue, debate*), whereas IHEAD checks whether the candidate head in the dependency tree is an issue word (e.g., *controversy, uncertain, unknown*). The general abstract-anaphora resolution features do not make use of the semantic properties of the word *issue*. Some of these features are derived empirically from the training data (e.g., ST, L, D). The EL feature is borrowed from Müller (2008) and encodes the embedding level of the candidate within the candidate sentence. The MC feature tries to capture the idea of the THIS-NPs hypothesis (Gundel et al., 1993; Poesio and Modjeska, 2002) that the antecedents of *this*-NP anaphors are not the center of the previous utterance. The general abstract-anaphora features in the SR feature class capture the semantic role of the candidate in the candidate sentence. We used the Illinois Semantic Role Labeler<sup>9</sup> for SR features. The general abstract-anaphora features also contain a few lexical features (e.g., M, SC). But these features are independent of the semantic properties of the word *issue*. The general abstract-anaphora resolution features also contain dependency-tree features, lexical-

<sup>8</sup>The threshold 5 was empirically derived. Antecedents in our training data had on average 17 words.

<sup>9</sup>[http://cogcomp.cs.illinois.edu/page/software\\_view/SRL](http://cogcomp.cs.illinois.edu/page/software_view/SRL)

<b>ISSUE PATTERN (IP)</b>	
ISWHETHER	1 iff the candidate follows the pattern SBAR → (IN whether) (S ...)
ISTHAT	1 iff the candidate follows the pattern SBAR → (IN that) (S ...)
ISIF	1 iff the candidate follows the pattern SBAR → (IN iff) (S ...)
ISQUESTION	1 iff the candidate node is SBARQ or SQ
<b>SYNTACTIC TYPE (ST)</b>	
ISNP	1 iff the candidate node is of type NP
ISS	1 iff the candidate node is a sentence node
ISSBAR	1 iff the candidate node is an SBAR node
ISSQ	1 iff the candidate node is an SQ or SBARQ node
MIXED	1 iff the candidate node is of type <i>mixed</i>
<b>EMBEDDING LEVEL (EL) (Müller, 2008)</b>	
TLEMBEDDING	level of embedding of the given candidate in its top clause (the root node of the syntactic tree)
IEMBEDDING	level of embedding of the given candidate in its immediate clause (the closest parent of type S or SBAR)
<b>MAIN CLAUSE (MC)</b>	
MCLAUSE	1 iff the candidate is in the main clause
<b>DISTANCE (D)</b>	
ISSAME	1 iff the candidate is in the same sentence as anaphor
SADJA	1 iff the candidate is in the adjacent sentence
ISREM	1 iff the candidate occurs 2 or more sentences before the anaphor
POSITION	1 iff the antecedent occurs before anaphor
<b>SEMANTIC ROLE LABELLING (SR)</b>	
IVERB	1 iff the governing verb of the given candidate is an <i>issue</i> verb
ISA0	1 iff the candidate is the <i>agent</i> of the governing verb
ISA1	1 iff the candidate is the <i>patient</i> of the governing verb
ISA2	1 iff the candidate is the <i>instrument</i> of the governing verb
ISAM	1 iff the candidate plays the role of <i>modification</i>
ISNOR	1 iff the candidate plays no well-defined semantic role in the sentence
<b>DEPENDENCY TREE (DT)</b>	
IHEAD	1 iff the candidate head in the dependency tree is an issue word (e.g., <i>controversial, unknown</i> )
ISSUBJ	1 iff the dependency relation of the candidate to its head is of type <i>nominal, controlling</i> or <i>clausal subject</i>
ISOBJ	1 iff the dependency relation of the candidate to its head is of type <i>direct object</i> or <i>preposition obj</i>
ISDEP	1 iff the dependency relation of the candidate to its head is of type <i>dependent</i>
ISROOT	1 iff the candidate is the root of the dependency tree
ISPREP	1 iff the dependency relation of the candidate to its head is of type <i>preposition</i>
ISCONT	1 iff the dependency relation of the candidate to its head is of type <i>continuation</i>
ISCOMP	1 iff the dependency relation of the candidate to its head is of type <i>clausal</i> or <i>adjectival complement</i>
ISSENT	1 iff candidate's head is the root node
<b>PRESENCE OF MODALS (M)</b>	
MODAL	1 iff the given candidate contains a modal verb
<b>PRESENCE OF SUBORDINATING CONJUNCTION (SC)</b>	
ISCONT	1 iff the candidate starts with a contrastive subordinating conjunction (e.g., <i>however, but, yet</i> )
ISCAUSE	1 iff the candidate starts with a causal subordinating conjunction (e.g., <i>because, as, since</i> )
ISCOND	1 iff the candidate starts with a conditional subordinating conjunction (e.g., <i>if, that, whether or not</i> )
<b>LEXICAL OVERLAP (LO)</b>	
TOS	normalized ratio of the overlapping words in candidate and the title of the article
AOS	normalized ratio of the overlapping words in candidate and the anaphor sentence
DWS	proportion of domain-specific words in the candidate
<b>CONTEXT (C)</b>	
ISPPREP	1 iff the preceding word of the candidate is a preposition
ISFPREP	1 iff the following word of the candidate is a preposition
ISPPUNCT	1 iff the preceding word of the candidate is a punctuation
ISFPUNCT	1 iff the following word of the candidate is a punctuation
<b>LENGTH (L)</b>	
LEN	length of the candidate in words

---

Table 2: Feature sets for *this-issue* resolution. All features are extracted automatically.

overlap features, and context features.

### 4.3 Candidate Ranking Model

Given an anaphor  $a_i$  and a set of candidate antecedents  $C = \{C_1, C_2, \dots, C_k\}$ , the problem of anaphora resolution is to choose the best candidate antecedent for  $a_i$ . We follow the candidate-ranking model proposed by Denis and Baldrige (2008). The advantage of the candidate-ranking model over the mention-pair model is that it overcomes the strong independence assumption made in mention-pair models and evaluates how good a candidate is relative to *all* other candidates.

We train our model as follows. If the anaphor is a *this-issue* anaphor, the set  $C$  is extracted using the candidate extraction algorithm from Section 4.1. Then a corresponding set of feature vectors,  $C_f = \{C_{f1}, C_{f2}, \dots, C_{fk}\}$ , is created using the features in Table 2. The training instances are created as described by Soon et al. (2001). Note that the instance creation is simpler than for general coreference resolution because of the absence of anaphoric chains in our data. For every anaphor  $a_i$  and eligible candidates  $C_f = \{C_{f1}, C_{f2}, \dots, C_{fk}\}$ , we create training examples  $(a_i, C_{fi}, label), \forall C_{fi} \in C_f$ . The label is 1 if  $C_i$  is the true antecedent of the anaphor  $a_i$ , otherwise the label is  $-1$ . The examples with label 1 get the rank of 1, while other examples get the rank of 2. We use SVM<sup>rank</sup> (Joachims, 2002) for training the candidate-ranking model. During testing, the trained model is used to rank the candidates of each test instance of *this-issue* anaphor.

## 5 Evaluation

In this section we present the evaluation of each component of our resolution system.

### 5.1 Evaluation of Candidate Extraction

The set of candidate antecedents extracted by the method from Section 4.1 contained the correct antecedent 92% of the time. Each anaphor had, on average, 23.80 candidates, of which only 5.19 candidates were nominal type. The accuracy dropped to 84% when we did not extract mixed type candidates. The error analysis of the 8% of the instances where we failed to extract the correct antecedent revealed that most of these errors were parsing errors

which could not be corrected by our candidate extraction method.<sup>10</sup> In these cases, the parts of the antecedent had been placed in completely different branches of the parse tree. For example, in (5), the correct antecedent is a combination of the NP from the  $S \rightarrow VP \rightarrow NP \rightarrow PP \rightarrow \mathbf{NP}$  branch and the PP from  $S \rightarrow VP \rightarrow \mathbf{PP}$  branch. In such a case, concatenating sister constituents does not help.

- (5) The data from this pilot study (VP (VBP provide) (NP (NP no evidence) (PP (IN for) (NP **a difference in hemodynamic effects between pulse HVHF and CPFA**))) (PP **in patients with septic shock already receiving CRRT**)). A larger sample size is needed to adequately explore **this issue**.

### 5.2 Evaluation of *this-issue* Resolution

We propose two metrics for abstract anaphora evaluation. The simplest metric is the percentage of antecedents on which the system and the annotated gold data agree. We denote this metric as *EXACT-M* (Exact Match) and compute it as the ratio of number of correctly identified antecedents to the total number of marked antecedents. This metric is a good indicator of a system's performance; however, it is a rather strict evaluation because, as we noted in section 1, issues generally have no precise boundaries in the text. So we propose another metric called RLL, which is similar to the ROUGE-L metric (Lin, 2004) used for the evaluation of automatic summarization. Let the marked antecedents of the gold corpus for  $k$  anaphor instances be  $G = \langle g_1, g_2, \dots, g_k \rangle$  and the system-annotated antecedents be  $A = \langle a_1, a_2, \dots, a_k \rangle$ . Let the number of words in  $G$  and  $A$  be  $m$  and  $n$  respectively. Let  $LCS(g_i, a_i)$  be the number of words in the longest common subsequence of  $g_i$  and  $a_i$ . Then the precision ( $P_{RLL}$ ) and recall ( $R_{RLL}$ ) over the whole data set are computed as shown in equations (2) and (3).  $P_{RLL}$  is the total number of word overlaps between the gold and system-annotated antecedents normalized by the number of words in system-annotated antecedents and  $R_{RLL}$  is the total number of such word overlaps normalized by the number of words in the gold antecedents. If the system picks too much text for antecedents,  $R_{RLL}$  is high but  $P_{RLL}$  is low. The F-score,

<sup>10</sup>Extracting candidate constituents from the dependency trees did not add any new candidates to the set of candidates.

		5-fold Cross-Validation				Test			
		$P_{RLL}$	$R_{RLL}$	$F_{RLL}$	EX-M	$P_{RLL}$	$R_{RLL}$	$F_{RLL}$	EX-M

Table 3: *this-issue* resolution results with SVM<sup>rank</sup>. All means evaluation using all features. Issue-specific features = {IP, IVERB, IHEAD}. EX-M is EXACT-M.

$F_{RLL}$ , combines these two scores.

$$P_{RLL} = \frac{1}{n} \sum_{i=1}^k LCS(g_i, a_i) \quad (2)$$

$$R_{RLL} = \frac{1}{m} \sum_{i=1}^k LCS(g_i, a_i) \quad (3)$$

$$F_{RLL} = \frac{2 \times P_{RLL} \times R_{RLL}}{P_{RLL} + R_{RLL}} \quad (4)$$

The lower bound of  $F_{RLL}$  is 0, where no true antecedent has any common substring with the predicted antecedents and the upper bound is 1, where all the predicted and true antecedents are exactly the same. In our results we represent these scores in terms of percentage.

There are no implemented systems that resolve *issue* anaphora or abstract anaphora signalled by label nouns in arbitrary text to use as a comparison. So we compare our results against two baselines: *adjacent sentence* and *random*. The adjacent sentence baseline chooses the previous sentence as the correct antecedent. This is a high baseline because in our data 84.1% of the antecedents lie within the adjacent sentence. The random baseline chooses a candidate drawn from a uniform random distribution over the set of candidates.<sup>11</sup>

<sup>11</sup>Note that our  $F_{RLL}$  scores for both baselines are rather high because candidates often have considerable overlap with one another; hence a wrong choice may still have a high  $F_{RLL}$  score.

We carried out two sets of systematic experiments in which we considered all combinations of our twelve feature classes. The first set consists of 5-fold cross-validation experiments on our training data. The second set evaluates how well the model built on the training data works on the unseen test data.

Table 3 gives results of our system. The first two rows are the baseline results. Rows 3 to 8 give results for some of the best performing feature sets. All systems based on our features beat both baselines on F-scores and EXACT-M. The empirically derived feature sets IP (issue patterns) and D (distance) appeared in almost all best feature set combinations. Removing D resulted in a 6 percentage points drop in  $F_{RLL}$  and a 4 percentage points drop in EXACT-M scores. Surprisingly, feature set ST (syntactic type) was not included in most of the best performing set of feature sets. The combination of syntactic and semantic feature sets {IP, D, EL, MC, L, SR, DT} gave the best  $F_{RLL}$  and EXACT-M scores for the cross-validation experiments. For the test-data experiments, the combination of semantic and lexical features {D, C, LO, L, SC, SR, DT} gave the best  $F_{RLL}$  results, whereas syntactic, discourse, and semantic features {IP, D, C, EL, L, SC, SR, DT} gave the best EXACT-M results. Overall, row 3 of the table gives reasonable results for both cross-validation and test-data experiments with no statistically significant difference to the corresponding best

EXACT-M scores in rows 6 and 5 respectively.<sup>12</sup>

To pinpoint the errors made by our system, we carried out three experiments. In the first experiment, we examined the contribution of *issue*-specific features versus non-*issue* features (rows 9 and 10). Interestingly, when we used only non-*issue* features, the performance dropped only slightly. The  $F_{RLL}$  results from using only *issue*-specific features were below baseline, suggesting that the more general features associated with abstract anaphora play a crucial role in resolving *this-issue* anaphora.

In the second experiment, we determined the error caused by the candidate extractor component of our system. Row 12 of the table gives the result when an oracle candidate extractor was used to add the correct antecedent in the set of candidates whenever our candidate extractor failed. This did not affect cross-validation results by much because of the rarity of such instances. However, in the test-data experiment, the EXACT-M improvements that resulted were statistically significant. This shows that our resolution algorithm was able to identify antecedents that were arbitrary spans of text.

In the last experiment, we examined the effect of the reduction of the candidate search space. We assumed an oracle candidate sentence extractor (Row 13) which knows the exact candidate sentence in which the antecedent lies. We can see that both RLL and EXACT-M scores markedly improved in this setting. In response to these results, we trained a decision-tree classifier to identify the correct antecedent sentence with simple location and length features and achieved 95% accuracy in identifying the correct candidate sentence.

## 6 Discussion and Conclusions

We have demonstrated the possibility of resolving complex abstract anaphora, namely, *this-issue* anaphora having arbitrary antecedents. The work takes the annotation work of Botley (2006) and Dipper and Zinsmeister (2011) to the next level by resolving *this-issue* anaphora automatically. We proposed a set of 43 automatically extracted features that can be used for resolving abstract anaphora.

<sup>12</sup>We performed a simple one-tailed,  $k$ -fold cross-validated paired  $t$ -test at significance level  $p = 0.05$  to determine whether the difference between the EXACT-M scores of two feature classes is statistically significant.

Our results show that general abstract-anaphora resolution features (i.e., other than *issue*-specific features) play a crucial role in resolving *this-issue* anaphora. This is encouraging, as it suggests that the approach could be generalized for other NPs — especially NPs having similar semantic constraints such as *this problem*, *this decision*, and *this conflict*.

The results also show that reduction of search space markedly improves the resolution performance, suggesting that a two-stage process that first identifies the broad region of the antecedent and then pinpoints the exact antecedent might work better than the current single-stage approach. The rationale behind this two-stage process is twofold. First, the search space of abstract anaphora is large and noisy compared to nominal anaphora.<sup>13</sup> And second, it is possible to reduce the search space and accurately identify the broad region of the antecedents using simple features such as the location of the anaphor in the anaphor sentence (e.g., if the anaphor occurs at the beginning of the sentence, the antecedent is most likely present in the previous sentence).

We chose scientific articles over general text because in the former domain the actual referents are seldom discourse deictic (i.e., not present in the text). In the news domain, for instance, which we have also examined and are presently annotating, a large percentage of *this-issue* antecedents lie outside the text. For example, newspaper articles often quote sentences of others who talk about the issues in their own world, as shown in example (6).

- (6) As surprising and encouraging to organizers of the movement are the Wall Street names added to their roster. Prominent among them is Paul Singer, a hedge fund manager who is straight and chairman of the conservative Manhattan Institute. He has donated more than \$8 million to various same-sex marriage efforts, in states including California, Maine, New Hampshire, New Jersey, New York and Oregon, much of it since 2007.

“It’s become something that gradually peo-

<sup>13</sup>If we consider all well-defined syntactic constituents of a sentence as issue candidates, in our data, a sentence has on average 43.61 candidates. Combinations of several well-defined syntactic constituents only add to this number. Hence if we consider the antecedent candidates from the previous 2 or 3 sentences, the search space can become quite large and noisy.

ple like myself weren't afraid to fund, weren't afraid to speak out on," Mr. Singer said in an interview. "I'm somebody who is philosophically very conservative, and on **this issue** I thought that this really was important on the basis of liberty and actual family stability."

In such a case, the antecedent of *this issue* is not always in the text of the newspaper article itself, but must be inferred from the context of the quotation and the world of the speaker quoted. That said, we do not use any domain-specific information in our *this-issue* resolution model. Our features are solely based on distance, syntactic structure, and semantic and lexical properties of the candidate antecedents which could be extracted for text in any domain.

*Issue* anaphora can also be signalled by demonstratives other than *this*. However, for our initial study, we chose *this issue* for two reasons. First, in our corpus as well as in other general corpora such as the New York Times corpus, *issue* occurs much more frequently with *this* than other demonstratives. Second, we did not want to increase the complexity of the problem by including the plural *issues*.

Our approach needs further development to make it useful. Our broad goal is to resolve abstract anaphora signalled by label nouns in all kinds of text. At present, the major obstacle is that there is very little annotated data available that could be used to train an abstract anaphora resolution system. And the understanding of abstract anaphora itself is still at an early stage; it would be premature to think about unsupervised approaches. In this work, we studied the narrow problem of resolution of *this-issue* anaphora in the medical domain to get a good grasp of the general abstract-anaphora resolution problem.

A number of extensions are planned for this work. First, we will extend the work to resolve other abstract anaphors (e.g., *this decision*, *this problem*). Second, we will experiment with a two-stage resolution approach. Third, we would like to explore the effect of including serious discourse structure features in our model. (The feature sets SC and C encode only shallow discourse information.) Finally, during annotation, we noted a number of *issue* patterns (e.g., *An open question is X, X is under debate*); a possible extension is extracting issues and problems from text using these patterns as seed patterns.

## 7 Acknowledgements

We thank Dr. Brian Budgell from the Canadian Memorial Chiropractic College for annotating our data and for helpful discussions. We also thank the anonymous reviewers for their detailed and constructive comments. This research was financially supported by the Natural Sciences and Engineering Research Council of Canada and by the University of Toronto.

# Entity based Q&A retrieval

Amit Singh

IBM Research

Bangalore, India

amising3@in.ibm.com

## Abstract

Bridging the lexical gap between the user's question and the question-answer pairs in the Q&A archives has been a major challenge for Q&A retrieval. State-of-the-art approaches address this issue by implicitly expanding the queries with additional words using statistical translation models. While useful, the effectiveness of these models is highly dependant on the availability of quality corpus in the absence of which they are troubled by noise issues. Moreover these models perform word based expansion in a context agnostic manner resulting in translation that might be mixed and fairly general. This results in degraded retrieval performance. In this work we address the above issues by extending the lexical word based translation model to incorporate semantic concepts (entities). We explore strategies to learn the translation probabilities between words and the concepts using the Q&A archives and a popular entity catalog. Experiments conducted on a large scale real data show that the proposed techniques are promising.

## 1 Introduction

Over the past few years community-based question answering (CQA) portals like Naver, Yahoo! Answers, Baidu Zhidao and WikiAnswers have attracted great attention from both academia and industry (Adamic et al., 2008; Singh and Visweswariah, 2011). These portals foster collaborative creation of content by allowing the users to both submit questions to be answered and answer

questions asked by other users. These portals aim to provide highly focused access to this information by directly returning pertinent question and answer (Q&A) pairs to the users questions, instead of a long list of ranked URLs. This is in noted contrast to the usual search paradigm, where the question is used to search the database of potential answers, in this case the question is used to search the database of previous questions, which in turn are associated with answers. This involves addressing the word mismatch problem between the users question and the question-answer pairs in the archive. This is the major challenge for Q&A retrieval.

Researchers have proposed the use of translation models (Berger and Lafferty, 1999; Jeon et al., 2005; Xue et al., 2008) to solve this problem. As a principled approach to capturing semantic word relations, statistical translation language models are built by using the IBM model 1 (Brown et al., 1993) and have been shown to outperform traditional document language models on Q&A retrieval task. The basic idea is to estimate the likelihood of translating a document<sup>1</sup> to a query by exploiting the dependencies that exists between query words and document words. For example the document containing the word *wheezing* may well answer the question containing the term *Asthma*. They learn the these dependencies (encoded as translation probabilities) between words using parallel mono-lingual corpora created from the Q&A pairs. While useful, the effectiveness of these models is highly dependant on the availability of quality corpus (Lee et al.,

<sup>1</sup>we will use (Q&A, document), (word, term) and (user query, question) interchangeably

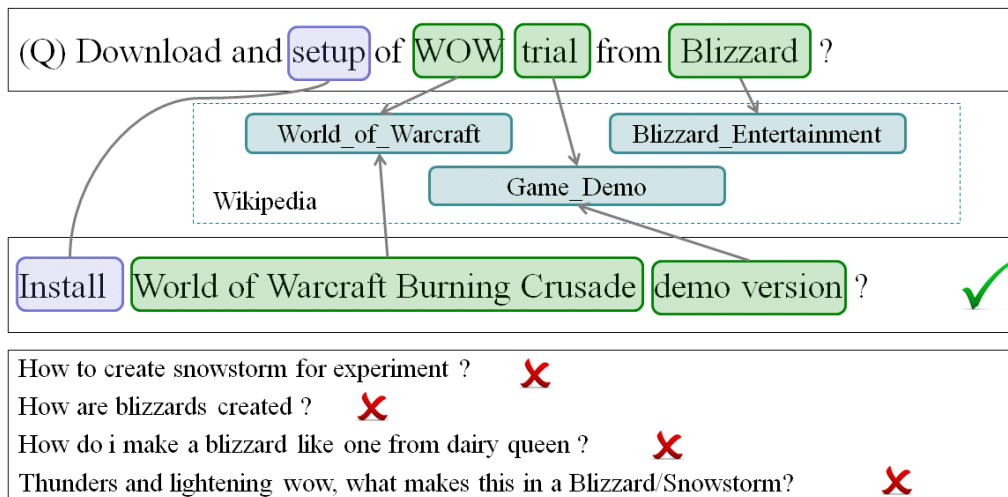

Figure 1: Need for entity based expansions

2008). Also these models only capture shallow semantics between words via the co-occurrence statistics, while some of the more explicit relationships between words and entities is freely available externally. Being context agnostic (Zhou et al., 2007) is another very common criticism hailed on translation models as it results in noisy and generic translations.

Example shown in Figure 1 captures these problems. Specifically, the word `Blizzard` can refer to an American game development company that develops `World of Warcraft` game or it could refer to a severe snowstorm. Expanding query without taking the gaming context established by the word `WOW` (acronym for `World of Warcraft`) into account would lead to topic drift. Also it would be difficult to learn relationships between `World of Warcraft Burning Crusade` and `Blizzard` from the Q&A corpus alone due to the sparsity of co-occurrence counts as these can be expressed in several lexical forms, some of which are multi word phrases.

In this paper we argue that solution to all the above problems lies in a unified model in which entities are a primary citizen. The guiding hypothesis being, an entity based representation provides a less ambiguous representation of the users question and provides for a more semantically accurate expansion if the relationship between entities and words can be estimated more reliably. Our main contributions are

1. We propose Entity based Translation Language

Model (ETLM) for Q&A retrieval that accommodates semantic information associated between entities and words. Being closely related to the general source-channel framework (Berger and Lafferty, 1999), the model enjoys its benefits, while mitigating some of its shortcomings. Specifically it provides for context aware expansions of the query by exploiting entity annotations on both, the document and the query side. Entity annotations also provide a means to handle the “many-to-one” (Moore, 2004) translation limitation in the IBM model, due to which each word in the target document can be generated by at most one word in the question<sup>2</sup>. For the same reasons, it also alleviates another related limitation by enabling translation between contiguous words across the query and documents (Moore, 2004).

2. We learn relationships between entities and terms by proposing new ways of organizing monolingual parallel corpus and simultaneously leveraging external resources like Wikipedia from which one can derive these relationships reliably. This helps alleviate the noise problem associated with learning translation models on Q&A archive described above. An important point to note is that, our technique has merits independent to the choice of the entity catalog. In this work we use

<sup>2</sup>entity mentions can be of more than unit word length

$D$	original Q&A collection
$E$	set of all entities in catalog
$d(e)$	description of entity $e$
$C$	$D$ annotated with $e \in E$
$q_{user}$	users question
$q$	$q_{user}$ annotated with $e \in E$
$t$	token span
$t_q, t_d$	token span in $q$ and $d$
$V$	word vocabulary

Table 1: Notation.

Wikipedia, as it is a popular choice due to its large and ever expanding coverage and its ability to keep up with world events on a timely basis.

3. We provide detailed evaluation of impact of modelling assumptions and model components on retrieval performance on a large scale real data from Yahoo Answers comprising  $\sim 5$  million Q&A pairs.

Rest of the paper is organized as follows: In the next section, we define ETLM and outline its details. This is followed by Section 3 which gives the details of entity annotators and its performance. Section 4 describes our experiments on the retrieval method used Q&A retrieval. In Section 5 we compare and contrast related literature. Finally, we conclude in Section 6.

## 2 Our Approach

**Problem Definition:** Let  $D = d_1, d_2, \dots, d_n$  denote the Q&A collection. Here  $d_i$  refers to the  $i$ -th Q&A data consisting of a question  $q_i$  and its answer  $a_i$ . Given the user question  $q_{user}$ , the task of Q&A retrieval is to rank  $d_i$  according to  $score(q_{user}, d_i)$ . Figure 2 outlines the approach to compute this score in the ETLM framework.

**Offline processing:** Using the entity catalog  $E$ , we learn the entity annotation models  $EA_{offline}$  and  $EA_{online}$  for annotation of entities in the Q&A corpus and the query respectively. Refer Section 3 for details. For each  $d_i \in D$ , we then annotate references to entities in Wikipedia using  $EA_{offline}$  re-

sulting in annotated Q&A corpus  $C$ . We then compute relationships between entities and words using  $C$  and  $E$ . These relationships are used to learn our ETLM model.

**Online processing:** At runtime, annotate the user query  $q_{user}$  with entities using  $EA_{online}$  to create an enriched question  $q$ . Issue this query over the annotated corpus  $C$  and rank the candidates as per the ETLM model described below.

### 2.1 ETLM Model

Let the annotated query  $q$  (and similarly annotated Q&A pair  $d$ ) be composed of sequence of token spans  $T_q$  (and  $T_d$ ). Each token span  $t_q$  (similarly  $t_d$ ) corresponds to sequence of contiguous words occurring in the running text. These  $t_q$ 's can correspond to entity mentions, phrases or words. Let  $e_q$  denote the tokens spans that are annotated and  $ne_q$  that are not ( $T_q = e_q \cup ne_q$ ). For example, in the query,  $\underbrace{\text{What}}_{ne_q} \underbrace{\text{is}}_{ne_q} \underbrace{\text{a}}_{ne_q} \underbrace{\text{Quadratic Formula}}_{e_q}?$ ,

token span Quadratic Formula is linked to an entity corresponding to Quadratic Equation<sup>3</sup>, while all other token spans are marked as  $ne_q$ .

For the sake of simplicity, in this work we do not identify phrases i.e.  $ne_q$  is always of unit word length<sup>4</sup>. In the ETLM framework, the similarity between a query  $q$  and a document  $d$  within a collection  $C$  is given by the probability

$$score(q, d) \sim P(q|d) = \prod_{\substack{t_q \in q \\ t_q = e_q \cup ne_q}} P(t_q|d)$$

$$P(t_q|d) = (1 - \lambda)P_{ml}(t_q|d) + \lambda P_{ml}(t_q|C)$$

$$P_{ml}(t_q|d) = \sum_{t_d \in d} T(t_q|t_d)P_{ml}(t_d|d) \quad (1)$$

Intuitively this indicates a generative process for creating  $q$  from  $d$ . Ideally both  $q$  and  $d$  are “only” composed of  $e$  i.e.  $\forall t_q \in q; t_q \in E_U$ , where  $E_U$  is the universal set of entities<sup>5</sup> (similarly for all  $t_d$ ). This is because when the document was created, each and every  $t_d \in d$  had a sense attached to it. however in reality, for various reasons, set of target entities are clearly a subset of  $E_U$  (for e.g.  $E$ : set of all entities

<sup>3</sup>[http://en.wikipedia.org/wiki/Quadratic\\_equation](http://en.wikipedia.org/wiki/Quadratic_equation)

<sup>4</sup>its not a restriction as the model is valid for  $ne_q$  consisting of more than one word.

<sup>5</sup>language for creating  $q$  and  $d$

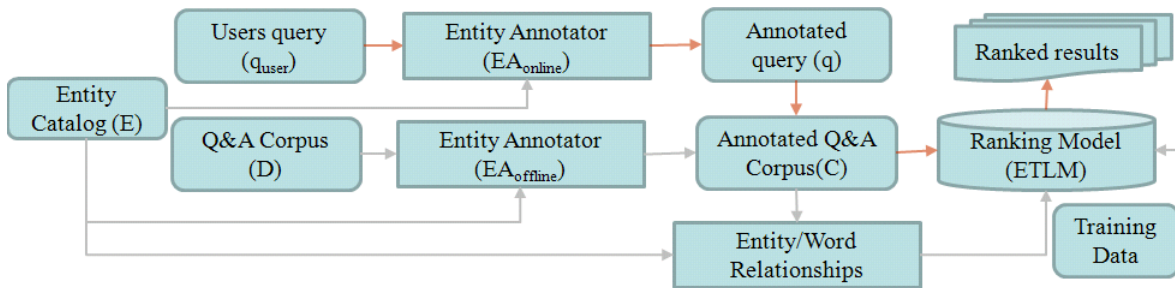

Figure 2: ETLM Architecture (gray and brown arrows indicate offline and online processes respectively)

in the catalog) also not all of them may be recognized by the annotation system.

$T(t_q|t_d)$  in Equation 1 denotes the probability that a token span  $t_q$  is the translation of token span  $t_d$ . This induces the desired query expansion effect. The key task is to estimate  $P_{ml}(t_q|C)$ ,  $T(t_q|t_d)$  and  $P_{ml}(t_d|d)$ ;  $t_q \in e_q \cup ne_q$  and  $t_d \in e_d \cup ne_d$

## 2.2 Estimating Model Parameters

We adopt 2 different approach for estimating  $T(t_q|t_d)$ , leading to 2 different configurations of ETLM system . As the name suggests,  $ETLM_{qa}$  is estimated from Q&A data ( $C$  and  $D$ ) while we leverage the entity catalog (in our case it is Wikipedia) for  $ETLM_{wiki}$ .

### 2.3 $ETLM_{qa}$ : Estimate from parallel corpus

Following (Xue et al., 2008) we pool the question and answers from  $D$  to create a master parallel corpus  $P = (q_1, a_1), \dots, (q_n, a_n) \cup (a_1, q_1), \dots, (a_n, q_n)$ . This is used for learning  $T(ne|ne')$ <sup>6</sup>. Similarly we create  $P^*$  from  $C$ . We then derive 2 different parallel corpora from  $P$  and  $P^*$  as follows

$P_{entity}$  We remove all non linked tokens  $ne$  from  $P^*$  thereby reducing it to parallel corpus over  $e$ . This is used for learning  $T(e|e')$  i.e. translation probabilities between two entities  $e$  and  $e'$  in  $E$ .

$P_{hybrid}$  This is hybrid of  $P_{entity}$  and  $P$  where in one part of Q&A pair consists on only  $ne$  while other consists of only  $e$ . This is used for learning  $T(ne|e)$  and  $T(e|ne)$ .

To handle entities  $e$ , we introduce special id's in the  $ne$  space. Thus our universal token span set is given

<sup>6</sup>subscript of  $q$  and  $d$  has been dropped as translation probability learnt agnostic to it, due to pooling.

by  $V \cup E$ . This is done so that  $T(t_q|t_d)$  is learnt from  $P$ ,  $P_{entity}$  and  $P_{hybrid}$ , w/o any modification to the corresponding translation algorithm (Brown et al., 1993). Lets call this approach  $ETLM_{qa'}$ .

We explored another intuitive approach  $ETLM_{qa}$ , to learn  $T(e|e')$ ,  $T(e|ne)$ ,  $T(ne|e)$  and  $T(ne|ne')$  directly by using only  $P^*$  as our parallel corpus. We do so by redistributing the probability mass i.e. when calculating  $T(e|e')$ , we redistribute probability mass spread over all the  $ne$  to  $e$  given by Equation 2 and 3. Similar process is followed for  $T(e|ne)$ ,  $T(ne|e)$  and  $T(ne|ne')$ .

$$S(e|e') = \frac{T(e|e')}{\sum_{t \in V} T(t|e')} \quad (2)$$

$$T(e|e') = \frac{S(e|e')}{\sum_{t \in E} T(t|e')} \quad (3)$$

Remaining model components are calculated using Equation 4 and 5. Here  $d$  refers to question part of the Q&A pair.

$$P_{ml}(t_q|C) = \frac{tf_{t_q,C} + 1}{\sum_{t' \in C} tf_{t',C} + |C|} \quad (4)$$

$$P_{ml}(t_q|d) = \frac{tf_{t_q,d}}{\sum_{t' \in d} tf_{t',d}} \quad (5)$$

### 2.4 $ETLM_{wiki}$ : Estimating from Wikipedia

Number of symmetric measures have been proposed (Medelyan et al., 2009) to measure semantic relationships between entities and words using Wikipedia. For our problem we need an asymmetric measure. We use co-citation information in Wikipedia to detect relatedness between entities ( $T(e|e')$ ) and co-occurrence counts to estimate

$T(ne|ne')$  as follows: .

$$T(e|e') = \frac{co(e, e')}{\sum_{e''} co(e'', e')} \quad (6)$$

$$T(ne|ne') = \frac{cf(ne, ne')}{\sum_{ne''} cf(ne'', ne')} \quad (7)$$

$$T(ne|e) = \frac{tf_{ne, D(e)} + 1}{|D(e)| + |V|} \quad (8)$$

$$T(e|ne) = \frac{tf_{ne, D(e)} + 1}{\sum_{e' \in E} tf_{ne, D(e')} + |E|} \quad (9)$$

Here  $d(e)$  represents the page corresponding to entity  $e$ .  $D(e)$  represents concatenation of  $d(e)$  and all context of size 5 surrounding anchor text in Wikipedia that link to  $e$ .  $cf(ne, ne')$  is the number context windows of fixed size containing both  $ne$  and  $ne'$  in Wikipedia. In our case, we set the window size at 10 (because this size turned out to be reasonable in our pilot experiments).  $tf_{t, d(e)}$  is the frequency of  $t$  in  $d(e)$ ;  $co(e, e')$  indicates number of entities in Wikipedia that have a hyperlink to both  $e$  and  $e'$ . As links from pages with a small number of outgoing links are generally considered to be more valuable than links from pages with a high outgoing link degree, we tried with weighted version of 6 where the co-citations are weighted by the outdegree of Wikipedia page corresponding to entity  $s$  that link to  $e$  and  $e'$ . Lets denote the weighted version by  $ETLM_{wiki}$  and unweighted version by  $ETLM_{wiki'}$ .  $P_{ml}(t_q|C)$  and  $P_{ml}(t_q|d)$  are estimated as per Equation 4 and 5 respectively.

## 2.5 Self translation probability

To make sure self translation probability is not underestimated i.e.  $T(t|t) \geq T(t'|t)$  always holds true, we introduce new parameter  $\gamma$  as  $T(t|t') = \gamma + (1 - \gamma)T(t|t')$ ;  $\gamma = 0$  when  $t \neq t'$  and  $\gamma > 0.5$  otherwise.

## 2.6 $ETLM_{combo}$ : Combining $ETLM_{qa}$ and $ETLM_{wiki}$

Often, combining language models yields better results than any of the individual language models themselves. Linear interpolation is often the technique of choice in language modelling for combining models to exploit complementary features of the component models. It involves taking a weighted

sum of the probabilities given by the component language models. An advantage of the linear interpolation is that it is simple and fast to calculate. If the inputs are probability estimates, also the output is a probability estimate. The mixture translation model  $T_{combo}(e|e')$  over  $M$  component models is given by Equation 10.

$$T_{combo}(t|t') = \sum_{j=1}^M \alpha_j T_j(t|t') \quad (10)$$

$$t \in E \cup V; \quad \sum_{j=1}^M \alpha_j = 1; \quad \alpha_j \geq 0$$

One can immediately notice that  $T_{combo}(t|t')$  has one global weight for each of the  $M$  component models which might not be ideal. With access to large training data one could employ more powerful context dependent interpolation techniques (Liu et al., 2008). In our case we have 2 components  $T_{qa}$  and  $T_{wiki}$  and four classes for each;  $\alpha_{wiki}^{(e, e')\gamma}$ ,  $\alpha_{wiki}^{(e, ne)}$ ,  $\alpha_{wiki}^{(ne, ne')}$  and  $\alpha_{wiki}^{(ne, e)}$ , one corresponding to each class of  $T(t|t')$ . respectively.

## 3 Entity Annotation

In this section we describe our entity annotation system. Recently there has been lot of work addressing the problem of annotating text with links to Wikipedia entities (Mihalcea and Csomai, 2007; Bunescu and Pasca, 2006; Milne and Witten, 2008; Kulkarni et al., 2009; Ratinov et al., 2011; Ferragina and Scaiella, 2010). We adopt a similar approach, wherein we first find the best disambiguation (BESTDISAMBIGUATION) for a given mention and then decide to prune it (PRUNE), via the dummy mapping NA (similar to “no assignment” (Kulkarni et al., 2009)).

### 3.1 BESTDISAMBIGUATION

As defined earlier,  $e \in E$  represent an entity corresponding to URN of a Wikipedia article. Let  $E_m = \{e_{m,1}, e_{m,2}, \dots, e_{m,|E_m|}\}$   $e_{m,i} \in E$  represent the set of possible disambiguations for a mention  $m$  ( $m$  is an index over all mentions in the corpus). Given a mention  $m$ , task is to find best disambiguation  $e$  from Wikipedia. Without loss of gener-

$$\gamma \alpha_{qa}^{(e, e')} = 1 - \alpha_{wiki}^{(e, e')}$$

ality, we consider  $e_{m,*} \in E_m$  as the correct answer. Let  $\phi(m, e_{m,j})$  represent the mapping onto features between an entity mention  $m$  and the Wikipedia entity  $e_{m,j}$  and  $\vec{w}$  be the corresponding weight vector and  $D(e_{m,j}) = \vec{w} \phi(m, e_{m,j})$  represent the disambiguation score. The task is to learn  $\vec{w}$  such that  $\operatorname{argmax}_{e_{m,j}} D(e_{m,j})$  gives the best disambiguation for the mention  $m$ .

We pose this as a ranking problem and solve it using max-margin technique (Joachims, 2002; Joachims, 2006) as follows

$$\begin{aligned} & \underset{\vec{w}, \xi}{\text{minimize}} && \frac{1}{2} \vec{w} \cdot \vec{w} + C \sum \xi_{i,j} \\ & \text{subject to} && \\ & && \forall m, \forall e_{m,j} \in E_m - e_{m,*} : \\ & && \vec{w} \phi(m, e_{m,*}) > \vec{w} \phi(m, e_{m,j}) + \xi_{i,j} \\ & && \forall i, \forall j : \xi_{i,j} \geq 0 \end{aligned} \quad (11)$$

where  $\sum \xi_{i,j}$  is the total training error that upper bounds the number of pair preferences violations. This is controlled by adjusting the parameter  $C$ . Note that Equation 11 means pairwise comparison between the correct disambiguation  $e_{m,*}$  and other disambiguation candidates  $e_{m,j}$  such that  $j \neq *$  index corresponding to  $*$ .

### 3.2 PRUNE

The disambiguation phase produces one candidate disambiguation per mention. To discard any unmeaningful annotations a simple strategy similar to LOCAL (Kulkarni et al., 2009) is followed where the  $D(e_{m,*})$  is compared against a predefined threshold  $\rho_{na}$ , so that if  $D(e_{m,*}) < \rho_{na}$  then that annotation for mention  $m$  is discarded by linking  $m$  to NA. The parameter  $\rho_{na}$  allows the algorithm to back-off when short of evidence.

### 3.3 FEATUREMAP $\phi(m, e_{m,j})$

**Sense probability prior (SP):** It represents the prior probability that a mention name  $s$  points to a specific entity in Wikipedia. For example, without any other information, mention name “tree” will more likely refer to the entity woody plant<sup>8</sup>, rather than the less

<sup>8</sup>en.wikipedia.org/wiki/Tree

popular notion related to graphs<sup>9</sup>.

**Entity Probability prior (EP):** It captures the popularity knowledge as a distribution of entities, i.e., the  $EP(e_i)$  should be larger than  $EP(e_j)$  if  $e_i$  is more popular than  $e_j$ . This score is independent of the mention name.

**Context specific features:** It captures the textual similarity between weighted word vectors corresponding to the context of the mention (window around the mention) and textual description associated with the entity (Wikipedia page).

Let  $EA_{online}$  and  $EA_{offline}$  represent configurations for annotating user question and corpus respectively. For  $EA_{online}$ , user question represents the document from which context specific features are computed. For  $EA_{offline}$ , question and the answer(best) is concatenated to represents the document. Based on the “one sense per discourse” assumption, one additional heuristic is used in  $EA_{offline}$  where, for the same Q&A pair, if same name mention is repeated multiple times across the question and the answer then one with the maximum  $D(e_{m,*}) > \rho_{na}$  is annotated for all instances.

### 3.4 Annotation Experiments

We used 2010 version of Wikipedia as our knowledge base. It contains more than 2.5 million entities. Annotations were done by volunteers fluent in english. Volunteers were told to be as exhaustive as possible and tag all possible name mentions, even if to mark them as “NA”. Inter-annotator agreement=92.1%; Kappa coefficient = 0.72. As our corpus, we collected 8.3K manual annotations spanning 1315 Q&A pairs. 2.8K of the annotations were assigned to NA. 2.1K annotations (out of 8.3K) were made in the question of which 551 were assigned to NA. We use Precision, Recall and  $F_1$  score micro-averaged across documents as the evaluation measures. We do a linear scan of data to identify entity mentions by first tokenizing and then identifying token sequences that maximally match an entity ID in the entity name dictionary (constructed using Wikipedia anchor text, redirect pages). Figure 3 outlines the performance of  $EA_{offline}$  and  $EA_{online}$ . We measured  $EA_{offline}$  in 3 test data configurations; (1)  $EA_{offline}$ : measured over entire

<sup>9</sup>en.wikipedia.org/wiki/Tree\_(data\_structure)

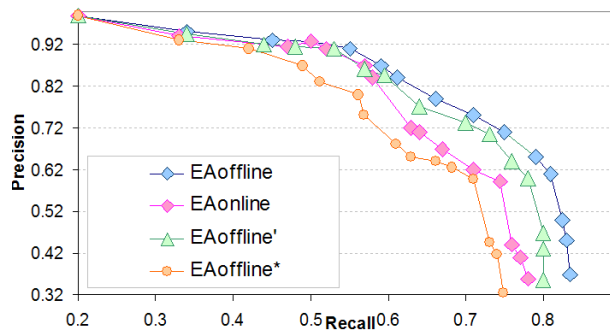

Figure 3: Precision v/s Recall

annotation set; 2)  $EA_{offline'}$  is measured only on annotations made in question. this is done to compare it with  $EA_{online}$ ; 3)  $EA_{offline^*}$  is similar to (2), only difference is that for (2) entire Q&A pair is the context, while here only question part is the context. This is done to check if separate annotators are required for online and offline phase. As seen in Figure 3, this indeed is necessary as  $EA_{offline^*}$  performs worse than  $EA_{online}$ . Closer look at the feature weights revealed that in  $EA_{offline}$  context specific features have much more weightage when compared to its weight in  $EA_{online}$ , on the contrary  $EA_{online}$  weighs SP significantly higher.

## 4 Evaluation

We now describe the empirical evaluation where we compare our techniques against the baseline techniques. We use several standard measures (R-Precision, MAP, MRR, Precision@k) in evaluation. We first describe the dataset used followed by describing an exhaustive set of results across techniques and performance measures.

### 4.1 Dataset

We crawled a dataset of  $\sim 5$  million questions and answers from Yahoo! Answers spanning all the leaf level categories. Tokenization and stop word removal were the only preprocessing steps performed. We have used a stoplist<sup>10</sup> having a vocabulary of 429 common words to remove the stopwords.

In our retrieval experiments we used 339 queries (average length 5.6 words). We employed pooling technique used in the TREC conference series.

<sup>10</sup><http://truereader.com/manuals/onix/stopwords1.html>

We pooled the top 25 Q&A pairs from retrieval results generated by varying the retrieval algorithms and the search field. Relevance judgments were marked by human annotators without disclosing the identity of method used for retrieval. The annotators were asked to label candidate as “relevant” or “irrelevant” based on semantic similarity with the query. Answer quality/correctness was not a criteria. In case of disagreement between two volunteers, authors made the final judgment. Inter-annotator agreement was 87.9% and Kappa coefficient = 0.68. Over all we had collected more than 12K relevance judgements corresponding to these queries, of which  $>2.3K$  were marked as relevant.

### 4.2 Baselines

To evaluate the effectiveness of our models we compared them against the following baselines

**Traditional models:** VSM (Zobel and Moffat, 2006) and OKAPI BM25 (Robertson et al., 1996) ( $k_1$ ,  $b$ , and  $k_3$  are parameters that are set to 1.2, 0.75 and  $\infty$  respectively).

**Translation based language models:** TLM (Jeon et al., 2005), TransLM (using answers) (Xue et al., 2008) and CTM (Lee et al., 2008).

For our experiments we used a set of 50 queries to select the model parameters. Translation based language model use 2 parameters; smoothing parameter  $\lambda$  in the Language Model and  $\beta$  to control the self-translation impact in the TransLM. Final values of parameters used in our experiments were  $\lambda = 0.2$  (Zhai and Lafferty, 2004) and  $\beta = 0.75$  (Xue et al., 2008). For CTM, we used *tf-idf* based weighing scheme (Lee et al., 2008) to remove words from the (Q||A) corpus  $P$ . Word elimination threshold of 20% was selected based on the above 50 queries. Final values of ETLM parameters used in our experiments were  $\lambda = 0.18$  and  $\gamma = 0.65$ .

### 4.3 Result Analysis

Table 2 presents the performance of the various techniques. Under each measure, we highlight the best performing technique. Performance of all the translation based models is better than VSM and OKAPI thereby confirming the importance of addressing the lexical gap. Using high confidence annotations for

	MAP	%chg	MRR	%chg	R-Prec	%chg	Prec@5	%chg	Prec@10	%chg
VSM	0.221		0.421		0.21		0.202		0.15	
OKAPI	0.298		0.532		0.271		0.264		0.214	
TLM	0.337		0.583		0.318		0.297		0.239	
TransLM	0.352		0.612		0.347		0.332		0.261	
CTM	0.361		0.641		0.351		0.341		0.279	
ETLM <sub>qa</sub>	0.390 <sup>†</sup>	8.03	0.699 <sup>†</sup>	9.05	0.379 <sup>†</sup>	7.98	0.367 <sup>†</sup>	7.62	0.302 <sup>†</sup>	8.24
ETLM <sub>wiki</sub>	0.413 <sup>†</sup>	14.40	0.719 <sup>†</sup>	12.17	0.399 <sup>†</sup>	13.68	0.391 <sup>†</sup>	14.66	0.323 <sup>†</sup>	15.77
ETLM <sub>combo</sub>	<b>0.427<sup>†</sup></b>	18.28	<b>0.726<sup>†</sup></b>	13.26	<b>0.413<sup>†</sup></b>	17.66	<b>0.407<sup>†</sup></b>	19.35	<b>0.331<sup>†</sup></b>	18.64

Table 2: Comparisons of retrieval models. † indicate a statistically significant improvement over the CTM using paired t-test with p-value < 0.05. %chg indicates change over CTM as it is the most competitive baseline

query expansion in ETLM, leads to an improved performance as compared to the all the baseline methods that do not consider this signal. This is validated by the fact that ETLM<sub>qa</sub> and ETLM<sub>wiki</sub> can achieve statistically significant improvements in terms of all the measures. The reason for this improvement is the context sensitive computation of  $T(t|t')$  leading to reduced spurious expansions and improved top expansions, this is made possible because of entity disambiguation. This computation in baselines happens on word by word basis without exploiting contextual information. ETLM<sub>qa</sub> performs worse than ETLM<sub>wiki</sub>. On close inspection of failure cases and translation probability tables we found that  $T(e|e')$  for ETLM<sub>qa</sub> was much worse than ETLM<sub>wiki</sub>. This is because for getting good estimates of  $T(e|e')$ , we need enough instances where both  $e$  and  $e'$  need to be correctly annotated in the same Q&A pair. Failure in this leads to sparse counts thereby reducing the gap in  $T(e|e')$  scores for related and unrelated  $e$ . Figure 4 shows the impact of choices made for learning the translation probabilities  $T(t|t')$ . We found that ETLM<sub>wiki</sub> performs slightly better than ETLM<sub>wiki'</sub>, indicating the utility of weighted co-citation measure for computing  $T(e|e')$ . We believe that embedding other measures that are better in capturing relationships from Wikipedia, should improve the performance. Similarly ETLM<sub>qa</sub> also performs better than ETLM<sub>qa'</sub>. This is because for creating  $P_{entity}$  all  $ne$  are removed. This leads to count sparsity problem dis-

Figure 4: Performance of ETLM configurations

cussed above, but slightly worse. Due to absence of  $ne$ , in ETLM<sub>qa'</sub>  $e'$  in  $d$  are thought to be being generated “only” from  $e$  in  $q$ . On the contrary in ETLM<sub>qa</sub>,  $e'$  had an option of mapping to  $ne$  in  $q$ . An interesting observation is that while the performances of different configurations vary, all of them perform better than CTM which is the best baseline.

#### 4.4 Impact of Annotations on retrieval

Since entities are central in our model, impact of entity annotation on  $q_{user}$  is one of the most important aspect to be studied. Figure 5 shows the plot of retrieval measures obtained by varying  $\rho_{na}$  in EA<sub>online</sub>. CTM is shown by horizontal lines. As explained in Section 3, value of  $\rho_{na}$  is inversely proportional to aggressiveness of annotation. Which implies for high values, EA<sub>online</sub> will annotate only those mentions in query that its highly confident about. Beyond a value no annotations are made.

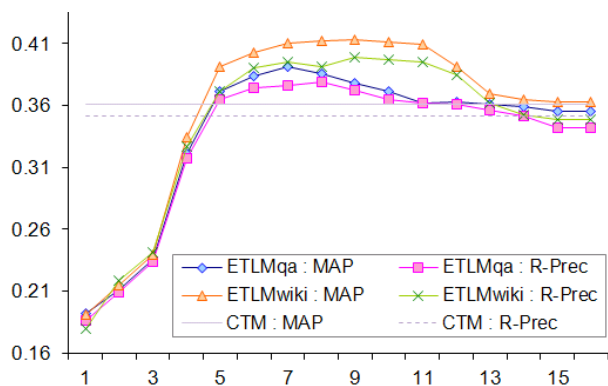

Figure 5: Impact of query annotation on retrieval. x-axis represents value of  $\rho_{na}$  used to control annotation

This is represented on the extreme right in Figure 5. One important observation is that, even with no annotations made in query, performance of  $ETLM_{qa}$  and  $ETLM_{wiki}$  is competitive to CTM. This is evidence for addressing the noise related issue for which CTM is designed. For large range of values, all ETLM configurations are above CTM. As we decrease  $\rho_{na}$  performance increases smoothly and then after a certain point ( $\rho_{na} = 5$ ) it starts decreasing.

#### 4.5 $ETLM_{combo}$

We believe that  $T(t|t')$  learnt from one source would encode word association characteristics which might not be exactly the same across sources.  $ETLM_{combo}$  tries to address this by combining the two models. Values for mixing parameters are :  $\alpha_{wiki}^{(e,e')} = 0.95$ <sup>11</sup>,  $\alpha_{wiki}^{(e,ne)} = 0.75$ ,  $\alpha_{wiki}^{(ne,ne')} = 0.7$  and  $\alpha_{wiki}^{(ne,e)} = 0.75$ . The interpolation weights were obtained by optimizing the retrieval performance by doing a using grid search over the parameter space. Same 50 queries were used for tuning. As seen entity relationships obtained from Wikipedia are far superior to one from Q&A corpus. As seen in Table 2 combining the two models improves the performance.

## 5 Related Work

Recently Q&A retrieval has been garnering lot of attention. Translation model (TLM) (Jeon et al., 2005) has been extensively employed in question search and has been shown to outperform the traditional IR methods significantly (VSM, BM25, LM). Existing

<sup>11</sup>  $\alpha_{qa}^{(e,e')} = (1 - 0.95)$

work can be broadly grouped under the following topics:

(a) *Improved training of translation models by exploiting answer content/inter-word co-occurrence relations and restriction to reliable parallel corpora:* Translation-based language model (TRLM) (Xue et al., 2008) improved stability of TLM by providing better probability estimates and also exploited answers for question retrieval. It further improved the retrieval results and obtained the state-of-the-art performance. Another line of work on translation models focused on providing suitable parallel data to learn the translation probabilities. Compact translation models (CTM) (Lee et al., 2008) tried to further improve the translation probabilities based on question-answer pairs by selecting the most important terms to build compact translation models. We show that such special-purpose models to control noisy translations may not be necessary because models learnt using entity annotations are robust to noise in Q&A data.

Instead of using noisy Q&A data, new approach (Bernhard and Gurevych, 2009) to build parallel corpus from reliable sources has showed improvements. They proposed to use as a parallel training data comprising of set the definitions and glosses provided for the same term by different lexical semantic resources. We move beyond terms and capture relationships between entities and terms using the page contents and link structure in Wikipedia.

Apart from translation models there are other approaches (Gao et al., 2004) that try to extend the existing language models for adhoc retrieval by incorporating term relationships or dependencies. Some expand queries using word relationships derived from co-occurrence thesaurus (Bai et al., 2005; Qiu and Frei, 1993), hand-crafted thesaurus (Liu et al., 2004; Voorhees, 1994) and combination of both (Cao et al., 2005).

(b) *Incorporation of query context information in translation models using latent factor modeling and smoothing approaches:* All these existing approaches mentioned above are considered to be context independent, in that they do not take into account any contextual information in modeling word word relationships. Topic signature model (Zhou et al., 2007) exploited contextual information

by decomposing a document into a set of weighted topic signatures and use it for model smoothing. This model turns out to be inefficient when confronted with ambiguous words and phrases because it is unable to disambiguate the sense of topic signatures. Others (Liu and Croft, 2004) perform semantic smoothing by means of clustering. Recently (Tu et al., 2010; Cai et al., 2011; Zhou et al., 2011) showed improved performance by performing sense based smoothing for document retrieval, latent topic mining and phrase based retrieval respectively. Contrary to these approaches we used entity disambiguation to capture contextual information for improving Q&A retrieval.

(c) *Complementary ideas for improving retrieval performance that can be used alongside translation models:* Other work on question retrieval include the use of category information available (Cao et al., 2010), learning-to-rank techniques (Bian et al., 2008; Surdeanu et al., 2008; Bunescu and Huang, 2010), proposed a syntactic tree matching ((Wang et al., 2009) or question structure for important phrase matching (Duan et al., 2008)). These methods seem orthogonal to ours, in some cases complementary and can be leveraged to get an even better performance

There also exists work where exploiting entity based representation has been found helpful in information retrieval (Singh et al., 2009; Egozi et al., 2011; Meij et al., 2008; Grootjen and van der Weide, 2006). In our work we use entity annotations in Q&A retrieval context. There is also some work on using Wikipedia in general web search (Xu et al., 2009).

## 6 Conclusion

In this work we extend word based model to incorporate semantic concepts for addressing the lexical gap issue in retrieval models for large online Q&A collections. Compared to the existing translation based model, our model is more robust and effective in that it can perform context aware expansions. We proposed ways to embed rich information freely available in Wikipedia into our models and combine it one learnt from Q&A corpus. Experiments performed on a large real Q&A data demon-

strate that all configurations of ETLM significantly outperforms existing models for Q&A retrieval.

# Constructing Task-Specific Taxonomies for Document Collection Browsing

Hui Yang

Georgetown University  
37th and O street, NW  
Washington, DC, 20057  
huiyang@cs.georgetown.edu

## Abstract

Taxonomies can serve as browsing tools for document collections. However, given an arbitrary collection, pre-constructed taxonomies could not easily adapt to the specific topic/task present in the collection. This paper explores techniques to *quickly* derive *task-specific* taxonomies supporting browsing in arbitrary document collections. The supervised approach directly learns semantic distances from users to propose meaningful task-specific taxonomies. The approach aims to produce globally optimized taxonomy structures by incorporating path consistency control and user-generated task specification into the general learning framework. A comparison to state-of-the-art systems and a user study jointly demonstrate that our techniques are highly effective.

## 1 Introduction

Taxonomies are widely used for knowledge standardization, knowledge sharing, and inferencing in natural language processing (NLP) tasks (Harabagiu et al., 2003; Szpektor et al., 2004). However, another common function of taxonomies, *browsing*, has received little attention in the NLP community. Browsing is the task of exploring and accessing information through a structure, e.g. a hierarchy, built upon a given document collection. In fact, taxonomies serve as browsing tools in many venues, including the Library of Congress Subject Headings (LCSH, 2011) for the U.S. Library of Congress and the Open Directory Project (ODP, 2011) for about

5% of the entire Web. We call taxonomies supporting browsing as *browsing taxonomies*.

When used for browsing, concepts<sup>1</sup> in taxonomies are linked to documents containing them and taxonomic structures are navigated to find particular documents. Users can navigate through a browsing taxonomy to explore the documents in the collection. A browsing taxonomy benefits information access by providing corpus overview for a document collection and allowing more focused reading by presenting together documents about the same concept.

Most existing browsing taxonomies, such as LCSH and ODP, are manually constructed to support large collections in general domains. Not only their constructions are expensive and slow, but also their structures are static and difficult to adapt to specific tasks. In situations where document collections are given ad-hoc, such as search result organization (Carpineto et al., 2009), email collection exploration (Yang and Callan, 2008), and literature investigation (Chau et al., 2011), existing taxonomies may even not be able to provide the right coverage of concepts. It is necessary to explore *ad-hoc* (semi-)automatic techniques to *quickly* derive *task-specific* browsing taxonomies for arbitrary document collections.

(Hovy, 2002) pointed out that one key challenge in taxonomy construction is multiple perspectives embedded in concepts and relations. One cause for multiple perspectives is the inherent facets in concepts, e.g., *jewelries* can be organized by *price* or by *gemstone types*. Another cause is task specification or even personalization. For example, when building a taxonomy for search results of query *trip to*

<sup>1</sup>English terms or entities; usually nouns or noun phrases.

DC, Jane may organize the concepts based on *places of interests* while Tom may organize them based on *dates in visit*. Typically, a taxonomy only conveys one or two perspectives from many choices. It is difficult to decide which perspective should be present. One realistic solution is to leave the decision to the constructor independent of the confusion that comes from facets, task specification or personalization.

When multiple perspectives present in the same taxonomy, it is not uncommon that the perspectives are mixed. For example, along a path *financial institute*→*bank*→*river bank*, *financial institute*→*bank* shows one perspective and *bank*→*river bank* shows another. We call this problem *path inconsistency*. Many approaches on automatic taxonomy construction suffer from this problem because their foci are on accurately identifying local relations between concept pairs (Etzioni et al., 2005; Pantel and Pennacchiotti, 2006) instead of on global control over the entire taxonomic structure. More recently, approaches attempted to build the full taxonomy structure (Snow et al., 2006; Yang and Callan, 2009; Kozareva and Hovy, 2010), however, few have looked into how to incorporate task specifications into taxonomy construction.

In this paper, we extended an existing taxonomy construction approach (Yang and Callan, 2009) to build task-specific taxonomies for document collection browsing. The extension comes in two parts: handling path consistency and incorporating specifications from users. We uniquely employ pairwise semantic distance as an entry point to incrementally build browsing taxonomies. A supervised distance learning algorithm not only allows us to incorporate multiple semantic features to evaluate the proximity between concepts, but also allows us to learn the metric function from personal preferences. Users can thus manually modify the taxonomies and to some extent teach the algorithm to predict his/her way to organize the concepts. Moreover, by minimizing the overall semantic distances among concepts and restricting minimal semantic distances along a path, we find the best hierarchical structure as the browsing taxonomy.

Our contributions include:

- A supervised learning mechanism to capture task-specific or personalized requirements for organizing a browsing taxonomy;

- A strategy to address path inconsistency due to word sense ambiguity and/or mixed perspectives;

- A general scheme to capture user inputs in taxonomy construction;

- A user study to evaluate the effectiveness of task-specific taxonomies for browsing activities.

## 2 Related Work

Document collection browsing has been studied as an alternative to the ranked list representation for search results by the Information Retrieval (IR) community. The popular IR approaches include clustering (Cutting et al., 1992) and monothetic concept hierarchies (Sanderson and Croft, 1999; Lawrie et al., 2001; Kummamuru et al., 2004; Carpineto et al., 2009). Clustering approaches hierarchically cluster documents in a collection and label the clusters. Monothetic approaches organize the concepts into hierarchies and link documents to related concepts. Both approaches are mainly based on pure statistics, such as document frequency (Sanderson and Croft, 1999) and conditional probability (Lawrie et al., 2001). The major drawback of these pure statistical approaches is their neglect of semantics among concepts. As a consequence, they often fail to produce semantically meaningful taxonomies.

The NLP community has extensively studied automatic taxonomy construction. Although traditional research on taxonomy construction focuses on extracting local relations between concept pairs (Hearst, 1992; Berland and Charniak, 1999; Ravichandran and Hovy, 2002; Girju et al., 2003; Etzioni et al., 2005; Pantel and Pennacchiotti, 2006; Kozareva et al., 2008), more recent efforts have been made in building full taxonomies. For example, (Snow et al., 2006) proposed to estimate taxonomic structure via maximizing the overall likelihood of a taxonomy. (Kozareva and Hovy, 2010) proposed to connect local concept pairs by finding the longest path in a subsumption graph. Yang and Callan proposed the Minimum Evolution (*ME*) framework to model the semantic distance  $d(c_x, c_y)$  between concepts  $c_x$  and  $c_y$  as a weighted combination of various lexical, statistical, and semantic features:  $\sum_j \text{weight}_j * \text{feature}_j(c_x, c_y)$  and estimate the taxonomic structure by minimizing the overall semantic distances.

Researcher also attempted to carve out taxonomies from existing ones. For example, Stoica et al. (Stoica and Hearst, 2007) managed to extract a browsing taxonomy from hypernym relations within WordNet (Fellbaum, 1998).

To support browsing in arbitrary collections, in this paper, we propose to incorporate task specification in a taxonomy. One way to achieve it is to define task-specific distances among concepts. Moreover, through controlling distance scores among concepts, we can enforce path consistency in taxonomies. For example, when the distance between *financial institute* and *river bank* is big, the path *financial institute*→*bank*→*river bank* will be pruned and the concepts will be repositioned. Inspired by *ME*, we take a distance learning approach to deal with path consistency (Section 3) and task specification (Section 4) in taxonomy construction.

### 3 Build Structure-Optimized Taxonomies

This section presents how to automatically build taxonomies. We take two steps to build browsing taxonomy for a given document collection. The first step is to extract the concepts and the second is to organize the concepts. For concept extraction, we take a simple but effective approach: (1) We first parse the document collection and exhaustively extract nouns, noun phrases, and named entities that occur >5 times in the collection. (2) We then filter out part-of-speech errors and typos by a Web-based frequency test. In the test, we search each candidate concept in the Google search engine and remove a candidate if it appears <4 times within the top 10 Google snippets. (3) We finally cluster similar concept candidates into groups by Latent Semantic Analysis (Bellegarda et al., 1996) and select the candidate with the highest *tfidf* value within a group to form the concept set  $C$ . Although our extraction algorithm is very effective with 95% precision and 80% recall in a manual evaluation, sometimes  $C$  may still miss some important concepts for the collection. This can be later corrected by users interactively through adding new concepts (Section 4).

To organize the concepts in  $C$  into taxonomic structures, we extend the incremental clustering framework proposed by *ME* (Yang and Callan,

2009). In *ME*, concepts are inserted one at a time. At each insertion, a concept  $c_z$  is at the parent (or child) position for every existing node in the current taxonomy. The evaluation of the best position depends on the semantic distance between  $c_z$  and its temporary child (or parent) node and the semantic distance among all other concepts in the taxonomy. An advantage in *ME* is that it allows incorporating various constraints to the taxonomic structure. For example, *ME* can handle concept generality-specificity by learning different semantic distance functions for general concepts which are located at upper levels and specific concepts which are located at lower levels in a taxonomy.

In this section, we introduce a new semantic distance learning method (Section 3.1) and extend *ME* by controlling path consistency (Section 3.2).

#### 3.1 Estimating Semantic Distances

Pair-wise semantic distances among concepts build the foundation for taxonomy construction. *ME* models the semantic distance  $d(c_x, c_y)$  between concepts  $c_x$  and  $c_y$  as a linear combination of underlying feature functions. Similar to *ME*, we also assume that “there are some underlying feature functions that measure semantic dissimilarity for concepts and a good semantic distance is a combination of these features”. Different from *ME*, we model the semantic distance  $d(c_x, c_y)$  between concepts  $(c_x, c_y)$  as a Mahalanobis distance (Mahalanobis, 1936):  $d_{c_x, c_y} = \sqrt{\Phi(c_x, c_y)^T W^{-1} \Phi(c_x, c_y)}$ , where  $\Phi(c_x, c_y)$  is the set of underlying feature functions  $\{\phi_k : (c_x, c_y)\}$  with  $k=1, \dots, |\Phi|$ .  $W$  is the weight matrix, whose diagonal values weigh the various feature functions. We use the same set of features as proposed in *ME*.

Mahalanobis distance is a general parametric function widely used in distance metric learning (Yang, 2006). It measures the dissimilarity between two random vectors of the same distribution with a covariance matrix  $W$ , which scales the data points from their original values by  $W^{1/2}$ . When only diagonal values of  $W$  are taken into account,  $W$  is equivalent to assigning weights to different axes in the random vectors.

We choose Mahalanobis distance for two reasons. (1) It is in a parametric form so that it allows us to learn a distance function by supervised learning and

provides an opportunity to assign different weights for each type of semantic features. (2) When  $W$  is properly constrained to be positive semi-definite (PSD) (Bhatia, 2006), a Mahalanobis-formatted distance will be guaranteed to satisfy non-negativity and triangle inequality, which was not addressed in  $ME$ . As long as these two conditions are satisfied, one may learn other forms of distance functions to represent a semantic distance.

We can estimate  $W$  by minimizing the squared errors between training semantic distances  $d$  and the expected value  $\hat{d}$ . We also need to constrain  $W$  to be PSD to satisfy triangle inequality and non-negativity. The objective function for semantic distance estimation is:

$$\min_W \sum_{x=1}^{|\mathcal{C}|} \sum_{y=1}^{|\mathcal{C}|} \left( d_{c_x, c_y} - \sqrt{\Phi(c_x, c_y)^T W^{-1} \Phi(c_x, c_y)} \right)^2 \quad (1)$$

subject to  $W \succeq 0$

In this implementation, we used (Sedumi, 2011) and (Yalmip, 2011) to solve the semi-definite programming (SDP).

To generate the training semantic distances, we collected 100 hypernym taxonomy fragments from WordNet (Fellbaum, 1998) and ODP. The semantic distance for a concept pair  $(c_x, c_y)$  in a training taxonomy fragment is generated by assuming every edge is weighted as 1 and summing up the edge weights along the shortest path from  $c_x$  to  $c_y$  in the taxonomy fragment. In Section 4, we will show how to use user inputs as training data to capture task-specifications in taxonomy construction.

### 3.2 Enforcing Path Consistency

In  $ME$ , the main taxonomy structure optimization framework is based on minimization of overall semantic distance among all concepts in the taxonomy and the minimum evolution assumption. We extend the framework by introducing another optimization objective to the framework: path consistency objective. The idea is that in any root-to-leaf path in a taxonomy, all concepts on the path should be about the same topic or the same perspective. Within a root-to-leaf path, the concepts need to be coherent no matter how far away they are apart. It suggests that a good path's sum of the semantic distances should be small.

#### Algorithm: Automatic Taxonomy Optimization.

```

 $W = \min_W \sum_{x=1}^{|\mathcal{C}|} \sum_{y=1}^{|\mathcal{C}|} ((d_{c_{tr_x}, c_{tr_y}} - \sqrt{\Phi(c_{tr_x}, c_{tr_y})^T W^{-1} \Phi(c_{tr_x}, c_{tr_y})})^2);$ 
foreach  $c_z \in \mathcal{C} \setminus S$ 
   $S \leftarrow S \cup \{c_z\};$ 
  if  $W \succeq 0$ 
     $d(c_z, \cdot) = \sqrt{\Phi(c_z, \cdot)^T W^{-1} \Phi(c_z, \cdot)};$ 
     $R \leftarrow R \cup \{\arg \min_{R(c_z, \cdot)} (\lambda \text{obj}_{ME} + (1 - \lambda) \text{obj}_{path})\};$ 
Output  $T(S, R)$ 

```

Figure 1: An algorithm for taxonomy structure optimization with path consistency control.  $\mathcal{C}$  denotes the entire concept set,  $S$  the current concept set, and  $R$  the current relation set.  $N(c_{tr_x})$  is the neighborhood of a training concept  $c_{tr_x}$ , including its parent and child(ren).  $R(c_z, \cdot)$  indicates the set of relations between a new concept  $c_z$  and all other existing concepts.  $T$  is the taxonomy with concept set  $S$  and relation set  $R$ .

Therefore, we propose to minimize the sum of semantic distances along a root-to-leaf path. Particularly, when adding a new concept  $c_z$  into an existing browsing hierarchy  $T$ , we try it at different positions in  $T$ . At each temporary position, we can calculate the sum of the semantic distances along the root-to-leaf path  $P_{c_z}$  that contains the new concept  $c_x$ . The path consistency objective is given by:

$$\text{obj}_{path} = \min_{P_{c_z}} \sum_{c_x, c_y \in P_{c_z}, x < y} d(c_x, c_y) \quad (2)$$

where  $x < y$  defines the order of the concepts to avoid counting the same pair of pair-wise distances twice.

Towards modeling path consistency in taxonomy construction, we introduce a Pareto co-efficient  $\lambda \in [0, 1]$  to control the contributions from  $\text{obj}_{ME}$ , the overall semantic distance minimization objective as proposed in  $ME$ , and  $\text{obj}_{path}$ , the path distance minimization objective. The optimization is:

$$\min \lambda \text{obj}_{ME} + (1 - \lambda) \text{obj}_{path} \quad (3)$$

where  $\text{obj}_{ME} = |\sum_{c_x, c_y \in \mathcal{C}^n \cup \{c_z\}, x < y} d(c_x, c_y) - \sum_{c_x, c_y \in \mathcal{C}^n, x < y} d(c_x, c_y)|$ ,  $0 \leq \lambda \leq 1$ , and  $\mathcal{C}^n$  is the concept set after  $n^{\text{th}}$  concept is added. Empirically, we set  $\lambda = 0.8$ .

The algorithm shown in Figure 1 outlines our greedy algorithm to build taxonomies with path consistency control. Each time when a new concept arrives, the algorithm first estimates its semantic distances based on  $W$  learned from the training data,

then finds the optimal position for the concept by minimizing overall semantic distances and path inconsistency, and gradually grows the structure into a full taxonomy.

The order of adding concepts may affect the final taxonomy structure. We hence insert concepts in an arbitrary order with 10 random restarts with different initial concepts and pick the taxonomy that minimizes both objectives among all candidate structures.

## 4 Incorporating Task Specification

This section studies how to incorporate user-defined task specifications in taxonomy construction. Although the automatic algorithm proposed in Section 3 is able to well-organize most concepts for a given document collection, it has not yet addressed the issue of mixed perspective in taxonomy construction. For concepts with multiple perspectives, we need to decide which perspective is more appropriate for the browsing taxonomy. This task-specific requirement can only be captured by the user/constructor who builds and uses the browsing taxonomy. Moreover, the automatic algorithm relies on training data from WordNet and ODP, which are known for imperfect term organizations such as unbalanced granularity among terms at the same level. To correct the wrong relations learned from imperfect training data, we propose to utilize user inputs in the learning process.

Particularly, we formulate taxonomy construction as a user-teaching-machine-learning process. To guide how to organize the concepts, a user trains the supervised distance learning model via a taxonomy construction interface that allows the user to intuitively modify a taxonomy. The interface supports editing actions such as dragging and dropping, adding, deleting, and renaming nodes. When a user put  $c_x$  under  $c_y$ , i.e.  $c_x \rightarrow c_y$ , this action indicates that the user wants a relation represented by  $c_x \rightarrow c_y$  to be true in this taxonomy. We did not expect users to make all the edits. In a human-computer-interaction cycle, a user is not restricted to give a certain number of edits. Based on a user study (Section 5.5), an average number of edits per interaction is 3.6, which can be achieved with ease by most users.

The algorithm shown in Figure 2 provides the

### Algorithm: Interactive Taxonomy Construction.

1.  $T(S, R) = \text{CreateInitialTaxonomy}()$ ;
2.  $U^{(0)} = \{\text{Unmodified Concepts}\} = C \setminus S$ ,  
 $G^{(0)} = \{\text{Modified concepts}\} = S$ ,  $M^{(0)} = \emptyset$ ,  $i = 0$ ;
3. **while** (not Satisfied) or  $U^{(i)} \neq \emptyset$
4.  $M^{(i)} = \text{CollectManualGuidance}(G^{(i)}, U^{(i)})$ ;
5.  $W^{(i)} = \text{LearnDistanceMetricFunction}(M^{(i)})$ ;

7.  $(G^{(i+1)}, U^{(i+1)}) = \text{UpdateTaxonomy}(D^{(i)}, U^{(i)}, G^{(i)})$ ;
8.  $i = i + 1$ ;
9. **Output**  $G^{(i)}$  as the taxonomy.

Figure 2: Interactive taxonomy construction procedure.

pseudo code for the interactive taxonomy construction procedure. It starts with automatic construction of initial taxonomies using the techniques presented in Section 3 (Line 1). We then capture the user inputs as *manual guidance* (Line 4) and make use of it to adjust the distance learning model (Line 5), make new predictions for semantic distances of other concepts (Line 6), and organize those concepts to agree with the user and update the taxonomy accordingly (Line 7). Line 2 initiates three variables, the unmodified concepts  $U$ , the modified concepts  $G$ , and the manual guidance  $M$ , indexed by the iteration number  $i$ . The process iterates until the user is satisfied with the taxonomy’s organization (Line 3).

Learning and predicting distances have been presented in Section 3.1. In this section, we present how to capture manual guidance (Section 4.1) and update the taxonomies accordingly (Section 4.2).

### 4.1 Manual Guidance as the Training Data

Taxonomies are tree-structured. It is not trivial to model a taxonomy, especially changes in a taxonomy, and feed that into a learning algorithm. In this section, we propose a general scheme to capture changes, i.e., user inputs during interactions, in taxonomy construction.

We propose to convert a taxonomy into matrices of neighboring nodes. We compare the changes between a series of snapshots of the changing taxonomy to identify the user inputs. Specifically, before a user starts editing in an interaction cycle, we represent the organization of concepts as a *before matrix*; likewise, after the user finishes all edits in one cycle, we represent the new organization of concepts as an *after matrix*. For both matrices, the  $(x, y)^{th}$  entry indicates whether (or how confident) a relation  $r(c_x, c_y)$  is true.  $r$  could be any type of relation

Figure 3: An example taxonomy before and after human edits (Concepts unchanged; relation type = *sibling*).

between the concepts. Figure 3 shows an example taxonomy’s before and after matrices.

We define *manual guidance*  $M$  as a submatrix which consists of entries in the *after matrix*  $B$ ; at these entries, there exist differences between the *before matrix*  $A$  and the *after matrix*  $B$ . Formally,

$$M = B[r; c]$$

$$r = \{i : b_{ij} - a_{ij} \neq 0\}$$

$$c = \{j : b_{ij} - a_{ij} \neq 0\}$$

where  $a_{ij}$  is the  $(i, j)^{th}$  entry in  $A$ ,  $b_{ij}$  is the  $(i, j)^{th}$  entry in  $B$ ,  $r$  indicates the rows and  $c$  indicates the columns.

Note that manual guidance is not simply the matrix difference between  $A$  and  $B$ . It is part of the after matrix because it is the after matrix that indicates where the user wants the concept hierarchy to develop. The manual guidance for the example shown in Figure 3 is:  $M = B[2, 3, 4; 2, 3, 4] =$

	Oscars	Best supporting	Best picture
Oscars	1	0	0
Best supporting	0	1	1
Best picture	0	1	1

When the user adds or deletes concepts, we expand rows and columns in  $A$  and  $B$  by filling 0 for non-diagonal entries and 1 for diagonal entries. The expanded before and after matrices  $A'$  and  $B'$  are used in the calculation.

For taxonomies with concept changes, we define *manual guidance with concept set change*  $M_{change}$  as a submatrix which consists of some entries of the *after matrix*  $B$ ; at these entries, there exist differences from the *expanded before matrix*  $A'$  to the ex-

panded after matrix  $B'$ . Note that the concepts corresponding to these entries should exist in the unexpanded set of concepts. Formally, manual guidance with concept set change

$$M_{change} = B[r'; c']$$

$$r' = \{i : b'_{ij} - a'_{ij} \neq 0, \text{ concept } c_i \in C_B\}$$

$$c' = \{j : b'_{ij} - a'_{ij} \neq 0, \text{ concept } c_j \in C_B\}$$

where  $a'_{ij}$  is the  $(i, j)^{th}$  entry in  $A'$ ,  $b'_{ij}$  is the  $(i, j)^{th}$  entry in  $B'$ ,  $C_B$  is the set of concepts in the unexpanded after matrix  $B$ ,  $r$  indicates the rows and  $c$  indicates the columns.

Based on manual guidance  $M$ , we can create training data for the supervised distance learning algorithm (Section 3.1). In particular, we transform the manual guidance into a distance matrix  $D = 1 - M$ , which is used as the training data. The learning algorithm is then able to learn a good model which best preserves the regularity defined by the task and the user. The difference is that the training data here is derived from manual guidance while in the automatic algorithm we use training data from WordNet and ODP.

## 4.2 Update the Taxonomy

According to the algorithm shown in Figure 2, after learning  $W^{(i)}$ , the weight matrix at the  $i^{th}$  iteration, from the manual guidance, we can use it to predict the pair-wise semantic distances for the unmodified concepts and further group them in the taxonomy.

When the pair-wise distance score for a concept pair  $(c_l, c_m)$  is small ( $<0.5$ ), we consider the relation between the concept pair is true; when it is big ( $\geq 0.5$ ), false. How to organize concepts whose relations are true, is decided again by the relation type in the distance matrix. If  $r$  is “sibling”,  $c_l$  and  $c_m$  are put under the same parent. If  $r$  is “is-a”,  $c_m$  is put under  $c_l$  as one of  $c_l$ ’s children. The user interface then presents the updated taxonomy to the user and waits for the next round of manual guidance.

Since only a few changes are made during each human-computer interaction, the learning model may suffer from overfitting and the taxonomic structure may change too rapidly. To avoid such issues caused by too few manual guidance, we employ background training taxonomy fragments from WordNet and ODP, to smooth the learning models and achieve less variance.

## 5 Evaluation

We conduct experiments and a user study to evaluate the effectiveness of our approach. We have two goals for the evaluation. One is to evaluate how the browsing taxonomies constructed by our approach compare with those constructed by other baseline systems. Another is to investigate how well our system can learn from task-specifications based on user supervision.

### 5.1 Datasets

The datasets we used in the evaluation are collections of Web documents crawled for complex search tasks. For each task, we created the dataset by submitting 4 to 5 queries to and collecting the returned Web documents from two search engines *bing.com* and *google.com*. For example, queries “trip to DC”, “Washington DC”, “DC”, and “Washington” were submitted for the task “planning a trip to DC”. In total, we created 50 Web datasets on the topics such as *find a good kindergarten, purchase a used car, plan a trip to DC, how to make a cake, find a good wedding videographer, write a survey paper for health care systems, find the best deals for a Mother’s day gift, write a survey paper for social network, write a survey paper for EU’s finance, and write a survey paper for information technology.*

Around 1000 Web documents are collected for each dataset. We filter out spams and advertisements and then search for more relevant Web documents to make the total number 1000. However, not all topics can retrieve 1000 documents. Among all 50 datasets, the average number of documents is 988.5. The average number of unique words in a dataset is 698,875.

### 5.2 Comparing with Baseline Systems

We compare the following 5 systems.

- Subsumption: the automatic algorithm proposed by (Sanderson and Croft, 1999), the most effective state-of-the-art browsing hierarchy construction technique as reported by (Lawrie et al., 2001).
- KH: the automatic taxonomy construction algorithm proposed by (Kozareva and Hovy, 2010).

- ME: the automatic taxonomy construction algorithm proposed by (Yang and Callan, 2009). This framework does not perform path consistency control nor learning from users.
- DistOpt: our automatic taxonomy construction algorithm with path consistency control.
- PDistOpt: our interactive approach with human supervision. The process starts from a flat list of concepts. The user built the browsing taxonomy from the list in a user study (Section 5.5).

### 5.3 Browsing Effectiveness

A popular measure to evaluate the quality of the browsing taxonomies is the expected mutual information measure (EMIM (Lawrie et al., 2001)). It calculates the mutual information between the language model in a taxonomy  $T$  and the language model in a document collection  $Z$ . It is defined as:

$$I(C; V) = \sum_{c \in C, v \in V} P(c, v) \log \frac{P(c, v)}{P(c)P(v)},$$

where  $P(c, v) = \sum_{d \in Z} P(d)P(c|d)P(v|d)$ ,  $C$  is the set of concepts in  $T$ ,  $V$  is the set of non-stopwords in  $Z$ , and  $d$  is a document in  $Z$ . EMIM only evaluates the content of a browsing taxonomy, not its structure. However, it is still popularly used to indicate how representative a browsing taxonomy is for a document collection.

Table 1 shows the EMIM of the browsing taxonomies constructed by the five systems under evaluation. Based on the mean EMIM over the 50 datasets, we can rank the systems in terms of EMIM in the descending order as PDistOpt  $\gg$  DistOpt  $\gg$  ME  $>$  KH  $\gg$  Subsumption.<sup>2</sup> It shows that DistOpt is the best performing *automatic* algorithm to generate browsing taxonomies. DistOpt is 109% and statistically significantly more effective than ME ( $p$ -value $<.001$ , t-test), 159% and statistically significantly more effective than KH ( $p$ -value $<.001$ , t-test), and 17 times and statistically significantly more effective than Subsumption ( $p$ -value $<.001$ , t-test). It strongly suggests that our techniques are

<sup>2</sup> $\gg$  indicates statistically significant difference between the left and the right hand sides ( $p < .001$ , t-test) and  $>$  indicates moderate statistical significance between the left and the right hand sides ( $p < .05$ , t-test). We will use the same symbols throughout the remainder of this paper.

Table 1: Expected Mutual Information (in 1000\*EMIM).

Example dataset	Subs.	KH	ME	DistOpt	PDistOpt
kindergarten	0.4	3.8	3.9	5.6	7.3
health care	0.5	2.8	3.1	7.8	8.3
used car	0.1	0.2	0.1	2.8	3.6
trip to DC	0.2	4.3	4.5	6.4	6.8
finance	0.01	0.01	0.1	0.6	0.6
gift	0.2	1.2	1.2	3.8	4.7
social network	0.1	1.5	1.3	2.4	3.2
information	0.3	1.9	2.3	3.5	4.9
cake	0.2	1.2	3.1	6.6	6.8
videographer	0.4	1.8	1.6	4.9	5.6
<b>Mean of 50 sets</b>	<b>0.24</b>	<b>1.7</b>	<b>2.1</b>	<b>4.4</b>	<b>5.2</b>

more effective than the state-of-the-art systems in constructing browsing taxonomies.

Moreover, Table 1 shows that the PDistOpt taxonomies is 18% more effective than the DistOpt taxonomies in terms of EMIM. The result is also statistically significant ( $p$ -value<.01, t-test). It indicates that incorporating user preferences in browsing taxonomy construction is able to produce even more effective browsing taxonomies than all automated methods.

Another popular evaluation measure<sup>3</sup> for browsing effectiveness is reach time (Carpineto et al., 2009). It is defined as:

$$t_{reach} = \frac{1}{|R|} \sum_{d_i \in R} L(c_i) + p_i,$$

where  $R$  is the relevant documents,  $c_i$  is the concept that connects to a relevant document  $d_i$ ,  $L(c_i)$  is the path length from the root to reach  $c_i$ , and  $p_i$  is the position that  $d_i$  appears in the document cluster associated with  $c_i$ . Reach time evaluates both the content and the structure of a browsing taxonomy. This measure needs relevance judgements about a query for the documents organized by the taxonomies. We obtained the relevance judgements by using the majority votes from a user study involving 29 subjects followed by expert reviews. Three experts manually examined the majority votes and reached agreements on all relevance judgements.

Table 2 elaborates reach time for the systems. Based on the mean reach time over 50 datasets, we obtain a similar ranking of the systems as suggested by EMIM. The ranking based on reach time

<sup>3</sup>Other proposed measures include coverage and compactness (Kummamuru et al., 2004).

Table 2: Reach time.

Example dataset	Subs.	KH	ME	DistOpt	PDistOpt
kindergarten	14.4	9.8	9.9	8.7	4.3
health care	12.3	9.8	6.8	4.5	3.3
used car	15.4	12.4	10.2	8.7	7.6
trip to DC	11.2	10.3	9.8	8.7	5.8
finance	24.5	18.3	19.7	18.7	15.6
gift	11.2	8.4	7.7	5.6	5.4
social network	14.3	9.8	7.8	7.6	6.8
information	10.6	9.5	8.8	8.9	6.7
cake	8.9	4.8	4.5	3.4	3.2
videographer	9.5	8.8	7.6	6.9	4.5
<b>Mean of 50 sets</b>	<b>14.2</b>	<b>12.2</b>	<b>9.8</b>	<b>7.2</b>	<b>5.2</b>

Figure 4: Path error rate.

is: PDistOpt >> DistOpt >> ME > KH >> Subsumption. It shows that the best performing *automatic* system is DistOpt, which on average can produce taxonomies to reach a relevant document by visiting only 7.2 nodes, including 5.2 non-leaf concepts and 2 documents in the leaf cluster on average. To find all relevant documents in a collection sized around 1000, this reach time is very fast. The interactive PDistOpt unsurprisingly gives even better reach time, 5.2 nodes on average.

#### 5.4 Path Consistency

To evaluate how well path consistency is handled, we compare the *path error rate* generated by our approach and by other baseline systems. This evaluation is only applied to automatic algorithms.

The path error is defined as the average number of wrong ancestor-descendant pairs in a taxonomy. It is only applied for concepts that are *not* immediately connected. It can be judged and calculated as follows. Three human assessors manually evaluated the path errors by (1) gathering the paths by performing a depth-first traverse in the taxonomy from the root concept; (2) along each path, counting the number of wrong ancestor-descendant pairs; (3) summing up

Figure 5: Perceived browsing effectiveness.

the errors that all assessors agree on and normalizing the sum by the taxonomy size.

Figure 4 shows the path error rate generated by all the automated algorithms under evaluation. We can see that DistOpt produces the least path error. The algorithms can be ranked in terms of the ability to handle path consistency as DistOpt  $\gg$  ME  $\gg$  KH  $\gg$  Subsumption. DistOpt statistically significantly reduces path errors from not using the path consistency control (ME) by 500% ( $p$ -value  $< .001$ , t-test). It strongly indicates that our technique is effective to maintain path consistency. We conclude that DistOpt best handles path consistency among all the system under evaluation.

## 5.5 User Study

Besides objective evaluations, we conducted an user study consisting of two parts: qualitative comparison of the systems under evaluation, and using our taxonomy construction user interface to interactively construct personalized browsing taxonomies.

Twenty-nine (Thirty subjects initially, one was excluded because of incomplete data entry) graduate and undergraduate students from various majors in two universities participated in the study. They were all familiar with use of computers and highly proficient in English. Each user study lasted for 4 hours.

In the first half of the user study, the participants were first introduced to the taxonomy construction user interface for about 10 minutes to get familiar with its functions. After that, the participants performed an exercise task which lasted about 5 minutes and then started the real tasks. For each dataset, the participants were asked to interactively work with PDistOpt to build browsing taxonomies.

Once the real tasks were done, the participants spend 5 minutes to answer a questionnaire regarding their experience and opinions.

In the second half of the user study, we asked the participants to use and compare the provided browsing taxonomies with the following task in mind.

Imagine your have a task [task name]. You use a browsing taxonomy designed for the collection of Web documents about this task. Use the browsing taxonomy to find all useful topics for your task. Identify at least one document for each topic.

For each dataset, we asked the participants to rate the browsing taxonomies built by the systems under evaluation by answering the following question about *perceived browsing effectiveness* - “How well did the browsing taxonomy help you to complete the task?”. Ratings in the 5-point Likert-type scale, ranging from “very good”(5), “good”(4), “fair”(3), “bad”(2), to “trash”(1), are used to rate browsing effectiveness perceived by the participants.

### 5.5.1 Perceived Browsing Effectiveness

Figure 5 shows the mean and 95% confidence interval for the *perceived browsing effectiveness* for browsing taxonomies constructed by the systems under evaluation. These perceived browsing effectiveness can be ranked in descending order as PDistOpt  $\gg$  DistOpt  $>$  ME  $\gg$  KH  $>$  Subsumption. PDistOpt shows the highest mean perceived browsing effectiveness, which is as high as 4.4. Such high rating shows that browsing taxonomy with personalization could well satisfy users’ information needs and are perceived as very effective in browsing by the users.

### 5.5.2 Accuracy of System Predictions

When a user provided manual guidance to the interactive system, during each human-computer interaction cycle, the system made predictions based on the user’s edits. He or she could directly judge the correctness of these machine-predicted modifications on-the-fly by selecting an option “yes” or “no” from the “Accept the change?” menu. Note that these were personalized tasks and the predictions were evaluated by the user according

Table 3: Accuracy of system predictions.

	Max	Min	Avg
accuracy of system predictions	0.98	0.92	0.94

Table 4: Perceived learning ability.

	Max	Min	Avg
perceived learning ability	4.2	2.8	3.61
which dataset	health care	finance	-

to his/her own standard. We calculate the accuracy of system predictions as:  $\text{Accuracy} = \frac{1}{I} \sum_{i=1}^I \frac{\text{number of accepted predictions in } i^{\text{th}} \text{ cycle}}{\text{number of predictions in } i^{\text{th}} \text{ cycle}}$ , where  $I$  is the total number of human-computer interaction cycles when constructing a browsing taxonomy. A high accuracy indicates that the system learns well from user edits. This evaluation is only applied to PDistOpt.

Table 3 shows that for all datasets, the mean accuracy of the system predictions is above 0.92. The average value is 0.94. This high accuracy clearly demonstrates that the system successfully learns from a user and makes highly accurate predictions on how the user would organize the concepts.

### 5.5.3 Perceived Learning Ability

After completing constructing a browsing taxonomy, a participant was asked immediately to rate how well the system learned from his/her edits. The question was “*How well did the system appear to learn your method of organizing the concepts?*”. We also used the 5-point Likert-type scale to rate this *perceived system learning ability*. This evaluation is only applied to PDistOpt.

Table 4 shows the max, min, and average responses of perceived system learning ability. The mean perceived learning ability is 3.61, with a standard derivation of 0.45. It suggests that the learning ability of the system was only perceived as moderately good. This result contradicts with the conclusion that we drew based on the more objective measure, accuracy of system prediction (Section 5.5.2).

We further investigate why the participants were only moderately satisfied with the system’s learning ability. From the after session questionnaire, we found that participants thought that some datasets such as “finance” were more difficult than other datasets such as “health care”. For example, the

dataset “finance” was considered by all participants as “very difficult” while “health care” was considered as “very easy”. The participants also complained that they were not familiar with the difficult datasets. It is interesting that when a dataset is less familiar for the users, the system was perceived performing badly too. It may suggest that when people are not familiar with the tasks, they provide less promising edits, the system learns from the lower quality training data, and in the end the users perceive the output as poor system learning ability.

## 6 Conclusion

Document collection browsing is another common use of taxonomies. Given an arbitrary collection, a taxonomy must suit the specific domain in order to support browsing. This paper explores techniques to *quickly* derive *task-specific* taxonomies supporting browsing in arbitrary document sets. In particular, we uniquely employ pair-wise semantic distance as an entry point to incrementally build browsing taxonomies. The supervised distance learning algorithm not only allows us to incorporate multiple semantic features to evaluate the proximity between concepts, but also allows us to learn the metric function from personal preferences. Users can thus manually modify the taxonomies and to some extent teach the algorithm to predict his/her way to organize the concepts. Moreover, by minimizing the overall semantic distances among concepts and restricting minimal semantic distances along a path, we find the best hierarchical structure as the browsing hierarchy. It guarantees that semantically close concepts are put together so that users will have a good idea about why the concepts are put together. This greatly increases the interpretability of a constructed browsing hierarchy than the existing approaches. This makes our approach more flexible and more general to effectively creating browsing taxonomies to support more complicated and more realistic tasks such as Web information triage.

## Acknowledgments

## Abstract

Cost-sensitive classification, where the *features* used in machine learning tasks have a cost, has been explored as a means of balancing knowledge against the expense of incrementally obtaining new features. We introduce a setting where humans engage in classification with incrementally revealed features: the collegiate trivia circuit. By providing the community with a web-based system to practice, we collected tens of thousands of implicit word-by-word ratings of how useful features are for eliciting correct answers. Observing humans' classification process, we improve the performance of a state-of-the-art classifier. We also use the dataset to evaluate a system to compete in the incremental classification task through a reduction of reinforcement learning to classification. Our system learns **when** to answer a question, performing better than baselines and most human players.

## 1 Introduction

A typical machine learning task takes as input a set of features and learns a mapping from features to a label. In such a setting, the objective is to minimize the error of the mapping from features to labels. We call this traditional setting, where all of the features are consumed, *rapacious* machine learning.<sup>1</sup>

This not how humans approach the same task. They do not exhaustively consider every feature. After a certain point, a human has made a decision and no longer needs additional features. Even indefatigable computers cannot always exhaustively consider every feature. This is because the result

<sup>1</sup>Earlier drafts called this “batch” machine learning, which confused the distinction between batch and online learning. We gladly adopt “rapacious” to make this distinction clearer and to cast traditional machine learning—that always examines all features—as a resource hungry approach.

is time sensitive, such as in interactive systems, or because processing time is limited by the sheer quantity of data, as in sifting e-mail for spam (Pujara et al., 2011). In such settings, often the best solution is incremental: allow a decision to be made without seeing all of an instance's features. We discuss the incremental classification framework in Section 2.

Our understanding of how humans conduct incremental classification is limited. This is because complicating an already difficult annotation task is often an unwise tradeoff. Instead, we adapt a real world setting where humans are already engaging (eagerly) in incremental classification—trivia games—and develop a cheap, easy method for capturing human incremental classification judgments.

After qualitatively examining how humans conduct incremental classification (Section 3), we show that knowledge of a human's incremental classification process improves state-of-the-art *rapacious* classification (Section 4). Having established that these data contain an interesting signal, we build Bayesian models that, when embedded in a Markov decision process, can engage in effective incremental classification (Section 5), and develop new hierarchical models combining local and thematic content to better capture the underlying content (Section 7). Finally, we conclude in Section 8 and discuss extensions to other problem areas.

## 2 Incremental Classification

In this section, we discuss previous approaches that explore how much *effort* or resources a classifier needs to come to a decision, a problem not as thoroughly examined as the question of whether the decision is right or not.<sup>2</sup> Incremental classification is

<sup>2</sup>When have an *externally* interrupted feature stream, the setting is called “any time” (Boddy and Dean, 1989; Horsch and Poole, 1998). Like “budgeted” algorithms (Wang et al., 2010), these are distinct but related problems.

not equivalent to *missing* features, which have been studied at training time (Cesa-Bianchi et al., 2011), test time (Saar-Tsechansky and Provost, 2007), and in an online setting (Rostamizadeh et al., 2011). In contrast, incremental classification allows the learner to decide whether to acquire additional features.

A common paradigm for incremental classification is to view the problem as a Markov decision process (MDP) (Zubek and Dietterich, 2002). The incremental classifier can either request an additional feature or render a classification decision (Chai et al., 2004; Ji and Carin, 2007; Melville et al., 2005), choosing its actions to minimize a known cost function. Here, we assume that the *environment* chooses a feature in contrast to a learner, as in some active learning settings (Settles, 2011). In Section 5, we use a MDP to decide whether additional features need to be processed in our application of incremental classification to a trivia game.

## 2.1 Trivia as Incremental Classification

A real-life setting where humans classify documents incrementally is quiz bowl, an academic competition between schools in English-speaking countries; hundreds of teams compete in dozens of tournaments each year (Jennings, 2006). Note the distinction between quiz bowl and Jeopardy, a recent application area (Ferrucci et al., 2010). While Jeopardy also uses signaling devices, these are only usable *after a question is completed* (interrupting Jeopardy’s questions would make for bad television). Thus, Jeopardy is *rapacious* classification followed by a race to see—among those who know the answer—who can punch a button first. Moreover, buzzes *before* the question’s end are penalized.

Two teams listen to the same question.<sup>3</sup> In this context, a question is a series of clues (features) referring to the same entity (for an example question, see Figure 1). We assume a fixed feature ordering for a test sequence (i.e., you cannot request specific features). Teams interrupt the question at any point by “buzzing in”; if the answer is correct, the team gets points and the next question is read. Otherwise, the team loses points and the other team can answer.

<sup>3</sup>Called a “starter” (UK) or “tossup” (US) in the lingo, as it often is followed by a “bonus” given to the team that answers the starter; here we only concern ourselves with tossups answerable by both teams.

After losing a race for the Senate, this politician edited the Omaha World-Herald. This man resigned from one of his posts when the President sent a letter to Germany protesting the Lusitania sinking, and he advocated coining silver at a 16 to 1 rate compared to gold. He was the three-time Democratic Party nominee for President but lost to McKinley twice and then Taft, although he served as Secretary of State under Woodrow Wilson, and he later argued against Clarence Darrow in the Scopes Monkey Trial. For ten points, name this man who famously declared that “we shall not be crucified on a Cross of Gold”.

Figure 1: Quiz bowl question on William Jennings Bryan, a late nineteenth century American politician; obscure clues are at the beginning while more accessible clues are at the end. Words (excluding stop words) are shaded based on the number of times the word triggered a buzz from any player who answered the question (darker means more buzzes; buzzes contribute to the shading of the previous five words). Diamonds (◇) indicate buzz positions.

The answers to quiz bowl questions are well-known entities (e.g., scientific laws, people, battles, books, characters, etc.), so the answer space is relatively limited; there are no open-ended questions of the form “why is the sky blue?” However, there are no multiple choice questions—as there are in Who Wants to Be a Millionaire (Lam et al., 2003)—or structural constraints—as there are in crossword puzzles (Littman et al., 2002).

Now that we introduced the concepts of questions, answers, and buzzes, we pause briefly to define them more formally and explicitly connect to machine learning. In the sequel, we will refer to: **questions**, sequences of words (tokens) associated with a single answer; **features**, inputs used for decisions (derived from the tokens in a question); **labels**, a question’s correct response; **answers**, the responses (either correct or incorrect) provided; and **buzzes**, positions in a question where users halted the stream of features and gave an answer.

Quiz bowl is not a typical problem domain for natural language processing; why should we care about it? First, it is a real-world instance of incremental classification that happens hundreds of thousands of times most weekends. Second, it is a classification problem intricately intertwined with core computational linguistics problems such as anaphora resolution, online sentence processing, and semantic priming. Finally, quiz bowl’s inherent fun makes it easy to acquire human responses, as we describe in the next section.

Figure 2: Users plotted based on *accuracy* vs. the *number of tokens*—on average—the user took to give an answer. Dot size and colour represent the *total* number of questions answered. Users that answered questions later in the question had higher accuracy. However, there were users that were able to answer questions relatively early without sacrificing accuracy.

### 3 Getting a Buzz through Crowdsourcing

We built a corpus with 37,225 quiz bowl questions with 25,498 distinct labels from 121 tournaments written for tournaments between 1999 and 2010. We created a webapp<sup>4</sup> that simulates the experience of playing quiz bowl. Text is incrementally revealed (at a pace adjustable by the user) until users press the space bar to “buzz”. Users then answer, and the webapp judges correctness using a string matching algorithm. Players can override the automatic check if the system mistakenly judged an answer incorrect. Answers of previous users are displayed after answering a question; this enhances the sense of community and keeps users honest (e.g., it’s okay to say that “wj bryan” is an acceptable answer for the label “william jennings bryan”, but “asdf” is not). We did not see examples of nonsense answers from malicious users; in contrast, users were stricter than we expected, perhaps because protesting required effort.

To collect a set of labels with many buzzes, we focused on the 1186 labels with more than four distinct questions. Thus, we shuffled the labels into a canonical order shown to all users (e.g., everyone saw a question on “Jonathan Swift” and then a question on “William Jennings Bryan”, but because these labels have many questions the specific questions

<sup>4</sup>Play online or download the datasets at <http://umiacs.umd.edu/~jbg/qb>.

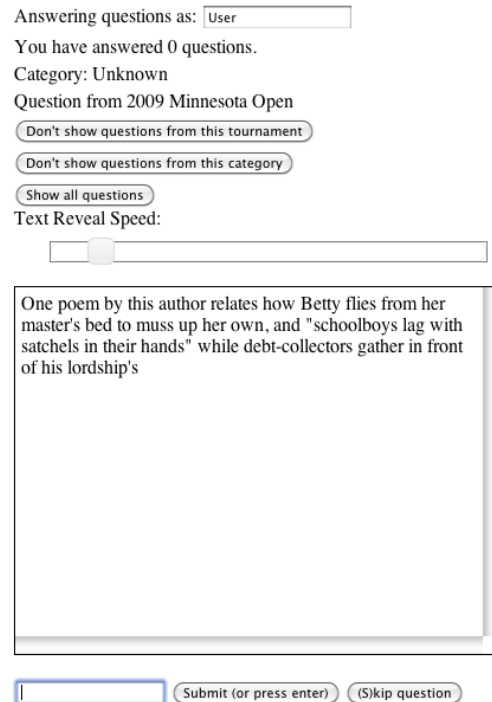

Figure 3: A screenshot of the webapp used to collect data. Users see a question revealed one word at a time. They signal buzzes by clicking on the answer button and input an answer.

were different for each user). Participants were eager to answer questions; over 7000 questions were answered in the first day, and over 43000 questions were answered in two weeks by 461 users.

To represent a “buzz”, we define a function  $b(q, f)$  (“b” for buzz) as the number of times that feature  $f$  occurred in question  $q$  at most five tokens before a user correctly buzzed on that question.<sup>5</sup> Aggregating buzzes across questions (summing over  $q$ ) shows different features useful for eliciting a buzz (Figure 4(a)). Some features coarsely identify the type of answer sought, e.g., “author”, “opera”, “city”, “war”, or “god”. Other features are relational, connecting the answer to other clues, e.g., “namesake”, “defeated”, “husband”, or “wrote”. The set of buzzes help narrow which words are important for matching a question to its answer; for an example, see how the word cloud for all of the buzzes on “Wuthering

<sup>5</sup>This window was chosen qualitatively by examining the patterns of buzzes; this is person-dependent, based on reading comprehension, reaction time, and what reveal speed the user chose. We leave explicitly modeling this for future work.

(a) Buzzes over all Questions (b) Wuthering Heights Question Text (c) Buzzes on Wuthering Heights

Figure 4: Word clouds representing all words that were a part of a buzz (a), the original text appearing in seven questions on the book “Wuthering Heights” by Emily Bronte (b), and the buzzes of users on those questions (c). The buzzes reflect what users remember about the work and is more focused than the complete question text.

Heights” (Figure 4(c)) is much more focused than the word cloud for *all* of the words from the questions with that label (Figure 4(b)).

#### 4 Buzzes Reveal Useful Features

If we restrict ourselves to a finite set of labels, the process of answering questions is a multiclass classification problem. In this section, we show that information gleaned from humans making a similar decision can help improve rapacious machine learning classification. This validates that our crowdsourcing technique is gathering useful information.

We used a state-of-the-art maximum entropy classification model, MEGAM (Daumé III, 2004), that accepts a per-class mean prior for feature weights and applied MEGAM to the 200 most frequent labels (11,663 questions, a third of the dataset). The prior mean of the feature weight is a convenient, simple way to incorporate human feature utility; apart from the mean, all default options are used.

Specifying the prior requires us to specify a weight for each pair of label and feature. The weight combines buzz information (described in Section 3) and tf-idf (Salton, 1968). The tf-idf value is computed by treating the training set of questions with the same label as a single document.

Buzzes and tf-idf information were combined into the prior  $\mu$  for label  $a$  and feature  $f$  as  $\mu_{a,f} =$

$$\left[ \beta b(a, f) + \alpha \mathbb{I}[b(a, f) > 0] + \gamma \right] \text{tf-idf}(a, f). \quad (1)$$

We describe our weight strategies in increasing order of human knowledge. If  $\alpha$ ,  $\beta$ , and  $\gamma$  are zero, this is a naïve **zero** prior. If  $\gamma$  only is nonzero, this is a linear transformation of features’ **tf-idf**. If only  $\alpha$  is nonzero, this is a linear transformation of buzzed

Weighting	$\alpha$	$\beta$	$\gamma$	Error
zero	-	-	-	0.37
tf-idf	-	-	3.5	0.14
buzz-binary	7.1	-	-	0.10
buzz-linear	-	1.5	-	0.16
buzz-tier	-	1.1	0.1	<b>0.09</b>

Table 1: Classification error of a rapacious classifier able to draw on human incremental classification. The best weighting scheme for each dataset is in **bold**. Missing parameter values (-) mean that the parameter is fixed to zero for that weighting scheme.

words’ tf-idf weights. If only  $\beta$  is non-zero, *number* of buzzes is now a linear multiplier of the tf-idf weight (**buzz-linear**). Finally we allow unbuzzed words to have a separate linear transformation if both  $\beta$  and  $\gamma$  are non-zero (**buzz-tier**).

Grid search (width of 0.1) on development set error was used to set parameters. Table 1 shows test error for weighting schemes and demonstrates that adding human information as a prior improves classification error, leading to a 36% error reduction over tf-idf alone. While not directly comparable (this classifier is rapacious, not incremental, and has a predefined answer space), the average user had an error rate of 16.7%.

#### 5 Building an Incremental Classifier

In the previous section we improved rapacious classification using humans’ incremental classification. A more interesting problem is how to compete against humans in incremental classification. While in the previous section we used human data for a *training* set, here we use human data as an *evaluation* set. Doing so requires us to formulate an incremental representation of the contents of questions and to learn a strategy to decide when to buzz.

Because this is the first machine learning algorithm for quiz bowl, we attempt to provide reasonable rapacious baselines and compare against our new strategies. We believe that our attempts represent a reasonable explanation of the problem space, but additional improvements could improve performance, as discussed in Section 8.

A common way to represent state-dependent strategies is via a Markov decision process (MDP). The most salient component of a MDP is the policy, i.e., a mapping from the state space to an action. In our context, a state is a sequence of (thus far revealed) tokens, and the action is whether to buzz or not. To learn a policy, we use a standard reinforcement learning technique (Langford and Zadrozny, 2005; Abbeel and Ng, 2004; Syed et al., 2008): given a representation of the state space, learn a classifier that can map from a state to an action. This is also a common paradigm for other incremental tasks, e.g., shift-reduce parsing (Nivre, 2008).

Given examples of the correct answer given a configuration of the state space, we can learn a MDP without explicitly representing the reward function. In this section, we define our method of defining actions and our representation of the state space.

## 5.1 Action Space

We assume that there are only two possible actions: buzz now or wait. An alternative would be a more expressive action space (e.g., an action for every possible answer). However, this conflates the question of *when* to buzz with *what* to answer. Instead, we call the distinct component that provides *what to answer* the **content model**. We describe an initial content model in Section 5.2, below, and improve the models further in Section 7. For the moment, assume that a content model maintains a posterior distribution over labels and when needed can provide its best guess (e.g., given the features seen, the best answer is “William Jennings Bryan”).

Given the action space, we need to specify where examples of state space and action come from. In the language of classification, we need to provide  $(x, y)$  pairs to learn a mapping  $x \mapsto y$ . The classifier attempts to learn that action  $y$  is (“buzz”) in all states where the content model gave a correct response given state  $x$ . Negative examples (“wait”) are applied to states where the content model gave

a wrong answer. Every token in our training set corresponds to a classification example; both states are prevalent enough that we do not to explicitly need to address class imbalance. This resembles approaches that merge different classifiers (Riedel et al., 2011) or attempt to estimate confidence of models (Blatz et al., 2004). However, here we use *partial* observations.

This is a simplification of the problem and corresponds to a strategy of “buzz as soon as you know the answer”, ignoring all other factors. While reasonable, this is not always optimal. For example, if you know your opponent is unlikely to answer a question, it is better to wait until you are more confident. Incorrect answers might also help your opponent, e.g., by eliminating an incorrect answer. Moreover, strategies in a game setting (rather than a single question) are more complicated. For example, if a right answer is worth +10 points and the penalty for an incorrect question is -5, then a team leading by 15 points on the last question should never attempt to answer. Investigating such gameplay strategies would require a “roll out” of game states (Tesauro and Galperin, 1996) to explore the efficacy of such strategies. While interesting, we leave these issues to future work.

We also investigated learning a policy directly from users’ buzzes directly (Abbeel and Ng, 2004), but this performed poorly because the content model is incompatible with the players’ abilities and the high variation in players’ ability and styles (compare Figure 2).

## 5.2 State Space

Recall that our goal is to learn a classifier that maps states to actions; above, we defined the action space (the classifier’s output) but not the state space, the classifier’s input. The straightforward parameterization of the state space would be all of the words that have been revealed. However, such a feature set is very sparse.

We use three components to form the state space: what information has been observed, what the content model believes is the correct answer, how confident the content model is, and whether the content model’s confidence is changing. We describe each in more detail below.

**Text** In addition to the obvious, sparse parameterization that contains all of the features thus far ob-

served, we also include the total number of tokens revealed and whether the phrase “for ten points” has appeared.<sup>6</sup>

**Guess** An additional feature that we used to represent the state space is the current guess of the content model; i.e., the argmax of the posterior.

**Posterior** The posterior feature (**Pos** for short) captures the shape of the posterior distribution: the probability of the current guess (the max of the posterior), the difference between the top two probabilities and the probabilities associated with the fifteen most probable labels under the posterior.

**Change** As features are revealed, there is often a rapid transition from a state of confusion—when there are many candidates with no clear best choice—to a state of clarity with the posterior pointing to only one probable label. To capture when this happens, we add a binary feature to reflect when the best guess has changed when a single feature has been revealed.

**Other Features** We thought that other features would be useful. While useful on their own, no features that we tried were useful when the content model’s **posterior** was also used as a feature. Features that we attempted to use were: a logistic regression model attempting to capture the probability that any player would answer (Silver et al., 2008), a regression predicting how many individuals would buzz in the next  $n$  words, the year the question was written, the category of the question, etc.

### 5.3 Naïve Content Model

The action space is only deciding *when* to answer, having abdicated responsibility for *what* to answer. So where do the answers come from? We assume that at any point we can ask “what is the highest probability label given my current feature observations?” We call the component of our model that answers this question the *content model*.

Our first content model is a naïve Bayes model (Lewis, 1998) trained over a text collection. This generative model assumes labels for questions come from a multinomial distribution  $\phi \sim \text{Dir}(\alpha)$

<sup>6</sup>The phrase “for ten points” (abbreviated FTP) appears in all quiz bowl questions to signal the question’s last sentence or clause. It is a signal to answer soon, as the final “giveaway” clue is next.

and assumes that label  $l$  has a word distribution  $\theta_l \sim \text{Dir}(\lambda)$ . Each question  $n$  has a label  $z_n$  and its words are generated from  $\theta_{z_n}$ . Given labeled observations, we use the *maximum a posteriori* (MAP) estimate of  $\theta_l$ .

Why use a generative model when a discriminative classifier could use a richer feature space? The most important reason is that, by definition, it makes sense to ask a generative model the probability of a label given a *partial* observation; such a question is not well-formed for discriminative models, which expect a complete feature set. Another important consideration is that generative models can predict future, unrevealed features (Chai et al., 2004); however, we do not make use of that capability here.

In addition to providing our answers, the content model also provides an additional, critically important feature for our state space: its **posterior (pos** for short) probability. With every revealed feature, the content model updates its posterior distribution over labels given that  $t$  tokens have been revealed in question  $n$ ,

$$p(z_n | w_1 \dots w_t, \phi, \theta). \quad (2)$$

To train our naïve Bayes model, we semi-automatically associate labels with a Wikipedia page (correcting mistakes manually) and then form the MAP estimate of the class multinomial distribution from the Wikipedia page’s text. We did this for the 1065 labels that had at least three human answers, excluding ambiguous labels associated with multiple concepts (e.g., “europa”, “steppenwolf”, “georgia”, “paris”, and “v”).

Features were taken to be the 25,000 most frequent tokens and bigrams<sup>7</sup> that were not stop words; features were extracted from the Wikipedia text in the same manner as from the question tokens.<sup>8</sup>

After demonstrating our ability to learn an incremental classifier using this simple content model, we extend the content model to capture local context and correlations between similar labels in Section 7.

<sup>7</sup>We used NLTK (Loper and Bird, 2002) to filter stop words and we used a  $\chi^2$  test to identify bigrams with that rejected the null hypothesis at the 0.01 level.

<sup>8</sup>The Dirichlet scaling parameter  $\lambda$  was set to 10,000 given our relatively large vocabulary (25,000) and to not penalize a label’s posterior probability if there were unseen features; this corresponds to a pseudocount of 0.4.  $\alpha$  was set to 1.0.

## 6 Pitting the Algorithm Against Humans

With a state space and a policy, we now have all the necessary ingredients to have our algorithm compete against humans. Classification, which allows us to learn a policy, was done using the default settings of LIBLINEAR (Fan et al., 2008). To determine where the algorithm buzzes, we provide a sequence of state spaces until the policy classifier determines that it is time to buzz.

We simulate competition by taking the human answers and buzzes as a given and ask our algorithm (independently) to provide its decision on when to buzz on a test set. We compare the two buzz positions. If the algorithm buzzed earlier with the right answer, we consider it to have “won” the question; equivalently, if the algorithm buzzed later, we consider it to have “lost” that question. Ties are rare (less than 1% of cases), as the algorithm had significantly different behavior from humans; in the case where there was a tie, ties were broken in favor of the machine.

Because we have a large, diverse population answering questions, we need aggregate measures of human performance to get a comprehensive view of algorithm performance. We use the following metrics for each question in the test set:

- **best**: the earliest *anyone* buzzed correctly
- **median**: the first buzz after 50% of human buzzes
- **mean**: for each recorded buzz compute a reward and we average over all rewards

We compare the algorithm against baseline strategies:

- **rap** The rapacious strategy waits until the end of the question and answers the best answer possible.
- **ftp** Waiting until when “for 10 points” is said, then giving the best answer possible.
- **index<sub>n</sub>** Waiting until the first feature after the  $n^{th}$  token has been processed, then giving the best answer possible. The indices were chosen as the quartiles for question length (by convention, most questions are of similar length).

We compare these baselines against policies that decide *when* to buzz based on the state.

Recall that the non-oracle algorithms were unaware of the true reward function. To best simulate conventional quiz bowl settings, a correct answer was +10 and the incorrect answer was −5. The full payoff matrix for the computer is shown in Table 2.

Cases where the opponent buzzes first but is wrong are equivalent to rapacious classification, as there is no longer any incentive to answer early. Thus we exclude such situations (Outcomes 3, 5, 6 in Table 2) from the dataset to focus on the challenge of processing clues incrementally.

	Computer	Human	Payoff
1	first and wrong	right	−15
2	—	first and correct	−10
3	first and wrong	wrong	−5
4	first and correct	—	+10
5	wrong	first and wrong	+5
6	right	first and wrong	+15

Table 2: Payoff matrix (from the computer’s perspective) for when agents “buzz” during a question. To focus on incremental classification, we exclude instances where the human interrupts with an *incorrect* answer, as after an opponent eliminates themselves, the answering reduces to rapacious classification.

Table 3 shows the algorithm did much better when it had access to the posterior. While incremental algorithms outperform rapacious baselines, they lose to humans. Against the median and average players, they lose between three and four points per question, and nearly twice that against the best players.

Although the content model is simple, this poor performance is not from the content model never producing the correct answer. To see this, we also computed the optimal actions that could be executed. We called this strategy the oracle strategy; it was able to consistently win against its opponents. Thus, while the content model was able to come up with correct answers often enough to on average win against opponents (even the best human players), we were unable to consistently learn winning policies.

There are two ways to solve this problem: create deeper, more nuanced policies (or the features that feed into them) or refine content models that provide the signal needed for our policies to make sound decisions. We chose to refine the content model, as we felt we had added all of the obvious features for learning effective policies.

## 7 Expanding the Content Model

When we asked quiz bowlers how they answer questions, they said that they first determine the category

Strategy	Features	Mean	Best	Median	Index
Classify	text	-8.72	-10.04	-6.50	40.36
	+guess	-5.71	-8.40	-3.95	66.02
	+pos	-4.13	-7.56	-2.70	67.97
	+change	<b>-4.02</b>	<b>-7.41</b>	<b>-2.63</b>	77.33
Oracle	text	3.36	0.61	4.35	49.90
Rapacious Baseline	all	-6.61	-9.03	-4.42	100.19
	ftp	-5.22	-8.62	-4.23	88.65
	index <sub>30</sub>	-7.89	-8.71	-6.41	32.23
	index <sub>60</sub>	-5.16	<b>-7.56</b>	-3.71	61.90
	index <sub>90</sub>	<b>-5.02</b>	-8.62	<b>-3.50</b>	87.13

Table 3: Performance of strategies against users. The human scoring columns show the average points per question (positive means winning on average, negative means losing on average) that the algorithm would expect to accumulate per question versus each human amalgam metric. The index column notes the average index of the token when the strategy chose to buzz.

of a question, which substantially narrows the answer space. Ideally, the content model should conduct the same calculus—if a question seems to be about mathematics, all answers related with mathematics should be more likely in the posterior. This was consistent with our error analysis; many errors were non-sensical (e.g., answering “entropy” for “Johannes Brahms”, when an answer such as “Robert Schumann”, another composer, would be better).

In addition, assuming independence between features given a label causes us to ignore potentially informative multiword expressions such as quotations, titles, or dates. Adding a language model to our content model allows us to capture some of these phenomena.

To create a model that jointly models categories and local context, we propose the following model:

1. Draw a distribution over labels  $\phi \sim \text{Dir}(\alpha)$
2. Draw a background distribution over words  $\theta_0 \sim \text{Dir}(\lambda_0 \vec{1})$ 
  - (a) For each category  $c$  of questions, draw a distribution over words  $\theta_c \sim \text{Dir}(\lambda_1 \theta_0)$ .
    - i. For each label  $l$  in category  $c$ , draw a distribution over words  $\theta_{l,c} \sim \text{Dir}(\lambda_2 \theta_c)$
    - A. For each type  $v$ , draw a bigram distribution  $\theta_{l,c,v} \sim \text{Dir}(\lambda_3 \theta_{l,c})$
3. Draw a distribution over labels  $\phi \sim \text{Dir}(\alpha)$ .
4. For each question with category  $c$  and  $N$  words, draw answer  $l \sim \text{Mult}(\phi)$ :
  - (a) Assume  $w_0 \equiv \text{START}$
  - (b) Draw  $w_n \sim \text{Mult}(\theta_{l,c,w_{n-1}})$  for  $n \in \{1 \dots N\}$

This creates a language model over categories, la-

els, and observed words (we use “words” loosely, as bigrams replace some word pairs). By constructing the word distributions using hierarchical distributions based on domain and ngrams (a much simpler parametric version of more elaborate methods (Wood and Teh, 2009)), we can share statistical strength across related contexts. We assume that labels are (only) associated with their majority category as seen in our training data and that category assignments are observed. All scaling parameters  $\lambda$  were set to 10,000,  $\alpha$  was 1.0, and the vocabulary was still 25,000.

We used the maximal seating assignment (Wallach, 2008) for propagating counts through the Dirichlet hierarchy. Thus, if the word  $v$  appeared  $B_{l,u,v}$  times in label  $l$  following a preceding word  $u$ ,  $S_{l,v}$  times in label  $l$ ,  $T_{c,v}$  times in category  $c$ , and  $G_v$  times in total, we estimate the probability of a word  $v$  appearing in label  $k$ , category  $t$ , and after word  $u$  as  $p(w_n = v \mid \text{lab} = l, \text{cat} = c, w_{n-1} = u; \vec{\lambda}) =$

$$\frac{B_{l,u,v} + \lambda_3 \frac{S_{l,v} + \lambda_2 \frac{T_{c,v} + \lambda_1 \frac{G_v + \lambda_0/V}{G_{\cdot} + \lambda_0}}{T_{c,\cdot} + \lambda_2}}{S_{l,\cdot} + \lambda_2}}{B_{l,u,\cdot} + \lambda_3}, \quad (3)$$

where we use  $\cdot$  to represent marginalization, e.g.  $T_{c,\cdot} = \sum_{v'} T_{c,v'}$ . As with naïve Bayes, Bayes’ rule provides posterior label probabilities (Equation 2).

We compare the naïve model with models that capture more of the content in the text in Table 4; these results also include intermediate models between naïve Bayes and the full content model: “cat” (omit 2.a.i.A) and “bigram” (omit 2.a). These models perform much better than the naïve Bayes models seen in Table 3. They are about even against the mean and median players and lose four points per question against top players.

## 7.1 Qualitative Analysis

In this section, we explore what defects are preventing the model presented here from competing with top players, exposing challenges in reinforcement learning, interpreting pragmatic cues, and large data. Three examples of failures of the model are in Figure 5. This model is the best performing model of the previous section.

**Too Slow** The first example is a question on Maurice Ravel, a French composer known for *Boléro*. The question leads off with Ravel’s orchestral version of

Strategy	Model	Mean	Best	Median	Index
Classify	naive	-4.02	-7.41	-2.63	77.33
	cat	-1.69	-5.22	0.12	67.97
	bigram	-3.80	-7.66	-2.51	78.69
	bgrm+cat	<b>-0.86</b>	<b>-4.46</b>	<b>0.83</b>	63.42
Oracle	naive	3.36	0.61	4.35	49.90
	cat	4.48	1.64	5.47	47.88
	bigram	3.58	0.87	4.61	49.34
	bgrm+cat	<b>4.67</b>	<b>1.99</b>	<b>5.74</b>	46.49

Table 4: As in Table 3, performance of strategies against users, but with enhanced content models. Modeling both bigrams and label categories improves overall performance.

Mussorgsky’s piano piece “Pictures at an Exhibition”. Based on that evidence, the algorithm considers “Pictures at an Exhibition” the most likely but does not yet buzz. When it receives enough information to be sure about the correct answer, over half of the players had already buzzed. Correcting this problem would require a more aggressive strategy, perhaps incorporating the identity of the opponent or estimating the difficulty of the question.

**Mislead by the Content Model** The second example is a question on Enrico Fermi, an Italian-American physicist. The first clues are about magnetic fields near a Fermi surface, which causes the content model to view “magnetic field” as the most likely answer. The question’s text, however, has pragmatic cues “this man” and “this Italian” which would have ruled out the abstract answer “magnetic field”. Correcting this would require a model that jointly models content and bigrams (Hardisty et al., 2010), has a coreference system as its content model (Haghighi and Klein, 2007), or determines the correct question type (Moldovan et al., 2000).

**Insufficient Data** The third example is where our approach had no chance. The question is a very difficult question about George Washington, America’s first president. As a sign of its difficulty, only half the players answered correctly, and only near the end of the question. The question concerns lesser known episodes from Washington’s life, including a mistress caught in the elements. To the content model, of the several hypotheses it considers, the closest match it can find is “Yasunari Kawabata”, who wrote the novel *Snow Country*, whose plot matches some of these keywords. To answer these types of question,

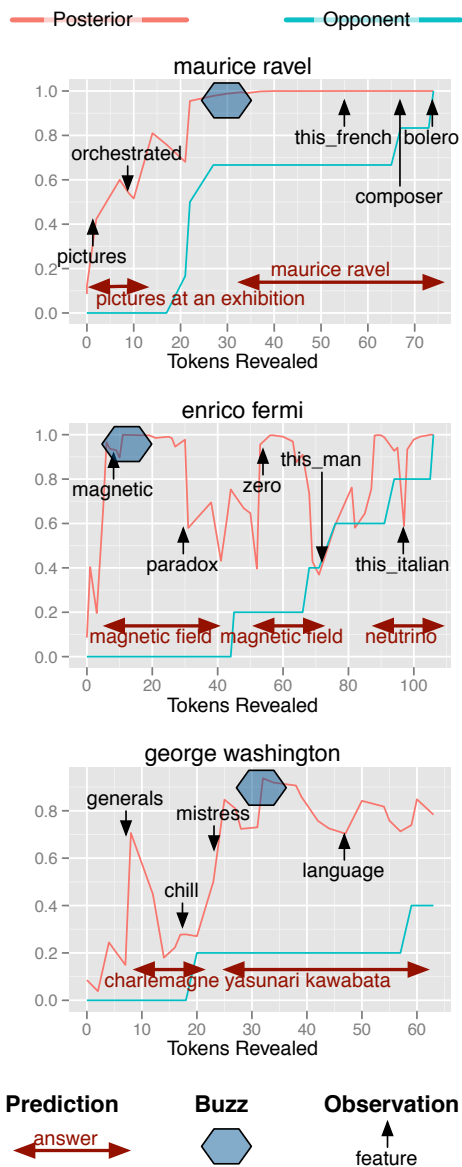

Figure 5: Three questions where our algorithm performed poorly. It gets “Maurice Ravel” (top) right but only after over half the humans had answered correctly (i.e., the buzz’s hexagon appears when the cyan line is above 0.6); on “Enrico Fermi” (middle) it confuses the correct type of answer (person vs. concept); on “George Washington” (bottom) it lacks information to answer correctly. Lines represent the current estimate posterior probability of the answer (red) and the proportion of opponents who have answered the question correctly (cyan). The label of each of the three questions is above each chart. Words are in black with arrows and arrows, and the current argmax answer is at the bottom of the graph in red. The buzz location is the hexagon.

the repository used to train the content model would have to be orders of magnitude larger to be able to link the disparate clues in the question to a consistent target. The content model would also benefit from weighting later (more informative) features higher.

## 7.2 Assumptions

We have made assumptions to solve a problem that is subtly different than the game of quiz bowl that a human would play. Some of these were simplifying assumptions, such as our assumption that the algorithm has a closed set of possible answers (Section 5.3). Even with this advantage, the algorithm is unable to compete with human players, who choose answers from an unbounded set. On the other hand, to focus on incremental classification, we idealized our human opponents so that they never give incorrect answers (Section 6). This causes our estimates of our performance to be lower than they would be against real players.

## 8 Conclusion and Future Work

We make three contributions. First, we introduce a new setting for exploring the problem of incremental classification: trivia games. This problem is intrinsically interesting because of its varied topics and competitive elements, has a great quantity of standardized, machine-readable data, and also has the boon of being cheaply and easily annotated. We took advantage of that ease and created a framework for quickly and efficiently gathering examples of humans doing incremental classification.

There are other potential uses for the dataset; the progression of clues from obscure nuggets to could help determine how “known” a particular aspect of an entity is (e.g., that William Jennings Bryant gave the “Cross of Gold” speech is better known his resignation after the Lusitania sinking, Figure 1). Which could be used in educational settings (Smith et al., 2008) or summarization (Das and Martins, 2007).

The second contribution shows that humans’ incremental classification improves state-of-the-art rapacious classification algorithms. While other frameworks (Zaidan et al., 2008) have been proposed to incorporate user clues about features, the system described here provides analogous features without the need for explicit post-hoc reflection, has faster anno-

tation throughput, and is much cheaper.

The problem of answering quiz bowl questions is itself a challenging task that combines issues from language modeling, large data, coreference, and reinforcement learning. While we do not address all of these problems, our third contribution is a system that learns a policy in a MDP for incremental classification even in very large state spaces; it can successfully compete with skilled human players.

Incorporating richer content models is one of our next steps. This would allow us to move beyond the closed-set model and use a more general coreference model (Haghighi and Klein, 2007) for identifying answers and broader corpora for training. In addition, using larger corpora would allow us to have more comprehensive doubly-hierarchical language models (Wood and Teh, 2009). We are also interested in adding richer models of opponents to the state space that would adaptively adjust strategies as it learned more about the strengths and weaknesses of its opponent (Waugh et al., 2011).

Further afield, our presentation of sentences closely resembles paradigms for cognitive experiments in linguistics (Thibadeau et al., 1982) but are much cheaper to conduct. If online processing effects (Levy et al., 2008; Levy, 2011) could be observed in buzzing behavior; e.g., if a confusingly worded phrase depresses buzzing probability, it could help validate cognitively-inspired models of online sentence processing.

Incremental classification is a natural problem, both for humans and resource-limited machines. While our data set is trivial (in a good sense), learning how humans process data and make decisions in a cheap, easy crowdsourced application can help us apply new algorithms to improve performance in settings where features aren’t free, either because of computational or annotation cost.

## Acknowledgments

We thank the many players who played our online quiz bowl to provide our data (and hopefully had fun doing so) and Carlo Angiuli, Arnav Moudgil, and Jerry Vinokurov for providing access to quiz bowl questions. This research was supported by NSF grant #1018625. Jordan Boyd-Graber is also supported by the Army Research Laboratory through ARL Cooperative Agreement W911NF-09-2-0072. ## Abstract

We present a systematic analysis of existing multi-domain learning approaches with respect to two questions. First, many multi-domain learning algorithms resemble ensemble learning algorithms. (1) Are multi-domain learning improvements the result of ensemble learning effects? Second, these algorithms are traditionally evaluated in a balanced class label setting, although in practice many multi-domain settings have domain-specific class label biases. When multi-domain learning is applied to these settings, (2) are multi-domain methods improving because they capture domain-specific class biases? An understanding of these two issues presents a clearer idea about where the field has had success in multi-domain learning, and it suggests some important open questions for improving beyond the current state of the art.

## 1 Introduction

Research efforts in recent years have demonstrated the importance of domains in statistical natural language processing. A mismatch between training and test domains can negatively impact system accuracy as it violates a core assumption in many machine learning algorithms: that data points are independent and identically distributed (*i.i.d.*). As a result, numerous domain adaptation methods (Chelba and Acero, 2004; Daumé III and Marcu, 2006; Blitzer et al., 2007) target settings with a training set from one domain and a test set from another.

Often times the training set itself violates the *i.i.d.* assumption and contains multiple domains. In this

case, training a single model obscures domain distinctions, and separating the dataset by domains reduces training data. Instead, multi-domain learning (MDL) can take advantage of these domain labels to improve learning (Daumé III, 2007; Dredze and Crammer, 2008; Arnold et al., 2008; Finkel and Manning, 2009; Zhang and Yeung, 2010; Saha et al., 2011). One such example is sentiment classification of product reviews. Training data is available from many product categories and while all data should be used to learn a model, there are important differences between the categories (Blitzer et al., 2007)<sup>1</sup>.

While much prior research has shown improvements using MDL, this paper explores what properties of an MDL setting matter. Are previous improvements from MDL algorithms discovering important distinctions between features in different domains, as we would hope, or are other factors contributing to learning success? The key question of this paper is: when do domains matter?

Towards this goal we explore two issues. First, we explore the question of whether domain distinctions are used by existing MDL algorithms in meaningful ways. While differences in feature behaviors between domains will hurt performance (Blitzer et al., 2008; Ben-David et al., 2009), it is not clear if the improvements in MDL algorithms can be attributed to correcting these errors, or whether they are benefiting from something else. In particular, there are many similarities between MDL and ensemble methods, with connections to instance bag-

<sup>1</sup>Blitzer et al. (2007) do not consider the MDL setup, they consider a single source domain, and a single target domain, with little or no labeled data available for the target domain.

ging, feature bagging and classifier combination. It may be that gains in MDL are the usual ensemble learning improvements.

Second, one simple way in which domains can change is the distribution of the prior over the labels. For example, reviews of some products may be more positive on average than reviews of other product types. Simply capturing this bias may account for significant gains in accuracy, even though nothing is learned about the behavior of domain-specific features. Most prior work considers datasets with balanced labels. However, in real world applications, where labels may be biased toward some values, gains from MDL could be attributed to simply modeling domain-specific bias. A practical advantage of such a result is ease of implementation and the ability to scale to many domains.

Overall, irrespective of the answers to these questions, a better understanding of the performance of existing MDL algorithms in different settings will provide intuitions for improving the state of the art.

## 2 Multi-Domain Learning

In the multi-domain learning (MDL) setting, examples are accompanied by both a class label and a domain indicator. Examples are of the form  $(\mathbf{x}_i, y, d_i)$ , where  $\mathbf{x}_i \in \mathbb{R}^N$ ,  $d_i$  is a domain indicator,  $\mathbf{x}_i$  is drawn according to a fixed domain-specific distribution  $D_{d_i}$ , and  $y_i$  is the label (e.g.  $y_i \in \{-1, +1\}$  for binary labels). Standard learning ignores  $d_i$ , but MDL uses these to improve learning accuracy.

Why should we care about the domain label? Domain differences can introduce errors in a number of ways (Ben-David et al., 2007; Ben-David et al., 2009). First, the domain-specific distributions  $D_{d_i}$  can differ such that they favor different features, i.e.  $p(\mathbf{x})$  changes between domains. As a result, some features may only appear in one domain. This aspect of domain difference is typically the focus of unsupervised domain adaptation (Blitzer et al., 2006; Blitzer et al., 2007). Second, the features may behave differently with respect to the label in each domain, i.e.  $p(y|\mathbf{x})$  changes between domains. As a result, a learning algorithm cannot generalize the behavior of features from one domain to another. The key idea behind many MDL algorithms is to target one or both of these properties of domain difference

to improve performance.

Prior approaches to MDL can be broadly categorized into two classes. The first set of approaches (Daumé III, 2007; Dredze et al., 2008) introduce parameters to capture domain-specific behaviors while preserving features that learn domain-general behaviors. A key of these methods is that they do not explicitly model any relationship between the domains. Daumé III (2007) proposes a very simple “easy adapt” approach, which was originally proposed in the context of adapting to a specific target domain, but easily generalizes to MDL. Dredze et al. (2008) consider the problem of learning how to combine different domain-specific classifiers such that behaviors common to several domains can be captured by a shared classifier, while domain-specific behavior is still captured by the individual classifiers. We describe both of these approaches in § 3.2.

The second set of approaches to MDL introduce an explicit notion of relationship between domains. For example, Cavallanti et al. (2008) assume a fixed task relationship matrix in the context of online multi-task learning. The key assumption is that instances from two different domains are half as much related to each other as two instances from the same domain. Saha et al. (2011) improve upon the idea of simply using a fixed task relationship matrix by instead *learning* it adaptively. They derive an online algorithm for updating the task interaction matrix.

Zhang and Yeung (2010) derive a convex formulation for adaptively learning domain relationships. We describe their approach in § 3.2. Finally, Daumé III (2009) proposes a joint task clustering and multi-task/multi-domain learning setup, where instead of just learning pairwise domain relationships, a hierarchical structure among them is inferred. Hierarchical clustering of tasks is performed in a Bayesian framework, by imposing a hierarchical prior on the structure of the task relationships.

In all of these settings, the key idea is to learn both domain-specific behaviors and behaviors that generalize between (possibly related) domains.

## 3 Data

To support our analysis we develop several empirical experiments. We first summarize the datasets and methods that we use in our experiments, then

proceed to our exploration of MDL.

### 3.1 Datasets

A variety of multi-domain datasets have been used for demonstrating MDL improvements. In this paper, we focus on two datasets representative of many of the properties of MDL.

**Amazon (AMAZON)** Our first dataset is the Multi-Domain Amazon data (version 2.0), first introduced by Blitzer et al. (2007). The task is binary sentiment classification, in which Amazon product reviews are labeled as positive or negative. Domains are defined by product categories. We select the four domains used in most studies: `books`, `dvd`, `electronics` and `kitchen appliances`.

The original dataset contained 2,000 reviews for each of the four domains, with 1,000 positive and 1,000 negative reviews per domain. Feature extraction follows Blitzer et al. (2007): we use case insensitive unigrams and bigrams, although we remove rare features (those that appear less than five times in the training set). The reduced feature set was selected given the sensitivity to feature size of some of the MDL methods.

**ConVote (CONVOTE)** Our second dataset is taken from segments of speech from United States Congress floor debates, first introduced by Thomas et al. (2006). The binary classification task on this dataset is that of predicting whether a given speech segment supports or opposes a bill under discussion in the floor debate. We select this dataset because, unlike the AMAZON data, CONVOTE can be divided into domains in several ways based on different metadata attributes available with the dataset. We consider two types of domain divisions: the bill identifier and the political party of the speaker. Division based on the bill creates domain differences in that each bill has its own topic. Division based on political party implies preference for different issues and concerns, which manifest as different language. We refer to these datasets as BILL and PARTY.

We use Version 1.1 of the CONVOTE dataset, available at <http://www.cs.cornell.edu/home/llee/data/convote.html>. More specifically, we combine the training, development and test folds from the `data_stage_three/` version, and sub-sample to generate different versions

of the dataset required for our experiments. For BILL we randomly sample speech segments from three different bills. The three bills and the number of instances for each were chosen such that we have sufficient data in each fold for every experiment. For PARTY we randomly sample speech segments from the two major political parties (Democrats and Republicans). Feature processing was identical to AMAZON, except that the threshold for feature removal was two.

### 3.2 Learning Methods and Features

We consider three MDL algorithms, two are representative of the first approach and one of the second approach (learning domain similarities) (§2). We favored algorithms with available code or that were straightforward to implement, so as to ensure reproducibility of our results.

**FEDA** Frustratingly easy domain adaptation (FEDA) (Daumé III, 2007; Daumé III et al., 2010b; Daumé III et al., 2010a) is an example of a classifier combination approach to MDL. The feature space is a cross-product of the domain and input features, augmented with the original input features (shared features). Prediction is effectively a linear combination of a set of domain-specific weights and shared weights. We combine FEDA with both the SVM and logistic regression algorithms described below to obtain FEDA-SVM and FEDA-LR.

**MDR** Multi-domain regularization (MDR) (Dredze and Crammer, 2008; Dredze et al., 2009) extends the idea behind classifier combination by explicitly formulating a classifier combination scheme based on Confidence-Weighted learning (Dredze et al., 2008). Additionally, classifier updates (which happen in an online framework) contain an explicit constraint that the combined classifier should perform well on the example. Dredze et al. (2009) consider several variants of MDR. We select the two best performing methods: MDR-L2, which uses the underlying algorithm of Crammer et al. (2008), and MDR-KL, which uses the underlying algorithm of Dredze et al. (2008). We follow their approach to classifier training and parameter optimization.

**MTRL** The multi-task relationship learning (MTRL) approach proposed by Zhang and Yeung

(2010) achieves states of the art performance on many MDL tasks. This method is representative of methods that learn similarities between domains and in turn regularize domain-specific parameters accordingly. The key idea in their work is the use of a matrix-normal distribution  $p(\mathbf{X}|\mathbf{M}, \mathbf{\Omega}, \mathbf{\Sigma})$  as a prior on the matrix  $\mathbf{W}$  created by column-wise stacking of the domain-specific classifier weight vectors.  $\mathbf{\Omega}$  represents the covariance matrix for the variables along the columns of  $\mathbf{X}$ . When used as a prior over  $\mathbf{W}$  it models the covariance between the domain-specific classifiers (and therefore the tasks).  $\mathbf{\Omega}$  is learned jointly with the domain-specific classifiers. This method has similar benefits to FEDA in terms of classifier combination, but also attempts to model domain relationships. We use the implementation of MTRL made available by the authors<sup>2</sup>. For parameter tuning, we perform a grid search over the parameters  $\lambda_1$  and  $\lambda_2$ , using the following values for each (a total of 36 combinations):  $\{0.00001, 0.0001, 0.001, 0.01, 0.1, 1\}$ .

In addition to these multi-task learning methods, we consider a common baseline: ignoring the domain distinctions and learning a single classifier over all the data. This reflects single-domain learning, in which no domain knowledge is used and will indicate baseline performance for all experiments. While some earlier research has included a separate *one classifier per domain* baseline, it almost always performs worse, since splitting the domains provides much less data to each classifier (Dredze et al., 2009). So we omit this baseline for simplicity.

To obtain a single classifier we use two classification algorithms: SVMs and logistic regression.

**Support Vector Machines** A single SVM run over all the training data, ignoring domain labels. We use the SVM implementation available in the LIBLINEAR package (Fan et al., 2008). In particular, we use the  $L_2$ -regularized  $L_2$ -loss SVM (option `-s 1` in version 1.8 of LIBLINEAR, and also option `-B 1` for including a standard bias feature). We tune the SVM using five-fold stratified cross-validation on the training set, using the following values for the trade-off parameter  $C$ :  $\{0.0001, 0.001, 0.01, 0.1, 0.2, 0.3, 0.5, 1\}$ .

<sup>2</sup><http://www.cse.ust.hk/~zhangyu/codes/MTRL.zip>

**Logistic Regression (LR)** A single logistic regression model run over all the training data, ignoring domain labels. Again, we use the  $L_2$ -regularized LR implementation available in the LIBLINEAR package (option `-s 0`, and also option `-B 1`). We tune the LR model using the same strategy as the one used for SVM above, including the values of the trade-off parameter  $C$ .

For all experiments, we measure average accuracy over  $K$ -fold cross-validation, using 10 folds for AMAZON, and 5 folds for both BILL and PARTY.

## 4 When Do Domains Matter?

We now empirically explore two questions regarding the behavior of MDL.

### 4.1 Ensemble Learning

**Question:** *Are MDL improvements the result of ensemble learning effects?*

Many of the MDL approaches bear a striking resemblance to ensemble learning. Traditionally, ensemble learning combines the output from several different classifiers to obtain a single improved model (Maclin and Opitz, 1999). It is well established that ensemble learning, applied on top of a diverse array of quality classifiers, can improve results for a variety of tasks. The key idea behind ensemble learning, that of combining a diverse array of models, has been applied to settings in which data preprocessing is used to create many different classifiers. Examples include instance bagging and feature bagging (Dietterich, 2000).

The core idea of using diverse inputs in making classification decisions is common in the MDL literature. In fact, the top performing and only successful entry to the 2007 CoNLL shared task on domain adaptation for dependency parsing was a straightforward implementation of ensemble learning by creating variants of parsers (Sagae and Tsujii, 2007). Many MDL algorithms, among them Dredze and Crammer (2008), Daumé III (2009), Zhang and Yeung (2010) and Saha et al. (2011), all include some notion of learning domain-specific classifiers on the training data, and combining them in the best way possible. To be clear, we *do not* claim that these approaches can be reduced to an existing ensemble learning algorithm. There are crucial elements

in each of these algorithms that separate them from existing ensemble learning algorithms. One example of such a distinction is the learning of domain relationships by both Zhang and Yeung (2010) and Saha et al. (2011). However, we argue that their core approach, that of combining parameters that are trained on variants of the data (all data or individual domains), is an ensemble learning idea.

Consider instance bagging, in which multiple classifiers are each trained on random subsets of the data. The resulting classifiers are then combined to form a final model. In MDL, we can consider each domain a subset of the data, albeit non-random and non-overlapping. The final model combines the domain-specific parameters and parameters trained on other instances, which in the case of FEDA are the shared parameters. In this light, these methods are a complex form of instance bagging, and their development could be justified from this perspective.

However, given this justification, are improvements from MDL simply the result of standard ensemble learning effects, or are these methods really learning something about domain behavior? If knowledge of domain was withheld from the algorithm, could we expect similar improvements? As we will do in each empirical experiment, we propose a contrarian hypothesis:

**Hypothesis:** *Knowledge of domains is irrelevant for MDL.*

**Empirical Evaluation** We evaluate this hypothesis as follows. We begin by constructing a true MDL setting, in which we attempt to improve accuracy through knowledge of the domains. We will apply three MDL algorithms (FEDA, MDR, and MTRL) to our three multi-domain datasets (AMAZON, BILL, and PARTY) and compare them against a single classifier baseline. We will then withhold knowledge of the true domains from these algorithms and instead provide them with random “pseudo-domains,” and then evaluate the change in their behavior. The question is whether we can obtain similar benefits by ignoring domain labels and relying strictly on an ensemble learning motivation (instance bagging).

For the “True Domain” setting, we apply the MDL algorithms as normal. For the “Random Domain” setting, we randomly shuffle the domain labels within a given class label within each fold, thus

maintaining the same number of examples for each domain label, and also retaining the same class distribution within each randomized domain. The resulting “pseudo-domains” are then similar to random subsets of the data used in ensemble learning.

Following the standard practice in previous work, for this experiment we use a balanced number of examples from each domain and a balanced number of positive and negative labels (no class bias). For AMAZON (4 domains), we have 10 folds of 400 examples per fold, for BILL (3 domains) 5 folds of 60 examples per fold, and for PARTY (2 domains) 5 folds of 80 examples per fold. In the “Random Domain” setting, since we are randomizing the domain labels, we increase the number of trials. We repeat each cross-validation experiment 5 times with different randomization of the domain labels each time.

**Results** Results are shown in Table 1. The first row shows absolute (average) accuracy for a single classifier trained on all data, ignoring domain distinctions. The remaining cells indicate absolute improvements against the baseline.

First, we note for the well-studied AMAZON dataset that our results with true domains are consistent with the previous literature. FEDA is known to not improve upon a single classifier baseline for that dataset (Dredze et al., 2009). Both MDR-L2 and MDR-KL improve upon the single classifier baseline, again as per Dredze et al. (2009). And finally, MTRL also improves upon the single classifier baseline. Although the MTRL improvement is not as dramatic as in the original paper<sup>3</sup>, the average accuracy that we achieve for MTRL (84.2%) is better than the best average accuracy in the original paper (83.65%).

The main comparison to make in Table 1 is between having knowledge of true domains or not. “Random Domain” in the table is the case where domain identifiers are randomly shuffled within a given fold. Ignoring the significance test results for now, overall the results indicate that knowing the true domains is useful for MDL algorithms. Randomizing the domains does not work better than knowing true domains in any case. However, in all except one case, the improvements of MDL algorithms are

<sup>3</sup>This might be due to a different version of the dataset being used in a cross-validation setup, rather than their train/test setup, and also because of differences in baseline approaches.

	AMAZON		BILL		PARTY

Table 1: A comparison between MDL methods with access to the “True Domain” labels and methods that use “Random Domain” information, essentially ensemble learning. The first row has raw accuracy numbers, whereas the remaining entries are absolute improvements over the baseline. ▲: Significantly better than the corresponding SVM or LR baseline, with  $p < 0.05$ , using a paired  $t$ -test. ▼: Significantly worse than corresponding baseline, with  $p < 0.05$ , using a paired  $t$ -test.

significantly better only for the AMAZON dataset<sup>4</sup>. And interestingly, exactly in the same case, randomly shuffling the domains also gives significant improvements compared to the baseline, showing that there is an ensemble learning effect in operation for MDR-L2 and MDR-KL on the AMAZON dataset. For FEDA, randomizing the domains significantly hurts its performance on the AMAZON data, as is the case for MDR-KL on the PARTY data. Therefore, while our contrarian hypothesis about irrelevance of domains is not completely true, it is indeed the case that some MDL methods benefit from the ensemble learning effect.

A second observation to be made from these results is that, while all of empirical research on MDL assumes the definition of domains as a given, the question of how to split a dataset into domains given various metadata attributes is still open. For example, in our experiments, in general, using the political party as a domain distinction gives us more improvements over the corresponding baseline approach<sup>5</sup>.

We provide a detailed comparison of using true

<sup>4</sup>Some numbers in Table 1 might appear to be significant, but are not. That is because of high variance in the performance of the methods across the different folds.

<sup>5</sup>The BILL and the PARTY datasets are not directly comparable to each other, although the prediction task is the same.

vs. randomized domains in Table 6, after presenting the second set of experimental results.

## 4.2 Domain-specific Class Bias

**Question:** *Are MDL methods improving because they capture domain-specific class biases?*

In previous work, and the above section, experiments have assumed a balanced dataset in terms of class labels. It has been in these settings that MDL methods improve. However, this is an unrealistic assumption. Even in our datasets, the original versions demonstrated class bias: Amazon product reviews are generally positive, votes on bills are rarely tied, and political parties vote in blocs. While it is common to evaluate learning methods on balanced data, and then adjust for imbalanced real world datasets, it is unclear what effect *domain-specific* class bias will have on MDL methods. Domains can differ in their proportion of examples of different classes. For example, it is quite likely that less controversial bills in the United States Congress will have more yes votes than controversial bills. Similarly, if instead of the category of a product, its brand is considered as a domain, it is likely that some brands receive a higher proportion of positive reviews than others.

Improvements from MDL in such settings may simply be capturing domain-specific class biases.

Table 2: The table shows the distribution of instances across domains and class labels *within one fold* of each of the datasets, for four different class bias trials. These datasets with varying class bias across domains were used for the experiments described in §4.2

Consider two domains, where each domain is biased towards the opposite label. In this case, domain-specific parameters may simply be capturing the bias towards the class label, increasing the weight uniformly of features predictive of the dominant class. Similarly, methods that learn domain similarity may be learning class bias similarity.

Why does the effectiveness of these domain-specific bias parameters matter? First, if capturing domain-specific class bias is the source of improvement, there are much simpler methods for learning that can be just as effective. This would be especially important in settings where we have many domains, and learning domain-specific parameters for each feature becomes infeasible. Second, if class bias accounted for most of the improvement in learning, it suggests that such settings could be amenable to unsupervised adaptation of the bias parameters.

**Hypothesis:** *MDL largely capitalizes on domain-specific class bias.*

**Empirical Evaluation** To evaluate our hypothesis, for each of our three datasets we create 4 random versions, each with some domain-specific class-bias. A summary of the dataset partitions is shown in Table 2. For example, for the AMAZON dataset, we create 4 versions (cb1 . . . cb4), where each domain has 100 examples *per fold* and each domain has a different balance between positive and negative classes. For each of these settings, we conduct a 10-fold cross validation experiment, then average the CV results for each of the 4 settings. The resulting accuracy numbers therefore reflect an average across many types of bias, each evaluated many times. We do a similar experiment for the BILL and PARTY datasets, except we use 5-fold CV.

In addition to the multi-domain and baseline methods, we add a new baseline: `DOM-ID`. In this setting, we augment the baseline classifier (which ignores domain labels) with a new feature that indicates the domain label. While we already include a general bias feature, as is common in classification tasks, these new features will capture domain-specific bias. This is the only change to the baseline classifier, so improvements over the baseline are indicative of the change in domain-bias that can be captured using these simple features.

**Results** Results are shown in Table 3. The table follows the same structure as Table 1, with the addition of the results for the `DOM-ID` approach. We first examine the efficacy of MDL in this setting. An observation that is hard to miss is that MDL results in these experiments show significant improvements in almost all cases, as compared to only a few cases in Table 1, despite the fact that even the baseline approaches have a higher accuracy. This shows that MDL results can be highly influenced by systematic differences in class bias across domains. Note that there is also a significant negative influence of class bias on MTRL for the AMAZON data.

A comparison of the MDL results on true domains to the `DOM-ID` baseline gives us an idea of how much MDL benefits purely from class bias differences across domains. We see that in most cases, about half of the improvement seen in MDL is accounted for by a simple baseline of using the domain identifier as a feature, and all but one of the improvements from `DOM-ID` are significant. This

Table 3: A comparison between MDL methods with class biased data. Similar to the setup where we evaluate the ensemble learning effect, we have a setting of using randomized domains. ▲: Significantly better than the corresponding SVM or LR baseline, with  $p < 0.05$ , using a paired  $t$ -test. ▼: Significantly worse than corresponding baseline, with  $p < 0.05$ , using a paired  $t$ -test.

suggests that in a real-world scenario where difference in class bias across domains is quite likely, it is useful to consider `DOM-ID` as a simple baseline that gives good empirical performance. To our knowledge, using this approach as a baseline is not standard practice in MDL literature.

Finally, we also include the “Random Domain” evaluation in the our class biased version of experiments. Each “Random Domain” result in Table 3 is an average over 20 cross-validation runs (5 randomized trials for each of the four class biased trials `cb1` ... `cb4`). This setup combines the effects of ensemble learning and bias difference across domains. As seen in the table, for MDL algorithms the results are consistently better as compared to knowing the true domains for the `AMAZON` dataset. For the other datasets, the performance after randomizing the domains is still significantly better than the baseline. This evaluation on randomized domains further strengthens the conclusion that differences in bias across domains play an important role, even in the case of noisy domains. Looking at the performance of `DOM-ID` with randomized domains, we see that in all cases the `DOM-ID` baseline performs *better* with randomized domains. While the difference is significant mostly only on the `AMAZON`

	+	20	40	60	80

Table 4: The table shows the distribution of instances across domains and class labels *within one fold* of the `AMAZON` dataset, for four different class bias trials. For the `BILL` and `PARTY` datasets, similar folds with consistent bias were created (number of examples used was different). These datasets with *consistent class bias* across domains were used for the experiments described in §4.2.1

dataset (details in Table 6, columns under “**Varying Class Bias**,”) this trend is still counter-intuitive. We suspect this might be because randomization creates a noisy version of the domain labels, which helps learners to avoid over-fitting that single feature.

### 4.2.1 Consistent Class Bias

We also performed a set of experiments that apply MDL algorithms to a setting where the datasets have different class biases (unlike the experiments reported in Table 1, where the classes are balanced), but, unlike the experiments reported in Table 3, the class bias is the *same* within each of the domains. We refer to this as the case of *consistent class bias* across domains. The distribution of classes within each domain within each fold is shown in Table 4. The results for this set of experiments are reported in Table 5. The structure of Table 5 is identical to that of Table 1. Comparing these results to those in Table 1, we can see that in most cases the improvements seen using MDL algorithms are lower than those seen in Table 1. This is likely due to the higher baseline performance in the *consistent class bias* case. A notable difference is in the performance of MTRL — it is significantly worse for the AMAZON dataset, and significantly better for the PARTY dataset. For the AMAZON dataset, we believe that the domain distinctions are less meaningful, and hence forcing MTRL to learn the relationships results in lower performance. For the PARTY dataset, in the case of a class-biased setup, knowing the party is highly predictive of the vote (in the original CONVOTE dataset, Democrats mostly vote “no” and Republicans mostly vote “yes”), and this is rightly exploited by MTRL.

### 4.2.2 True vs. Randomized Domains

In Table 6 we analyze the difference in performance of MDL methods when using true vs. randomized domain information. For the three sets of results reported earlier, we evaluated whether using true domains as compared to randomized domains gives significantly **better**, significantly **worse** or **equal** performance. Significance testing was done using a paired  $t$ -test with  $\alpha = 0.05$  as before. As the table shows, for the first set of results where the class labels were balanced (overall, as well as within each domain), using true domains was significantly better mostly only for the AMAZON dataset. FEDASVM was the only approach that was consistently better with true domains across all datasets. Note, however, that it was significantly better than the baseline approach only for PARTY.

For the second set of results (Table 3) where the

class bias varied across the different domains, using true domains was either no different from using randomized domains, or it was significantly worse. In particular, it was consistently significantly worse to use true domains on the AMAZON dataset. This questions the utility of domains on the AMAZON dataset in the context of MDL in a domain-specific class bias scenario. Since randomizing the domains works better for all of the MDL methods on AMAZON, it suggests that an ensemble learning effect is primarily responsible for the significant improvements seen on the AMAZON data, when evaluated in a domain-specific class bias setting.

Finally, for the case of consistent class bias across domains, the trend is similar to the case of no class bias — using true domains is useful. This table further supports the conclusion that domain-specific class bias highly influences multi-domain learning.

## 5 Discussion and Open Questions

Our analysis of MDL algorithms revealed new trends that suggest further avenues of exploration. We suggest three open questions in response.

**Question:** *When are MDL methods most effective?*

Our empirical results suggest that MDL can be more effective in settings with domain-specific class biases. However, we also saw differences in improvements for each method, and for different domains. Differences emerge between the AMAZON and CONVOTE datasets in terms of the ensemble learning hypothesis. While there has been some theoretical analyses on the topic of MDL (Ben-David et al., 2007; Ben-David et al., 2009; Mansour et al., 2009; Daumé III et al., 2010a), our results suggest performing new analyses that relate ensemble learning results with the MDL setting. These analyses could provide insights into new algorithms that can take advantage of the specific properties of each multi-domain setting.

**Question:** *What makes a good domain for MDL?*

To the best of our knowledge, previous work has assumed that domain identities are provided to the learning algorithm. However, in reality, there may be many ways to split a dataset into domains. For example, consider the CONVOTE dataset, which we split both by BILL and PARTY. The choice of splits

	AMAZON		BILL		PARTY

Table 6: The table shows the datasets (AM:AMAZON, BI:BILL, PA:PARTY) for which a given MDL method using true domain information was significantly **better**, significantly **worse**, or not significantly different (**equal**) as compared to using randomized domain information with the same MDL method.

impacted MDL. This poses new questions: what makes a good domain? How should we choose to divide data along possible metadata properties? If we can gain improvements simply by randomly creating new domains (“Random Domain” setting in our experiments) then there may be better ways to take advantage of the provided metadata for MDL.

**Question:** *Can we learn class-bias for unsupervised domain adaptation?*

Experiments with domain-specific class biases revealed that a significant part of the improvements could be achieved by adding domain-specific bias features. Limiting the multi-domain improvements to a small set of parameters raises an interesting question: can these parameters be adapted to a new domain without labeled data? Traditionally, domain

adaptation without target domain labeled data has focused on learning the behavior of new features; beliefs about existing feature behaviors could not be corrected without new training data. However, by collapsing the adaptation into a single bias parameter, we may be able to learn how to adjust this parameter in a fully unsupervised way. This would open the door to improvements in this challenging setting for real world problems where class bias was a significant factor.

## Abstract

Representation learning is a promising technique for discovering features that allow supervised classifiers to generalize from a source domain dataset to arbitrary new domains. We present a novel, formal statement of the representation learning task. We argue that because the task is computationally intractable in general, it is important for a representation learner to be able to incorporate expert knowledge during its search for helpful features. Leveraging the Posterior Regularization framework, we develop an architecture for incorporating biases into representation learning. We investigate three types of biases, and experiments on two domain adaptation tasks show that our biased learners identify significantly better sets of features than unbiased learners, resulting in a relative reduction in error of more than 16% for both tasks, with respect to existing state-of-the-art representation learning techniques.

## 1 Introduction

Supervised natural language processing (NLP) systems have been widely used and have achieved impressive performance on many NLP tasks. However, they exhibit a significant drop-off in performance when tested on domains that differ from their training domains. (Gildea, 2001; Sekine, 1997; Pradhan et al., 2007) One major cause for poor performance on out of-domain texts is the traditional representation used by supervised NLP systems (Ben-David et al., 2007). Most systems depend on lexical features, which can differ greatly between domains, so that important words in the test data may never be seen

in the training data. The connection between words and labels may also change across domains. For instance, “signaling” appears only as a present participle (VBG) in WSJ text (as in, “signaling that...”), but predominantly as a noun (as in “signaling pathway”) in biomedical text.

Recently, several authors have found that learning new features based on distributional similarity can significantly improve domain adaptation (Blitzer et al., 2006; Huang and Yates, 2009; Turian et al., 2010; Dhillon et al., 2011). This framework is attractive for several reasons: experimentally, learned features can yield significant improvements over standard supervised models on out-of-domain tests. Moreover, since the representation-learning techniques are unsupervised, they can easily be applied to arbitrary new domains. There is no need to supply additional labeled examples for each new domain.

Traditional representations still hold one significant advantage over representation-learning, however: because features are hand-crafted, these representations can readily incorporate the linguistic or domain expert knowledge that leads to state-of-the-art in-domain performance. In contrast, the only guide for existing representation-learning techniques is a corpus of unlabeled text.

To address this shortcoming, we introduce representation-learning techniques that incorporate a domain expert’s preferences over the learned features. For example, out of the set of all possible distributional-similarity features, we might prefer those that help predict the labels in a labeled training data set. To capture this preference, we might bias a representation-learning algorithm towards features with low joint entropy with the labels in the training data. This particular biased form of

representation learning is a type of semi-supervised learning that allows our system to learn *task-specific* representations from a source domain’s training data, rather than the single representation for all tasks produced by current, unsupervised representation-learning techniques.

We present a novel formal statement of representation learning, and demonstrate that it is computationally intractable in general. It is therefore critical for representation learning to be flexible enough to incorporate the intuitions and knowledge of human experts, to guide the search for representations efficiently and effectively. Leveraging the Posterior Regularization framework (Ganchev et al., 2010), we present an architecture for learning representations for sequence-labeling tasks that allows for biases. In addition to a bias towards task-specific representations, we investigate a bias towards representations that have similar features across domains, to improve domain-independence; and a bias towards multi-dimensional representations, where different dimensions are independent of one another. In this paper, we focus on incorporating the biases with HMM-type representations (Hidden Markov Model). However, this technique can also be applied to other graphical model-based representations with little modification. Our experiments show that on two different domain-adaptation tasks, our biased representations improve significantly over unbiased ones. In a part-of-speech tagging experiment, our best model provides a 25% relative reduction in error over a state-of-the-art Chinese POS tagger, and a 19% relative reduction in error over an unbiased representation from previous work.

The next section describes background and previous work. Section 3 introduces our framework for learning biased representations. Section 4 describes how we estimate parameters for the biased objective functions efficiently. Section 5 details our experiments and results, and section 6 concludes and outlines directions for future work.

## 2 Background and Previous Work

### 2.1 Terminology and Notation

A *representation* is a set of features that describe data points. Formally, given an instance set  $\mathcal{X}$ , it is a function  $\mathcal{R} : \mathcal{X} \rightarrow \mathcal{Y}$  for some suitable space  $\mathcal{Y}$  (of-

ten  $\mathbf{R}^d$ ), which is then used as the input space for a classifier. For instance, a traditional representation for POS tagging over vocabulary  $V$  would include (in part)  $|V|$  dimensions, and would map a word to a binary vector with a 1 in only one of the dimensions. By a *structured representation*, we mean a function  $R$  that incorporates some form of joint inference. In this paper, we use Viterbi decoding of variants of Hidden Markov Models (HMMs) for our structured representations, although our techniques are applicable to arbitrary (Dynamic) Bayes Nets. A *domain* is a probability distribution  $D$  over the instance set  $\mathcal{X}$ ;  $R(D)$  denotes the induced distribution over  $\mathcal{Y}$ . In *domain adaptation* tasks, a learner is given samples from a *source* domain  $D_S$ , and is evaluated on samples from a *target* domain  $D_T$ .

### 2.2 Theoretical Background

Ben-David *et al.* (2010) give a theoretical analysis of domain adaptation which shows that the choice of representation is crucial. A good choice is one that minimizes error on the training data, but equally important is that the representation must make data from the two domains look similar. Ben-David *et al.* show that for every hypothesis  $h$ , we can provably bound the error of  $h$  on the target domain by its error on the source domain plus a measure of the distance between  $D_S$  and  $D_T$ :

$$\mathbb{E}_{x \sim D_T} \mathcal{L}(x, R, f, h) \leq \mathbb{E}_{x \sim D_S} \mathcal{L}(x, R, f, h) + d_1(R(D_S), R(D_T))$$

where  $\mathcal{L}$  is a loss function,  $f$  is the target function, and the variation divergence  $d_1$  is given by

$$d_1(D, D') = 2 \sup_{B \in \mathcal{B}} |Pr_D[B] - Pr_{D'}[B]| \quad (1)$$

where  $\mathcal{B}$  is the set of measurable sets under  $D, D'$ .

### 2.3 Problem Formulation

Ben-David *et al.*’s theory provides learning bounds for domain adaptation under a fixed  $R$ . We now reformulate this theory to define the task of representation learning for domain adaptation as the following optimization problem: given a set of unlabeled instances  $U_S$  drawn from the source domain and unlabeled instances  $U_T$  from the target domain, as well as a set of labeled instances  $L_S$  drawn from

the source domain, identify a function  $R^*$  from the space of possible representations  $\mathcal{R}$ :

$$R^* = \operatorname{argmin}_{R \in \mathcal{R}} \left\{ \min_{h \in \mathcal{H}} (\mathbb{E}_{x \sim D_S} \mathcal{L}(x, R, f, h)) + d_1(R(D_S), R(D_T)) \right\} \quad (2)$$

Unlike most learning problems, where the representation  $R$  is fixed, this problem formulation involves a search over the space of representations and hypotheses. The equation also highlights an important underlying tension: the best representation for the source domain would naturally include domain-specific features, and allow a hypothesis to learn domain-specific patterns. We are aiming, however, for the best *general* classifier, that happens to be trained on training data from one or a few domains. Domain-specific features would contribute to distance between domains, and to classifier errors on data taken from unseen domains. By optimizing for this combined objective function, we allow the optimization method to trade off between features that are best for classifying source-domain data and features that allow generalization to new domains.

Naturally, the objective function in Equation 2 is completely intractable. Just finding the optimal hypothesis for a fixed representation of the training data is intractable for many hypothesis classes. And the  $d_1$  metric is intractable to compute from samples of a distribution, although Ben-David *et al.* propose some tractable bounds (2007; 2010). We view Equation 2 as a high-level goal rather than a computable objective. We leverage prior knowledge to bias the representation learner towards attractive regions of the representations space  $\mathcal{R}$ , and we develop efficient, greedy optimization techniques for learning effective representations.

## 2.4 Previous Work

There is a long tradition of research on representations for NLP, mostly falling into one of three categories: 1) vector space models and dimensionality reduction techniques (Salton and McGill, 1983; Turney and Pantel, 2010; Sahlgren, 2005; Deerwester *et al.*, 1990; Honkela, 1997) 2) using structured representations to identify clusters based on distributional similarity, and using those clusters as features (Lin and Wu, 2009; Candito and Crabbé, 2009; Huang

and Yates, 2009; Ahuja and Downey, 2010; Turian *et al.*, 2010; Huang *et al.*, 2011); 3) and structured representations that induce multi-dimensional real-valued features (Dhillon *et al.*, 2011; Emami *et al.*, 2003; Morin and Bengio, 2005). Our work falls into the second category, but builds on the previous work by demonstrating how to improve the distributional-similarity clusters with prior knowledge. To our knowledge, we are the first to apply semi-supervised representation learning techniques for structured NLP tasks.

Most previous work on domain adaptation has focused on the case where some labeled data is available in both the source and target domains (Daumé III, 2007; Jiang and Zhai, 2007; Daumé III *et al.*, 2010). Learning bounds are known (Blitzer *et al.*, 2007; Mansour *et al.*, 2009). A few authors have considered domain adaptation with no labeled data from the target domain (Blitzer *et al.*, 2006; Huang *et al.*, 2011) by using features based on distributional similarity. We demonstrate empirically that incorporating biases into this type of representation-learning process can significantly improve results.

## 3 Biased Representation Learning

As before, let  $U_S$  and  $U_T$  be unlabeled data, and  $L_S$  be labeled data from the source domain only. Previous work on representation learning with Hidden Markov Models (HMMs) (Huang and Yates, 2009) has estimated parameters  $\theta$  for the HMM from unlabeled data alone, and then determined the Viterbi-optimal latent states for training and test data to produce new features for a supervised classifier. The objective function for HMM learning in this case is marginal log-likelihood, optimized using the Baum-Welch algorithm:

$$\mathcal{L}(\theta) = \sum_{\mathbf{x} \in U_S \cup U_T} \log \sum_{\mathbf{y}} p(\mathbf{x}, \mathbf{Y} = \mathbf{y} | \theta) \quad (3)$$

where  $\mathbf{x}$  is a sentence,  $\mathbf{Y}$  is the sequence of latent random variables for the sentence, and  $\mathbf{y}$  is an instance of the latent sequence. The joint distribution in an HMM factors into observation and transition distributions, typically mixtures of multinomials:

$$p(\mathbf{x}, \mathbf{y} | \theta) = P(y_1) P(x_1 | y_1) \prod_{i \geq 2} P(y_i | y_{i-1}) P(x_i | y_i)$$

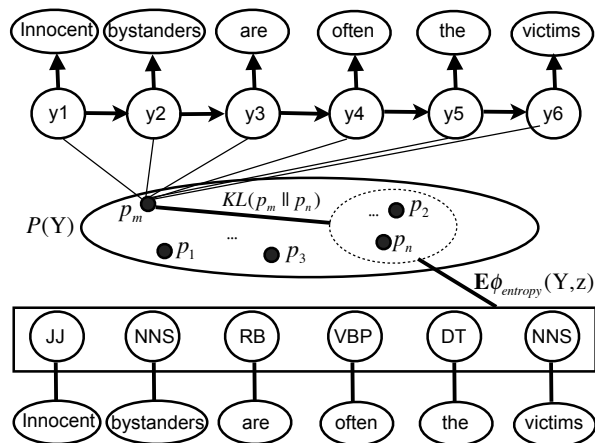

Figure 1: Illustration of how the entropy bias is incorporated into HMM learning. The dotted oval shows the space of desired distributions in the hidden space, which have small or zero entropy with the real labels. The learning algorithm aims to maximize the log-likelihood of the unlabeled data, and to minimize the KL divergence between the real distribution,  $p_m$ , and the closest desired distribution,  $p_n$ .

Intuitively, this form of representation learning identifies clusters of distributionally-similar words: those words with the same Viterbi-optimal latent state. The Viterbi-optimal latent states are then used as features for the supervised classifier. Our previous work (2009) has shown that the features from the learned HMM significantly improve the accuracy of POS taggers and chunkers on benchmark domain adaptation datasets.

We use the HMM model from our previous work (2009) as our baseline. Our techniques follow the same general setup, as it provides an efficient and empirically-proven starting point for exploring (one part of) the space of possible representations. Note, however, that the HMM on its own does not provide even an approximate solution to the objective function in our problem formulation (Eqn. 2), since it makes no attempt to find the representation that minimizes loss on labeled data. To address this and other concerns, we modify the objective function for HMM training. Specifically, we encode biases for representation learning by defining a set of *properties*  $\phi$  that we believe a good representation function would minimize. One possible bias is that the HMM states should be predictive of the labels in labeled training

data. We can encode this as a property that computes the entropy between the HMM states and the labels. For example, in Figure 1, we want to learn the best HMM distribution for the sentence “Innocent bystanders are often the victims” for POS tagging task. The hidden sequence  $y_1, y_2, y_3, y_4, y_5, y_6$  can have any distribution  $p_1, p_2, p_3, \dots, p_m, \dots, p_n$  from the latent space  $\mathcal{Y}$ . Since we are doing POS tagging, we want the distribution to learn the information encoded in the original POS labels “JJ NNS RB VBP DT NNS”. Therefore, by calculating the entropy between the hidden sequence and real labels, we can identify a subset of desired distributions that have low entropy, shown in the dotted oval. By minimizing the KL divergence between the learned distribution and the set of desired distributions, we can find the best distribution which is the closest to our desire.

The following subsections describe the specific properties we investigate; here we show how to incorporate them into the objective function. Let  $\mathbf{z}$  be the sequence of labels in  $L_S$ , and let  $\phi(\mathbf{x}, \mathbf{y}, \mathbf{z})$  be a property of the completed data that we wish the learned representation to minimize, based on our prior beliefs. Let  $Q$  be the subspace of the possible distributions over  $\mathbf{Y}$  that have a small expected value for  $\phi$ :  $Q = \{q(\mathbf{Y}) | \mathbf{E}_{\mathbf{Y} \sim q}[\phi(\mathbf{x}, \mathbf{Y}, \mathbf{z})] \leq \xi\}$ , for some constant  $\xi$ . We then add penalty terms to the objective function (3) for the divergence between the HMM distribution  $p$  and the “good” distributions  $q$ , as well as for  $\xi$ :

$$\mathcal{L}(\theta) - \min_{q, \xi} [\mathbf{KL}(q(\mathbf{Y}) || p(\mathbf{Y} | \mathbf{x}, \theta)) + \sigma |\xi|] \quad (4)$$

$$\text{s.t. } \mathbf{E}_{\mathbf{Y} \sim q}[\phi(\mathbf{x}, \mathbf{Y}, \mathbf{z})] \leq \xi \quad (5)$$

where  $\mathbf{KL}$  is the Kullback-Leibler divergence, and  $\sigma$  is a free parameter indicating how important the bias is compared with the marginal log likelihood.

To incorporate multiple biases, we define a vector of properties  $\phi$ , and we constrain each property  $\phi_i \leq \xi_i$ . Everything else remains the same, except that in the penalty term  $\sigma |\xi|$ , the absolute value is replaced with a suitable norm:  $\sigma \|\xi\|$ . To allow ourselves to place weights on the relative importance of the different biases, we use a norm of the form  $\|\mathbf{x}\|_A = \sqrt{(\mathbf{x}^t A \mathbf{x})}$ , where  $A$  is a diagonal matrix whose diagonal entries  $A_{ii}$  are free parameters that provide weights on the different properties. For our

experiments, we set the free parameters  $\sigma$  and  $A_{ii}$  using a grid search over development data, as described in Section 5.<sup>1</sup>

### 3.1 A Bias for Task-specific Representations

Current representation learning techniques are unsupervised, so they will generate the exact same representation for different tasks. Yet it is exceedingly rare that two state-of-the-art NLP systems for different tasks share the same feature set, even if they do tend to share some core set of lexical features.

Traditional non-learned (*i.e.*, manually-engineered) representations essentially always include task-specific features. In response, we propose to bias our representation learning such that the learned representations are optimized for a specific task. In particular, we propose a property that measures how difficult it is to predict the labels in training data, given the learned latent states. Our *entropy property* uses conditional entropy of the labels given the latent state as the measure of unpredictability:

$$\phi^{entropy}(\mathbf{y}, \mathbf{z}) = - \sum_i \tilde{P}(y_i, z_i) \log \tilde{P}(z_i | y_i) \quad (6)$$

where  $\tilde{P}$  is the empirical probability and  $i$  indicates the  $i$ th position in the data. We can plug this feature into Equation 5 to obtain a new version of Equation 4 as an objective function for task-specific representations. We refer to this model as **HMM+E**. Unlike previous formulations for supervised and semi-supervised dimensionality reduction (Zhang et al., 2007; Yang et al., 2006), our framework works efficiently for structured representations.

### 3.2 A Bias for Domain-Independent Features

Following the theory in Section 2.2, we devise a biased objective to provide an explicit mechanism for minimizing the distance between the source and target domain. As before, we construct a property of the completed data:

$$\phi^{distance}(\mathbf{y}) = d_1(\tilde{P}_S, \tilde{P}_T)$$

where  $\tilde{P}_S(Y)$  is the empirical distribution over latent state values estimated from source-domain latent states, and similarly for  $\tilde{P}_T(Y)$ . Essentially,

<sup>1</sup>Note that  $\xi$ , unlike  $A$  and  $\sigma$ , is not a free parameter. It is explicitly minimized in the modified objective function.

minimizing this property will bias the the representation towards features that appear approximately as often in the source domain as the target domain. We refer to the model trained with a bias of minimizing  $\phi^{distance}$  as **HMM+D**, and the model with both  $\phi^{distance}$  and  $\phi^{entropy}$  biases as **HMM+D+E**.

### 3.3 A Bias for Multi-Dimensional Representations

Words are multidimensional objects. In English, words can be nouns or verbs, singular or plural, count or mass, just to name a few dimensions along which they may vary. Factorial HMMs (FHMMs) (Ghahramani and Jordan, 1997) can learn multi-dimensional models, but inference and learning are complex and computationally expensive even in supervised settings. Our previous work (2010) created a multi-dimensional representation called an “I-HMM” by training several HMM layers independently; we showed that by finding several latent categories for each word, this representation can provide useful and domain-independent features for supervised learners. In this work, we also learn a similar multi-dimensional model (**I-HMM+D+E**), but within each layer we add in the two biases described above. While more efficient than FHMMs, the drawback of these I-HMM-based models is that there is no mechanism to encourage the different HMM models to learn different things. As a result, the layers may produce similar or equivalent features describing the dominant aspect of distributional similarity in the data, but miss features that are less strong, but still important, in the data.

To encourage learning a truly multi-dimensional representation, we add a bias towards I-HMM models in which each layer is different from all previous layers. We define an entropy-based *predictability* property that measures how predictable each previous layer is, given the current one. Formally, let  $y_i^l$  denote the hidden state at the  $i$ th position in layer  $l$  of the model. For a given layer  $l$ , this property measures the conditional entropy of  $\mathbf{y}_m$  given  $\mathbf{y}_l$ , summed over layers  $m < l$ , and subtracts this from the maximum possible entropy:

$$\phi_l^{predict}(\mathbf{y}) = MAX + \sum_{i;m < l} \tilde{P}(y_i^l, y_i^m) \log \tilde{P}(y_i^m | y_i^l)$$

The entropy between layer  $l$  and the previous layer-

$s$   $m$  measures how unpredictable the previous layers are, given layer  $l$ . By biasing the model such that  $MAX$  minus the entropy approaches zero, we encourage layer  $l$  towards completely different features from previous layers. We call the model with this bias **P-HMM+D+E**.

## 4 Efficient Parameter Estimation

Several machine learning paradigms have been developed recently for incorporating biases and constraints into parameter estimation (Liang et al., 2009; Chang et al., 2007; Mann and McCallum, 2007). We leverage the Posterior Regularization (PR) framework for our problem because of its flexibility in handling different kinds of biases; we provide a brief overview of the technique here, but see (Ganchev et al., 2010) for full details.

### 4.1 Overview of PR

PR introduces a modified EM algorithm to handle constrained objectives, like Equation 4. The modified E-step estimates a distribution  $q(\mathbf{Y})$  that is close to the current estimate of  $p(\mathbf{Y}|\mathbf{x}, \theta)$ , but also close to the ideal set of distributions that (in expectation) have  $\phi = 0$  for each property  $\phi$ . The M step remains the same, except that it re-estimates parameters with respect to expected latent states computed with  $q$  rather than  $p$ .

E step:

$$q^{t+1} = \arg \min_q \min_{\xi} \mathbf{KL}(q(\mathbf{Y})||p(\mathbf{Y}|\mathbf{x}, \theta^t)) + \sigma \|\xi\|$$

$$\text{s.t. } \mathbf{E}_q[\phi(\mathbf{x}, \mathbf{Y}, \mathbf{z})] \leq \xi$$

M step:

$$\theta^{t+1} = \operatorname{argmax}_{\theta} \mathbf{E}_{q^{t+1}}[\log p(\mathbf{x}, \mathbf{Y}|\theta^t)]$$

To make the optimization task in the E-step more tractable, PR transforms it to a dual problem:

$$\max_{\lambda \geq 0, \|\lambda\|_* \leq \sigma} -\log \sum_{\mathbf{Y}} p(\mathbf{Y}|\mathbf{x}, \theta) \exp\{-\lambda \cdot \phi(\mathbf{x}, \mathbf{Y}, \mathbf{z})\}$$

where  $\|\cdot\|_*$  is the dual norm of  $\|\cdot\|$ . The gradient of this dual objective is  $-\mathbf{E}_q[\phi(\mathbf{x}, \mathbf{Y}, \mathbf{z})]$ . A projected subgradient descent algorithm is used to perform the optimization.

### 4.2 Modifying $\phi$ for Tractability

In unstructured settings, this optimization problem is relatively straightforward. However, for structured representations, we need to ensure that the dynamic programming algorithms needed for inference remain tractable for the biased objectives. For efficient PR over structured models, the properties  $\phi$  need to be decomposed as a sum over the cliques in the structured model. Unfortunately, the properties we mention above do not decompose so nicely, so we must resort to approximations.

In order to efficiently compute the expected value of the entropy property with respect to  $\mathbf{Y} \sim q$ , we need to be able to compute each component  $\mathbf{E}_{Y_i \sim q}[\phi^{entropy}(Y_i, z_i)]$  separately. Yet  $\tilde{P}$  depends on the setting of other latent states  $Y_j$  in the corpus. To avoid this problem, we pre-compute the expected empirical distributions over the completed data. For each specific value  $y$  and  $z$ :

$$\tilde{P}_q(y, z) = \frac{1}{|L_S|} \sum_x \sum_{i=1}^{|x|} \mathbf{1}[z_i = z] q(Y_i = y)$$

$$\tilde{P}_q(y) = \frac{1}{|L_S|} \sum_x \sum_{i=1}^{|x|} q(Y_i = y)$$

These expected empirical distributions  $\tilde{P}_q$  can be computed efficiently using standard inference algorithms, such as the forward algorithm for HMMs. Note that  $\tilde{P}_q$  depends on  $q$ , but unlike the original  $\tilde{P}$  from Equation 6, they do not depend on the data completions  $\mathbf{y}$ . Thus we can compute  $\tilde{P}_q$  once for each  $q^t$ , and then substitute it for  $\tilde{P}$  for all values of  $\mathbf{Y}$  in the computation of  $\mathbf{E}_{\mathbf{Y} \sim q} \phi^{entropy}(\mathbf{Y}, \mathbf{z})$ , making this computation tractable. For the entropy-based predictability properties, the calculation is similar, but instead of using the label  $z$ , we use the decoded states  $y_i^l$  from previous layers.

For the distance property, Ben-David *et al.*'s analysis depends on a particular notion of distance (Eqn. 1) that is computationally intractable. They also propose more tractable lower bounds, but these are again incompatible with the PR framework. Since no computationally feasible exact algorithm exists for this distance feature, we resort to a crude but efficient approximation of this measure: for each pos-

sible value  $y$  of the latent states, we define:

$$\begin{aligned} \phi_y^{dist}(\mathbf{y}) &= \sum_{i|x_i \in U_S} \frac{\mathbf{1}[y_i = y]q(Y_i = y)}{|U_S|} \\ &- \sum_{i|x_i \in U_T} \frac{\mathbf{1}[y_i = y]q(Y_i = y)}{|U_T|} \end{aligned}$$

Each of these individual properties is tractable for structured models. Combining these properties using the  $\|\cdot\|_A$  norm results in a Euclidean distance (weighted by  $A$ ) between the frequencies of features in each domain, rather than  $d_1$  distance.

## 5 Experiments

We tested the structured representations with biases on two NLP tasks: Chinese POS tagging and English NER. In both cases, we use a domain adaptation setting where no labeled data is available for the target domain — a particularly difficult setting, but one that provides a strong test for an NLP system’s ability to generalize. In our work (Huang and Yates, 2009), we used a plain HMM for domain adaptation tasks in which there is labeled source data and unlabeled source and target data, but no labeled target data for training. Therefore, here, we use the HMM technique as a baseline, and build on it by including biases.

### 5.1 Chinese POS tagging

We use the UCLA Corpus of Written Chinese, which is a part of The Lancaster Corpus of Mandarin Chinese (LCMC). The UCLA Corpus consists of 11,192 sentences of word-segmented and POS-tagged text in 13 genres. We use gold-standard word segmentation labels during training and testing. The LCMC tagset consists of 50 Chinese POS tags. Each genre averages 5284 word tokens, for a total of 68,695 tokens among all genres. We use the ‘news’ genre as our source domain and randomly select 20% of every other genre as labeled test data. To train our representation models, we use the ‘news’ text, plus the remaining 80% of the texts from the other genres. We use 90% of the labeled news text for training, and 10% for development. We replace *hapax legomena* in the unlabeled data with the special symbol \*UNKNOWN\*, and also do the same for word types in the labeled test sets that never appear in our unlabeled training texts.

Figure 2: Grid search for parameters on news text

Following our previous HMM setup in (Huang and Yates, 2009) for consistency, we use an HMM with 80 latent states. For our multi-layer models, we use 7 layers of HMMs. We tuned the free parameters  $\sigma$  and  $A$  on development data. We varied  $\sigma$  from 0.1 to 1000. To tune  $A$ , we start by setting the diagonal entry for  $\phi^{entropy}$  to 1, without loss of generality. We then tie all the entries in  $A$  for  $\phi_y^{dist}$  to a single parameter  $\alpha$ , and tie all of the entries for  $\phi_y^{predict}$  to a parameter  $\beta$ . We vary  $\alpha$  and  $\beta$  over the set  $\{0.01, 0.1, 1, 10, 100\}$ . Figure 2 shows our results for  $\sigma$  and  $\alpha$  on news development data. A setting of  $\alpha = 0.01$  and  $\sigma = 100$  performs best, with all  $\sigma = 100$  doing reasonably well. Results for each of these models on the general fiction test text confirm the general trends seen on development data — a comforting sign, since this indicates we can optimize the free parameters on in-domain development data, rather than requiring labeled data from the target domain. Our models tended to perform better with increasing  $\beta$  on development data, though with diminishing returns. We pick the largest setting tested,  $\beta = 100$ , for our final models.

We use a linear-chain Conditional Random Field (CRF) for our supervised classifier. To incorporate the learned representations, we use the Viterbi Algorithm to find the optimal latent state sequence from each HMM-based model and then use the optimal states as features in the CRF. Table 1 presents the full list of features in the CRF. To handle Chinese, we add in two features introduced in previous work (Wang et al., 2009): radical features and repeated characters. A *radical* is a portion of a Chinese character that consists of a small number of pen or brush strokes in a regular pattern.

Table 1: Features used in our Chinese POS tagging CRF systems.  $c$  represents a character within a word.

Table 2 shows our results. We compare against the Baseline CRF without any additional representations and the unbiased HMM, a state-of-the-art domain adaptation technique from previous work, over all 13 domains (source and target). We also compare against a state-of-the-art Chinese POS tagger for in-domain text, the CRF-based Stanford tagger (Tseng et al., 2005), retrained for this corpus. HMM+D+E outperforms the Stanford tagger on 10 out of 12 target domains and the unbiased HMM on all domains, while the P-HMM+D+E outperforms the Stanford tagger (2.6% average improvement) and HMM (1.7%) on all 12 target domains. The I-HMM+D+E is slightly better than the HMM+D+E (.3%), but incorporating the multi-dimensional bias

(P-HMM+D+E) adds an additional 0.6% improvement.

Our interpretation for the success of I-HMM+D+E and P-HMM+D+E is that the increase in the state space of the models yields improved performance. Because P-HMM+D+E biases against redundant states found in I-HMM+D+E, it effectively increases the state space beyond I-HMM+D+E. Ahuja and Downey (2010) and our own work with HMMs as representations (2010) have previously shown that increasing the state space of the HMM can significantly improve the representation, but memory constraints eventually prevent further progress this way. The I-HMM+D+E and P-HMM+D+E models can provide similar benefits, but because they split parameters across multiple HMMs, they can accommodate much greater state spaces in the same amount of memory.

We also tested the entropy and distance biases separately. Figure 4 shows the result of the distance-biased HMM+D on the general-fiction test text, as we vary  $\sigma$  over the set  $\{0.1, 1, 10, 100, 1000\}$  (we observed similar results for other domains). For all values of  $\sigma$ , the biased representation outperforms the unbiased HMM. There is also a strong negative correlation between the expected value of  $\|\phi_{distance}\|$  and the resulting accuracy, as expected from Ben-David *et al.*'s theoretical analysis. The HMM+E model outperforms the HMM on the (source) news domain by 0.3%, but actually performs worse for most target domains. We suspect that the entropy feature, which is learned only from labeled source-domain data, makes the representation biased towards features that are important in the source domain only. However, after we add in the distance bias and a parameter to balance the weights from both biases, the representation is able to capture the label information as well as the target domain features. Thus, the representation won't solely depend on source data. HMM+D+E, which combines both biases, outperforms HMM+D, suggesting that task-specific features for domain adaptation can be helpful, but only if there is some control for the domain-independence of the features.

## 5.2 English Named Entity Recognition

To evaluate on a second task, we turn to Named Entity Recognition. We use the training data from the

Table 2: **POS tagging accuracy: The P-HMM+D+E tagger outperforms the unbiased HMM tagger and the Stanford tagger on all target domains.** The ‘avg’ column includes source-domain development data results. Differences between the P-HMM+D+E and the Stanford tagger are statistically significant at  $p < 0.01$  on average and on 11 out of 12 target domain. We used the two-tailed Chi-square test with Yates’ correction.

Figure 4: Greater distance between domains correlates with worse target-domain tagging accuracy.

CoNLL 2003 shared task for our labeled training set, consisting of 204k tokens from the newswire domain. We tested the system on the MUC7 formal run test data, consisting of 59k tokens of stories on the telecommunications and aerospace industries.

To train our representations, we use the CoNLL training data and the MUC7 training data without labels. We again use a CRF, with features introduced by Zhang and Johnson (2003) for our baseline. We use the same setting of free parameters from our POS tagging experiments.

Results are shown in Table 3. Our best biased representation P-HMM+D+E outperformed the unbiased HMM representation by 3.6%, and beats the I-HMM+D+E by 1.6%. The domain-distance and multi-dimensional biases help most, while the task-specific bias helps somewhat, but only when the domain-distance bias is included. The best sys-

tem tested on this dataset achieved a slightly better F1 score (78.84) (Turian et al., 2010), but used a much larger training corpus (they use RCV1 corpus which contains approximately 63 million tokens). Other studies (Turian et al., 2010; Huang et al., 2011) have performed a detailed comparison between these types of systems, so we concentrate on comparisons between biased and unbiased representations here.

### 5.3 Does the task-specific bias actually help?

In this section, we test whether the task-specific bias (entropy bias) actually learns something task-specific. We learn the entropy-biased representations for two tasks on the same set of sentences, labeled differently for the two tasks: English POS tagging and Named Entity Recognition. Then we switch the representations to see whether they will help or hurt the performance on the other task. We randomly picked 500 sentences from WSJ section

Representation/Task	POS Accuracy	NER F1
HMM	88.5	66.3
HMM+E(POS labels)	89.7	64.5
HMM+E(NER labels)	86.5	68.0

Table 4: Results of POS tagging and Named Entity recognition tasks with different representations. With the entropy-biased representation, the system has better performance on the task which the bias is trained for, but worse performance on the other task.

0-18 as our labeled training data and 500 sentences from WSJ section 20-23 as testing data. Because WSJ data does not have gold standard NER tags, we manually labeled these sentences with NER tags. For simplicity, we only use three types of NER tags: person, organization and location. The result is shown in Table 4. When the entropy bias uses labels from the same task as the classifier, the performance is improved: about 1.2% in accuracy on POS tagging and 1.7% in F1 score on NER. Switching the representations for the tasks actually hurts the performance compared with the unbiased representation. The results suggest that the entropy bias does indeed yield a task-specific representation.

## 6 Conclusion and Future Work

We introduce three types of biases into representation learning for sequence labeling using the PR framework. Our experiments on POS tagging and NER indicate domain-independent biases and multi-dimensional biases significantly improve the representations, while the task-specific bias improves performance on out-of-domain data if it is combined with the domain-independent bias. Our results indicate the power of representation learning in building domain-agnostic classifiers, but also the complexity of the task and the limitations of current techniques, as even the best models still fall significantly short of in-domain performance. Important considerations for future work include identifying further effective and tractable biases, and extending beyond sequence-labeling to other types of NLP tasks.

## Abstract

We introduce a novel approach named *unambiguity regularization* for unsupervised learning of probabilistic natural language grammars. The approach is based on the observation that natural language is remarkably unambiguous in the sense that only a tiny portion of the large number of possible parses of a natural language sentence are syntactically valid. We incorporate an inductive bias into grammar learning in favor of grammars that lead to unambiguous parses on natural language sentences. The resulting family of algorithms includes the expectation-maximization algorithm (EM) and its variant, Viterbi EM, as well as a so-called softmax-EM algorithm. The softmax-EM algorithm can be implemented with a simple and computationally efficient extension to standard EM. In our experiments of unsupervised dependency grammar learning, we show that unambiguity regularization is beneficial to learning, and in combination with annealing (of the regularization strength) and sparsity priors it leads to improvement over the current state of the art.

## 1 Introduction

Machine learning offers a potentially powerful approach to learning probabilistic grammars from data. Because of the high cost of manual sentence annotation, there is substantial interest in unsupervised grammar learning, i.e., the induction of a grammar from a corpus of unannotated sentences. The simplest such approaches attempt to maximize the like-

lihood of the grammar given the training data, typically using expectation-maximization (EM) (Baker, 1979; Lari and Young, 1990; Klein and Manning, 2004). More recent approaches incorporate additional prior information of the target grammar into learning. For example, Kurihara and Sato (2004) used Dirichlet priors over rule probabilities to obtain smoothed estimates of the probabilities. Johnson et al. (2007) used Dirichlet priors with hyperparameters set to values less than 1 to encourage sparsity of grammar rules. Finkel et al. (2007) and Liang et al. (2007) proposed to use the hierarchical Dirichlet process prior to bias learning towards concise grammars without the need to pre-specify the number of nonterminals. Cohen et al. (2008) and Cohen and Smith (2009) employed the logistic normal prior to model the correlations between grammar symbols. Gillenwater et al. (2010) incorporated a sparsity bias on grammar rules into learning by means of posterior regularization.

More recently, Spitkovsky et al. (2010) and Poon and Domingos (2011) observed that the use of Viterbi EM (also called hard EM) in place of standard EM can lead to significantly improved results in unsupervised learning of probabilistic grammars from natural language and image data respectively, even if no prior information is used. This finding is surprising because Viterbi EM is a degenerate case of standard EM and is therefore generally considered to be less effective in locating the optimum of the objective function. Spitkovsky et al. (2010) speculated that the observed advantage of Viterbi EM over standard EM is due to standard EM reserving too much probability mass to spurious parses in

\*Part of the work was done while at Iowa State University.

the E-step. However, it is still unclear as to why Viterbi EM can avoid this problem.

Against this background, we propose the use of a novel type of prior information for unsupervised learning of probabilistic natural language grammars, namely the syntactic unambiguity of natural language. Although it is often possible to correctly parse a natural language sentence in more than one way, natural language is remarkably unambiguous in the sense that the number of plausible parses of a natural language sentence is rather small in comparison with the total number of possible parses. Thus, we incorporate into learning an inductive bias in favor of grammars that lead to unambiguous parses on natural language sentences, by using the posterior regularization framework (Ganchev et al., 2010). We name this approach *unambiguity regularization*. The resulting family of algorithms includes standard EM and Viterbi EM, as well as an algorithm that falls between standard EM and Viterbi EM which we call softmax-EM. The softmax-EM algorithm can be implemented with a simple and computationally efficient extension to standard EM. The fact that Viterbi EM is a special case of our approach also gives an explanation of the advantage of Viterbi EM observed in previous work: it is because Viterbi EM implicitly utilizes unambiguity regularization. In our experiments of unsupervised dependency grammar learning, we show that unambiguity regularization is beneficial to learning, and in combination with annealing (of the regularization strength) and sparsity priors it leads to improvement over the current state of the art.

It should be noted that our approach is closely related to the deterministic annealing (DA) technique studied in the optimization literature (Rose, 1998). However, DA has a very different motivation than ours and differs from our approach in a few important algorithmic details, as will be discussed in section 5. When applied to unsupervised grammar learning, DA has been shown to lead to worse parsing accuracy than standard EM (Smith and Eisner, 2004); in contrast, we show that our approach leads to significantly higher parsing accuracy than standard EM in unsupervised dependency grammar learning.

The rest of the paper is organized as follows. Section 2 analyzes the degree of unambiguity of natural

language grammars. Section 3 introduces the unambiguity regularization approach and shows that standard EM, Viterbi EM and softmax-EM are its special cases. We show the experimental results in section 4, discuss related work in section 5 and conclude the paper in section 6.

## 2 The (Un)ambiguity of Natural Language Grammars

A grammar is said to be ambiguous on a sentence if the sentence can be parsed in more than one way by the grammar. It is widely acknowledged that natural language grammars are ambiguous on a significant proportion of natural language sentences. For example, Manning and Schütze (1999) show that a sentence randomly chosen from the Wall Street Journal — “The post office will hold out discounts and service concessions as incentives” — has at least five plausible syntactic parses. When we parse this sentence using the Berkeley parser (Petrov et al., 2006), one of the state-of-the-art English language parsers, we find many alternative parses in addition to the parses shown in (Manning and Schütze, 1999). Indeed, with a probabilistic context-free grammar of only 26 nonterminals (as used in the Berkeley parser), the estimated total number of possible parses<sup>1</sup> of the example sentence is  $2 \times 10^{37}$ . However, upon closer examination, we find that among this very large number of possible parses, only a few have significant probabilities. Figure 1 shows the probabilities of the 100 best parses of the example sentence. We can see that most of the parses have probabilities that are negligible compared with the probability of the best parse (i.e., the parse with the largest probability). Quantitatively, we find that the probabilities of the parses decrease roughly exponentially as we go from the best parse to the less likely parses. We confirmed this observation by examining the parses of many other natural language sentences obtained using the Berkeley parser. This observation suggests that natural language grammars are indeed remarkably unambiguous on natural language sentences, in the sense that for a typical

<sup>1</sup>Given a sentence of length  $m$  and a complete Chomsky normal form grammar with  $n$  nonterminals, the number of all possible parses is  $C_{m-1} \times n^{2m-1}$ , where  $C_{m-1}$  is the  $(m-1)$ -th Catalan number. This number is further increased if there are unary rules between nonterminals in the grammar.

Figure 1: The probabilities of the 100 best parses of the example sentence.

natural language sentence, the probability mass of the parses is concentrated to a tiny portion of all possible parses. This is not surprising in light of the fact that the main purpose of natural language is communication and in the course of language evolution the selection pressure for more efficient communication would favor unambiguous languages.

To highlight the unambiguity of natural language grammars, here we compare the parse probabilities shown in Figure 1 with the parse probabilities produced by two other probabilistic context-free grammars. In figure 2(a) we show the probabilities of the 100 best parses of the example sentence produced by a random grammar. The random grammar has a similar number of nonterminals as in the Berkeley parser, and its grammar rule probabilities are sampled from a uniform distribution and then normalized. It can be seen that unlike the natural language grammar, the random grammar produces a very uniform probability distribution over parses. Figure 2(b) shows the probabilities of the 100 best parses of the example sentence produced by a maximum-likelihood grammar learned from the unannotated Wall Street Journal corpus of the Penn Treebank using the EM algorithm. An exponential decrease can be observed in the probabilities, but the probability mass is still much less concentrated than in the case of the natural language grammar. Again, we confirmed this observation by repeating the experiments on many other natural language sentences. This suggests that both the random grammar and the maximum-likelihood grammar are far more ambiguous on natural language sentences than true natural

language grammars.

### 3 Learning with Unambiguity Regularization

Motivated by the preceding observation, we want to incorporate into learning an inductive bias in favor of grammars that are unambiguous on natural language sentences. First of all, we need a precise definition of the ambiguity of a grammar on a sentence. Assume a grammar with a fixed set of grammar rules and let  $\theta$  be the rule probabilities. Let  $x$  represent a sentence and let  $z$  represent the parse of  $x$ . One natural measurement of the ambiguity is the information entropy of  $z$  conditioned on  $x$  and  $\theta$ :

$$H(z|x, \theta) = - \sum_z p_\theta(z|x) \log p_\theta(z|x)$$

The lower the entropy is, the less ambiguous the grammar is on sentence  $x$ . When the entropy reaches 0, the grammar is strictly unambiguous on sentence  $x$ , i.e., sentence  $x$  has a unique parse according to the grammar.

Now we need to modify the objective function of grammar learning to favor low ambiguity of the learned grammar in parsing natural language sentences. One approach is to use a prior distribution that favors grammars with low ambiguity on the sentences that they generate. Since the likelihood term in the objective function would ensure that the learned grammar will have high probability of generating natural language sentences, combining the likelihood and the prior would lead to low ambiguity of the learned grammar on natural language sentences. Unfortunately, adding this prior to the objective function makes learning intractable. Hence, here we adopt an alternative approach using the posterior regularization framework (Ganchev et al., 2010). Posterior regularization biases learning in favor of solutions with desired behavior by constraining the model posteriors on the unlabeled data. In our case, we use the constraint that the probability distributions on the parses of the training sentences given the learned grammar must have low entropy, which is equivalent to requiring the learned grammar to have low ambiguity on the training sentences.

Let  $\mathbf{X} = \{x_1, x_2, \dots, x_n\}$  denote the set of training sentences,  $\mathbf{Z} = \{z_1, z_2, \dots, z_n\}$  denote the set

Figure 2: The probabilities of the 100 best parses of the example sentence produced by (a) a random grammar and (b) a maximum-likelihood grammar learned by the EM algorithm.

of parses of the training sentences, and  $\theta$  denote the rule probabilities of the grammar. We use the slack-penalized version of the posterior regularization objective function:

$$\begin{aligned}
 J(\theta) &= \log p(\theta|\mathbf{X}) \\
 &\quad - \min_{q, \xi} \left( \mathbf{KL}(q(\mathbf{Z})||p_{\theta}(\mathbf{Z}|\mathbf{X})) + \sigma \sum_i \xi_i \right) \\
 \text{s.t. } \forall i, H(z_i) &= - \sum_{z_i} q(z_i) \log q(z_i) \leq \xi_i
 \end{aligned}$$

where  $\sigma$  is a nonnegative constant that controls the strength of the regularization term;  $q$  is an auxiliary distribution such that  $q(\mathbf{Z}) = \prod_i q(z_i)$ . The first term in the objective function is the log posterior probability of the grammar parameters given the training corpus, and the second term minimizes the KL-divergence between the auxiliary distribution  $q$  and the posterior distribution on  $\mathbf{Z}$  while constrains  $q$  to have low entropy. We can incorporate the constraint into the objective function, so we get

$$\begin{aligned}
 J(\theta) &= \log p(\theta|\mathbf{X}) \\
 &\quad - \min_q \left( \mathbf{KL}(q(\mathbf{Z})||p_{\theta}(\mathbf{Z}|\mathbf{X})) + \sigma \sum_i H(z_i) \right)
 \end{aligned}$$

To optimize this objective function, we can perform coordinate ascent on a two-variable function:

$$\begin{aligned}
 F(\theta, q) &= \log p(\theta|\mathbf{X}) \\
 &\quad - \left( \mathbf{KL}(q(\mathbf{Z})||p_{\theta}(\mathbf{Z}|\mathbf{X})) + \sigma \sum_i H(z_i) \right)
 \end{aligned}$$

There are two steps in each coordinate ascent iteration. In the first step, we fix  $q$  and optimize  $\theta$ . It can be shown that

$$\begin{aligned}
 \theta^* &= \arg \max_{\theta} F(\theta, q) \\
 &= \arg \max_{\theta} \mathbf{E}_q[\log(p_{\theta}(\mathbf{X}, \mathbf{Z})p(\theta))]
 \end{aligned}$$

This is equivalent to the M-step in the EM algorithm. The second step fixes  $\theta$  and optimizes  $q$ .

$$\begin{aligned}
 q^* &= \arg \max_q F(\theta, q) \\
 &= \arg \min_q \left( \mathbf{KL}(q(\mathbf{Z})||p_{\theta}(\mathbf{Z}|\mathbf{X})) + \sigma \sum_i H(z_i) \right)
 \end{aligned}$$

It is different from the E-step of the EM algorithm in that it contains an additional regularization term  $\sigma \sum_i H(z_i)$ . Ganchev et al. (2010) propose to use the projected subgradient method to solve this optimization problem in the general case of posterior regularization. In our case, however, it is possible to obtain an analytical solution as shown below.

First, note that the optimization objective of this step can be rewritten as the sum over functions of individual training sentences.

$$\mathbf{KL}(q(\mathbf{Z})||p_{\theta}(\mathbf{Z}|\mathbf{X})) + \sigma \sum_i H(z_i) = \sum_i f_i(q)$$

where

$$\begin{aligned}
 f_i(q) &= \mathbf{KL}(q(z_i)||p_{\theta}(z_i|x_i)) + \sigma H(z_i) \\
 &= \sum_{z_i} \left( q(z_i) \log \frac{q(z_i)^{1-\sigma}}{p_{\theta}(z_i|x_i)} \right)
 \end{aligned}$$

So we can optimize  $f_i(q)$  for each training sentence  $x_i$ . The optimum of  $f_i(q)$  depends on the value of the constant  $\sigma$ .

**Case 1:**  $\sigma = 0$ .

$f_i(q)$  contains only the KL-divergence term, so the second step in the coordinate ascent iteration becomes the standard E-step of the EM algorithm.

$$q^*(z_i) = p_{\theta}(z_i|x_i)$$

**Case 2:**  $0 < \sigma < 1$ .

The space of valid assignments of the distribution  $q(z_i)$  is a unit  $(m-1)$ -simplex, where  $m$  is the number of valid parses of sentence  $x_i$ . Denote this space by  $\Delta$ .

**Theorem 1.**  $f_i(q)$  is strictly convex on the unit simplex  $\Delta$  when  $0 < \sigma < 1$ .

*Proof Sketch.* Define  $g(x) = x \log x$ , where  $g(0)$  is defined to be 0. For any  $t \in (0, 1)$ , for any two points  $q_1$  and  $q_2$  in the unit simplex  $\Delta$ , we can show that

$$\begin{aligned} & t f_i(q_1) + (1-t) f_i(q_2) - f_i(tq_1 + (1-t)q_2) \\ &= (1-\sigma) \sum_{z_i} \begin{bmatrix} t g(q_1(z_i)) + (1-t) g(q_2(z_i)) \\ -g(tq_1(z_i) + (1-t)q_2(z_i)) \end{bmatrix} \end{aligned}$$

It is easy to prove that  $g(x)$  is strictly convex on the interval  $[0, 1]$ . Because  $\forall z_i, 0 \leq q_1(z_i), q_2(z_i) \leq 1$ , we have

$$\begin{aligned} & t g(q_1(z_i)) + (1-t) g(q_2(z_i)) \\ & > g(tq_1(z_i) + (1-t)q_2(z_i)) \end{aligned}$$

Because  $1 - \sigma > 0$ , we have

$$t f_i(q_1) + (1-t) f_i(q_2) - f_i(tq_1 + (1-t)q_2) > 0$$

□

By applying the Lagrange multiplier, we get the stationary point of  $f_i(q)$  on the unit simplex  $\Delta$ :

$$q^*(z_i) = \alpha_i p_{\theta}(z_i|x_i)^{\frac{1}{1-\sigma}} \quad (1)$$

where  $\alpha_i$  is the normalization factor

$$\alpha_i = \frac{1}{\sum_{z_i} p_{\theta}(z_i|x_i)^{\frac{1}{1-\sigma}}}$$

Because  $f_i(q)$  is strictly convex on the unit simplex  $\Delta$ , this stationary point is the global minimum. Note that because  $\frac{1}{1-\sigma} > 1$ ,  $q^*(z_i)$  can be seen as the result of applying a variant of the softmax function to  $p_{\theta}(z_i|x_i)$ . To compute  $q^*$ , note that  $p_{\theta}(z_i|x_i)$  is the product of a set of grammar rule probabilities, so we can raise all the rule probabilities of the grammar to the power of  $\frac{1}{1-\sigma}$  and then run the normal E-step of the EM algorithm. The normalization of  $q^*$  is included in the normal E-step.

With  $q^*$ , the objective function becomes

$$\begin{aligned} F(\theta, q^*) &= (1-\sigma) \sum_i \log \sum_{z_i} p(z_i, x_i|\theta)^{\frac{1}{1-\sigma}} \\ &+ \log p(\theta) - \log p(\mathbf{X}) \end{aligned}$$

The first term is proportional to the log “likelihood” of the corpus computed with the exponentiated rule probabilities. So we can use the parsing algorithm to efficiently compute the value of the objective function (on the training corpus or on a separate development set) to determine when the coordinate ascent iteration shall be terminated.

**Case 3:**  $\sigma = 1$

We need to minimize

$$f_i(q) = - \sum_{z_i} (q(z_i) \log p_{\theta}(z_i|x_i))$$

Because  $\log p_{\theta}(z_i|x_i) \leq 0$  for any  $z_i$ , the minimum of  $f_i(q)$  is reached at

$$q^*(z_i) = \begin{cases} 1 & \text{if } z_i = \arg \max_{z_i} p_{\theta}(z_i|x_i) \\ 0 & \text{otherwise} \end{cases}$$

**Case 4:**  $\sigma > 1$

**Theorem 2.**  $f_i(q)$  is strictly concave on the unit simplex  $\Delta$  when  $\sigma > 1$ .

The proof is the same as that of theorem 1, except that  $1 - \sigma$  is now negative which reverses the direction of the last inequality in the proof.

**Theorem 3.** The minimum of  $f_i(q)$  is attained at a vertex of the unit simplex  $\Delta$ .

*Proof.* Assume the minimum of  $f_i(q)$  is attained at  $q^*$  that is not a vertex of the unit simplex  $\Delta$ , so there are at least two assignments of  $z_i$ , say  $z^1$  and  $z^2$ , such that  $q^*(z^1)$  and  $q^*(z^2)$  are nonzero.

Let  $q'$  be the same distribution as  $q^*$  except that  $q'(z^1) = 0$  and  $q'(z^2) = q^*(z^1) + q^*(z^2)$ . Let  $q''$  be the same distribution as  $q^*$  except that  $q''(z^1) = q^*(z^1) + q^*(z^2)$  and  $q''(z^2) = 0$ . Obviously, both  $q'$  and  $q''$  are in the unit simplex  $\Delta$  and  $q' \neq q''$ . Let  $t = \frac{q^*(z^2)}{q^*(z^1) + q^*(z^2)}$ , and obviously we have  $0 < t < 1$ . So we get  $q^* = tq' + (1-t)q''$ . According to Theorem 2,  $f_i(q)$  is strictly concave on the unit simplex  $\Delta$ , so we have  $f_i(q^*) > tf_i(q') + (1-t)f_i(q'')$ . Without loss of generality, suppose  $f_i(q') \geq f_i(q'')$ . So we have  $tf_i(q') + (1-t)f_i(q'') \geq f_i(q'')$  and therefore  $f_i(q^*) > f_i(q'')$ , which means  $f_i(q)$  does not attain the minimum at  $q^*$ . This contradicts the assumption.  $\square$

Now we need to find out at which of the vertices of the unit simplex  $\Delta$  is the minimum of  $f_i(q)$  attained. At the vertex where the probability mass is concentrated at the assignment  $z$ , the value of  $f_i(q)$  is  $-\log p_\theta(z|x_i)$ . So the minimum is attained at

$$q^*(z_i) = \begin{cases} 1 & \text{if } z_i = \arg \max_{z_i} p_\theta(z_i|x_i) \\ 0 & \text{otherwise} \end{cases}$$

It can be seen that the minimum in the case of  $\sigma > 1$  is attained at the same point as in the case of  $\sigma = 1$ , at which all the probability mass is assigned to the best parse of the sentence. So  $q^*$  can be computed using the E-step of the Viterbi EM algorithm. Denote the best parse by  $z_i^*$ . With  $q^*$ , the objective function becomes

$$F(\theta, q^*) = \sum_i \log p(z_i^*, x_i|\theta) + \log p(\theta) - \log p(\mathbf{X})$$

The first term is the sum of the log probabilities of the best parses of the corpus. So again we can use the parsing algorithm to efficiently compute it to decide when to terminate the iterative algorithm.

### Summary

Our unambiguity regularization approach is an extension of the EM algorithm. The behavior of our approach is controlled by the value of the nonnegative parameter  $\sigma$ . A larger value of  $\sigma$  corresponds to a stronger bias in favor of an unambiguous grammar. When  $\sigma = 0$ , our approach reduces to the standard EM algorithm. When  $\sigma \geq 1$ , our approach

reduces to the Viterbi EM algorithm, which considers only the best parses of the training sentences in the E-step. When  $0 < \sigma < 1$ , our approach falls between standard EM and Viterbi EM: it applies a softmax function (Eq.1) to the distributions of parses of the training sentences in the E-step. The softmax function can be computed by simply exponentiating the grammar rule probabilities before the standard E-step, which does not increase the time complexity of the E-step. We refer to the algorithm in the case of  $0 < \sigma < 1$  as the *softmax-EM* algorithm.

### 3.1 Annealing the Strength of Regularization

In unsupervised learning of probabilistic grammars, the initial grammar is typically very ambiguous (e.g., a random grammar). So we need to set  $\sigma$  to a value that is large enough to induce unambiguity. On the other hand, natural language grammars do contain some degree of ambiguity, so if the value of  $\sigma$  is too large, then the learned grammar might be excessively unambiguous and thus not a good model of natural languages. Hence, it is unclear how to choose an optimal value of  $\sigma$ .

One way to avoid choosing a fixed value of  $\sigma$  is to anneal its value. We start learning with a large value of  $\sigma$  (e.g.,  $\sigma = 1$ ) to strongly push the learner away from the highly ambiguous initial grammar; then we gradually reduce the value of  $\sigma$ , possibly ending with  $\sigma = 0$ , to avoid inducing excessive unambiguity in the learned grammar. Note that if the value of  $\sigma$  is annealed to 0, then our approach can be seen as providing an unambiguous initialization for standard EM.

### 3.2 Unambiguity Regularization with Mean-field Variational Inference

Variational inference approximates the posterior of the model given the data. It typically leads to more accurate predictions than the maximum a posteriori (MAP) estimation. In addition, for certain types of prior distributions (e.g., a Dirichlet prior with hyperparameters set to values less than 1), variational inference is able to find a solution when MAP estimation fails. Here we incorporate unambiguity regularization into mean-field variational inference.

The objective function with unambiguity regular-

ization for mean-field variational inference is:

$$F(q(\theta), q(\mathbf{Z})) = \log p(\mathbf{X}) - \left( \text{KL}(q(\theta)q(\mathbf{Z})||p(\theta, \mathbf{Z}|\mathbf{X})) + \sigma \sum_i H(z_i) \right)$$

where  $\forall i, H(z_i) = - \sum_{z_i} q(z_i) \log q(z_i)$

We can perform coordinate ascent that alternately optimizes  $q(\theta)$  and  $q(\mathbf{Z})$ . Since the regularization term does not contain  $q(\theta)$ , the optimization of  $q(\theta)$  is exactly the same as in the standard mean-field variational inference. To optimize  $q(\mathbf{Z})$ , we have

$$q^*(\mathbf{Z}) = \arg \min_{q(\mathbf{Z})} \left( \text{KL}(q(\mathbf{Z})||\tilde{p}(\mathbf{X}, \mathbf{Z})) + \sigma \sum_i H(z_i) \right)$$

where  $\tilde{p}(\mathbf{X}, \mathbf{Z})$  is defined as

$$\log \tilde{p}(\mathbf{X}, \mathbf{Z}) = E_{q(\theta)}[\log p(\theta, \mathbf{Z}, \mathbf{X})] + \text{const}$$

Now we can follow a derivation similar to that in the setting of MAP estimation with unambiguity regularization, and we can obtain a similar result but with  $p_\theta(z_i|x_i)$  replaced with  $\tilde{p}(x_i, z_i)$  in each of the four cases.

Note that if Dirichlet priors are used over grammar rule probabilities  $\theta$ , then  $\tilde{p}(x_i, z_i)$  can be represented as the product of a set of weights in mean-field variational inference (Kurihara and Sato, 2004). Therefore in order to compute  $q^*(z_i)$ , when  $0 < \sigma < 1$ , we simply need to raise all the weights to the power of  $\frac{1}{1-\sigma}$  before running the normal step of computing  $q^*(z_i)$  in standard mean-field variational inference; and when  $\sigma \geq 1$ , we can simply use the weights to find the best parse of the training sentence and assign probability 1 to it.

## 4 Experiments

We tested the effectiveness of unambiguity regularization in unsupervised learning of a type of dependency grammar called the dependency model with valence (DMV) (Klein and Manning, 2004). We report the results on the Wall Street Journal corpus (with section 2-21 for training and section 23 for testing) in section 4.1–4.3, and the results on the corpora of eight additional languages in section

Value of $\sigma$	Testing Accuracy		
	$\leq 10$	$\leq 20$	All
0 (standard EM)	46.2	39.7	34.9
0.25	53.7	44.7	<b>40.3</b>
0.5	51.9	42.9	38.8
0.75	51.6	43.1	38.8
1 (Viterbi EM)	<b>58.3</b>	<b>45.2</b>	39.4

Table 1: The dependency accuracies of grammars learned by our approach with different values of  $\sigma$ .

4.4. On each corpus, we trained the learner on the gold-standard part-of-speech tags of the sentences of length  $\leq 10$  with punctuation stripped off. We started our algorithm with the informed initialization proposed in (Klein and Manning, 2004), and terminated the algorithm when the increase in the value of the objective function fell below a threshold of 0.001%. To evaluate a learned grammar, we used the grammar to parse the testing corpus and computed the dependency accuracy which is the percentage of the dependencies that are correctly matched between the parses generated by the grammar and the gold standard parses. We report the dependency accuracy on subsets of the testing corpus corresponding to sentences of length  $\leq 10$ , length  $\leq 20$ , and the entire testing corpus.

### 4.1 Results with Different Values of $\sigma$

We compared the performance of our approach with five different values of the parameter  $\sigma$ : 0 (i.e., standard EM), 0.25, 0.5, 0.75, 1 (i.e., Viterbi EM). Table 1 shows the experimental results. It can be seen that learning with unambiguity regularization (i.e., with  $\sigma > 0$ ) consistently outperforms learning without unambiguity regularization (i.e.,  $\sigma = 0$ ). The grammar learned by Viterbi EM has significantly higher dependency accuracy in parsing short sentences. We speculate that this is because short sentences are less ambiguous and therefore a strong unambiguity regularization is especially helpful in learning the grammatical structures of short sentences. On the testing sentences of all lengths,  $\sigma = 0.25$  achieves the best dependency accuracy, which suggests that controlling the strength of unambiguity regularization can contribute to improved performance.

Table 2: The dependency accuracies of grammars learned by our approach (denoted by “UR”) with annealing and prior, compared with previous published results.

## 4.2 Results with Annealing and Prior

We annealed the value of  $\sigma$  from 1 to 0 when running our approach. We reduced the value of  $\sigma$  at a constant speed such that it reaches 0 at iteration 100. The results of this experiment (shown as “UR-Annealing” in Table 2) suggest that annealing the value of  $\sigma$  not only helps circumvent the problem of choosing an optimal value of  $\sigma$ , but may also lead to substantial improvements over the results of learning using any fixed value of  $\sigma$ .

Dirichlet priors with the hyperparameter  $\alpha$  set to a value less than 1 are often used to induce parameter sparsity. We added Dirichlet priors over grammar rule probabilities and ran the variational inference version of our approach. The value of  $\alpha$  was set to 0.25 as suggested by previous work (Cohen et al., 2008; Gillenwater et al., 2010). When tested with different values of  $\sigma$ , adding Dirichlet priors with  $\alpha = 0.25$  consistently boosted the dependency accuracy of the learned grammar by 1–2%. When the value of  $\sigma$  was annealed during variational inference with Dirichlet priors, the dependency accuracy was further improved (shown as “UR-Annealing&Prior” in Table 2).

The first part of Table 2 also compares our results with the best results that have been published in the literature for unsupervised learning of the DMV model (with different priors or regularizations than ours). It can be seen that our best result (unambiguity regularization with annealing and prior) clearly outperforms previous results. Furthermore, we ex-

pect our approach to be more computationally efficient than the other approaches, because our approach only inserts an additional parameter exponentiation step into each iteration of standard EM or variational inference, in contrast to the other three approaches all of which involve additional gradient descent optimization steps in each iteration.

## 4.3 Results on Extended Models

It has been pointed out that the DMV model is very simplistic and cannot capture many linguistic phenomena; therefore a few extensions of DMV have been proposed, which achieve significant improvement over DMV in unsupervised grammar learning (Headden et al., 2009; Blunsom and Cohn, 2010). We examined the effect of unambiguity regularization on E-DMV, an extension of DMV (with two different settings: (2,2) and (3,3)) (Headden et al., 2009; Gillenwater et al., 2010). As shown in the second part of Table 2, unambiguity regularization with annealing on E-DMV achieves better dependency accuracies than the state-of-the-art approaches to unsupervised parsing with extended dependency models. Addition of Dirichlet priors, however, did not further improve the accuracies in this setting. Note that E-DMV is an unlexicalized extension of DMV that is relatively simple. We speculate that the performance of unambiguity regularization can be further improved if applied to more advanced models like LexTSG-DMV (Blunsom and Cohn, 2010).

## 4.4 Results on More Languages

We examined the effect of unambiguity regularization with the DMV model on the corpora of eight additional languages<sup>2</sup>. The experimental results of all the nine languages are summarized in Table 3. It can be seen that learning with unambiguity regularization (i.e., with  $\sigma > 0$ ) outperforms learning without unambiguity regularization (i.e.,  $\sigma = 0$ ) on eight out of the nine languages, but the optimal value of  $\sigma$  is very different across languages. Annealing the value of  $\sigma$  from 1 to 0 does not always lead to further improvement over using the optimal value of  $\sigma$

<sup>2</sup>The corpora are from the PASCAL Challenge on Grammar Induction (<http://wiki.cs.ox.ac.uk/InducingLinguisticStructure/SharedTask>).

for each language, but on average it has better performance than using any fixed value of  $\sigma$  and hence is useful when the optimal value of  $\sigma$  is hard to identify.

## 5 Related Work

Deterministic annealing (DA) (Rose, 1998; Smith and Eisner, 2004) also extends the standard EM algorithm by exponentiating the posterior probabilities of the hidden variables in the E-step. However, the goal of DA is to improve the optimization of a non-concave objective function, which is achieved by setting the exponent in the E-step to a value *close to 0*, so that the distribution of the hidden variables becomes *nearly uniform* and the objective function becomes almost concave and therefore easy to optimize; this exponent is then gradually *increased to 1* to optimize the original objective function. In contrast, the goal of unambiguity regularization is to bias learning in favor of unambiguous grammars, which is achieved by setting the exponent in the E-step (i.e.,  $\frac{1}{1-\sigma}$  in Eq.1) to a value *larger than 1*, so that the distribution of the hidden variables becomes *less uniform* (i.e., parses become less ambiguous); in our annealing approach, the exponent is *initialized to a very large value* (positive infinity in our experiment) to push the learner away from the ambiguous initial grammar, and then gradually *decreased to 1* to avoid inducing excessive unambiguity in the learned grammar. The empirical results of Smith and Eisner (2004) show that DA resulted in lower parsing accuracy compared with standard EM in unsupervised constituent parsing; and a “skew” posterior term had to be inserted into the E-step formulation of DA to boost its accuracy over that of standard EM. In contrast, the results of our experiments show that unambiguity regularization leads to significantly higher parsing accuracy than standard EM.

Unambiguity regularization is also related to the minimum entropy regularization framework for semi-supervised learning (Grandvalet and Bengio, 2005; Smith and Eisner, 2007), which tries to minimize the entropy of the class label or hidden variables on unlabeled data in addition to maximizing the likelihood of labeled data. However, entropy regularization is either motivated by the theoretical result that unlabeled data samples are informa-

tive when classes are well separated (Grandvalet and Bengio, 2005), or derived from the expected conditional log-likelihood (Smith and Eisner, 2007). In contrast, our approach is motivated by the observed unambiguity of natural language grammars. One implication of this difference is that if our approach is applied to semi-supervised learning, the regularization term would be applied to labeled sentences as well (by ignoring the labels) because the target grammar shall be unambiguous on all the training sentences.

The sparsity bias, which favors a grammar with fewer grammar rules, has been widely used in unsupervised grammar learning (Chen, 1995; Johnson et al., 2007; Gillenwater et al., 2010). Although a more sparse grammar is often less ambiguous, in general that is not always the case. We have shown that unambiguity regularization could lead to better performance than approaches utilizing the sparsity bias, and that the two types of biases can be applied together for further improvement in the learning performance.

## 6 Conclusion

We have introduced unambiguity regularization, a novel approach to unsupervised learning of probabilistic natural language grammars. It is based on the observation that natural language grammars are remarkably unambiguous in the sense that in parsing natural language sentences they tend to concentrate the probability mass to a tiny portion of all possible parses. By using posterior regularization, we incorporate an inductive bias into learning in favor of grammars that are unambiguous on natural language sentences. The resulting family of algorithms includes standard EM and Viterbi EM, as well as the softmax-EM algorithm which falls between standard EM and Viterbi EM. The softmax-EM algorithm can be implemented by adding a simple parameter exponentiation step into standard EM. In our experiments of unsupervised dependency grammar learning, we show that unambiguity regularization is beneficial to learning, and by incorporating regularization strength annealing and sparsity priors our approach outperforms the current state-of-the-art grammar learning algorithms. For future work, we plan to combine unambiguity regularization with

## Abstract

Extracting opinion expressions from text is usually formulated as a token-level sequence labeling task tackled using Conditional Random Fields (CRFs). CRFs, however, do not readily model potentially useful segment-level information like syntactic constituent structure. Thus, we propose a semi-CRF-based approach to the task that can perform sequence labeling at the segment level. We extend the original semi-CRF model (Sarawagi and Cohen, 2004) to allow the modeling of arbitrarily long expressions while accounting for their likely syntactic structure when modeling segment boundaries. We evaluate performance on two opinion extraction tasks, and, in contrast to previous sequence labeling approaches to the task, explore the usefulness of segment-level syntactic parse features. Experimental results demonstrate that our approach outperforms state-of-the-art methods for both opinion expression tasks.

## 1 Introduction

Accurate opinion expression identification is crucial for tasks that benefit from fine-grained opinion analysis (Wiebe et al., 2005): e.g., it is a first step in characterizing the sentiment and intensity of the opinion; it provides a textual anchor for identifying the opinion holder and the target or topic of an opinion; and these, in turn, form the basis of opinion-oriented question answering and opinion summarization systems. In this paper, we focus on opinion expressions as defined in Wiebe et al. (2005) —

subjective expressions that denote emotions, sentiment, beliefs, opinions, judgments, or other *private states* (Quirk et al., 1985) in text. These include *direct subjective expressions* (DSEs): explicit mentions of private states or speech events expressing private states; and *expressive subjective expressions* (ESEs): expressions that indicate sentiment, emotion, etc. without explicitly conveying them. Following are two example sentences labeled with DSEs and ESEs.

- (1) The International Committee of the Red Cross, [as usual]<sub>[ESE]</sub>, [has refused to make any statements]<sub>[DSE]</sub>.
- (2) The Chief Minister [said]<sub>[DSE]</sub> that [the demon they have reared will eat up their own vitals]<sub>[ESE]</sub>.

As a type of information extraction task, opinion expression extraction has been successfully tackled in the past via sequence tagging methods: Choi et al. (2006) and Breck et al. (2007), for example, apply conditional random fields (CRFs) (Lafferty et al., 2001) using sophisticated token-level features. In token-level sequence labeling, labels are assigned to single tokens, and the label of each token depends on the current token and the label of the previous token (we consider the usual first-order assumption). Segment-based features — features that describe a set of related contiguous tokens, e.g., a phrase or constituent — might provide critical information for identifying opinion expressions; they cannot, however, be readily and naturally represented in the CRF model.

Our goal in this work is to extract opinion expressions at the segment level with semi-Markov conditional random fields (semi-CRFs). Semi-CRFs (Sarawagi and Cohen, 2004) are more powerful than CRFs in that they allow one to construct features to capture characteristics of the subsequences of a sentence. They are defined on semi-Markov chains where labels are attached to segments instead of tokens and label dependencies are modeled at the segment-level. Previous work has shown that semi-CRFs outperform CRFs on named entity recognition (NER) tasks (Sarawagi and Cohen, 2004; Okanohara et al., 2006). However, to the best of our knowledge, semi-CRF techniques have not been investigated for opinion expression extraction.

The contribution of this paper is a semi-CRF-based approach for opinion expression extraction that leverages parsing information to provide better modeling of opinion expressions. Specifically, possible segmentations are generated by taking into account likely syntactic structure during learning and inference. As a result, arbitrarily long expressions can be modeled and their boundaries can be influenced by probable syntactic structure. We also explore the impact of syntactic features for extracting opinion expressions.

We evaluate our model on two opinion extraction tasks: identifying direct subjective expressions (DSEs) and expressive subjective expressions (ESEs). Experimental results show that our approach outperforms the state-of-the-art approach for the task by a large margin. We also identify useful syntactic features for the task.

## 2 Related Work

Previous research to extract direct subjective expressions exists, but is mainly focused on single-word expressions (Wiebe et al., 2005; Wilson et al., 2005; Munson et al., 2005). More recent studies tackle opinion expression extraction at the expression level. Breck et al. (2007) formulate the problem as a token-level sequence labeling problem; their CRF-based approach was shown to significantly outperform two subjectivity-clue-based baselines. Others extend the token-level approach to jointly identify opinion holders (Choi et al., 2006), and to determine the polarity and inten-

sity of the opinion expressions (Choi and Cardie, 2010). Reranking the output of a simple sequence labeler has been shown to further improve the extraction of opinion expressions (Johansson and Moschitti, 2010; Johansson and Moschitti, 2011); importantly, their reranking approach relied on features that encoded syntactic structure. All of the above approaches, however, are based on token-level sequence labeling, which ignores potentially useful phrase-level information.

Semi-CRFs (Sarawagi and Cohen, 2004) are general CRFs that relax the Markovian assumptions to allow sequence labeling at the segment level. Previous work has shown that semi-CRFs are superior to CRFs for NER and Chinese word segmentation (Sarawagi and Cohen, 2004; Okanohara et al., 2006; Andrew, 2006). The task of opinion expression extraction is known to be harder than traditional NER since subjective expressions exhibit substantial lexical variation and their recognition requires more attention to linguistic structure.

Parsing has been leveraged to improve performance for numerous natural language tasks. In opinion mining, numerous studies have shown that syntactic parsing features are very helpful for opinion analysis. A lot of work uses syntactic features to identify opinion holders and opinion topics (Bethard et al., 2005; Kim and Hovy, 2006; Kobayashi et al., 2007; Joshi and Carolyn, 2009; Wu et al., 2009; Choi et al., 2005). Jakob et al. (2010) recently employed dependency path features for the extraction of opinion targets. Johansson and Moschitti (2010; Johansson and Moschitti (2011)) also successfully employed syntactic features that indicate dependency relations between opinion expressions for the task of opinion expression extraction. However, as their approach is based on the output of a sequence labeler, these features cannot be encoded to help the learning of the sequence labeler.

## 3 Approach

We formulate the extraction of opinion expressions as a sequence labeling problem. Unlike previous sequence-labeling approaches to the task (e.g., Breck et al. (2007)), however, we aim to model segment-level, rather than token-level, information. As a result, we explore the use of semi-CRFs, which

can assign labels to segments instead of tokens; hence, features can be defined at the segment level. For example, features like  $\llbracket X \text{ is a verb phrase} \rrbracket$  can be easily encoded in the model. In the following subsections, we first introduce standard semi-CRFs and then describe our semi-CRF-based approach for opinion expression extraction.

### 3.1 Semi-CRFs

In semi-CRFs, each observed sentence  $x$  is represented as a sequence of consecutive segments  $s = \langle s_1, \dots, s_n \rangle$ , where  $s_i$  is a triple  $s_i = (t_i, u_i, y_i)$ ,  $t_i$  denotes the start position of segment  $s_i$ ,  $u_i$  denotes the end position, and  $y_i$  denotes the label of the segment. Segments are restricted to have positive length less than or equal to a maximum length of  $L$  that has been seen in the corpus ( $1 \leq u_i - t_i + 1 \leq L$ ).

Features in semi-CRFs are defined at the segment level rather than the word level. The feature function  $g(i, x, s)$  is a function of  $x$ , the current segment  $s_i$ , and the label  $y_{i-1}$  of the previous segment  $s_{i-1}$  (we consider the usual first-order Markovian assumption). It can also be written as  $g(x, t_i, u_i, y_i, y_{i-1})$ . The conditional probability of a segmentation  $s$  given a sequence  $x$  is defined as

$$p(s|x) = \frac{1}{Z(x)} \exp \left\{ \sum_i \sum_k \lambda_k g_k(i, x, s) \right\} \quad (1)$$

where

$$Z(x) = \sum_{s' \in S} \exp \left\{ \sum_i \sum_k \lambda_k g_k(i, x, s') \right\}$$

and the set  $S$  contains all possible segmentations obtained from segment candidates with length ranging from 1 to the maximum length  $L$ .

The correct segmentation  $s$  of a sentence is defined as a sequence of entity segments (i.e., the entities to be extracted) and non-entity segments. For example, the correct segmentation of sentence (2) in Section 1 is  $\langle (\text{The}, \text{NONE}), (\text{Chief}, \text{NONE}), (\text{Minister}, \text{NONE}), (\text{said}, \text{DSE}), (\text{that}, \text{NONE}), (\text{the demon they have reared will eat up their own vitals}, \text{ESE}), (., \text{NONE}) \rangle$ . Here, non-entity segments are represented as unit-length segments.

### 3.2 Semi-CRF-based Approach for Opinion Expression Extraction

In this section, we present an extended version of semi-CRFs in which we can make use of parsing information in learning entity boundaries and labels for opinion expression extraction.

As discussed in Section 3.1, the maximum entity length  $L$  is fixed during training to generate segment candidates in the standard semi-CRFs. In opinion expression extraction,  $L$  is unbounded since opinion expressions may be clauses or whole sentences, which can be arbitrarily long. Thus, fixing an upper bound on segment length based on the observed entities may lead to an incorrect removal of segments during inference. Also note that possible segment candidates are generated based on the length constraint, which means any span of the text consisting of no more than  $L$  words would be considered as a possible segment. This would lead to the consideration of implausible segments, e.g., “The Chief” in sentence (2) is an incorrect segment within the multi-word expression “The Chief Minister”.

To address these problems, we propose techniques to incorporate parsing information into the modeling of segments in semi-CRFs. More specifically, we construct segment units from the parse tree of each sentence<sup>1</sup>, and then build up possible segment candidates based on those units. In the parse tree, each leaf phrase or leaf word is considered to be a segment unit. Each segment unit performs as the smallest unit in the model (words within a segment unit will be automatically assigned the same label). The segment units are highlighted in rectangles in the parse tree example in Figure 1. As the segment units are not separable, we avoid implausible segments, which truncate multi-word expressions. For example, “both ridiculous and”, would not be considered a possible segment in our model.

To generate segment candidates for the model, we consider meaningful combinations of consecutive segment units. Intuitively, a sentence is made up of several parts, and each has its own grammatical role or meaning. We define the boundary of these parts based on the parse tree structure. Specifically,

<sup>1</sup>We use the Stanford Parser <http://nlp.stanford.edu/software/lex-parser.shtml> to generate the parse trees.

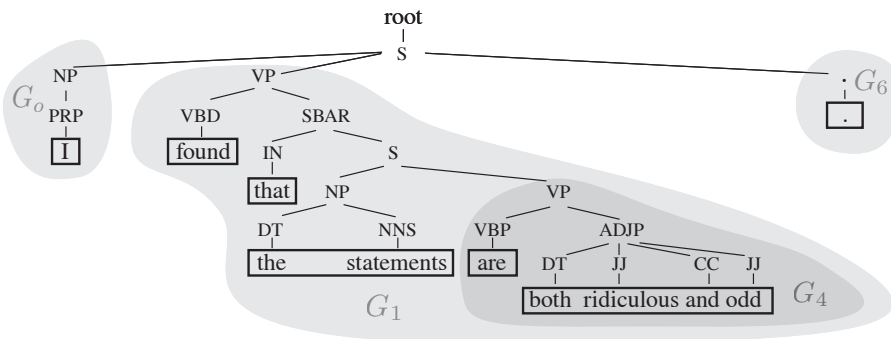

Figure 1: A parse tree example. There are seven segment units in the sentence. The shaded regions correspond to segment groups, where  $G_i$  represents the segment group starting from segment unit  $U_i$ .

we consider each segment unit to belong to a meaningful group defined by the span of its parent node. Two consecutive segment units are considered to belong to the same group if the subtrees rooted in their parent nodes have the same rightmost child. For example, in Figure 1, segment units “are” and “both ridiculous and odd” belong to the same group, while “I” and “found” belong to different groups.

---

**Algorithm 1** Construction of segment candidates

---

**Input:** A training sentence  $x$

**Output:** A set of segment candidates  $S$

---

- 1: Obtain the segment units  $U = (U_1, \dots, U_m)$  by preorder traversal of the parse tree  $T$ , each  $U_i$  corresponds to a node in  $T$
  - 2: **for**  $i = 1$  to  $m$  **do**
  - 3:    $j \leftarrow i - 1$
  - 4:   **while**  $j < m - 1$  and  
        $\text{commonGroup}(U_i, \dots, U_{j+1})$  **do**
  - 5:      $j \leftarrow j + 1$
  - 6:     **for**  $k = i$  to  $j$  **do**
  - 7:       **for**  $t = 0$  to  $j - k$  **do**
  - 8:          $s \leftarrow \text{segment}(U_k, \dots, U_{k+t})$
  - 9:          $S \leftarrow S \cup s$
  - 10: **Return**  $S$
- 

Following this idea, we generate possible segment candidates by Algorithm 1. Starting from each segment unit  $U_i$ , we first find the rightmost segment unit  $U_j$  that belongs to the same group as  $U_i$ . Function  $\text{commonGroup}(U_i, \dots, U_j)$  returns True if  $U_i, \dots, U_j$  are within the same group (the parent nodes of  $U_i, \dots, U_j$  have the same right-

most child in their subtrees), otherwise it returns False. Then we enumerate all possible combinations of segment units  $U_i, \dots, U_k$  where  $i \leq k \leq j$ .  $\text{segment}(U_i, \dots, U_j)$  denotes the segment obtained by concatenating words in the consecutive segment units  $U_i, \dots, U_j$ . This way, segment candidates are generated without constraints on length and are meaningful for learning entity boundaries.

Based on the generated segment candidates, the correct segmentation for each training sentence can be obtained as follows. For opinion expressions that do not match any segment candidate, we break them down into smaller segments using a greedy matching process. Starting from the start position of the expression, we search for the longest candidate that is contained in the expression, add it to the correct segmentation for the sentence, set the start position to be the next position, and repeat the process. Using this process, the correct segmentation of sentence (2) would be  $s = \langle (\text{The Chief Minister}, \text{NONE}), (\text{said}, \text{DSE}), (\text{that}, \text{NONE}), (\text{the demon they have reared}, \text{ESE}), (\text{will eat up their own vitals}, \text{ESE}), (.,) \rangle$ . Note that here non-entities correspond to segment units instead of single-word segments in the original semi-CRF model.<sup>2</sup>

After obtaining the set of possible segment candidates and the correct segmentation  $s$  for each training sentence, the semi-CRF model can be trained. The goal of learning is to find the optimal parameter  $\lambda$  by maximizing log-likelihood. We use the limited-

<sup>2</sup>There are cases where words within a segment unit have different labels. This may be due to errors by the human annotators or the errors in the parser. In such cases, we consider each word within the segment unit as a segment.

memory BFGS algorithm (Liu and Nocedal, 1989) for optimization in our implementation, where the gradient of the log-likelihood  $L$  (corresponding to one instance  $x$ ) is computed:

$$\frac{\partial L}{\partial \lambda_k} = \sum_i g_k(x, t_i, u_i, y_i, y_{i-1}) - \sum_{s' \in S} \sum_{y, y'} \sum_j g_k(x, t'_j, u'_j, y, y') p(y, y' | x) \quad (2)$$

where  $S$  is all possible segmentations consisting of the generated segment candidates,  $p(y, y' | x)$  is the probability of having label  $y$  for the current segment  $s'_j$  (with boundary  $(t'_j, u'_j)$ ) and label  $y'$  for the previous segment  $s'_{j-1}$ .

We use a forward-backward algorithm to compute the marginal distribution  $p(y, y' | x)$  and the normalization factor  $Z(x)$  efficiently. For inference we seek the best segmentation  $s^* = \arg \max_s p(s | x)$ , where  $p(s | x)$  is defined by Equation 1. We implement efficient inference using an extension of Viterbi algorithm to segments. In particular, define  $V(j, y)$  as the largest unnormalized probability of  $p(s_{1:j} | x)$  with label  $y$  at the ending position  $j$ . Then we have

$$V(j, y) = \max_{(i,j) \in s_{:,j}} \max_{y'} \phi(x, i, j, y, y') V(i-1, y')$$

where

$$\phi(x, i, j, y, y') = \exp \left\{ \sum_k \lambda_k g_k(x, i, j, y, y') \right\}$$

and  $s_{:,j}$  denotes the set of the generated segment candidates ending at position  $j$ . The best segmentation can be obtained from tracing the path of  $\max_y V(n, y)$ .

### 3.3 Features

Here we described the features used in our model. Very generally, we include CRF-style features that are segment-level extensions of the token-level features. We also include new segment-level features that can be naturally represented in semi-CRFs but not CRFs.

For CRF-style features, we consider the string representation of the current word, its part-of-speech, and a dictionary-derived feature, which is

based on a subjectivity lexicon provided by Wilson et al. (2005). The lexicon consists of a set of words that can act as strong or weak cues to subjectivity. If the current word appears as an entry in the lexicon, then a feature *strong* or *weak* will be fired if the entry is of that strength. These features have been successfully employed in previous work (Breck et al., 2007). To employ them in our model, we simply extend the feature definition to the segment level. For example, a token-level feature  $\llbracket x \text{ is } great \rrbracket$  will be extended to a segment-level feature  $\llbracket s \text{ contains } great \rrbracket$ .

Previous work on semi-CRFs has explored features such as the length of the segment, the position of the segment in the current segmentation (at the beginning or at the end), indicators for the start word and end word within the segment, and indicators for words before and after the segment. These features have been shown useful for the task of NE recognition (Sarawagi and Cohen, 2004; Okanojima et al., 2006). However, we only found the position of the segment to be helpful for the extraction of opinion expressions, probably due to the lack of patterns in the length distribution and word choices of opinion expressions.

Besides the above features, we design new segment-level syntactic features to capture the syntactic patterns of opinion expressions. Syntactic patterns are often used to identify useful information in information extraction tasks. In our task, we found that the majority of opinion expressions involve verb phrases.<sup>3</sup> For example, “was encouraged”, “expressed goodwill”, “cannot accept” are all within a VP constituent. To capture such structural preferences, we define several syntax-based parse features for VP-related constituents.<sup>4</sup>

Let VPROOT denote a VP constituent whose parent node is not VP, and let VPLEAF denote a VP constituent whose children nodes are non-VP. Denote the head of VPLEAF as the predicate, and its next segment unit as the argument. If a segment consists of words in the VP nodes visited by the preorder

<sup>3</sup>The percentages of opinion expressions involving VP/NP/PP are 64.13%/18.43%/5.92% for DSEs and 43.22%/24.99%/11.77% for ESEs in the data set we used.

<sup>4</sup>We also conducted experiments with NP and PP-related features, and could not find any performance improvement for the tasks.

traversal from a VPROOT to a VPLEAF, then we refer to it as a verb-cluster segment. If a segment consists of a verb cluster and the argument in VPLEAF, we consider it as a VP segment. The following features are defined for verb-cluster segments and VP segments.

**VPcluster:** Indicates whether or not the segment matches the verb-cluster structure.

**VPpred:** A feature of the syntactic category and the word of the head of VPLEAF. The head of VPLEAF is the predicate of the verb phrase, which may encode some intention of opinions in the verb phrase. For example, if “warned” is the head of VPLEAF rather than “informed”, the chance of the segment being an opinion expression increases.

**VParg:** A feature of the syntactic category and the head word of the argument in VPLEAF. For example, the noun phrase “a negative stand” is the argument of the predicate “take” in the verb phrase “take a negative stand”. The argument in the verb phrase (could be a noun phrase, adjectival phrase or prepositional phrase) may convey some relevant information for identifying opinion expressions.

**VPsubj:** Whether the verb clusters or the argument in the segment contains an entry from the subjectivity lexicon. For example, the word “negative” is in the lexicon, so the segment “take a negative stand” has a feature ISVPSUBJ.

## 4 Experiments

For evaluation, we use the MPQA 1.2 corpus (Wiebe et al., 2005)<sup>5</sup>, a widely used data set for fine-grained opinion analysis. It contains 535 news articles, a total of 11,114 sentences with subjectivity-related annotations at the phrase level. We focus on the task of extracting two types of opinion expressions: direct subjective expressions (DSEs) and expressive subjective expressions (ESEs). Table 1 shows some statistics of the corpus. As in prior research that uses the corpus, we set aside the standard 135 documents as a development set and use 400 documents as the evaluation set. All experiments employ 10-fold cross validation on the evaluation set, and the average over all runs is reported.

<sup>5</sup>Available at <http://www.cs.pitt.edu/mpqa/>.

	DSEs	ESEs
Sentences with opinions(%)	55.89	57.93
TotalNum	9746	11730
MaxLength	15	40
Length $\geq 1$ (%)	43.38	71.65
Length $\geq 4$ (%)	9.44	35.01

Table 1: Statistics of opinion expressions in the MPQA Corpus.

### 4.1 Evaluation Metrics

We use precision, recall, and F-measure to evaluate the quality of the model. Precision is defined as  $\frac{|C \cap P|}{|P|}$  and recall, as  $\frac{|C \cap P|}{|C|}$ , where  $C$  and  $P$  are the sets of correct and predicted expression spans, respectively. F-measure is computed as  $\frac{2PR}{P+R}$ . Because the boundaries of opinion expressions are hard to define even for human annotators (Wiebe et al., 2005), previous research mainly focused on soft precision and recall measures for performance evaluation. Breck et al. (2007) introduced an overlap measure, which considers a predicted expression to be correct if it overlaps with a correct expression. We refer to this metric as *Binary Overlap*. Johanson and Moschitti (2010) provides a stricter measure that computes the proportion of overlapping spans: if a correct expression  $s$  overlaps with a predicted expression  $s'$ , the overlap contributes value  $\frac{|s \cap s'|}{|s'|}$  to  $|C \cap P|$  instead of value 1. We refer to this metric as *Proportional Overlap*. To compare with previous work, we present our results according to both metrics.

### 4.2 Baseline Methods

As a baseline, we use the token-level CRF-based approach of Breck et al. (2007) applied to the MPQA dataset. We employ a very similar, but not identical set of features: indicators for specific words at the current location and neighboring words in a  $[-4, +4]$  window, part-of-speech features, and opinion lexicon features for tokens that are contained in the subjectivity lexicon (see Section 3.3). We do not include WordNet, Levin’s verb categorization, and FrameNet features.

We also include two variants of standard CRFs as baselines: segment-CRF and syntactic-CRF. They incorporate segmentation information into standard CRFs without modifying the Markovian assump-

Method	DSE Extraction			ESE Extraction		
	Precision	Recall	F-measure	Precision	Recall	F-measure
CRF	82.83	49.38	61.87	78.56	43.57	56.05
segment-CRF	82.52	51.48	63.41	78.90	44.46	56.88

Table 3: Results for extracting opinion expressions with Proportional-Overlap metric. Notation is the same as above.

tion. Segment-CRF treats segment units obtained from the parser as word tokens. For example, in Figure 1, the segment units *the statement* and *both ridiculous and odd* will be treated as word tokens. Syntactic-CRF encodes segment-level syntactic information in a standard token-level CRF as input features. We consider the VP-related segment features introduced in Section 3.3. VPPRE and VPARG are added to the head word of the corresponding verb phrase, and VPSUBJ and VPCLUSTER are added to each token within the corresponding segment.

Another baseline method is the original semi-CRF model (Sarawagi and Cohen, 2004). To the best of our knowledge, our work is the first to explore the use of semi-CRFs on the extraction of opinion expressions. They are considered to be more powerful than CRFs since they allow information to be represented at the expression level. The model requires an input of the maximum entity length. We set it to 15 for DSE and 40 for ESE. For segment features, we used the same features as in our approach (see Section 3.3).

### 4.3 Results

Table 2 and Table 3 show the results of DSE and ESE extraction using two different metrics. The standard token-based CRF baseline of Breck et al. (2007) is labeled **CRF**; the original semi-CRF baseline is labeled **semi-CRF**; and our extended semi-CRF approach is labeled **new-semi-CRF**. For semi-CRF and new-semi-CRF, the results were obtained using two different settings of features: the basic feature set includes features described in Section 3.3 excluding the segment-level syntactic features. In the second feature setting (labeled as **w/ syn** in the tables), we further augment the basic features with the syntactic parse features.

Using the basic features, we observe that semi-CRF-based approaches significantly outperform CRF and its two variants segment-CRF and syntactic-CRF in F-Measure on both DSE and ESE extraction, and new-semi-CRF achieves the best results. By simply incorporating the segmentation prior into the standard CRF, segment-CRF achieves a slight improvement over standard CRF, but the results are still worse than those of semi-CRF and new-semi-CRF. However, adding segment-level

Table 4: Effect of syntactic features on extracting opinion expressions with Binary-Overlap metric

syntactic features into standard CRF yields slightly reduced performance. This is not surprising as encoding segment-level information into the token-level CRF is not natural. These experiments indicate that simply encoding segmentation information into standard CRF cannot result in large performance gains. The promising F-measure results obtained by semi-CRF and new-semi-CRF confirm that relaxing the Markovian assumption on segments leads to better modeling of opinion expressions. We can also see that new-semi-CRF consistently outperforms the original semi-CRF model. This further confirms the benefit of taking into account syntactic parsing information in modeling segments. In Table 3, we observe the same general results trend as in Table 2. The scores are generally lower since the metric *Proportional Overlap* is stricter than *Binary Overlap*.

We also study the impact of syntactic parse features on the semi-Markov CRF models. Here we consider the combination of VPPRE, VPARG and VPSUBJ since they turned out to be the most helpful features for our tasks. Interestingly, we found that after incorporating the syntactic parse features, performance decreases on semi-CRF. This indicates that syntactic information does not help if learning and inference take place on segment candidates generated without accounting for parse information. In contrast, our approach incorporates syntactic parsing information in modeling segments and meaningful segmentations. We can see in Tables 2 and 3 that adding syntactic features successfully boosts the performance of our approach.

To further explore the effect of the syntactic fea-

tures, we include the results of our model with different configurations of syntactic features in Table 4 (here we focus on the *Binary Overlap* metric as the results with *Proportional Overlap* demonstrate a similar conclusion). We can see that using the basic features and the combination of VPPRE, VPARG and VPSUBJ yields the best results for both DSE and ESE extraction. For DSE extraction, combining these three features improves the precision noticeably from 67.72% to 70.12% while the recall slightly improves. This indicates that VP-related structural information is very helpful for modeling segments as DSEs. However, this trend is not so clear for ESE extraction. This may be due to the fact that DSEs often involve verb phrases while ESEs are represented via a variety of syntactic structures.

**Comparison with previous work.** In Table 5, we compare our results to the previous work on opinion expression extraction (here we also focus on the *Binary Overlap* metric due to the similar trend demonstrated by the *Proportional Overlap* metric). Breck et al. (2007) presents the state-of-the-art sequence labeling approach on the tasks of DSE and ESE extraction. Their best results are shown as **Breck et al. Baseline** in the table. Johansson and Moschitti (2010) use a reranking technique on the best  $k$  outputs of a sequence labeler to further improve their sequence labeling results on the task of extracting DSEs, ESEs and OSEs (Objective Speech Events) (we don't consider OSEs here). Results using our re-implementation of their approach using *SVM<sup>struct</sup>* (Tsochantaridis et al., 2004) on the output of CRF are labeled **CRF+Reranking Baseline** in the table. We use the same features and

parameter settings as in their approach. **Our approach+Reranking** are results obtained by applying the reranking step on the output of our new-semi-CRF approach.

We can see that our approach outperforms the Breck et al. Baseline on both DSE extraction and ESE extraction in spite of the fact that we do not use their WordNet, Levin’s verb categorization, and FrameNet features. The CRF+Reranking Baseline does provide a performance increase over the the baseline CRF results, but overall it cannot beat the other methods since the CRF baseline is very low. As one might expect, reranking also succeeds in boosting the performance of new-semi-CRF, achieving the best performance on F-measure for both DSE and ESE extraction. Note that the interannotator agreement results for these two tasks are 75% for DSE and 72% for ESE using a similar metric to *Binary Overlap*. Our results are much closer to these interannotator scores than previous systems especially for DSEs.

Task	Method	F-measure
DSE Extraction	Breck et al. Baseline	70.65
	CRF+Reranking Baseline	63.87
	Our approach	72.36
	Our approach+Reranking	<b>73.12</b>
ESE Extraction	Breck et al. Baseline	63.43
	CRF+Reranking Baseline	58.21
	Our approach	65.67
	Our approach+Reranking	<b>67.01</b>

Table 5: Comparison of our work with previous work on opinion expression extraction using the Binary-Overlap metric

#### 4.4 Discussion

We note that our new-semi-CRF approach outperforms the original semi-CRF w.r.t. both precision and recall, but compared to CRF, our approach yields a clear improvement on recall but not on precision. An error analysis helps explain why. We found that our semi-CRF approach predicted almost the same number of DSEs as the gold standard labels while CRF only predicted half of them (for ESE extraction, the trend is similar). With more predicted entities, the precision is sacrificed but recall is boosted substantially, and overall we see an increase in F-measure.

Looking further into the errors, we found several mistakes that could potentially be fixed to yield better a precision score. Some errors were due to the false prediction of speech events like “said” or “told” as DSEs in cases where they actually just introduced statements of fact without expressing any private state. Adding features to distinguish such cases should help improve performance. Other errors were due to inadequate modeling of the context surrounding the expressions. For example, “enjoy a relative advantage” was falsely predicted as an ESE. If incorporating information about the subject of this verb phrase which is “products”, this mistake could be avoided since “products” cannot hold or express private state. We also noticed some errors caused by inaccurate parsing and hope to study ways to account for these in our approach as future work.

By comparing the extraction results across different methods, we see that full parsing provides many benefits for modeling segment boundaries and improving the prediction precision for opinion expression extraction. For example, given the sentence, “... who are living [a lot better]<sub>[ESE]</sub> ...”, both CRF and the original semi-CRF extract “lot better” as an ESE, while our approach correctly extracts “a lot better” as an ESE. And we also found many cases where the original semi-CRF cannot extract the opinion expressions while our approach can. Another benefit of utilizing parsing is to speed up learning and inference. Although in theory, the computational cost of parsing is  $O(g \times n^3)$  where  $g$  is the grammar size and  $n$  is the sentence length while the cost of semi-CRFs is  $O(K^2 \times L \times n)$  where  $K$  is the number of labels and  $L$  is the maximum entity length, feature extraction overhead and the potentially large number of learning iterations in parameter optimization may lead to a long training time for semi-CRFs. In our experiments on the MPQA data set, our machine with Intel Core 2 Duo CPU and 4GB RAM took 2 hours to fully parse 11,114 sentences using the Stanford Parser, and also 2 hours to train the standard semi-CRF. With the parsing information, our semi-CRF-based approach is able to finish training in 15 minutes. As full parsing would be expensive when the average sentence length is very large, it would be interesting to study how to utilize parsing with less cost in our task.

## 5 Conclusion

In this paper we propose a semi-CRF-based approach for extracting opinion expressions that takes into account during learning and inference the structural information available from syntactic parsing. Our approach allows opinion expressions to be identified at the segment level and their boundaries to be influenced by their probable syntactic structure. Experimental evaluations show that our model outperforms the best existing approaches on two opinion extraction tasks. In addition, we identify useful syntactic parse features for these tasks that have not been explored in previous work. Our error analysis indicates that adding additional features that account for subjectivity cues in the local context might further improve the performance. In future work, we hope to explore better ways of utilizing parsing information with less cost. Also, we will apply our model to additional opinion analysis tasks such as fine-grained opinion summarization and relation extraction.

## Abstract

This paper proposes a novel approach to extract opinion targets based on word-based translation model (WTM). At first, we apply WTM in a monolingual scenario to mine the associations between opinion targets and opinion words. Then, a graph-based algorithm is exploited to extract opinion targets, where candidate opinion relevance estimated from the mined associations, is incorporated with candidate importance to generate a global measure. By using WTM, our method can capture opinion relations more precisely, especially for long-span relations. In particular, compared with previous syntax-based methods, our method can effectively avoid noises from parsing errors when dealing with informal texts in large Web corpora. By using graph-based algorithm, opinion targets are extracted in a global process, which can effectively alleviate the problem of error propagation in traditional bootstrap-based methods, such as *Double Propagation*. The experimental results on three real world datasets in different sizes and languages show that our approach is more effective and robust than state-of-art methods.

## 1 Introduction

With the rapid development of e-commerce, most customers express their opinions on various kinds of entities, such as products and services. These reviews not only provide customers with useful information for reference, but also are valuable for

merchants to get the feedback from customers and enhance the qualities of their products or services. Therefore, mining opinions from these vast amounts of reviews becomes urgent, and has attracted a lot of attentions from many researchers.

In opinion mining, one fundamental problem is opinion target extraction. This task is to extract items which opinions are expressed on. In reviews, opinion targets are usually nouns/noun phrases. For example, in the sentence of “*The phone has a colorful and even amazing screen*”, “*screen*” is an opinion target. In online product reviews, opinion targets often are products or product features, so this task is also named as product feature extraction in previous work (Hu et al., 2004; Ding et al., 2008; Liu et al., 2005; Popescu et al., 2005; Wu et al., 2005; Su et al., 2008).

To extract opinion targets, many studies regarded opinion words as strong indicators (Hu et al., 2004; Popescu et al., 2005; Liu et al., 2005; Qiu et al., 2011; Zhang et al., 2010), which is based on the observation that opinion words are usually located around opinion targets, and there are associations between them. Therefore, most pervious methods iteratively extracted opinion targets depending upon the associations between opinion words and opinion targets (Qiu et al., 2011; Zhang et al., 2010). For example, “*colorful*” and “*amazing*” is usually used to modify “*screen*” in reviews about cell phone, so there are strong associations between them. If “*colorful*” and “*amazing*” had been known to be opinion words, “*screen*” is likely to be an opinion target in this domain. In addition, the extracted opinion targets can be used to expand more opinion words according to their associations. It’s a mutual reinforcement procedure.

Therefore, mining associations between opinion targets and opinion words is a key for opinion

target extraction (Wu et al., 2009). To this end, most previous methods (Hu et al., 2004; Ding et al., 2004; Wang et al., 2008), named as *adjacent methods*, employed the *adjacent rule*, where an opinion target was regarded to have opinion relations with the surrounding opinion words in a given window. However, because of the limitation of window size, opinion relations cannot be captured precisely, especially for long-span relations, which would hurt estimating associations between opinion targets and opinion words. To resolve this problem, several studies exploited syntactic information such as dependency trees (Popescu et al., 2005; Qiu et al., 2009; Qiu et al., 2011; Wu et al., 2009; Zhang et al., 2010). If the syntactic relation between an opinion word and an opinion target satisfied a designed pattern, then there was an opinion relation between them. Experiments consistently reported that *syntax-based methods* could yield better performance than *adjacent methods* for small or medium corpora (Zhang et al., 2010). The performance of *syntax-based methods* heavily depends on the parsing performance. However, online reviews are often informal texts (including grammar mistakes, typos, improper punctuations etc.). As a result, parsing may generate many mistakes. Thus, for large corpora from Web including a great deal of informal texts, these *syntax-based methods* may suffer from parsing errors and introduce many noises. Furthermore, this problem maybe more serious on non-English language reviews, such as Chinese reviews, because that the performances of parsing on these languages are often worse than that on English.

To overcome the weakness of the two kinds of methods mentioned above, we propose a novel unsupervised approach to extract opinion targets by using word-based translation model (WTM). We formulate identifying opinion relations between opinion targets and opinion words as a word alignment task. We argue that an opinion target can find its corresponding modifier through monolingual word alignment. For example in Figure 1, the opinion words “colorful” and “amazing” are aligned with the target “screen” through word alignment. To this end, we use WTM to perform monolingual word alignment for mining associations between opinion targets and opinion words. In this process, several factors, such as word co-occurrence frequencies, word positions

etc., can be considered globally. Compared with *adjacent methods*, WTM doesn’t identify opinion relations between words in a given window, so long-span relations can be effectively captured (Liu et al., 2009). Compared with *syntax-based methods*, without using parsing, WTM can effectively avoid errors from parsing informal texts. So it will be more robust. In addition, by using WTM, our method can capture the “one-to-many” or “many-to-one” relations (“one-to-many” means that, in a sentence one opinion word modifies several opinion targets, and “many-to-one” means several opinion words modify one opinion target). Thus, it’s reasonable to expect that WTM is likely to yield better performance than traditional methods for mining associations between opinion targets and opinion words.

Based on the mined associations, we extract opinion targets in a ranking framework. All nouns/noun phrases are regarded as opinion target candidates. Then a graph-based algorithm is exploited to assign confidences to each candidate, in which candidate opinion relevance and importance are incorporated to generate a global measure. At last, the candidates with higher ranks are extracted as opinion targets. Compared with most traditional methods (Hu et al. 2004; Liu et al., 2005; Qiu et al., 2011), we don’t extract opinion targets iteratively based on the bootstrapping strategy, such as *Double Propagation* (Qiu et al., 2011), instead all candidates are dynamically ranked in a global process. Therefore, error propagation can be effectively avoided and the performance can be improved.

Figure 1: Word-based translation model for opinion relation identification

The main contributions of this paper are as follows.

- 1) We formulate the opinion relation identification between opinion targets and opinion words as a word alignment task. To our best knowledge, none of previous methods deal with this task using monolingual word alignment model (in Section 3.1).

- 2) We propose a graph-based algorithm for opinion target extraction in which candidate opinion relevance and importance are incorporated into a unified graph to estimate candidate confidence. Then the candidates with higher confidence scores are extracted as opinion targets (in Section 3.2).
- 3) We have performed experiments on three datasets in different sizes and languages. The experimental results show that our approach can achieve performance improvement over the traditional methods. (in Section 4).

The rest of the paper is organized as follows. In the next section, we will review related work in brief. Section 3 describes our approach in detail. Then experimental results will be given in Section 4. At the same time, we will give some analysis about the results. Finally, we give the conclusion and the future work.

## 2 Related Work

Many studies have focused on the task of opinion target extraction, such as (Hu et al., 2004; Ding et al., 2008; Liu et al., 2006; Popescu et al., 2005; Wu et al., 2005; Wang et al., 2008; Li et al., 2010; Su et al., 2008; Li et al., 2006). In general, the existing approaches can be divided into two main categories: supervised and unsupervised methods.

In supervised approaches, the opinion target extraction task was usually regarded as a sequence labeling task (Jin et al. 2009; Li et al. 2010; Wu et al., 2009; Ma et al. 2010; Zhang et al., 2009). Jin et al. (2009) proposed a lexicalized HMM model to perform opinion mining. Li et al. (2010) proposed a Skip-Tree CRF model for opinion target extraction. Their methods exploited three structures including linear-chain structure, syntactic structure, and conjunction structure. In addition, Wu et al. (2009) utilized a SVM classifier to identify relations between opinion targets and opinion expressions by leveraging phrase dependency parsing. The main limitation of these supervised methods is that labeling training data for each domain is impracticable because of the diversity of the review domains.

In unsupervised methods, most approaches regarded opinion words as the important indicators for opinion targets (Hu et al., 2004; Popescu et al., 2005; Wang et al., 2008; Qiu et al., 2011; Zhang et al., 2010). The basic idea was that reviewers often

use the same opinion words when they comment on the similar opinion targets. The extraction procedure was often a bootstrapping process which extracted opinion words and opinion targets iteratively, depending upon their associations. Popescu et al. (2005) used syntactic patterns to extract opinion target candidates. After that they computed the point-wise mutual information (PMI) score between a candidate and a product category to refine the extracted results. Hu et al. (2004) exploited an association rule mining algorithm and frequency information to extract frequent explicit product features. The adjective nearest to the frequent explicit feature was extracted as an opinion word. Then the extracted opinion words were used to extract infrequent opinion targets. Wang et al. (2008) adopted the similar idea, but their method needed a few seeds to weakly supervise the extraction process. Qiu et al. (2009, 2011) proposed a *Double Propagation* method to expand a domain sentiment lexicon and an opinion target set iteratively. They exploited direct dependency relations between words to extract opinion targets and opinion words iteratively. The main limitation of Qiu's method is that the patterns based on dependency parsing tree may introduce many noises for the large corpora (Zhang et al., 2010). Meanwhile, *Double Propagation* is a bootstrapping strategy which is a greedy process and has the problem of error propagation. Zhang et al. (2010) extended Qiu's method. Besides the patterns used in Qiu's method, they adopted some other patterns, such as phrase patterns, sentence patterns and "no" pattern, to increase recall. In addition they used the HITS (Klernberg et al., 1999) algorithm to compute the feature relevance scores, which were simply multiplied by the log of feature frequencies to rank the extracted opinion targets. In this way, the precision of result can be improved.

## 3 Opinion Target Extraction Using Word-Based Translation Model

### 3.1 Method Framework

As mentioned in the first section, our approach for opinion target extraction is composed of the following two main components:

- 1) *Mining associations between opinion targets and opinion words*: Given a collection of reviews, we adopt a word-based translation

model to identify potential opinion relations in all sentences, and then the associations between opinion targets and opinion words are estimated.

- 2) **Candidate confidence estimation:** Based on these associations, we exploit a graph-based algorithm to compute the confidence of each opinion target candidate. Then the candidates with higher confidence scores are extracted as opinion targets.

### 3.2 Mining associations between opinion targets and opinion words using Word-based Translation Model

This component is to identify potential opinion relations in sentences and estimate associations between opinion targets and opinion words. We assume opinion targets and opinion words respectively to be nouns/noun phrases and adjectives, which have been widely adopted in previous work (Hu et al., 2004; Ding et al., 2008; Wang et al., 2008; Qiu et al., 2011). Thus, our aim is to find potential opinion relations between nouns/noun phrases and adjectives in sentences, and calculate the associations between them. As mentioned in the first section, we formulate opinion relation identification as a word alignment task. We employ the word-based translation model (Brown et al. 1993) to perform monolingual word alignment, which has been widely used in many tasks, such as collocation extraction (Liu et al., 2009), question retrieval (Zhou et al., 2011) and so on. In our method, every sentence is replicated to generate a parallel corpus, and we apply the bilingual word alignment algorithm to the monolingual scenario to align a noun/noun phrase with its modifier.

Given a sentence with  $n$  words  $S = \{w_1, w_2, \dots, w_n\}$ , the word alignment  $A = \{(i, a_i) | i \in [1, n]\}$  can be obtained by maximizing the word alignment probability of the sentence as follows.

$$\hat{A} = \arg \max_A P(A | S) \quad (1)$$

where  $(i, a_i)$  means that a noun/noun phrase at position  $i$  is aligned with an adjective at position  $a_i$ . If we directly use this alignment model to our task, a noun/noun phrase may align with the irrelevant

words other than adjectives, like prepositions or conjunctions and so on. Thus, in the alignment procedure, we introduce some constraints: 1) nouns/noun phrases (adjectives) must be aligned with adjectives (nouns/noun phrases) or null words; 2) other words can only align with themselves.

Totally, we employ the following 3 WTMs (IBM 1~3) to identify opinion relations.

$$\begin{aligned} P_{IBM-1}(A | S) &\propto \prod_{j=1}^n t(w_j | w_{a_j}) \\ P_{IBM-2}(A | S) &\propto \prod_{j=1}^n t(w_j | w_{a_j}) d(j | a_j, n) \\ P_{IBM-3}(A | S) &\propto \prod_{i=1}^n n(\phi_i | w_i) \prod_{j=1}^n t(w_j | w_{a_j}) d(j | a_j, n) \end{aligned} \quad (2)$$

There are three main factors:  $t(w_j | w_{a_j})$ ,  $d(j | a_j, n)$  and  $n(\phi_i | w_i)$ , which respectively models different information.

- 1)  $t(w_j | w_{a_j})$  models the co-occurrence information of two words in corpora. If an adjective co-occurs with a noun/noun phrase frequently in the reviews, this adjective has high association with this noun/noun phrase. For example, in reviews of cell phone, “big” often co-occurs with “phone’s size”, so “big” has high association with “phone’s size”.

- 2)  $d(j | a_j, l)$  models word position information, which describes the probability of a word in position  $a_j$  aligned with a word in position  $j$ .

- 3)  $n(\phi_i | w_i)$  models the fertility of words, which describe the ability of a word for “one-to-many” alignment.  $\phi_i$  denotes the number of words that are aligned with  $w_i$ . For example, “Iphone4 has amazing screen and software”. In this sentence, “amazing” is used to modify two words: “screen” and “software”. So  $\phi$  equals to 2 for “amazing”.

Therefore, in Eq. (2),  $P_{IBM-1}(A | S)$  only models word co-occurrence information.  $P_{IBM-2}(A | S)$  additionally employs word position information. Besides these two information,  $P_{IBM-3}(A | S)$  considers the ability of a word for “one-to-many” alignment. In the following experiments section, we will discuss the performance difference among these models in detail. Moreover, these models

may capture “one-to-many” or “many-to-one” opinion relations (mentioned in the first section). In our knowledge, it isn’t specifically considered by previous methods including *adjacent methods* and *syntax-based methods*. Meanwhile, the alignment results may contain empty-word alignments, which means a noun/noun phrase has no modifier or an adjective modify nothing in the sentence.

After gathering all word pairs from the review sentences, we can estimate the translation probabilities between nouns/noun phrases and adjectives as follows.

$$p(w_N | w_A) = \frac{\text{Count}(w_N, w_A)}{\text{Count}(w_A)} \quad (3)$$

where  $p(w_N | w_A)$  means the translation probabilities from adjectives to nouns/noun phrases. Similarly, we can obtain translation probability  $p(w_A | w_N)$ . Therefore, similar to (Liu et al. 2009), the association between a noun/noun phrase and an adjective is estimated as follows.

$$\text{Association}(w_N, w_A) = (t/p(w_N | w_A) + (1-t)/p(w_A | w_N))^{-1} \quad (4)$$

where  $t$  is the harmonic factor to combine these two translation probabilities. In this paper, we set  $t = 0.5$ . For demonstration, we give some examples in Table 1. We can see that our method using WTM can successfully capture associations between opinion targets and opinion words.

	battery life	sound	software

poor	0.032	0.000	0.026
long	0.025	0.000	0.000

Table 1: Examples of associations between opinion targets and opinion words.

### 3.3 Candidate Confidence Estimation

In this component, we compute the confidence of each opinion target candidate and rank them. The candidates with higher confidence are regarded as the opinion targets. We argue that the confidence of a candidate is determined by two factors: 1) *Opinion Relevance*; 2) *Candidate Importance*.

**Opinion Relevance** reflects the degree that a candidate is associated to opinion words. If an adjective has higher confidence to be an opinion word, the noun/noun phrase it modifies will have higher confidence to be an opinion target.

Similarly, if a noun/noun phrase has higher confidence to be an opinion target, the adjective which modifies it will be highly possible to be an opinion word. It’s an iterative reinforcement process, which indicates that existing graph-based algorithms are applicable.

**Candidate Importance** reflects the salience of a candidate in the corpus. We assign an importance score to an opinion target candidate  $f$  according to its *tf-idf* score, which is further normalized by the sum of *tf-idf* scores of all candidates.

$$\text{Importance}(c) = \frac{\text{tf-idf}(c)}{\sum_c \text{tf-idf}(c)} \quad (5)$$

where  $c$  represents a candidate,  $tf$  is the term frequency in the dataset, and  $df$  is computed by using the Google n-gram corpus<sup>1</sup>.

To model these two factors, a bipartite graph is constructed, the vertices of which include all nouns/noun phrases and adjectives. As shown in Figure 2, the white vertices represent nouns/noun phrases and the gray vertices represent adjectives. An edge between a noun/noun phrase and an adjective represents that there is an opinion relation between them. The weight on the edges represents the association between them, which are estimated by using WTM, as shown in Eq. (4).

To estimate the confidence of each candidate on this bipartite graph, we exploit a graph-based algorithm, where we use  $C$  to represent candidate confidence vector, a  $n \times 1$  vector. We set the candidate initial confidence with candidate importance score, i.e.  $C^0 = S$ , where  $S$  is the candidate initial confidence vector and each item in  $S$  is computed using Eq. (5).

Figure 2: Bipartite graph for modeling relations between opinion targets and opinion words

<sup>1</sup> <http://books.google.com/ngrams/datasets>

Then we compute the candidate confidence by using the following iterative formula.

$$C^{t+1} = M^T \times M \times C^t \quad (6)$$

where  $C^t$  is the candidate confidence vector at time  $t$ , and  $C^{t+1}$  is the candidate confidence vector at time  $t+1$ .  $M$  is an opinion relevance matrix, a  $m \times n$  matrix, where  $M_{i,j}$  is the associated weight between a noun/noun phrase  $i$  and an adjective  $j$ .

To consider the candidate importance scores, we introduce a reallocate condition: combining the candidate opinion relevance with the candidate importance at each step. Thus we can get the final recursive form of the candidate confidence as follows.

$$C^{t+1} = (1-\lambda) \times M^T \times M \times C^t + \lambda \times S \quad (7)$$

where  $\lambda \in [0,1]$  is the proportion of candidate importance in the candidate confidence. When  $\lambda=1$ , the candidate confidence is completely determined by the candidate importance; and when  $\lambda=0$ , the candidate confidence is determined by the candidate opinion relevance. We will discuss its effect in the section of experiments.

To solve Eq. (7), we rewrite it as the following form.

$$C = \lambda \times (I - (1-\lambda) \times M^T \times M)^{-1} \times S \quad (8)$$

where  $I$  is an identity matrix. To handle the inverse of the matrix, we expand the Eq. (8) as a power series as following.

$$C = \lambda \times [I + B + \dots + B^k] \times S \quad (9)$$

where  $B = (1-\lambda) \times M^T \times M$  and  $k \in [0, \infty)$  is an approximate factor. In experiments, we set  $k=100$ . Using this equation, we estimate confidences for opinion target candidates. The candidates with higher confidence scores than the threshold will be extracted as the opinion targets.

## 4 Experiments

### 4.1 Datasets and Evaluation Metrics

In our experiments, we select three real world datasets to evaluate our approach. The first dataset is *COAE2008 dataset2*<sup>2</sup>, which contains Chinese reviews of four different products. The detailed

information can be seen in Table 2. Moreover, to evaluate our method comprehensively, we collect a larger collection named by *Large*, which includes three corpora from three different domains and different languages. The detailed statistical information of this dataset is also shown in Table 2. Restaurant is crawled from the Chinese Web site: [www.dianping.com](http://www.dianping.com). The Hotel and MP3<sup>3</sup> were used in (Wang et al., 2011), which are respectively clawed from [www.tripadvisor.com](http://www.tripadvisor.com) and [www.amazon.com](http://www.amazon.com). For each collection, we perform random sampling to generate testing dataset, which include 6,000 sentences for each domain. Then the opinion targets in *Large* were manually annotated as the gold standard for evaluations. Three annotators are involved in the annotation process as follows. First, every noun/noun phrase and its contexts in review sentences are extracted. Then two annotators were required to judge whether every noun/noun phrase is opinion target or not. If a conflict happens, a third annotator will make judgment for final results. The inter-agreement was 0.72. In total, we respectively obtain 1,112, 1,241 and 1,850 opinion targets in Hotel, MP3 and Restaurant. The third dataset is Customer Review Datasets<sup>4</sup> (English reviews of five products), which was also used in (Hu et al., 2004; Qiu et al., 2011). They have labeled opinion targets. The detailed information can be found in (Hu et al., 2004).

each word is assigned. Stanford NLP tool<sup>5</sup> is used to perform POS-tagging and dependency parsing. The method in (Zhu et al., 2009) is used to identify noun phrases. We select precision, recall and F-measure as the evaluation metrics. We also perform a significant test, i.e., a t-test with a default significant level of 0.05.

## 4.2 Our Methods vs. State-of-art Methods

To prove the effectiveness of our method, we select the following state-of-art unsupervised methods as baselines for comparison.

- 1) **Hu** is the method described in (Hu et al., 2004), which extracted opinion targets by using adjacent rule.
- 2) **DP** is the method described in (Qiu et al., 2011), which used *Double Propagation* algorithm to extract opinion targets depending on syntactic relations between words.
- 3) **Zhang** is the method described in (Zhang et al., 2010), which is an extension of *DP*. They extracted opinion targets candidates using syntactic patterns and other specific patterns. Then HITS (Kleinberg 1999) algorithm combined with candidate frequency is employed to rank the results for opinion target extraction.

**Hu** is selected to represent *adjacent* methods for opinion target extraction. And **DP** and **Zhang** are

selected to represent *syntax-based* methods. The parameter settings in these three baselines are the same as the original papers. In special, for *DP* and *Zhang*, we used the same patterns for different language reviews. The overall performance results are shown in Table 3, 4 and 5, respectively, where “P” denotes precision, “R” denotes recall and “F” denotes F-measure. *Ours* denotes full model of our method, in which we use IBM-3 model for identifying opinion relations between words. Moreover, we set  $\phi_{\max} = 2$  in Eq. (2) and  $\lambda = 0.3$  in Eq. (7). From results, we can make the following observations.

- 1) *Ours* achieves performance improvement over other methods. This indicates that our method based on word-based translation model is effective for opinion target extraction.
- 2) The graph-based methods (*Ours* and *Zhang*) outperform the methods using *Double Propagation (DP)*. Similar observations have been made by Zhang et al. (2010). The reason is that graph-based methods extract opinion targets in a global framework and they can effectively avoid the error propagation made by traditional methods based on *Double Propagation*. Moreover, *Ours* outperforms *Zhang*. We believe the reason is that *Ours* consider the opinion relevance and the candidate importance in a unified graph-based framework. By contrast, *Zhang* only simply

<sup>5</sup> <http://nlp.stanford.edu/software/tagger.shtml>

plus opinion relevance with frequency to determine the candidate confidence.

- 3) In Table 4, the improvement made by *Ours* on Restaurant (Chinese reviews) is larger than that on Hotel and MP3 (English reviews). The same phenomenon can be found when we compare the improvement made by *Ours* in Table 3 (Chinese reviews) with that in Table 5 (English reviews). We believe that reason is that syntactic patterns used in *DP* and *Zhang* were exploited based on English grammar, which may not be suitable to Chinese language. Moreover, another reason is that the performance of parsing on Chinese texts is not better than that on English texts, which will hurt the performance of *syntax-based methods* (*DP* and *Zhang*).
- 4) Compared the results in Table 3 with the results in Table 4, we can observe that *Ours* obtains larger improvements with the increase of the data size. This indicates that our method is more effective for opinion target extraction than state-of-art methods, especially for large corpora. When the data size increase, the methods based on syntactic patterns will introduce more noises due to the parsing errors on informal texts. On the other side, *Ours* uses WTM other than parsing to identify opinion relations between words, and the noises made by inaccurate parsing can be avoided. Thus, *Ours* can outperform baselines.
- 5) In Table 5, *Ours* makes comparable results with baselines in *Customer Review Datasets*, although there is a little loss in precision in some domains. We believe the reason is that the size of *Customer Review Datasets* is too small. As a result, WTM may suffer from data sparseness for association estimation. Nevertheless, the average recall is improved.

**An Example** In Table 6, we show top 10 opinion targets extracted by *Hu*, *DP*, *Zhang* and *Ours* in MP3 of *Large*. In *Hu* and *DP*, since they didn't rank the results, their results are ranked according to frequency in this experiment. The errors are marked in bold face. From these examples, we can see *Ours* extracts more correct opinion targets than others. In special, *Ours* outperforms *Zhang*. It indicates the effectiveness of our graph-based method for candidate confidence estimation. Moreover, *Ours* considers candidate importance besides opinion relevance, so some specific

opinion targets are ranked to the fore, such as "voice recorder", "fm radio" and "lcd screen".

### 4.3 Effect of Word-based Translation Model

In this subsection, we aim to prove the effectiveness of our WTM for estimating associations between opinion targets and opinion words. For comparison, we select two baselines for comparison, named as *Adjacent* and *Syntax*. These baselines respectively use adjacent rule (Hu et al. 2004; Wang et al., 2008) and syntactic patterns (Qiu et al., 2009) to identify opinion relations in sentences. Then the same method (Eq.3 and Eq.4) is used to estimate associations between opinion targets and opinion words. At last the same graph-based method (in Section 3.3) is used to extract opinion targets. Due to the limitation of the space, the experimental results only on *COAE2008 dataset2* and *Large* are shown in Figure 3.

Figure 3: Experimental comparison among different relation identification methods

Hu	quality, <b>thing</b> , drive, feature, battery, sound, <b>time</b> , music, price
DP	quality, battery, software, device, screen, file, <b>thing</b> , feature, battery life
Zhang	quality, size, battery life, <b>hour</b> , version, function, upgrade, <b>number</b> , music
Ours	quality, battery life, voice recorder, video, fm radio, battery, file system, screen, lcd screen

Table 6: Top 10 opinion targets extracted by different methods.

In Figure 3, we observe that *Ours* using WTM makes significant improvements compared with

two baselines, both on precision and recall. It indicates that WTM is effective for identifying opinion relations, which makes the estimation of the associations be more precise.

#### 4.4 Effect of Our Graph-based Method

In this subsection, we aim to prove the effectiveness of our graph-based method for opinion target extraction. We design two baselines, named as *WTM\_DP* and *WTM\_HITS*. Both *WTM\_DP* and *WTM\_HITS* use WTM to mine associations between opinion targets and opinion words. Then, *WTM\_DP* uses *Double Propagation* adapted in (Wang et al. 2008; Qiu et al. 2009) to extract opinion targets, which only consider the candidate opinion relevance. *WTM\_HITS* uses a graph-based method of Zhang et al. (2010) to extract opinion targets, which consider both candidate opinion relevance and frequency. Figure 4 gives the experimental results on *COAE2008 dataset2* and *Large*. In Figure 4, we can observe that our graph-based algorithm outperforms not only the method based on *Double Propagation*, but also the previous graph-based approach.

Figure 4: Experimental Comparison between different ranking algorithms

#### 4.5 Parameter Influences

##### 4.5.1 Effect of Different WTMs

In section 3, we use three different WTMs in Eq. (2) to identify opinion relations. In this subsection, we make comparison among them. Experimental results on *COAE2008 dataset2* and *Large* are

shown in Figure 5. *Ours\_1*, *Ours\_2* and *Ours\_3* respectively denote our method using different WTMs (IBM 1~3). From the results in Figure 5, we observe that *Ours\_2* outperforms *Ours\_1*, which indicates that word position is useful for identifying opinion relations. Furthermore, *Ours\_3* outperforms other models, which indicates that considering the fertility of a word can produce better performance.

##### 4.5.2 Effect of $\lambda$

In our method, when we employ Eq. (7) to assign confidence score to each candidate,  $\lambda \in [0,1]$  decides the proportion of candidate importance in our method. Due to the limitation of space, we only show the F-measure of *Ours* on *COAE2008 dataset2* and *Large* when varying  $\lambda$  in Figure 6.

In Figure 6, curves increase firstly, and decrease with the increase of  $\lambda$ . The best performance is obtained when  $\lambda$  is around 0.3. It indicates that candidate importance and candidate opinion relevance are both important for candidate confidence estimation. The performance of opinion target extraction benefits from their combination.

Figure 5. Experimental results by using different word-based translation model.

Figure 6. Experimental results when varying  $\lambda$

## 5 Conclusions and Future Work

This paper proposes a novel graph-based approach to extract opinion targets using WTM. Compared with previous *adjacent methods* and *syntax-based methods*, by using WTM, our method can capture opinion relations more precisely and therefore be more effective for opinion target extraction, especially for large informal Web corpora.

In future work, we plan to use other word alignment methods, such as discriminative model (Liu et al., 2010) for this task. Meanwhile, we will add some syntactic information into WTM to constrain the word alignment process, in order to identify opinion relations between words more precisely. Moreover, we believe that there are some verbs or nouns can be opinion words and they may be helpful for opinion target extraction. And we think that it's useful to add some prior knowledge of opinion words (sentiment lexicon) in our model for estimating candidate opinion relevance.

## Abstract

We investigate the use of language in food writing, specifically on restaurant menus and in customer reviews. Our approach is to build predictive models of concrete external variables, such as restaurant menu **prices**. We make use of a dataset of menus and customer reviews for thousands of restaurants in several U.S. cities. By focusing on prediction tasks and doing our analysis at scale, our methodology allows quantitative, objective measurements of the words and phrases used to describe food in restaurants. We also explore interactions in language use between menu prices and **sentiment** as expressed in user reviews.

## 1 Introduction

What words might a menu writer use to justify the high price of a steak? How does describing an item as *chargrilled* vs. *charbroiled* affect its price? When a customer writes an unfavorable review of a restaurant, how is her word choice affected by the restaurant's prices? In this paper, we explore questions like these that relate restaurant menus, prices, and customer sentiment. Our goal is to understand how language is used in the food domain, and we direct our investigation using external variables such as restaurant menu **prices**.

We build on a thread of NLP research that seeks linguistic understanding by predicting real-world quantities from text data. Recent examples include prediction of stock volatility (Kogan et al., 2009) and movie revenues (Joshi et al., 2010). There, prediction tasks were used for quantitative evaluation and objective model comparison, while analysis of learned models gave insight about the social process behind the data.

We echo this pattern here as we turn our attention to language use on restaurant menus and in user restaurant reviews. We use data from a large corpus of restaurant menus and reviews crawled from the web and formulate several prediction tasks. In addition to predicting menu prices, we also consider predicting **sentiment** along with price.

The relationship between language and sentiment is an active area of investigation (Pang and Lee, 2008). Much of this research has focused on customer-written reviews of goods and services, and perspectives have been gained on how sentiment is expressed in this type of informal text. In addition to sentiment, however, other variables are reflected in a reviewer's choice of words, such as the price of the item under consideration. In this paper, we take a step toward joint modeling of multiple variables in review text, exploring connections between price and sentiment in restaurant reviews.

Hence this paper contributes an exploratory data

analysis of language used to describe food (by its purveyors and by its consumers). While our primary goal is to understand the language used in our corpus, our findings bear relevance to economics and hospitality research as well. This paper is a step on the way to the eventual goal of using linguistic analysis to understand social phenomena like sales and consumption.

## 2 Related Work

There are several areas of related work scattered throughout linguistics, NLP, hospitality research, and economics.

Freedman and Jurafsky (2011) studied the use of language in food advertising, specifically the words on potato chip bags. They argued that, due to the ubiquity of food writing across cultures, ethnic groups, and social classes, studying the use of language for describing food can provide perspective on how different socioeconomic groups self-identify using language and how they are linguistically targeted. In particular, they showed that price affects how “authenticity” is realized in marketing language, a point we return to in §5. This is an example of how price can affect how an underlying variable is expressed in language. Among other explorations in this paper, we consider how price interacts with expression of sentiment in user reviews of restaurants.

As mentioned above, our work is related to research in predicting real-world quantities using text data (Koppel and Shtrimberg, 2006; Ghose et al., 2007; Lerman et al., 2008; Kogan et al., 2009; Joshi et al., 2010; Eisenstein et al., 2010; Eisenstein et al., 2011; Yogatama et al., 2011). Like much of this prior work, we aim to learn how language is used in a specific context while building models that achieve competitive performance on a quantitative prediction task.

Along these lines, there is recent interest in exploring the relationship between product sales and user-generated text, particularly online product reviews. For example, Ghose and Ipeirotis (2011) studied the sales impact of particular properties of review text, such as readability, the presence of spelling errors, and the balance between subjective and objective statements. Archak et al. (2011) had a

similar goal but decomposed user reviews into parts describing particular aspects of the product being reviewed (Hu and Liu, 2004). Our paper differs from price modeling based on product reviews in several ways. We consider a large set of weakly-related products instead of a homogeneous selection of a few products, and the reviews in our dataset are not product-centered but rather describe the overall experience of visiting a restaurant. Consequently, menu items are not always mentioned in reviews and rarely appear with their exact names. This makes it difficult to directly use review features in a pricing model for individual menu items.

Menu planning and pricing has been studied for many years by the culinary and hospitality research community (Kasavana and Smith, 1982; Kelly et al., 1994), often including recommendations for writing menu item descriptions (Miller and Pavesic, 1996; McVety et al., 2008). Their guidelines frequently include example menus from successful restaurants, but typically do not use large corpora of menus or automated analysis, as we do here. Other work focused more specifically on particular aspects of the language used on menus, such as the study by Zwicky and Zwicky (1980), who made linguistic observations through manual analysis of a corpus of 200 menus.

Relatedly, Wansink et al. (2001; 2005) showed that the way that menu items are described affects customers’ perceptions and purchasing behavior. When menu items are described evocatively, customers choose them more often and report higher satisfaction with quality and value, as compared to when they are given the same items described with conventional names. Wansink et al. did not use a corpus, but rather conducted a small-scale experiment in a working cafeteria with customers and collected surveys to analyze consumer reaction. While our goals are related, our experimental approach is different, as we use automated analysis of thousands of restaurant menus and rely on a set of one million reviews as a surrogate for observing customer behavior.

Finally, the connection between products and prices is also a central issue in economics. However, the stunning heterogeneity in products makes empirical work challenging. For example, there are over 50,000 menu items in New York that include

City	# Restaurants			# Menu Items			# Reviews		
	train	dev.	test	train	dev.	test	train	dev.	test
Boston	930	107	113	63,422	8,426	8,409	80,309	10,976	11,511

Total	10,019	1,252	1,252	733,360	90,917	91,697	1,179,254	147,891	152,916

Table 1: Dataset statistics.

the word *chicken*. What is the price of chicken? This is an important practical and daunting matter when measuring inflation (e.g., Consumer Price Index is measured with a precisely-defined basket of goods). Price dispersion across goods and the variation of the goods is an important area of industrial organization economic theory. For example, economists are interested in models of search, add-on pricing, and obfuscation (Baye et al., 2006; Ellison, 2005).

### 3 Data

We crawled Allmenus.com ([www.allmenus.com](http://www.allmenus.com)) to gather menus for restaurants in seven U.S. cities: Boston, Chicago, Los Angeles, New York, Philadelphia, San Francisco, and Washington, D.C. Each menu includes a list of item names with optional text descriptions and prices. Most Allmenus restaurant pages contain a link to the corresponding page on Yelp ([www.yelp.com](http://www.yelp.com)) with metadata and user reviews for the restaurant, which we also collected.

The metadata consist of many fields for each restaurant, which can be divided into three categories: location (city, neighborhood, transit stop), services available (take-out, delivery, wifi, parking, etc.), and ambience (good for groups, noise level, attire, etc.). Also, the category of food and a price range (\$ to \$\$\$\$), indicating the price of a typical meal at the restaurant) are indicated. The user reviews include a star rating on a scale of 1 to 5.

The distribution of prices of individual menu items is highly skewed, with a mean of \$9.22 but a median of \$6.95. On average, a restaurant has 73 items on its menu with a median price of \$8.69 and 119 Yelp reviews with a median rating of 3.55

Figure 1: Frequency distributions of restaurant price ranges (left) and review ratings (right).

stars. The star rating and price range distributions are shown in Figure 1.

The set of restaurants was randomly split into three parts (80% for training, 10% for development, 10% for evaluation), independently for each city. The sizes of the splits and the full set of dataset statistics are provided in Table 1.

### 4 Predictive Tasks

We consider several prediction tasks using the dataset just described. These include predicting **individual menu item prices** (§5), predicting the **price range** for each restaurant (§6), and finally jointly predicting **median price and sentiment** for each restaurant (§7). To do this, we use two types of models: linear regression (§5 and §6) and logistic regression (§7), both with  $\ell_1$  regularization when sparsity is desirable. We tune the regularization coefficient by choosing the value that minimizes development set loss (mean squared error and log loss, respectively).

For evaluation, we use mean absolute error (MAE) and mean relative error (MRE). Given a dataset  $\langle \mathbf{x}_i, y_i \rangle_{i=1}^N$  with inputs  $\mathbf{x}_i$  and outputs  $y_i$ , and

denoting predicted outputs by  $\hat{y}_i$ , these are defined as follows:

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^N |y_i - \hat{y}_i|$$

$$\text{MRE} = \frac{1}{N} \sum_{i=1}^N \left| \frac{y_i - \hat{y}_i}{y_i} \right|$$

In practice, since we model log-prices but evaluate on real prices, the final prediction is often a non-linear transformation of the output of the linear classifier of weight vector  $\mathbf{w}$ , which we denote by:  $\hat{y}_i = f(\mathbf{w}^\top \mathbf{x}_i)$ .

We also frequently report the total number of features available in the training set for each model (nf) as well as the number of non-zero feature weights following learning (nnz).

## 5 Menu Item Price Prediction

We first consider the problem of predicting the **price** of each item on a menu. In this case, every instance  $\mathbf{x}_i$  corresponds to a single item in the menu parametrized by the features detailed below and  $y_i$  is the item’s price. In this section, our models always use the logarithm of the price<sup>1</sup> as output values and therefore:  $\hat{y}_i = e^{\mathbf{w}^\top \mathbf{x}_i}$ .

**Baselines** We evaluate several baselines which make independent predictions for each distinct item name. The first two predict the mean or the median of the prices in the training set for a given item name, and use the overall price mean or median when a name is missing in the training set. The third baseline is an  $\ell_1$ -regularized linear regression model trained with a single binary feature for each item name in the training data. These baselines are shown as the first three rows in Table 2.

We note that there is a wide variation of menu item names in the dataset, with more than 400,000 distinct names. Although we address this issue later by introducing local text features, we also performed simple normalization of the item names for all of the baselines described above. To do this normalization, we first compiled a stop word list based on the most frequent words in the item names.<sup>2</sup> We

removed stop words and then ordered the words in each item name lexicographically, in order to collapse together items such as *coffee black* and *black coffee*. This normalization reduced the unique item name count by 40%, strengthening the baselines.

### 5.1 Features

We use  $\ell_1$ -regularized linear regression for feature-rich models. We now introduce several sets of features that we add to the normalized item names:<sup>3</sup>

- I. **METADATA**: Binary features for each restaurant metadata field mentioned above, excluding price range. A separate binary feature is included for each unique  $\langle \text{field}, \text{value} \rangle$  tuple.
- II. **MENUNAMES**:  $n$ -grams in menu item names. We used binary features for unique unigrams, bigrams, and trigrams. Here, stop words were retained as they can be informative (e.g., *with* and *large* correlate with price).
- III. **MENUDESC**:  $n$ -grams in menu item descriptions, as in **MENUNAMES**.

**Review Features** In addition to these features, we consider leveraging the large amount of text present in user reviews to improve predictions. We attempted to find mentions of menu items in the reviews and to include features extracted from the surrounding words in the model. Perfect item mentions being relatively rare, we consider inexact matches weighted by a coefficient measuring the degree of resemblance: we used the Dice similarity between the set of words in the sentence and in the item name. We then extracted  $n$ -gram features from this sentence, and tried several ways to use them for price prediction.

Given a review sentence, one option is to add the corresponding features to every item matching this sentence, with a value equal to the similarity coefficient. Another option is to select the best matching item and use the same real-valued features but only for this single item. Binary feature values can be used instead of the real-valued similarity coefficient. We also experimented with the use of part-of-speech tags in order to restrict our features to adjective and adverb  $n$ -grams instead of the full vocabulary. All of

<sup>1</sup>The price distribution is more symmetric in the log domain.

<sup>2</sup>This list can be found in the supplementary material.

<sup>3</sup>The normalized item names are present as binary features in all of our regression models

	MAE	MRE	nf	nnz
Predict mean	3.70	43.32	n/a	n/a
Predict median	3.67	43.93	n/a	n/a
Regression	3.66	45.64	267,945	240,139
METADATA	3.55	43.11	268,450	258,828
$\widehat{PR}$	3.47	43.11	267,946	205,176
MENUNAMES	3.23	38.33	896,631	230,840
+ MENUDESC	3.19	36.23	1,981,787	151,785
+ $\widehat{PR}$	3.08	34.51	1,981,788	140,954
+ METADATA	3.08	34.97	1,982,363	148,774
+ MENTIONS	3.06	34.37	4,959,488	458,462

Table 2: Results for menu item price prediction. MAE = mean absolute error (\$), MRE = mean relative error (%), nf = total number of features, nnz = number of features with non-zero weight.

these attempts yielded negative or only slightly positive results, of which we include only one example in our experiments: the MENTIONS feature set consists of  $n$ -grams for the best matching item with the Dice coefficient as the feature value.

We also tried to incorporate the reviews by using them in aggregate via predictions from a separate model; we found this approach to work better than the methods described above which all use features from the reviews directly in the regression model. In particular, we use the review features in a separate model that we will describe below (§6) to predict the price range of each restaurant. The model uses unigrams, bigrams, and trigrams extracted from the reviews. We use the estimated price range (which we denote  $\widehat{PR}$ ) as a single additional real-valued feature for individual item price prediction.

## 5.2 Results

Our results are shown in Table 2. We achieve a final reduction of 50 cents in MAE and nearly 10% in MRE compared with the baselines. Using menu name features (MENUNAMES) brings the bulk of the improvement, though menu description features (MENUDESC) and the remaining features also lead to small gains. Interestingly, as the MENUDESC and  $\widehat{PR}$  features are added to the model, the regularization favors more general features by selecting fewer and fewer non-zero weights.

While METADATA features improve over the baselines when used alone, they do not lead to improved performance over the MENU\* +  $\widehat{PR}$  features, suggesting that the text features may be able to sub-

stitute for the information in the metadata, at least for prediction of individual item prices.

The MENTIONS features resulted in a small improvement in MAE and MRE, but at the cost of expanding the model size significantly. A look at the learned feature weights reveals that most of the selected features seem more coincidental than generic (*rachel's*, highly negative) when not totally unintuitive (*those suicide*, highest positive). This suggests that our method of extracting features from mentions is being hampered by noise. We suspect that these features could be more effective with a better method of linking menu items to mentions in review text.

## 5.3 Analysis

We also inspected the feature weights of our learned models. By comparing the weights of related features, we can see the relative differences in terms of contribution to menu item prices. Table 3 shows example feature weights, manually arranged into several categories (taken from the model with MENUNAMES + MENUDESC +  $\widehat{PR}$  + METADATA).

Table 3(a) shows selected features for the “ambience” field in the Yelp restaurant metadata and pane (b) lists some unigrams related to cooking methods. Pane (c) shows feature weights for  $n$ -grams often used to market menu items; we see larger weights for words targeting those who want to eat organically- or locally-grown food (*farmhouse*, *heirloom*, *wild*, and *hormone*), compared to those looking for comfort food (*old time favorite*, *traditional*, *real*, and *fashioned*). This is related to observations made by Freedman and Jurafsky (2011) that cheaper food is marketed by appealing to tradition and historicity, with more expensive food described in terms of naturalness, quality of ingredients, and the preparation process (e.g., *hand picked*, *wild caught*, etc.). Relatedly, in pane (e) we see that *real* mashed potatoes are expected to be cheaper than those described as *creamy* or *smooth*.

Pane (d) shows feature weights for trigrams containing units of chicken; we can see an ordering in terms of size (*bits* < *cubes* < *strips* < *cuts*) as well as the price increase associated with the use of the word *morsels* in place of less refined units. We also see a difference between *pieces* and *pcs*, with the latter being frequently used to refer to entire cuts of

Table 3: Selected features from model for menu item price prediction. See text for details.

chicken (e.g., wings, thighs, etc.) and the former more often used as a synonym for *chunks*.

Panes (f), (g), and (h) reveal price differences due to slight variations in word form. We find that, even though *crispy* has a higher weight than *crisp*, *crisp bacon* is more expensive than *crispy bacon*. We also find that food items prefixed with *roast* lead to more expensive prices than the similar *roasted*, except in the case of *pork*, though here the different forms may be evoking two different preparation styles.

Also of note is the slight difference between the nonstandard *mash potato* and *mashed potato*. We observed lower weights with other nonstandard spellings, notably *portobella* having lower weight than each of the more common spellings *portabella*, *portobello*, and *portabello*.

## 6 Restaurant Price Range Prediction

In addition to predicting the prices of individual menu items, we also considered the task of predicting the **price range** listed for each restaurant on its Yelp page. The values for this field are integers from 1 to 4 and indicate the price of a typical meal from the restaurant.

For this task, we again train an  $\ell_1$ -regularized linear regression model with integral price ranges as the true output values  $y_i$ . Each input  $x_i$  corresponds to the feature vector for an entire restaurant. For evaluation, we round the predicted values to the nearest integer:  $\hat{y}_i = \text{ROUND}(w^\top x_i)$  and report the corresponding mean absolute error and accuracy.

We compared this simple approach with an ordinal regression model (McCullagh, 1980) trained with the same  $\ell_1$  regularizer and noted very little improvement (77.32% vs. 77.15% accuracy for METADATA). Therefore, we only report in this section results for the linear regression model.

In addition to the feature sets used for individual menu item price prediction, we used features on reviews (REVIEWS). Specifically, we used binary features for unigrams, bigrams, and trigrams in the full set of reviews for each restaurant. A stopword list was derived from the training data.<sup>4</sup> Bigrams and trigrams were filtered if they ended with stopwords. Additionally, features occurring fewer than three times in the training set were discarded.

<sup>4</sup>This list is included in the supplementary material.

Features	MAE	Acc.	nf	nnz
Predict mode	0.5421	48.22	n/a	n/a
MENU*	0.3875	66.29	1,910,622	995
METADATA	0.2372	77.15	591	219
REVIEWS	0.2172	79.76	3,027,470	1,567
+METADATA	0.2111	80.36	3,027,943	1,376

Table 4: Results for restaurant price range prediction. MAE = mean absolute error, Acc = classification accuracy (%), nf = total number of features, nnz = number of features with non-zero weight.

## 6.1 Results

Our results for price range prediction are shown in Table 4. Predicting the most frequent price range gave us an accuracy of 48.22%. Performance improvements were obtained by separately adding menu (MENU\*), metadata (METADATA), and review features (REVIEWS). Unlike individual item price prediction, the reviews were more helpful than the menu features for predicting overall price range. This is not surprising, since reviewers will often generally discuss price in their reviews. We combined metadata and review features to get our best accuracy, exceeding 80%.

We also wanted to perform an analysis of sentiment in the review text. To do this, we trained a logistic regression model predicting polarity for each review; we used the REVIEWS feature set, but this time considering each review as a single training instance. The polarity of a review was determined by whether or not its star rating was greater than the average rating across all reviews in the dataset (3.7 stars). We achieved an accuracy of 87% on the test data. We omit full details of these models because the polarity prediction task for user reviews is well-known in the sentiment analysis community and our model is not an innovation over prior work (Pang and Lee, 2008). However, our purpose in training the model was to use the learned weights for understanding the text in the reviews.

## 6.2 Interpreting Reviews

Given learned models for predicting a restaurant’s price range from its set of reviews as well as polarity for each review, we can turn the process around and use the feature weights to analyze the review text. Restricting our attention to reviews of 50–60 words, Table 5 shows sample reviews from our test

set that lead to various predictions of price range and sentiment.<sup>5</sup>

This technique can also be useful when trying to determine the “true” star rating for a review (if provided star ratings are noisy), or to show the most positive and most negative reviews for a product within a particular star rating. The 5-point scale is merely a coarse approximation to the reviewer’s mental state; using fitted models can provide additional clues to decode the reviewer’s sentiment.

We can also do a more fine-grained analysis of review text by noting the contribution to the price range prediction of each position in the text stream. This is straightforward because our features are simply  $n$ -grams of the review text. In Figure 2, we show the influence of each word in a review sentence on the predicted polarity (brown) and price range (yellow). The height of a bar at a given position is proportional to the sum of the feature weights for every unigram, bigram, and trigram containing the token at that position (there are at most 6 active  $n$ -grams at a position).

The first example shows the smooth shift in expressed sentiment from the beginning of the sentence to the end. The second sentence is a difficult example for sentiment analysis, since there are several positive words and phrases early but the sentiment is chiefly expressed in the final clause. Our model noted the steady positive sentiment early in the sentence but identified the crucial negation due to strong negative weight on bigrams *fresh but*, *left me*, and *me yearning*. In both examples, the yellow bars show that price estimates are reflected mainly through isolated mentions of offerings and amenities (*drinks*, *atmosphere*, *security*, *good service*).

## 7 Joint Prediction of Price and Sentiment

Although we observe no interesting correlation ( $r = 0.06$ ) between median star rating and median item price in our dataset, this does not imply that senti-

<sup>5</sup>To choose the 9 reviews in the table, we took the reviews from our test set in the desired length range and computed predicted sentiment and price range for each; then we scaled the predicted price range so that its range matched that of predicted sentiment, and maximized various linear combinations of the two. This accounts for the four corners. The others were found by maximizing a linear combination of one (possibly negated) prediction minus the absolute value of the other.

	← cheap		expensive →
↑ ⊕	i love me a cheap vietnamese sandwich . mmm , pate . this place has the best ones i 've had in the city , and i conveniently live a few blocks away . the ladies behind the counter are always courteous and fast , and who can beat a \$ 3 sandwich ?! crazy ass deli .	this place is tiny ! the pork buns are so tender and flavorful . i dream about these things . manila clams were awesome , not the biggest clam fan either , but i loved it . mmm 7 spice chips . i ca n't wait to go back !	amazing service and desserts . nice wine list and urban decor . i went with a girlfriend and we split an entree , appetizer and dessert and they happily brought us separate portions which were just the right size . the bread is awesome , too . definitely a bit of a splurge , but worth it in moderation .
	great place to get fast food that tastes good . paneer and chicken are both good . i would prefer to go thursday thru saturday night . thats when they have their good shift working . also it stays open late until 4 am on weekends . really enjoyable !	had some solid thai here for lunch last week . ordered the special of the day , a chicken curry . quick service and nice interior . only issue was , had a bit of a stomach ache afterwards ? prefer their sister restaurant , citizen thai and the monkey , in north beach .	weekday evening was quiet , not every table was filled . our waiter was amicable and friendly , which is always a plus . the coconut bread pudding was ok and very sweet . it 's definitely a dessert plate that can be shared with a glass of wine .
↓ ⊖	for some reason my friend wanted me to go here with him . it was a decent standard greasy slice of pizza . it was n't bad by any means , but it was nothing special at all . on the plus side , cheap and fast . so in summary : cheap , fast , greasy , average .	ugh ! the salt ! all 5 dishes we ordered were so unbearably salty , i 'd rather just have the msg . greasy , oily , salty - there is much better chinese food to be had in sf than here . i was very disappointed and wo n't be back .	downhill alert ... had a decent lunch at dragon well this week marred by pretty spotty service . our waiter just did n't have it together , forgetting to bring bowls for our split soup , our beverages , etc . . food was good but pretty pricey for what we got .

Table 5: Reviews from the test set deemed by our model to have particular values of sentiment and price.

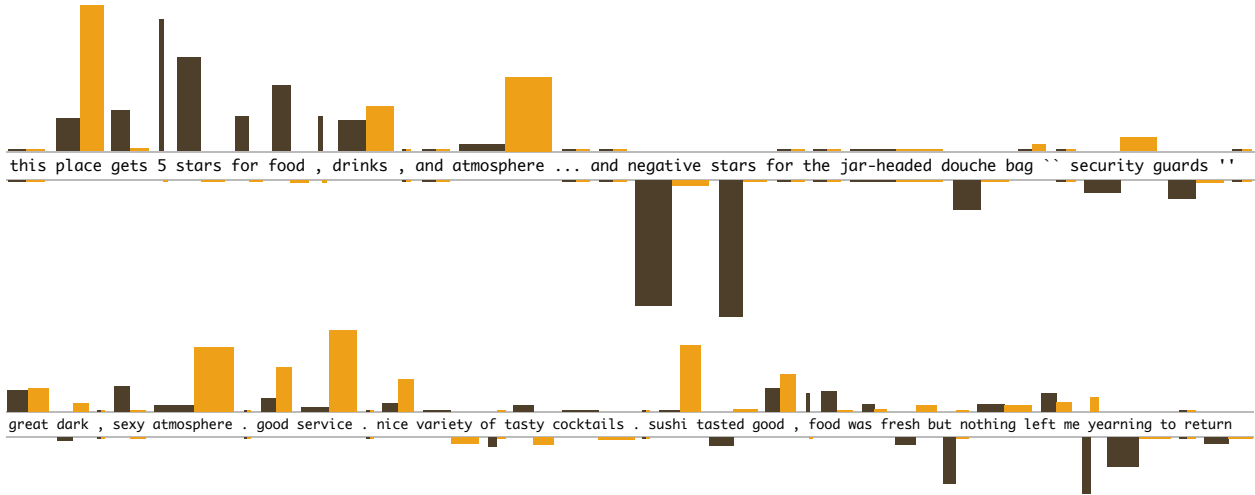

Figure 2: Local (position-level) sentiment (brown) and price (yellow) estimates for two sentences in the test corpus.

ment and price are independent of each other.<sup>6</sup> We try to capture this interaction by modeling at the same time review polarity and item price: we consider the task of jointly predicting **aggregate sentiment and price** for a restaurant.

For every restaurant in our dataset, we compute its median item price  $\bar{p}$  and its median star rating  $\bar{r}$ . The average of these two values for the entire dataset (\$8.69 and 3.55 stars) split the plane  $(\bar{p}, \bar{r})$  in four sections: we assign each restaurant to one of these quadrants which we denote  $\downarrow \ominus$ ,  $\downarrow \oplus$ ,  $\uparrow \ominus$  and  $\uparrow \oplus$ . This allows us to train a 4-class logistic regres-

sion model using the REVIEWS feature set for each restaurant. We achieve an accuracy of 65% on the test data, but we are mainly interested in interpreting the estimated feature weights.

### 7.1 Analysis

To visualize the top feature weights learned by the model, we have to map the four weight vectors learned by the model back to the underlying two-dimensional sentiment/price space. Therefore, we compute the following values:

$$\begin{aligned} \mathbf{w}_{\$} &= (\mathbf{w}_{\uparrow \oplus} + \mathbf{w}_{\uparrow \ominus}) - (\mathbf{w}_{\downarrow \oplus} + \mathbf{w}_{\downarrow \ominus}) \\ \mathbf{w}_{\star} &= (\mathbf{w}_{\uparrow \oplus} + \mathbf{w}_{\downarrow \oplus}) - (\mathbf{w}_{\uparrow \ominus} + \mathbf{w}_{\downarrow \ominus}) \end{aligned}$$

<sup>6</sup>Price and sentiment are both endogenous outcomes reflecting the characteristics of the restaurant. E.g., “better” restaurants can charge higher prices.

We then select for display the features which are the furthest from the origin ( $\max w_{\S}^2 + w_{\star}^2$ ) and represent the selected  $n$ -grams as points in the sentiment/price space to obtain Figure 3.

We notice that the spread of the sentiment values is larger, which suggests that reviews give stronger clues about consumer experience than about the cost of a typical meal. However, obvious price-related adjectives (*inexpensive* vs. *expensive*) appear in this limited selection, as well as certain phrases indicating both sentiment and price (*overpriced* vs. *very reasonable*). Other examples of note: *gem* is used in strongly-positive reviews of cheap restaurants; for expensive restaurants, reviewers use *highly recommended* or *amazing*. Also, phrases like *no flavor* and *manager* appear in negative reviews of more expensive restaurants, while *dirty* appears more often in negative reviews of cheaper restaurants.

## 8 Conclusion

We have explored linguistic relationships between food prices and customer sentiment through quantitative analysis of a large corpus of menus and reviews. We have also proposed visualization techniques to better understand what our models have learned and to see how they can be applied to new data. More broadly, this paper is an example of using extrinsic variables to drive model-building for linguistic data, and future work might explore richer extrinsic variables toward a goal of task-driven notions of semantics.

## Abstract

We present an automatic method for mapping *language-specific* part-of-speech tags to a set of *universal tags*. This unified representation plays a crucial role in cross-lingual syntactic transfer of multilingual dependency parsers. Until now, however, such conversion schemes have been created manually. Our central hypothesis is that a valid mapping yields POS annotations with coherent linguistic properties which are consistent across source and target languages. We encode this intuition in an objective function that captures a range of distributional and typological characteristics of the derived mapping. Given the exponential size of the mapping space, we propose a novel method for optimizing over soft mappings, and use entropy regularization to drive those towards hard mappings. Our results demonstrate that automatically induced mappings rival the quality of their manually designed counterparts when evaluated in the context of multilingual parsing.<sup>1</sup>

## 1 Introduction

In this paper, we explore an automatic method for mapping *language-specific* part-of-speech tags to a *universal tagset*. In multilingual parsing, this unified input representation is required for cross-lingual syntactic transfer. Specifically, the universal tagset annotations enable an unlexicalized parser to capitalize on annotations from one language when learning a model for another.

<sup>1</sup>The source code and data for the work presented in this paper is available at <http://groups.csail.mit.edu/rbg/code/unitag/emnlp2012>

While the notion of a universal POS tagset is widely accepted, in practice it is hardly ever used for annotation of monolingual resources. In fact, available POS annotations are designed to capture language-specific idiosyncrasies and therefore are substantially more detailed than a coarse universal tagset. To reconcile these cross-lingual annotation differences, a number of mapping schemes have been proposed in the parsing community (Zeman and Resnik, 2008; Petrov et al., 2011; Naseem et al., 2010). In all of these cases, the conversion is performed manually and has to be repeated for each language and annotation scheme anew.

Despite the apparent simplicity, deriving a mapping is by no means easy, even for humans. In fact, the universal tagsets manually induced by Petrov et al. (2011) and by Naseem et al. (2010) disagree on 10% of the tags. An example of such discrepancy is the mapping of the Japanese tag “PVfin” to the universal tag “particle” according to one scheme, and to “verb” according to another. Moreover, the quality of this conversion has a direct implication on the parsing performance. In the Japanese example above, this difference in mapping yields a 6.7% difference in parsing accuracy.

The goal of our work is to induce the mapping for a new language, utilizing existing manually-constructed mappings as training data. The existing mappings developed in the parsing community rely on gold POS tags for the target language. A more realistic scenario is to employ the mapping technique to resource-poor languages where gold POS annotations are lacking. In such cases, a mapping algorithm has to operate over automatically in-

duced clusters on the target language (e.g., using the Brown algorithm) and convert them to universal tags. We are interested in a mapping approach that can effectively handle both gold tags and induced clusters.

Our central hypothesis is that a valid mapping yields POS annotations with coherent linguistic properties which are consistent across languages. Since universal tags play the same linguistic role in source and target languages, we expect similarity in their *global distributional statistics*. Figure 1a shows statistics for two close languages, English and German. We can see that their unigram frequencies on the five most common tags are very close. Other properties concern *POS tag per sentence statistics* – e.g., every sentence has to have at least one verb. Finally, the mappings can be further constrained by *typological properties* of the target language that specify likely tag sequences. This information is readily available even for resource poor language (Haspelmath et al., 2005). For instance, since English and German are prepositional languages, we expect to observe adposition-noun sequences but not the reverse (see Figure 1b for sample sentences). We encode these heterogeneous properties into an objective function that guides the search for the optimal mapping.

Having defined a quality measure for mappings, our goal is to find the optimal mapping. However, such partition optimization problems<sup>2</sup> are NP hard (Garey and Johnson, 1979). A naive approach to the problem is to greedily improve the map, but it turns out that this approach yields poor quality mappings. We therefore develop a method for optimizing over soft mappings, and use entropy regularization to drive those towards hard mappings. We construct the objective in a way that facilitates simple monotonically improving updates corresponding to solving convex optimization problems.

We evaluate our mapping approach on 19 languages that include representatives of Indo-European, Semitic, Basque, Japonic and Turkic families. We measure mapping quality based on the target language parsing accuracy. In addition to considering gold POS tags for the target language,

---

<sup>2</sup>Instances of related hard problems are 3-partition and subset-sum.

we also evaluate the mapping algorithm on automatically induced POS tags. In all evaluation scenarios, our model consistently rivals the quality of manually induced mappings. We also demonstrate that the proposed inference procedure outperforms greedy methods by a large margin, highlighting the importance of good optimization techniques. We further show that while all characteristics of the mapping contribute to the objective, our largest gain comes from distributional features that capture global statistics. Finally, we establish that the mapping quality has a significant impact on the accuracy of syntactic transfer, which motivates further study of this topic.

## 2 Related Work

**Multilingual Parsing** Early approaches for multilingual parsing used parallel data to bridge the gap between languages when modeling syntactic transfer. In this setup, finding the mapping between various POS annotation schemes was not essential; instead, the transfer algorithm could induce it directly from the parallel data (Hwa et al., 2005; Xi and Hwa, 2005; Burkett and Klein, 2008). However, more recent transfer approaches relinquish this data requirement, learning to transfer from non-parallel data (Zeman and Resnik, 2008; McDonald et al., 2011; Cohen et al., 2011; Naseem et al., 2010). These approaches assume access to a common input representation in the form of universal tags, which enables the model to connect patterns observed in the source language to their counterparts in the target language.

Despite ongoing efforts to standardize POS tags across languages (e.g., EAGLES initiative (Eynde, 2004)), many corpora are still annotated with language-specific tags. In previous work, their mapping to universal tags was performed manually. Yet, even though some of these mappings have been developed for the same CoNLL dataset (Buchholz and Marsi, 2006; Nivre et al., 2007), they are not identical and yield different parsing performance (Zeman and Resnik, 2008; Petrov et al., 2011; Naseem et al., 2010). The goal of our work is to automate this process and construct mappings that are optimized for performance on downstream tasks (here we focus on parsing). As our results show, we achieve this goal

Figure 1: Illustration of similarities in POS tag statistics across languages. (a) The unigram frequency statistics on five tags for two close languages, English and German. (b) Sample sentences in English and German. Verbs are shown in blue, prepositions in red and noun phrases in green. It can be seen that noun phrases follow prepositions.

on a broad range of languages and evaluation scenarios.

**Syntactic Category Refinement** Our work also relates to work in syntactic category refinement in which POS categories and parse tree non-terminals are refined in order to improve parsing performance (Finkel et al., 2007; Klein and Manning, 2003; Matsuzaki et al., 2005; Petrov et al., 2006; Petrov and Klein, 2007; Liang et al., 2007). Our work differs from these approaches in two ways. First, these methods have been developed in the monolingual setting, while our mapping algorithm is designed for multilingual parsing. Second, these approaches are trained on the syntactic trees of the target language, which enables them to directly link the quality of newly induced categories with the quality of syntactic parsing. In contrast, we are not given trees in the target language. Instead, our model is informed by mappings derived for other languages.

### 3 Task Formulation

The input to our task consists of a *target* corpus written in a language  $T$ , and a set of non-parallel *source* corpora written in languages  $\{S_1, \dots, S_n\}$ . In the source corpora, each word is annotated with both a language-specific POS tag and a universal POS tag (Petrov et al., 2011). In the target corpus each word is annotated only with a language-specific POS tag, either gold or automatically induced.

Our goal is to find a map from the set of  $L_T$  target language tags to the set of  $K$  universal tags. We as-

sume that each language-specific tag is only mapped to one universal tag, which means we never split a language-specific tag and  $L_T \geq K$  holds for every language. We represent the map by a matrix  $A$  of size  $K \times L_T$  where  $A(c|f) = 1$  if the target language tag  $f$  is mapped to the universal tag  $c$ , and  $A(c|f) = 0$  otherwise.<sup>3</sup> Note that each column of  $A$  should contain a single value of 1. We will later relax the requirement that  $A(c|f) \in \{0, 1\}$ . A candidate mapping  $A$  can be applied to the target language to produce sentences labeled with universal tags.

### 4 Model

In this section we describe an objective that reflects the quality of an automatic mapping.

Our key insight is that for a good mapping, the statistics over the universal tags should be similar for source and target languages because these tags play the same role cross-linguistically. For example, we should expect the frequency of a particular universal tag to be similar in the source and target languages.

One choice to make when constructing an objective is the source languages to which we want to be similar. It is clear that choosing all languages is not a good idea, since they are not all expected to have distributional properties similar to the target language. There is strong evidence that projecting from single languages can lead to good parsing performance

<sup>3</sup>We use  $c$  and  $f$  to reflect the fact that universal tags are a coarse version (hence  $c$ ) of the language specific fine tags (hence  $f$ ).

(McDonald et al., 2011). Therefore, our strategy is to choose a single source language for comparison. The choice of the source language is based on similarity between typological properties; we describe this in detail in Section 5.

We must also determine which statistical properties we expect to be preserved across languages. Our model utilizes three linguistic phenomena which are consistent across languages: POS tag global distributional statistics, POS tag per sentence statistics, and typology-based ordering statistics. We define each of these below.

#### 4.1 Mapping Characterization

We focus on three categories of mapping properties. For each of the relevant statistics we define a function  $F_i(A)$  that has low values if the source and target statistics are similar.

**Global distributional statistics:** The unigram and bigram statistics of the universal tags are expected to be similar across languages with close typological profiles. We use  $p_S(c_1, c_2)$  to denote the bigram distribution over universal tags in the source language, and  $p_T(f_1, f_2)$  to denote the bigram distribution over language specific tags in the target language. The bigram distribution over universal tags in the target language depends on  $A$  and  $p_T(f_1, f_2)$  and is given by:

$$p_T(c_1, c_2; A) = \sum_{f_1, f_2} A(c_1|f_1)A(c_2|f_2)p_T(f_1, f_2) \quad (1)$$

To enforce similarity between source and target distributions, we wish to minimize the KL divergence between the two: <sup>4</sup>

$$F_{bi}(A) = D_{KL}[p_S(c_1, c_2)|p_T(c_1, c_2; A)] \quad (2)$$

We similarly define  $F_{uni}(A)$  as the distance between unigram distributions.

**Per sentence statistics:** Another defining property of POS tags is their average count per sentence. Specifically, we focus on the verb count per sentence, which we expect be similar across languages.

<sup>4</sup>We use the KL divergence because it assigns low weights to infrequent universal tags. Furthermore, this choice results in a simple, EM-like parameter estimation algorithm as discussed in Section 5.

To express this constraint, we use  $n_v(s, A)$  to denote the number of verbs (i.e., the universal tags corresponding to verbs according to  $A$ ) in sentence  $s$ . This is a linear function of  $A$ . We also use  $E[n_v(s, A)]$  to denote the average number of verbs per sentence, and  $V[n_v(s, A)]$  to denote the variance. We estimate these two statistics from the source language and denote them by  $E_{Sv}, V_{Sv}$ . Good mappings are expected to follow these patterns by having a variance upper bounded by  $V_{Sv}$  and an average lower bounded by  $E_{Sv}$ .<sup>5</sup> This corresponds to minimizing the following objectives:

$$\begin{aligned} F_{Ev}(A) &= \max [0, E_{Sv} - E[n_v(s, A)]] \\ F_{Vv}(A) &= \max [0, V[n_v(s, A)] - V_{Sv}] \end{aligned}$$

Note that the above objectives are convex in  $A$ , which will make optimization simpler. We refer to the two terms jointly as  $F_{verb}(A)$ .

**Typology-based ordering statistics:** Typological features can be useful for determining the relative order of different tags. If we know that the target language has a particular typological feature, we expect its universal tags to obey the given relative ordering. Specifically, we expect it to agree with ordering statistics for source languages with a similar typology. We consider two such features here. First, in pre-position languages the preposition is followed by the noun phrase. Thus, if  $T$  is such a language, we expect the probability of a noun phrase following the adposition to be high, i.e., cross some threshold. Formally, we define  $C_1 = \{\text{noun, adj, num, pron, det}\}$  and consider the set of bigram distributions  $\mathcal{S}_{pre}$  that satisfy the following constraint:

$$\sum_{c \in C_1} p_T(\text{adp}, c) \geq a_{pre} \quad (3)$$

where  $a_{pre} = \sum_{c \in C_1} p_S(\text{adp}, c)$  is calculated from the source language. This constraint set is non-convex in  $A$  due to the bilinearity of the bigram term. To simplify optimization<sup>6</sup> we take an

<sup>5</sup>The rationale is that we want to put a lower bound on the number of verbs per sentence, and induce it from the source language. Furthermore, we expect the number of verbs to be well concentrated, and we induce its maximal variance from the source language.

<sup>6</sup>In Section 5 we shall see that this makes optimization easier.

approach inspired by the posterior regularization method (Ganchev et al., 2010) and use the objective:

$$F_C(A) = \min_{r(c_1, c_2) \in \mathcal{S}_{\text{pre}}} D_{KL}[r(c_1, c_2) | p_T(c_1, c_2; A)] \quad (4)$$

The above objective will attain lower values for  $A$  such that  $p_T(c_1, c_2; A)$  is close to the constraint set. Specifically, it will have a value of zero when the bigram distribution induced by  $A$  has the property specified in  $\mathcal{S}_{\text{pre}}$ . We similarly define a set  $\mathcal{S}_{\text{post}}$  for post-positional languages.

As a second typological feature, we consider the Demonstrative-Noun ordering. In DN languages we want the probability of a determiner to come before  $C_2 = \{\text{noun, adj, num}\}$ , (i.e., frequent universal noun-phrase tags), to cross a threshold. This constraint translates to:

$$\sum_{c \in C_2} p_T(\text{det}, c) \geq a_{\text{det}} \quad (5)$$

where  $a_{\text{det}} = \sum_{c \in C_2} p_S(\text{det}, c)$  is a threshold determined from the source language. We denote the set of distributions that have this property by  $\mathcal{S}_{\text{DN}}$ , and add them to the constraint in (4). The overall constraint set is denoted by  $\mathcal{S}$ .

## 4.2 The Overall Objective

We have defined a set of functions  $F_i(A)$  that are expected to have low values for good mappings. To combine those, we use a weighted sum:  $F_\alpha(A) = \sum_i \alpha_i \cdot F_i(A)$ . (The weights in this equation are learned; we discussed the procedure in Section 5)

Optimizing over the set of mappings is difficult since each mapping is a discrete set whose size is exponential size in  $L_T$ . Technically, the difficulty comes from the requirement that elements of  $A$  are integral and its columns sum to one. To relax this restriction, we will allow  $A(c|f) \in [0, 1]$  and encourage  $A$  to correspond to a mapping by adding an entropy regularization term:

$$H[A] = - \sum_f \sum_c A(c|f) \log A(c|f) \quad (6)$$

This term receives its minimal value when the conditional probability of the universal tags given a language-specific tag is 1 for one universal tag and zero for the others.

The overall objective is then:  $F(A) = F_\alpha(A) + \lambda \cdot H[A]$ , where  $\lambda$  is the weight of the entropy term.<sup>7</sup> The resulting optimization problem is:

$$\min_{A \in \Delta} F(A) \quad (7)$$

where  $\Delta$  is the set of non-negative matrices whose columns sum to one:

$$\Delta = \left\{ A : \begin{array}{l} A(c|f) \geq 0 \quad \forall c, f \\ \sum_{c=1}^K A(c|f) = 1 \quad \forall f \end{array} \right\} \quad (8)$$

## 5 Parameter Estimation

In this section we describe the parameter estimation process for our model. We start by describing how to optimize  $A$ . Next, we discuss the weight selection algorithm, and finally the method for choosing source languages.

### 5.1 Optimizing the Mapping $A$

Recall that our goal is to solve the optimization problem in Eq. (7). This objective is non convex since the function  $H[A]$  is concave, and the objective  $F(A)$  involves bilinear terms in  $A$  and logarithms of their sums (see Equations (1) and (2)).

While we do not attempt to solve the problem globally, we do have a simple update scheme that monotonically decreases the objective. The update can be derived in a similar manner to expectation maximization (EM) (Neal and Hinton, 1999) and convex concave procedures (Yuille and Rangarajan, 2003). Figure 2 describes our optimization algorithm. The key ideas in deriving it are using posterior distributions as in EM, and using a variational formulation of entropy. The term  $F_c(A)$  is handled in a similar way to the posterior regularization algorithm derivation. A detailed derivation is provided in the supplementary file.<sup>8</sup>

The  $k^{\text{th}}$  iteration of the algorithm involves several steps:

- In step 1, we calculate the current estimate of the bigram distribution over tags,  $p_T(c_1, c_2; A^k)$ .

<sup>7</sup>Note that as  $\lambda \rightarrow \infty$ , only valid maps will be selected by the objective.

<sup>8</sup>The supplementary file is available at <http://groups.csail.mit.edu/rbg/code/unitag/emnlp2012>.

- In step 2, we find the bigram distribution in the constraint set  $\mathcal{S}$  that is closest in  $KL$  divergence to  $p_T(c_1, c_2; A^k)$ , and denote it by  $r^k(c_1, c_2)$ . This optimization problem is convex in  $r(c_1, c_2)$ .
- In step 3, we calculate the bigram posterior over language specific tags given a pair of universal tags. This is analogous to the standard E-step in EM.
- In step 4, we use the posterior in step 3 and the bigram distributions  $p_S(c_1, c_2)$  and  $r^k(c_1, c_2)$  to obtain joint counts over language specific and universal bigrams.
- In step 5, we use the joint counts from step 4 to obtain counts over pairs of language specific and universal tags.
- In step 6, analogous to the M-step in EM, we optimize over the mapping matrix  $A$ . The objective is similar to the Q function in EM, and also includes the  $F_{verb}(A)$  term, and a linear upper bound on the entropy term. The objective can be seen to be convex in  $A$ .

As mentioned above, each of the optimization problems in steps 2 and 6 is convex, and can therefore be solved using standard convex optimization solvers. Here, we use the CVX package (Grant and Boyd, 2008; Grant and Boyd, 2011). It can be shown that the algorithm improves  $F(A)$  at every iteration and converges to a local optimum.

The above algorithm generates a mapping  $A$  that may contain fractional entries. To turn it into a *hard* mapping we round  $A$  by mapping each  $f$  to the  $c$  that maximizes  $A(c|f)$  and then perform greedy improvement steps (one  $f$  at a time) to further improve the objective. The regularization constant  $\lambda$  is tuned to minimize the  $F_\alpha(A)$  value of the rounded  $A$ .

## 5.2 Learning the Objective Weights

Our  $F_\alpha(A)$  objective is a weighted sum of the individual  $F_i(A)$  functions. In the following, we describe how to learn the  $\alpha_i$  weights for every target language. We would like  $F_\alpha(A)$  to have low values when  $A$  is a *good* map. Since our performance goal is parsing accuracy, we consider a map to be good

**Initialize**  $A^0$ .

**Repeat**

**Step 1 (calculate current bigram estimate):**

$$p_T(c_1, c_2; A^k) = \sum_{f_1, f_2} A^k(c_1|f_1)A^k(c_2|f_2)p_T(f_1, f_2)$$

**Step 2 (incorporate constraints):**

$$r^k(c_1, c_2) = \arg \min_{r \in \mathcal{S}} D_{KL}[r(c_1, c_2)|p_T(c_1, c_2; A^k)]$$

**Step 3 (calculate model posterior):**

$$p(f_1, f_2|c_1, c_2; A^k) \propto A^k(c_1|f_1)A^k(c_2|f_2)p_T(f_1, f_2)$$

**Step 4: (complete joint counts):**

$$N^k(c_1, c_2, f_1, f_2) = p(f_1, f_2|c_1, c_2; A^k) (r^k(c_1, c_2) + p_S(c_1, c_2))$$

**Step 5 (obtain pairwise):**

$$M^k(c, f) = N_1^k(c, f) + N_2^k(c, f)$$

where  $N_1^k(c, f) = \sum_{c_2, f_2} N^k(c, c_2, f, f_2)$  and similarly for  $N_2^k(c, f)$ .

**Step 6 (M step with entropy linearization):** Set  $A^{k+1}$  to be the solution of

$$\min_{A \in \Delta} - \sum_{c, f} [M^k(c, f) \log A(c|f) + A(c|f) \log A^k(c|f)] + F_{verb}(A)$$

**Until** Convergence of  $A^k$

Figure 2: An iterative algorithm for minimizing our objective in Eq. (7). For simplicity we assume that all the weights  $\alpha_i$  and  $\lambda$  are equal to one. It can be shown that the objective monotonically decreases in every iteration.

if it results in high parsing accuracy, as measured when projecting a parser from  $T$  to  $S$ .

Since we do not have annotated parses in  $T$ , we use the other source languages  $S = \{S_1, \dots, S_n\}$  to learn the weight. For each  $S_i$  as the target, we first train a parser for each language in  $S \setminus \{S_i\}$  as if it was the source, using the map of Petrov et al. (2011), and choose  $S_i^* \in S \setminus \{S_i\}$  which gives the highest parsing accuracy on  $S_i$ . Next we generate 7000 candidate mappings for  $S_i$  by randomly perturbing the map of (Petrov et al., 2011). We evaluate the quality of each candidate  $A$  by projecting the parser of  $S_i^*$  to  $S_i$ , and recording the parsing accuracy. Among all the candidates we choose the highest accuracy one and denote it by  $A^*(S_i)$ . We now want the score  $F(A^*(S_i))$  to be lower than that of all other candidates. To achieve this, we train a ranking SVM whose inputs are pairs of maps  $A^*(S_i)$  and an-

other worse  $A(S_i)$ . These map pairs are taken from many different target languages, i.e. many different  $S_i$ . The features given to the SVM are the terms of the score  $F_i(A)$ . The goal of the SVM is to weight these terms such that the better map  $A^*(S_i)$  has a lower score. The weights assigned by the SVM are taken as  $\alpha_i$ .

### 5.3 Source Language Selection

As noted in Section 4 we construct  $F(A)$  by choosing a single source language  $S$ . Here we describe the method for choosing  $S$ . Our goal is to choose  $S$  that is closest to  $T$  in terms of typology. Assume that languages are described by binary typological vectors  $\mathbf{v}_L$ . We would like to learn a diagonal matrix  $D$  such that  $d(S, T; D) = (\mathbf{v}_S - \mathbf{v}_T)^T D (\mathbf{v}_S - \mathbf{v}_T)$  reflects the similarity between the languages. In our context, a good measure of similarity is the performance of a parser trained on  $S$  and projected on  $T$  (using the optimal map  $A$ ). We thus seek a matrix  $D$  such that  $d(S, T; D)$  is ranked according to the parsing accuracy. The matrix  $D$  is trained using an SVM ranking algorithm that tries to follow the ranking of parsing accuracy. Similar to the technique for learning the objective weights, we train across many pairs of source languages.<sup>9</sup>

The typological features we use are a subset of the features described in “The World Atlas of Languages Structure” (WALS, (Haspelmath et al., 2005)), and are shown in Table 1.

## 6 Evaluation Set-Up

**Datasets** We test our model on 19 languages: Arabic, Basque, Bulgarian, Catalan, Chinese, Czech, Danish, Dutch, English, German, Greek, Hungarian, Italian, Japanese, Portuguese, Slovene, Spanish, Swedish, and Turkish. Our data is taken from the CoNLL 2006 and 2007 shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007). The CoNLL datasets consist of manually created dependency trees and language-specific POS tags. Following Petrov et al. (2011), our model maps these language-specific tags to a set of 12 universal tags: noun, verb, adjective, adverb, pronoun, determiner, adposition, numeral, conjunction, particle, punctuation mark and X (a general tag).

<sup>9</sup>Ties are broken using the  $F(A)$  objective.

**Evaluation Procedure** We perform a separate experiment for each of the 19 languages as the target and a source language chosen from the rest (using the method from Section 5.3). For the selected source language, we assume access to the mapping of Petrov et al. (2011).

**Evaluation Measures** We evaluate the quality of the derived mapping in the context of the target language parsing accuracy. In both the training and test data, the language-specific tags are replaced with universal tags: Petrov’s tags for the source languages and learned tags for the target language. We train two non-lexicalized parsers using source annotations and apply them to the target language. The first parser is a non-lexicalized version of the MST parser (McDonald et al., 2005) successfully used in the multilingual context (McDonald et al., 2011). In the second parser, parameters of the target language are estimated as a weighted mixture of parameters learned from supervised source languages (Cohen et al., 2011). For the parser of Cohen et al. (2011), we trained the model on the four languages used in the original paper — English, German, Czech and Italian. When measuring the performance on each of these four languages, we selected another set of four languages with a similar level of diversity.<sup>10</sup>

Following the standard evaluation practice in parsing, we use directed dependency accuracy as our measure of performance.

**Baselines** We compare mappings induced by our model against three baselines: the manually constructed mapping of Petrov et al. (2011), a randomly constructed mapping and a greedy mapping. The greedy mapping uses the same objective as our full model, but optimizes it using a greedy method. In each iteration, this method makes  $|L_T|$  passes over the language-specific tags, selecting a substitution that contributes the most to the objective.

**Initialization** To reduce the dimension of our algorithm’s search space and speed up our method, we start by clustering the language-specific POS tags of the target into  $|K| = 12$  clusters using an unsuper-

<sup>10</sup>We also experimented with a version of the Cohen et al. (2011) model trained on all the source languages. This set-up resulted in decreased performance. For this reason, we chose to train the model on the four languages.

ID	Feature Description	Values
81A	Order of Subject, Object and Verb	SVO, SOV, VSO, VOS, OVS, OSV
85A	Order of Adposition and Noun	Postpositions, Prepositions, Inpositions
86A	Order of Genitive and Noun	Genitive-Noun, Noun-Genitive
87A	Order of Adjective and Noun	Adjective-Noun, Noun-Adjective
88A	Order of Demonstrative and Noun	Demonstrative-Noun, Noun-Demonstrative, before and after

Table 1: The set of typological features that we use for source language selection. The first column gives the ID of the feature as listed in WALS. The second column describes the feature and the last column enumerates the allowable values for each feature; besides these values each feature can also have a value of ‘No dominant order’.

vised POS induction algorithm (Lee et al., 2010).<sup>11</sup> Our mapping algorithm then learns the connection between these clusters and universal tags.

For initialization, we perform multiple random restarts and select the one with the lowest final objective score.

## 7 Results

We first present the results of our model using the gold POS tags for the target language. Table 2 summarizes the performance of our model and the baselines.

**Comparison against Baselines** On average, the mapping produced by our model yields parsers with higher accuracy than all of the baselines. These results are consistent for both parsers (McDonald et al., 2011; Cohen et al., 2011). As expected, random mappings yield abysmal results — 20.2% and 12.7% for the two parsers. The low accuracy of parsers that rely on the *Greedy* mapping — 29.9% and 25.4% — show that a greedy approach is a poor strategy for mapping optimization.

Surprisingly, our model slightly outperforms the mapping of (Petrov et al., 2011), yielding an average accuracy of 56.7% as compared to the 55.4% achieved by its manually constructed counterpart for the direct transfer method (McDonald et al., 2011). Similar results are observed for the mixture weights parser (Cohen et al., 2011). The main reason for these differences comes from mistakes introduced in the manual mapping. For example, in Czech tag “R” is labeled as “pronoun”, while actually it should be mapped to “adposition”. By correcting this mistake, we gain 5% in parsing accuracy for the direct transfer parser.

<sup>11</sup>This pre-clustering results in about 3% improvement, presumably since it uses contextual information beyond what our algorithm does.

Overall, the manually constructed mapping and our model’s output disagree on 21% of the assignments (measured on the token level). However, the extent of disagreement is not necessarily predictive of the difference in parsing performance. For instance, the manual and automatic mappings for Catalan disagree on 8% of the tags and their parsing accuracy differs by 5%. For Greek on the other hand, the disagreement between mappings is much higher — 17%, yet the parsing accuracy is very close. This phenomenon shows that not all mistakes have equal weight. For instance, a confusion between “pronoun” and “noun” is less severe in the parsing context than a confusion between “pronoun” and “adverb”.

**Impact of Language Selection** To assess the quality of our language selection method, we compare the model against an oracle that selects the best source for a given target language. As Table 2 shows our method is very close to the oracle performance, with only 0.7% gap between the two. In fact, for 10 languages our method correctly predicts the best pairing. This result is encouraging in other contexts as well. Specifically, McDonald et al. (2011) have demonstrated that projecting from a single oracle-chosen language can lead to good parsing performance, and our technique may allow such projection without an oracle.

**Relations between Objective Values and Optimization Performance** The suboptimal performance of the Greedy method shows that choosing a good optimization strategy plays a critical role in finding the desired mapping. A natural question to ask is whether the objective value is predictive of the end goal parsing performance. Figure 3 shows the objective values for the mappings computed by our method and the baselines for four languages. Over-

Table 2: Directed dependency accuracy of our model and the baselines using gold POS tags for the target language. The first section of the table is for the direct transfer of the MST parser (McDonald et al., 2011). The second section is for the weighted mixture parsing model (Cohen et al., 2011). The first two columns (Random and Greedy) of each section present the parsing performance with a random or a greedy mapping. The third column (Petrov) shows the results when the mapping of Petrov et al. (2011) is used. The fourth column (Model) shows the results when our mapping is used and the fifth column in the first section (Best Pair) shows the performance of our model when the best source language is selected for every target language. The last column (Tag Diff.) presents the difference between our mapping and the mapping of Petrov et al. (2011) by showing the percentage of target language tokens for which the two mappings select a different universal tag.

all, our method and the manual mappings reach similar values, both considerably better than other baselines. While the parsing performance correlates with the objective, the correlation is not perfect. For instance, on Greek our mapping has a better objective value, but lower parsing performance.

**Ablation Analysis** We next analyze the contribution of each component of our objective to the resulting performance.<sup>12</sup> The strongest factor in our objective is the distributional features capturing global statistics. Using these features alone achieves an average accuracy of 51.1%, only 5.6% less than the full model score. Adding just the verb-related constraints to the distributional similarity objectives improves the average model performance by 2.1%.

<sup>12</sup>The results are consistent for both parsers, here we report the accuracy for the direct transfer method (McDonald et al., 2011).

Adding just the typological constraints yields a very modest performance gain of 0.5%. This is not surprising — the source language is selected to be typologically similar to the target language, and thus its distributional properties are consistent with typological features. However, adding both the verb-related constraints and the typological constraints results in a synergistic performance gain of 5.6% over the distributional similarity objective, a gain which is much better than the sum of the two individual gains.

### Application to Automatically Induced POS Tags

A potential benefit of the proposed method is to relate automatically induced clusters in the target language to universal tags. In our experiments, we induce such clusters using Brown clustering,<sup>13</sup> which

<sup>13</sup>In our experiments, we employ Liang’s implementation <http://cs.stanford.edu/~pliang/software/>. The number of clusters is set to 30.

Figure 3: Objective values for the different mappings used in our experiments for four languages. Note that the goal of the optimization procedure is to minimize the objective value.

has been successfully used for similar purposes in parsing research (Koo et al., 2008). We then map these clusters to the universal tags using our algorithm.

The average parsing accuracy on the 19 languages is 45.5%. Not surprisingly, automatically induced tags negatively impact parsing performance, yielding a decrease of 11% when compared to mappings obtained using manual POS annotations (see Table 2). To further investigate the impact of inaccurate tags on the mapping performance, we compare our model against the oracle mapping model that maps each cluster to the most common universal tag of its members. Parsing accuracy obtained using this method is 45.1%, closely matching the performance of our mapping algorithm.

An alternative approach to mapping words into universal tags is to directly partition words into  $K$  clusters (without passing through language specific tags). In order for these clusters to be meaningful as universal tags, we can provide several prototypes for each cluster (e.g., “walk” is a verb etc.). To test this approach we used the prototype driven tagger of Haghighi and Klein (2006) with 15 prototypes per universal tag.<sup>14</sup> The resulting universal tags yield an average parsing accuracy of 40.5%. Our method (using Brown clustering as above) outperforms this

<sup>14</sup>Oracle prototypes were obtained by taking the 15 most frequent words for each universal tag. This yields almost the same total number of prototypes as those in the experiment of (Haghighi and Klein, 2006).

baseline by about 5%.

## 8 Conclusions

We present an automatic method for mapping *language-specific* part-of-speech tags to a set of *universal tags*. Our work capitalizes on manually designed conversion schemes to automatically create mappings for new languages. Our experimental results demonstrate that automatically induced mappings rival the quality of their hand-crafted counterparts. We also establish that the mapping quality has a significant impact on the accuracy of syntactic transfer, which motivates further study of this topic. Finally, our experiments show that the choice of mapping optimization scheme plays a crucial role in the quality of the derived mapping, highlighting the importance of optimization for the mapping task.

## Abstract

In modern Chinese articles or conversations, it is very popular to involve a few English words, especially in emails and Internet literature. Therefore, it becomes an important and challenging topic to analyze Chinese-English mixed texts. The underlying problem is how to tag part-of-speech (POS) for the English words involved. Due to the lack of specially annotated corpus, most of the English words are tagged as the oversimplified type, “foreign words”. In this paper, we present a method using dynamic features to tag POS of mixed texts. Experiments show that our method achieves higher performance than traditional sequence labeling methods. Meanwhile, our method also boosts the performance of POS tagging for pure Chinese texts.

## 1 Introduction

Nowadays, Chinese-English mixed texts are prevalent in modern articles or emails. More and more English words are used in Chinese texts as names of organizations, products, terms and abbreviations, such as “eBay”, “iPhone”, “GDP”, “Android” etc. On the other hand, it is also a common phenomenon to use Chinese-English mixed texts in daily conversation, especially in communication among employers in large international corporations.

There are some challenges for analyzing Chinese-English mixed texts:

1. How to define the POS tags for English words in these mixed texts. Since the standard of POS tags for English and Chinese are different, we cannot use English POS to tag the English words in mixed texts.

2. Due to lack of annotated corpus for mixed texts, most of the English words are tagged as “foreign words”, which is oversimplified. So we cannot use them in further processing for the syntactic and semantic analysis.
3. Most English words used in mixed texts are often out-of-vocabulary (OOV), which thus increases the difficulties to tag them.

Currently, the mainstream method of Chinese POS tagging is joint segmentation & tagging with cross-labels, which can avoid the problem of error propagation and achieve higher performance on both subtasks (Ng and Low, 2004). Each label is the cross-product of a segmentation label and a tagging label, e.g. {B-NN, I-NN, E-NN, S-NN, ...}. The features are generated by position-based templates on character-level.

Since the main part of mixed texts is in Chinese and the role of English word is more like Chinese, we use Chinese POS tags (Xia, 2000) to tag English words. Since the categories of the most commonly used English words are nouns, verbs and adjectives, we can use “NN”, “NR”, “VV”, “VA”, “JJ” to label their POS tags.

For the English proper nouns and verbs, there are no significant differences in Chinese and English POS tags except that English features plural and tense forms.

For the English nouns, these are some English nouns used as verbs, such as “我很 [fan/VV] 他。(I adore him very much.)” where “fan” means “adore” and is used as a verb.

For the English adjectives, there are two corresponding Chinese POS tags “VA” and “JJ”. For example, the roles of some English words in Table 1,

Table 1: The POS tags of English Adjectives in Mixed Texts

Chinese	English
我 非 常 [profes-sional/VA]。	I am very profes-sional.
感觉很 [high/VA]。	Feel very high.
他是 [super/JJ] [star/NN]	He is a super star.

such as “professional” and “high”, are different with their original ones.

Therefore, the POS tagging for mixed texts cannot be settled with simple methods, such as looking up in a dictionary.

One of the main differences between Chinese and English in POS tagging is that the two languages have character-based features and word-based features respectively. To ensure the consistency of tagging models, we prefer to use word-level information in Chinese, which is both useful for Chinese-English mixed texts and Chinese-only texts. For instance, in a sentence “X 或者 Y ... (X or Y ...)”, the word Y ought to have the same POS tag as the word X. Another example is that the word following a pronoun is usually a verb, and adjectives often describe nouns. Some related works show that word-level features can improve the performance of Chinese POS tagging (Jiang et al., 2008; Sun, 2011).

In this paper, we propose a method to tag mixed texts with dynamic features. Our method combines these dynamic features, which are dynamically generated at the decoding stage, with traditional static features. For Chinese-English mixed texts, the traditional features cannot yield a satisfied result due to lack of training data. The proposed dynamic features can improve the performance by using the information of a word, such as POS tag or length of the whole word, which is proven effective by experiments.

The rest of the paper is organized as follows: In section 2, we introduce the sequence labeling models, then we describe our method of dynamic features in section 3 and analyze its complexity in section 4. Section 5 describes the training method. The experimental results are manifested in section 6. Finally, We review the relevant research works in section 7 and conclude our work in section 8.

## 2 Sequence Labeling Models

Sequence labeling is the task of assigning labels  $\mathbf{y} = y_1, \dots, y_n$  to an input sequence  $\mathbf{x} = x_1, \dots, x_n$ . Given a sample  $\mathbf{x}$ , we define the feature  $\Phi(\mathbf{x}, \mathbf{y})$ . Thus, we can label  $\mathbf{x}$  with a score function,

$$\hat{\mathbf{y}} = \arg \max_{\mathbf{y}} F(\mathbf{w}, \Phi(\mathbf{x}, \mathbf{y})), \quad (1)$$

where  $\mathbf{w}$  is the parameter of function  $F(\cdot)$ .

For sequence labeling, the feature can be denoted as  $\phi_k(y_i, y_{i-1}, \mathbf{x}, i)$ , where  $i$  stands for the position in the sequence and  $k$  stands for the number of feature templates.

we use online Passive-Aggressive (PA) algorithm (Crammer and Singer, 2003; Crammer et al., 2006) to train the model parameters. Following (Collins, 2002), the average strategy is used to avoid the over-fitting problem.

## 3 Dynamic Features

The form of traditional features is shown in Table 2, where  $C$  represents a Chinese character, and  $T$  represents the character-based tag. The subscript  $i$  indicates its position related to the current character.

Table 2: Traditional Feature Templates

$C_i, T_0(i = -2, -1, 0, 1, 2)$
$C_i, C_j, T_0(i, j = -2, -1, 0, 1, 2 \text{ and } i \neq j)$
$T_{-1}, T_0$

Traditional features are generated by position-fixed templates. Since the length of Chinese word is unfixed, their meanings are incomplete. We categorize them as “static” features since they can be calculated before tagging (except “ $T_{-1}, T_0$ ”).

The form of dynamic features is shown in Table 3, where  $WORD$  represents a Chinese word, and  $POS (LEN)$  is the POS tag (length) of the word. The subscript of dynamic feature template indicates its position related to the current word.

Table 4 shows an example. If the current position is “Apple”, then  $\{POS_{-1}=CC, POS_{-2}=NR, WORD_{-1}=\text{“和”}, LEN_{-2}=2\}$ . Since these features are unavailable before tagging, we call them “dynamic” features.

Table 3: Examples of Dynamic Feature Templates

$POS_i, POS_j, T_0(i, j = -2, -1, 0 \text{ and } i \neq j)$
$POS_i, WORD_j, T_0(i, j = -2, -1, 0)$
$WORD_i, LEN_j, POS_k, T_0(i, j, k = -2, -1, 0)$
...

Dynamic features are more flexible because the number of involved characters is dependent on the length of previous words. Unlike static features, dynamic features do not merely rely on the input sequence  $C_{1:n}$ , so the weights of dynamic features, in which  $POS/LEN$  are involved, can be trained by Chinese-only texts and used by mixed texts, which resolve the problem of the lack of training data.

#### 4 Tagging with Dynamic Features

In the tagging stage, we use the current best result to approximately calculate the unknown tag information. For an input sequence  $C_{1:n}$ , the current best tags from index 0 to  $i-1$  can be calculated by Viterbi algorithm and they can be used to generate dynamic features for index  $i$ . The specific algorithm is shown in Algorithm 1.

Here is an example to explain the time complexity of the dynamic features. Normal template  $x_{i-2}x_{i-1}y_i$  requires to look for the positions of  $i-2$  and  $i-1$  related to the current character  $x_i$ , but dynamic template  $pos_{i-2}pos_{i-1}y_i$  needs to know the pos tags of two words. If the length of  $word_{i-1}/word_{i-2}$  is 2, then the positions of  $i-4, i-3, i-2, i-1$  are needed to generate the dynamic features.

For all dynamic features, it is unnecessary to repetitively calculate the  $POS/WORD/LEN$  array. Apart from that one time calculation of the array, no distinction can be found between the time complexity of the dynamic features and the traditional features. For input  $C_{1:n}$ , the time complexity is  $O(n*[O(op.2)+(T_s.num+T_d.num)*O(op.1)+O(op.4)])$ , n.b.  $O(op.1) = O(op.3)$ . Universally the dynamic features only require the information of position  $i-2$  and  $i-1$ , so the time complexity of calculating the  $POS/WORD/LEN$  array can be ignored as compared with the complexity of Viterbi algorithm and feature extraction. The approximate algorithm is thus faster than the Brute-Force way by

```

input : character sequence  $C_{1:n}$

    // create feature string  $F_s$  (Op.1)
     $F_s = \text{createFeature}(C_{1:n}, t_s)$ ;
     $W[i] += \text{getWeightVector}(F_s)$ ;
  end
  // create a list of  $\langle pos_k, word_k, len_k \rangle$ 
  // ( $k = 0, -1, -2 \dots$ ) (Op.2)
   $dList = \text{getCurrentBestPath}(Max, V_p)$ ;
  for  $t_d$  in  $T_d$  do
    // create dynamic features string  $F_d$ 
    // (Op.3)
     $F_d = \text{createFeature}(C_{1:n}, t_d, dList)$ ;
     $W[i] += \text{getWeightVector}(F_d)$ ;
  end
  // Update  $V_s[i], V_p[i]$  (Op.4)
   $\text{viterbi\_OneStep}(V_s[i-1], W[i], M)$ ;
   $Max = \arg \max_i (V_s[i])$ ;
end

```

**Algorithm 1:** Tagging Algorithm with Dynamic Features

using word-level information.

#### 5 Training

Given an example  $(\mathbf{x}, \mathbf{y})$ ,  $\hat{\mathbf{y}}$  are denoted as the incorrect labels with the highest score

$$\hat{\mathbf{y}} = \arg \max_{\mathbf{z} \neq \mathbf{y}} \mathbf{w}^T \Phi(\mathbf{x}, \mathbf{z}). \quad (2)$$

The **margin**  $\gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y}))$  is defined as

$$\gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y})) = \mathbf{w}^T \Phi(\mathbf{x}, \mathbf{y}) - \mathbf{w}^T \Phi(\mathbf{x}, \hat{\mathbf{y}}). \quad (3)$$

Thus, we calculate the **hinge loss**  $\ell(\mathbf{w}; (\mathbf{x}, \mathbf{y}))$ , (abbreviated as  $\ell_w$ ) by

Table 4: Example for Chinese-English Mixed POS Tagging

微	软	和	Apple	的	OS	风	格	不	同	。
B-NR	E-NR	S-CC	S-NR	S-DEG	S-NN	B-NN	E-NN	B-VA	E-VA	S-PU

$$\ell_w = \begin{cases} 0, & \gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y})) > 1 \\ 1 - \gamma(\mathbf{w}; (\mathbf{x}, \mathbf{y})), & \text{otherwise} \end{cases} \quad (4)$$

In round  $k$ , the new weight vector  $\mathbf{w}_{k+1}$  is calculated by

$$\mathbf{w}_{k+1} = \arg \min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_k\|^2 + \mathcal{C} \cdot \xi, \\ \text{s.t. } \ell(\mathbf{w}; (\mathbf{x}_k, \mathbf{y}_k)) \leq \xi \text{ and } \xi \geq 0 \quad (5)$$

where  $\xi$  is a non-negative slack variable, and  $\mathcal{C}$  is a positive parameter which controls the influence of the slack term on the objective function.

Following the derivation in PA (Crammer et al., 2006), we can get the update rule,

$$\mathbf{w}_{k+1} = \mathbf{w}_k + \tau_k (\Phi(\mathbf{x}_k, \mathbf{y}_k) - \Phi(\mathbf{x}_k, \hat{\mathbf{y}}_k)), \quad (6)$$

where

$$\tau_k = \min(\mathcal{C}, \frac{\ell_{w_k}}{\|\Phi(\mathbf{x}_k, \mathbf{y}_k) - \Phi(\mathbf{x}_k, \hat{\mathbf{y}}_k)\|^2}) \quad (7)$$

Our algorithm based on PA algorithm is shown in Algorithm 2.

## 6 Experiments

We implement our system based on FudanNLP<sup>1</sup>. We employ the commonly used label set {B, I, E, S} for the segmentation part of cross-labels. {B, I, E} represent *Begin*, *Inside*, *End* of a multi-node segmentation respectively, and S represents a *Single* node segmentation.

The  $F1$  score is used for evaluation, which is the harmonic mean of precision  $P$  (percentage of predict phrases that exactly match the reference phrases) and recall  $R$  (percentage of reference phrases that returned by system).

The feature templates, which are used to extract features, are listed in Table 5. We set traditional method (static features) as the baseline. The detailed experimental settings and results are reported in the following subsections.

### 6.1 POS Tagging for Chinese-only Texts

Before the experiments on Chinese-English mixed texts, we evaluate the performance of our method on Chinese-only texts. We use the CTB dataset from the POS tagging task of the Fourth International Chinese Language Processing Bakeoff (SIGHAN Bakeoff 2008)(Jin and Chen, 2008). The details are shown in Table 6.

The performance comparison on joint segmentation & POS tagging is shown in Table 7. Our method obtains an error reduction of 6.7% over the baseline. The reason is that our dynamic features can utilize

Table 6: POS Tagging Dataset in SIGHAN Bakeoff 2008

		Train Set (number)	Test Set (number)
Sentence		23444	2079
Word	Total	642246	59955
	NN	168896	16793
	NR	42906	3970
	VV	92887	8641
	VA	9106	649
	JJ	15640	1581

word-level information effectively and the feature templates are more flexible.

Table 7: Performances of POS Tagging on Chinese-only Texts with Static and Dynamic Features

Method	P	R	F1
Baseline	89.68	89.60	89.64
Our	<b>90.35</b>	<b>90.31</b>	<b>90.33</b>

## 6.2 POS Tagging for Chinese-English Mixed Texts

Without annotated corpus for Chinese-English mixed texts, we use synthetic data as the alternative. In Chinese-English mixed texts, English words of noun(NN/NR), verb(VV/VA) and adjective(JJ) categories are the most commonly used, so we randomly transform a certain percentage of Chinese words with these POS tags in the SIGHAN Bakeoff 2008 dataset(Jin and Chen, 2008) into their English counterparts.

### 6.2.1 Synthetic Data

Before trying out an experiment, we first study how to generate the data of mixed texts.

We use two ways to produce the synthetic data: “Respective Replacement” and “Unified Replacement”.

**Respective Replacement** We replace the selected Chinese words into their corresponding English counterparts.

**Unified Replacement** We replace the selected Chinese words with a unified label *ENG*. The reason we use the label *ENG* instead of real words is that we want to consider the context of these

words but not the words themselves and overcome the problem of out-of-vocabulary (OOV) English words.

For our experiments, we just select 5% of the Chinese nouns and verbs from SIGHAN dataset, and replace them in the above two ways. After replacement, the training and test data have 12780 and 1254 English words, respectively. 5189 words are generated by way of “Respective Replacement”. In the test data, 326 words are OOV, which comprises 25% of the whole vocabulary. The information of generated data is shown in Table 8.

Table 8: The Synthetic Chinese-English Mixed Dataset  $H$ 

Dataset		Numbers of <i>ENG</i>	
		NN	VV
$H$	Train Set	8191	4589
	Test Set	842	412

We use  $H_1$  to represent the dataset generated by way of “Respective Replacement”, and  $H_2$  for the dataset by way of with “Unified Replacement”. The experimental results on these two datasets are shown in Table 9.

Table 9: Performances of POS Tagging on Dataset  $H_1$  and  $H_2$ 

Method	Dataset	<i>ENG</i>	OOV	Total
		F1	$F1_{ooV}$	F1
Baseline	$H_1$	73.60	54.91	88.93
	$H_2$	77.59	73.93	89.11
Our	$H_1$	75.60	54.60	89.79
	$H_2$	<b>79.82</b>	<b>77.61</b>	<b>89.81</b>

From Table 9, we can see that the “Unified Replacement” way is better than the “Respective Replacement” way for both the baseline and our method. The main reason is that the “Unified Replacement” way can greatly improve the tagging performance of OOV words.

### 6.2.2 Detail Comparisons

For detail comparisons of all situations of mixed texts, we design six synthetic datasets,  $A/B/C/D_1/D_2/E$  by randomly selecting 10% or 15% of Chinese words (“NN/NR/VV/VA/JJ”) in the

above SIGHAN Bakeoff 2008 dataset, and replacing them with English label *ENG*.

The differences of these datasets are as following:

- Dataset *A* only contains English words with tags “NN/VV”.
- Dataset *B* contains English words with tags “NN/VV/VA”.
- Dataset *C* contains one more tag “NR” than Dataset *B*.
- Datasets *D*<sub>1</sub> and *D*<sub>2</sub> contain one more tag “JJ” than Dataset *B*. The difference between *D*<sub>1</sub> and *D*<sub>2</sub> is that *D*<sub>2</sub> has about 50% more English words than *D*<sub>1</sub> in training set.
- Dataset *E* contains English words with all the tags “NN/NR/VV/VA/JJ”.

The detailed information of datasets *A/B/C/D*<sub>1</sub>/*D*<sub>2</sub>/*E* is shown in Table 10.

Table 10: The Synthetic Chinese-English Mixed Dataset

Dataset		Numbers of <i>ENG</i>				
		NN	NR	VV	VA	JJ
<i>A</i>	Train	16302	0	9007	0	0
	Test	1675	0	841	0	0
<i>B</i>	Train	16116	0	8882	906	0
	Test	1573	0	830	58	0
<i>C</i>	Train	16312	4057	9067	899	0
	Test	1549	400	795	61	0
<i>D</i> <sub>1</sub>	Train	16042	0	8957	855	1539
	Test	1588	0	845	58	150
<i>D</i> <sub>2</sub>	Train	23705	0	13154	1300	2211
	Test	1588	0	845	58	150
<i>E</i>	Train	16066	4162	9156	886	1547
	Test	1647	415	809	57	141

The results are shown in Table 11. On dataset *E*, our method achieves 6.78% higher performance on tagging *ENG* labels than traditional static features. This result is reasonable because our model can use more flexible feature templates to extract features and reduce the problem of being dependent on specific English words.

Tables 12/13/14/15/16/17 show the detailed results on datasets *A/B/C/D*<sub>1</sub>/*D*<sub>2</sub>/*E*.

Table 11: Performances of POS Tagging on Datasets *A/B/C/D*<sub>1</sub>/*D*<sub>2</sub>/*E*

Dataset	Method	<i>ENG</i> labels	
		F1	Total F1
<i>A</i>	Baseline	80.25	88.74
	Our	<b>83.03</b>	<b>89.72</b>
<i>B</i>	Baseline	76.72	88.51
	Our	<b>80.54</b>	<b>89.55</b>
<i>C</i>	Baseline	68.16	88.13
	Our	<b>70.34</b>	<b>88.99</b>
<i>D</i> <sub>1</sub>	Baseline	71.30	88.33
	Our	<b>74.02</b>	<b>89.15</b>
<i>D</i> <sub>2</sub>	Baseline	69.59	88.09
	Our	<b>74.10</b>	<b>89.15</b>
<i>E</i>	Baseline	61.58	87.71
	Our	<b>68.36</b>	<b>88.83</b>

Experiment on dataset *A* gets the best result because “NN” and “VV” can be easily distinguished by its context. Sometimes, “VA” has the similar context with “VV”, experiment on dataset *B* shows its influence. The performances on datasets *B/C/E* descend in turn. The reason is that words with tag “NN” or “NR/JJ” have the similar usage/contexts in Chinese. Since we use the same form *ENG* instead of real words, there are no differences between these words, which leads to some errors. Though the datasets is generated randomly, we can see our method perform better on every dataset than the baseline.

### 6.3 POS Tagging for Mixed Texts with a Real Dataset

To investigate the actual performance, we collect a real dataset from Web, which consists of 142 representative Chinese-English mixed sentences. This dataset contains 4,238 Chinese characters and 275 English words. Since we focus on the performance for English words, we only label the POS tags of the English words. Table 18 shows some examples in the real dataset of mixed texts.

Table 17: Performances on Dataset  $E$ 

POS tag	Method	P	R	F1
NN	Baseline	72.41	68.85	70.59
	Our	71.18	84.88	<b>77.43</b>

You should [follow/VV] this man’s work.
强烈的视觉震撼!! 很 [COOL/VA]!
... very [COOL/VA]!

The information of the real dataset is shown in Table 19. If all involved English words are tagging as “NN”, the precision is just 56%.

Table 19: The Numbers of English Words with Different Tags in Dataset  $R$ 

Dataset	NN	VV	VA	NR
$R$	154	58	28	35

Since there is no noun-modifier “JJ” in our collected data. We use the models trained on dataset B and C to tag the real data. The results are shown in Table 20. The difference between model B and C is that model B regards all words with tag “NR” as “NN”. Since it is difficult to distinguish between “NR” and “NN” merely according to the context, model B performs better than model C.

The detail results of model B and C are shown in Table 21 and 22.

## 7 Related Works

In recent years, POS tagging has undergone great development. The mainstream method is to regard POS tagging as sequence labeling problems (Rabiner, 1990; Xue, 2003; Peng et al., 2004; Ng and Low, 2004).

However, the analysis of Chinese-English mixed texts is rarely involved in previous literature. In the aspect of the general multilingual POS tagging, most works focus on modeling cross-lingual correlations and tagging multilingual POS on respective monolingual texts, not on mixed texts (Cucerzan and Yarowsky, 2002; Yarowsky et al., 2001; Naseem et al., 2009).

Since we choose to use dynamic word-level features to improve the performance of POS tagging, we also review some works on word-level features.

Semi-Markov Conditional Random Fields (semi-CRF) (Sarawagi and Cohen, 2004) is a model in which segmentation task is implicitly included into the decoding algorithm. In this model, feature representation would be more flexible than traditional CRFs, since features can be extracted from the previous/the next segmentation within a window of variable size. The problem of this approach lies in that the decoding algorithm depends on the predefined window size to exploit the boundaries of segmentations but not the real length of words.

Bunescu (2008) presents an improved pipeline model in which the output of the previous subtasks are considered as hidden variables, and the hidden variables together with their probabilities denoting the confidence are used as probabilistic features in the next subtasks. One shortcoming of this method is inefficiency caused by the calculation of marginal probabilities of features. The other disadvantages of the pipeline method are error propagation and the need of separate training of different subtasks in the pipeline. Another disadvantage of pipeline method is error propagation.

Jiang et al. (2008) proposes a cascaded linear model for joint Chinese word segmentation and POS tagging. With a character-based perceptron as the core, combined with real-valued features such as language models, the cascaded model can efficiently utilize knowledge sources that are inconvenient to incorporate into the perceptron directly. However, they use POS tags or word information in a Brute-Force way, which may suffer from the problem of time complexity.

Sun (2011) presents a stacked sub-word model for joint Chinese word segmentation and POS tagging. By merging the outputs of the three predictors (including one word-based segmenter) into sub-word sequences, rich contextual features can be approximately derived. The experiments are conducted to show the effectiveness of using word-based information.

The difference between the above methods and ours is that our word-level features are dynamically generated in the decoding stage without exhaustive or preprocessed word segmentation.

## 8 Conclusion

In this paper, we focus on Chinese-English mixed texts and use dynamic features for POS tagging. To overcome the problem of the lack of annotated corpus on mixed texts, our features use both local and non-local information and take advantage of the characteristics of Chinese-English mixed texts. The experiments demonstrate the effectiveness of our method. It should be noted that our method is also effective for the mixed texts of Chinese and any foreign languages since we use “Unified Replacement”.

For future works, we plan to improve our approximate tagging algorithm to reduce error propagation. In addition, we will refer to an English dictionary to generate some useful features to distinguish between “NR” and “NN” in Chinese-English mixed texts and add some statistical features derived from English resources, such as the most common tag of each English word. We would also like to investigate these features in more applications of natural language processing, such as name entity recognition, information extraction, etc.

## Abstract

Despite significant recent work, purely unsupervised techniques for part-of-speech (POS) tagging have not achieved useful accuracies required by many language processing tasks. Use of parallel text between resource-rich and resource-poor languages is one source of weak supervision that significantly improves accuracy. However, parallel text is not always available and techniques for using it require multiple complex algorithmic steps. In this paper we show that we can build POS-taggers exceeding state-of-the-art bilingual methods by using simple hidden Markov models and a freely available and naturally growing resource, the Wiktionary. Across eight languages for which we have labeled data to evaluate results, we achieve accuracy that significantly exceeds best unsupervised and parallel text methods. We achieve highest accuracy reported for several languages and show that our approach yields better out-of-domain taggers than those trained using fully supervised Penn Treebank.

## 1 Introduction

Part-of-speech categories are elementary building blocks that play an important role in many natural language processing tasks, from machine translation to information extraction. Supervised learning of taggers from POS-annotated training text is a well-studied task, with several methods achieving near-human tagging accuracy (Ratnaparkhi, 1996; Toutanova et al., 2003; Shen et al., 2007). However, while English and a handful of other languages

are fortunate enough to have comprehensive POS-annotated corpora such as the Penn Treebank (Marcus et al., 1993), most of the world’s languages have no labeled corpora. The annotated corpora that do exist were costly to build (Abeillé, 2003), and are often not freely available or restricted to research-only use. Furthermore, much of the annotated text is of limited genre, normally focusing on newswire or literary text. Performance of treebank-trained systems degrades significantly when applied to new domains (Blitzer et al., 2006).

Unsupervised induction of POS taggers offers the possibility of avoiding costly annotation, but despite recent progress, the accuracy of unsupervised POS taggers still falls far behind supervised systems, and is not suitable for most applications (Berg-Kirkpatrick et al., 2010; Graça et al., 2011; Lee et al., 2010). Using additional information, in the form of tag dictionaries or parallel text, seems unavoidable at present. Early work on using tag dictionaries used a labeled corpus to extract all allowed word-tag pairs (Merialdo, 1994), which is quite an unrealistic scenario. More recent work has used a subset of the observed word-tag pairs and focused on generalizing dictionary entries (Smith and Eisner, 2005; Haghighi and Klein, 2006; Toutanova and Johnson, 2007; Goldwater and Griffiths, 2007). Using corpus-based dictionaries greatly biases the test results, and gives little information about the capacity to generalize to different domains.

Recent work by Das and Petrov (2011) builds a dictionary for a particular language by transferring annotated data from a resource-rich language through the use of word alignments in parallel text.

The main idea is to rely on existing dictionaries for some languages (e.g. English) and use parallel data to build a dictionary in the desired language and extend the dictionary coverage using label propagation. However, parallel text does not exist for many pairs of languages and the proposed bilingual projection algorithms are fairly complex.

In this work we use the Wiktionary, a freely available, high coverage and constantly growing dictionary for a large number of languages. We experiment with a very simple second-order Hidden Markov Model with feature-based emissions (Berg-Kirkpatrick et al., 2010; Graça et al., 2011). We outperform best current results using parallel text supervision across 8 different languages, even when the word type coverage is as low as 20%. Furthermore, using the Brown corpus as out-of-domain data we show that using the Wiktionary produces better taggers than using the Penn Treebank dictionary (88.5% vs 85.9%). Our empirical analysis and the natural growth rate of the Wiktionary suggest that free, high-quality and multi-domain POS-taggers for a large number of languages can be obtained by standard and efficient models.

The source code, the dictionary mappings and the trained models described in this work are available at <http://code.google.com/p/wikily-supervised-pos-tagger/>.

## 2 Related Work

The scarcity of labeled corpora for resource poor languages and the challenges of domain adaptation have led to several efforts to build systems for unsupervised POS tagging.

Several lines of research have addressed the fully unsupervised POS-tagging task: mutual information clustering (Brown et al., 1992; Clark, 2003) has been used to group words according to their distributional context. Using dimensionality reduction on word contexts followed by clustering has led to accuracy gains (Schütze, 1995; Lamar et al., 2010). Sequence models, HMMs in particular, have been used to represent the probabilistic dependencies between consecutive tags. In these approaches, each observation corresponds to a particular word and each hidden state corresponds to a cluster. However, using maximum likelihood training for such models

does not achieve good results (Clark, 2003): maximum likelihood training tends to result in very ambiguous distributions for common words, in contradiction with the rather sparse word-tag distribution. Several approaches have been proposed to mitigate this problem, including Bayesian approaches using an improper Dirichlet prior to favor sparse model parameters (Johnson, 2007; Gao and Johnson, 2008; Goldwater and Griffiths, 2007), or using the Posterior Regularization to penalize ambiguous posteriors distributions of tags given tokens (Graça et al., 2009). Berg-Kirkpatrick et al. (2010) and Graça et al. (2011) proposed replacing the multinomial emission distributions of standard HMMs by maximum entropy (ME) feature-based distributions. This allows the use of features to capture morphological information, and achieves very promising results. Despite these improvements, fully unsupervised systems require an oracle to map clusters to true tags and the performance still fails to be of practical use.

In this paper we follow a different line of work where we rely on a prior tag dictionary indicating for each word type what POS tags it can take on (Meraldo, 1994). The task is then, for each word token in the corpus, to disambiguate between the possible POS tags. Even when using a tag dictionary, disambiguating from all possible tags is still a hard problem and the accuracy of these methods is still far behind their supervised counterparts. The scarcity of large, manually-constructed tag dictionaries led to the development of methods that try to generalize from a small dictionary with only a handful of entries (Smith and Eisner, 2005; Haghighi and Klein, 2006; Toutanova and Johnson, 2007; Goldwater and Griffiths, 2007), however most previous works build the dictionary from the labeled corpus they learn on, which does not represent a realistic dictionary. In this paper, we argue that the Wiktionary can serve as an effective and much less biased tag dictionary.

We note that most of the previous dictionary based approaches can be applied using the Wiktionary and would likely lead to similar accuracy increases that we show in this paper. For example, the work of Ravi and Knight (2009) minimizes the number of possible tag-tag transitions in the HMM via an integer program, hence discarding unlikely transitions that would confuse the model. Models can also be trained jointly using parallel corpora in sev-

eral languages, exploiting the fact that different languages present different ambiguities (Snyder et al., 2008).

The Wiktionary has been used extensively for other tasks such as domain specific information retrieval (Müller and Gurevych, 2009), ontology matching (Krizhanovsky and Lin, 2009), synonymy detection (Navarro et al., 2009), sentiment classification (Chesley et al., 2006). Recently, Ding (2011) used the Wiktionary to initialize an HMM for Chinese POS tagging combined with label propagation.

### 3 The Wiktionary and tagged corpora

The Wiktionary<sup>1</sup> is a collaborative project that aims to produce a free, large-scale multilingual dictionary. Its goal is to describe all words from all languages (currently more than 400) using definitions and descriptions in English. The coverage of the Wiktionary varies greatly between languages: currently there are around 75 languages for which there exists more than 1000 word types, and 27 for which there exists more than 10,000 word types. Nevertheless, the Wiktionary has been growing at a considerable rate (see Figure 1), and the number of available words has almost doubled in the last three years. As more people use the Wiktionary, it is likely to grow. Unlike tagged corpora, the Wiktionary provides natural incentives for users to contribute missing entries and expand this communal resource akin to Wikipedia. As with Wikipedia, the questions of accuracy, bias, consistency across languages, and selective coverage are paramount. In this section, we explore these concerns by comparing Wiktionary to dictionaries derived from tagged corpora.

#### 3.1 Labeled corpora and Universal tags

We collected part-of-speech tagged corpora for 9 languages, from CoNLL-X and CoNLL-2007 shared tasks on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007). In this work we use the Universal POS tag set (Petrov et al., 2011) that defines 12 universal categories with a relatively stable functional definition across languages. These categories include NOUN, VERB, ADJ = adjective, ADV = adverb, NUM = number, ADP = adposition, CONJ = conjunction, DET = determiner, PRON =

<sup>1</sup><http://www.wiktionary.org/>

Figure 1: Growth of the Wiktionary over the last three years, showing total number of entries for all languages and for the 9 languages we consider (left axis). We also show the corresponding increase in average accuracy (right axis) achieved by our model across the 9 languages (see details below).

pronoun, PUNC = punctuation, PRT = particle, and X = residual (a category for language-specific categories which defy cross-linguistic classification). We found several small problems with the mapping<sup>2</sup> which we corrected as follows. In Spanish, the fine-level tag for date (“w”) is mapped to universal tag NUM, while it should be mapped to NOUN. In Danish there were no PRT, NUM, PUNC, or DET tags in the mapping. After examining the corpus guidelines and the mapping more closely, we found that the tag AC (Cardinal numeral) and AO (Ordinal numeral) are mapped to ADJ. Although the corpus guidelines indicate the category SsCatgram ‘adjective’ that encompasses both ‘normal’ adjectives (AN) as well as cardinal numeral (AC) and ordinal numerals (AO), we decided to tag AC and AO as NUM, since this assignment better fits the existing mapping. We also reassigned all punctuation marks, which were erroneously mapped to X, to PUNC and the tag U which is used for words *at*, *de* and *som*, to PRT.

#### 3.2 Wiktionary to Universal tags

There are a total of 330 distinct POS-type tags in Wiktionary across all languages which we have mapped to the Universal tagset. Most of the mapping was straightforward since the tags used in the Wiktionary are in fact close to the Universal tag set. Some exceptions like “Initialism”, “Suffix”

<sup>2</sup><http://code.google.com/p/universal-pos-tags/>

were discarded. We also mapped relatively rare tags such as “Interjection”, “Symbol” to the “X” tag. A example of POS tags for several words in the Wiktionary is shown in Table 1. All the mappings are available at <http://code.google.com/p/wikily-supervised-pos-tagger/>.

### 3.3 Wiktionary coverage

There are two kinds of coverage of interest: type coverage and token coverage. We define type coverage as the proportion of word types in the corpus that simply appear in the Wiktionary (accuracy of the tag sets are considered in the next subsection). Token coverage is defined similarly as the portion of all word tokens in the corpus that appear in the Wiktionary. These statistics reflect two aspects of the usefulness of a dictionary that affect learning in different ways: token coverage increases the density of supervised signal while type coverage increases the diversity of word shape supervision. At one extreme, with 100% word and token coverage, we recover the POS tag disambiguation scenario and, on the other extreme of 0% coverage, we recover the unsupervised POS induction scenario.

The type and token coverage of Wiktionary for each of the languages we are using for evaluation is shown in Figure 2. We plot the coverage bar for three different versions of Wiktionary (v20100326, v20110321, v20120320), arranged chronologically. We chose these three versions of the Wiktionary simply by date, not any other factors like coverage, quality or tagging accuracy.

As expected, the newer versions of the Wiktionary generally have larger coverage both on type level and token level. Nevertheless, even for languages whose type coverage is relatively low, such as Greek (el), the token level coverage is still quite good (more than half of the tokens are covered). The reason for this is likely the bias of the contributors towards more frequent words. This trend is even more evident when we break up the coverage by frequency of the words. Since the number of words varies from corpus to corpus, we normalize the word counts by the count of the most frequent word(s) in its corpus and group the normalized frequency into three categories labeled as “low”, “medium” and “high” and for each category, we calculate the word type coverage, shown in Figure 3.

Figure 2: Type-level (top) and token-level (bottom) coverage for the nine languages in three versions of the Wiktionary.

We also compared the coverage provided by the Wiktionary versus the Penn Treebank (PTB) extracted dictionary on the Brown corpus. Figure 4 shows that the Wiktionary provides a greater coverage for all sections of the Brown corpus, hence being a better dictionary for tagging English text in general. This is also reflected in the gain in accuracy on Brown over the taggers learned from the PTB dictionary in our experiments.

### 3.4 Wiktionary accuracy

A more refined notion of quality is the accuracy of the tag sets for covered words, as measured against dictionaries extracted from labeled tree bank corpora. We consider word types that are in both the Wiktionary (W) and the tree bank dictionaries (T). For each word type, we compare the two tag sets and distinguish five different possibilities:

1. Identical:  $W = T$
2. Superset:  $W \supset T$
3. Subset:  $W \subset T$
4. Overlap:  $W \cap T \neq \emptyset$

Wiktionary Entries				Universal POS Set
Language	Word	POS	Definition	
English	today	Adverb	# In the current [[era]]; nowadays.	{ADV, NOUN}
English	today	Adverb	# On the current [[day]] or [[date]].	
English	today	Noun	# A current day or date.	
German	achtzig	Numeral	# [[eighty]]	{NUM}
Swedish	SCB	Acronym	# [[statistiska]] ...	{NOUN}
Portuguese	nessa	Contraction	# {{contraction ...	<i>discard entry</i>

Table 1: Examples of constructing Universal POS tag sets from the Wiktionary.

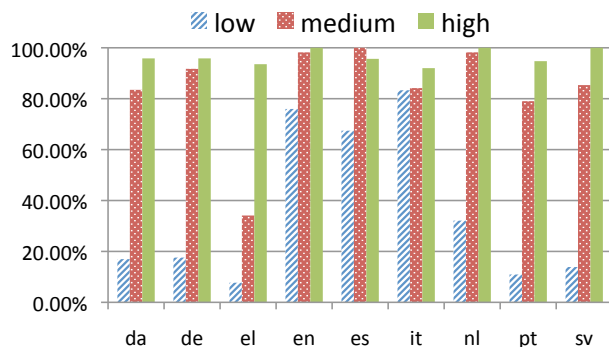

Figure 3: Word type coverage by normalized frequency: words are grouped by word count / highest word count ratio: low [0, 0.01), medium [0.01, 0.1), high [0.1, 1].

#### 5. Disjoint: $W \cap T = \emptyset$ .

In Figure 5, the word types are grouped into the categories described above. Most of the tag sets (around 90%) in the Wiktionary are identical to or supersets of the tree bank tag sets for our nine languages, which is surprisingly accurate. About 10% of the Wiktionary tag sets are subsets of, partially overlapping with, or disjoint from the tree bank tag sets. Our learning methods, which assume the given tag sets are correct, may be somewhat hurt by these word types, as we discuss in Section 5.6.

## 4 Models

Our basic models are first and second order Hidden Markov Models (HMM and SHMM). We also used feature-based max-ent emission models with both (HMM-ME and SHMM-ME). Below, we denote the sequence of words in a sentence as boldface  $\mathbf{x}$  and the sequence of hidden states which correspond to part-of-speech tags as boldface  $\mathbf{y}$ . To simplify notation, we assume that every tag sequence is prefixed

Figure 4: PTB vs. Wiktionary type coverage across sections of the Brown corpus.

with two conventional start tags  $y_0 = \text{start}$ ,  $y_{-1} = \text{start}$ , allowing us to write as  $p(y_1|y_0, y_{-1})$  the initial state probability of the SHMM.

The probability of a sentence  $\mathbf{x}$  along with a particular hidden state sequence  $\mathbf{y}$  in the SHMM is given by:

$$p(\mathbf{x}, \mathbf{y}) = \prod_{i=1}^{\text{length}(\mathbf{x})} p_t(y_i | y_{i-1}, y_{i-2}) p_o(x_i | y_i), \quad (1)$$

where  $p_o(x_i | y_i)$  is the probability of observing word  $x_i$  in state  $y_i$  (emission probability), and  $p_t(y_i | y_{i-1}, y_{i-2})$  is the probability of being in state  $y_i$ , given two previous states  $y_{i-1}, y_{i-2}$  (transition probability).

In this work, we compare multinomial and maximum entropy (log-linear) emission models. Specifically, the max-ent emission model is:

$$p_o(x|y) = \frac{\exp(\theta \cdot \mathbf{f}(x, y))}{\sum_{x'} \exp(\theta \cdot \mathbf{f}(x', y))} \quad (2)$$

where  $\mathbf{f}(x, y)$  is a feature function,  $\mathbf{x}$  ranges over all

Figure 5: The Wiktionary vs. tree bank tag sets. Around 90% of the Wiktionary tag sets are identical or subsume tree bank tag sets. See text for details.

word types, and  $\theta$  are the model parameters. We use the following feature templates:

- Word identity - lowercased word form if the word appears more than 10 times in the corpus.
- Hyphen - word contains a hyphen
- Capital - word is uppercased
- Suffix - last 2 and 3 letters of a word if they appear in more than 20 different word types.
- Number - word contains a digit

The idea of replacing the multinomial models of an HMM by maximum entropy models has been applied before in different domains (Chen, 2003), as well as in POS induction (Berg-Kirkpatrick et al., 2010; Graça et al., 2011).

We use the EM algorithm to learn the models, restricting the tags of each word to those specified by the dictionary. For each tag  $y$ , the observations probabilities  $p_o(x | y)$  were initialized randomly for every word type that allows tag  $y$  according to the Wiktionary and zero otherwise. For the M-step in max-ent models, there is no closed form solution so we need to solve an unconstrained optimization problem. We use L-BFGS with Wolfe’s rule line search (Nocedal and Wright, 1999). We found that EM achieved higher accuracy across languages compared to direct gradient approach (Berg-Kirkpatrick et al., 2010).

## 5 Results

We evaluate the accuracy of taggers trained using the Wiktionary using the 4 different models: A first order Hidden Markov Model (HMM), a second order Hidden Markov Model (SHMM), a first order Hidden Markov Model with Maximum Entropy emission models (HMM-ME) and a second order Hidden Markov Model with Maximum Entropy emission models (SHMM-ME). For each model we ran EM for 50 iterations, which was sufficient for convergence of the likelihood. Following previous work (Graça et al., 2011), we used a Gaussian prior with variance of 10 for the max-ent model parameters. We obtain hard assignments using posterior decoding, where for each position we pick the label with highest posterior probability: this produces small but consistent improvements over Viterbi decoding.

### 5.1 Upper and lower bounds

We situate our results against several upper bounds that use more supervision. We trained the SHMM-ME model with a dictionary built from the training and test tree bank (ALL TBD) and also with tree bank dictionary intersected with the Wiktionary (Covered TBD). The Covered TBD dictionary is more supervised than the Wiktionary in the sense that some of the tag set mismatches of the Wiktionary are cleaned using the true corpus tags. We also report results from training the SHMM-ME in the standard supervised fashion, using 50 (50 Sent.), 100 (100 Sent.) and all sentences (All Sent.).

As a lower bound we include the results for unsupervised systems: a regular HMM model trained with EM (Johnson, 2007) and an HMM model using a ME emission model trained using direct gradient (Berg-Kirkpatrick et al., 2010)<sup>3</sup>.

### 5.2 Bilingual baselines

Finally, we also compare our system against a strong set of baselines that use bilingual data. These approaches build a dictionary by transferring labeled data from a resource rich language (English) to a resource poor language (Das and Petrov, 2011). We compare against two such methods. The first, *projection*, builds a dictionary by transferring the pos

<sup>3</sup>Values for these systems were taken from the D&P paper.

tags from English to the new language using word alignments. The second method, *D&P*, is the current state-of-the-art system, and runs label propagation on the dictionary resulting from the *projected* method. We note that both of these approaches are orthogonal to ours and could be used simultaneously with the Wiktionary.

### 5.3 Analysis

Table 2 shows results for the different models across languages. We note that the results are not directly comparable since both the Unsupervised and the Bilingual results use a different setup, using the number of fine grained tags for each language as hidden states instead of 12 (as we do). This greatly increases the degrees of freedom of the model allowing it to capture more fine grained distinctions.

The first two observations are that using the ME entropy emission model always improves over the standard multinomial model, and using a second order model always performs better. Comparing with the work of *D&P*, we see that our model achieves better accuracy on average and on 5 out of 8 languages.

The most common errors are due to tag set idiosyncrasies. For instance, for English the symbol % is tagged as NUM by our system while in the Penn treebank it is tagged as Noun. Other common mistakes for English include tagging *to* as an adposition (preposition) instead of particle and tagging *which* as a pronoun instead of determiner. In the next subsections we analyze the errors in more detail.

Finally, for English we also trained the SHMM-ME model using the Celex2 dictionary available from LDC<sup>4</sup>. Celex2 coverage for the PTB corpus is much smaller than the coverage provided by the Wiktionary (43.8% type coverage versus 80.0%). Correspondingly, the accuracy of the model trained using Celex2 is 75.5% compared 87.1% when trained using the Wiktionary.

### 5.4 Performance vs. Wiktionary ambiguity

While many words overwhelmingly appear with one tag in a given genre, in the Wiktionary a large proportion of words are annotated with several tags, even when those are extremely rare events. Around

35% of word types in English have more than one tag according to the Wiktionary. This increases the difficulty of predicting the correct tag as compared to having a corpus-based dictionary, where words have a smaller level of ambiguity. For example, in English, for words with one tag, the accuracy is 95% (the reason it is not 100% is due to a discrepancy between the Wiktionary and the tree bank.) For words with two possible tags, accuracy is 81% and for three tags, it drops to 63%.

### 5.5 Generalization to unknown words

Comparing the performance of the proposed model for words in the Wiktionary against words not in the Wiktionary, we see an average drop from 89% to 63% for out-of-vocabulary words across nine languages. Table 2 shows that the average loss of accuracy between All TBD and Covered TBD of 4.5% (which is due purely to decrease in coverage) is larger than the loss between Covered TBD and the best Wiktionary model, of 3.2% (which is due to tag set inconsistency).

One advantage of the Wiktionary is that it is a general purpose dictionary and not tailored for a particular domain. To illustrate this we compared several models on the Brown corpus: the SHMM-ME model using the Wiktionary (Wik), against using a model trained using a dictionary extracted from the PTB corpus (PTBD), or trained fully supervised using the PTB corpus (PTB). We tested all these models on the 15 different sections of the Brown corpus. We also compare against a state-of-the-art POS-tagger tagger (ST)<sup>5</sup>.

Figure 6 shows the accuracy results for each model on the different sections. The fully supervised SHMM-ME model did not perform as well as the the Stanford tagger (about 3% behind on average), most likely because of generative vs. discriminate training of the two models and feature differences. However, quite surprisingly, the Wiktionary-tag-set-trained model performs much better not only than the PTB-tag-set-trained model but also the supervised model on the Brown corpus.

Table 2: Accuracy for Unsupervised, Bilingual, Wiktionary and Supervised models. Avg. is the average of all languages except English. Unsupervised models are trained without dictionary and use an oracle to map tags to clusters. Bilingual systems are trained using a dictionary transferred from English into the target language using word alignments. The *Projection* model uses a dictionary build directly from the part-of-speech projection. The *D&P* model extends the *Projection* model dictionary by using Label Propagation. Supervised models are trained using tree bank information with SHMM-ME: Covered TBD used tree bank tag set for the words only if they are also in the Wiktionary and All TBD uses tree bank tag sets for all words. 50, 100 and All Sent. models are trained in a supervised manner using increasing numbers of training sentences.

Figure 6: Model accuracy across the Brown corpus sections. ST: Stanford tagger, Wik: Wiktionary-tag-set-trained SHMM-ME, PTBD: PTB-tag-set-trained SHMM-ME, PTB: Supervised SHMM-ME. Wik outperforms PTB and PTBD overall.

## 5.6 Error breakdown

In Section 3.4 we discussed the accuracy of the Wiktionary tag sets and as Table 2 shows, a dictionary with better tag set quality generally (except for Greek) improves the POS tagging accuracy. In Figure 7, we group actual errors by the word type classified into the five cases discussed above: identical, superset, subset, overlap, disjoint. We also add oov – out-of-vocabulary word types. The largest source of error across languages are out-of-vocabulary (oov) word types at around 45% of the errors, followed by tag set mismatch types: subset, overlap, dis-

joint, which together comprise another 50% of the errors. As Wiktionary grows, these types of errors will likely diminish.

Figure 7: Tag errors broken down by the word type classified into the six classes: oov, identical, superset, subset, overlap, disjoint (see text for detail). The largest source of error across languages are out-of-vocabulary (oov) word types, followed by tag set mismatch types: subset, overlap, disjoint.

## 6 Conclusion

We have shown that the Wiktionary can be used to train a very simple model to achieve state-of-art weakly-supervised and out-of-domain POS taggers. The methods outlined in the paper are standard and easy to replicate, yet highly accurate and should serve as baselines for more complex propos-

als. These encouraging results show that using free, collaborative NLP resources can in fact produce results of the same level or better than using expensive annotations for many languages. Furthermore, the Wiktionary contains other possibly useful information, such as glosses and translations. It would be very interesting and perhaps necessary to incorporate this additional data in order to tackle challenges that arise across a larger number of language types, specifically non-European languages.

## Acknowledgements

We would like to thank Slav Petrov, Kuzman Ganchev and André Martins for their helpful feedback in early versions of the manuscript. We would also like to thank to our anonymous reviewers for their comments and suggestions. Ben Taskar was partially supported by a Sloan Fellowship, ONR 2010 Young Investigator Award and NSF Grant 1116676.

Sapienza Università di Roma

{navigli,ponzetto}@di.uniroma1.it

## Abstract

We present a multilingual joint approach to Word Sense Disambiguation (WSD). Our method exploits BabelNet, a very large multilingual knowledge base, to perform graph-based WSD across different languages, and brings together empirical evidence from these languages using ensemble methods. The results show that, thanks to complementing wide-coverage multilingual lexical knowledge with robust graph-based algorithms and combination methods, we are able to achieve the state of the art in both monolingual and multilingual WSD settings.

## 1 Introduction

Nowadays the textual information needed by a user accessing websites for content such as news reports, commentaries and encyclopedic knowledge is provided in an increasingly wide range of languages. For example, even though English is still the majority language of the Web, the Chinese and Spanish languages are moving fast to capture their “juicy share”, and more languages are about to join them in the near future. This language explosion clearly forces researchers to focus on the challenging problem of being able to analyze and understand text written in any language. However, it also opens up novel perspectives for multilingual Natural Language Processing (NLP) such as, for instance, the development of approaches aimed at “joining forces” and taking advantage of the lexico-semantic knowledge provided in the different languages to improve text understanding. These two aspects are strongly intertwined: on the one hand, enabling

language-independent text understanding would allow for the harvesting of more knowledge in arbitrary languages, while, on the other hand, bringing together the lexical and semantic information available in different languages would improve the quality of text understanding in arbitrary languages.

However, these two goals have hitherto never been achieved, as is attested to by the fact that research in a core language understanding task such as Word Sense Disambiguation (Navigli, 2009, WSD) has always been focused mostly on English. Historically, English became established as the language used and understood by the scientific community and, consequently, most resources were developed for it, including large-scale computational lexicons like WordNet (Fellbaum, 1998) and sense-tagged corpora like SemCor (Miller et al., 1993). As a result WSD in other languages was hindered by a lack of resources, which in turn led to poor results or low involvement on the part of the research community (Magnini et al., 2004; Màrquez et al., 2004; Orhan et al., 2007; Okumura et al., 2010). Nonetheless, already in the 1990s it had been remarked that WSD could be improved by means of multilingual information: a recurring idea proposed by several researchers was that plausible translations of a word in context would restrict its possible senses to a manageable subset of meanings (Dagan et al., 1991; Gale et al., 1992; Resnik and Yarowsky, 1999). While the lack of resources at that time hampered the development of effective multilingual approaches to WSD, recently this idea has been revamped with the organization of SemEval tasks dealing with cross-lingual WSD (Lefever and Hoste, 2010) and cross-lingual lexical substitution (Mihalcea et al., 2010). At the same time, new re-

search on the topic has been done, including the use of statistical translations of sentences into many languages as features for supervised models (Banea and Mihalcea, 2011; Lefever et al., 2011), and the projection of monolingual knowledge onto another language (Khapra et al., 2011).

Yet the above two goals, i.e., disambiguating in an arbitrary language and using lexical and semantic knowledge from many languages in a joint way to improve the WSD task, have not hitherto been attained. In this paper, we address both objectives and propose a graph-based approach to multilingual joint Word Sense Disambiguation. Our proposal brings together the lexical knowledge from different languages by exploiting empirical evidence for disambiguation from each of them, and then combining this information in a synergistic way: each language provides a piece of sense evidence for the meaning of a target word in context, and subsequent integration of these various pieces enables them to (soft) constrain each other. The results show that this way we are able to improve over previous, high-performing graph-based methods in both a monolingual and multilingual setting, thus showing for the first time the beneficial effects of exploiting multilingual knowledge in a joint fashion.

## 2 Related Work

Parallel corpora have been used in the literature for the automatic creation of a sense-tagged dataset for supervised WSD in different languages (Gale et al., 1992; Chan and Ng, 2005; Zhong and Ng, 2009). Other approaches include the use of a coherence index for identifying the tendency to lexicalize senses differently across languages (Ide, 2000) and the clustering of source words which translate into the same target word, then used to perform WSD using a similarity measure (Diab, 2003). A historical approach (Brown et al., 1991) uses bilingual corpora to perform unsupervised word alignment and determine the most appropriate translation for a target word from a set of contextual features.

All the above approaches to multilingual or cross-lingual WSD rely on bilingual corpora, including those which exploit existing multilingual WordNet-like resources (Ide et al., 2002), or use automatically induced multilingual co-occurrence graphs (Silberer

and Ponzetto, 2010). However, this requirement is often very hard to satisfy, especially if we need wide coverage. To overcome this limitation, in this work we make use of BabelNet (Navigli and Ponzetto, 2010), a very large multilingual lexical knowledge base. This resource – complementary in nature to other recent efforts presented by de Melo and Weikum (2010), Nastase et al. (2010) and Meyer and Gurevych (2012), *inter alia* – provides a truly multilingual semantic network by combining Wikipedia’s multilinguality with the output of a state-of-the-art machine translation system to achieve high coverage for all languages. The key insight here is that Word Sense Disambiguation and Machine Translation (MT) are highly intertwined tasks, as previously shown by Carpuat and Wu (2007) and Chan et al. (2007), who successfully used sense information to boost state-of-the-art statistical MT. In this work we focus instead on the benefits of using multilingual information for WSD by exploiting the structure of a multilingual semantic network.

## 3 Multilingual Joint WSD

We present our methodology for multilingual WSD: we first introduce BabelNet, the resource used in our work (Section 3.1) and then present our algorithm for multilingual joint WSD (Section 3.2), including its main components, namely graph-based WSD, ensemble methods and translation weighting (sections 3.3, 3.4 and 3.5).

### 3.1 BabelNet

BabelNet (Navigli and Ponzetto, 2010) follows the structure of a traditional lexical knowledge base and, accordingly, consists of a labeled directed graph whose nodes represent concepts and named entities, and whose edges express semantic relations between them. Concepts and relations are harvested from the largest available semantic lexicon of English, i.e., WordNet, and a wide-coverage collaboratively-edited encyclopedia, i.e., Wikipedia<sup>1</sup>, thus making BabelNet a multilingual ‘encyclopedic dictionary’ which combines lexicographic information with encyclopedic knowledge on the basis of an unsupervised mapping framework. In addition to a core

<sup>1</sup><http://www.wikipedia.org>. In the following, we refer to Wikipedia pages and senses using SMALL CAPS.

semantic network, BabelNet provides a multilingual lexical dimension. Each of its nodes, called *Babel synsets*, contains a set of lexicalizations of the concept for different languages, e.g.,  $\{\text{bank}_n^{\text{EN}}, \text{Bank}_n^{\text{DE}}, \text{banca}_n^{\text{IT}}, \dots, \text{banco}_n^{\text{ES}}\}$ <sup>2</sup>. Multilingual lexicalizations for all concepts are collected from Wikipedia’s inter-language links (e.g., the English Wikipedia page BANK links to the Italian BANCA), as well as by acquiring missing translations by means of a statistical machine translation system applied to sense-tagged data from SemCor and Wikipedia itself – for instance, most occurrences of  $\text{bank}_n^1$  in SemCor<sup>3</sup> are translated into German and Italian as Ufer and riva, respectively. As a result of combining human-edited translations from Wikipedia and automatically generated ones from sense-labeled data, BabelNet is able to achieve wide coverage for all its languages (Catalan, English, French, German, Italian and Spanish): accordingly, we chose it to perform graph-based WSD in a multilingual setting since it is specifically focused on lexical knowledge. In addition, BabelNet is available for any language required to perform standard SemEval cross-lingual disambiguation tasks (e.g., Spanish, in order to perform cross-lingual lexical substitution). Since previous work in knowledge-based WSD shows the benefits of using rich lexical resources (Navigli and Lapata, 2010; Ponzetto and Navigli, 2010), BabelNet is a suitable choice for performing graph-based multilingual WSD.

### 3.2 Exploiting multilingual information in a knowledge-based WSD framework

We present a multilingual approach to WSD which exploits three main factors:

- i) the fact that translations of a target word provide complementary information on the range of its candidate senses in context;
- ii) the wide-coverage, multilingual lexical knowledge stored in BabelNet;
- iii) the support for disambiguation from different languages in a synergistic, unified way.

<sup>2</sup>BabelNet senses are referred to with  $w_p^l$ , namely the sense of a word  $w$  in a language  $l$  with part of speech  $p$ .

<sup>3</sup>We denote WordNet senses with  $w_p^i$ , namely the  $i$ -th sense of a word  $w$  with part of speech  $p$ .

---

#### Algorithm 1 Multilingual joint WSD

---

**Input:** a word sequence  $\sigma = (w_1, \dots, w_n)$   
a target word  $w \in \sigma$   
BabelNet  $BN$   
an ensemble method  $M$

**Output:** a distribution of scores for the senses of  $w$

(▷ indicates a comment)

- 1:  $S \leftarrow \text{Synsets}_{BN}(w)$
- 2:  $T \leftarrow \{w\}$
- 3: **for each**  $s \in S$
- 4:    $T \leftarrow T \cup \text{getTranslations}(s)$
- 5:  $ctx \leftarrow \sigma - \{w\}$
- 6: ▷  $LScore := \{lScore_{i,j}\}_{i=1,\dots,|T|, j=1,\dots,|S|}$
- 7: **for each**  $t_i \in T$
- 8:    $\sigma' \leftarrow \{t_i\} \cup ctx$
- 9:   ▷  $G_i := (V_i, E_i)$
- 10:    $G_i \leftarrow \text{createGraph}(\sigma', BN)$
- 11:   **for each**  $s_j \in S \cap V_i$
- 12:      $lScore_{i,j} \leftarrow \text{score}(G_i, s_j)$
- 13: ▷  $Score := (score_1, \dots, score_{|S|})$
- 14:  $Score \leftarrow M(LScore)$
- 15: **return**  $Score$

---

We call this approach *multilingual joint WSD*, since disambiguation is performed by exploiting different languages *together at the same time*. To this end, we first perform graph-based WSD using the target word in context as input, and then combine sense evidence from its translations using an ensemble method. The key idea of our joint approach is that sense evidence from different translations provides complementary views for the senses of a target word in context. Therefore, combining such evidence should produce more accurate sense predictions. We view WSD as a sense ranking problem. Given a word sequence  $\sigma = (w_1, \dots, w_n)$ , we disambiguate a target word  $w \in \sigma$  by scoring each of its senses and selecting the highest-ranking one:

$$\hat{s} = \arg \max_{s \in \text{Synsets}_{BN}(w)} \text{score}(s), \quad (1)$$

where  $\text{Synsets}_{BN}(w)$  is the set of Babel synsets containing the different senses for  $w$ .<sup>4</sup> We score these

<sup>4</sup>Babel synsets unambiguously identify different senses of the target word, e.g.,  $\{\text{bank}_n^{\text{EN}}, \text{Bank}_n^{\text{DE}}, \text{banco}_n^{\text{ES}}, \dots, \text{banca}_n^{\text{IT}}\}$  corresponds to the ‘financial institute’ sense of  $\text{bank}_n^{\text{EN}}$  (i.e.,  $\text{bank}_n^2$  in WordNet).

synsets using Algorithm 1, which we illustrate in the following by means of the example sentence ‘bank bonuses are paid in stock’, where we focus on  $\text{bank}_n^{\text{EN}}$  as the target word and  $\{\text{bonus}_n^{\text{EN}}, \text{pay}_v^{\text{EN}}, \text{stock}_n^{\text{EN}}\}$  as its context. The following steps are performed:

**Initialization.** We start by gathering the data required for disambiguation (lines 1–5). First, we collect in line 1 the set  $S$  of Babel synsets corresponding to the different senses of the target word  $w$  – namely, the synsets containing the ‘financial institution’, ‘money container’, ‘building’ senses of  $\text{bank}_n^{\text{EN}}$ , among others. Next, we obtain the multilingual lexicalizations of the target word: to this end, we first include in  $T$  the word  $w$  itself (line 2), and then iterate through each synset  $s \in S$  to collect the translations of each of its senses in the languages of interest (lines 3–4). For instance, given the English word  $\text{bank}_n^{\text{EN}}$ , we collect its sense-specific German, Italian and Spanish translations and obtain a set of multilingual terms  $T = \{\text{bank}_n^{\text{EN}}, \dots, \text{Bank}_n^{\text{DE}}, \text{Sparbüchse}_n^{\text{DE}}, \text{Bankgebäude}_n^{\text{DE}}, \dots, \text{banca}_n^{\text{IT}}, \text{salvadanaio}_n^{\text{IT}}, \dots, \text{banco}_n^{\text{ES}}, \text{hucha}_n^{\text{ES}}\}$ . Finally, we create a disambiguation context  $ctx$  by taking the word sequence  $\sigma$  and removing  $w$  from it (line 5, as a result, e.g.,  $ctx = \{\text{bonus}_n^{\text{EN}}, \text{pay}_v^{\text{EN}}, \text{stock}_n^{\text{EN}}\}$ ).

**Collecting sense distributions.** In the next phase (lines 6–12), we collect a scoring distribution over the different synsets  $S$  of  $w$  for each term  $t_i \in T$ . Each distribution quantifies the empirical support for the different senses of the target word, obtained using  $t_i$  and the context  $ctx$ : we store this information in a  $|T| \times |S|$  matrix  $LScore$ , where each cell  $lScore_{i,j}$  quantifies the support for synset  $s_j \in S$ , computed using the term in  $t_i \in T$ . We calculate the scores as follows:

- We select at each step an element  $t_i$  from  $T$  (line 7), for instance  $\text{banco}_n^{\text{ES}}$ .
- Next, we create a multilingual context  $\sigma'$  by combining  $t_i$  with the words in  $ctx$  (line 8, e.g., we set  $\sigma' = \{\text{banco}_n^{\text{ES}}, \text{bonus}_n^{\text{EN}}, \text{pay}_v^{\text{EN}}, \text{stock}_n^{\text{EN}}\}$ ).
- We use  $\sigma'$  to build a graph  $G_i = (V_i, E_i)$  by computing the paths in BabelNet which connect the synsets of  $t_i$  with those of the other words in  $\sigma'$  (line 10, see Section 3.3 for details on the

*createGraph* function). Note that by selecting at each step a different element from  $T$  we create a new graph where different sets of Babel synsets get activated by the context words in  $ctx$ . In our example, Figures 1(a)–(c) show the graphs obtained by setting at different steps  $t_i$  to  $\text{bank}_n^{\text{EN}}$ ,  $\text{banco}_n^{\text{ES}}$  and  $\text{Bank}_n^{\text{DE}}$ , respectively (we show excerpts by using only  $\text{stock}_n^{\text{EN}}$  as context word for ease of readability).

- Finally, we compute the support from term  $t_i$  for each synset  $s_j \in S$  of the target word by applying a graph connectivity measure to  $G_i$  and store the result in  $lScore_{i,j}$  (lines 11–12). For instance, using degree as graph measure, we can compute the following scores from the graph in Figure 1(b):

$$\begin{array}{ccccc} & & \text{bank}_n^2 & \text{bank}_n^8 & \text{bank}_n^9 \\ \text{banco}_n^{\text{ES}} & & 2 & 0 & 1 \end{array}$$

By repeating the process for each term in  $T$  (lines 7–12) we compute all values in the matrix  $LScore$ . For instance, given  $T = \{\text{bank}_n^{\text{EN}}, \text{banco}_n^{\text{ES}}, \text{Bank}_n^{\text{DE}}\}$ , we create the set of graphs in Figures 1(a)–(c), and compute from each of them the following scores (again, using degree as scoring measure):

$$LScore = \begin{array}{ccccc} & & \text{bank}_n^2 & \text{bank}_n^8 & \text{bank}_n^9 \\ \text{bank}_n^{\text{EN}} & \left[ \begin{array}{ccc} 2 & 2 & 1 \end{array} \right. \\ \text{banco}_n^{\text{ES}} & \left[ \begin{array}{ccc} 2 & 0 & 1 \end{array} \right. \\ \text{Bank}_n^{\text{DE}} & \left[ \begin{array}{ccc} 2 & 0 & 0 \end{array} \right. \end{array}$$

**Combining sense distributions.** In the last step (line 14) we aggregate the scores associated with each term of  $T$  using an ensemble method  $M$  (see Section 3.4 for details). For instance,  $M$  could simply consist of summing the scores associated with each sense over all distributions and thus return a score of 6, 2, and 2 for  $\text{bank}_n^2$ ,  $\text{bank}_n^8$  and  $\text{bank}_n^9$ , respectively. As a result of the execution of Algorithm 1, the combined scoring distribution is returned (line 15). This sense distribution in turn can be used to select the best sense using Equation 1.

The main hunch behind our approach is that using information from different languages improves disambiguation performance, as in the example of Figure 1 where more accurate disambiguation is performed by combining scores computed from translations in different languages, as opposed to using

Figure 1: Multilingual graph construction for the input sentence ‘bank bonuses are paid in stock’. We show excerpts using only  $\text{stock}_n^{\text{EN}}$  as context word for ease of readability.

monolingual sense evidence only. Figure 1(a) shows the graph created to disambiguate the English target word  $\text{bank}_n^{\text{EN}}$  in our example sentence. In the graph, some of the possible senses of this word are activated, including the correct one ( $\text{bank}_n^2$ ) but also related, yet incorrect ones such as  $\text{bank}_n^8$  and  $\text{bank}_n^9$ . Figure 1(b) and 1(c) show instead the graphs obtained from replacing the target word with its Spanish and German translations, respectively. In these graphs, different subsets of the senses of  $\text{bank}_n^{\text{EN}}$  are activated, together with others pertaining to the translations only (e.g., the meaning of  $\text{banco}_n^{\text{ES}}$  corresponding to the English  $\text{bench}_n^1$ ). However, the sense that is consistently activated across all graphs is the correct one – i.e.,  $\text{bank}_n^{\text{EN}}$  as financial institution – which is in fact the sense selected by our multilingual approach by means of combining the scoring distributions from all these graphs.

### 3.3 Graph-based WSD

We use graph-based algorithms to exploit multilingual knowledge from BabelNet for WSD. These are a natural choice for our approach, since BabelNet is

a semantic network, and such algorithms have been shown to achieve high performance across domains (Agirre et al., 2009; Navigli et al., 2011), as well as to compete with supervised methods on a variety of lexical disambiguation tasks (Ponzetto and Navigli, 2010). To this end, we use the method of Navigli and Lapata (2010) and construct a directed graph  $G = (V, E)$  for an input word sequence  $\sigma = (w_1, \dots, w_n)$ <sup>5</sup> using the lexical and semantic relations found in BabelNet. The result of this procedure is a subgraph of BabelNet containing (1) the senses of the words in context, (2) all edges and intermediate senses found in BabelNet along all paths that connect them. Given  $G$ , a target word  $w \in \sigma$  and its set of senses in BabelNet  $S \subseteq V$ , we compute a score distribution  $(score_1, \dots, score_{|S|})$  over  $S$ , where  $score_j$  refers to the confidence score for the  $j$ -th sense of  $w$ , e.g.  $\text{bank}_n^2$ , based on some connectivity measure applied to  $G$ . In this paper, we specifically focus on two such measures.

<sup>5</sup>In our experiments we always take  $\sigma$  to be a single sentence, thus disambiguating on a sentence-by-sentence basis.

**Degree Centrality (Degree):** The first measure ranks the senses of a given word in the graph based on the number of their incident edges, namely:

$$score_j = |\{\{s_j, v\} \in E : v \in V\}|.$$

This standard connectivity measure weights a sense as more appropriate if it has a higher degree. We chose context-based Degree since, albeit simple, it had previously been shown to yield a highly competitive performance on various WSD tasks (Navigli and Lapata, 2010; Ponzetto and Navigli, 2010).

**Inverse path length sum (PLength):** We then developed a graph connectivity measure which scores each sense by summing over the inverse length of all paths which connect it to other senses in the graph:

$$score_j = \sum_{p \in paths(s_j)} \frac{1}{e^{length(p)-1}},$$

where  $paths(s_j)$  is the set of simple paths connecting  $s_j$  to the senses of other context words,  $length(p)$  is the number of edges in the path  $p$  and each path is scored with the exponential inverse decay of the path length. This measure overcomes the locality of Degree by aggregating over all paths between a sense of the target word and those of the context words, thus being able to capture the richness of the BabelNet subgraph and the semantic density of the underlying knowledge base.

### 3.4 Ensemble methods for multilingual WSD

At the core of our algorithm lies the combination of the scores generated using the different translations of the target word  $w$ . For this purpose, we apply so-called *ensemble* methods, which have been shown to improve the performance of both supervised (Florian et al., 2002) and unsupervised WSD systems (Brody et al., 2006). Given  $|T|$  lexicalizations and  $|S|$  senses for  $w$ , the input to the combination component consists of a  $|T| \times |S|$  matrix  $LScore$ , where each cell  $lScore_{i,j}$  quantifies the empirical support for sense  $s_j$  from a term  $t_i \in T$  (see Section 3.2 for an example). The ensemble method computes from this translation-sense matrix a combined scoring, expressing the *joint* confidence across terms in different languages over the set of senses  $S$ . In this work, we use the ‘Probability Mixture’ (PMixture) method

proposed by Brody et al. (2006), which they show to be the best performing for WSD. This method takes the scores associated with each term, normalizes and combines them by summing across distributions. Formally, it computes the score for the  $j$ -th sense of  $w$  as follows:

$$score_j = \sum_{i=1}^{|T|} p(s_{i,j}), \quad p(s_{i,j}) = \frac{lScore_{i,j}}{\sum_{s=1}^{|S|} lScore_{i,s}}.$$

For instance, using the (normalized) sense distributions from our example, the ensemble distribution will be the following:

	bank <sub>n</sub> <sup>2</sup>	bank <sub>n</sub> <sup>8</sup>	bank <sub>n</sub> <sup>9</sup>
bank <sub>n</sub> <sup>EN</sup>	0.40	0.40	0.20

### 3.5 Weighting multilingual sense distribution

Computing a sense distribution for each translation using the same graph connectivity measure assumes that all translations are equal. However, a *leitmotif* of multilingual WSD research is that translations restrict the set of candidate senses of the target word in the source language. In our example of Figure 1, for instance, Bank<sub>n</sub><sup>DE</sup> provides structural support only for the financial sense of English *bank*, since this is the only sense it covers. Within our framework this can potentially lead to skewed sense distributions when only some senses of the target word have a translation. In such cases, in fact, scores tend to be concentrated mostly on the senses covered by the translations, with the result that sense evidence for uncovered English senses is disregarded. In order to cope with this issue, we weight the elements of each sense distribution  $lScore_i$  for the  $i$ -th translation  $t_i \in T$  by a factor of  $1 + \log_2 cov(t_i, w)$ , where  $cov(t_i, w)$  is the number of Babel synsets where  $t_i$  co-occurs with the target word  $w$  – i.e., the number of senses of  $w$  that it covers (we use the log function to dampen the effect of high coverage values). This is to say, in order to level off the effects of unbalanced sense coverage we assume that, all things being equal, the more senses a translation covers, the stronger the disambiguation evidence it provides in context for specific senses. As a result, the contributions of each translation are weighted differently

and we are thus able to dampen the effects of a highly skewed distribution like, for instance, that of  $\text{Bank}_n^{\text{DE}}$ :

	$\text{bank}_n^2$	$\text{bank}_n^8$	$\text{bank}_n^9$
$\text{bank}_n^{\text{EN}}$	1.72	1.72	0.86
$\text{banco}_n^{\text{ES}}$	1.34	0.00	0.66
$\text{Bank}_n^{\text{DE}}$	1.00	0.00	0.00
Weighted PMixture	4.04	1.70	1.52

## 4 Experiments

We evaluate our approach in two different settings, namely a monolingual all-words WSD task in Section 4.1, as well as two different cross-lingual disambiguation gold standards in Section 4.2.

### 4.1 Monolingual WSD

**Experimental setting.** We first evaluate the performance of multilingual joint WSD on a standard monolingual dataset, namely the SemEval-2010 domain WSD task 17 (Agirre et al., 2010), since it provides the latest dataset for fine-grained WSD in English. We opt for an English all-words task for two main reasons: first, it is a well-established and widely-participated task in the WSD community – thus ensuring a comparison of our method with a wide range of state-of-the-art approaches, including other graph-based techniques (e.g., Personalized PageRank), as well as weakly-supervised and supervised approaches (see Agirre et al. (2010) for details on the participating systems); second, we want to assess whether a multilingual approach benefits lexical disambiguation in *all* settings, namely *even* in a standard monolingual one. We use in our experiments the dataset’s nouns-only subset (1032 instances), since BabelNet currently contains multilingual lexicalizations for nouns only (and thus no multilingual strategy can be applied to other parts of speech). We perform graph-based WSD with BabelNet in two different configurations, namely a monolingual and multilingual setting. The multilingual system performs WSD by means of the full joint multilingual approach described in Algorithm 1. The monolingual approach, instead, simply uses the English input sentence for disambiguation – that is, we skip lines 3–4 of Algorithm 1. Knowledge-based systems typically suffer from a low recall – i.e., they cannot provide an answer if no information

	Algorithm	P	R	F <sub>1</sub>
Monolingual graph	Degree	50.6	45.2	47.7
	PLength	51.0	47.3	49.1
Multilingual ensemble	Degree <sup>†</sup>	53.9	48.6	51.1
	PLength <sup>†</sup>	<b>54.3</b>	50.2	<b>52.2</b>
	SemCor MFS	51.9	<b>51.2</b>	51.5
	Random	25.3	25.3	25.3

Table 1: Performance on SemEval-2010 all-words domain WSD (nouns only subset). Best results for each measure are bolded. † indicates statistically significant differences with respect to the monolingual setting.

can be found with senses of the context words. To overcome this issue, in both settings we use a type-based fallback strategy which assigns to the target word the sense which has been most frequently assigned by the system to other instances of the word in the dataset.

**Results and discussion.** We report our results in terms of precision (P), recall (R) and F<sub>1</sub> measure in Table 1, where we compare the monolingual variant (rows 1–2 of the table) with our multilingual approach (rows 3–4). Following standard practice, (1) we benchmark our method against two baselines, namely a random sense assignment and the most frequent sense (MFS) from SemCor; (2) we test for statistical significance by computing a 95% confidence interval on the recall score (i.e., the main evaluation measure for the WSD task) using bootstrap resampling (Noreen, 1989).

The results show that our multilingual approach improves over the monolingual one by a substantial (i.e., statistically significant) margin. Combining multilingual information from different languages yields a higher precision (+3.3 for both graph algorithms) and recall (+3.4 and +2.9 for Degree and PLength, respectively). Manual inspection of the output reveals that these increases in precision are due to translations in different languages constraining each other – e.g., an implausible English sense is ‘ruled out’ from the sense distributions of the other languages (cf. the example in Figure 1). The increases in recall, instead, indicate that using translations triggers responses in those cases where no sense of the English target word can be connected to the senses of the context words – i.e., some trans-

	Algorithm	P	R	F <sub>1</sub>

	PLength	55.0	54.2	54.6
Multilingual ensemble	Degree <sup>†</sup>	61.6	59.5	60.5
	PLength <sup>†</sup>	<b>62.5</b>	<b>60.4</b>	<b>61.4</b>
	CFILT	61.4	59.4	60.4
	IIITH	56.4	55.3	55.8

Table 2: Performance on SemEval-2010 all-words domain WSD (nouns only subset) using the most frequent sense assigned by the system as back-off strategy when no sense assignment is attempted.

lations activate senses in the knowledge base which are closer to the senses of the context words. The result is an overall increase in F<sub>1</sub> measure of 3.4 and 3.1 points for Degree and PLength, respectively, which makes it possible for us to beat the MFS baseline (notably a difficult competitor for WSD systems). Among the different graph algorithms, PLength consistently outperforms Degree: however, the differences are not statistically significant.

In order to better understand the impact of our approach we follow previous work (e.g., Navigli and Lapata (2010)) and explore a weakly-supervised setting where the system attempts no sense assignment if the highest score among those assigned to the senses of a target word is below a certain threshold. If this is the case, in order to provide an answer for all items, we output the most frequent sense assigned by the system to other instances of the target word, and fall back to SemCor’s MFS if no assignment has been attempted. We estimate the optimal value for the threshold by maximizing F<sub>1</sub> on a development set obtained by combining the Senseval-2 (Palmer et al., 2001) and Senseval-3 (Snyder and Palmer, 2004) English all-words datasets. The results for this setting are shown in Table 2, where we also compare with the top-performing systems from the SemEval competition, namely CFILT (Kulkarni et al., 2010) and IIITH (Reddy et al., 2010).

By complementing our multilingual method with the MFS heuristic we achieve a performance comparable with the state of the art on this task. Again, the multilingual ensemble approach consistently outperforms the monolingual one and enables us to achieve the best overall results for this dataset: without mul-

tilingual information, in fact, we achieve only average performance above the MFS level, whereas by effectively combining sense evidence from multilingual translations we are able to boost the F<sub>1</sub> measure by a 6-8 point margin, and thus outperform the top-ranking SemEval systems. While differences with CFILT are not statistically significant, we still take this to be good news, since our system is general purpose in nature and, accordingly, does not use any domain information such as manually-labeled examples for the most frequent domain words (CFILT) or a domain-specific sense ranking (IIITH).

## 4.2 Cross-lingual lexical disambiguation

Using a multilingual lexical resource makes it possible to perform WSD in any of its languages. Accordingly, we complement our evaluation on English texts with a second set of experiments where we quantify the impact of our approach on a lexical disambiguation task in a multilingual setting. To this end, we use the SemEval-2010 cross-lingual lexical substitution (Mihalcea et al., 2010, CL-LS, henceforth) and WSD (Lefever et al., 2011, CL-WSD) tasks and evaluate our methodology on performing disambiguation across different languages. Both cross-lingual WSD tasks cast disambiguation as a word translation problem: given an English polysemous noun in context as input, the system disambiguates it by providing a translation into another language (translations are deemed correct if they preserve the meaning of the source word in the target language). Their main difference, instead, lies in the range of translations which are assumed to be valid: that is, while CL-LS assumes no predefined sense inventory (i.e., any translation can be potentially correct), CL-WSD makes use of a sense inventory built on the basis of the Europarl corpus (Koehn, 2005).

Our approach to lexical disambiguation involves two steps: first, given a target word in context, we disambiguate it as usual to the highest-ranked Babel synset; next, given the translations in the selected synset, we return the most suitable lexicalization in the language of interest. Since the selected synset can contain multiple translations in a target language for the input English word, we explore using an unsupervised strategy to select the most reliable translation from multiple candidates. To this end, we return for each test instance only the

	Algorithm	P/R/F <sub>1</sub>
	Baseline	23.80
Monolingual graph	Degree	30.52
	PLength	30.64
Multilingual ensemble	Degree	32.21
	PLength	<b>32.47</b>
	UBA-T	32.17

Table 3: Performance on SemEval-2010 lexical substitution (best results are bolded).

most frequent translation found in the Babel synset. Given that the two tasks make different assumptions on the sense inventory (no fixed inventory for CL-LS vs. Europarl-based for CL-WSD), the frequency of a translation is calculated as either the number of Babel synsets in which it occurs (CL-LS), or its frequency of alignment with the target word, as obtained by applying GIZA++ (Och and Ney, 2003) to Europarl (CL-WSD). To provide an answer for all instances, we return this most frequent translation even when no sense assignment is attempted – i.e., no sense of the target word is connected to any other sense of the context words – or a tie occurs.

**Results and discussion.** We report our results for CL-LS and CL-WSD in Tables 3 and 4. We evaluate using the nouns-only subset of the CL-LS dataset and the full CL-WSD dataset, consisting of 300 and 1,000 instances of nouns in context, respectively. The evaluation scheme is based on the SemEval-2007 English lexical substitution task (McCarthy and Navigli, 2009), and consists of an adaptation of the metrics of precision and recall for the translation setting. For each task, we compare our monolingual and multilingual approaches against the best performing SemEval systems for these tasks, namely UBA-T (Basile and Semeraro, 2010) and UVT-v (van Gompel, 2010) for CL-LS and CL-WSD, respectively, as well as a recent supervised proposal that exploits automatically generated multilingual features from parallel text and translated contexts (Lefever et al., 2011, Parasense). For each task we also report its official baseline, namely the first translation from an online-dictionary<sup>6</sup> for CL-LS, and the most frequent word alignment obtained by

<sup>6</sup>[www.spanishdict.com](http://www.spanishdict.com)

applying GIZA++ to the Europarl data for CL-WSD.

Our cross-lingual results confirm all trends of the English monolingual evaluation, namely that: a) our joint multilingual approach substantially improves over the simple monolingual graph-based approach; b) it enables us to achieve state-of-the-art performance for these tasks. In the case of both CL-LS and CL-WSD, using a rich multilingual knowledge base like BabelNet makes it possible to achieve a respectable performance already with the simple monolingual approach, thus indicating the viability of a knowledge-rich approach to sense-driven word translation. The use of multilingual ensembles always improves the monolingual setting for all languages, and allows us to achieve the best overall results for both CL-LS and CL-WSD. Similarly to the case of monolingual WSD, manual inspection of the output reveals that translations help us rule out incorrect senses and let the disambiguation algorithm focus on the more coherent set of senses for the input context in a way similar to the one highlighted by the example in Figure 1. As a result of this we are able to improve the performance of both monolingual Degree and PLength, and compete with the state of the art on all disambiguation tasks.

## 5 Conclusions

In this paper we presented a multilingual joint approach to WSD. Key to our methodology is the effective use of a wide-coverage multilingual knowledge base, BabelNet, which we exploit to perform graph-based WSD across languages and combine complementary sense evidence from translations in different languages using an ensemble method. This is the first proposal to exploit structured multilingual information within a joint, knowledge-rich framework for WSD. The APIs to perform multilingual WSD using BabelNet are freely available for research purposes (Navigli and Ponzetto, 2012b).

Thanks to multilingual joint WSD we achieve state-of-the-art performance on three different gold standards. The good news about these results is that not only can further advances be achieved by using multilingual lexical knowledge, but, more importantly, that combining multilingual sense evidence from different languages at the same time yields consistent improvements over a monolingual ap-

proach in both monolingual and cross-lingual lexical disambiguation tasks – that is, ‘joining forces pays off’. Effectively leveraging multilingual knowledge for WSD helps overcome the shortcomings of the underlying resource (noise, coverage, etc.), thus indicating that further performance boosts can come in the future from even better multilingual lexical resources. Moreover, our methodology is general-purpose and can be adapted to tasks other than WSD: in fact, we have already taken the first steps in this direction by showing the beneficial effects of a joint multilingual approach to computing semantic relatedness (Navigli and Ponzetto, 2012a). In addition, we plan in the very near future to generalize our multilingual joint approach and apply it to high-end tasks such as multilingual textual entailment (Mehdad et al., 2011) and sentiment analysis (Lu et al., 2011) – so as to provide a general framework for knowledge-rich multilingual NLP.

# A New Minimally-Supervised Framework for Domain Word Sense Disambiguation

Stefano Faralli and Roberto Navigli

Dipartimento di Informatica

Sapienza Università di Roma

{faralli,navigli}@di.uniroma1.it

## Abstract

We present a new minimally-supervised framework for performing domain-driven Word Sense Disambiguation (WSD). Glossaries for several domains are iteratively acquired from the Web by means of a bootstrapping technique. The acquired glosses are then used as the sense inventory for fully-unsupervised domain WSD. Our experiments, on new and gold-standard datasets, show that our wide-coverage framework enables high-performance results on dozens of domains at a coarse and fine-grained level.

## 1 Introduction

Domain information pervades most of the text we read every day. If we just think of the Web, the vast majority of its textual content is domain oriented. A case in point is Wikipedia, which provides encyclopedic coverage for a huge number of knowledge domains (Medelyan et al., 2009), but most blogs, Web sites and newspapers also provide a great deal of information focused on specific areas of knowledge. When it comes to automatic text understanding, then, it is crucial to take into account the domain specificity of a piece of text, so as to perform a focused and as-precise-as-possible analysis which, in its turn, can enable domain-aware applications such as question answering and information extraction. Domain knowledge also has the potential to improve open-text applications such as summarization (Ceylan et al., 2010) and machine translation (Foster et al., 2010).

Research in Word Sense Disambiguation (Navigli, 2009, WSD), the task aimed at the automatic labeling of text with word senses, has been oriented towards domain text understanding for several years now. Many approaches have been devised, including the identification of domain-specific predominant senses (McCarthy et al., 2007; Lapata and Keller, 2007), the development of domain resources (Magnini and Cavaglia, 2000; Magnini et al., 2002), their application to WSD (Gliozzo et al., 2004), and the effective use of link analysis algorithms such as Personalized PageRank (Agirre et al., 2009; Navigli et al., 2011). More recently, semi-supervised approaches to domain WSD have been proposed which aim at decreasing the amount of supervision needed to carry out the task (Khapra et al., 2010).

High-performance domain WSD, however, has been hampered by the widespread use of a general-purpose sense inventory, i.e., WordNet (Miller et al., 1990; Fellbaum, 1998). Unfortunately WordNet does not contain many specialized terms, making it difficult to use it in work on arbitrary specialized domains. While Wikipedia has recently been considered a valid alternative (Mihalcea, 2007), it is mainly focused on covering named entities and, strictly speaking, does not contain a formal wide-coverage sense inventory (not even in disambiguation pages, which are often incomplete, especially in the lexicographic sense).

In this paper we provide three main contributions:

- We tackle the above issues by introducing a new framework based on the minimally-supervised acquisition of specialized glossaries for dozens of domains.

- In turn, we use the acquired domain glossaries as a sense inventory for domain WSD. As a result, we redefine the domain WSD task as one of picking out the most appropriate gloss (fine-grained setting) or domain (coarse-grained setting) from a multi-domain glossary.
- We show that our framework represents a considerable departure from the common usage of a general-purpose sense inventory such as WordNet, in that, thanks to the wide coverage of domain meanings, it enables high-performance unsupervised WSD on many domains in the range of 69-80% F1.

Furthermore, our approach can be customized to any set of domains of interest, and new senses, i.e., glosses, can be added at any time (either manually or automatically) to the multi-domain sense inventory.

## 2 Related Work

Domain WSD has been the focus of much interest in the last few years. An important research direction identifies distributionally similar neighbors in raw text as cues for determining the predominant sense of a target word by means of a semantic similarity measure (McCarthy et al., 2004; Koeling et al., 2005; McCarthy et al., 2007). Other distributional methods include the use of a word-category cooccurrence matrix, where categories are coarse senses obtained from an existing thesaurus (Mohammad and Hirst, 2006), and synonym-based word occurrence counts (Lapata and Keller, 2007). Domain-informed methods have also been proposed which make use of domain labels as cues for disambiguation purposes (Gliozzo et al., 2004).

Domain-driven approaches have been shown to obtain the best performance among the unsupervised alternatives (Strapparava et al., 2004), especially when domain kernels are coupled with a syntagmatic one (Gliozzo et al., 2005). However, their performance is typically lower than supervised systems. On the other hand, supervised systems fall short of carrying out high-performance WSD within domains, the main reason being the need for retraining on each new specific knowledge domain. Nonetheless, the knowledge acquisition bottleneck can be relieved by means of domain adaptation (Chan and

Ng, 2006; Chan and Ng, 2007; Agirre and de Lacalle, 2009) or by effectively injecting a general-purpose corpus into a smaller domain-specific training set (Khapra et al., 2010).

However, as mentioned above, most work on domain WSD uses WordNet as a sense inventory. But even if WordNet senses have been enriched with topically-distinctive words and concepts (Agirre and de Lacalle, 2004; Cuadros and Rigau, 2008), manually-developed domain labels (Magnini et al., 2002), and disambiguated semantic relations (Navigli, 2005), the main obstacle of being stuck with an open-ended fine-grained sense inventory remains. Recent results on the *SPORTS* and *FINANCE* gold standard dataset (Koeling et al., 2005) show that domain WSD can achieve accuracy in the 50-60% ballpark when a state-of-the-art algorithm such as Personalized PageRank is paired with a distributional approach (Agirre et al., 2009) or with semantic model vectors acquired for many domains (Navigli et al., 2011).

In this paper, we take domain WSD to the next level by proposing a new framework based on the minimally-supervised acquisition of large domain sense inventories thanks to which high performance can be attained on virtually any domain using unsupervised algorithms. Glossary acquisition approaches in the literature are mostly focused on pattern-based definition extraction (Fujii and Ishikawa, 2000; Hovy et al., 2003; Fahmi and Bouma, 2006, among others) and lattice-based supervised models (Navigli and Velardi, 2010) starting from an initial terminology, while we jointly bootstrap the lexicon and the definitions for several domains with minimal supervision and without the requirement of domain-specific corpora. To do so, we adapt bootstrapping techniques (Brin, 1998; Agichtein and Gravano, 2000; Pasca et al., 2006) to the novel task of domain glossary acquisition from the Web.

Approaches to domain sense modeling have already been proposed which go beyond the WordNet sense inventory (Duan and Yates, 2010). Distinctive collocations are extracted from corpora and used as features to bootstrap a supervised WSD system. Experiments in the biomedical domain show good performance, however only in-domain ambiguity is addressed. In contrast, our approach tackles cross-

Figure 1: The bootstrapping process for glossary acquisition.

domain ambiguity, by working with virtually any set of domains and minimizing the requirements by harvesting domain terms and definitions from the Web, bootstrapped using a small number of seeds.

The existing approach closest to ours is that of Huang and Riloff (2010), who devised a bootstrapping approach to induce semantic class taggers from domain text. The semantic classes are associated with arbitrary NPs and must be established beforehand. Our objective, instead, is to perform domain disambiguation at the word level. To do this, we redefine the domain WSD problem as one of selecting the most suitable gloss from those available in our full-fledged multi-domain glossary.

### 3 A Minimally-Supervised Framework for Domain WSD

In this section we present our new framework for performing domain WSD. The framework consists of two phases: glossary bootstrapping (Section 3.1) and domain WSD (Section 3.2).

#### 3.1 Phase 1: Bootstrapping Domain Glossaries

The objective of the first phase is to acquire a multi-domain glossary from the Web with minimal supervision. We initially select a set  $D$  of domains of interest. For each individual domain  $d \in D$  we start with an empty set of HTML patterns  $P_d$  (i.e.,  $P_d := \emptyset$ ), used for gloss harvesting. During this phase we iteratively populate the pattern set by means of six steps, described in the next six subsections and depicted in Figure 1. The final output of this phase will be a glossary  $G_d$  consisting of domain terms and their automatically-harvested glosses.

##### 3.1.1 Step 1: Initial seed selection

First, given the domain  $d$ , we manually pick out  $K$  hypernymy relation seeds  $S_d =$

$\{(t_1, h_1), \dots, (t_K, h_K)\}$ , where the pair  $(t_i, h_i)$  contains a domain term  $t_i$  and its generalization  $h_i$  (e.g., *(firewall, security system)*). The only constraint we impose is that the selected relations must be distinctive for the domain  $d$  of interest. The chosen hypernymy relations have to be as topical and representative as possible for the given domain (e.g., *(compiler, computer program)* is an appropriate pair for computer science, while *(byte, unit of measurement)* is not, as it might cause the extraction of several glossaries of various units and measures). Note that this is the only human intervention in the entire glossary acquisition process.

We now set the iteration counter  $k$  to 1 and start the first iteration of the process (steps 2-5). After each iteration  $k$ , we keep track of the set of glosses  $G_d^k$ , acquired during iteration  $k$ .

##### 3.1.2 Step 2: Seed queries

For each seed pair  $(t_i, h_i)$ , we submit the following three queries to a Web search engine: “ $t_i$ ” “ $h_i$ ” glossary<sup>1</sup>, “ $t_i$ ” “ $h_i$ ” definition, “ $t_i$ ” “ $h_i$ ” dictionary and collect the 64 top-ranking results for each query<sup>2</sup>. Each resulting page is a candidate glossary for the domain  $d$  identified by our relation seeds  $S_d$ .

##### 3.1.3 Step 3: Pattern and glossary extraction

We initialize the glossary for iteration  $k$  as follows:  $G_d^k := \emptyset$ . Next, from each resulting page, we harvest all the text snippets  $s$  starting with  $t_i$  and ending with  $h_i$  (e.g., *firewall* -- a *security system*), i.e.,  $s = t_i \dots h_i$ . For each such text snippet  $s$ , we perform five substeps:

a) **extraction of the term/gloss separator:** we

<sup>1</sup>In what follows, we use the typewriter font for keywords and term/gloss separators.

<sup>2</sup>We use the Google AJAX API, which returns 64 results.

Term	Gloss	Hypernym	# seeds	Gloss score
dynamic packet filter	A <b>firewall</b> facility that monitors the state of <u>connections</u> and uses this <u>information</u> to determine which <u>network packets</u> to allow through the <b>firewall</b>	firewall	2	0.75
peripheral	<u>Hardware</u> that extends the capabilities of the <u>computer</u> , such as a <u>printer</u> , <u>modem</u> , or <u>scanner</u> .	hardware	1	0.83
die	An integrated circuit <b>chip</b> cut from a finished <u>wafer</u> .	integrated circuit	1	0.75
constructor	a <u>method</u> used to help create a new <u>object</u> and initialise its <u>data</u>	method	0	1.00
schema	In database terminology, a schema is the organization of the <u>tables</u> , the <u>fields</u> in each <u>table</u> , and the <u>relationships</u> between <u>fields</u> and <u>tables</u> .	database	0	0.78

Table 1: Examples of extracted terms, glosses and hypernyms (seeds are in bold, domain terms are underlined).

start from  $t_i$  and move right until we extract the longest sequence  $p_M$  of HTML tags and non-alphanumeric characters, which we call the *term/gloss separator*, between  $t_i$  and the glossary definition (e.g., “</b> --” between “firewall” and “a” in the above example);

- b) **gloss extraction:** we expand the snippet  $s$  to the right of  $h_i$  in search of the entire gloss of  $t_i$ , i.e., until we reach a non-formatting tag element (e.g., <span>, <p>, <div>), while ignoring formatting elements such as <b>, <i> and <a> which are typically included within a definition sentence. As a result, we obtain the sequence  $t_i p_M gloss_s(t_i) p_R$ , where  $gloss_s(t_i)$  is our gloss for seed term  $t_i$  in snippet  $s$  (which includes  $h_i$  by construction) and  $p_R$  is the non-formatting HTML tag element to the right of the extracted gloss. For example, we extend the above definition for *firewall* to: “a <i>security system</i> for protecting against illegal entry to a local area network.”.

- c) **pattern instance extraction:** we extract the following pattern instance:

$$p_L t_i p_M gloss_s(t_i) p_R,$$

where  $p_L$  and  $p_R$  are, respectively, the left boundary of  $t_i$  and the right boundary of  $gloss_s(t_i)$ , and  $p_M$  is the term/gloss separator extracted at step 3(a). The two boundaries  $p_L$  and  $p_R$  are obtained by extracting the longest sequence of HTML tags and non-alphanumeric characters obtained when moving to the left of  $t_i$  and the right of  $gloss_s(t_i)$ , respectively<sup>3</sup>. For the above example, we extract the following pattern instance:

<sup>3</sup>The minimum and maximum length of both  $p_L$  and  $p_R$  are set to 4 and 50 characters, respectively, as a result of a tuning phase described in Section 4.1.

$p_L = “<p><b>”, t_i = “firewall”, p_M = “</b> --”, gloss_s(t_i) = “a <i>security system</i> for protecting against illegal entry to a local area network.”, p_R = “</p>”.$

- d) **pattern extraction:** we generalize the above pattern instance to the following pattern:

$$p_L * p_M * p_R,$$

i.e., we replace  $t_i$  and  $gloss_s(t_i)$  with \*. In the above example, we obtain the following pattern:

$$<p><b> * </b> -- * </p>.$$

Finally, we add the generalized pattern to the set of patterns  $P_d$ , i.e., we set  $P_d := P_d \cup \{p_L * p_M * p_R\}$ . We also add the first sentence of the retrieved definition  $gloss_s(t_i)$  to our glossary  $G_d^k$ , i.e.,  $G_d^k := G_d^k \cup \{(t_i, first(gloss_s(t_i)))\}$ , where  $first(g)$  returns the first sentence of gloss  $g$ .

- e) **pattern matching:** we look for additional pairs of terms/glosses in the Web page containing the snippet  $s$  by matching the page against the generalized pattern  $p_L * p_M * p_R$ . We then add to  $G_d^k$  the new (term, gloss) pairs matching the generalized pattern.

As a result of this step, we obtain a glossary  $G_d^k$  for the terms discovered at iteration  $k$ .

### 3.1.4 Step 4: Gloss ranking and filtering

Importantly not all the extracted definitions pertain to the domain of interest. In order to rank by domain pertinence the glosses obtained at iteration  $k$ , we define the terminology  $T_1^{k-1}$  of the terms accumulated up until iteration  $k - 1$  as follows:  $T_1^{k-1} := \bigcup_{i=1}^{k-1} T^i$ , where  $T^i := \{t : \exists(t, g) \in G_d^i\}$ .

Gloss	Domain
Measures undertaken to return a degraded ecosystem’s functions and values, including its hydrology, plant and . .	BIOLOGY
The renewing or repairing of a natural system so that its functions and qualities are comparable to its original. . .	GEOGRAPHY
The reign of Charles II in England.	ROYALTY

A process used by radio astronomers to eliminate the smoothing effect observed in radio maps that is caused by. . .	PHYSICS

Table 2: Examples of glosses harvested for the term *restoration*.

For the base step  $k = 1$ , we define  $T_1^0 := T^1$ , i.e., we use the first-iteration terminology itself. To rank the glosses, we first transform each acquired gloss  $g$  to its bag-of-words representation  $Bag(g)$ , which contains all the single- and multi-word expressions in  $g$ . We then score each gloss  $g$  by the ratio of domain terms found in its bag of words:

$$score(g) = \frac{|Bag(g) \cap T_1^{k-1}|}{|Bag(g)|}. \quad (1)$$

In Table 1 we show some glosses in the computer science domain (second column, domain terms are underlined) together with their score (last column). Next, we use a threshold  $\theta$  (tuned on a held-out domain, described in Section 4.1) to remove from  $G_d^k$  those glosses  $g$  whose  $score(g) < \theta$ .

### 3.1.5 Step 5: Seed selection for next iteration

We now aim at selecting the new set of hypernym relation seeds to be used to start the next iteration. We perform three substeps:

a) **Hypernym extraction:** for each newly-acquired term/gloss pair  $(t, g) \in G_d^k$ , we automatically extract a candidate hypernym  $h$  from the textual gloss  $g$ . To do this we use a simple unsupervised heuristic which just selects the first term in the gloss. More sophisticated, supervised approaches could have been used for hypernym extraction from glosses (Navigli and Velardi, 2010). However, note that, for the purposes of our glossary extraction task, it is not crucial to extract accurate hypernyms, but rather to harvest terms  $h$  which are very likely to occur in the glosses of  $t$ . We show an example of hypernym extraction for some terms in Table 1 (we report the term in column 1, the gloss in column 2 and the hypernyms extracted by our hypernym extraction technique in column 3).

b) **(Term, Hypernym)-ranking:** we sort all the glosses in  $G_d^k$  by the number of seed terms found in each gloss. In the case of ties (i.e., glosses with the same number of seed terms), we further sort the glosses by the score shown in Formula 1. We show the number of seed terms and the scores for some glosses in Table 1 (columns 4 and 5, respectively), where seed terms are in bold and domain terms (i.e., in  $T_1^{k-1}$ ) are underlined.

c) **New seed selection:** as new seeds we select the (term, hypernym) pairs corresponding to the  $K$  top-ranking glosses.

If  $k$  equals the maximum number of iterations, we stop. Else, we increment the iteration counter (i.e.,  $k := k + 1$ ) and jump to step (2) of our glossary bootstrapping algorithm after replacing  $S_d$  with the new set of seeds.

The output of the glossary bootstrapping phase is a domain glossary  $G_d := \bigcup_{i=1, \dots, max} G_d^i$ , where  $max$  is the total number of iterations.

### 3.1.6 Step 6: Increasing Coverage

Given the nature of Web domain glossaries one can rarely find terms and definitions for general terms (e.g., *jurisprudence* for the LAW domain). In order to cover this gap, we apply domain filtering (see Section 3.1.4) to all the glosses contained in a general-purpose dictionary (we use WordNet). We then add the surviving term/gloss pairs to  $G_d$ .

## 3.2 Phase 2: Domain WSD

Now that we have acquired a glossary for each domain in our set  $D$ , we can create a multi-domain glossary  $\mathcal{G} := \{(t, g), d) : d \in D, (t, g) \in G_d\}$ . Our glossary  $\mathcal{G}$  is thus a set of term/gloss pairs for many domains. Note that one pair might individually belong to more than one domain, as glossary bootstrapping is performed separately for each domain. In Table 2 we show an example of the

glosses acquired for the term *restoration*. We observe that 5 out of 6 senses are not available in WordNet (namely: the BIOLOGY, GEOGRAPHY, LAW, MEDIA and PHYSICS senses). Many of them are domain-specific meanings for the general concept of “the act of restoring”, with the BIOLOGY and GEOGRAPHY senses being very similar. However, this is a perfectly acceptable phenomenon as any of the two senses, i.e., glosses, would be equally valid when disambiguating a domain text dealing with ecosystem restoration.

### 3.2.1 Gloss-driven WSD

We redefine the task of domain WSD as one of selecting the most suitable gloss, if one exists, for an input term  $t$ . For instance, consider the sentence: “He performed the *restoration* of heavily corrupted images”. An appropriate option for this occurrence would be the MEDIA sense of *restoration* in Table 2.

Our gloss-driven WSD paradigm has the desirable property of automatically providing two levels of sense granularity: a domain, coarse-grained level, similar in spirit to Word Domain Disambiguation (Sanfilippo et al., 2006), in which the sense inventory of a term  $t$  is just the set of domains for which  $t$  is covered (e.g., BIOLOGY, GEOGRAPHY, ROYALTY, LAW, MEDIA, PHYSICS in the example of Table 2), and a fine-grained level, which requires the selection of the gloss which best describes the sense denoted by the given word occurrence. A second desirable property of our gloss-driven WSD paradigm is that it relies on a flexible framework, which allows for the bootstrapping of new domain glossaries or the expansion of existing ones. However, while these two properties – i.e., double level of granularity distinctions and flexibility – are naturally inherent in the gloss-driven paradigm, the same cannot be said for mainstream open-text WSD in which general-purpose static dictionaries are typically used.

In order to evaluate our framework for domain WSD, we propose two fully unsupervised algorithms for gloss-driven domain WSD. Ideally, high performance could be obtained using state-of-the-art supervised WSD systems. However, in order to train such systems, a wide-coverage sense-labeled corpus should be available for each domain, a heavy task which we leave to future work. Instead, our objective is to show that high-performance domain WSD

can be enabled with little effort by our framework.

### 3.2.2 Algorithm 1: WSD with Personalized PageRank

**Domain Glossaries as Graphs** For each domain  $d \in D$ , we create an undirected graph  $N_d = (V_d, E_d)$  as follows:  $V_d$  is the set of concepts identified by term/gloss pairs in the domain glossary  $G_d$ , i.e.,  $V_d := G_d$ ;  $E_d$  is the set of edges between pairs of concepts, where an edge  $\{(t, g), (t', g')\}$  exists if and only if  $t'$  is such that  $t' \neq t$  and  $t'$  occurs in the bag of words of the gloss  $g$  of  $t$ . In other words,  $t$  is connected to all the domain senses of words used in its definition  $g$ .

**Graph-based WSD** Given an input text, for each domain  $d \in D$ , we produce its bag of domain content words  $C_d = \{w_1, w_2, \dots, w_n\}$  by performing tokenization, lemmatization and compounding based on the lexicon of domain  $d$ . Then, given a target word  $t$ , we use  $C_d \setminus \{t\}$  as the context to disambiguate  $t$  within the domain  $d$ . In order to carry out domain WSD, i.e., to pick out the most suitable sense of  $t$  across domains, we apply a state-of-the-art graph-based algorithm, namely Personalized PageRank (Haveliwala, 2002, PPR), to each domain graph  $N_d$ . PPR is a variant of the popular PageRank algorithm (Brin and Page, 1998) in which the damping probability mass is concentrated on a selected number of graph nodes, instead of being uniformly distributed across all nodes. Specifically, following Agirre and Soroa (2009) we concentrate the probability mass on the nodes  $(t', g') \in V_d$  for which the term  $t'$  is a context word, i.e.,  $t' \in C_d$ . Next, for each domain  $d \in D$ , we run PPR for a given number of iterations and obtain as output a probability distribution  $PPV_d$  over the graph nodes. Finally, we select the most suitable gloss of  $t$  as follows:

$$Sense_{PPR}(t) = \arg \max_{g: \exists d \in D, (t, g) \in V_d} PPV_d(t, g) \quad (2)$$

where  $PPV_d(t, g)$  is the PPR probability for the term/gloss pair  $(t, g)$  and  $Sense_{PPR}(t)$  contains the best interpretation of  $t$  across all the domains  $D$ .

### 3.2.3 Algorithm 2: PPR Boosted with Domain Distribution Information

The words in a given text do not typically deal with a single domain. Instead, they touch different

Table 4: Hypernymy relation seeds used to bootstrap glossary acquisition in four of the 30 domains.

areas of knowledge which are intertwined with each other within the discourse. For example, a text dealing with VIDEOGAMES will often concern domains such as BUSINESS, COMPUTING, SPORTS, etc. Given an input text, we can capture its relevance for each domain by calculating the following domain score:

$$\beta_d = \frac{|C_d|}{\sum_{d' \in D} |C_{d'}|} \quad (3)$$

where, as above,  $C_d$  is the set of content words from the input text which are covered by domain  $d$ . We thus propose a second algorithm which synergistically combines the spreading effect of PPR with the domain distribution information. The best sense for a given term  $t$  is calculated as follows:

$$Sense_{DomPPR}(t) = \arg \max_{g: \exists d \in D, (t,g) \in V_d} \beta_d PPV_d(t, g) \quad (4)$$

that is, we select as the most suitable gloss for  $t$  the one which maximizes the product of its domain relevance score by its domain  $PPV_d$  value. Note that the same gloss can occur in multiple domains and that it might obtain different scores depending on the domain. Again, since the approach is gloss-driven, we do not see this as a problem, but rather as a natural characteristic of our framework.

## 4 Experimental Setup

### 4.1 Domains

We selected 30 domains starting from the Wikipedia featured articles<sup>4</sup>. We show the domain labels in Ta-

<sup>4</sup>[http://en.wikipedia.org/wiki/Wikipedia:Featured\\_articles](http://en.wikipedia.org/wiki/Wikipedia:Featured_articles)

Table 5: Statistics on the multi-domain acquired glossary.

	From the Web	From WordNet	From both	Total
Terms	74,295	83,904	18,313	176,512
Glosses	153,920	68,731	596	223,247

ble 3 (some labels have been conveniently shortened, e.g., PHYSICS should read PHYSICS & ASTRONOMY). We manually identified 8 hypernym/hyponym seeds for each domain, totalizing 240 seeds. We used two criteria for selecting a seed: i) it covers a separate segment of the domain, and ii) it has to be specialized enough to avoid ambiguity. We show the seeds used in four of our domains in Table 4. We bootstrapped our glossary acquisition technique (cf. Section 3.1) on each domain and performed 5 iterations. For increasing the coverage of domain terms we used WordNet glosses (see Section 3.1.6). As a result, we obtained 30 domain glossaries. We also kept aside a 31st domain, namely FASHION, which we employed for tuning the minimum and maximum length of both  $p_L$  and  $p_R$  in Section 3.1.3 and the threshold  $\theta$  used to filter out non-domain glosses in Section 3.1.4.

In Table 5 we show the statistics for the acquired multi-domain glossary by distinguishing Web-derived and WordNet terms and glosses.

### 4.2 Sense Inventory

Our sense inventory is given by the 30-domain glossary obtained as a result of our glossary bootstrapping phase. Overall we collected 176,512 and 223,247 distinct terms and glosses, respectively, with an important contribution from both the Web

and WordNet (see Table 5). The average number of glosses per term in our inventory is 1.9 (3.6 glosses on polysemous terms). However, note that a monosemous word in our domain sense inventory does not necessarily make disambiguation easier, as i) we might have missed other domain-specific senses, ii) an uncovered, non-domain sense might fit a word occurrence (in this case, the domain WSD algorithms might be (wrongly) biased towards returning the only possible choice if a non-zero disambiguation score is calculated for it).

In order to determine the suitability of our multi-domain sense inventory, we compared it with the latest version of WordNet Domains (Magnini et al., 2002, WND 3.2), a well-known resource which provides domain labels for almost 65,000 nominal WordNet synsets (we removed all the synsets tagged with the `FACTOTUM` label, which indicates no domain specificity). Since WND uses about 160 finer-grained domain labels, we manually mapped them to our 30 labels when possible (e.g. `SOCCER` and `SWIMMING` were mapped to `SPORTS`), totaling 62,100 domain-labeled synsets.

We calculated the coverage of our sense inventory against WND at the synset and the sense level, for each non-`FACTOTUM` synset. Given a WordNet synset  $S$ , let  $d = \bigcup_{s \in S} d_s$  be the union of the domains  $d_s$  provided for each synonym  $s \in S$  by our sense inventory ( $d_s = \emptyset$  if not present), and let  $d'$  be the domain labels assigned to  $S$  by WND. A synset is covered if  $d$  and  $d'$  intersect. At the sense level, instead, we consider a synonym  $s \in S$  to be covered if  $d_s$  and  $d'$  intersect. Our synset and sense coverage is 65.9% (40,969/62,100) and 63.7% (71,950/112,875), respectively. We also calculated an extra-coverage of 203.2% (229,384/112,875), that is the fraction of domain senses which are not available in WND, but we are able to provide in our sense inventory (see e.g. the example in Table 2) over the total number of senses in WND. While coverage and extra-coverage provide a good indicator of the completeness of our sense inventory, we need to calculate its precision to determine its correctness. To do so, we randomly sampled 500 domain glosses of terms for which no WordNet sense was tagged with the same domain in WND. A manual validation of this sample resulted in an 87.0% (435/500) estimate of the precision of our sense inventory.

### 4.3 Datasets

**A dataset for 30 domains** We used the Gigaword corpus (Graff and Cieri, 2003) to extract a 6-paragraph text snippet for each of the 30 domains. As a result, we obtained a domain dataset made up of 180 paragraphs to which we applied tokenization, lemmatization and compounding, totaling 1432 domain content words overall (47.7 content words per domain on average). The average polysemy of the words in the dataset was of 9.7 glosses and 4.4 domains per word. Each content word was manually tagged with the most suitable glosses from our multi-domain glossary (3.9 glosses, i.e., senses per word were assigned on average). The annotation task was performed by two annotators with adjudication.

**Sports and Finance** We also experimented with the gold standard produced by Koeling et al. (2005). The dataset covers two domains: `SPORTS` and `FINANCE`. The dataset comprises 41 ambiguous words (with an average polysemy of 6.7 senses), many of which express different meanings in the two domains. In each domain, and for each word, around 100 sentences were sense-annotated with WordNet.

**Environment** Finally, we also carried out an experiment on the `ENVIRONMENT` dataset from the Semeval-2010 domain WSD task (Agirre et al., 2010). The dataset includes 1,398 content words (of which 1,032 content nouns) tagged with WordNet senses.

### 4.4 Systems

We applied the two algorithms proposed in Section 3.2, namely vanilla PPR and domain-boosted PPR. For both versions of PPR we employed UKB, a readily-available implementation of PPR for WSD<sup>5</sup>, successfully experimented by Agirre and Soroa (2009) and Agirre et al. (2009).

### 4.5 Baselines

**Random baseline** We compared our algorithms with the random baseline, which associates a random gloss among those available for each word occurrence according to a uniform distribution.

<sup>5</sup><http://ixa2.si.ehu.es/ukb/>

**Predominant domain** We also compared our algorithms with a predominant sense baseline which assigns to each word occurrence the domain label with the highest domain score  $\beta_d$  among those available for the word (cf. Formula 3). Note that this is a strong baseline, because it aims at identifying the domain covered by the majority of terms in the input text, however it can disambiguate only at a coarse-grained level, i.e., at the domain level.

## 5 Experimental Results

**30 domains** We ran our WSD systems and the baselines on our 30-domain dataset, on a sentence-by-sentence basis. We calculated results at the two levels of granularity enabled by our WSD framework: a coarse-grained setting where systems output the most appropriate domain label for each word item to be disambiguated; a fine-grained setting where systems are required to output the most suitable gloss for the input word. The results are shown in Table 6. Domain PPR outperforms Vanilla PPR by some points in precision, recall and F1 in both the coarse-grained and the fine-grained setting, achieving an F1 around 80% and 69%, respectively (differences in recall performance are statistically significant using a  $\chi^2$  test). The predominant domain baseline, available only in the coarse-grained setting, lags behind Domain PPR by more than 3 points in precision and 2 in recall. While these differences are not statistically significant, the variance across domains is much higher, thus suggesting lower reliability of the method.

These results were obtained in a fully unsupervised setting in which no structured knowledge was provided, unlike previous applications of PPR to WSD (Agirre et al., 2009; Agirre and Soroa, 2009) which relied on the underlying WordNet graph, a manually created resource. Furthermore, our graph contains “noisy” semantic relations, as we connect each gloss to all the senses of its gloss words (cf. Section 3.2.2). Finally, we note that the results shown in Table 6 could never have been obtained with WordNet. In fact, drawing on our domain mapping, we calculated that the correct domain sense is not in WordNet for about 68% of the words in the dataset. Instead, the results in Table 6 show that our framework enables high-performance unsupervised

	Coarse-grained			Fine-grained		
	P	R	F1	P	R	F1
Vanilla PPR	76.7	74.3 <sup>†</sup>	75.5	66.1	64.1 <sup>†</sup>	65.1
Domain PPR	81.2	78.7 <sup>†</sup>	79.9	69.7	67.6 <sup>†</sup>	68.6
Predom. domain	77.9	76.8	77.3	-	-	-
Random baseline	42.5	42.5	42.5	44.1	44.1	44.1

Table 6: Performance results on the 30-domain dataset (<sup>†</sup> differences between the two systems are statistically significant using a  $\chi^2$  test,  $p < 0.05$ ).

WSD thanks to the wide coverage of domain meanings.

As regards the random baseline, this performs 42.5% and 44.1% in the two settings. Despite the higher polysemy of glosses (9.7 glosses vs. 4.4 domains per word in the dataset), the performance is higher in the fine-grained setting because often there is more than one gloss covering the same meaning of a domain word.

**Sports, Finance and Environment** For the SPORTS, FINANCE and ENVIRONMENT datasets (cf. Section 4.3) we did not have gloss-based sense annotations, so we could not perform a fine-grained evaluation. Therefore, we first studied the different systems at a coarse level on the basis of the domain distribution of the senses returned for the word items in the dataset. We show the 3 most frequent domain labels for each system and each dataset in Figure 2. The figure seems to confirm our results showing Domain PPR as being more robust than its Vanilla version. Next, to get a more accurate evaluation, we randomly sampled 200 sentences from each dataset and manually validated the coarse-grained senses, i.e., domain assignments, output by each system on this set of sentences. We remark that several words in the datasets did not pertain to the domain of interest. For instance, *will* and *share* do not have any sports sense in WordNet, while the same applies to *half* and *chip* for the business domain. Table 7 shows the results of our validation, where a domain output by a system was considered correct if a suitable gloss existed for that domain in our inventory.

The results show that our framework enables coarse-grained recall in the 70-80% ballpark even on difficult gold standard datasets for which fine-grained recall with WordNet struggles to surpass the 50-60% range. For instance, the best performance

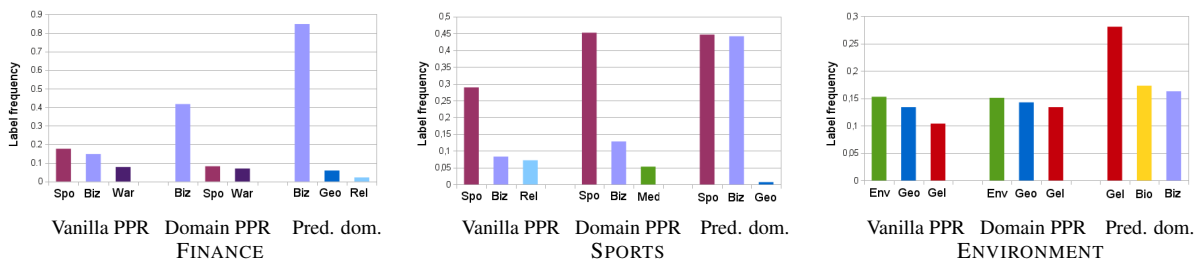

Figure 2: Frequency of the most common domain labels returned by our 3 systems on standard domain datasets.

	FINANCE			SPORTS			ENVIRONMENT		
	P	R	F1	P	R	F1	P	R	F1
Vanilla PPR	57.8	56.5	57.1	65.5	63.2	64.3	81.5	77.9	79.7
Domain PPR	77.8	76.1	76.9	72.1	71.3	71.7	83.1	79.4	81.2
Predom. domain	80.0	78.3	79.1	72.6	70.1	71.3	72.7	70.6	71.6

Table 7: Coarse-grained performance results on gold-standard domain datasets.

on the ENVIRONMENT dataset was around 60% recall (Kulkarni et al., 2010) using a semi-supervised WSD system, trained on the domain. Similarly, both the FINANCE and SPORTS datasets are notoriously difficult gold standards on which state-of-the-art recall using WordNet is lower than 60% (Navigli et al., 2011).

Interestingly, the predominant domain baseline shows a bias towards BUSINESS, thus performing best on the FINANCE dataset. This is because of the large number of terms covered in our domain glossary, and consequently the high overlap with cue words in context. On the other two domains, we observe performance in line with our 30-domain experiment.

## 6 Conclusion

We have here presented a new framework for domain Word Sense Disambiguation. We depart from the use of general-purpose sense inventories like WordNet and propose a bootstrapping approach to the acquisition of sense inventories for virtually any domain. While we selected 30 domains for this study, nothing would prevent us from using a smaller or larger set of these domains, or a set of completely different domains.

Our work provides three main contributions:

- i) we propose a new, flexible approach to glossary bootstrapping which harvests hundreds of thousands of term/gloss pairs; the resulting multi-

domain glossary is shown to have wide coverage across domains and to include a large amount of terms not available in WordNet;

- ii) we propose a novel framework for fully-unsupervised domain WSD which uses the multi-domain glossary as our sense inventory;
- iii) we show that high performance can be achieved by means of simple, unsupervised WSD algorithms (around 80% and 69% in a coarse- and fine-grained setting, respectively).

Note that our aim here has not been to determine which system performs best, but rather to show that a reliable, full-fledged framework for domain WSD can be set up with minimal supervision. Additionally, our framework can be applied to any language of interest, provided enough glossaries are available online, by simply translating the keywords used for our queries.

The multi-domain glossary (and sense inventory) together with the seeds used for bootstrapping are available from <http://lcl.uniroma1.it/dwsd>.

## Abstract

A popular tradition of studying semantic representation has been driven by the assumption that word meaning can be learned from the linguistic environment, despite ample evidence suggesting that language is *grounded* in perception and action. In this paper we present a comparative study of models that represent word meaning based on linguistic and perceptual data. Linguistic information is approximated by naturally occurring corpora and sensorimotor experience by feature norms (i.e., attributes native speakers consider important in describing the meaning of a word). The models differ in terms of the mechanisms by which they integrate the two modalities. Experimental results show that a closer correspondence to human data can be obtained by uncovering latent information shared among the textual and perceptual modalities rather than arriving at semantic knowledge by concatenating the two.

## 1 Introduction

Distributional models of lexical semantics have seen considerable success at accounting for a wide range of behavioral data in tasks involving semantic cognition (Landauer and Dumais, 1997; Griffiths et al., 2007). These models have also enjoyed lasting popularity in natural language processing. Examples involve information retrieval (Salton et al., 1975), word sense discrimination (Schütze, 1998), text segmentation (Choi et al., 2001), and numerous studies of lexicon acquisition (Grefenstette, 1994;

Lin, 1998). Despite their widespread use, distributional models have been criticized as “disembodied” in that they learn exclusively from linguistic information but are not *grounded* in perception and action (Perfetti, 1998; Barsalou, 1999; Glenberg and Kaschak, 2002).

This lack of grounding contrasts with many experimental studies suggesting that word meaning is acquired not only from exposure to the linguistic environment but also from our interaction with the physical world (Landau et al., 1998; Bornstein et al., 2004). Beyond language acquisition, there is considerable evidence across both behavioral experiments and neuroimaging studies that the perceptual associates of words play an important role in language processing (for a review see Barsalou (2008)).

It is thus no surprise that recent years have witnessed the emergence of perceptually grounded distributional models. An important question in the formulation of such models concerns the provenance of perceptual information. A few models use feature norms as a proxy for sensorimotor experience (Howell et al., 2005; Andrews et al., 2009; Steyvers, 2010; Johns and Jones, 2012). These are obtained by asking native speakers to write down attributes they consider important in describing the meaning of a word. The attributes represent perceived physical and functional properties associated with the referents of words. For example, *apples* are typically green or red, round, shiny, smooth, crunchy, tasty, and so on; *dogs* have four legs and bark, whereas *chairs* are used for sitting. Other models focus solely on the visual modality under the assumption that it represents a major source of data from

which humans can learn semantic representations of both linguistic and non-linguistic communicative actions (Regier, 1996). For example, Feng and Lapata (2010) learn semantic representations from corpora of texts paired with naturally co-occurring images (e.g., news articles and their associated pictures), whereas Bruni et al. (2011) learn textual and visual representations independently from distinct data sources.

Aside from the type of data used to capture perceptual information, another important issue concerns how the two modalities (perceptual and textual) are integrated. A simple solution would be to learn both modalities independently (Bruni et al., 2011) or to infer one modality by means of the other (Johns and Jones, 2012) and to arrive at a grounded representation simply by concatenating the two. An alternative is to learn from both modalities *jointly* (Andrews et al., 2009; Feng and Lapata, 2010; Steyvers, 2010). According to this view, semantic knowledge is gained by simultaneously learning from the statistical structure within each modality assuming both data sources have been generated by a shared set of meanings or topics.

In this paper we undertake the first comparative study of perceptually grounded distributional models. We examine three models with different assumptions regarding the integration of perceptual and linguistic data. The first model, originally proposed by Andrews et al. (2009), is an extension of latent Dirichlet allocation (LDA, Blei et al. (2003)). It simultaneously considers the distribution of words across contexts in a text corpus and the distribution of words across perceptual features and extracts joint information from both data sources. Our second model is based on Johns and Jones (2012) who represent the meaning of a word as the concatenation of its textual and its perceptual vector. Interestingly, their model allows to infer a perceptual vector for words without feature norms, simply by taking into account similar words for which perceptual information is available.

Finally, we propose Canonical Correlation Analysis (Hotelling, 1936; Hardoon et al., 2004) as our third model. CCA is a data analysis and dimensionality reduction method similar to PCA. While PCA deals with only one data space, CCA is a technique for joint dimensionality reduction across two

Features	table	dog	apple
has_4_legs	.28	.60	0
used_for_eating	.50	0	0
a_pet	0	.40	0
is_brown	0	0	0
is_crunchy	0	0	.58
is_round	.22	0	.42
has_fangs	0	0	0

Table 1: Feature norms for the nouns *table*, *dog*, and *apple* shown as a distribution.

(or more) spaces that provide heterogeneous representations of the same objects. The assumption is that the representations in these two spaces contain some joint information that is reflected in correlations between them.

In all three models we use feature norms as a proxy for perceptual information. Despite their shortcomings (e.g., they often cover a small fraction of the vocabulary of an adult speaker due to the effort involved in eliciting them), feature norms provide detailed knowledge about meaning representations and are a useful starting point for studying the integration of perceptual and textual information without being susceptible to the effects of noise, e.g., coming from image processing. In other words, feature norms can serve as an upper bound of what can be achieved when integrating detailed perceptual information with vanilla text-based distributional models.

Our experimental results demonstrate that joint models give a better fit to human word similarity and association data than a model that considers only one data source, or the simple concatenation of the two sources.

## 2 Perceptually Grounded Models

In this study we examine semantic representation models that rely on linguistic and perceptual data. The linguistic environment is approximated by corpora such as the British National Corpus (BNC). As mentioned earlier, we resort to feature norms as proxy for perceptual information. In our experiments, we relied on the norming study of McRae et al. (2005), in which a large number of human participants were presented with a series of words and

asked to list relevant features of the words' referents. Table 1 presents examples of features participants listed for the nouns *apple*, *dog*, and *table*. The number of participants listing a certain feature for a word can be used to compute a probability distribution over features given the word:

$$P(f_k|w) = \frac{f(f_k, w)}{\sum_{m=1}^F f(f_m, w)} \quad (1)$$

where  $f(f_k, w)$  is the number of participants who listed feature  $f_k$  for word  $w$  and  $F$  is the total number of features.

In the remainder of this section we will describe our models and how they arrive at an integrated perceptual and linguistic representation.

## 2.1 Feature-topic Model

Andrews et al. (2009) present an extension of LDA (Blei et al., 2003) where words in documents as well as their associated features are treated as observed variables that are explained by a generative process. The underlying training data consists of a corpus  $\mathcal{D}$  where each document is represented by words and their frequency of occurrence within the document. In addition, those words of a document that are also included in the feature norms are paired with one of their features, where a feature is sampled according to the feature distribution given that word. For example, suppose a document  $d_j$  consists of the sentence *Mix in the apple, celery, raisins, and apple juice*. Suppose further that all content words except of *mix* and *juice* are included in the feature norms. Then, a representation for  $d_j$  is *mix:1, apple;is\_red:2, celery;has\_leaves:1, raisin;is\_edible:1, juice:1*.

The plate diagram in Figure 1 illustrates the graphical model in detail. Each document  $d_j$  in  $\mathcal{D}$  is generated by a mixture of components  $\{x_1, \dots, x_c, \dots, x_C\} \in \mathcal{C}$ ; a component  $x_c$  comprises a latent discourse topic coupled with a feature cluster originating from the feature norms. A discourse topic belonging to  $x_c$ , in turn, is a distribution  $\phi_c \in \phi = \{\phi_1, \dots, \phi_C\}$  over words, and a feature cluster is a distribution  $\psi_c \in \psi = \{\psi_1, \dots, \psi_C\}$  over features.

In order to create document  $d_j$ , a distribution  $\pi_j$  over components is sampled from a Dirichlet distri-

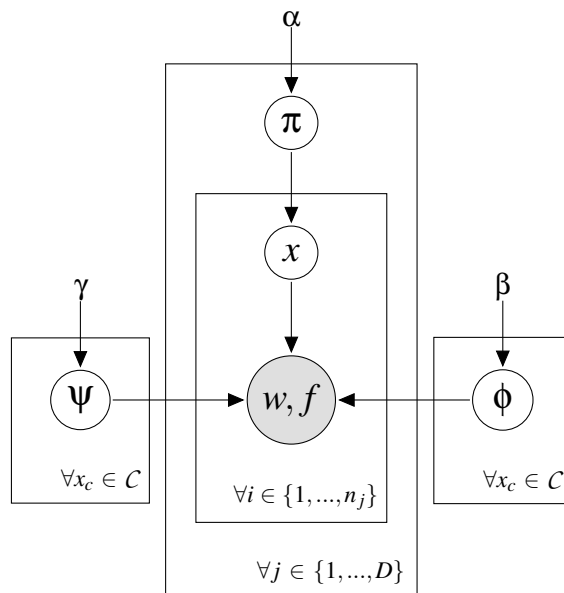

Figure 1: Feature-topic model. The components  $x_{ji}$  of a document  $d_j$  are sampled from  $\pi_j$ . For each  $x_c = x_{ji}$ , a word  $w_{ji}$  is drawn from distribution  $\phi_c$  and a feature  $f_{ji}$  is drawn from distribution  $\psi_c$ .

bution parametrized by  $\alpha$ . To generate each word  $w_{ji} \in \{w_{j1}, \dots, w_{jn_j}\}$ , a component  $x_c = x_{ji}$  is drawn from  $\pi_j$ ;  $w_{ji}$  is then drawn from the corresponding distribution  $\phi_c$ . If  $w_{ji}$  is in the feature norms, it is coupled with a feature  $f_{ji}$  which is correspondingly drawn from  $\psi_c$ . A symmetric Dirichlet prior with hyperparameters  $\beta$  and  $\gamma$  is placed on  $\phi$  and  $\psi$ , respectively. The probability of the corpus  $\mathcal{D}$  is defined as:

$$P((w \cup f)_{1:D} | \phi, \psi, \alpha) = \prod_{j=1}^D \int d\pi_j \prod_{i=1}^{n_j} P(\pi_j | \alpha) \sum_{c=1}^C P(w_{ji} | x_{ji} = x_c, \phi) P(f_{ji} | x_{ji} = x_c, \psi) P(x_{ji} = x_c | \pi_j) \quad (2)$$

where  $D$  is the number of documents and  $C$  the predefined number of components. Computing the posterior distribution  $P(\phi, \psi, \alpha, \beta, \gamma | (w \cup f)_{1:D})$  of the hidden variables given the data is generally intractable:

$$P(\phi, \psi, \alpha, \beta, \gamma | (w \cup f)_{1:D}) \propto P((w \cup f)_{1:D} | \phi, \psi, \alpha) P(\phi | \beta) P(\psi | \gamma) P(\alpha) P(\beta) P(\gamma) \quad (3)$$

Equation (3) may be approximated using the Gibbs

$$apple \begin{bmatrix} x_1 & x_2 & x_{12} & \dots & x_{28} & x_{75} & x_{107} & x_{119} & x_{125} & x_{148} & x_{182} & \dots & x_{266} & x_{326} & x_{349} & x_{350} \\ 3e-5 & 3e-5 & 0 & \dots & 5e-4 & 9e-4 & .09 & .002 & 7.6e-5 & 2e-4 & .003 & \dots & 0 & 0 & 3e-6 & 0 \end{bmatrix}$$

$$apple \begin{bmatrix} \dots & d_{16} & \dots & d_{322} & \dots & d_{2469} & d_{2470} & \dots & d_D & a\_fruit & has\_fangs & is\_crunchy & \dots & is\_yellow & is\_red & is\_green & is\_round \\ \dots & 1 & \dots & 1 & \dots & 0 & 1 & \dots & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$apple \begin{bmatrix} \dots & d_{16} & \dots & d_{322} & \dots & d_{2469} & d_{2470} & \dots & d_D & a\_fruit & has\_fangs & is\_crunchy & \dots & is\_yellow & is\_red & is\_green & is\_round \\ \dots & 1 & \dots & 1 & \dots & 0 & 1 & \dots & 0 & .006 & 1.8e-5 & 8e-4 & \dots & .004 & .004 & .006 & .02 \end{bmatrix}$$

Figure 3: Example representation for *apple* before (first row) and after (second row) applying the perceptual inference method of Johns and Jones (2012).

sampling procedure described in Andrews et al. (2009).

Inducing feature-topic components from a document collection  $\mathcal{D}$  with the extended LDA model just described gives two sets of parameters: word probabilities given components  $P_W(w_i|X = x_c)$  for  $w_i, i = 1, \dots, N$ , and feature probabilities given components  $P_F(f_k|X = x_c)$  for  $f_k, k = 1, \dots, F$ . For example, most of the probability mass of component  $x_{107}$  would be reserved for the words *apple*, *fruit*, *lemon*, *orange*, *tree* and the features *is\_red*, *tastes\_sweet*, *is\_round* and so on.

Word meaning in this model is represented by the distribution  $P_{X|W}$  over the learned components (see Figure 2 for an example). Assuming a uniform distribution over components  $x_c$  in  $\mathcal{D}$ ,  $P_{X|W}$  can be approximated as:

$$P_{X=x_c|W=w_i} = \frac{P(w_i|x_c)P(x_c)}{P(w_i)} \approx \frac{P(w_i|x_c)}{\sum_{l=1}^C P(w_i|x_l)} \quad (4)$$

where  $C$  is the total number of components. The model can be also used to infer features for words that were not originally included in the feature norms. The probability distribution  $P_{F|W}$  over features given a word  $w_i$  is simply inferred by summing over all components  $x_c$  for each feature  $f_k$ :

$$P_F(f_k|W = w_i) = \sum_{c=1}^C P(f_k|x_c)P(x_c|w_i) \quad (5)$$

## 2.2 Global Similarity Model

Johns and Jones (2012) propose an approach for generating perceptual representations for words by means of global lexical similarity. Their model does

not place so much emphasis on the integration of perceptual and linguistic information, rather its main focus is on inducing perceptual representations for words with no perceptual correlates. Their idea is to assume that lexically similar words also share perceptual features and hence it should be possible to transfer perceptual information onto words that have none from their linguistically similar neighbors.

Let  $T \in \{1,0\}^{N \times D}$  denote a binary term-document matrix, where each cell records the presence or absence of a term in a document. Let  $P \in [0,1]^{N \times F}$  denote a perceptual matrix, representing a probability distribution over features for each word (see Table 1). A word’s meaning is represented by the concatenation of its textual and perceptual vectors (see Figure 3). If a word has not been normed, its perceptual vector will be all zeros. Johns and Jones (2012) propose a two-step estimation process for words without perceptual vectors. Initially, a perceptual vector is constructed based on the word’s weighted similarity to other words that have non-zero perceptual vectors:

$$\mathbf{p}_{inf} = \sum_{i=1}^N \mathbf{t}_i * sim(\mathbf{t}_i, \mathbf{p})^\lambda \quad (6)$$

where  $\mathbf{p}$  is the representation of a word with a textual vector but an empty perceptual vector,  $\mathbf{t}_i$  are composite representations consisting of textual and perceptual vectors, *sim* is a measure of distributional similarity such as cosine,  $\lambda$  a weighting parameter, and  $\mathbf{p}_{inf}$  the resulting inferred representation of the word. The process is repeated a second time, so as to incorporate the inferred perceptual vector in the computation of the inferred vectors of all other words. An example of this inference procedure is illustrated in Figure 3.

$$\begin{array}{l}
\text{apple} \left[ \begin{array}{cccccccc} \dots & d_{16} & \dots & d_{322} & \dots & d_{2470} & \dots & d_D \\ \dots & .006 & \dots & .003 & \dots & .1e-6 & \dots & 0 \end{array} \right] \left[ \begin{array}{cccccccc} a\_fruit & has\_fangs & is\_crunchy & \dots & is\_yellow & is\_red & is\_green & is\_round \\ .13 & 0 & .06 & \dots & .04 & .14 & .09 & .04 \end{array} \right] \\
\text{apple} \left[ \begin{array}{cccccccc} k_1 & k_2 & k_3 & \dots & k_{409} & k_{410} & \dots & k_{410} \\ -.003 & -.01 & .002 & \dots & -.002 & -.01 & \dots & \dots \end{array} \right] \left[ \begin{array}{cccccccc} k_1 & k_2 & k_3 & \dots & k_{409} & k_{410} & \dots & k_{410} \\ .008 & -.03 & -.008 & \dots & -.02 & -.07 & \dots & \dots \end{array} \right]
\end{array}$$

Figure 4: Example representation for *apple* before (first row) and after (second row) applying CCA.

### 2.3 Canonical Correlation Analysis

Our third model uses Canonical Correlation Analysis (CCA, Hardoon et al. (2004)) to learn a joint semantic representation from the textual and perceptual views. Given two random variables  $\mathbf{x}$  and  $\mathbf{y}$  (or two sets of vectors), CCA can be seen as determining two sets of basis vectors in such a way, that the correlation between the projections of the variables onto these bases is mutually maximized (Borga, 2001). In effect, the representation-specific details pertaining to the two views of the same phenomenon are discarded and the underlying hidden factors responsible for the correlation are revealed.

In our case the linguistic view is represented by a term-document matrix,  $T \in \mathbb{R}^{N \times D}$ , containing information about the occurrence of each word in each document. The perceptual view is captured by a perceptual matrix,  $P \in [0, 1]^{N \times F}$ , representing words as a probability distribution over normed features. CCA is concerned with describing linear dependencies between two sets of variables of relatively low dimensionality. Since the correlation between the linguistic and perceptual views may exist in some nonlinear relationship, we used a kernelized version of CCA (Hardoon et al., 2004) which first projects the data into a higher-dimensional feature space and then performs CCA in this new feature space. The two kernel matrices are  $K_T = TT'$  and  $K_P = PP'$ . After applying CCA we obtain two matrices projected onto  $L$  basis vectors,  $C_t \in \mathbb{R}^{N \times L}$ , resulting from the projection of the textual matrix  $T$  onto the new basis and  $C_p \in \mathbb{R}^{N \times L}$ , resulting from the projection of the corresponding perceptual feature matrix. The meaning of a word can thus be represented by its projected textual vector in  $C_T$ , its projected perceptual vector in  $C_P$  or their concatenation. Figure 4 shows an example of the textual and perceptual vectors for the word *apple* which were used as input for CCA (first row) and their new representation after the projection onto new basis vectors (second row).

The CCA model as sketched above will only ob-

tain full representations for words with perceptual features available. One solution would be to apply the method from Johns and Jones (2012) to infer the perceptual vectors and then perform CCA on the inferred vectors. Another approach which we assess experimentally (see Section 4) is to create a perceptual vector for a word that has none from its  $k$ -most (textually) similar neighbors, simply by taking the average of their perceptual vectors. This inference procedure can be applied to the original vectors or the projected vectors in  $C_T$  and  $C_P$ , respectively, once CCA has taken place.

### 2.4 Discussion

Johns and Jones (2012) primarily present a model of perceptual inference, where textual data is used to infer perceptual information for words not included in feature norms. There is no means in this model to obtain a joint representation resulting from the mutual influence of the perceptual and textual views. As shown in the example in Figure 3 the textual vector on the left-hand side does not undergo any transformation whatsoever. The generative model put forward by Andrews et al. (2009) learns meaning representations by simultaneously considering documents and features. Rather than simply adding perceptual information to textual data it integrates both modalities jointly in a *single* representation which is desirable, at least from a cognitive perspective. It is unlikely that we have separate representations for different aspects of word meaning (Rogers et al., 2004). Similarly to Johns and Jones (2012), Andrews et al's (2009) feature-topic model can also infer perceptual representations for words that have none. The inference is performed automatically in an implicit manner during component induction.

In CCA, textual and perceptual data represent two different views of the same objects and the model operates on these views *directly* without combining or manipulating any of them a priori. Instead, the combination of the two modalities is realized via

correlating the linear relationships between them. A drawback of the model lies in the need of additional methods for inferring perceptual representations for words not available in feature norms.

### 3 Experimental Setup

**Data** All our experiments used a lemmatized version of the British National Corpus (BNC) as a source of textual information. The feature norms of McRae et al. (2005) were used as a proxy for perceptual information. The BNC comprises 4,049 texts totalling approximately 100 million words. McRae et al.’s feature norms consist of 541 words and 2,526 features; 824 of these features occur with at least two different words.

**Evaluation Tasks** Our evaluation experiments compared the models discussed above on three tasks. Two of them have been previously used to evaluate semantic representation models, namely word association and word similarity. In order to simulate word association, we used the human norms collected by (Nelson et al., 1998).<sup>1</sup> These were established by presenting a large number of participants with a cue word (e.g., *rice*) and asking them to name an associate word in response (e.g., *Chinese, wedding, food, white*). For each cue word, the norms provide a set of associates and the frequencies with which they were named. We can thus compute the probability distribution over associates for each cue. Analogously, we can estimate the degree of similarity between a cue and its associates using our models (see the following section for details on the similarity measures we employed). The norms contain 63,619 unique normed cue-associate pairs in total. Of these, 25,968 pairs were covered by all models and 520 appeared in McRae et al.’s (2005) norms. Using correlation analysis, we examined the degree of linear relationship between the human cue-associate probabilities and the automatically derived similarity values.

Our word similarity experiments used the WordSimilarity-353 test collection (Finkelstein et al., 2002)<sup>2</sup> which consists of relatedness judgments

for word pairs. For each pair, a similarity judgment (on a scale of 0 to 10) was elicited from 13 or 16 human subjects (e.g., *tiger-cat* are very similar, whereas *delay-racism* are not). The average rating for each pair represents an estimate of the perceived similarity of the two words. The task varies slightly from word association. Here, participants are asked to rate perceived similarity rather than to generate the first word that came to mind in response to a cue word. The collection contains similarity ratings for 353 word pairs. Of these, 76 pairs appeared in our corpus and 3 in McRae et al.’s (2005) norms. Again, we evaluated how well model produced similarities correlate with human ratings. Throughout this paper we report correlation coefficients using Pearson’s  $r$ .

Our third task assessed the models’ ability to infer perceptual vectors for words that have none. To do this, we conducted 10-fold cross-validation on McRae et al.’s (2005) norms. We treated the perceptual vectors in each test fold as unseen, and used the data in the corresponding training fold together with the models presented in Section 2 to infer them. Then, for each word, we examined how close the inferred vector was to the actual one, via correlation analysis.

**Model Parameters** The feature-topic model has a few parameters that must be instantiated. These include,  $C$ , the number of predefined components and the priors  $\alpha$ ,  $\beta$ , and  $\gamma$ . Following Andrews et al. (2009), the components  $C$  were set to 350.<sup>3</sup> A vague inverse gamma prior was placed on  $\alpha$ ,  $\beta$ , and  $\gamma$ .<sup>4</sup> To measure word similarity within this model, we adopt Griffiths et al.’s (2007) definition. The underlying idea is that word association can be expressed as a conditional distribution. If we have seen word  $w_1$ , then we can determine the probability that  $w_2$  will be also generated by computing  $P(w_2|w_1)$ . Assuming that both  $w_1$  and  $w_2$  came from a single component,  $P(w_2|w_1)$  can be estimated as:

$$P(w_2|w_1) = \sum_{c=1}^C P(w_2|x_c)P(x_c|w_1) \quad (7)$$

$$P(x_c|w_1) \propto P(w_1|x_c)P(x_c)$$

<sup>3</sup>As we explain in Section 4 the feature-topic model was compared to a vanilla LDA model trained on the BNC only. For that model,  $C$  was set to 250.

<sup>4</sup>That is  $P(\bullet) = \exp(-\frac{1}{\bullet})\bullet^{-2}$ .

<sup>1</sup>Available at <http://www.usf.edu/Freeassociation>.

<sup>2</sup>Available at <http://www.cs.technion.ac.il/~gabril/resources/data/wordsim353/>.

where  $P(x_c)$  is uniform, a single component  $x_c$  is sampled from the distribution  $P(x_c|w_1)$ , and an overall estimate is obtained by averaging over all  $C$  components.

Johns and Jones’ (2012) model uses binary textual vectors to represent word meaning. If the word is present in a given document, that vector element is coded as one; if it is absent, it is coded as zero. We built a binary term-document matrix from the BNC over 14,000 lemmas. The value of the similarity weighting parameter  $\lambda$  was set to the same values reported by Johns and Jones ( $\lambda_1=3$  for Step 1 and  $\lambda_2 = 13$  for Step 2).

For the CCA model, we represented the textual view with a term-document co-occurrence matrix. Matrix cells were set to their tf-idf values.<sup>5</sup> The textual and perceptual matrices were projected onto 410 vectors. As mentioned in Section 2.3, CCA does not naturally lend itself to inferring perceptual vectors, yet a perceptual vector for a word can be created from its  $k$ -nearest neighbors. We inferred a perceptual vector by averaging over the perceptual vectors of the word’s  $k$  most similar words; textual similarity between two words was measured using the cosine of the angle of the two vectors representing them. To find the optimal value for  $k$ , we used one third of Nelson’s (1998) cues as development set. The highest correlation was achieved with  $k = 2$  when the perceptual vectors were created prior to CCA and  $k = 8$  when they were inferred on the projected textual and perceptual matrices.

## 4 Results

Our experiments were designed to answer three questions: (1) Does the integration of perceptual and textual information yield a better fit with behavioral data compared to a model that considers only one data source? (2) What is the best way to integrate the two modalities, e.g., via simple concatenation or jointly? (3) How accurately can we approximate the perceptual information when the latter is absent?

To answer the first question, we assessed the models’ performance when textual and perceptual information are both available. The results in Table 2 are thus computed on the subset of Nelson’s (1998)

<sup>5</sup>Experiments with a binarized version of the term-document matrix consistently performed worse.

Models	Modality	Pearson’s $r$
Feature-topic	+t +p	.35
Feature-topic	+t -p	.12

Global similarity	-t +p	.22
CCA	+t +p	.32
CCA	+t -p	.14
CCA	-t +p	.29
Upper Bound	—	.91

Table 2: Performance of feature-topic, global similarity, and CCA models on a subset of the Nelson et al. (1998) norms when taking into account the textual and perceptual modalities on their own (+t-p and -t+p) and in combination (+t+p). All correlation coefficients are statistically significant ( $p < 0.01$ ).

norms (520 cue-associate pairs) that also appeared in McRae et al. (2005) and for which a perceptual vector was present. The table shows different instantiations of the three models depending on the type of modality taken into account: textual, perceptual or both.

As can be seen, Andrews et al.’s (2009) feature-topic model provides a better fit with the association data when both modalities are taken into account (+t+p). A vanilla LDA model constructed solely on the BNC (+t-p) or McRae et al.’s (2005) feature norms (-t+p) yields substantially lower correlations. We observe a similar pattern with Johns and Jones’ (2012) global similarity model. Concatenation of perceptual and textual vectors yields the best fit with the norming data, relying on perceptual information alone (-t+p) comes close, whereas textual information on its own seems to have a weaker effect (+t-p).<sup>6</sup> The CCA model takes perceptual and textual information as input in order to find a projection onto basis vectors that are maximally correlated. Although by definition the CCA model must operate on the two views, we can nevertheless isolate the contribution of each modality by considering the vectors resulting from the projection of the tex-

<sup>6</sup>In this evaluation setting, the model does not infer any perceptual representations; perceptual vectors are taken directly from McRae et al. (2005).

tual matrix (+t-p), the perceptual matrix (-t+p) or their concatenation (+t+p). We obtain best results with the latter representation; again we observe that the perceptual information is more dominant.

Overall we find that the feature-topic model and CCA perform best. In fact the correlations achieved by the two models do not differ significantly, using a *t*-test (Cohen and Cohen, 1983). The performance of the global similarity model is significantly worse than the feature-topic model and CCA ( $p < 0.01$ ). Recall that the feature-topic model (+t+p) represents words as distributions over components, whereas the global similarity model simply concatenates the textual and perceptual vectors. The same input is also given to CCA which in turn attempts to interpret the data by inferring common relationships between the two views. In sum, we can conclude that the higher correlation with human judgments indicates that integrating textual and perceptual modalities jointly is preferable to concatenation.

However, note that all models in Table 2 fall short of the human upper bound which we measured by calculating the *reliability* of Nelson et al.’s (1998) norms. Reliability estimates the likelihood of a similarly-composed group of participants presented with the same task under the same circumstances producing identical results. We split the collected cue-associate pairs randomly into two halves and computed the correlation between them; this correlation was averaged across 200 random splits. These correlations were adjusted by applying the Spearman-Brown prediction formula (Voorspoels et al., 2008).

The results in Table 2 are computed on a small fraction of Nelson et al.’s (1998) norms. One might even argue that the comparison is slightly unfair as the global similarity model is more geared towards inferring perceptual vectors rather than integrating the two modalities in the best possible way. To gain a better understanding of the models’ behavior and to allow comparisons on a larger dataset and more equal footing, we also report results on the entire dataset (20,556 cue-associate pairs).<sup>7</sup> This entails that the models will infer perceptual vectors for the

<sup>7</sup>This excludes the data used as development set for tuning the *k*-nearest neighbors for CCA.

Models	Pearson’s <i>r</i>

words that are not attested in McRae et al.’s norms. Recall from Section 2.3 that CCA does not have a dedicated inference mechanism. We thus experimented with three options (a) interfacing the inference method of Johns and Jones (2012) with CCA (global similarity  $\ll$  CCA) (b) creating a perceptual vector from the words’ *k*-nearest neighbors before (*k*-NN  $\ll$  CCA) or (c) after CCA takes place (CCA  $\ll$  *k*-NN).

Our results are summarized in Table 3. The upper bound was estimated in the same fashion as for the smaller dataset. Despite being statistically significant ( $p < 0.01$ ), the correlation coefficients are lower. This is hardly surprising as perceptual information is approximate and in several cases likely to be wrong. Interestingly, we observe similar modeling trends, irrespective of whether the models are performing perceptual inference or not. The feature-topic model achieves the best fit with the data, followed by CCA. The inference method here does not seem to have much of an impact: CCA  $\ll$  *k*-NN does as well as global similarity  $\ll$  CCA. This is perhaps expected as the inference procedure adopted by Johns and Jones (2012) is a generalization of our *k*-nearest neighbor approach. The global similarity model performs worst; we conjecture that this is due to the way semantic information is integrated rather than the inference method itself. CCA works with similar input, yet achieves better correlations with the human data, due to its ability to represent the commonalities shared by the two modalities. Taken together the results in Tables 2 and 3 provide an answer to our second question. Models that capture latent information shared between the two modalities

Models	Pearson's $r$

create more accurate semantic representations compared to simply treating the two as independent data sources.

In order to isolate the influence of the inference method from the resulting semantic representation we evaluated the inferred perceptual vectors on their own by computing their correlation with the original feature distributions in McRae et al.'s (2005) norms. The correlation coefficients are reported in Table 4 and were computed by averaging the coefficients obtained for individual words. Here, the global similarity model achieves the highest correlation, and for a good reason. It is the only model with an emphasis on inference, the other two models do not have such a dedicated mechanism. CCA has in fact none, whereas in the feature-topic model the inference of missing perceptual information is a by-product of the generative process. The results in Table 4 indicate that the perceptual vectors are not reconstructed very accurately (the highest correlation coefficient is .25) and that better inference mechanisms are required for perceptual information to have a positive impact on semantic representation.

In Table 5 we examine the models' performance on semantic similarity rather than association using the WordSimilarity-353 dataset (Finkelstein et al., 2002). The models were evaluated on 76 word pairs that appeared in the BNC. We inferred the perceptual vectors for 51 words. We computed the upper bound using the reliability method described earlier. Again, the joint models achieve better results than the simple concatenation model. The feature-topic and CCA models perform comparably, with the global similarity model lagging substantially behind. In sum, our results indicate that the issue of how to best integrate the two modalities has a

greater impact on the resulting semantic representations compared to the mechanism by which missing perceptual information is inferred.

## 5 Conclusions

In this paper, we have presented a comparative study of semantic representation models which compute word meaning on the basis of linguistic and perceptual information. The models differ in terms of the mechanisms by which they integrate the two modalities. In the feature-topic model (Andrews et al., 2009), the textual and perceptual views are integrated via a set of latent components that are inferred from the *joint* distribution of textual words and perceptual features. The model based on Canonical Correlation Analysis (Hardoon et al., 2004) integrates the two views by deriving a *consensus* representation based on the correlation between the linguistic and perceptual modalities. Johns and Jones' (2012) similarity-based model simply concatenates the two representations. In addition, it uses the linguistic representations of words to infer perceptual information when the latter is absent.

Experiments on word association and similarity show that all models benefit from the integration of perceptual data. We also find that joint models are superior as they obtain a closer fit with human judgments compared with an approach that simply concatenates the two views. We have also examined how these models perform on the perceptual inference task which has implications for the wider applicability of grounded semantic representation models. Johns and Jones' (2012) inference mechanism goes some way towards reconstructing the information contained in the feature norms, however, further

work is needed to achieve representations accurate enough to be useful in semantic tasks.

In this paper we have used McRae et al.'s (2005) norms without any extensive feature engineering other than applying a frequency cut-off. In the future we plan to experiment with feature selection methods in an attempt to represent perceptual information more succinctly. For example, it may be that different features are appropriate for different word classes (e.g., color versus event denoting nouns). Although feature norms are a useful first approximation of perceptual data, the effort involved in eliciting them limits the scope of any computational model based on normed data. A natural avenue for future work would be to develop semantic representation models that exploit perceptual data that is both naturally occurring and easily accessible (e.g., images, physical simulations).

**Acknowledgments** We are grateful to Brendan Johns for his help with the re-implementation of his model. Thanks to Frank Keller and Michael Roth for their input on earlier versions of this work, Ioannis Konstas for his help with the final version, and members of the ILCC at the School of Informatics for valuable discussions and comments. We acknowledge the support of EPSRC through project grant EP/I032916/1.

## Abstract

State-of-the-art statistical parsers and POS taggers perform very well when trained with large amounts of in-domain data. When training data is out-of-domain or limited, accuracy degrades. In this paper, we aim to compensate for the lack of available training data by exploiting similarities between test set sentences. We show how to augment sentence-level models for parsing and POS tagging with inter-sentence consistency constraints. To deal with the resulting global objective, we present an efficient and exact dual decomposition decoding algorithm. In experiments, we add consistency constraints to the MST parser and the Stanford part-of-speech tagger and demonstrate significant error reduction in the domain adaptation and the lightly supervised settings across five languages.

## 1 Introduction

State-of-the-art statistical parsers and POS taggers perform very well when trained with large amounts of data from their test domain. When training data is out-of-domain or limited, the performance of the resulting model often degrades. In this paper, we aim to compensate for the lack of available training data by exploiting similarities between test set sentences. Most parsing and tagging models are defined at the sentence-level, which makes such inter-sentence information sharing difficult. We show how to augment sentence-level models with inter-sentence constraints to encourage consistent decisions in similar

contexts, and we give an efficient algorithm with formal guarantees for decoding such models.

In POS tagging, most taggers perform very well on word types that they have observed in training data, but they perform poorly on unknown words. With a global objective, we can include constraints that encourage a consistent tag across all occurrences of an unknown word type to improve accuracy. In dependency parsing, the parser can benefit from surface-level features of the sentence, but with sparse or out-of-domain training data these features are very noisy. Using a global objective, we can add constraints that encourage similar surface-level contexts to exhibit similar syntactic behaviour.

The first contribution of this work is the use of Markov random fields (MRFs) to model global constraints between sentences in dependency parsing and POS tagging. We represent each word as a node, the tagging or parse decision as its label, and add constraints through edges. MRFs allow us to include global constraints tailored to these problems, and to reason about inference in the corresponding global models.

The second contribution is an efficient dual decomposition algorithm for decoding a global objective with inter-sentence constraints. These constraints generally make direct inference challenging since they tie together the entire test corpus. To alleviate this issue, our algorithm splits the global inference problem into subproblems - decoding of individual sentences, and decoding of the global MRF. These subproblems can be solved efficiently through known methods. We show empirically that by iteratively solving these subproblems, we can find the

\* Both authors contributed equally to this work.

exact solution to the global model.

We experiment with domain adaptation and lightly supervised training. We demonstrate that global models with consistency constraints can improve upon sentence-level models for dependency parsing and part-of-speech tagging. For domain adaptation, we show an error reduction of up to 7.7% when adapting the second-order projective MST parser (McDonald et al., 2005) from newswire to the QuestionBank domain. For lightly supervised learning, we show an error reduction of up to 12.8% over the same parser for five languages and an error reduction of up to 10.3% over the Stanford trigram tagger (Toutanova et al., 2003) for English POS tagging. The algorithm requires, on average, only 1.7 times the costs of sentence-level inference and finds the exact solution on the vast majority of sentences.

## 2 Related Work

Methods that combine inter-sentence information with sentence-level algorithms have been applied to a number of NLP tasks. The most similar models to our work are skip-chain CRFs (Sutton and McCallum, 2004), relational markov networks (Taskar et al., 2002), and collective inference with symmetric clique potentials (Gupta et al., 2010). These models use a linear-chain CRF or MRF objective modified by potentials defined over pairs of nodes or clique templates. The latter model makes use of Lagrangian relaxation. Skip-chain CRFs and collective inference have been applied to problems in IE, and RMNs to named entity recognition (NER) (Bunescu and Mooney, 2004). Finkel et al. (2005) also integrated non-local information into entity annotation algorithms using Gibbs sampling.

Our model can be applied to a variety of off-the-shelf structured prediction models. In particular, we focus on dependency parsing which is characterized by a more complicated structure compared to the IE tasks addressed by previous work.

Another line of work that integrates corpus-level declarative information into sentence-level models includes the posterior regularization (Ganchev et al., 2010; Gillenwater et al., 2010), generalized expectation (Mann and McCallum, 2007; Mann and McCallum, ), and Bayesian measurements (Liang et al., 2009) frameworks. The power of these methods has

been demonstrated for a variety of NLP tasks, such as unsupervised and semi-supervised POS tagging and parsing. The constraints used by these works differ from ours in that they encourage the posterior label distribution to have desired properties such as sparsity (e.g. a given word can take a small number of labels with a high probability). In addition, these methods use global information during training as opposed to our approach which applies test-time inference global constraints.

The application of dual decomposition for inference in MRFs has been explored by Wainwright et al. (2005), Komodakis et al. (2007), and Globerson and Jaakkola (2007). In NLP, Rush et al. (2010) and Koo et al. (2010) applied dual decomposition to enforce agreement between different sentence-level algorithms for parsing and POS tagging. Work on dual decomposition for NLP is related to the work of Smith and Eisner (2008) who apply belief propagation to inference in dependency parsing, and to constrained conditional models (CCM) (Roth and Yih, 2005) that impose inference-time constraints through an ILP formulation.

Several works have addressed semi-supervised learning for structured prediction, suggesting objectives based on the max-margin principles (Altun and McAllester, 2005), manifold regularization (Belkin et al., 2005), a structured version of co-training (Brefeld and Scheffer, 2006) and an entropy-based regularizer for CRFs (Wang et al., 2009). The complete literature on domain adaptation is beyond the scope of this paper, but we refer the reader to Blitzer and Daume (2010) for a recent survey.

Specifically for parsing and POS tagging, self-training (Reichart and Rappoport, 2007), co-training (Steedman et al., 2003) and active learning (Hwa, 2004) have been shown useful in the lightly supervised setup. For parser adaptation, self-training (McClosky et al., 2006; McClosky and Charniak, 2008), using weakly annotated data from the target domain (Lease and Charniak, 2005; Rimell and Clark, 2008), ensemble learning (McClosky et al., 2010), hierarchical bayesian models (Finkel and Manning, 2009) and co-training (Sagae and Tsujii, 2007) achieve substantial performance gains. For a recent survey see Plank (2011). Constraints similar to those we use for POS tagging were used by Subramanya et al. (2010) for POS tagger adaptation.

Their work, however, does not show how to decode a global, corpus-level, objective that enforces these constraints, which is a major contribution of this paper.

Inter-sentence syntactic consistency has been explored in the psycholinguistics and NLP literature. Phenomena such as parallelism and syntactic priming – the tendency to repeat recently used syntactic structures – have been demonstrated in human language corpora (e.g. WSJ and Brown) (Dubey et al., 2009) and were shown useful in generative and discriminative parsers (e.g. (Cheung and Penn, 2010)). We complement these works, which focus on consistency between consecutive sentences, and explore corpus level consistency.

### 3 Structured Models

We begin by introducing notation for sentence-level dependency parsing as a structured prediction problem. The goal of dependency parsing is to find the best parse  $y$  for a tagged sentence  $x = (w_1/t_1, \dots, w_n/t_n)$  with words  $w$  and POS tags  $t$ . Define the *index set* for dependency parsing as

$$\mathcal{I}(x) = \{(m, h) : m \in \{1 \dots n\}, \\ h \in \{0 \dots n\}, m \neq h\}$$

where  $h = 0$  represents the root word. A dependency parse is a vector  $y = \{y(m, h) : (m, h) \in \mathcal{I}(x)\}$  where  $y(m, h) = 1$  if  $m$  is a modifier of the head word  $h$ . We define the set  $\mathcal{Y}(x) \subset \{0, 1\}^{|\mathcal{I}(x)|}$  to be the set of all valid dependency parses for a sentence  $x$ . In this work, we use projective dependency parses, but the method also applies to the set of non-projective parse trees.

Additionally, we have a scoring function  $f : \mathcal{Y}(x) \rightarrow \mathbb{R}$ . The optimal parse  $y^*$  for a sentence  $x$  is given by,  $y^* = \arg \max_{y \in \mathcal{Y}(x)} f(y)$ . This sentence-level decoding problem can often be solved efficiently. For example in commonly used projective dependency parsing models (McDonald et al., 2005), we can compute  $y^*$  efficiently using variants of the Viterbi algorithm.

For this work, we make the assumption that we have an efficient algorithm to find the argmax of

$$f(y) + \sum_{(m,h) \in \mathcal{I}(x)} u(m, h)y(m, h) = f(y) + u \cdot y$$

where  $u$  is a vector in  $\mathbb{R}^{|\mathcal{I}(x)|}$ . In practice,  $u$  will be a vector of Lagrange multipliers associated with the dependencies of  $y$  in our dual decomposition algorithm given in Section 6.

We can construct a very similar setting for POS tagging where the goal is to find the best tagging  $y$  for a sentence  $x = (w_1, \dots, w_n)$ . We skip the formal details here.

We next introduce notation for Markov random fields (MRFs) (Koller and Friedman, 2009). An MRF consists of an undirected graph  $G = (V, E)$ , a set of possible labels for each node  $L_i$  for  $i \in \{1, \dots, |V|\}$ , and a scoring function  $g$ . The index set for MRFs is

$$\mathcal{I}^{\text{MRF}} = \{(i, l) : i \in \{1 \dots |V|\}, l \in L_i\} \\ \cup \{((i, j), l_i, l_j) : (i, j) \in E, l_i \in L_i, l_j \in L_j\}$$

A label assignment in the MRF is a binary vector  $z$  with  $z(i, l) = 1$  if the label  $l$  is selected at node  $i$  and  $z((i, j), l_i, l_j) = 1$  if the labels  $l_i, l_j$  are selected for the nodes  $i, j$ .

In applications such as parsing and POS tagging, some of the label assignments are not allowed. For example, in dependency parsing the resulting structure must be a tree. Consequently, if every node in the MRF corresponds to a word in a document and its label corresponds to the index of its head word, the resulting dependency structure for each sentence must be acyclic. The set of all valid label assignments (one label per node) is given by  $\mathcal{Z} \subset \{0, 1\}^{|\mathcal{I}^{\text{MRF}}|}$ .

We score label assignments in the MRF with a scoring function  $g : \mathcal{Z} \rightarrow \mathbb{R}$ . The best assignment  $z^*$  in an MRF is given by,  $z^* = \arg \max_{z \in \mathcal{Z}} g(z)$ . We focus on pairwise MRFs where this function  $g$  is a linear function of  $z$  whose parameters are denoted by  $\theta$

$$g(z) = z \cdot \theta = \sum_{(i,l) \in \mathcal{I}^{\text{MRF}}} z(i, l)\theta(i, l) + \\ \sum_{((i,j), l_i, l_j) \in \mathcal{I}^{\text{MRF}}} z((i, j), l_i, l_j)\theta((i, j), l_i, l_j)$$

As in parsing, we make the assumption that we have an efficient algorithm to find the argmax of

$$g(z) + \sum_{(i,l) \in \mathcal{I}^{\text{MRF}}(x)} u(i, l)z(i, l)$$

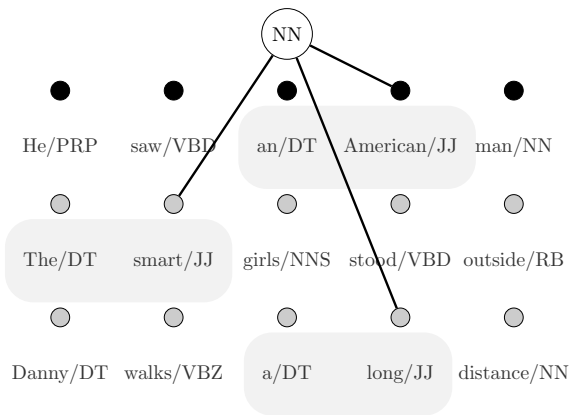

Figure 1: An example constraint from dependency parsing. The black nodes are modifiers observed in the training data. Each gray node corresponds to a possible modifier in the test corpus. The constraint applies to all modifiers in the context DT JJ. The white node corresponds to the consensus POS tag of the head word of these modifiers.

#### 4 A Parsing Example

In this section we give a detailed example of global constraints for dependency parsing. The aim is to construct a global objective that encourages similar contexts across the corpus to exhibit similar syntactic behaviour. We implement this objective using an MRF with a node for each word in the test set. The label of each node is the index of the word it modifies. We add edges to this MRF to reward consistency among similar contexts. Furthermore, we add nodes with a fixed label to incorporate contexts seen in the training data.

Specifically, we say that the context of a word is its POS tag and the POS tags of some set of the words around it. We expand on this notion of context in Section 8; for simplicity we assume here that the context includes only the previous word’s POS tag. Our constraints are designed to bias words in the same context to modify words with similar POS tags.

Figure 1 shows a global MRF over a small parsing example with one training sentence and two test sentences. The MRF contains a node associated with each word instance, where the label of the node is the index of the word it modifies. In this corpus, the context DT JJ appears once in training and twice in testing. We hope to choose head words with similar

POS tags for these two test contexts biased by the observed training context.

More concretely, for each context  $c \in \{1, \dots, C\}$ , we have a set  $S_c$  of associated word indices  $(s, m)$  that appear in the context, where  $s$  is a sentence index and  $m$  is a position in that sentence. For instance, in our example  $S_1 = \{(1, 2), (2, 4)\}$  consists of all positions in the test set where we see JJ preceded by DT. Furthermore, we have a set  $O_c$  of indices  $(s, m, \text{TR})$  of observed instances of the context in the training data where TR denotes a training index. In our example  $O_1 = \{(1, 4, \text{TR})\}$  consists of the one training instance. We associate each word instance with a single context  $c$ .

We then define our MRF to include one consensus node for each set  $S_c$  as well as a word node for each instance in the set  $S_c \cup O_c$ . Thus the set of variables corresponds to  $V = \{1, \dots, C\} \cup (\bigcup_{c=1}^C S_c \cup O_c)$ . Additionally, we include an edge from each node  $i \in S_c \cup O_c$  to its consensus node  $c$ ,  $E = \{(i, c) : c \in \{1, \dots, C\}, i \in S_c \cup O_c\}$ . The word nodes from  $S_c$  have the label set of possible head indices  $L_{(s,m)} = \{0, \dots, n_s\}$  where  $n_s$  is the length of the sentence  $s$ . The observed nodes from  $O_c$  have a singleton label set  $L_{(s,m,\text{TR})}$  with the observed index. The consensus nodes have the label set  $L_c = \mathcal{T} \cup \{\text{NULL}\}$  where  $\mathcal{T}$  is the set of POS tags and the NULL symbol represents the constraint being turned off.

We can now define the scoring function  $g$  for this MRF. The scoring function aims to reward consistency among the head POS tag at each word and the consensus node

$$\theta((i, c), l_i, l_c) = \begin{cases} \delta_1 & \text{if } \text{pos}(l_i) = l_c \\ \delta_2 & \text{if } \text{pos}(l_i) \text{ is close to } l_c \\ \delta_3 & l_c = \text{NULL} \\ 0 & \text{otherwise} \end{cases}$$

where  $\text{pos}$  maps a word index to its POS tag. The parameters  $\delta_1 \geq \delta_2 \geq \delta_3 \geq 0$  determine the bonus for identical POS tags, similar POS tags, and for turning off the constraint.

We construct a similar model for POS tagging. We choose sets  $T_c$  corresponding to the  $c$ ’th unknown word type in the corpus. The MRF graph is identical to the parsing case with  $T_c$  replacing  $S_c$  and we no longer have  $O_c$ . The label sets for the word nodes are now  $L_{(s,m)} = \mathcal{T}$  where the label is

the POS tag chosen at that word, and the label set for the consensus node is  $L_c = \mathcal{T} \cup \{\text{NULL}\}$ . We use the same scoring function as in parsing to enforce consistency between word nodes and the consensus node.

## 5 Global Objective

Recall the definition of sentence-level parsing, where the optimal parse  $y^*$  for a single sentence  $x$  under a scoring function  $f$  is given by:  $y^* = \arg \max_{y \in \mathcal{Y}(x)} f(y)$ . We apply this objective to a set of sentences, specified by the tuple  $X = (x_1, \dots, x_r)$ , and the product of possible parses  $\mathcal{Y}(X) = \mathcal{Y}(x_1) \times \dots \times \mathcal{Y}(x_r)$ . The sentence-level decoding problem is to find the optimal dependency parses  $Y^* = (Y_1^*, \dots, Y_r^*) \in \mathcal{Y}(X)$  under a global objective

$$Y^* = \arg \max_{Y \in \mathcal{Y}(X)} F(Y) = \arg \max_{Y \in \mathcal{Y}(X)} \sum_{s=1}^r f(Y_s)$$

where  $F : \mathcal{Y}(X) \rightarrow \mathbb{R}$  is the global scoring function.

We now consider scoring functions where the global objective includes inter-sentence constraints. Objectives of this form will not factor directly into individual parsing problems; however, we can choose to write them as the sum of two convenient terms: (1) A simple sum of sentence-level objectives; and (2) A global MRF that connects the local structures.

For convenience, we define the following index set.

$$\mathcal{J}(X) = \{(s, m, h) : \begin{array}{l} s \in \{1, \dots, r\}, \\ (m, h) \in \mathcal{I}(x_s) \end{array}\}$$

This set enumerates all possible dependencies at each sentence in the corpus. We say the parses  $Y_s$  are consistent with a label assignment  $z$  if for all  $(s, m, h) \in \mathcal{J}(X)$  we have that  $z((s, m), h) = Y_s(m, h)$ . In other words, the labels in  $z$  match the head words chosen in parse  $Y_s$ .

With this notation we can write the full global decoding objective as

$$(Y^*, z^*) = \arg \max_{Y \in \mathcal{Y}(X), z \in \mathcal{Z}} F(Y) + g(z) \quad (1)$$

$$\text{s.t. } \forall (s, m, h) \in \mathcal{J}(X), z((s, m), h) = Y_s(m, h)$$

```

Set  $u^{(1)}(s, m, h) \leftarrow 0$  for all  $(s, m, h) \in \mathcal{J}(X)$ 
for  $k = 1$  to  $K$  do
   $z^{(k)} \leftarrow \arg \max_{z \in \mathcal{Z}} (g(z) + \sum_{(s, m, h) \in \mathcal{J}(X)} u^{(k)}(s, m, h) z((s, m), h))$ 
   $Y^{(k)} \leftarrow \arg \max_{Y \in \mathcal{Y}(X)} (F(Y) - \sum_{(s, m, h) \in \mathcal{J}(X)} u^{(k)}(s, m, h) Y_s(m, h))$ 
  if  $Y_s^{(k)}(m, h) = z^{(k)}((s, m), h)$ 
    for all  $(s, m, h) \in \mathcal{J}(X)$  then
      return  $(Y^{(k)}, z^{(k)})$ 
  for all  $(s, m, h) \in \mathcal{J}(X)$ ,
     $u^{(k+1)}(s, m, h) \leftarrow u^{(k)}(s, m, h) + \alpha_k (z^{(k)}((s, m), h) - Y_s^{(k)}(m, h))$ 
return  $(Y^{(K)}, z^{(K)})$ 

```

Figure 2: The global decoding algorithm for dependency parsing models.

The solution to this objective maximizes the local models as well as the global MRF, while maintaining consistency among the models. Specifically, the MRF we use in the experiments has a simple naive Bayes structure with the consensus node connected to all relevant word nodes.

The global objective for POS tagging has a similar form. As before we add a node to the MRF for each word in the corpus. We use the POS tag set as our labels for each of these nodes. The index set contains an element for each possible tag at each word instance in the corpus.

## 6 A Global Decoding Algorithm

We now consider the decoding question: how to find the structure  $Y^*$  that maximizes the global objective. We aim for an efficient solution that makes use of the individual solvers at the sentence-level. For this work, we make the assumption that the graph chosen for the MRF has small tree-width, e.g. our naive Bayes constraints, and can be solved efficiently using dynamic programming.

Before we describe our dual decomposition algorithm, we consider the difficulty of solving the global objective directly. We have an efficient dynamic programming algorithm for solving dependency parsing at the sentence-level, and efficient algorithms for solving the MRF. It follows that we

could construct an intersected dynamic programming algorithm that maintains the product of states over both models. This algorithm is exact, but it is very inefficient. Solving the intersected dynamic program requires decoding simultaneously over the entire corpus, with an additional multiplicative factor for solving the MRF. On top of this cost, we need to alter the internal structure of the sentence-level models.

In contrast, we can construct a dual decomposition algorithm which is efficient, produces a certificate when it finds an exact solution, and directly uses the sentence-level parsing models. Considering again the global objective of equation 1, we note that the difficulty in decoding this objective comes entirely from the constraints  $z((s, m), h) = Y_s(m, h)$ . If these were not there, the problem would factor into two parts, an optimization of  $F$  over the test corpus  $\mathcal{Y}(X)$  and an optimization of  $g$  over possible MRF assignments  $\mathcal{Z}$ . The first problem factors naturally into sentence-level parsing problems and the second can be solved efficiently given our assumptions on the MRF topology  $G$ .

Recent work has shown that a relaxation based on dual decomposition often produces an exact solution for such problems (Koo et al., 2010). To apply dual decomposition, we introduce Lagrange multipliers  $u(s, m, h)$  for the agreement constraints between the sentence-level models and the global MRF. The Lagrangian dual is the function  $L(u) = \max_z g(z, u) + \max_y F(y, u)$  where

$$g(z, u) = g(z) + \sum_{(s,m,h) \in \mathcal{J}(X)} u(s, m, h) z((s, m), h),$$

$$F(y, u) = F(Y) - \sum_{(s,m,h) \in \mathcal{J}(X)} u(s, m, h) Y_s(m, h)$$

In order to find  $\min_u L(u)$ , we use subgradient descent. This requires computing  $g(z, u)$  and  $F(y, u)$  for fixed values of  $u$ , which by our assumptions from Section 3 are efficient to calculate.

The full algorithm is given in Figure 2. We start with the values of  $u$  initialized to 0. At each iteration  $k$ , we find the best set of parses  $Y^{(k)}$  over the entire corpus and the best MRF assignment  $z^{(k)}$ . We then update the value of  $u$  based on the difference between  $Y^{(k)}$  and  $z^{(k)}$  and a rate parameter  $\alpha$ . On the next iteration, we solve the same decoding prob-

	$\geq 0.7$	$\geq 0.8$	$\geq 0.9$	1.0
All Contexts	66.8	57.9	46.8	33.3
Head in Context	76.0	67.9	57.2	42.3

Table 1: Exploratory statistics for constraint selection. The table shows the percentage of context types for which the probability of the most frequent head tag is at least  $p$ . Head in Context refers to the subset of contexts where the most frequent head is within the context itself. Numbers are based on Section 22 of the Wall Street Journal and are given for contexts that appear at least 10 times.

lems modified by the new value of  $u$ . If at any point the current solutions  $Y^{(k)}$  and  $z^{(k)}$  satisfy the consistency constraint, we return their current values. Otherwise, we stop at a max iteration  $K$  and return the values from the last iteration.

We now give a theorem for the formal guarantees of this algorithm.

**Theorem 1** *If for some  $k \in \{1 \dots K\}$  in the algorithm in Figure 2,  $Y_s^{(k)}(m, h) = z^{(k)}(s, m, h)$  for all  $(s, m, h) \in \mathcal{J}$ , then  $(Y^{(k)}, z^{(k)})$  is a solution to the maximization problem in equation 1.*

We omit the proof for brevity. It is a slight variation of the proof given by Rush et al. (2010).

## 7 Consistency Constraints

In this section we describe the consistency constraints used for the global models of parsing and tagging.

**Parsing Constraints.** Recall from Section 4 that we choose parsing constraints based on the word context. We encourage words in similar contexts to choose head words with similar POS tags.

We use a simple procedure to select which constraints to add. First define a context template to be a set of offsets  $\{r, \dots, s\}$  with  $r \leq 0 \leq s$  that specify the neighboring words to include in a context. In the example of Figure 1, the context template  $\{-1, 0, 1, 2\}$  applied to the word `girls/NNS` would produce the context `JJ NNS VBD RB`. For each word in the corpus, we consider all possible templates with  $s - r < 4$ . We use only contexts that predict the head POS of the context in the training data with probability 1 and prefer long over short contexts. Once we select the context of each word, we add a consensus node for each context type in

the corpus. We connect each word node to its corresponding consensus node.

Local context does not fully determine the POS tag of the head word, but for certain contexts it provides a strong signal. Table 1 shows context statistics for English. For 46.8% of the contexts, the most frequent head tag is chosen  $\geq 90\%$  of the time. The pattern is even stronger for contexts where the most frequent head tag is within the context itself. In this case, for 57.2% of the contexts the most frequent head tag is chosen  $\geq 90\%$  of the time. Consequently, if more than one context can be selected for a word, we favor the contexts where the most frequent head POS is inside the context.

**POS Tagging Constraints.** For POS tagging, our constraints focus on words not observed in the training data. It is well-known that each word type appears only with a small number of POS tags. In Section 22 of the WSJ corpus, 96.35% of word types appear with a single POS tag.

In most test sets we are unlikely to see an unknown word more than once or twice. To fix this sparsity issue, we import additional unannotated sentences for each unknown word from the New York Times Section of the NANC corpus (Graff, 1995). These sentences give additional information for unknown word types.

Additionally, we note that morphologically related words often have similar POS tags. We can exploit this relationship by connecting related word types to the same consensus node. We experimented with various morphological variants and found that connecting a word type with the type generated by appending the suffix “s” was most beneficial. For each unknown word type, we also import sentences for its morphologically related words.

## 8 Experiments and Results

We experiment in two common scenarios where parsing performance is reduced from the fully supervised, in-domain case. In domain adaptation, we train our model completely in one source domain and test it on a different target domain. In lightly supervised training, we simulate the case where only a limited amount of annotated data is available for a language.

	Base	ST	Model	ER
WSJ $\rightarrow$ QTB	89.63	89.99	90.43	7.7
QTB $\rightarrow$ WSJ	74.89	74.97	75.76	3.5

Table 2: Dependency parsing UAS for domain adaptation. WSJ is the Penn TreeBank. QTB is the QuestionBank. ER is error reduction. Results are significant using the sign test with  $p \leq 0.05$ .

**Data for Domain Adaptation** We perform domain adaptation experiments in English using the WSJ PennTreebank (Marcus et al., 1993) and the QuestionBank (QTB) (Judge et al., 2006). In the WSJ  $\rightarrow$  QTB scenario, we train on sections 2-21 of the WSJ and test on the entire QTB (4000 questions). In the QTB  $\rightarrow$  WSJ scenario, we train on the entire QTB and test on section 23 of the WSJ.

**Data for Lightly Supervised Training** For all English experiments, our data was taken from the WSJ PennTreebank: training sentences from Section 0, development sentences from Section 22, and test sentences from Section 23. For experiments in Bulgarian, German, Japanese, and Spanish, we use the CONLL-X data set (Buchholz and Marsi, 2006) with training data taken from the official training files. We trained the sentence-level models with 50-500 sentences. To verify the robustness of our results, our test sets consist of the official test sets augmented with additional sentences from the official training files such that each test file consists of 25,000 words. Our results on the official test sets are very similar to the results we report and are omitted for brevity.

**Parameters** The model parameters,  $\delta_1$ ,  $\delta_2$ , and  $\delta_3$  of the scoring function (Section 4) and  $\alpha$  of the Lagrange multipliers update rule (Section 6), were tuned on the English development data. In our dual decomposition inference algorithm, we use  $K = 200$  maximum iterations and tune the decay rate following the protocol described by Koo et al. (2010).

**Sentence-Level Models** For dependency parsing we utilize the second-order projective MST parser (McDonald et al., 2005)<sup>1</sup> with the gold-standard POS tags of the corpus. For POS tagging we use the Stanford POS tagger (Toutanova et al., 2003)<sup>2</sup>.

Table 3: Dependency parsing UAS by size of training set and language. English data is from the WSJ. Bulgarian, German, Japanese, and Spanish data is from the CONLL-X data sets. Base is the second-order, projective dependency parser of McDonald et al. (2005). ST is a self-training model based on Reichart and Rappoport (2007). Model is the same parser augmented with inter-sentence constraints. ER is error reduction. Using the sign test with  $p \leq 0.05$ , all 50, 100, and 200 results are significant, as are Eng and Ger 500.

	50		100		200		500	
	Base	Model (ER)	Base	Model (ER)	Base	Model (ER)	Base	Model (ER)
Acc	79.67	81.77 (10.33)	85.42	86.37 (6.52)	88.63	89.37 (6.51)	91.59	91.98 (4.64)
Unk	62.88	67.16 (11.53)	71.10	73.32 (7.68)	75.82	78.07 (9.31)	80.67	82.28 (8.33)

Table 4: POS tagging accuracy. Stanford POS tagger refers to the maximum entropy trigram tagger of Toutanova et al. (2003). Our inter-sentence POS tagger augments this baseline with global constraints. ER is error reduction. All results are significant using the sign test with  $p \leq 0.05$ .

**Evaluation and Baselines** To measure parsing performance, we use unlabeled attachment score (UAS) given by the CONLL-X dependency parsing shared task evaluation script (Buchholz and Marsi, 2006). We compare the accuracy of dependency parsing with global constraints to the sentence-level dependency parser of McDonald et al. (2005) and to a self-training baseline (Steedman et al., 2003; Reichart and Rappoport, 2007). The parsing baseline is equivalent to a single round of dual decomposition. For the self-training baseline, we parse the test corpus, append the labeled test sentences to the training corpus, train a new parser, and then re-parse the test set. We run this procedure for a single iteration.

For POS tagging we measure token level POS accuracy for all the words in the corpus and also for unknown words (words not observed in the training data). We compare the accuracy of POS tagging with global constraints to the accuracy of the Stanford POS tagger<sup>3</sup>.

**Domain Adaptation Accuracy** Results are presented in Table 2. The constrained model reduces the error of the baseline on both cases. Note that when the base parser is trained on the WSJ corpus its UAS performance on the QTB is 89.63%. Yet, the constrained model is still able to reduce the baseline error by 7.7%.

<sup>3</sup>We do not run self-training for POS tagging as it has been shown unuseful for this application (Clark et al., 2003).

**Lightly Supervised Accuracy** The parsing results are given in Table 3. Our model improves over the baseline parser and self-training across all languages and training set sizes. The best results are for Japanese and English with error reductions of 2.33 – 12.82% and 1.93 – 6.64% respectively. The self-training baseline achieves small gains on some languages, but generally performs similarly to the standard parser.

The POS tagging results are given in Table 4. Our model improves over the baseline tagger for the entire training size range. For 50 training sentences we reduce 10.33% of the overall error, and 11.53% of the error on unknown words. Although the tagger performance substantially improves when the training set grows to 500 sentences, our model still provides an overall error reduction of 4.64% and of 8.33% for unknown words.

## 9 Discussion

**Efficiency** Since dual decomposition often requires hundreds of iterations to converge, a naive implementation would be orders of magnitude slower than the underlying sentence-level model. We use two techniques to speed-up the algorithm.

First, we follow Koo et al. (2010) and use lazy decoding as part of dual decomposition. At each iteration  $k$ , we cache the result of the MRF  $z^{(k)}$  and set of parse tree  $Y^{(k)}$ . In the next iteration, we only

Figure 3: Efficiency of dependency parsing decoding for three languages. The plot shows the speed of each iteration of the subgradient algorithm relative to a round of unconstrained parsing.

Most Effective Contexts	
WSJ $\rightarrow$ QTB	QTB $\rightarrow$ WSJ
<b>WRB</b> VBP	VBD NN <b>NN</b> ,
DT JJS NN <b>IN</b>	IN PRP <b>VBZ</b>
VBP PRP <b>VB</b>	<b>JJ</b> JJ NN ,
DT <b>NN</b> NN VB	IN <b>JJ</b> JJ NN
RBS JJ NN <b>IN</b>	<b>NN</b> POS NN NN

Table 5: The five most effective constraint contexts from the domain adaptation experiments. The bold POS tag indicates the modifier word of the context.

Figure 4: Subset of sentences with the context **WRB** VBP from WSJ  $\rightarrow$  QTB domain adaptation. In the first round, the parser chooses VBN for the first sentence, which is inconsistent with similar contexts. The constraints correct this choice in later rounds.

recompute the solution  $Y_s^*$  for a sentence  $s$  if the weight  $u(s, m, h)$  for some  $m, h$  was updated. A

similar technique is applied to the MRF.

Second, during the first iteration of the algorithm we apply max-marginal based pruning using the threshold defined by Weiss and Taskar (2010). This produces a pruned hypergraph for each sentence, which allows us to avoid recomputing parse features and to solve a simplified search problem.

To measure efficiency, we compare the time spent in dual decomposition to the speed of unconstrained inference. Across experiments, the mean dual decomposition time is 1.71 times the cost of unconstrained inference. Figure 3 shows how this time is spent after the first iteration. The early iterations are around 1% of the total cost, and because of lazy decoding this quickly drops to almost nothing.

**Exactness** To measure exactness, we count the number of sentences for which we should remove the constraints in order for the model to reach convergence. For dependency parsing, across languages removing constraints on 0.6% of sentences yields exact convergence. Removing these constraints has very little effect on the final outcome of the model. For POS tagging, the algorithm finds an exact solution after removing constraints from 0.2% of the sentences.

**Constraint Analysis** We can also look at the number, size, and outcome of the constraints chosen in the experiments. In the lightly supervised experiments, the average number of constraints is 3298 for 25000 tokens, where the median constraint connects 19 different tokens. Of these constraints around 70% are active (non-NULL). The domain adaptation experiments have a similar number of constraints with around 75% of constraints active. In both experiments many of the constraints are found to be consistent after the first iteration, but as Figure 3 implies, other constraints take multiple iterations to converge.

**Qualitative Analysis** In order to understand why these simple consistency constraints are effective, we take a qualitative look at the the domain adaptation experiments on the QuestionBank. Table 5 ranks the five most effective contextual constraints from both experiments. For the WSJ  $\rightarrow$  QTB experiment, the most effective constraint relates the initial question word with an adjacent verb. Figure 4 shows

sentences where this constraint applies in the QuestionBank. For the QTB  $\rightarrow$  WSJ experiment, the effective contexts are mostly long base noun phrases. These occur often in the WSJ but are rare in the simpler QuestionBank sentences.

## 10 Conclusion

In this work we experiment with inter-sentence consistency constraints for dependency parsing and POS tagging. We have proposed a corpus-level objective that augments sentence-level models with such constraints and described an exact and efficient dual decomposition algorithm for its decoding. In future work, we intend to explore efficient techniques for joint parameter learning for both the global MRF and the local models.

# Unified Dependency Parsing of Chinese Morphological and Syntactic Structures

Zhongguo Li      Guodong Zhou

## Abstract

Most previous approaches to syntactic parsing of Chinese rely on a preprocessing step of word segmentation, thereby assuming there was a clearly defined boundary between morphology and syntax in Chinese. We show how this assumption can fail badly, leading to many out-of-vocabulary words and incompatible annotations. Hence in practice the strict separation of morphology and syntax in the Chinese language proves to be untenable. We present a unified dependency parsing approach for Chinese which takes unsegmented sentences as input and outputs both morphological and syntactic structures with a single model and algorithm. By removing the intermediate word segmentation, the unified parser no longer needs separate notions for words and phrases. Evaluation proves the effectiveness of the unified model and algorithm in parsing structures of words, phrases and sentences simultaneously.<sup>1</sup>

## 1 Introduction

The formulation of the concept of words has baffled linguists from ancient to modern times (Hockett, 1969). Things are even worse for Chinese, partly due to the fact that its written form does not delimit words explicitly. While we have no doubt that there are linguistic units which are definitely words (or phrases, for that matter), it's a sad truth that in many cases we cannot manage to draw such a clear boundary between morphology and syntax, for which we now give two arguments.

<sup>1</sup>Corresponding author is Guodong Zhou.

The first argument is that many sub-word linguistic units (such as suffixes and prefixes) are so productive that they can lead to a huge number of out-of-vocabulary words for natural language processing systems. This phenomenon brings us into an awkward situation if we adhere to a rigid separation of morphology and syntax. Consider character 者 ‘someone’ as an example. On the one hand, there is strong evidence that it's not a word as it can never be used alone. On the other hand, taking it as a mere suffix leads to many out-of-vocabulary words because of the productivity of such characters. For instance, Penn Chinese Treebank (CTB6) contains 失败者 ‘one that fails’ as a word but not 成功者 ‘one that succeeds’, even with the word 成功 ‘succeed’ appearing 207 times. We call words like 成功者 ‘one that succeeds’ *pseudo* OOVs. By definition, pseudo OOVs are OOVs since they do not occur in the training corpus, though their components are frequently-seen words. Our estimation is that over 60% of OOVs in Chinese are of this kind (Section 2).

Of course, the way out of this dilemma is to parse the internal structures of these words. That is to say, we can still regard characters like 者 as suffixes, taking into account the fact that they cannot be used alone. Meanwhile, pseudo OOVs can be largely eliminated through analyzing their structures, thus greatly facilitating syntactic and semantic analysis of sentences. In fact, previous studies have revealed other good reasons for parsing internal structures of words (Zhao, 2009; Li, 2011).

The second argument is that in Chinese many linguistic units can form both words and phrases with exactly the same meaning and part-of-speech, which

Figure 1: Unified parsing of words and phrases.

causes lots of *incompatible annotations* in currently available corpora. Take character 法 ‘law’ as an example. It is head of both 刑法 ‘criminal law’ and 环境保护法 ‘environmental protection law’, but CTB6 treat it as a suffix in the former (with the annotation being 刑法\_NN) and a word in the later (the annotation is 环境\_NN 保护\_NN 法\_NN). These annotations are incompatible since in both cases the character 法 ‘law’ bears exactly the same meaning and usage (e.g. part-of-speech). We examined several widely used corpora and found that about 90% of affixes were annotated incompatibly (Section 2). Incompatibility can be avoided through parsing structures of both words and phrases. Figure 1 conveys this idea. A further benefit of unified parsing is to reduce data sparseness. As an example, in CTB6 器 ‘machine’ appears twice in phrases but 377 times in words (e.g. 加速器 ‘accelerator’). Word structures in Chinese can be excellent guide for parsing phrase structures, and vice versa, due to their similarity.

The present paper makes two contributions in light of these issues. Firstly, in order to get rid of pseudo OOVs and incompatible annotations, we have annotated structures of words in CTB6, after which statistical models can learn structures of words as well as phrases from the augmented treebank (Section 4). Although previous authors have noticed the importance of word-structure parsing (Li, 2011; Zhao, 2009), no detailed description about annotation of word structures has been provided in the literature. Secondly, we designed a unified dependency parser whose input is unsegmented sentences and its output incorporates both morphological and syntactic structures with a single model and algorithm (Section 5). By removing the intermediate step of word segmentation, our unified parser no longer depends on the unsound notion that there is a clear boundary between words and phrases. Evaluation (Section 6) shows that our unified parser achieves satisfactory accuracies in parsing both morphological and syntactic structures.

corpus	OOV	pseudo	percent
CTB6	158	112	70.9
MSR	1,783	1,307	73.3
PKU	2,860	1,836	64.2
AS	3,020	2,143	71.0
CITYU	1,665	1,100	66.0

Table 1: Statistics of pseudo OOVs for five corpora.

## 2 Pseudo OOVs and Incompatible Annotations

In this section we show the surprisingly pervasive nature of pseudo OOVs and incompatible annotations through analysis of five segmented corpora, which are CTB6 and corpus by MSR, PKU, AS and CITYU provided in SIGHAN word segmentation Bakeoffs<sup>2</sup>.

First we use the standard split of training and testing data and extract all OOVs for each corpus, then count the number of pseudo OOVs. Table 1 gives the result. It’s amazing that for every corpus, over 60% of OOVs are pseudo, meaning they can be avoided if their internal structures were parsed. Reduction of OOVs at such a large scale can benefit greatly downstream natural language processing systems.

We then sample 200 word types containing a productive affix from each corpus, and check whether the affix also occurs somewhere else in a phrase, i.e. the affix is annotated as a word in the phrase. The results are in Table 2. It’s clear and somewhat shocking that most affixes are annotated incompatibly. We believe it is not the annotators to blame, rather the root cause lies deeply in the unique characteristics of the Chinese language. This becomes obvious in comparison with English, where suffix like ‘-ism’ in ‘capitalism’ cannot be used alone as a word in phrases.<sup>3</sup> Incompatible annotations can be removed only through unified parsing of word and phrase structures, as mentioned earlier and illustrated in Figure 1.

<sup>2</sup><http://www.sighan.org/bakeoff2005/>

<sup>3</sup>Actually English allows examples like “pre- and post-war imperialism” where a prefix like “pre” can appear on its own as long as the hyphen is present and it is in a coordination structure. Note that such examples are much rarer than what we discuss in this paper for Chinese. We thank the reviewer very much for pointing this out and providing this example for us.

corpus	incompatible	percent
CTB6	190	95
MSR	178	89
PKU	192	96
AS	182	91
CITYU	194	97

Table 2: Statistics of incompatibly annotated affixes in 200 sampled words for five segmented corpora.

Figure 2: Example output of unified dependency parsing of Chinese morphological and syntactic structures.

### 3 Unified Parsing Defined

Given an unsegmented sentence 甘肃省重视保险业 ‘Gansu province attaches great importance to insurance industry’, the output of unified dependency parser is shown in Figure 2. As can be seen, this output contains information about word (such as 重视\_VV) as well as phrase structures (such as 重视\_VV 保险\_NN 业\_NN), which is what we mean by ‘unified’ parsing. Now, it’s no longer vital to differentiate between morphology and syntax for Chinese. People could regard 保险业 ‘insurance industry’ as a word or phrase, but either way, there will be no disagreements about its internal structure. From the perspective of the unified parser, linguistic units are given the same labels as long as they function similarly (e.g, they have the same parts-of-speech).

As a bonus, output of unified parsing incorporates Chinese word segmentation, part-of-speech tagging and dependency parsing. To achieve these goals, previous systems usually used a pipelined approach by combining several statistical models, which was further complicated by different decoding algorithms for each of these models. The present paper shows that a single model does all these jobs. Besides being much simpler in engineering such a parser, this approach is also a lot more plausible for modeling human language understanding.

## 4 Annotation of Word Structures

Unified parsing requires a corpus annotated with both morphological and syntactic structures. Such a corpus can be built with the least effort if we begin with an existing treebank such as CTB6 already annotated with syntactic structures. It only remains for us to annotate internal structures of words in this treebank.

### 4.1 Scope of Annotation

In order to get rid of pseudo OOVs and incompatible annotations, internal structures are annotated for two kinds of words. The first kind contains words with a productive component such as suffix or prefix. One example is 陈述人 ‘speaker’ whose suffix is the very productive 人 ‘person’ (e.g, in CTB6 there are about 400 words having this suffix). The second kind includes words with compositional semantics. Examples are 星期一 ‘Monday’ and 星期天 ‘Sunday’. Though 星期 ‘week’ is not very productive, the meaning of words with this prefix is deducible from semantics of their components.

Other compound words such as 研究 ‘research’ have no productive components and are not a cause of pseudo OOVs. They are universally considered as words instead of phrases due to their non-compositional semantics. Hence their structures are not annotated in the present research. Meanwhile, for single-morpheme words with no structures whatsoever, like 伊拉克 ‘Iraq’ and 蝙蝠 ‘bat’, annotation of internal structures is of course unnecessary either.

Of all the 54, 214 word types in CTB6, 35% are annotated, while the percentage is 24% for the 782, 901 word tokens. Around 80% of sentences contain words whose structures need annotation. Our annotations will be made publicly available for research purposes.

### 4.2 From Part-of-speches to Constituents

Of all 33 part-of-speech tags in CTB, annotation of word structures is needed for nine tags: NN, VV, JJ, CD, NT, NR, AD, VA and OD. Since part-of-speech tags are preterminals and can only have one terminal word as its child, POS tags of words become constituent labels after annotation of word structures. The mapping rules from POS tags to constituent labels are listed in Table 3. Readers should note that

POS tags	constituent label
NR, NN, NT	NP
JJ	ADJP
AD	ADVP
CD, OD	QP
VV, VA	VP

Table 3: Correspondence between POS tags and constituent labels after annotation.

Figure 3: Example annotation for the word 教育界\_NN in CTB6: POS tag NN changes to constituent label NP after annotation.

such mapping is not arbitrary. The constraint is that in the treebank the POS tag must somewhere be the unique child of the constituent label. Figure 3 depicts an example annotation, in which we also have an example of NP having a tag NN as its only child.

### 4.3 Recursive Annotation

Some words in CTB have very complex structures. Examples include 原子核物理学家 ‘physicist majoring in nuclear physics’, 反托拉斯法 ‘anti-trust laws’ etc. Structures of these words are annotated to their full possible depth. Existence of such words are characteristic of the Chinese language, since they are further demonstrations of the blurred boundary between morphology and syntax. A full-fledged parser is needed to analyze structures of these words, which incidentally provides us with another motivation for unified morphological and syntactic parsing of Chinese.

## 5 Unified Dependency Parsing

All previous dependency parsers for Chinese take it for granted that the input sentence is already segmented into words (Li et al., 2011). Most systems even require words to be tagged with their part-of-speeches (Zhang and Nivre, 2011). Hence current off-the-shelf algorithms are inadequate for parsing

unsegmented sentences. Instead, a new unified parsing algorithm is given in this section.

### 5.1 Transitions

To map a raw sentence directly to output shown in Figure 2, we define four transitions for the unified dependency parser. They act on a stack containing the incremental parsing results, and a queue holding the incoming Chinese characters of the sentence:

**SHIFT:** the first character in the queue is shifted into the stack as the start of a new word. The queue should not be empty.

**LEFT:** the top two words of the stack are connected with an arc, with the top one being the head. There should be at least two elements on the stack.

**RIGHT:** the top two words of the stack are connected, but with the top word being the child. The precondition is the same as that of LEFT.

**APPEND:** the first character in the queue is appended to the word at the top of the stack. There are two preconditions. First, the queue should not be empty. Second, the top of the stack must be a word with no arcs connected to other words (i.e. up to now it has got neither children nor parent).

We see that these transitions mimic the general arc-standard dependency parsing models. The first three of them were used, for example, by Yamada and Matsumoto (2003) to parse English sentences. The only novel addition is APPEND, which is necessary because we are dealing with raw sentences. Its sole purpose is to assemble characters into words with no internal structures, such as 西雅图 ‘Seattle’. Thus this transition is the key for removing the need of Chinese word segmentation and parsing unsegmented sentences directly.

To also output part-of-speech tags and dependency labels, the transitions above can be augmented accordingly. Hence we can change SHIFT to SHIFT·X where X represents a certain POS tag. Also, LEFT and RIGHT should be augmented with appropriate dependency relations, such as LEFT·SUBJ for a dependency between verb and subject.

As a demonstration of the usage of these transitions, consider sentence 我喜欢西雅图 ‘I love Seattle’. Table 4 lists all steps of the parsing process. Readers interested in implementing their own

step	stack	queue	action
1		我喜欢西雅图	SHIFT·PN
2	我_PN	喜欢西雅图	SHIFT·VV
3	我_PN 喜_VV	欢西雅图	APPEND
4	我_PN 喜欢_VV	西雅图	LEFT·SUBJ
5	我_PN $\xleftarrow{\text{SUBJ}}$ 喜欢_VV	西雅图	SHIFT·NR
6	我_PN $\xleftarrow{\text{SUBJ}}$ 喜欢_VV 西_NR	雅图	APPEND
7	我_PN $\xleftarrow{\text{SUBJ}}$ 喜欢_VV 西雅_NR	图	APPEND
8	我_PN $\xleftarrow{\text{SUBJ}}$ 喜欢_VV 西雅图_NR		RIGHT·OBJ
9	我_PN $\xleftarrow{\text{SUBJ}}$ 喜欢_VV $\xrightarrow{\text{OBJ}}$ 西雅图_NR		STOP

Table 4: Parsing process of a short sentence with the four transitions defined above.

unified dependency parsers are invited to study this example carefully.

## 5.2 Model

Due to structural ambiguity, there might be quite a lot of possibilities for parsing a given raw sentence. Hence at each step in the parsing process, all four transitions defined above may be applicable. To resolve ambiguities, each candidate parse is scored with a global linear model defined as follows.

For an input sentence  $x$ , the parsing result  $F(x)$  is the one with the highest score in all possible structures for this  $x$ :

$$F(x) = \arg \max_{y \in \text{GEN}(x)} \text{Score}(y) \quad (1)$$

Here  $\text{GEN}(x)$  is a set of all possible parses for sentence  $x$ , and  $\text{Score}(y)$  is a real-valued linear function:

$$\text{Score}(y) = \Phi(y) \cdot \vec{w} \quad (2)$$

where  $\Phi(y)$  is a global feature vector extracted from parsing result  $y$ , and  $\vec{w}$  is a vector of weighting parameters. Because of its linearity,  $\text{Score}(y)$  can be computed incrementally, following the transition of each parsing step. Parameter vector  $\vec{w}$  is trained with the generalized perceptron algorithm of Collins (2002). The early-update strategy of Collins and Roark (2004) is used so as to improve accuracy and speed up the training.

## 5.3 Feature Templates

For a particular parse  $y$ , we now describe the way of computing its feature vector  $\Phi(y)$  in the linear

	Description	Feature Templates
1	top of S	S0wt; S0w; S0t
2	next top of S	S1wt; S1w; S1t
3	S0 and S1	S1wtS0wt; S1wtS0w S1wS0wt; S1wtS0t S1tS0wt; S1wS0w; S1tS0t
4	char unigrams	Q0; Q1; Q2; Q3
5	char bigrams	Q0Q1; Q1Q2; Q2Q3
6	char trigrams	Q0Q1Q2; Q1Q2Q3
7	ST+unigrams	STwtQ0; STwQ0; STtQ0
8	ST+bigrams	STwtQ0Q1; STwQ0Q1 STtQ0Q1
9	ST+trigrams	STwtQ0Q1Q2 STwQ0Q1Q2; STtQ0Q1Q2
10	parent P of ST	PtSTtQ0; PtSTtQ0Q1 PtSTtQ0Q1Q2
11	leftmost child LC and rightmost child RC	STtLCtQ0; STtLCtQ0Q1 STtLCtQ0Q1Q2 STtRCtQ0; STtRCtQ0Q1 STtRCtQ0Q1Q2

Table 5: Transition-based feature templates. Q0 is the first character in Q, etc. w = word, t = POS tag.

model of Equation (2). If S denotes the stack holding the partial results, and Q the queue storing the incoming Chinese characters of a raw sentence, then transition-based parsing features are extracted from S and Q according to those feature templates in Table 5.

Although we employ transition-based parsing, nothing prevents us from using graph-based features. As shown by Zhang and Clark (2011), depen-

	Description	Feature Templates
1	parent word	Pwt; Pw; Pt
2	child word	Cwt; Cw; Ct
3	P and C	PwtCwt; PwtCw; PwCwt PtCwt; PwCw; PtCt PwtCt
4	neighbor word of P and C left (L) or right (R)	PtPLtCtCLt; PtPLtCtCRt PtPRtCtCLt; PtPRtCtCRt PtPLtCLt; PtPLtCRt PtPRtCLt; PtPRtCRt PLtCtCLt; PLtCtCRt PRtCtCLt; PRtCtCRt PtCtCLt; PtCtCRt PtPLtCt; PtPRtCt
5	sibling(S) of C	CwSw; CtSt; CwSt CtSw; PtCtSt
6	leftmost and rightmost child	PtCtCLCt PtCtCRCt
7	left (la) and right (ra) arity of P	Ptla; Ptr Pwla; Pwra

Table 6: Graph-based feature templates for the unified parser. Most of these templates are adapted from those used by Zhang and Clark (2011). w = word; t = POS tag.

dependency parsers using both transition-based and graph-based features tend to achieve higher accuracy than parsers which only make use of one kind of features. Table 6 gives the graph-based feature templates used in our parser. All such templates are instantiated at the earliest possible time, in order to reduce as much as possible situations where correct parses fall out of the beam during decoding.

## 5.4 Decoding Algorithm

We use beam-search to find the best parse for a given raw sentence (Algorithm 1). This algorithm uses double beams. The first beam contains unfinished parsing results, while the second holds completed parses. Double beams are necessary because the number of transitions might well be different for different parses, and those parses that finished earlier are not necessarily better parses. During the searching process, correct parse could fall off the beams, resulting in a search error. However, in practice beam search decoding algorithm works quite well.

In addition, it's not feasible to use dynamic programming because of the complicated features used in the model.

The  $B$  in Algorithm 1 is the width of the two beams. In our experiments we set  $B$  to 64. This value of  $B$  was determined empirically by using the standard development set of the data, with the goal of achieving the highest possible accuracy within reasonable time. Note that in line 20 of the algorithm, the beam for completed parsers are pruned at each iteration of the parsing process. The purpose of this action is to keep this beam from growing too big, resulting in a waste of memory space.

## 6 Experiments and Evaluation

We describe the experiments carried out and our method of evaluation of the unified dependency parser. We used Penn2Malt<sup>4</sup> to convert constituent trees of CTB to dependency relations. The head rules for this conversion was given by Zhang and Clark (2008). In all experiments, we followed the stan-

<sup>4</sup><http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html>

	P	R	F
our method, labeled	78.54	80.93	79.72
our method, unlabeled	81.01	83.77	82.37

standard split of the data into training, testing and development data (Zhang and Clark, 2011). Though we annotated structures of words in CTB6, most previously results were on CTB5, a subset of the former treebank. Hence we report our results of evaluation on CTB5 for better comparability.

## 6.1 Dependency Parsing of Morphological and Syntactic Structures

If we look back at the Figure 2, it’s clear that a dependency relation is correctly parsed if and only if three conditions are met: Firstly, words at both ends of the dependency are correctly segmented. Secondly, part-of-speech tags are correct for both words. Thirdly, the direction of the dependency relation are correct. Of course, if labeled precision and recall is to be measured, the label of the dependency relation should also be correctly recovered. Let  $nc$  be the number of dependencies correctly parsed with respect to these criterion,  $no$  be the total number of dependencies in the output, and  $nr$  the number of dependencies in the reference. Then precision is defined to be  $p = nc/no$  and recall is defined to be  $r = nc/nr$ .

### 6.1.1 Results on the Original CTB5

We first train our unified dependency parser with the original treebank CTB5. In this case, all words are considered to be flat, with no internal structures. The result are shown in Table 7. Note that on exactly the same testing data, i.e, the original CTB5, unified parser performs much better than the result of a pipelined approach reported by Zhang and Clark (2011). There are about 30% of relative error reduction for the unlabeled dependency parsing results. This is yet another evidence of the advantage of joint modeling in natural language processing, details of which will be discussed in Section 7.

	P	R	F
original dependencies in CTB5	82.13	84.49	83.29
ZN2011 with Gold segmentation & POS	N/A	N/A	84.40
original dependencies plus word structures	85.71	87.18	86.44

Table 8: Evaluation results on CTB5 with word structures annotated. All results are labeled scores.

### 6.1.2 Results on CTB with Structures of Words Annotated

Then we train the parser with CTB5 augmented with our annotations of internal structures of words. For purpose of better comparability, we report results on both the original dependencies of CTB5 and on the dependencies of CTB5 plus those of the internal structures of words. The results are shown in Table 8. First, note that compared to another result by Zhang and Nivre (2011), whose input were sentences with gold standard word segmentation and POS tags, our F-score is only slightly lower even with input of unsegmented sentences. This is understandable since gold-standard segmentation and POS tags greatly reduced the uncertainty of parsing results.

For the unified parser, the improvement of F-score from 79.72% to 83.29% is attributed to the fact that with internal structures of words annotated, parsing of syntactic structures is also improved due to the similarity of word and phrase structures mentioned in Section 1, and also due to the fact that many phrase level dependencies are now facing a much less severe problem of data sparsity. The improvement of F-score from 83.29% to 86.44% is attributed to the annotation of word structures. Internal structures of words are be mostly local in comparison with phrase and sentence structures. Therefore, with the addition of word structures, the overall dependency parsing accuracy naturally can be improved.

## 6.2 Chinese Word Segmentation

From the example in Figure 2, it is clear that output of unified parser contains Chinese word segmentation information. Therefore, we can get results of word segmentation for each sentence in the test sets,

Table 10: Joint word segmentation and POS tagging scores. K2009 is result of Kruengkrai et al. (2009). ZC2011 is result of Zhang and Clark (2011).

and evaluate their accuracies. For maximal comparability, we train the unified parser on the original CTB5 data used by previous studies. The result is in Table 9. Despite the fact that the performance of our unified parser does not exceed the best reported result so far, which probably might be caused by some minute implementation specific details, it’s fair to say that our parser performs at the level of state-of-the-art in Chinese word segmentation.

### 6.3 Joint Word Segmentation and POS Tagging

From Figure 2 we see that besides word segmentation, output of the unified parser also includes part-of-speech tags. Therefore, it’s natural that we evaluate the accuracy of joint Chinese word segmentation and part of speech tagging, as reported in previous literature (Kruengkrai et al., 2009). The results are in Table 10, in which for ease of comparison, again we train the unified parser with the vanilla version of CTB5. We can see that unified parser performs at virtually the same level of accuracy compared with previous best systems.

## 7 Related Work

Researchers have noticed the necessity of parsing the internal structures of words in Chinese. Li (2011) gave an method that could take raw sentences as input and output phrase structures and internal structures of words. This paper assumes that the input are unsegmented, too, and our output also includes both word and phrase structures. There are

Figure 4: Example output of Zhao’s parser.

two key differences, though. The first is we output dependency relations instead of constituent structures. Although dependencies can be extracted from the constituent trees of Li (2011), the time complexity of their algorithm is  $O(n^5)$  while our parser runs in linear time. Secondly, we specify the details of annotating structures of words, with the annotations being made publicly available.

Zhao (2009) presented a dependency parser which regards each Chinese character as a word and then analyzes the dependency relations between characters, using ordinary dependency parsing algorithms. Our parser is different in two important ways. The first is we output both part-of-speech tags and labeled dependency relations, both of which were absent in Zhao’s parser. More importantly, the APPEND transition for handling flat words were unseen in previous studies as far as we know. The difference can best be described with an example: For the sentence in Section 3, Zhao’s parser output the result in Figure 4 while in contrast our output is Figure 2.

In recent years, considerable efforts have been made in joint modeling and learning in natural language processing (Lee et al., 2011; Sun, 2011; Li et al., 2011; Finkel and Manning, 2009; Kruengkrai et al., 2009; Jiang et al., 2008; Goldberg and Tsarfaty, 2008). Joint modeling can improve the performance of NLP systems due to the obvious reason of being able to make use of various levels of information simultaneously. However, the thesis of this paper, i.e, unified parsing of Chinese word and phrase structures, bears a deeper meaning. As demonstrated in Section 1 and by Li (2011), structures of words and phrases usually have significant similarity, and the distinction between them is very difficult to define, even for expert linguists. But for real world applications, such subtle matters can safely be ignored if we could analyzed morphological and syntactic structures in a unified framework. What applications really cares is structures instead of whether a linguistic unit is a word or phrase.

Another notable line of research closely related to the present work is to annotate and parse the flat structures of noun phrases (NP) (Vadas and Curran, 2007; Vadas and Curran, 2011). This paper differs from those previous work on parsing NPs in at least two significant ways. First, we aim to parse all kinds of words (e.g, nouns, verbs, adverbs, adjectives etc) whose structures are not annotated by CTB, and whose presence could cause lots of pseudo OOVs and incompatible annotations. Second, the problem we are trying to solve is a crucial observation specific to Chinese language, that is, in lots of cases forcing a separation of words and phrases leads to awkward situations for NLP systems. Remember that in Section 2 we demonstrated that all corpora we examined had the problem of pseudo OOVs and incompatible annotations. In comparison, the problem Vadas and Curran (2007) tried to solve is a lack of annotation for structures of NPs in currently available treebanks, or to put it in another way, a problem more closely related to treebanks rather than certain languages.

## 8 Discussion and Conclusion

Chinese word segmentation is an indispensable step for traditional approaches to syntactic parsing of Chinese. The purpose of word segmentation is to decide what goes to words, with the remaining processing (e.g, parsing) left to higher level structures of phrases and sentences. This paper shows that it could be very difficult to make such a distinction between words and phrases. This difficulty cannot be left unheeded, as we have shown quantitatively that in practice it causes lots of real troubles such as too many OOVs and incompatible annotations. We showed how these undesirable consequences can be resolved by annotation of the internal structures of words, and by unified parsing of morphological and syntactic structures in Chinese.

Unified parsing of morphological and syntactic structures of Chinese can also be implemented with a pipelined approach, in which we first segment input sentences into words or affixes (i.e, with the finest possible granularity), and then we do part-of-speech tagging followed by dependency (or constituent) parsing. However, a unified parsing approach using a single model as presented in this

paper offers several advantages over pipelined approaches. The first one is that joint modeling tends to result in higher accuracy and suffer less from error propagation than do pipelined methods. Secondly, both the unified model and the algorithm are conceptually much more simpler than pipelined approaches. We only need one implementation of the model and algorithm, instead of several ones in pipelined approaches. Thirdly, our model and algorithm might comes closer to modeling the process of human language understanding, because human brain is more likely a parallel machine in understanding languages than an alternative pipelined processor. Hence this work, together with previous studies by other authors like Li (2011) and Zhao (2009), open up a possibly new direction for future research efforts in parsing the Chinese language.

## Abstract

Most current dependency parsers presuppose that input words have been morphologically disambiguated using a part-of-speech tagger before parsing begins. We present a transition-based system for joint part-of-speech tagging and labeled dependency parsing with non-projective trees. Experimental evaluation on Chinese, Czech, English and German shows consistent improvements in both tagging and parsing accuracy when compared to a pipeline system, which lead to improved state-of-the-art results for all languages.

## 1 Introduction

Dependency-based syntactic parsing has been the focus of intense research efforts during the last decade, and the state of the art today is represented by globally normalized discriminative models that are induced using structured learning. Graph-based models parameterize the parsing problem by the structure of the dependency graph and normally use dynamic programming for inference (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Bohnet, 2010), but other inference methods have been explored especially for non-projective parsing (Riedel and Clarke, 2006; Smith and Eisner, 2008; Martins et al., 2009; Martins et al., 2010; Koo et al., 2010). Transition-based models parameterize the problem by elementary parsing actions and typically use incremental beam search (Titov and Henderson, 2007; Zhang and Clark, 2008; Zhang and Clark, 2011). Despite notable differences in model structure, graph-based

and transition-based parsers both give state-of-the-art accuracy with proper feature selection and optimization (Koo and Collins, 2010; Zhang and Nivre, 2011; Bohnet, 2011).

It is noteworthy, however, that almost all dependency parsers presuppose that the words of an input sentence have been morphologically disambiguated using (at least) a part-of-speech tagger. This is in stark contrast to the best parsers based on PCFG models, such as the Brown parser (Charniak and Johnson, 2005) and the Berkeley parser (Petrov et al., 2006; Petrov and Klein, 2007), which not only can perform their own part-of-speech tagging but normally give better parsing accuracy when they are allowed to do so. This suggests that joint models for tagging and parsing might improve accuracy also in the case of dependency parsing.

It has been argued that joint morphological and syntactic disambiguation is especially important for richly inflected languages, where there is considerable interaction between morphology and syntax such that neither can be fully disambiguated without considering the other. Thus, Lee et al. (2011) show that a discriminative model for joint morphological disambiguation and dependency parsing outperforms a pipeline model in experiments on Latin, Ancient Greek, Czech and Hungarian. However, Li et al. (2011) and Hatori et al. (2011) report improvements with a joint model also for Chinese, which is not a richly inflected language but is nevertheless rich in part-of-speech ambiguities.

In this paper, we present a transition-based model for joint part-of-speech tagging and labeled dependency parsing with non-projective trees. Exper-

iments show that joint modeling improves both tagging and parsing accuracy, leading to state-of-the-art accuracy for richly inflected languages like Czech and German as well as more configurational languages like Chinese and English. To our knowledge, this is the first joint system that performs labeled dependency parsing. It is also the first joint system that achieves state-of-the-art accuracy for non-projective dependency parsing.

## 2 Transition-Based Tagging and Parsing

Transition-based dependency parsing was pioneered by Yamada and Matsumoto (2003) and Nivre et al. (2004), who used classifiers trained to predict individual actions of a deterministic shift-reduce parser. Recent research has shown that better accuracy can be achieved by using beam search and optimizing models on the entire sequence of decisions needed to parse a sentence instead of single actions (Zhang and Clark, 2008; Huang and Sagae, 2010; Zhang and Clark, 2011; Zhang and Nivre, 2011; Bohnet, 2011). In addition, a number of different transition systems have been proposed, in particular for dealing with non-projective dependencies, which were beyond the scope of early systems (Attardi, 2006; Nivre, 2007; Nivre, 2009; Titov et al., 2009).

In this section, we start by defining a transition system for joint tagging and parsing based on the non-projective transition system proposed in Nivre (2009). We then show how to perform beam search and structured online learning with this model, and conclude by discussing feature representations.

### 2.1 Transition System

Given a set  $P$  of part-of-speech tags and a set  $D$  of dependency labels, a *tagged dependency tree* for a sentence  $x = w_1, \dots, w_n$  is a directed tree  $T = (V_x, A)$  with labeling functions  $\pi$  and  $\delta$  such that:

1.  $V_x = \{0, 1, \dots, n\}$  is a set of nodes,
2.  $A \subseteq V_x \times V_x$  is a set of arcs,
3.  $\pi : V_x \rightarrow P$  is a labeling function for nodes,
4.  $\delta : A \rightarrow D$  is a labeling function for arcs,
5. 0 is the root of the tree.

The set  $V_x$  of *nodes* is the set of positive integers up to and including  $n$ , each corresponding to the linear position of a word in the sentence, plus an extra

artificial root node 0. The set  $A$  of *arcs* is a set of pairs  $(i, j)$ , where  $i$  is the *head* node and  $j$  is the *dependent* node. The functions  $\pi$  and  $\delta$  assign a unique part-of-speech label to each node/word and a unique dependency label to each arc, respectively. This notion of dependency tree differs from the standard definition only by including part-of-speech labels as well as dependency labels (Kübler et al., 2009).

Following Nivre (2008), we define a *transition system* for dependency parsing as a quadruple  $S = (C, T, c_s, C_t)$ , where

1.  $C$  is a set of *configurations*,
2.  $T$  is a set of *transitions*, each of which is a (partial) function  $t : C \rightarrow C$ ,
3.  $c_s$  is an *initialization function*, mapping a sentence  $x$  to a configuration  $c \in C$ ,
4.  $C_t \subseteq C$  is a set of *terminal configurations*.

A transition sequence for a sentence  $x$  in  $S$  is a sequence of configuration-transition pairs  $C_{0,m} = [(c_0, t_0), (c_1, t_1), \dots, (c_m, t_m)]$  where  $c_0 = c_s(x)$ ,  $t_m(c_m) \in C_t$  and  $t_i(c_i) = c_{i+1}$  ( $0 \leq i < m$ ).<sup>1</sup>

In this paper, we take the set  $C$  of configurations to be the set of all 5-tuples  $c = (\Sigma, B, A, \pi, \delta)$  such that  $\Sigma$  (the stack) and  $B$  (the buffer) are disjoint sublists of the nodes  $V_x$  of some sentence  $x$ ,  $A$  is a set of dependency arcs over  $V_x$ , and  $\pi$  and  $\delta$  are labeling functions as defined above. We take the initial configuration for a sentence  $x = w_1, \dots, w_n$  to be  $c_s(x) = ([0], [1, \dots, n], \{\}, \perp, \perp)$ , where  $\perp$  is the function that is undefined for all arguments, and we take the set  $C_t$  of terminal configurations to be the set of all configurations of the form  $c = ([0], [], A, \pi, \delta)$  (for any  $A, \pi$  and  $\delta$ ). The tagged dependency tree defined for  $x$  by  $c = (\Sigma, B, A, \pi, \delta)$  is the tree  $(V_x, A)$  with labeling functions  $\pi$  and  $\delta$ , which we write  $\text{TREE}(x, c)$ .

The set  $T$  of transitions is shown in Figure 1. The  $\text{LEFT-ARC}_d$  and  $\text{RIGHT-ARC}_d$  transitions both add an arc (with dependency label  $d$ ) between the two nodes on top of the stack and replaces these nodes by the head node of the new arc (which is the rightmost node for  $\text{LEFT-ARC}_d$  and the leftmost node for  $\text{RIGHT-ARC}_d$ ). The  $\text{SHIFT}_p$  transition extracts the

<sup>1</sup>This definition of transition sequence differs from that of Nivre (2008) but is equivalent and suits our presentation better.

Transition		Condition
LEFT-ARC <sub>d</sub>	$([\sigma i, j], B, A, \pi, \delta) \Rightarrow ([\sigma j], B, A \cup \{(j, i)\}, \pi, \delta[(j, i) \rightarrow d])$	$i \neq 0$
RIGHT-ARC <sub>d</sub>	$([\sigma i, j], B, A, \pi, \delta) \Rightarrow ([\sigma i], B, A \cup \{(i, j)\}, \pi, \delta[(i, j) \rightarrow d])$	
SHIFT <sub>p</sub>	$(\sigma, [i \beta], A, \pi, \delta) \Rightarrow ([\sigma i], \beta, A, \pi[i \rightarrow p], \delta)$	
SWAP	$([\sigma i, j], \beta, A, \pi, \delta) \Rightarrow ([\sigma j], [i \beta], A, \pi, \delta)$	$0 < i < j$

Figure 1: Transitions for joint tagging and dependency parsing extending the system of Nivre (2009). The stack  $\Sigma$  is represented as a list with its head to the right (and tail  $\sigma$ ) and the buffer  $B$  as a list with its head to the left (and tail  $\beta$ ). The notation  $f[a \rightarrow b]$  is used to denote the function that is exactly like  $f$  except that it maps  $a$  to  $b$ .

first node in the buffer, pushes it onto the stack and labels it with the part-of-speech tag  $p$ . The SWAP transition extracts the second topmost node from the stack and moves it back to the buffer, subject to the condition that the two top nodes on the stack are still in the order given by the sentence.

Except for the addition of a tag parameter  $p$  to the SHIFT transition, this is equivalent to the system described in Nivre (2009), which thanks to the SWAP transition can handle arbitrary non-projective trees. The soundness and completeness results given in that paper trivially carry over to the new system. The only thing to note is that, before a terminal configuration can be reached, every word has to be pushed onto the stack in a SHIFT<sub>p</sub> transition, which ensures that every node/word in the output tree will be tagged.

## 2.2 Inference and Learning

While early transition-based parsers generally used greedy best-first inference and locally trained classifiers, recent work has shown that higher accuracy can be obtained using beam search and global structure learning to mitigate error propagation. In particular, it seems that the globally learned models can exploit a much richer feature space than locally trained classifiers, as shown by Zhang and Nivre (2011). Since joint tagging and parsing increases the size of the search space and is likely to require novel features, we use beam search in combination with structured perceptron learning.

The beam search algorithm used to derive the best parse  $y$  for a sentence  $x$  is outlined in Figure 2. In addition to the sentence  $x$ , it takes as input a weight vector  $\mathbf{w}$  corresponding to a linear model for scoring transitions out of configurations and two pruned

```

PARSE( $x, \mathbf{w}, b_1, b_2$ )
1  $h_0.c \leftarrow c_s(x)$ 
2  $h_0.s \leftarrow 0.0$ 
3  $h_0.\mathbf{f} \leftarrow \{0.0\}^{dim(\mathbf{w})}$ 
4 BEAM  $\leftarrow [h_0]$ 
5 while  $\exists h \in \text{BEAM} : h.c \notin C_t$ 
6   TMP  $\leftarrow []$ 
7   foreach  $h \in \text{BEAM}$ 
8     foreach  $t \in T : \text{PERMISSIBLE}(h.c, t)$ 
9        $h.\mathbf{f} \leftarrow h.\mathbf{f} + \mathbf{f}(h.c, t)$ 
10       $h.s \leftarrow h.s + \mathbf{f}(h.c, t) \cdot \mathbf{w}$ 
11       $h.c \leftarrow t(h.c)$ 
12      TMP  $\leftarrow \text{INSERT}(h, \text{TMP})$ 
13   BEAM  $\leftarrow \text{PRUNE}(\text{TMP}, b_1, b_2)$ 
14  $h \leftarrow \text{TOP}(\text{BEAM})$ 
15  $y \leftarrow \text{TREE}(x, h.c)$ 
16 return  $y$ 

```

Figure 2: Beam search algorithm for joint tagging and dependency parsing of input sentence  $x$  with weight vector  $\mathbf{w}$  and beam parameters  $b_1$  and  $b_2$ . The symbols  $h.c$ ,  $h.s$  and  $h.\mathbf{f}$  denote, respectively, the configuration, score and feature representation of a hypothesis  $h$ ;  $h.c.A$  denotes the arc set of  $h.c$ .

ing parameters  $b_1$  and  $b_2$ . A parse hypothesis  $h$  is represented by a configuration  $h.c$ , a score  $h.s$  and a feature vector  $h.\mathbf{f}$  for the transition sequence up to  $h.c$ . Hypotheses are stored in the list BEAM, which is sorted by descending scores and initialized to hold the hypothesis  $h_0$  corresponding to the initial configuration  $c_s(x)$  with score 0.0 and all features set to 0.0 (lines 1–4). In the main loop (lines 5–13), a set of new hypotheses is derived and stored in the list TMP, which is finally pruned and assigned as the new value of BEAM. The main loop terminates

when all hypotheses in BEAM contain terminal configurations, and the dependency tree extracted from the top scoring hypothesis is returned (lines 14–16).

The set of new hypotheses is created in two nested loops (lines 7–12), where every hypothesis  $h$  in BEAM is updated using every permissible transition  $t$  for the configuration  $h.c$ . The feature representation of the new hypothesis is obtained by adding the feature vector  $\mathbf{f}(t, h.c)$  for the current configuration-transition pair to the feature vector of the old hypothesis (line 9). Similarly, the score of the new hypothesis is the sum of the score  $\mathbf{f}(t, h.c) \cdot \mathbf{w}$  of the current configuration-transition pair and the score of the old hypothesis (line 10). The feature representation/score of a complete parse  $y$  for  $x$  with transition sequence  $C_{0,m}$  is thus the sum of the feature representations/scores of the configuration-transition pairs in  $C_{0,m}$ :

$$\begin{aligned}\mathbf{f}(x, y) &= \sum_{(c,t) \in C_{0,m}} \mathbf{f}(c, t) \\ s(x, y) &= \sum_{(c,t) \in C_{0,m}} \mathbf{f}(c, t) \cdot \mathbf{w}\end{aligned}$$

Finally, the configuration of the new hypothesis is obtained by evaluating  $t(h.c)$  (line 11). The new hypothesis is then inserted into TMP in score-sorted order (line 12).

The pruning parameters  $b_1$  and  $b_2$  determine the number of hypotheses allowed in the beam and at the same time control the tradeoff between syntactic and morphological ambiguity. First, we extract the  $b_1$  highest scoring hypotheses with distinct dependency trees. Then we extract the  $b_2$  highest scoring remaining hypotheses, which will typically be tagging variants of dependency trees that are already in the beam. In this way, we prevent the beam from getting filled up with too many tagging variants of the same dependency tree, which was found to be harmful in preliminary experiments.

One final thing to note about the inference algorithm is that the notion of permissibility for a transition  $t$  out of a configuration  $c$  can be used to capture not only formal constraints on transitions – such as the fact that it is impossible to perform a  $\text{SHIFT}_p$  transition with an empty buffer or illegal to perform a  $\text{LEFT-ARC}_d$  transition with the special root node on top of the stack – but also to filter out unlike-

ly dependency labels or tags. Thus, in the experiments later on, we will typically constrain the parser so that  $\text{SHIFT}_p$  is permissible only if  $p$  is one of the  $k$  best part-of-speech tags with a score no more than  $\alpha$  below the score of the 1-best tag, as determined by a preprocessing tagger. We also filter out instances of  $\text{LEFT-ARC}_d$  and  $\text{RIGHT-ARC}_d$ , where  $d$  does not occur in the training data for the predicted part-of-speech tag combination of the head and dependent. This procedure leads to a significant speed up.

In order to learn a weight vector  $\mathbf{w}$  from a training set  $\{(x_j, y_j)\}_{j=1}^T$  of sentences with their tagged dependency trees, we use a variant of the structured perceptron, introduced by Collins (2002), which makes  $N$  iterations over the training data and updates the weight vector for every sentence  $x_j$  where the highest scoring parse  $y^*$  is different from  $y_j$ . More precisely, we use the passive-aggressive update of Crammer et al. (2006):

$$\mathbf{w}^{i+1} = \mathbf{w}^i + \tau(\mathbf{f}(x_j, y_j) - \mathbf{f}(x_j, y^*))$$

where

$$\tau = \frac{\mathbf{f}(x_j, y_j) - \mathbf{f}(x_j, y^*)}{\|\mathbf{f}(x_j, y_j) - \mathbf{f}(x_j, y^*)\|^2}$$

We also use the early update strategy found beneficial for parsing in several previous studies (Collins and Roark, 2004; Zhang and Clark, 2008; Huang and Sagae, 2010), which means that, during learning, we terminate the beam search as soon as the hypothesis corresponding to the gold parse  $y_j$  falls out of the beam and update with respect to the partial transition sequence constructed up to that point. Finally, we use the standard technique of averaging over all weight vectors, as originally proposed by Collins (2002).

### 2.3 Feature Representations

As already noted, the feature representation  $\mathbf{f}(x, y)$  of an input sentence  $x$  with parse  $y$  decomposes into feature representations  $\mathbf{f}(c, t)$  for the transitions  $t(c)$  needed to derive  $y$  from  $c_s(x)$ . Features may refer to any aspect of a configuration, as encoded in the stack  $\Sigma$ , the buffer  $B$ , the arc set  $A$  and the labelings  $\pi$  and  $\delta$ . In addition, we assume that each word  $w$  in the input is assigned up to  $k$  candidate part-of-speech tags  $\pi_i(w)$  with corresponding scores  $s(\pi_i(w))$ .

Features involving word prefixes and suffixes
$\pi_i(B_0)p_2(B_0), \pi_i(B_0)s_2(B_0), \pi_i(B_0)p_1(B_0)p_1(\Sigma_0)$
$\pi_i(\Sigma_0)p_1(\Sigma_0)p_1(\Sigma_1), \pi_i(\Sigma_0)s_1(\Sigma_0)s_1(\Sigma_0)$
$\pi_i(\Sigma_0)p_2(\Sigma_0)s_3(\Sigma_1), \pi_i(\Sigma_0)s_3(\Sigma_0)p_2(\Sigma_1)$
$\pi_i(\Sigma_0)w(B_0)s_1(\Sigma_0), \pi_i(\Sigma_0)w(B_0)s_2(\Sigma_0)$
Features involving tag score differences and ranks
$\pi_i(B_0)[s(\pi_1(B_0)) - s(\pi_i(B_0))]$
$\pi_i(B_0)\pi_i(\Sigma_0)[s(\pi_1(B_0)) - s(\pi_i(B_0))] i$
$\pi_i(B_0)[s(\pi_1(B_0)) - s(\pi_i(B_0))]\pi(\Sigma_0)$
$w(B_0)[s(\pi_1(B_0)) - s(\pi_i(B_0))]\pi(\Sigma_0)$

Figure 3: Specialized feature templates for tagging. We use  $\Sigma_i$  and  $B_i$  to denote the  $i$ th token in the stack  $\Sigma$  and buffer  $B$ , respectively, with indexing starting at 0, and we use the following functors to extract properties of a token:  $\pi_i()$  =  $i$ th best tag;  $s(\pi_i())$  = score of  $i$ th best tag;  $\pi()$  = finally predicted tag;  $w()$  = word form;  $p_i()$  = word prefix of  $i$  characters;  $s_i()$  = word suffix of  $i$  characters. Score differences are binned in discrete steps of 0.05.

The bulk of features used in our system are taken from Zhang and Nivre (2011), although with two important differences. First of all, like Hatori et al. (2011), we have omitted all features that presuppose an arc-eager parsing order, since our transition system defines an arc-standard order. Secondly, any feature that refers to the part-of-speech tag of a word  $w$  in the buffer  $B$  will in our system refer to the top-scoring tag  $\pi_1(w)$ , rather than the finally predicted tag. By contrast, for a word in the stack  $\Sigma$ , part-of-speech features refer to the tag  $\pi(w)$  chosen when shifting  $w$  onto the stack (which may or may not be the same as  $\pi_1(w)$ ).

In addition to the standard features for transition-based dependency parsing, we have added features specifically to improve the tagging step in the joint model. The templates for these features, which are specified in Figure 3, all involve the  $i$ th best tag assigned to the first word of the buffer  $B$  (the next word to be shifted in a  $\text{SHIFT}_p$  transition) in combination with neighboring words, word prefixes, word suffixes, score differences and tag rank.

Finally, in some experiments, we make use of two additional feature sets, which we call graph features (G) and cluster features (C), respectively. Graph features are defined over the factors of a graph-based dependency parser, which was shown to improve the accuracy of a transition-based parser by Zhang and Clark (2008). However, while their features were

limited to certain first- and second-order factors, we use features over second- and third-order factors as found in the parsers of Bohnet and Kuhn (2012). These features are scored as soon as the factors are completed, using a technique that is similar to what Hatori et al. (2011) call delayed features, although they use it for part-of-speech tags in the lookahead while we use it for subgraphs of the dependency tree. Cluster features, finally, are features over word clusters, as first used by Koo et al. (2008), which replace part-of-speech tag features.<sup>2</sup>

We use a hash kernel to map features to weights. It has been observed that most of the computing time in feature-rich parsers is spent retrieving the index of each feature in the weight vector (Bohnet, 2010). This is usually done via a hash table, but significant speedups can be achieved by using a hash kernel, which simply replaces table lookup by a hash function (Bloom, 1970; Shi et al., 2009; Bohnet, 2010). The price to pay for these speedups is that there may be collisions, so that different features are mapped to the same index, but this is often compensated by the fact that the lower time and memory requirements of the hash kernel enables the use of negative features, that is, features that are never seen in the training set but occur in erroneous hypotheses at training time and can therefore be helpful also at inference time. As a result, the hash kernel often improves accuracy as well as efficiency compared to traditional techniques that only make use of features that occur in gold standard parses (Bohnet, 2010).

### 3 Experiments

We have evaluated the model for joint tagging and dependency parsing on four typologically diverse languages: Chinese, Czech, English, and German.

#### 3.1 Setup

Most of the experiments use the CoNLL 2009 data sets with the training, development and test split used in the Shared Task (Hajič et al., 2009), but for better comparison with previous work we also report results for the standard benchmark data sets for Chinese and English. For Chinese, this is the Penn Chinese Treebank 5.1 (CTB5), converted

<sup>2</sup>For replicability, a complete description of all features can be found at <http://stp.lingfil.uu.se/~nivre/exp/emnlp12.html>.

Table 1: Accuracy scores for the CoNLL 2009 shared task development sets as a function of the number of tags  $k$  and the score threshold  $\alpha$ . Beam parameters fixed at  $b_1 = 40$ ,  $b_2 = 4$ .

with the head-finding rules and conversion tools of Zhang and Clark (2008), and with the same split as in Zhang and Clark (2008) and Li et al. (2011).<sup>3</sup> For English, this is the WSJ section of the Penn Treebank, converted with the head-finding rules of Yamada and Matsumoto (2003) and the labeling rules of Nivre (2006).<sup>4</sup>

In order to assign  $k$ -best part-of-speech tags and scores to words in the training set, we used a perceptron tagger with 10-fold jack-knifing. The same type of tagger was trained on the entire training set in order to supply tags for the development and test sets. The feature set of the tagger was optimized for English and German and provides state-of-the-art accuracy for these two languages. The 1-best tagging accuracy for section 23 of the Penn Treebank is 97.28, which is on a par with Toutanova et al. (2003). For German, we obtain a tagging accuracy of 97.24, which is close to the 97.39 achieved by the RF-Tagger (Schmid and Laws, 2008), which to our knowledge is the best tagger for German.<sup>5</sup> The results are not directly comparable to the RF-Tagger as it was evaluated on a different part of the Tiger Treebank and trained on a larger part of the Treebank. We could not use the larger training set as it contains the test set of the CoNLL 2009 data that we use to evaluate the joint model. For Czech, the 1-best tagging accuracy is 99.11 and for Chinese 92.65 on the CoNLL 2009 test set.

We trained parsers with 25 iterations and report

<sup>3</sup>Training: 001–815, 1001–1136. Development: 886–931, 1148–1151. Test: 816–885, 1137–1147.

<sup>4</sup>Training: 02-21. Development: 24. Test: 23.

<sup>5</sup>The RF-Tagger can take advantage of an additional lexicon and then reaches 97.97. The lexicon supplies entries for additional words that are not found in the training corpus and additional tags for words that do occur in the training data (Schmid and Laws, 2008).

results for the model obtained after the last iteration. For cluster features, available only for English and German, we used standard Brown clusters based on the English and German Gigaword Corpus. We restricted the vocabulary to words that occur at least 10 times, used 800 clusters, and took cluster prefixes of length 6 to define features.

We report the following evaluation metrics: part-of-speech accuracy (POS), unlabeled attachment score (UAS), labeled attachment score (LAS), and tagged labeled attachment score (TLAS). TLAS is a new metric defined as the percentage of words that are assigned the correct part-of-speech tag, the correct head and the correct dependency label. In line with previous work, punctuation is included in the evaluation for the CoNLL data sets but excluded for the two benchmark data sets.

### 3.2 Results

Table 1 presents results on the development sets of the CoNLL 2009 shared task with varying values of the two tag parameters  $k$  (number of candidates) and  $\alpha$  (maximum score difference to 1-best tag) and beam parameters fixed at  $b_1 = 40$  and  $b_2 = 4$ . We use the combined TLAS score on the development set to select the optimal settings for each language. For Chinese, we obtain the best result with 3 tags and a threshold of 0.1.<sup>6</sup> Compared to the baseline, we observe a POS improvement of 0.60 and a LAS improvement of 0.51. For Czech, we get the best TLAS with  $k = 3$  and  $\alpha = 0.2$ , where POS improves by 0.06 and LAS by 0.46. For English, the best setting is  $k = 2$  and  $\alpha = 0.1$  with a POS improvement of 0.17 and a LAS improvement of 0.62. For German, finally, we see the greatest improvement with  $k = 3$

<sup>6</sup>While tagging accuracy (POS) increases with larger values of  $\alpha$ , TLAS decreases because of a drop in LAS.

Table 2: Accuracy scores for the CoNLL 2009 shared task test sets. Rows 1–2: Top performing systems in the shared CoNLL Shared Task 2009; Gesmundo et al. (2009) was placed first in the shared task; for Bohnet (2010), we include the updated scores later reported due to some improvements of the parser. Rows 3–4: Baseline ( $k = 1$ ) and best settings for  $k$  and  $\alpha$  on development set. Rows 5–6: Wider beam ( $b_1 = 80$ ) and added graph features (G) and cluster features (C). Second beam parameter  $b_2$  fixed at 4 in all cases.

and  $\alpha = 0.3$ , where POS improves by 0.66 and LAS by 0.86.

Table 2 shows the results on the CoNLL 2009 test sets. For all languages except English, we obtain state-of-the-art results already with  $b_1 = 40$  (row 4), and for all languages both tagging and parsing accuracy improve compared to the baseline (row 3). The improvement in TLAS is statistically significant with  $p < 0.01$  for all languages (paired  $t$ -test). Row 5 shows the scores with a beam of 80 and the additional graph features. Here the LAS scores for Chinese, Czech and German are higher than the best results on the CoNLL 2009 data sets, and the score for English is highly competitive. For Chinese, we achieve 78.51 LAS, which is 1.5 percentage points higher than the reference score, while the POS score is 0.54 higher than our baseline. For Czech, we get 83.73 LAS, which is by far the highest score reported for this data set, together with state-of-the-art POS accuracy. For German, we obtain 89.05 LAS and 97.78 POS, which in both cases is substantially better than in the CoNLL shared task. We believe it is also the highest POS accuracy ever reported for a tagger/parser trained only on the Tiger Treebank. Row 6, finally, presents results with added cluster features for English and German, which results in additional improvements in all metrics.

Table 3 gives the results for the Penn Treebank converted with the head-finding rules of Yamada and Matsumoto (2003) and the labeling rules of Nivre (2006). We use  $k = 3$  and  $\alpha = 0.4$ , which gave the best results on the development set. The UAS improves by 0.24 when we do joint tagging and parsing. The POS accuracy improves slightly by 0.12

Parser	TLAS	UAS	LAS	POS
McDonald et al. (2005)		90.9		
McDonald and Pereira (2006)		91.5		
Zhang and Clark (2008)		92.1		
Huang and Sagae (2010)		92.1		
Koo and Collins (2010)		93.04		
Zhang and Nivre (2011)		92.9		
Martins et al. (2010)		93.26		
Koo et al. (2008) †		93.16		
Carreras et al. (2008) †		93.5		
Suzuki et al. (2009) †		93.79		
Baseline ( $k = 1$ ), $b_1 = 40$	89.42	92.79	91.71	97.28
Best dev setting, $b_1 = 40$	89.75	93.03	91.92	97.40
Adding G, $b_1 = 40$	90.12	93.38	92.44	97.33
Adding G+C, $b_1 = 80$ †	90.41	93.67	92.68	97.42

Table 3: Accuracy scores for WSJ-PTB converted with head rules of Yamada and Matsumoto (2003) and labeling rules of Nivre (2006). Best dev setting:  $k = 3$ ,  $\alpha = 0.4$ . Results marked with † use additional information sources and are not directly comparable to the others.

but to a lower degree than for the English CoNLL data where we observed an improvement of 0.20. Nonetheless, the improvement in the joint TLAS score is statistically significant at  $p < 0.01$  (paired  $t$ -test). Our joint tagger and dependency parser with graph features gives very competitive unlabeled dependency scores for English with 93.38 UAS. To the best of our knowledge, this is the highest score reported for a (transition-based) dependency parser that does not use additional information sources. By adding cluster features and widening the beam to  $b_1 = 80$ , we achieve 93.67 UAS. We also obtain a POS accuracy of 97.42, which is on a par with the best results obtained using semi-supervised taggers

Parser	TLAS	UAS	LAS	POS
MSTParser1		75.56		93.51
MSTParser2		77.73		93.51
Li et al. (2011) 3rd-order		80.60		92.80
Li et al. (2011) 2nd-order		80.55		93.08

Hatori et al. (2011) ZN		81.20		93.94
Baseline ( $k = 1$ , $b_1 = 40$ )	61.95	80.33	76.79	92.81
Best dev setting, $b_1 = 40$	62.54	80.59	77.06	93.11
Adding G, $b_1 = 80$	63.20	81.42	77.91	93.24

Table 4: Accuracy scores for Penn Chinese Treebank converted with the head rules of Zhang and Clark (2008). Best dev setting:  $k = 3$ ,  $\alpha = 0.1$ . MSTParser results from Li et al. (2011). UAS scores from Li et al. (2011) and Hatori et al. (2011) recalculated from the separate accuracy scores for root words and non-root words reported in the original papers.

(Søgaard, 2011).

Table 4 shows the results for the Chinese Penn Treebank CTB 5.1 together with related work. In experiments with the development set, we could confirm the results from the Chinese CoNLL data set and obtained the best results with the same settings ( $k = 3$ ,  $\alpha = 0.1$ ). With  $b_1 = 40$ , UAS improves by 0.25 and POS by 0.30, and the TLAS improvement is again highly significant ( $p < 0.01$ , paired  $t$ -test). We get the highest UAS, 81.42, with a beam of 80 and added graph features, in which case POS accuracy increases from 92.81 to 93.24. Since our tagger was not optimized for Chinese, we have lower baseline results for the tagger than both Li et al. (2011) and Hatori et al. (2011) but still manage to achieve the highest reported UAS.

The speed of the joint tagger and dependency parser is quite reasonable with about 0.4 seconds per sentence on the WSJ-PTB test set, given that we perform tagging and labeled parsing with a beam of 80 while incorporating the features of a third-order graph-based model. Experiments were performed on a computer with an Intel i7-3960X CPU (3.3 GHz and 6 cores). These performance values are preliminary since we are still working on the speed-up of the parser.

### 3.3 Analysis

In order to better understand the benefits of the joint model, we performed an error analysis for German

Confusion	Baseline		Joint	
	Freq	F-score	Freq	F-score
VVINF $\rightarrow$ VVFIN	28	91.1	2	97.7
VVINF $\rightarrow$ VVPP ADJ* NN	5		9	
VVFIN $\rightarrow$ VVINF	43	94.2	5	98.5
VVFIN $\rightarrow$ VVPP	20		2	
VAINF $\rightarrow$ VAFIN	10	99.1	1	99.9
NE $\rightarrow$ NN	184		128	
NE $\rightarrow$ ADJ* ADV FM	24	90.7	18	92.4
NE $\rightarrow$ XY	12		21	
NN $\rightarrow$ NE	85	97.5	67	98.1
NN $\rightarrow$ ADJ* XY ADV VV*	39		29	
PRELS $\rightarrow$ ART	13	92.9	5	95.4
PRELS $\rightarrow$ PWS	0		2	

Table 5: Selected entries from the confusion matrix for parts of speech in German with F-scores for the left-hand-side category. ADJ\* (ADJD or ADJA) = adjective; ADV = adverb; ART = determiner; APPR = preposition; NE = proper noun; NN = common noun; PRELS = relative pronoun; VVFIN = finite verb; VVINF = non-finite verb; VAFIN = finite auxiliary verb; VAINF = non-finite auxiliary verb; VVPP = participle; XY = not a word. We use  $\alpha^*$  to denote the set of categories with  $\alpha$  as a prefix.

and English, where we compared the baseline and the joint model with respect to F-scores for individual part-of-speech categories and dependency labels. For the part-of-speech categories, we found an improvement across the board for both languages, with no category having a significant decrease in F-score, but we also found some interesting patterns for categories that improved more than the average.

Table 5 shows selected entries from the confusion matrix for German, where we see substantial improvements for finite and non-finite verbs, which are often morphologically ambiguous but which can be disambiguated using syntactic context. We also see improved accuracies for common and proper nouns, which are both capitalized in standard German orthography and therefore often mistagged, and for relative pronouns, which are less often confused for determiners in the joint model.

Table 6 gives a similar snapshot for English, and we again see improvements for verb categories that are often morphologically ambiguous, such as past participles, which can be confused for past tense verbs, and present tense verbs in third person singular, which can be confused for nouns. We also see some improvement for the singular noun catego-

Confusion	Baseline		Joint	
	Freq	F-score	Freq	F-score
VBN → VBD	40	90.5	19	91.5
VBN → JJ VB VBP NN	13		18	
VBZ → NN NNS	19	97.8	13	98.3
VBZ → POS JJ RB	6		6	
NN → VBG VB VBN VBD	72		58	
NN → JJ JJR	79	96.8	69	97.2
NN → NN* RB IN DT	58		57	
RB → IN	126	92.4	93	92.9
RB → JJ* RP NN* RBR UH	86		89	

Table 6: Selected entries from the confusion matrix for parts of speech in English with F-scores for the left-hand-side category. DT = determiner; IN = preposition or subordinating conjunction; JJ = adjective; JJR = comparative adjective; NN = singular or mass noun; NNS = plural noun; POS = possessive clitic; RB = adverb; RBR = comparative adverb; RP = particle; UH = interjection; VB = base form verb; VBD = past tense verb; VBG = gerund or present participle; VBN = past participle; VBP = present tense verb, not 3rd person singular; VBZ = present tense verb, 3rd person singular. We use  $\alpha^*$  to denote the set of categories with  $\alpha$  as a prefix.

ry and for adverbs, which are less often confused for prepositions or subordinating conjunctions thanks to the syntactic information in the joint model.

For dependency labels, it is hard to extract any striking patterns and it seems that we mainly see an improvement in overall parsing accuracy thanks to less severe tagging errors. However, it is worth observing that, for both English and German, we see significant F-score improvements for the core grammatical functions subject (91.3 → 92.1 for German, 95.6 → 96.1 for English) and object (86.9 → 87.9 for German, 90.2 → 91.9 for English).

## 4 Related Work

Our work is most closely related to Lee et al. (2011), Li et al. (2011) and Hatori et al. (2011), who all present discriminative models for joint tagging and dependency parsing. However, all three models only perform unlabeled parsing, while our model incorporates dependency labels into the parsing process. Whereas Lee et al. (2011) and Li et al. (2011) take a graph-based approach to dependency parsing, Hatori et al. (2011) use a transition-based model similar to ours but limited to projective dependency trees. Both Li et al. (2011) and Hatori et al. (2011) only

evaluate their model on Chinese, and of these only Hatori et al. (2011) report consistent improvements in both tagging and parsing accuracy. Like our system, the parser of Lee et al. (2011) can handle non-projective trees and experimental results are presented for four languages, but their graph-based model is relatively simple and the baselines therefore well below the state of the art. We are thus the first to show consistent improvements in both tagging and (labeled) parsing accuracy across typologically diverse languages at the state-of-the-art level. Moreover, the capacity to handle non-projective dependencies, which is crucial to attain good performance on Czech and German, does not seem to hurt performance on English and Chinese, where the benchmark sets contain only projective trees.

The use of beam search in transition-based dependency parsing in order to mitigate the problem of error propagation was first proposed by Johansson and Nugues (2006), although they still used a locally trained model. Globally normalized models were first explored by Titov and Henderson (2007), who were also the first to use a parameterized SHIFT transition like the one found in both Hatori et al. (2011) and our own work, although Titov and Henderson (2007) used it to define a generative model by parameterizing the SHIFT transition by an input word. Zhang and Clark (2008) was the first to combine beam search with a globally normalized discriminative model, using structured perceptron learning and the early update strategy of Collins and Roark (2004), and also explored the addition of graph-based features to a transition-based parser. This approach was further pursued in Zhang and Clark (2011) and was used by Zhang and Nivre (2011) to achieve state-of-the-art results in dependency parsing for both Chinese and English through the addition of rich non-local features. Huang and Sagae (2010) combined structured perceptron learning and beam search with the use of a graph-structured stack to allow ambiguity packing in the beam, a technique that was reused by Hatori et al. (2011).

Finally, as noted in the introduction, although joint tagging and parsing is rare in dependency parsing, most state-of-the-art parsers based on PCFG models naturally incorporate part-of-speech tagging and usually achieve better parsing accuracy (albeit not always tagging accuracy) with a joint model than

with a pipeline approach (Collins, 1997; Charniak, 2000; Charniak and Johnson, 2005; Petrov et al., 2006). Models that in addition incorporate morphological analysis and segmentation have been explored by Tsarfaty (2006), Cohen and Smith (2007), and Goldberg and Tsarfaty (2008) with special reference to Hebrew parsing.

## 5 Conclusion

We have presented the first system for joint part-of-speech tagging and labeled dependency parsing with non-projective dependency trees. Evaluation on four languages shows consistent improvements in both tagging and parsing accuracy over a pipeline system with state-of-the-art results across the board. The error analysis reveals improvements in tagging accuracy for syntactically central categories, mainly verbs, with improvement in syntactic accuracy for core grammatical functions as a result. In future work we intend to explore joint models that incorporate not only basic part-of-speech tags but also more fine-grained morphological features.

## Abstract

Activities on social media increase at a dramatic rate. When an external event happens, there is a surge in the degree of activities related to the event. These activities may be temporally correlated with one another, but they may also capture different aspects of an event and therefore exhibit different bursty patterns. In this paper, we propose to identify event-related bursts via social media activities. We study how to correlate multiple types of activities to derive a global bursty pattern. To model smoothness of one state sequence, we propose a novel function which can capture the state context. The experiments on a large Twitter dataset shows our methods are very effective.

## 1 Introduction

Online social networks (e.g., Twitter, Facebook, Myspace) significantly influence the way we live. Activities on social media increase at a dramatic rate. Millions of users engage in a diverse range of routine activities on social media such as posting blog messages, images, videos or status messages, as well as interacting with items generated by others such as forwarding messages. When an event interesting to a certain group of individuals takes place, there is usually a surge in the degree of activities related to the event (e.g., a sudden explosion of tweets). Since social media activities may indicate the happenings of external events, can we leverage on the rich social media activities to help identify meaningful external events? This is the research problem we study in this paper. By external events, we refer to real-world events that happen external to the online space.

\*Corresponding author.

Figure 1: The amount of activities within a 10-hour window for two queries. Three types of activities are considered: (1) posting a tweet (upward triangle), (2) retweet (downward triangle), (3) posting a URL-embedded tweet (excluding retweet) (filled circle). As explained in Table 1, both bursts above are noisy.

Mining events from text streams is usually achieved by detecting bursty patterns (Swan and Allan, 2000; Kleinberg, 2003; Fung et al., 2005). However, previous work has mostly focused on traditional text streams such as scientific publications and news articles. There is still a lack of systematic investigations into the problem of identifying event-related bursty patterns via social media activities. There are at least two basic characteristics of social media that make the problem more interesting and challenging.

First, social media involve various types of activities taking place in real time. These activities may be temporally correlated with one another, but they may also capture different aspects of an event and therefore exhibit different bursty patterns. Most of previous methods (Swan and Allan, 2000; Kleinberg, 2003; Fung et al., 2005) deal with a single type of textual activities. When applied to social media, they oversimplify the complex nature of online so-

Bursty Activity	Time	# in $\mathcal{S}_r$	# in $\mathcal{S}_u$	# in $\mathcal{S}_t$	Noisy?
$\mathcal{S}_r, \mathcal{S}_t$ See Fig. 1(b)	23:00~23:59, Nov. 23, 2009	<b>108</b>	5	147	<b>Y</b>
	[Query= <b>eclipse</b> ] major bursty reason: The tweet from Robert Pattinson “@twilight: from rob cont . - i hope you are looking forward to <b>eclipse</b> as much as i am .” has been retweeted many times.

	[Query= <b>Nobel</b> ] major bursty reason: The news “Obama won <b>Nobel</b> Peace Prize” flood Twitter.				

Table 1: Examples of bursts. The first two bursts are judged as noise since they do not correspond to any meaningful external events. In fact, the reasons why a burst appears in social media can be quite diverse. In this paper, we only focus on event-related bursts.  $\mathcal{S}_t$  denotes posting a tweet,  $\mathcal{S}_u$  denotes posting a url-embedded tweet, and  $\mathcal{S}_r$  denotes retweet.

cial activities, and therefore they may not be well suitable to social media. Let us consider a motivating example. Figure 1 shows the change of the amount of activities of three different types over a 10-hour time window for two queries. If we consider only the total number of tweets, we can see that for both queries there is a burst. However, neither of the two bursts corresponds to a real-world event. The first burst was caused by the broadcast of an advertisement from several Twitter bots, and the second burst was caused by numerous retweets of a status update of a movie star<sup>1</sup>. The detailed explanations of why the two bursts are noisy are also shown in Table 1. On the other hand, interestingly, we can see that not all the activity streams display noisy bursty patterns at the same time. It indicates that we may make use of multiple views of different activities to detect event-related bursts. The intuition is that using multiple types of activities may help learn a better global picture of event-related bursty patterns. Learning may also be more resistant to noisy bursts.

Second, in social media, burst detection is challenged by irregular, unpredictable and spurious noisy bursts. To overcome this challenge, a reasonable assumption is that a burst corresponding to a real event should not fluctuate too much within a relatively short time window. To illustrate it, we present an example in Figure 2, in which we first use a simple threshold method to detect bursts and then analyze the effect of local smoothness. In particular, if the amount of activities at a certain time is above a pre-defined threshold, we set its state to 1, which indicates a bursty state. Otherwise, we set the state to 0. Figure 2(a) shows that for the query “Eclipse,” with a threshold of 50, the state sequence for the time window we consider is “0000100000.”

<sup>1</sup>The reasons for these bursts were revealed by manually checking the tweets during the corresponding periods.

Figure 2: Analysis of the effect of local smoothness on threshold method. It shows two examples of threshold methods for burst detection in a 10-hour window. The red line denotes the bursty threshold. If the number of activities is above the threshold in one time interval, the state of this time interval is judge as bursty. Detailed descriptions of these cases are shown in Table 1.

Although there is a burst in this sequence, its duration is very short. In fact, this is the first example shown in Table 1, which is a noisy burst. In contrast, in Figure 2(b), the state sequence for the query “Nobel” is “0000011111,” in which the longer and smoother burst corresponds to a true event. A good function for evaluating the smoothness of a state sequence should be able to discriminate these cases and model the context of state sequences effectively.

With its unique characteristics and challenges, there is an emergent need to deeply study the problem of event-related burst detection via social media activities. In this paper, we conduct a systematic investigation on this problem. We formulate this problem as burst detection from time series of social media activities. We develop an optimization model to learn bursty patterns based on multiple types of activities. We propose to detect bursts by considering both local state smoothness and correlation across multiple streams. We define a function to

quantitatively measure local smoothness of one single state sequence. We systematically evaluate three types of activities for burst detection on a large Twitter dataset and analyze different properties of these three streams for burst detection.

## 2 Problem Definition

Before formally introducing our problems, we first define some basic concepts.

**Activity:** An activity refers to some type of action that users perform when they are interested in some topic or event.

**Activity Stream:** An activity stream of length  $N$  and type  $m$  is a sequence of numbers  $(n_1^m, n_2^m, \dots, n_N^m)$ , where each  $n_i^m$  denotes the amount of activities of type  $m$  that occur during the  $i$ th time interval.

**Query:** A query  $Q$  is a sequence of terms  $q_1, \dots, q_{|Q|}$  which can represent the information needs of users. For example, an example query related to President Obama is “barack obama.”

**Event-related Burst:** Given a query  $Q$ , an event-related burst is defined as a period  $[t_s, t_e]$  in which some event related with  $Q$  takes place, where  $t_s$  and  $t_e$  are the start timestamp and end timestamp of the event period respectively. During the event period the amount of activities is significantly higher than average.

Based on these definitions, our task is to try to identify event-related bursts via multiple social media activity streams.

## 3 Identifying Event-related Bursts from Social Media

In this section, we discuss how to identify event-related bursts via social media activities. Formally, given a query  $Q$ , we first build  $M$  activity streams related with  $Q$  on  $T$  timestamps:  $\{(n_1^m, \dots, n_T^m)\}_{m=1}^M$ . The definition of *activity* in our methods is very general; it includes various types of social media activities, including textual and non-textual activities, e.g., a click on a shared photo and a link formation between two users.

Given the input, we try to infer a state sequence over these  $T$  timestamps:  $\mathbf{z} = (z_1, \dots, z_T)$ , where  $z_i$  is 1 or 0. 1 indicates a time point within a burst while 0 indicates a non-bursty time point.

## 3.1 Modeling a Single Activity Stream

### 3.1.1 Generation function

In probability theory and statistics, the Poisson distribution<sup>2</sup> is a discrete probability distribution that can measure the probability of a given number of “activities” occurring in a fixed time interval. We use the Poisson distribution to study the probability of observing the number of social media activities, and we treat one hour as one time interval in this paper.

**Homogeneous Poisson Distribution** The generative probability of the  $i$ th number in one activity stream of type  $m$  is defined as  $f(n_i^m, i, z_i^m) = \frac{(\lambda_{z_i^m})^{n_i^m} \exp(-\lambda_{z_i^m})}{n_i^{m!}}$ , where  $\lambda_0$  is the (normal) expectation of the number of activities in one time interval. If one state is bursty, it would emit activities with a faster rate and result in a larger expectation  $\lambda_1$ . We can set  $\lambda_1 = \lambda_0 \times \rho$ , where  $\rho > 1$ .

**Heterogeneous Poisson Distribution** The two-state machine in (Kleinberg, 2003) used two global references for all the time intervals: one for bursty and the other for non-bursty. In our experiments, we observe temporal patterns of user behaviors, i.e., activities in some hours are significantly more than those in the others. Instead of using fixed global rates  $\lambda_0$  and  $\lambda_1$ , we try to model temporal patterns of user behaviors by parameterizing  $\lambda_{(\cdot)}$  with the time index. By following (Ihler et al., 2006), we use a set of hour-specific rates  $\{\lambda_{1,h}\}_{h=1}^{24}$  and  $\{\lambda_{0,h}\}_{h=1}^{24}$ .<sup>3</sup> Given a time index  $h$ , we set  $\lambda_{0,h}$  to be the expectation of the number of activities in  $h$ th time interval every day, then we have  $\lambda_{1,h} = \lambda_{0,h} \times \rho$ . In this paper,  $\rho$  is empirally set as 1.5.

### 3.1.2 Smoothness of a State Sequence

For burst detection, the major aim is to identify steady and meaningful bursts and to discard transient and spurious bursts. Given a state sequence  $z_1 z_2 \dots z_T$ , to quantitatively measure the smoothness and compactness of it, we introduce some measures.

One simple method is to count the number of change in the state sequence. Formally, we use the following formula:

$$g_1(\mathbf{z}) = T - \sum_{i=1}^{T-1} \mathcal{I}(z_i \neq z_{i+1}), \quad (1)$$

<sup>2</sup>[http://en.wikipedia.org/wiki/Poisson\\_distribution](http://en.wikipedia.org/wiki/Poisson_distribution)

<sup>3</sup>We can also make the rates both day-specific and hour-specific, i.e.,  $\{\lambda_{(\cdot),d,h}\}_{h \in \{1, \dots, 24\}, d \in \{1, \dots, 7\}}$ .

where  $T$  is length of the state sequence and  $\mathcal{I}(\cdot)$  is an indicator function which returns 1 only if the statement is true. Let us take the state sequence “0000100000” (shown in Figure 2(a)) as an example to see how  $g_1$  works. State changes  $0_{\text{pos}=4} \rightarrow 1_{\text{pos}=5}$  and  $1_{\text{pos}=5} \rightarrow 0_{\text{pos}=6}$  each incur a cost of 1, therefore  $g_1(0000100000) = 10 - 2 = 8$ . Similarly, we can get  $g_1(0000000000) = 10$ . There is a cost difference between these two sequences, i.e.,  $\Delta_{g_1} = 2$ . Kleinberg (2003) uses state transition probabilities to model the smoothness of state sequences. With simple derivations, we can show that Kleinberg’s model essentially also uses a cost function that is linear in terms of the number of state changes in a sequence, and therefore similar to  $g_1$ .

In social media, very short noisy bursts like “0000100000” are very frequent. To discard such noises, we may multiply  $g_1$  by a big cost factor to punish short-term fluctuations. However, it is not sensitive to the state context<sup>4</sup> and may affect the detection of meaningful bursts. For example, state change  $0_{\text{pos}=4} \rightarrow 1_{\text{pos}=5}$  in “0000111100” would receive the same cost as that of  $0_{\text{pos}=4} \rightarrow 1_{\text{pos}=5}$  in “0000100000” although the later is more like a noise.

To better measure the smoothness of a state sequence, we propose a novel context-sensitive function, which sums the square of the length of the maximum subsequences in which all states are the same. Formally, we have

$$g_2(z_1, z_2, \dots, z_T) = \sum_{s_i < e_i} (e_i - s_i + 1)^2, \quad (2)$$

where  $s_i$  and  $e_i$  are the start index and end index of the  $i$ th subsequence respectively. To define “maximum”, we have the constraints  $z_{s_i} = z_{s_i+1} = \dots = z_{e_i}$ ,  $z_{s_i-1} \neq z_{s_i}$ ,  $z_{e_i} \neq z_{e_i+1}$ . For example,  $g_2(0000000000) = 10^2 = 100$ ,  $g_2(0000100000) = 4^2 + 1^2 + 5^2 = 42$ , we can see that  $\Delta_{g_2} = 100 - 42 = 58$ , which is significantly larger than  $\Delta_{g_1} (= 2)$ .  $g_2$  rewards the continuity of state sequences while punish the fluctuating changes, and it is context-sensitive. State change  $0_{\text{pos}=4} \rightarrow 1_{\text{pos}=5}$  in “0000111100” receives a cost of 4,<sup>5</sup> which is

<sup>4</sup>Here *context* refers to the window of hidden state sequences.

<sup>5</sup>Indeed,  $g_2$  is not designed for a single state change but for the overall smoothness patterns, so we choose a referring sequence generated by making the corresponding state negative to compute the cost, i.e.,  $|g_2(00000\underline{1}1110) - g_2(00000\underline{0}1110)| = 4$ .

much smaller than that of  $0_{\text{pos}=4} \rightarrow 1_{\text{pos}=5}$  in “0000100000”.  $g_2$  is also sensitive to the position of state changes, e.g.,  $g_2(0000100000) \neq g_2(0100000000)$ .

### 3.2 Burst Detection from a Single Activity Stream

Given an activity stream  $(n_1^m, \dots, n_T^m)$ , we would like to infer a state sequence over these  $T$  timestamps, i.e., to find out the most possible state sequence  $z = (z_1^m, \dots, z_T^m)$  based on the data, where  $z_i^m = 1$  or 0. We formulate this problem as an optimization problem. The cost of a state sequence includes two parts: generation of activities and smoothness of the state sequence. The objective function is to find a state sequence which incurs the minimum cost. Formally, we define the total cost function as

$$Cost(z) = \underbrace{-\sum_{i=1}^T \log f(n_i^m, i, z_i^m)}_{\text{generating cost}} + \underbrace{\left(-\Phi(z_1^m, \dots, z_T^m) \times \gamma_1\right)}_{\text{smoothness cost}}, \quad (3)$$

where  $\gamma_1 > 0$  is a scaling factor which balance these two parts.  $\Phi(\cdot)$  function is the smoothness function, and we can set it as either  $g_1(\cdot)$  or  $g_2(\cdot)$ .

To seek the optimal state sequence, we can minimize Equation 3. However, exact inference is hard due to the exponential search space. Instead of examining the smoothness of the whole state sequence, we propose to measure the smoothness of all the  $L$ -length subsequences, so called “local smoothness”. The assumption is that the states in a relatively short time window should not change too much. The new objective function is defined as

$$Cost(z) = -\sum_{i=1}^T \log f(n_i^m, i, z_i^m) - \left(\sum_{i \geq L} \Phi(z_i^m, \dots, z_{i+L-1}^m)\right) \times \gamma_1. \quad (4)$$

The objective function in Equation 4 can be solved efficiently by a dynamic programming algorithm shown in Algorithm 1. The time complexity of this algorithm is  $\mathcal{O}(T \cdot 2^L)$ . Note that the methods we present in Equation 4 and Algorithm 1 are quite general. They are independent of the concrete forms of  $f(\cdot)$  and  $\Phi(\cdot)$ , which leaves room for flexible adaptation or extension in specific tasks. In previous methods (Kleinberg, 2003),  $L$  is often fixed as

2. Indeed, as shown in Figure 2, in some cases, we may need a longer window to infer the global patterns. In our model,  $L$  can be tuned based on real datasets. We can seek a trade-off between efficiency and length of context windows.

---

**Algorithm 1:** Dynamic Programming for Equation 4.

---

```

1  $d[i][s][z_i \dots z_{i-L+1}]$  denotes the minimum cost of the first
   $i$  timestamps with the state subsequence:  $z_i \dots z_{i-L+1}$  and
   $z_i = s$ ;
2 set  $d[0][\cdot][\cdot] = 0$ ;
3 set  $c_1[i] = \log f(n_i^m, i, z_i^m)$ ;
4 set  $c_2[i] = \Phi(z_i, \dots, z_{i-L+1})$ ;
5  $b, b'$ : previous and current state window are represented as
   $L$ -bit binary numbers;
6 for  $i = 1$  to  $T$  do
7   for  $s = 0$  to  $2^L - 1$  do
8     for  $b = 0$  to  $2^L - 1$  do
9        $b' = (b \ll 1 | s) \& (1 \ll L - 1)$ ;
10       $d[i][s][b'] \leftarrow$ 
11         $\min(d[i][s][b'], d[i-1][s][b] + c_1[i] + c_2[i])$ ;
12    end
13 end
```

---

### 3.3 Correlating Multiple Activity Streams

In this section, we discuss how to correlate multiple activity streams to learn a global bursty patterns. The hidden state sequences corresponding to these activity streams are not fully independent. An external event may intricate surges in multiple activity streams simultaneously.

We propose to correlate multiple activity streams in an optimization model. The idea is that activity streams related with one query might be dependent, i.e., the states of multiple activity streams on the same timestamp tend to be the same<sup>6</sup>; if not, it would incur a cost. To implement this idea, we develop an optimization model. For convenience, we call the states of each activity stream as “local states” while the overall states learnt from multiple activity streams as “global states”.

The idea is that although various activity streams are different in the scale of frequencies, they tend to share similar trend patterns. We incorporate the correlation between local states on the same timestamp.

<sup>6</sup>In our experiments, we compute the cross correlation between different streams with a lag factor  $\delta$ , we find the cross correlation achieves maximum consistently when  $\delta = 0$ .

Formally, we have

$$\begin{aligned}
Cost(\mathbf{Z}) = & \sum_{m=1}^M \left\{ - \sum_{i=1}^T \log f(n_i^m, i, z_i^m) \right. \\
& \left. - \sum_{i \geq L} \Phi(z_i^m, \dots, z_{i+L-1}^m) \times \gamma_1 \right\} \\
& + \sum_{i=1}^T \sum_{m_1, m_2} \mathcal{I}(z_{i}^{m_1} \neq z_{i}^{m_2}) \times \gamma_2, \quad (5)
\end{aligned}$$

where  $\mathcal{I}(\cdot)$  is indicator function, and  $\gamma_2$  is the cost when a pair of states are different across multiple streams on the same timestamp.

The objective function in Equation 5 can be solved by a dynamic programming algorithm presented in Algorithm 2. The time complexity of this algorithm is  $\mathcal{O}(T \cdot 2^{M \cdot L + M})$ . Generally,  $L$  can be set as one small value, e.g.,  $L = 2$  to 6, and we can select just a few representative activity streams, i.e.,  $M = 2$  to 6. In this case, the algorithm can be efficient.

---

**Algorithm 2:** Dynamic Programming for Equation 5.

---

```

1  $d[i][z_i^1 \dots z_{i-L+1}^1; \dots; z_i^M \dots z_{i-L+1}^M]$  denotes the minimum
  cost of the first  $i$  timestamps with the local state
  subsequence  $z_i^m \dots z_{i-L+1}^m$  in the  $m$ th stream;
2 set  $d[0][\dots] = 0$ ;
3  $b^l, b^{l'}$ : previous and current state windows represented as
   $M \cdot L$ -bit binary numbers;
4  $c[i, b^l, b^{l'}]$  denotes all the cost in the  $t$ th timestamp;
5 for  $i = 1$  to  $T$  do
6   for  $b_l = 0$  to  $2^{M \cdot L} - 1$  do
7     deriving current local state sequences  $b^{l'}$  from  $b^l$ ;
8      $d[i][b^l] \leftarrow$ 
9        $\min(d[i][b^{l'}], d[i-1][b^l] + c[i, b^l, b^{l'}])$ ;
10  end
```

---

Given  $M$  types of activity streams, we can get  $M$  (local) state sequences  $\{(z_1^m, \dots, z_T^m)\}_{m=1}^M$ . The next question is how to learn a global state sequence  $(z_1^G, \dots, z_T^G)$  based on local state sequences. Here we give a few options:

**CONJUNCT**: we set a global state  $z_i$  as bursty if all local states are bursty, i.e.,  $z_i^G = \cap_{m=1}^M z_i^m$ .

**DISJUNCT**: we set a global state  $z_i$  as bursty if one of the local states is bursty, i.e.,  $z_i^G = \cup_{m=1}^M z_i^m$ .

**BELIEF**: we set a global state  $z_i$  as the most confident local state, i.e.,  $z_i^G = \operatorname{argmax}_m \operatorname{belief}(z_i^m)$ . The  $\operatorname{belief}(\cdot)$  function can be defined as the ratio between generating costs from states  $z_i^m$  and  $1 - z_i^m$ :  $\operatorname{belief}(z_i^m) = \frac{f(n_i^m, i, z_i^m)}{f(n_i^m, i, 1 - z_i^m)}$ .

Table 2: Basic statistics of our golden test collection.

# of queries	17
Aver. # of event-related bursts per query	19
Min. bursty interval	3 hours
Max. bursty interval	163 hours
Aver. bursty interval	17.8 hours

*L2G*: we treat the states of one local stream as the global states.

## 4 Experiments

### 4.1 Construction of Test Collection

We test our algorithms on a large Twitter dataset, which contains about 200 million tweets and ranges from July, 2009 to December 2009. We manually constructed a list of 17 queries that have high volumes of relevant tweets during this period. These queries have a very broad coverage of topics. Example queries are “Barack Obama”, “Apple”, “Earthquake”, “F1” and “Nobel Prize”. For each query, we invite two senior graduate students to manually identify their golden bursty intervals, and each bursty interval is represented as a pair of timestamps in terms of hours. Specifically, to generate the golden standard, given a query, the judges first manually generate a candidate list of external events<sup>7</sup>; then for each event, they look into the tweets within the corresponding period and check whether there is a surge on the frequency of tweets. If so, the judges further determine the start timepoint and end timepoint of it. If there is a conflict, a third judge will make the final decision. We used Cohen’s kappa coefficient to measure the agreement of between the first two judges, which turned out to be 0.67, indicating a good level of agreement<sup>8</sup>. We present basic statistics of the test collection in Table 2.

### 4.2 Evaluation Metrics

Before introducing our evaluation metrics, we first define the Bursty Interval Overlap Ratio (BIOR)

$$\text{BIOR}(f, \mathcal{X}) = \frac{\sum_{f' \in \mathcal{X}} \Delta l(f, f')}{L(f)},$$

$f$  is a bursty interval,  $\Delta l(f, f')$  is the length of overlap between  $f'$  and  $f$ ,  $L(f)$  is the length of

<sup>7</sup>We refer to some gold news resources, e.g., Google News and Yahoo! News.

<sup>8</sup>[http://en.wikipedia.org/wiki/Cohen's\\_kappa](http://en.wikipedia.org/wiki/Cohen's_kappa)

Figure 3: Examples to illustrate BIOR.  $X_0$ ,  $X_1$  and  $X_2$  are three sets of bursty intervals.  $X_0$  and  $X_2$  consist of one interval, and  $X_1$  consists of two intervals.  $\text{BIOR}(f, X_0)=1$ ,  $\text{BIOR}(f, X_1)=0.5$  and  $\text{BIOR}(f, X_2)=0.5$ .

bursty period of  $f$ .  $\mathcal{X}$  is a set of bursty intervals, BIOR measures the proportion of the timestamps in  $f$  which are covered by one of bursty intervals in  $\mathcal{X}$ . We use BIOR to measure partial match of intervals, because a system may not return all the exact bursty intervals<sup>9</sup>. We show some examples of BIOR in Figure 3.

We use modified Precision, Recall and F as basic measures. Given one query, P, R and F can be defined as follows

$$R = \frac{\sum_{f \in \mathcal{B}} \mathcal{I}\left(\frac{1}{|\mathcal{M}_f|} \text{BIOR}(f, \mathcal{M}) > 0.5\right)}{|\mathcal{B}|},$$

$$P = \frac{1}{|\mathcal{M}|} \sum_{f' \in \mathcal{M}} (\text{BIOR}(f', \mathcal{B})),$$

$$F = \frac{2 \times P \times R}{P + R},$$

where  $\mathcal{M}$  is the set of bursty intervals identified by one candidate method,  $\mathcal{B}$  is the set of bursty intervals in golden standards, and  $\mathcal{M}_f$  is the set of intervals which overlap with  $f$  in  $\mathcal{M}$ . We incorporate the factor  $\frac{1}{|\mathcal{M}_f|}$  in Recall to penalize the discontinuous coverage of the golden interval, and we also require that the overlap ratio with penalized factor is higher than a threshold of 0.5. Given two sets of bursty intervals which have the same value of BIOR, we prefer the one with fewer intervals. In Figure 3, we can easily derive  $X_1$  and  $X_2$  have the same value

<sup>9</sup>A simple evaluation method is that we label each one hour time slot as being part of a burst or not and compare with the gold standard. However, in our experiments, we find that some methods tend to break one meaningful burst into small parts and easier to be affected by small fluctuations although they may have a good coverage of bursty points. This is why we adopt a different evaluation approach.

Table 3: Average cross-correlation between different streams.

	$\mathcal{S}_t$	$\mathcal{S}_r$	$\mathcal{S}_u$
$\mathcal{S}_t$	1	0.830235	0.851514
$\mathcal{S}_r$	0.830235	1	0.59905
$\mathcal{S}_u$	0.851514	0.59905	1

of BIOR, when computing Recall, we prefer  $X_2$  to  $X_1$  since  $X_2$  consists of only one complete interval while  $X_1$  consists of two inconsecutive intervals.  $\mathcal{I}(\cdot)$  is an indicator function which returns 1 only if the statement is true. In our experiments, we use the average of R, P and F over all test queries.

### 4.3 Experiment Setup

#### Selecting activity streams

We consider three types of activity streams in Twitter: 1) posting a tweet, denoted as  $\mathcal{S}_t$ ; 2) forwarding a tweet (retweet), denoted as  $\mathcal{S}_r$ ; 3) posting a URL-embedded tweet, denoted as  $\mathcal{S}_u$ . It is natural to test the performance of  $\mathcal{S}_t$  in discovering bursty patterns, while  $\mathcal{S}_u$  and  $\mathcal{S}_r$  measure the influence of external events on users in Twitter in two different aspects.  $\mathcal{S}_r$ : An important convention in Twitter is the “retweeting” mechanism, through which users can actively spread the news or related information;  $\mathcal{S}_u$ : Another characteristic of Twitter is that the length of tweets is limited to 140 characters, which constrains the capacity of information. Users often embed a URL link in the tweets to help others know more about the corresponding information.

We compute the average cross correlation between different activity streams for these 17 queries in our test collection, and we summarize the results in Table 3. We can see that both  $\mathcal{S}_r$  and  $\mathcal{S}_u$  have a high correlation with  $\mathcal{S}_t$ , and  $\mathcal{S}_r$  has a relatively low correlation with  $\mathcal{S}_u$ .<sup>10</sup>

#### Methods for comparisons

$\mathcal{S}_{(\cdot)}$ : using Equation 4 and considers a single activity stream, namely  $\mathcal{S}_t$ ,  $\mathcal{S}_u$  and  $\mathcal{S}_r$ .

$MBurst_{(\cdot)}$ : using Equation 5 and considers multiple activity streams.

To compare our methods with previous methods, we adopt the following baselines:

*StateMachine*: This is the method proposed in (Kleinberg, 2003). We use heterogeneous Poisson

<sup>10</sup>We also consider the frequencies of unique users by hours, however, we find it has a extremely high correlation coefficient with  $\mathcal{S}_t$ , about 0.99, so we do not incorporate it.

function as generating functions instead of binomial function  $C_k^n$  because sometimes it is difficult to get the exact total number  $n$  in social media.

*Threshold*: If we find that the count in one time interval is higher than a predefined threshold, it is treated as a burst. The threshold is set as 1.5 times of the average number.

*PeakFinding*: This is the method proposed in (Marcus et al., 2011), which aims to automatically discover peaks from tweets.

*Binomial*: This is the method proposed in (Fung et al., 2007a), which uses a cumulative binomial distribution with a base probability estimated by removing abnormal frequencies.

As for multiple-stream burst detection, to the best of our knowledge, the only existing work is proposed by (Yao et al., 2010), which is supervised and requires a considerable amount of training time, so we do not compare our work with it. We compare our method with the following heuristic baselines:

*SimpleConjunct*: we first find the optimal state sequences for each single activity stream. We then derive a global state sequence by taking the conjunction of all local states.

*SimpleDisjunct*: we first find the optimal state sequences for each single activity stream, and then we derive a global state sequence by take the disjunction of all local states.

Another possible baseline is that we first merge all the activities, then apply the single-stream algorithm. However, in our data set, we find that the number of activities in  $\mathcal{S}_t$  is significantly larger than that of the two types.  $\mathcal{S}_t$  dominantly determines the final performance, so we do not incorporate it here as a comparison.

### 4.4 Experimental Results

#### Preliminary results on a single stream

We first examine the performance of our proposed method on a single stream. Note that, our method in Equation 4 has two merits: 1) the length of local window can be tuned on different datasets; 2) a novel state smoothness function is adopted.

We set the  $\Phi$  function in Equation 4 respectively as  $g_1$  and  $g_2$ , and apply our proposed methods to three streams ( $\mathcal{S}_t$ ,  $\mathcal{S}_r$ ,  $\mathcal{S}_u$ ) mentioned above. Note that, when  $L = 2$  and  $\Phi = g_1$ , our method becomes the algorithm in (Kleinberg, 2003). We tune the parameter  $\gamma_1$  in Equation 4 from 2 to 20 with a step of 2. We record the best F performance and compute

the corresponding standard deviation. In Table 5, we can observe that 1) streams  $\mathcal{S}_t$  and  $\mathcal{S}_r$  perform better than  $\mathcal{S}_u$ ; 2) the length of local window significantly affects the performance; 3)  $g_2$  is much better than  $g_1$  in our proposed burst detection algorithm; 4) generally speaking, a longer window size ( $L = 3, 4$ ) performs better than the most common used size 2 in (Kleinberg, 2003).

We can see that our proposed method is more effective than the other baselines. The major reason is that none of these methods consider state smoothness in a systematic way. In our preliminary experiments, we find that these baselines usually output a lot of bursts, most of which are broken meaningful bursts. To overcome this, baseline method StateMachine ( $g_1 + L = 2$ ) requires larger  $\rho$  and  $\gamma_1$ , which may discard relatively small meaningful bursts; while our proposed single stream method ( $g_2 + L = 3, 4$ ) tends to identify steady and consecutive bursts through the help of longer context window and context sensitive smoothness function  $g_2$ , it is more suitable to be applied to social media for burst detection.

Compared with the other baselines, (Kleinberg, 2003) is still one good and robust baseline since it models the state smoothness partially. These preliminary findings indicate that state smoothness is very important for burst detection, and the length of state context window will affect the performance significantly.

To get a deep analysis of the performance of different streams, we set up three classes, and each class corresponds to a single stream. Since for each query, we can obtain multiple results in different activity streams, we further categorize the 17 annotated queries to the stream which leads to the optimal performance on that query. Interestingly, we can see: 1) the *url* stream gives better performance on queries about big companies because users in Twitter usually talk about the release of new products or important evolutionary news via url-embedded tweets; 2) the *retweet* stream gives better performance on queries which correspond to unexpected or significant events, e.g., disasters. It is consistent with our intuitions that users in Twitter do actively spread such information. Combining previous analysis of Table 5, overall we find the *retweet* stream is more capable to identify bursts which correspond to significant events.

Table 4: Categorization of 17 queries according to the optimal performance.

Streams	Queries
url	<i>Apple,Microsoft,Nokia</i> , climate
retweet	<i>bomb,crash,earthquake,typhoon</i> , F1,Google,Olympics
all_tweet	Amazon, eclipse, Lakers, NASA, Nobel Prize, Barack Obama

Table 5: Performance (average F) on a single stream. “\*\*” indicates that the improvement our proposed single-stream method  $g_{2,L=4}$  over all the other baselines is accepted at the confidence level of 0.95, i.e., StateMachine, PeakingFinding, Binomial and Threshold.

$\Phi$	$L$	$\mathcal{S}_t$	$\mathcal{S}_r$	$\mathcal{S}_u$
$g_2$	4	0.545/0.015	0.543/0.037	0.451/0.036
	3	0.536/0.013	<b>0.549**</b> /0.019	0.464/0.025
	2	0.468/0.055	0.542/0.071	0.455/0.045
$g_1$	4	0.513/0.059	0.546/0.058	0.465/0.047
	3	0.469/0.055	0.542/0.071	0.455/0.045
	2	0.396/0.043	0.489/0.074	0.374/0.035
StateMachine		0.396	0.489	0.374
PeakFinding		0.410	0.356	0.302
Binomial		0.315	0.420	0.341
Threshold		0.195	0.181	0.175

### Preliminary results on multiple streams

After examining the basic results on a single stream, we continue to evaluate the performance of our proposed models on multiple activity streams. For *MBurst* in Equation 5, we have three parameters to set, namely  $L$ ,  $\gamma_1$  and  $\gamma_2$ . We do a grid search for both  $\gamma_1$  and  $\gamma_2$  from 1 to 12 with a step of 1, and we also examine the performance when  $L = 2, 3, 4$ . We can see that *MBurst* has four candidate methods to derive global states from local states; for *L2G*, we use the states of  $\mathcal{S}_t$  as the final states, and we empirically find that it performs best compared with the other two streams in *L2G*.

Recall that our proposed single-stream method is better than all the other single-stream baselines, so here single-best denotes our method in Equation 4 ( $\Phi = g_2, L = 4$ ) on  $\mathcal{S}_r$ . For *SimpleConjunct* and *SimpleDisjunct*, we first find the optimal state sequences for each single activity stream using our proposed method in Equation 4 ( $\Phi = g_2, L = 4$ ), and then we derive a global state sequence by take the conjunction or disjunction of all local states respectively.

Besides the best performance, we further compute the average of the top 10 results of each method by tuning parameters to check the average perfor-

Table 6: Performance (average F) on multiple streams. “\*” indicates that the improvement our proposed multiple-stream method over our proposed single-stream method at the confidence level of 0.9 in terms of average performance.

Methods	best	average
single-best ( $g_2 + \mathcal{S}_r$ )	0.549	0.526
SimpleConjunct	0.548	-
SimpleDisjunct	0.465	-
$MBurst+CONJUNCT_{r,t,u}$	0.555	0.548
$MBurst+DISJUNCT_{r,t,u}$	<b>0.576</b>	<b>0.570*</b>
$MBurst+BELIEF_{r,t,u}$	0.568	0.561
$MBurst+L2G_{r,t,u}(t)$	0.574	0.567
$MBurst+L2G_{r,t,u}(r)$	0.560	0.558

mance. The average performance can show the stability of models in some degree. If one model outputs the maximum in a very limited set of parameters, it may not work well in real data, especially in social media.

In Table 6, we can see  $MBurst+DISJUNCT_{r,t,u}$  gives the best performance.  $MBurst$  performs consistently better than *single-best* which is a very strong single-stream method, especially for average performance.  $MBurst+DISJUNCT_{r,t,u}$  has an improvement of average performance over *single-best* by 8.4%. And simply combining three different streams may hit results (*SimpleConjunct* and *SimpleDisjunct*). It indicates that  $MBurst$  is more stable and shows a higher performance.

For different methods to derive global bursty patterns, we can see that  $MBurst+DISJUNCT$  performs best while  $MBurst+CONJUNCT$  performs worst. Interestingly, however, *SimpleConjunct* is better than *SimpleDisjunct*, the major reason is that  $MBurst$  performs a local-state correlation of multiple activity streams to correct possible noisy fluctuations from single streams before the conjunction or disjunction of local states. After such correlation, the performance of each activity stream should improve. To see this, we present the optimal results of a single stream without/with local-state correlation in Table 7. Local-state correlation significantly boosts the performance of a single stream. Indeed, we find that the step of local-state correlation is more important for our multiple stream algorithm than the step of how to derive global states based on local states.

We test our  $MBurst$  algorithm with the setting:  $T = 4416$ ,  $L = 4$  and  $M = 3$ , and for all the test

Table 7: Comparison between the optimal results of a single stream with/without local-state correlation.

queries, our algorithm can respond in 2 seconds<sup>11</sup>, which is efficient to be deployed in social media.

### Parameter sensitivity

We have shown the performance of different parameter settings for single stream algorithm in Table 5. Next, we check parameter sensitivity in  $MBurst$ . In our experiments, we find a longer local window ( $L = 3, 4$ ) is better than  $L = 2$ , so we first set  $L = 4$ , then we select parameter settings of  $\gamma_2 = 4$  and  $\gamma_1 = 11$ , which give best performance for  $MBurst+DISJUNCT$ . We vary one with the other fixed to see how one single parameter affects the performance. The results are shown in Figure 4, and we can see  $MBurst+DISJUNCT$  is consistently better than single-best.

## 5 Related Work

Our work is related to burst detection from text streams. Pioneered by the automaton model proposed in (Kleinberg, 2003), many techniques have been proposed for burst detection such as the  $\chi^2$ -test based method (Swan and Allan, 2000), the parameter-free method (Fung et al., 2005) and moving average method (Vlachos et al., 2004). Our work is related to the applications of these burst detection algorithms for event detection (He et al., 2007; Fung et al., 2007b; Shan et al., 2012; Zhao et al., 2012).

<sup>11</sup>All experiments are tested in a Mac PC, 2.4GHz Intel Core 2 Duo.

Some recent work try to identify hot trends (Mathioudakis and Koudas, 2010; Zubiaga et al., 2011; Budak et al., 2011; Naaman et al., 2011) or make use of the burstiness (Sakaki et al., 2010; Aramki et al., 2011; Marcus et al., 2011) in social media. However, few of these methods consider modeling the local smoothness of one state sequence in a systematic way and often use a fixed window length of 2.

Little work considers making use of different types of social media activities for burst detection. (Yao et al., 2010; Kotov et al., 2011; Wang et al., 2007; Wang et al., 2009) conducted some preliminary studies of mining correlated bursty patterns from multiple sources. However, they either highly relies on high-quality training datasets or require a considerable amount of training time. Online social activities are dynamic, with a large number of new items generated continuously. In such a dynamic setting, burst detection algorithms should effectively collect evidence, efficiently adjust prediction models and respond to the users as social media activities evolve. Therefore it is not suitable to deploy such algorithms in social media.

Our work is also similar to studies which aim to mine and leverage knowledge from social media (Mathioudakis et al., 2010; Ruiz et al., 2012; Morales et al., 2012). We share the common point with these studies that we try to utilize the underlying rich knowledge in social media, while our focus of this work is quite different from theirs, i.e., to identify event-related bursts.

Another line of related research is Twitter related studies (Kwak et al., 2010; Sakaki et al., 2010). Our proposed methods can provide event-related bursts for downstream applications.

## 6 Conclusion

In this paper, we propose to identify event-related bursts via social media activities. We propose one optimization model to correlate multiple activity streams to learn the bursty patterns. To better measure local smoothness of the state sequence, we propose a novel state cost function. We test our methods in a large Twitter dataset. The experiment results show that our methods are both effective and efficient. Our work can provide a preliminary understanding of the correlation between the happenings of events and the degree of online social media activities.

Finally, we present a few promising directions which may potentially improve or enrich current work.

1) **Variable-length context.** In this paper,  $L$  is a pre-determined parameter which controls the size of context window. It cannot be modified when the algorithm runs. A large  $L$  will significantly increases the algorithm complexity, and we may not need a large  $L$  for all the states in a Markov chain. This problem can be addressed by using the variable-length hidden Markov model (Wang et al., 2006), which is able to learn the “minimum” context length for accurately determining each state.

2) **Incorporation of more useful features.** Our current model mainly considers temporal variations of streaming data and searches the surge patterns existing in it. In some cases, simple frequency information may not be capable to identify all the meaningful bursts. It can be potentially useful to leverage up more features to help filter out noisy bursts, e.g., semantic information (Zhao et al., 2010).

3) **Modeling multi-modality data.** We have examined our multi-stream algorithm by using three different activity streams. These streams are textual-based. It will be interesting to check our algorithm in multi-modality data streams. E.g., in Facebook, we may collect a stream consisting of the daily frequencies of photo sharing and another stream consisting of the daily frequencies of text status updates.

4) **Evaluation of the identified bursts.** In most of previous work, they seldom construct a gold standard for quantitative test, instead they qualitatively evaluate their methods. In our work, we invite human judges to generate the gold standard. It is time-consuming, and the bias from human judges cannot be completely eliminated although more judges can be invited. A possible evaluation method is to examine the identified bursts in downstream applications, e.g., event detection.

katjaf@google.com

## Abstract

We consider the task of predicting the gender of the YouTube<sup>1</sup> users and contrast two information sources: the comments they leave and the social environment induced from the affiliation graph of users and videos. We propagate gender information through the videos and show that a user's gender can be predicted from her social environment with the accuracy above 90%. We also show that the gender can be predicted from language alone (89%). A surprising result of our study is that the latter predictions correlate more strongly with the gender predominant in the user's environment than with the sex of the person as reported in the profile. We also investigate how the two views (linguistic and social) can be combined and analyse how prediction accuracy changes over different age groups.

## 1 Introduction

Over the past decade the web has become more and more social. The number of people having an identity on one of the Internet social networks (Facebook<sup>2</sup>, Google+<sup>3</sup>, Twitter<sup>4</sup>, etc.) has been steadily growing, many users communicate online on a daily basis. Their interactions open new possibilities for social sciences, and linguistics is no exception. For example, with the development and growth of Web 2.0, it has become possible to get access to masses of text data labeled with respect to different social

parameters such as country, age, gender, profession or religion. The study of language varieties between groups separated by a certain social variable belongs to the field of sociolinguistics which more generally investigates the effect of society on how language is used (Coulmas, 1998). Historically, sociolinguistics is connected to dialectology whose focus has been primarily on the phonetic aspect of the regional dialects but was later extended to sociolects (Chambers & Trudgill, 1998). A usual study would involve sampling speakers from a population, interviewing them and analyzing the linguistic items with respect to social variables (Hudson, 1980).

The last decade has seen several studies investigating the relationship between the language and the demographics of the users of blogs or Twitter (see Sec. 2 for references). Most of those studies used social network sites to collect labeled data-samples of text together with the demographics variable. However, they did not analyse how social environment affects language, although very similar questions have been recently posed (but not yet answered) by Ellist (2009). In our work we attempt to address precisely this issue. In particular, we consider the task of user gender prediction on YouTube and contrast two information sources: (1) the comments written by the user and (2) her social neighborhood as defined by the bipartite user-video graph. We use the comments to train a gender classifier on a variety of linguistic features. We also introduce a simple gender propagation procedure to predict person's gender from the user-video graph.

In what follows we will argue that although language does provide us with signals indicative of the

<sup>1</sup>[www.youtube.com](http://www.youtube.com)

<sup>2</sup>[www.facebook.com](http://www.facebook.com)

<sup>3</sup>[www.plus.google.com](http://www.plus.google.com)

<sup>4</sup>[www.twitter.com](http://www.twitter.com)

user's gender<sup>5</sup> (as reported in the user's profile), it is in fact more indicative of a socially defined gender. Leaving aside the debate on the intricate relationship between language and gender (see Eckert & McConnell-Ginet (2003) for a thorough discussion of the subject), we simply demonstrate that a classifier trained to predict the predominant gender in the user's social environment, as approximated by the YouTube graph of users and videos, achieves higher accuracy for both genders than the one trained to predict the user's inborn gender. We also investigate ways of how the language-based and the social views can be combined to improve prediction accuracy. Finally, we look at three age groups – teenagers, people in their twenties and people over thirty – and show that gender identity is more evident in the language of younger people but also that there is a higher correlation between their inborn gender and the predominant gender in their social environment.

The paper is organized as follows: we first review related work on the language of social media and user demographics (Sec. 2) and elaborate on the goals of our research (Sec. 3). Then we describe our data (Sec. 4), introduce the demographics propagation experiments (Sec. 5) and the experiments on supervised learning gender from language (Sec. 6).

## 2 Related work

Previous studies on language and demographics which looked at online data can be distinguished with respect to their aims. (1) Studies coming from the sociolinguistic community aim at empirically confirming hypotheses, such as that female speakers use more pronouns, or that males tend to use longer words. (2) A standard goal of an NLP study is to build an automatic system which accurately solves a given task which in the case of demographics is predicting user age, gender or country of origin. In this section we start by reviewing the first kind of studies, which are about data analysis and hypotheses checking. These are relevant for our choice of features. Then we briefly summarize a selection of

---

<sup>5</sup>Although it might be more correct to talk about the user's sex in place of gender (Eckert & McConnell-Ginet, 2003), we stick to the terminology adopted in previous NLP research on gender prediction.

studies on demographics prediction to better situate and motivate our approach.

### 2.1 Language and demographics analysis

Previous sociolinguistic studies mostly checked hypotheses formulated before the widespread use of the Internet, such as that women use hedges more often (Lakoff, 1973) or that men use more negations (Mulac et al., 2000), or looked at specific words or word classes. Newman et al. (2008) provide a comprehensive review of such work and a description of the non-web corpora used therein. Some of those hypotheses were confirmed by empirical evidence, some not.

For example, Herring & Paolillo (2006) analyse gender- and genre-specific use of language in online communication on a sample of about 130 blog entries. Looking at a number of stylistic features which had previously been claimed to be predictive of gender (Argamon et al., 2003; Koppel et al., 2004), such as personal pronouns, determiners and other function words, they find no gender effect. Unlike them, Kapidzic & Herring (2011) analyse recent chat communications and find that they are gendered. Similarly, Huffaker & Calvert (2005) investigate the question of identity of teenager bloggers (e.g., age, gender, sexuality) and find language features indicative of gender (e.g., use of emoticons by males). Burger & Henderson (2006) consider the relationship between different linguistic (e.g., text length, use of capital and punctuation letters) and non-linguistic (e.g., interests, mood) features and blogger's age and location. They find that many features correlate with the age and run an experiment with the goal of predicting whether the blog author is over 18.

### 2.2 Demographics prediction from language

The studies we review here used supervised machine learning to obtain models for predicting gender or age. Other demographic attributes, like location, ethnicity, or educational level, have also been predicted automatically (Gillick, 2010; Rao & Yarowsky, 2011, inter alia). Also, generative approaches have been applied to discover associations between language and demographics of social media users (Eisenstein et al., 2011, inter alia) but these are of less direct relevance for the present work. For su-

pervised approaches, major feature sources are the text the user has written and also her profile which may list the name, interests, friends, etc. There have also been studies which did not look at the language at all but considered the social environment only. For example, MacKinnon & Warren (2006) aim at predicting the age and the location of the LiveJournal<sup>6</sup> users. What they found is that there is a remarkable correlation between the age and the location of the user and those of her friends, although there are interesting exceptions.

Burger et al. (2011) train a gender classifier on tweets with word and character-based ngram features achieving accuracy of 75.5%. Adding the full name feature alone gives a boost to 89.1%, further features like self-written description and screen name further help to get 92%. Also, a self-training method exploring unlabeled data is described but its performance is worse. Other kinds of sociolinguistic features and a different classifier have been applied to gender prediction on tweets by Rao & Yarowsky (2010).

Nowson & Oberlander (2006) achieve 92% accuracy on the gender prediction task using ngram features only. Their corpus consist of 1,400/450 posts written by 47 females and 24 males, respectively. However, the ngram features were preselected based on whether they occurred with significant relative frequency in the language of one gender over the other. Since the complete dataset was used to preselect features, the results are inconclusive.

Yan & Yan (2006) train a Naive Bayes classifier to predict the gender of a blog entry author. In total they looked at 75,000 individual blog entries authored by 3,000 bloggers, all of them posted their genders on the profile page. They measure precision and recall w.r.t. the minority class (males) and get the best f-measure of 0.64 (precision and recall are 65% and 71%, respectively).

Rosenthal & McKeown (2011) predict the age of a blogger, most features they use are extracted from the blog posts, other features include blogger's interests, the number of friends, the usual time of posting, etc. Similarly to Schler et al. (2006), they run a classification experiment with three age classes removing intermediate ages and use the majority-class

baseline for comparison. In their other experiment they experiment with a binary classifier for age distinguishing between the pre- and post-social media generations and using the years from 1975-1988 as a boundary. The prediction accuracy increases as later years are taken.

Interestingly, it has been shown that demographics can be predicted in more restricted genres than the personal blog or tweets and from text fragments even shorter than tweets (Otterbacher, 2010; Popescu & Grefenstette, 2010).

### 3 Motivation for the present study

Similarly to previous NLP studies, our starting goal is to predict the self-reported user gender. The first novelty of our research is that in doing so we contrast two sources of information: the user's social environment and the text she has written. Indeed, a topic which has not yet been investigated much in the reviewed studies on language and user demographics is the relationship between the language of the user and her social environment. The data analysis studies (Sec. 2.1) verified hypotheses concerning the dependency between a language trait (e.g., average sentence length) and a demographic parameter (e.g., gender). The demographics prediction studies (Sec. 2.2) mostly relied on language and user profile features and considered users in isolation. An exception to this is Garera & Yarowsky (2009) who showed that, for gender prediction in a dialogue, it helps to know the interlocutor's gender. However, we aim at investigating the impact of the social environment in a much broader sense than the immediate interlocutors and in a much broader context than a conversation.

Language is a social phenomenon, and it is this fact that motivates all the sociolinguistic research. Many if not most language traits are not hard-wired or inborn but can be explained by looking at who the person interacts most with. Since every language speaker can be seen as a member of multiple overlapping communities (e.g., computer scientists, French, males, runners), the language of the person may reflect her membership in different communities to various degrees. Repeated interactions with other language speakers influence the way the person speaks (Baxter et al., 2006; Bybee, 2010), and

---

<sup>6</sup>[www.livejournal.com](http://www.livejournal.com)

the influence is observable on all the levels of the language representation (Croft, 2000). For example, it has been shown that the more a person is integrated in a certain community and the tighter the ties of the social network are, the more prominent are the representative traits of that community in the language of the person (Milroy & Milroy, 1992; Labov, 1994). In our study we adopt a similar view and analyse the implications it has for gender prediction. Given its social nature, does the language reflect the norms of a community the user belongs to or the actual value of a demographic variable?

In our study we address this issue with a particular modeling technique: we assume that the observed online behavior adequately reflects the offline life of a user (more on this in Sec. 4 and 5) and based on this assumption make inferences about the user's social environment. We use language-based features and a supervised approach to gender prediction to analyse the relationship between the language and the variable to be predicted. To our knowledge, we are the first to question whether it is really the in-born gender that language-based classifiers learn to predict. More concrete questions we are going to suggest answers to are as follows:

1. Previous studies which looked at online data relied on self-reported demographics. The profile data are known to be noisy, although it is hard to estimate the proportion of false profiles (Burger et al., 2011). Concerning the prediction task, how can we make use of what we know about the user's social environment to reduce the effect of noise? How can we benefit from the language samples from the users whose gender we do not know at all?
2. When analyzing the language of a user, how much are its gender-specific traits due to the user's inborn gender and to which extent can they be explained by her social environment? Using our modeling technique and a language-based gender classifier, how is its performance affected by what we know about the online social environment of the user?
3. Concerning gender predictions across different age groups, how does classifier performance

change? Judging from the online communication, do teenagers signal their gender identity more than older people? In terms of classifier accuracy, is it easier to predict a teenager's gender than the gender of an adult?

The final novelty of our study is that we are the first to demonstrate how YouTube can be used as a valuable resource for sociolinguistic research. In the following section we highlight the points which make YouTube interesting and unique.

## 4 Data

Most social networks strive to protect user privacy and by default do not expose profile information or reveal user activity (e.g., posts, comments, votes, etc.). To obtain data for our experiments we use YouTube, a video sharing site. Most of the YouTube registered users list their gender, age and location on their profile pages which, like their comments, are publicly available. YouTube is an interesting domain for sociolinguistic research for several reasons:

**High diversity:** it is not restricted to any particular topic (e.g., like political blogs) but covers a vast variety of topics attracting a very broad audience, from children interested in cartoons to academics watching lectures on philosophy<sup>7</sup>.

**Spontaneous speech:** the user comments are arguably more spontaneous than blogs which are more likely to conform to the norms of written language. At the same time they are less restricted than tweets written under the length constraint which encourages highly compressed utterances.

**Data availability:** all the comments are publicly available, so we have do not get a biased subset of what a user has written for the public. Moreover, we observe users' interactions in different environments because every video targets particular groups of people who may share origin (e.g., *elections in Greece*) or possession (e.g., *how to unlock iPhone*) or any other property. Some videos attract a well-defined group of people (e.g., *the family of a newborn child*), whereas some videos appeal to a very broad audience (e.g., *a kitten video*).

<sup>7</sup>For more information and statistics see the official YouTube demographics on <http://www.youtube.com/yt/advertise/affinities.html>.

female	male	nn
26%	62%	12%

Table 1: Gender distribution for the extracted 6.9M users.

From the users, videos and the comment relationship we build an affiliation graph (Easley & Kleinberg, 2010): a user and a video are connected if the user commented on the video (Fig. 1(a)). Our graph is unweighted although the number of comments could be used to weight edges. The co-comment graph is a stricter version of a more popular co-view graph used in, e.g., video recommendation studies (Baluja et al., 2008, *inter alia*).

We obtained a random sample of videos by considering all the videos whose YouTube ID has a specific prefix<sup>8</sup>. From those, we collected the profiles of the users whose commented on the videos. In total, we extracted about 6.9M profiles of users who have written at least 20 comments, not more than 30 comments were collected for every user. The threshold on the minimum number of comments is set in order to reduce the proportion of users who have used YouTube only a few times and possibly followed the suggestions of the site in their video choice. The users’ gender distributions is presented in Table 1. Although females, in particular teenagers, have been reported to be more likely to blog than males (Herring et al., 2004), males are predominant in our dataset. A random sample from a pool of users without the 20-comments threshold showed that there are more male commenters overall, although the difference is less remarkable for teenagers: 58% of the teenagers with known gender are male as opposed to 74% and 79% for the age groups 20-29 and 30+. Teenagers are also more numerous accounting for about 35% in our data.

Although we did not filter users based on their location or mother tongue as many users comment in multiple languages, the comment set is overwhelmingly English.

<sup>8</sup>The YouTube API ([http://code.google.com/apis/youtube/getting\\_started.html](http://code.google.com/apis/youtube/getting_started.html)) can be used to retrieve user profiles and video metadata as well as the comments.

## 5 Gender propagation

We first consider the user’s social environment to see whether there is any correlation between the gender of a user and the gender distribution in her vicinity, independent of the language. We use a simple propagation procedure to reach the closest neighbors of a user, that is, other users “affiliated” with the same videos. Specifically, we perform the following two steps:

1. We send the gender information (female, male or unknown) to all the videos the user has commented on. This way for every video we obtain a multinomial distribution over three classes (see Fig. 1(b)).
2. We send the gender distributions from every video back to all the users who commented on it and average over all the videos the user is connected with (see Fig. 1(c)). However, in doing so we adjust the distribution for every user so that her own demographics is excluded. This way we have a fair setting where the original gender of the user is never included in what she gets back from the connected videos. Thus, the gender of a user contributes to the vicinity distributions of all the neighbors but not to her own final gender distribution.

In line with our motivation and modeling technique, we chose such a simple method (and not, say, classification) in order to approximate the offline encounters of the user: does she more often meet women or men? The way we think of the videos is that they correspond to places (e.g., a cinema, a cosmetic shop, a pub) visited by the user where she is unintentionally or deliberately exposed to how other speakers use the language. Similar to Baxter et al. (2006), we assume that these encounters influence the way the person speaks. Note that if the user’s gender has no influence on her choice of videos, then, on average, we would expect every video to have the same distribution as in our data overall: 62% male, 26% female and 12% unknown (Table 1).

To obtain a single gender prediction from the propagated distribution, for a given user we select the gender class (female or male) which got more

Figure 1: Affiliation graph of users (circles) and videos (rectangles).

of the distribution mass. The exact procedure is as follows: given user  $u$  connected with videos  $V_u = \{v_1, \dots, v_m\}$ , there are  $m$  gender distributions sent to  $u$ :  $P_V(u) = \{p(g|v_i) : 1 \leq i \leq m, g \in \{f, m, n\}\}$ . A single distribution is obtained from  $P_V(u)$ :  $\hat{p}(g|u) = \sum_i p(g|v_i)/m$ .

To address the skewness in the data, i.e., the fact that 70% of our users (62/(26 + 62)) with known gender are male, we select the female gender if (a) it got more than zero mass and at least as much mass as male:  $\hat{p}(f) > 0 \wedge \hat{p}(f) \geq \hat{p}(m)$ , or (b) it got at least  $\tau$  of the mass:  $\hat{p}(f) \geq \tau$ . We set  $\tau = 0.26$  initially because it corresponds to the expected proportion of females (26%) but further experimented with different  $\tau$  values in the range of 0.25-0.4. We obtained best accuracy and f-measures with the threshold of 0.33, the difference in accuracy from the initial threshold of 0.26 being less than 2%. The fact that the optimal  $\tau$  value is different from the overall proportion of females (26%) is not surprising given that we aggregate per video distributions and not raw user counts.

The predictions obtained with the described propagation method are remarkably accurate, reaching 90% accuracy (Table 2). The baseline of assigning all the users the majority class (*all male*) provides us with the accuracy of 70% – the proportion of males among the users with known gender.

Although the purpose of this section is not to present a gender prediction method, we find it worth emphasizing that 90% accuracy is remarkable given that we only look at the immediate user vicinity. In the following section we are going to investigate how this social view on demographics can help us in

	Acc%	P%	R%	F1
Baseline	70	-	-	-
all	90	-	-	-
fem	-	84.3	80.8	83
male	-	92.2	93.8	93

Table 2: Precision and recall for propagated gender.

predicting gender from language.

## 6 Supervised learning of gender

In this section we start by describing our first gender prediction experiment and several extensions to it and then turn to the results.

### 6.1 Experiments

Similar to previous studies on demographics prediction, we start with a supervised approach and only look at the text (comments) written by the user. We do not rely on any information from the social environment of the user and do not use any features extracted from the user profile, like name, which would make the gender prediction task considerably easier (Burger et al., 2011). Finally, we do not extract any features from the videos the user has commented on because our goal here is to explore the language as a sole source of information. Here we simply want to investigate the extent to which the language of the user is indicative of her gender which is found in the profile and which, ignoring the noise, corresponds to the inborn gender.

In our experiments we use a distributed implementation of the maximum entropy learner (Berger et al., 1996; McDonald et al., 2010) which outputs

a distribution over the classes, the final prediction is the class with the greater probability. We take 80% of the users for training and generate a training instance for every user who made her gender visible on the profile page (4.9M). The remaining 20% of the data are used for testing (1.2M). We use the following three groups of features: (1) *character-based*: average comment length, ratio of capital letters to the total number of letters, ratio of punctuation to the total number of characters; (2) *token-based*: average comment length in words, ratio of unique words to the total tokens, lowercase unigrams with total count over all the comments (10K most frequent unigrams were used, the frequencies were computed on a separate comment set), use of pronouns, determiners, function words; (3) *sentence-based*: average comment length in sentences, average sentence length in words.

**Enhancing the training set.** The first question we consider is how the affiliation graph and propagated gender can be used to enhance our data for the supervised experiments. One possibility would be to train a classifier on a refined set of users by eliminating all those whose reported gender did not match the gender predicted by the neighborhood. This would presumably reduce the amount of noise by discarding the users who intentionally provided false information on their profiles. Another possibility would be to extend the training set with the users who did not make their gender visible to the public but whose gender we can predict from their vicinity. The idea here is similar to co-training where one has two independent views on the data. In this case a social graph view would be combined with the language-based view.

**Profile vs. vicinity gender prediction.** The next question posed in the motivation section is as follows: Does the fact that language is a social phenomenon and that it is being shaped by the social environment of the speaker impact our gender classifier? If there are truly gender-specific language traits and they are reflected in our features, then we should not observe any significant difference between the prediction results on the users whose gender matches the gender propagated from the vicinity and those whose gender does not match. A contrary hypothesis would be that what the classifier actually

learns to predict is not as much the inborn but a social gender. In this case, the classifier trained on the propagated gender labels should be more accurate than the one trained on the labels extracted from the profiles.

To address these questions we contrast two classifiers: (1) the one described in the beginning of the section which is trained on the gender labels collected from the user profiles; (2) a classifier trained on the vicinity gender, that is the dominating gender of the environment of a speaker as obtained with the procedure described in Section 5.

**Age groups and gender prediction.** Finally, we look at how gender predictions change with age and train three age-specific models to predict gender for teenagers (13-19), people in their twenties (20-29) and people over thirty (30+), the age is also extracted from the profiles. These groups are identified in order to check whether teenagers tend to signalize their gender identity more than older people, a hypothesis investigated earlier on a sample of blog posts (Huffaker & Calvert, 2005).

## 6.2 Results

We report the results of the supervised experiments for all the settings described above. As an estimate of the lowest bound we also give the results of the majority class baseline (*all male*) which guarantees 70% accuracy. For the supervised classifiers we report accuracy and per-gender precision, recall and f-measure. Table 3 presents the results for the starting classifier trained to predict profile gender.

	Acc%	P%	R%	F1	Total
Baseline	70	-	-	-	619K
all	89	-	-	-	619K
fem	-	83	78	80	182K
male	-	91	94	93	437K

Table 3: Results on the test set.

In order to investigate the relationship between the social environment of a person, her gender and the language, we split the users from the test set into two groups: those whose profile gender matched the gender propagated from the vicinity and those for whom there was a mismatch. Thus Table 4 presents the same results as Table 3 but separated for these

two groups of users. It also gives user counts w.r.t. the profile gender.

	Acc%	P%	R%	F1	Total
all (same)	94	-	-	-	557K
fem (same)	-	89	87	88	147K
male (same)	-	95	96	96	410K
all (diff)	47	-	-	-	62K
fem (diff)	-	54	39	45	35K
male (diff)	-	42	56	48	27K

Table 4: Results for users whose profile gender matches/differs from the vicinity gender.

**Enhanced training set.** In the next experiment we refined the training set by removing all the users whose vicinity gender did not match the gender reported in the profile. The evaluation was done on the unmodified set (Table 5). The predictions made by the model trained on a refined set of users turned out to be slightly less accurate than those made by the model trained on the full training set (Table 3). The refined model performed slightly ( $< 1\%$ ) better than the starting one on the users whose vicinity and the profile genders matched but got very poor results on the users with a gender mismatch, the accuracy being as low as 37%. The accuracy of the starting model on those users is 47% (Table 4).

	Acc%	P%	R%	F1
all	88	-	-	-
fem	-	83	76	79
male	-	90	94	92

Table 5: Results of the models trained on the refined training set.

In another experiment we extended the training data with the users whose gender was unknown but was predicted with the propagation method. However, a larger training set makes a difference only if there is a substantial performance gain over the increasing size of the training set. We observed only a minor gain in performance ( $< 1\%$ ) when the training data size was increased by an order of magnitude. Given that, it is not surprising that adding 12% did not affect the results.

### Language, the vicinity and the profile genders.

The gap in accuracies of predictions for the two user groups in Table 4 is remarkable: 47% vs. 94%. If we extrapolate what we observe in the affiliation graph to other online and offline life, then this result may suggest that gender traits are more prominent in the language of people spending more time with the people of their gender than in that of the people who spend more time with the people of the opposite gender. Given the remarkable difference, a further question arises whether the classifier actually learns to predict a kind of socially rather than the profile gender. To investigate this, we looked at the results of the model which knew nothing about the profile gender but was trained to predict the vicinity gender instead (Table 6). This model relied on the exact same set of features but both for training and testing it used the gender labels obtained from the propagation procedure described in Section 5.

	Acc%	P%	R%	F1
all	91	-	-	-
fem	-	86	80	83
male	-	92	95	94

Table 6: Results of the models trained and tested on the propagated gender.

According to all the evaluation metrics, for both genders the performance of the classifier trained and tested on the propagated gender is higher (cf. Table 3): the differences in f-measure for female and male are four and two points respectively, both statistically significant. This indicates that it is the predominant *environment* gender that a language-based classifier is better at learning rather than the inborn gender.

**Predictions across age groups.** Finally, to address the question of whether gender differences are more prominent and thus easier to identify in the language of younger people, we looked at the accuracy of gender predictions across three age groups. Table 7 summarizes the results and gives the accuracy of the all male baseline as well as of the propagation procedure (*Prop-acc*). Although the overall accuracy over the three groups does not degrade much, from 89% to 87%, both precision and recall do decrease significantly for females. This is not

directly reflected in the accuracy because the number of females drops dramatically from 42% among teenagers to 26% and then 21% in the latter groups. For a comparison, the accuracy of the propagated gender (*Prop-acc*) also decreases from younger to older age groups although it is slightly higher than that of language-based predictions. One conclusion we can make at this point is that a teenager’s gender is easier to predict from the language which is in line with the hypothesis that younger people signalize their gender identities more than older people. Another observation is that, as the person gets older, we can be less sure about her gender by looking at her social environment. This in turn might be an explanation of why there are less gender signals in the language of a person: the environment becomes more mixed, and the influence of both genders becomes more balanced.

	13-19	20-29	30+	Overall
Base-acc%	58	74	79	70
Prop-acc%	91	90	88	90
Accuracy%	89	89	87	89
Fem-P%	87	81	74	83
Fem-R%	87	76	62	78
Fem-F1	87	78	68	80
Male-P%	90	92	90	91
Male-R%	90	94	94	94
Male-F1	90	93	92	93

Table 7: Results across the age groups.

## 7 Conclusions

In our study we addressed the gender prediction task from two perspectives: (1) the social one where we looked at an affiliation graph of users and videos and propagated gender information between users, and (2) the language one where we trained a classifier on features which have been claimed to be indicative of gender. We demonstrated that both perspectives provide us with comparably accurate predictions (around 90%) but that they are far from being independent. We also investigated a few ways of how the performance of a language-based classifier can be enhanced by the social aspect, compared the accuracy of predictions across different age groups

and found support for hypotheses made in earlier sociolinguistic studies.

We are not the first to predict gender from language features with online data. However, to our knowledge, we are the first to contrast the two views, social and language-based, using online data and to question whether there is a clear understanding of what gender classifiers actually learn to predict from language. Our results indicate that from the standard language cues we are better at predicting a social gender, that is the gender defined by the environment of a person, rather than the inborn gender.

The theoretical significance of this result is that it provides support for the usage-based view on language (Bybee, 2010), namely that the person’s language is largely shaped by the interactions with her social environment. On the practical side, it may have implications for targeted advertisement as it enriches the understanding of what gender classifiers predict.

**Acknowledgements:** I am thankful to Enrique Alfonso, Keith Hall and the EMNLP reviewers for their feedback.

## Abstract

The question “how predictable is English?” has long fascinated researchers. While prior work has focused on formal English typically used in news articles, we turn to texts generated by users in online settings that are more informal in nature. We are motivated by a novel application scenario: given the difficulty of typing on mobile devices, can we help reduce typing effort with message completion, especially in conversational settings? We propose a method for automatic response completion. Our approach models both the language used in responses and the specific context provided by the original message. Our experimental results on a large-scale dataset show that both components help reduce typing effort. We also perform an information-theoretic study in this setting and examine the entropy of user-generated content, especially in conversational scenarios, to better understand predictability of user generated English.

## 1 Introduction

How predictable is language? As early as 1951, long before large quantities of texts (or the means to process them) were easily available, Shannon had raised this question and proceeded to answer it with a set of clever analytical estimations. He studied the predictability of printed English, or “how well can the next letter of a text be predicted when the preceding  $N$  letters are known” (Shannon, 1951). This was quantified as the conditional entropy, which measures the amount of information conveyed from statistics over the preceding *context*. In this paper, we discuss a novel application setting which mirrors the predictability study as defined by Shannon.

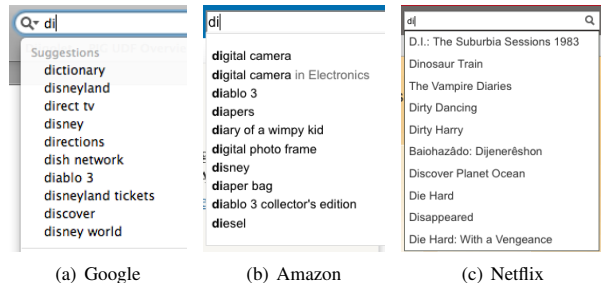

Figure 1: Query completion as users type into the “Search using Google” box on a browser, as well as the search box in Amazon and Netflix.

**Text completion for user-generated texts:** Consider a user who is chatting with her contact or posting to a social media site using a mobile device. If we can predict the next word given the preceding words that were already typed in, we can help reduce the typing cost by offering users suggestions of possible completions of their partially typed messages (e.g., in a drop-down list). If the intended word is ranked reasonably high, the user can select the word instead of typing it. Assuming a lower cost associated with selections, this could lead to less typing effort for the user.

An interface like this would be quite familiar to Web users today. Providing suggestions of possible completions to partially typed queries, which we will refer to as *query completion*,<sup>1</sup> is a common feature of search boxes (Figure 1). In spite of the similarity in the interface, the underlying technical challenge can be quite different. Query completion does not necessarily rely on language models: can-

<sup>1</sup>Note that this feature is often tagged as “query suggestion” in the user interface; we avoid that terminology since it is often used to refer to query re-formulation (of a completely entered query) in the literature, which is a very different task.

didate completions can be limited to popular queries that were previously submitted to the site or entries in a closed database of available objects, and ranking can be done by overall popularity. In contrast, our scenario requires generation of unseen texts.

Given the difficulty of generating full-length text, we consider a more realistic setting, where we perform completion on a word-by-word basis. Each time, we propose candidate completions at the word-level when the user is about to start a new word, or has partially entered the first few letters; once this word is successfully completed, we move on to the next one. This predict-verify-predict process exactly mirrors the human experiment described by Shannon (1951), except we do this at the word-level rather than the letter-level: having the user examine and verify predictions at the letter level would not be a practical solution for the intended application.

**The response completion task:** In addition, our task has another interesting difference from Shannon’s human experiment. Consider the mobile-device user mentioned previously. If the user is *replying* to a piece of text (e.g., an instant message sent by a contact), we have an additional source of contextual information in the *stimulus*, or the text which triggered the *response* that the user is trying to type. Can we learn from previously observed stimulus-response pairs (which we will refer to as *exchanges*)? That is, can we take advantage of this conversational setting and effectively use the information provided by stimulus to better predict the next word in the response? We refer to this task as the *response completion* task.

Our task is different from “chatter-bots” (Weizenbaum, 1966), where the goal is to generate a response to an input that would resemble a human conversation partner. Instead, we want to complete a response as the replier intends to. Recently, Ritter et. al (2011) experimented with automatic response generation in social media. They had a similar conversational setting, but instead of completion based on partial input, they attempted to generate a response in its entirety given only the stimulus. While many of the generated responses are deemed possible replies to the stimulus, they have a low chance of actually matching the real response given by the user: they reported BLEU scores between 0 and 2

for various systems. This clearly shows the difficulty of the task. While we are addressing a more modest setting, would the problem prove to be too difficult even in this case?

In this paper, we propose a method for automatic response completion. Our approach models the generic language used in responses, as well as the contextual information provided by the stimulus. We construct a large-scale dataset of user-generated textual exchanges, and our experimental results show that both components help reduce typing effort. In addition, to better understand predictability of user generated English, we perform an information-theoretic study in this conversational setting to investigate the entropy of user-generated content.

## 2 Related work

There has been previous work in the area of human-computer interaction that examined text entry for mobile devices (MacKenzie and Soukoreff, 2002). In particular, one line of work looked into *predictive text input*, which examined input effort reduction by language prediction. Previous work in predictive text input had very different focus from our study. Oftentimes, the focus was to model actual typing efforts using mobile device keypads, examine the speed and cognitive load of different input methods, and evaluate with empirical user studies in lab settings (James and Reischel, 2001; How and Kan, 2005), where the underlying technique for language prediction can be as simple as unigram frequency (James and Reischel, 2001), or restricted to narrow domains such as grocery shopping lists (Nurmi et al., 2009). In addition, to the best of our knowledge, no previous work in predictive text input addressed the conversational setting.

As discussed in Section 1, the response generation task (Ritter et al., 2011) also considered the conversational setting, but the MT-based technique was not well-suited to produce responses as intended by the user. There has been extensive previous research in language modeling (Rosenfeld, 2000). While previous work has explored Web text sources that are “better matched to a conversational speaking style” (Bulyko et al., 2003), we are not aware of much previous work that has taken advantage of information in the stimulus for word predictions in responses.

Previous work on entropy of language stems from the field of information theory (Shannon, 1948), starting with Shannon (1951). An extensive bibliography covering early related work (e.g., insights into the structure of language via information theory, entropy estimates via other techniques and/or for different languages, as well as a broad range of applications of such estimates) can be found in (Cover and King, 1978). More recently, Brown et. al (1992) computed an upper bound for the entropy of English with a trigram model, using the Brown corpus. Some other related works on this topic include (Teahan and Cleary, 1996; Moradi et al., 1998). There was also a recent study using entropy in the context of Web search (Mei and Church, 2008). In other settings, entropy has also been employed as a tool for studying the linguistic properties of ancient scripts (e.g., Indus Script) (Rao et al., 2009). While this seems like an interesting application of information theory for linguistic studies, it has also generated some controversies (Farmer et al., 2004).

In contrast, our work departs from traditional scenarios significantly. We perform entropy studies over texts generated in online settings which are more informal in nature. Additionally, we utilize the properties of language predictability within a novel application for automatically completing responses in conversational settings. Also, in our case we do not have to worry about issues like “*is this a language or not?*” because we work with real English news data which include articles written by professional editors and comments generated by users reading those articles.

### 3 Model

In this section, we first state our problem more formally, followed by descriptions of the basic  $N$ -gram language model we use, as well as two approaches that model both stimulus and preceding words in response as the context for the next-word generation. Given the intended application, we hope to achieve better prediction without incurring significant increase in model size.

#### 3.1 Problem definition

Consider a stimulus-response pair, where the stimulus is a sequence of tokens  $\mathbf{s} = (s_1, s_2, \dots, s_m)$ ,

and the response is a sequence of tokens  $\mathbf{r} = (r_1, r_2, \dots, r_n)$ . Let  $\mathbf{r}_{1..i} = (r_1, r_2, \dots, r_i)$ , our task is to generate and rank candidates for  $r_{i+1}$  given  $\mathbf{s}$  and  $\mathbf{r}_{1..i}$ .

Note the models described in this section do not assume any knowledge of partial input for  $r_{i+1}$ . For the setting where the first  $c$  characters of  $r_{i+1}$  were also entered, we can restrict the candidate list to the subset with the matching prefix, and use the same ranking function.

#### 3.2 Generic Response Language Model

First, we consider an  $N$ -gram language model trained on all responses in the training data as our generic response language model. Here we consider  $N = 3$ . Normally, trigram models use back-off to both bigrams and unigrams; in order to compare the effectiveness of trigram models vs. bigram models under comparable model size, we use back-off only to unigrams in both cases:

$$\begin{aligned} \text{trigram: } P(r_{i+1} | \mathbf{r}_{1..i}) &= \lambda_1 * P_3(r_{i+1} | r_i, r_{i-1}) \\ &\quad + (1 - \lambda_1) * P_1(r_{i+1}) \end{aligned}$$

$$\begin{aligned} \text{bigram: } P(r_{i+1} | \mathbf{r}_{1..i}) &= \lambda_1 * P_2(r_{i+1} | r_i) \\ &\quad + (1 - \lambda_1) * P_1(r_{i+1}) \end{aligned}$$

If we ignore the context provided by texts in the stimulus, we can simply generate and rank candidate words from the dictionary according to the generic response LM:  $P(r_{i+1} | \mathbf{r}_{1..i})$ .

As we will discuss in more detail in Section 6.2, modeling  $\mathbf{s}$  and  $\mathbf{r}_{1..i}$  jointly in the prediction of  $r_{i+1}$  would be rather expensive. In the following sections, we follow two main approaches to break this down into separate components:  $P(r_{i+1} | \mathbf{r}_{1..i})$  and  $P(r_{i+1} | \mathbf{s})$ , and model each one separately.

#### 3.3 Translating Stimuli to Responses

As mentioned in Section 1, Ritter et. al (2011) have considered a related task of generating a response in its entirety given only the text in the stimulus. They cast the problem as a translation task, where the stimulus is considered as the source language and the response is considered as the target language. We can adapt this approach for our response completion task.

Consider the noisy channel model used in statistical machine translation:  $P(\mathbf{r}|\mathbf{s}) \propto P(\mathbf{r}) * P(\mathbf{s}|\mathbf{r})$ . In

order to predict  $r_{i+1}$  given  $\mathbf{r}_{1..i}$  and  $\mathbf{s}$ , for each candidate  $r_{i+1}$ , in principle one can marginalize over all possible completions of  $\mathbf{r}_{1..i+1}$ , and rank candidate  $r_{i+1}$  by that. That is, let  $P(n)$  be the distribution of response length, let  $\mathbf{r}'$  be a possible completion of  $\mathbf{r}_{1..i+1}$  (i.e., a response whose first  $i + 1$  tokens match  $\mathbf{r}_{1..i+1}$ ). For each possible  $n > i$ , we need to marginalize over all possible  $\mathbf{r}'$  of length  $n$ , and rank  $r_{i+1}$  according to

$$P(\mathbf{r}_{1..i+1} | \mathbf{s}) = \sum_{n>i} P(n) \cdot \sum_{|\mathbf{r}'|=n} P(\mathbf{r}' | \mathbf{s})$$

Clearly this will be computationally expensive. Instead, we take a greedy approach, and choose  $r_{i+1}$  which yields the optimal partial response (without looking ahead):

$$P(\mathbf{r}_{1..i+1} | \mathbf{s}) \propto P(\mathbf{r}_{1..i+1}) * P(\mathbf{s} | \mathbf{r}_{1..i+1})$$

which is equivalent to ranking candidate  $r_{i+1}$  by

$$P(r_{i+1} | \mathbf{r}_{1..i}) * P(\mathbf{s} | \mathbf{r}_{1..i+1}) \quad (1)$$

Since the first component is our LM model, and the second component is a translation model, we denote this as the *LM+TM model*. We use IBM Model-1 to learn the translation table on the training data. At test time, equal number of candidates are generated by each component, and combined to be ranked by Eq. 1.

### 3.4 Mixture Model

One potential concern over applying the translation model is that the response can often contain novel information not implied by the stimulus. While technically this could be generated from the so-called *null* token used in machine translation (added to the source text to account for target text with no clear alignment in the source text), significant amount of text corresponding to new information not in the source text is not what null tokens are meant to be capturing. In general, our problem here is a lack of clear word-to-word or phrase-to-phrase mapping in a stimulus-response pair, at least not what one would expect in clean parallel data.

Alternatively, one can model the response generation process with a mixture model: with probability  $\lambda_s$ , we generate a word according to a distribution

over  $\mathbf{s}$  ( $P(w | \mathbf{s})$ ), and with probability  $1 - \lambda_s$ , we generate a word using the response language model:

$$\begin{aligned} P(r_{i+1} | \mathbf{s}, \mathbf{r}_{1..i}) &= \lambda_s \cdot P(r_{i+1} | \mathbf{s}) \\ &+ (1 - \lambda_s) \cdot P(r_{i+1} | \mathbf{r}_{1..i}) \end{aligned} \quad (2)$$

We examine two concrete ways of exploiting the context provided by  $\mathbf{s}$ .

**Model 1 — LM + Selection model** First, we examine a very simple instantiation of  $P(w | \mathbf{s})$  where we select a token in  $\mathbf{s}$  uniformly at random. This is based on the intuition that to be semantically coherent, a reply often needs to repeat certain content words in the stimulus. (Similar intuition has been explored in the context of text coherency (Barzilay and Lapata, 2005).) This is particularly useful for words that are less frequently used: they may not be able to receive enough statistics to be promoted otherwise. More specifically,

$$P(r_{i+1} | \mathbf{s}) = \frac{\mathbf{1}_{r_{i+1} \in \mathbf{s}}}{|\mathbf{s}|}$$

We can take  $\lambda_s$  to be a constant  $\lambda_{select}$ , which can be estimated in the training data as the probability of a response token being a repetition of a token in the corresponding stimulus.

**Model 2 — LM + Topic model** Another way to incorporate information provided in  $\mathbf{s}$  is to use it to constrict the topic in  $\mathbf{r}$ . We can learn a topic model over conversations in the training data using Latent Dirichlet Allocation (LDA) (Blei et al., 2003). At test time, we identify the most likely topic of the conversation based on  $\mathbf{s}$ , and expect  $r_{i+1}$  to be generated from this topic. That is,

$$P(r_{i+1} | \mathbf{s}) = P(r_{i+1} | t^*)$$

$$\text{where } t^* = \operatorname{argmax}_t P(\text{topic} = t | \mathbf{s})$$

More specifically, we first train a topic model on  $(\mathbf{s}, \mathbf{r})$  pairs from the training data. Given a new stimulus  $\mathbf{s}$ , we then select the highest ranked topic as being representative of  $\mathbf{s}$ . Note that alternatively we could consider all possible topic assignments; in that case we would have had to sum probabilities over all topics, and that could also introduce noise. A similar strategy has been previously employed for

other topic modeling applications in information retrieval, where documents are smoothed with their highest ranked topic (Yi and Allan, 2009). We lower the weight  $\lambda_s$  if  $P(t^* | s)$  is low. That is, we use  $\lambda_s = \lambda_{topic} * P(t^* | s)$  in Eq. 2.

## 4 Data

In order to investigate text completion in a conversational setting, we need to construct a large-scale dataset with textual exchanges among users. An ideal dataset would have been a collection of instant messages, but these type of datasets are difficult to obtain given privacy concerns. To the best of our knowledge, existing SMS (short message service) datasets only contain isolated text spans and do not provide enough information to reconstruct the conversations. There are, however, a high volume of textual exchanges taking places in public forums. Many sites with a user comment environment allow other users to reply to existing comments, where the original comment and its reply can form a (stimulus, response) pair for our purposes.

To this end, we extracted (comment, reply) pairs from Yahoo! News<sup>2</sup>, where under each news article, a user can post a new comment or reply to an existing comment. In fact, a popular comment can have a long thread of replies where multi-party discussions take place. To ensure the reply is a direct response to the original comment, we took only the first reply to a comment, and consider the resulting pair as a textual exchange in the form of a (stimulus, response) pair. We gathered data from a period of 14 weeks between March and May, 2011. A random sample yielded a total of 1,487,995 exchanges, representing 237,040 unique users posting responses to stimuli comments authored by 357,811 users. In the raw dataset (i.e., before tokenization), stimuli average at 59 tokens (332 characters), and responses average at 26 tokens (144 characters).

We took the first 12 weeks of data as training data (1,269,732 exchanges) and the rest 2 weeks of data as test data (218,263 exchanges).

<sup>2</sup>Note that previous work has used a dataset with 1 million Twitter conversations extracted from a scraping of the site (Ritter et al., 2011), where a status update and its replies in Twitter form “conversations”. This dataset is no longer publicly available. At the time of this writing, we were not able to identify a data source to re-construct a dataset like that.

## 5 Experiments

### 5.1 Evaluation measures

**Recall@k** : Here, we follow a standard evaluation strategy used to assess ranking quality in information retrieval applications. For each word, we check if the correct answer is one of the top- $k$  tokens being suggested. We then compute the recall at different values of  $k$ . While this is a straight-forward measure to assess the overall quality of different top- $k$  lists, it is not tailored to suit our specific task of response completion. In particular, this measure (a) does not distinguish between (typing) savings for a short word versus a long one, and (b) does not distinguish between the correct answer being higher up in the list versus lower as long as the word is present in the top- $k$  list.

**TypRed** : Our main evaluation measure is based on “reduction in typing effort for a user of the system”, which is a more informative measure for our task. We estimate the typing reduction via a hypothetical typing model<sup>3</sup> in the following manner:

Suppose we show top  $k$  predictions for a given setting. Now, there are two possible scenarios:

1. if the user does not find the correct answer in the top- $k$  list, he/she gives up on this word and will have to type the entire word. The typing cost is then estimated to be the number of characters in the word  $l_w$ ;
2. if the user spots the correct answer in the list, the cost for choosing the word is proportional to the rank of the word  $rank_w$ , with a fixed cost ratio  $c_0$ . Suppose the user scrolls down the list using the down-arrow ( $\downarrow$ ) to reach the intended word (instead of typing), then  $rank_w \cdot c_0$  reflects the scrolling effort required, where  $c_0$  is the relative cost of scrolling down versus typing a character.

In general, pressing a fixed key can have a lower cost than typing a new one, in addition, we can imagine a virtual keyboard where navigational keys occupy bigger real-estate, and thus incur less cost to press. As a result, it’s reasonable to assume  $c_0$  value that is smaller than 1. In all our experiments,  $c_0 = 0.5$  unless otherwise noted. Note that if the

<sup>3</sup>More accurate measures can be developed by observing user behavior in a lab setting. We leave this as future work.

System	TypRed ( $c = 0$ )	TypRed ( $c = 1$ )	TypRed ( $c = 2$ )
1. Generic Response LM (trigram)	15.10	22.57	14.29
2. Generic Response LM (trigram) + TM	9.03	17.53	11.56
3. Mixture Model 1: Generic Response LM (trigram) + Selection	<b>15.18*</b>	<b>23.43*</b>	<b>15.13*</b>
4. Mixture Model 2: Generic Response LM (trigram) + Topic Model	15.10	22.57	14.33

Table 1: Comparison of various prediction models (in terms of TypRed score @ rank 5) on all (stimulus,response) pairs from a large test collection (218,263 exchanges) when the first  $c$  characters of each word are typed in by the user. A higher score indicates better performance. \* indicates statistical significance ( $p < 0.05$ ) over the baseline score.

typing model assumes a user selects the intended word using an interface that is similar to a mousing device, the cost may increase with  $rank_w$  at a sub-linear rate; in that case, our measure will be over-estimating the cost.

In order to have a consistent measure that always improves as the ranking improves, we assume a clever user who will choose to finish the word by typing or by selecting, depending on which cost is lower. Combining these two cases under the clever-user model, we estimate the reduction in typing cost for every word as follows:

$$TypRed(w, rank_w) = 100 \cdot \left[ 1 - \frac{\min(l_w, rank_w \cdot c_0)}{l_w} \right]$$

where  $w$  is the correct word,  $l_w$  is the length of  $w$ , and  $rank_w$  is the rank of  $w$  in the top- $k$  list. A higher value of TypRed implies higher savings achieved in typing cost and thereby better prediction performance.

## 5.2 Experimental setup

We run experiments using the models described in Section 3 under two different settings: (1) *previous words* from the response are provided, and (2) *previous words from response + first  $c$  characters of the current word* are provided.

During the candidate generation phase, for every position in the response message we present the top 1,000 candidates (as scored by the generic response language model or mixture models). We reserve a small subset of ( $\sim 1,000$ ) exchanges as development data for tuning parameters from our models.

For the generic response language models, we set the interpolation weight  $\lambda_1 = 0.9$ . For the selection-based mixture model, we estimate the mixture weights on the training data and set  $\lambda_{select}$

(0.09). For the topic-based mixture model, we ran a grid search with different parameter settings for  $\lambda_{topic}$  on the held-out development set and chose the value (0.01) that gave the best performance (in terms of TypRed).

## 5.3 Results

**Previous words from response observed:** We first present results for the setting where only previous words from the response are provided as context. We use TypRed scores as our evaluation measure here (higher TypRed implies more savings in typing effort). Even with a unigram LM we achieve a small but non-negligible reduction (TypRed=2.15) in the typing cost. But a bigram LM significantly improves performance (TypRed=11.91), and with trigram LM we observe even better performance (TypRed=15.10). Since the trigram LM yields a high performance, we set this as our default LM for all other models.

Recall that in all experiments, we set  $c_0$ , the cost ratio of selecting a candidate from the ranked top- $k$  list (via scrolling) versus typing a character to a value of 0.5. But we also experimented with a hypothetical setting where  $c_0 = 1$  and noticed that the trigram LM achieves a slightly lower but still significant typing reduction (TypRed score of 9.58 versus 15.10 for the earlier case).

The first column of Table 1 ( $c = 0$ ) compares the performance of other models for this setting. We find that adding a translation model (LM+TM) does not help for this task; in fact, it results in lower scores than using the LM alone. This suggests that a translation-based generative approach may not be suitable, if the goal is to predict text as intended by the user. This is consistent with previous observations on a related task (Ritter et al., 2011), as we

discussed in Section 1.

In contrast, the mixture models do much better. In fact, LM+Selection model produces better results than trigram LM alone. We also note that estimating the mixture parameter on the training data rather than using a fixed value increases TypRed scores: 14.02 with a fixed  $\lambda_{select} = 0.5$  versus 15.18 with  $\lambda_{select}^* = 0.09$ . This comparison also holds for  $c > 0$  — that is, a naive version of LM+Selection that selects a word from the stimulus whenever the prefix allows would not have worked well.

In principle the LM+Topic model is potentially more powerful in that  $P(w | s)$  is not limited to the words in  $s$ . However, in our experiments it does not yield any considerable improvement over the original LM. We postulate that this could be due to the following reason: once the context provided by  $s$  is reduced to the topic level, it is not specific enough to provide additional information over preceding words in the response.

**Previous words from response + first  $c$  characters of current word observed:** Table 1 also compares the TypRed performance of all the models under settings where  $c > 0$ . We notice striking improvements in performance for  $c = 1$  which is consistent across all models. Our best model is able to save the user approximately 23% in terms of typing effort (according to TypRed scores). Interestingly a lot less reduction was observed for  $c = 2$ : the second character, on average, does not improve the ranking enough to justify the cost of typing this extra character.

Next, we pick our best model (Mixture Model 1) and perform some further analysis. We examine the effect of providing longer list (shown in Table 2) and notice little further improvement beyond  $k = 10$ . We also note that the TypRed improvement achieved over the baseline (LM) model at rank 10 is more than twice the gain achieved at rank 5.

We also evaluated its performance using a standard measure (Recall@k). Figure 2 plots the recall achieved by the system at different ranks  $k$ . An increasing recall at even high ranks ( $k = 100$ ) suggests that the quality of the candidate list retrieved by this model is good. This also suggests that there is still room for improvements, and we leave that as interesting future work.

Rank ( $k$ )	TypRed score
1	9.02
5	15.18
10	16.14
15	16.28
20	16.29
25	16.29

Table 2: Comparison of typing reductions achieved over the entire test data when top  $k$  list is provided to the user.

Figure 2: Recall @ rank  $k$  for Mixture Model 1 on the entire test data.

Figure 3: Average TypRed score versus Word length (# of characters) for Mixture Model 1 when the first  $c$  characters of the word is typed in by the user.

Finally, in Figure 3, we plot the average TypRed scores against individual token (word) length. Figure 3 indicates that the model is able to achieve a higher reduction for shorter words compared to very long ones. This demonstrates the utility of such a response completion system, especially since shorter words are predominant in conversational settings. We also compared the average reduction achieved on messages of different lengths (number of words). Overall we observe consistent reduction for different message lengths. This suggests our system can

be useful for both Tweet-like short messages as well as more lengthy exchanges in detailed discussions.

## 5.4 Discussion

Table 3 displays some sample translations learned using the TM model described in Section 3.3. Interestingly, emoticons and informal expressions like :) or lmao in the stimulus tend to evoke similar type of expressions in the response (as seen in Table 3). Some translations (e.g., *feeling* → *better*) are indicative of question/answer type of exchanges in our data. But most of the other translations are noisy or uninformative (e.g., *Are* → *.*). This provides further evidence as to why a translation-based approach is not well suited for this particular task and hence does not perform as well as other methods.

Finally, in Table 4, we provide a few sample topics generated by the LDA topic model (which is used by Mixture Model 2 described in Section 3.4). We find that while a few topics display some semantic coherence (e.g., political figures), many of them are noisy (or too generic) which further supports our earlier observation that they are not useful enough to help in the prediction task.

## 6 Entropy of user comments

We adapt the notion of predictability of English as examined by Shannon (1951) from letter-prediction to token-prediction, and define the predictability of

English as how well can the next token be predicted when the preceding  $N$  tokens are known. How much does the immediate context in the response help reduce the uncertainty? How does user-generated content compare with more formal English in this respect? And how about the corresponding stimuli — given the preceding  $N$  tokens, does the knowledge of stimulus further reduce the uncertainty? These questions motivated a series of studies over entropy in different datasets.<sup>4</sup>

### 6.1 Comparison of $N$ -gram entropy

Following Shannon (1951), we consider the following function  $F_N$ , which can be called the  $N$ -gram entropy, as the measure of predictability:

$$F_N = - \sum_{i,j} p(b_i, j) \log_2 p(j | b_i)$$

where  $b_i$  is a block of  $N - 1$  tokens,  $j$  is an arbitrary token following  $b_i$ , and  $p(j | b_i)$  is the conditional probability of  $j$  given  $b_i$ . This conditional entropy reflects how much is the uncertainty of the next token reduced by knowing the preceding  $N - 1$  tokens.

Under this measure, is user-generated content more predictable or less predictable than the more formal “printed” English examined by Shannon? Maybe it is more predictable, since most users in informal settings use simpler English, which may contain fewer variations than the complex structures observed in more formal English. Or perhaps it is less predictable — variations among different users (who may not follow proper grammar) may lead to more uncertainty in the prediction of “the next word”. Which would be the case?

To answer this question empirically, we construct a reference dataset written in more formal English ( $D_f$ ) to be compared against the user comments dataset described in Section 4 ( $D_u$ ). If  $D_f$  covers very different topics from  $D_u$ , then even if we do observe differences in entropy, it could be due to topical differences. A standard mixed-topic dataset like

<sup>4</sup>Note that our findings are not to be interpreted as prediction performance over unseen texts. For that, one needs to compute cross-entropy between training and test corpora. Since Section 5 is already addressing this question with proper training / test split, in this section, we focus on the variability of language usage in a corpus. This also avoids having to control for “comparable” training/test splits in different types of datasets.

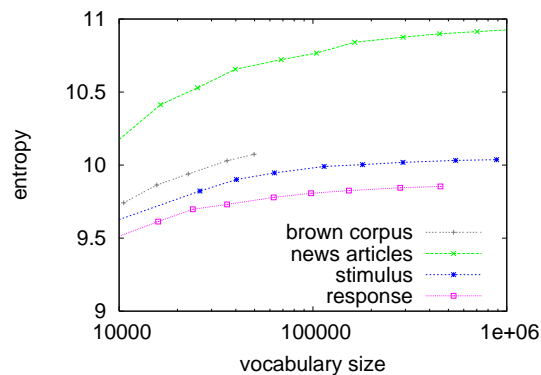

the Brown Corpus (Kucera and Francis, 1967) may not be ideal in this sense (e.g., it contains fiction categories such as “Romance and Love Story”, which may not be represented in our  $D_u$ ). Instead, we obtained a sample of news articles on Yahoo! News during March - May, 2011, and extracted unique sentences from these articles. This yields a  $D_f$  with more comparable subject matters to  $D_u$ .<sup>5</sup>

Next, we compare both the entropy over unigrams and  $N$ -gram entropy in three datasets: the news article dataset described above, and comments data (Section 4) separated into stimuli and responses. We also report corresponding numbers computed on the Brown Corpus as references. Note that datasets with different vocabulary size can lead to different entropy: the entropy of picking a word from the vocabulary uniformly at random would have been different. Thus, we sample each dataset at different rates, and plot the (conditional) entropy in the sample against the corresponding vocabulary size.

As shown in Figure 4(a), the entropy of unigrams in  $D_u$  (both stimuli and responses) is consistently lower than in  $D_f$ .<sup>6</sup> On the other hand, both stimuli and responses exhibit higher uncertainty in bigram entropy (Figure 4(b)) and trigram entropy (Figure 4(c)). That is, when no contexts are provided, word choices (from similarly-sized vocabularies) in  $D_f$  is more evenly distributed than in  $D_u$ ; but once the preceding words are given, the next word is more predictable in  $D_f$  than in  $D_u$ . We postulate that the difference in unigram entropy could be due to (a) more balanced topic coverage in  $D_f$  vs. more skewed topic coverage in  $D_u$ , or (b) professional reporters mastering a more balanced use of the vocabulary. If (b) is the main reason, however, the lower trigram entropy in  $D_f$  would seem unexpected — shouldn’t professional journalists also have a more balanced use of different phrases? Upon further contemplation, what we hypothesized earlier could be true: professional writers use the “proper” English expected in news coverage, which could limit

<sup>5</sup>We note that this does not guarantee the exact same topic distribution as in the comment data.

<sup>6</sup>For reference, Shannon (1951) estimated the entropy of English to be 11.82 bits per word, due to an incorrect calculation of a 8727-word vocabulary given Zipf distribution. The correct number should be 9.27 bits per word for a vocabulary size of 12,366 (Yavuz, 1978).

their trigram uncertainties; on the other hand, users are not bound by conventions (or even grammars), which could lead to higher variations.

Interestingly, distributions in the stimulus dataset are closer to news articles: they have a higher unigram entropy than responses, but a lower trigram entropy at comparable vocabulary sizes. In particular, recall from Section 4 that our comments dataset contains roughly 237K repliers and 357K original com-

Figure 5: Predicting the next word in responses: bigram entropy vs. bigram+stimulus entropy vs. trigram entropy.

menters. If higher trigram entropy is due to variance among different users, the stimulus dataset should have had a higher trigram entropy. We leave an explanation of this interesting behavior as future work.

## 6.2 Information in stimuli

We now examine the next question: does knowing words in the stimulus further reduce the uncertainty of the next word in the response? For simplicity, we model the stimulus as a collection of unigrams. Consider the following conditional entropy:

$$G_N = - \sum_{i,k,j} p(b_i, j, s_k) \log_2 p(j | b_i, s_k)$$

where  $b_i$  is a block of  $N - 1$  tokens in a response  $\mathbf{r}$ ,  $j$  is an arbitrary token following  $b_i$ , and  $s_k$  is an arbitrary token in the corresponding stimulus  $\mathbf{s}$  for  $\mathbf{r}$ . Note that for each  $b_i$ , we consider every token in the corresponding  $\mathbf{s}$ . That is, a (stimulus, response) pair with  $m$  and  $n$  tokens respectively generates  $m * (n - N + 1)$  observations of  $(b_i, j, s_k)$  tuples. We refer to this as the  $N$ -gram+stimulus entropy. If knowing  $s_k$  in addition to  $b_i$  does not provide extra information, then  $p(j | b_i, s_k) = p(j | b_i)$ , and  $G_N = F_N$ .

Figure 5 plots  $G_N$  for  $N = 2$ . Interestingly, we observe  $F_2 > G_2 > F_3$  (this trend holds for larger values of  $N$ , omitted here for clarity). That is, knowing both the preceding  $N - 1$  tokens and tokens in the stimulus results lowers the uncertainty over the next token in response (bigram+stimulus entropy < bigram entropy); on the other hand, this is not as effective as knowing one more token in the preceding block (trigram entropy < bigram+stimulus entropy).

Note that from the model size perspective, modeling  $p(j | b_i, s_k)$  as in  $G_N$  would have been much

more expensive than  $p(j | b_i)$  in  $F_{N+1}$ . Take the case of  $G_2$  vs.  $F_3$ . Let  $V$  be the vocabulary of user comments (ignore for now differences in responses and stimuli). While both seem to require computations over  $V \times V \times V$ , the number of unique observed  $(b_i, j, s_k)$  tuples for  $G_2$  (i.e., number of unique bigrams in responses paired up with unigrams in corresponding stimuli) is 725,458,892, whereas the number of unique observed  $(b_i, j)$  pairs for  $F_3$  (i.e., number of unique trigrams) is only 14,692,952. This means modeling trigrams would result in a model 2% the size of bigram+stimulus, yet it could achieve better reduction in uncertainty.

Note that in order to reduce model complexity, the models proposed in Section 3 all broke down  $P(r_{i+1} | \mathbf{s}, \mathbf{r}_{1..i})$  into independent components  $P(r_{i+1} | \mathbf{s})$  and  $P(r_{i+1} | \mathbf{r}_{1..i})$ , rather than modeling the effect of  $\mathbf{s}$  and  $\mathbf{r}_{1..i}$  jointly as the underlying model corresponding to  $G_N$ . Indeed, it would have been impractical to model  $p(j | b_i, s_k)$  directly. Our studies confirmed the validity of this choice: even if we look at the performance on the training data itself (i.e., ignoring data sparseness issues), the smaller trigram model would have yielded better results than the significantly more expensive bigram+stimulus model. Still, since  $G_N$  shows a consistent improvement over  $F_N$ , there could be more information in the stimulus that we are not yet fully utilizing, which can be interesting future work.

## 7 Conclusions

In this paper, we examined a novel application: automatic response completion in conversational settings. We investigated the effectiveness of several models that incorporate contextual information provided by the partially typed response as well as the stimulus. We found that the partially typed response provides strong signals. In addition, using a mixture model which also incorporates stimulus content yielded the best overall result. We also performed empirical studies to examine the predictability of user-generated content. Our analysis (entropy estimates along with upper-bound numbers observed from experiments) suggest that there can be interesting future work to explore the contextual information provided by the stimulus more effectively and further improve the response completion task.

## Abstract

The geographical properties of words have recently begun to be exploited for geolocating documents based solely on their text, often in the context of social media and online content. One common approach for geolocating texts is rooted in information retrieval. Given training documents labeled with latitude/longitude coordinates, a grid is overlaid on the Earth and *pseudo-documents* constructed by concatenating the documents within a given grid cell; then a location for a test document is chosen based on the most similar pseudo-document. Uniform grids are normally used, but they are sensitive to the dispersion of documents over the earth. We define an alternative grid construction using *k*-d trees that more robustly adapts to data, especially with larger training sets. We also provide a better way of choosing the locations for pseudo-documents. We evaluate these strategies on existing Wikipedia and Twitter corpora, as well as a new, larger Twitter corpus. The adaptive grid achieves competitive results with a uniform grid on small training sets and outperforms it on the large Twitter corpus. The two grid constructions can also be combined to produce consistently strong results across all training sets.

## 1 Introduction

The growth of the Internet in recent years has provided unparalleled access to informational resources. It is often desirable to extract summary metadata from such resources, such as the date of writing or the location of the author – yet only a small portion of available documents are explicitly annotated in this fashion. With sufficient training

data, however, it is often possible to infer this information directly from a document’s text. For example, clues to the geographic location of a document may come from a variety of word features, e.g. toponyms (*Toronto*), geographic features (*mountain*), culturally local features (*hockey*), and stylistic or dialectical differences (*cool* vs. *kewl* vs. *kool*).

This article focuses on text-based document geolocation, the prediction of the latitude and longitude of a document. Among the uses for this are region-based search engines; tracing the sources of historical documents; location attribution while summarizing large documents; tailoring of ads while browsing; phishing detection when a user account is accessed from an unexpected location; and “activist mapping” (Cobarrubias, 2009), as in the Ushahidi project.<sup>1</sup> Geolocation has also been used as a feature in automatic news story identification systems (Sankaranarayanan et al., 2009).

One of the first works on document geolocation is Ding et al. (2000), who attempt to automatically determine the geographic scope of web pages. They focus on named locations, e.g. cities and states, found in gazetteers. Locations are predicted based on toponym detection and heuristic resolution algorithms. A related, recent effort is Cheng et al. (2010), who geolocate Twitter users by resolving their profile locations against a gazetteer of U.S. cities and training a classifier to identify geographically local words.

An alternative to using a discrete set of locations from a gazetteer is to use information retrieval (IR) techniques on a set of geolocated training documents. A new test document is compared with each

<sup>1</sup><http://ushahidi.com/>

training document and a location chosen based on the location(s) of the most similar training document(s). For image geolocation, Chen and Grauman (2011) perform mean-shift clustering over training images to discretize locations, then estimate a test image’s location with weighted voting from the  $k$  most similar documents. For text, both Serdyukov et al. (2009) and Wing and Baldrige (2011) use a similar approach, but compute document similarity based on language models rather than image features. Additionally, they group documents via a uniform geodesic grid rather than a clustered set of locations. This reduces the number of similarity computations and removes the need to perform location clustering altogether, but introduces a new parameter controlling the granularity of the grid. Kinsella et al. (2011) predict the locations of tweets and users by comparing text in tweets to language models associated with zip codes and broader geopolitical enclosures. Sadilek et al. (2012) discretize by simply clustering data points within a small distance threshold, but only perform geolocation within fixed city limits.

While the above approaches discretize the continuous surface of the earth, Eisenstein et al. (2010) predict locations based on Gaussian distributions over the earth’s surface as part of a hierarchical Bayesian model. This model has many advantages (e.g. the ability to compute a complete probability distribution over locations), but we suspect it will be difficult to scale up to the large document collections needed for high accuracy.

We build on the IR approach with grids while addressing some of the shortcomings of a uniform grid. Uniform grids are problematic in that they ignore the geographic dispersion of documents and forgo the possibility of greater-granularity geographic resolution in document-rich areas. Instead, we construct a grid using a  $k$ -d tree, which adapts to the size of the training set and the geographic dispersion of the documents it contains. This can better benefit from more data, since it enables the training set to support more pseudo-documents when there is sufficient evidence to do so, while still ensuring that all pseudo-documents contain comparable amounts of data. It also has the desirable property of generally requiring fewer active cells than a uniform grid, drastically reducing the computation time required to label a test

document.

We show that consistently strong results, robust across both Wikipedia and Twitter datasets, are obtained from the union of the pseudo-documents from a uniform and adaptive grid. In addition, a simple difference in the choice of location for a given grid cell – the centroid of the training documents in the cell, rather than the cell midpoint – results in across-the-board improvements. We also construct and evaluate on a much larger dataset of geolocated tweets than has been used in previous papers, demonstrating the scalability and robustness of our methods and confirming the ability of the adaptive grid to more effectively use larger datasets.

## 2 Data

We work with three datasets: a corpus of geotagged Wikipedia articles and two corpora of geotagged tweets.

**GEOWIKI** is a collection of 1,019,490 geotagged English articles from Wikipedia. The dump from Wikimedia requires significant processing to obtain article text and location, so we rely on the preprocessed data used by Wing and Baldrige (2011).

**GEOTEXT** is a small dataset consisting of 377,616 messages from 9,475 users tweeting across 48 American states, compiled by Eisenstein et al. (2010). A document in this dataset is the concatenation of all tweets by a single user, with a location derived from the earliest tweet with specific, GPS-assigned latitude/longitude coordinates.

**UTGEO2011** is a new dataset designed to address the sparsity problems resulting from the size of the previous dataset. It is based on 390 million tweets collected across the entire globe between September 4th and November 29th, 2011, using the publicly available Twitter Spritzer feed and global search API. Not all collected tweets were geotagged. To be comparable to GEOTEXT, we discarded tweets outside of North America (outside of the bounding box with latitude/longitude corners at (25, -126) and (49, -60)). Following Eisenstein et al. (2010), we consider all tweets of a user concatenated as a single document, and use the earliest collected GPS-assigned location as the gold location. Users without a gold location were discarded. To remove many spammers and

robots, we only kept users following 5 to 1000 people, followed by at least 5 users, and authoring no more than 1000 tweets in the three month period. The resulting dataset contains 38 million tweets from 449,694 users, or roughly 85 tweets per user on average. We randomly selected 10,000 users each for development and held-out test evaluation. The remaining 429,694 users serve as a training set termed **UTGEO2011-LARGE**. We also randomly selected a 10,000 user training subset (**UTGEO2011-SMALL**) to facilitate comparisons with GEOTEXT and allow us to investigate the relative improvements for different models with more training data.

Our code and the UTGEO2011 data set are both available for download.<sup>2</sup>

### 3 Model

Assume we have a collection  $\mathbf{d}$  of documents and their associated location labels  $\mathbf{l}$ . These documents may be actual texts, or they can be pseudo-documents comprised of a number of texts grouped via some algorithm (such as the grids discussed in the next section).

For a test document  $d_i$ , its similarity to each labeled document is computed, and the location of the most similar document assigned to  $d_i$ . Given an abstract function *sim* that can be instantiated with an appropriate similarity function (e.g. cosine distance or Kullback-Leibler divergence),

$$loc(d_i) = loc(\arg \max_{d_j \in \mathbf{d}} sim(d_i, d_j)).$$

This is a winner-takes-all strategy, which we follow in this paper. In related work on image geolocation, Hays and Efros (2008) use the same general framework, but compute the location based on the  $k$ -nearest neighbors (kNN) rather than the top one. They compute a distribution from the 120 nearest neighbors using mean shift clustering (Comaniciu and Meer, 2002) and choose the cluster with the most members. This produced slightly better results than choosing only the closest image. In future work, we will explore the kNN approach to see if it is more effective for text geolocation.

<sup>2</sup>[https://github.com/utcompling/textgrunder/wiki/RollerEtAl\\_EMNLP2012](https://github.com/utcompling/textgrunder/wiki/RollerEtAl_EMNLP2012)

Following previous work in document geolocation, particularly Serdyukov et al. (2009) (henceforth SMvZ) and Wing and Baldridge (2011) (henceforth W&B), we geolocate texts using a language modeling approach to information retrieval (Ponte and Croft, 1998; Zhai and Lafferty, 2001). For each document  $d_i$ , we construct a unigram probability distribution  $\theta_{d_i}$  over the vocabulary.

We smooth documents using the pseudo-Good-Turing method of W&B, a nonparametric discounting model that backs off from the unsmoothed distribution  $\tilde{\theta}_{d_i}$  of the document to the unsmoothed distribution  $\tilde{\theta}_D$  of all documents. A general discounting model is as follows:

$$P(w|\theta_{d_i}) = \begin{cases} (1 - \lambda_{d_i})P(w|\tilde{\theta}_{d_i}), & \text{if } P(w|\tilde{\theta}_{d_i}) > 0 \\ \lambda_{d_i} \frac{P(w|\tilde{\theta}_D)}{U_{d_i}}, & \text{otherwise,} \end{cases}$$

where  $U_{d_i} = 1 - \sum_{w \in d_i} P(w|\tilde{\theta}_D)$  is a normalization factor that is precomputed when the distribution for  $d_i$  is constructed. The discount factor  $\lambda_{d_i}$  indicates how much probability mass to reserve for unseen words. For pseudo-Good-Turing, it is

$$\lambda_{d_i} = \frac{|w \in d_i \text{ s.t. } \text{count}(w \in d_i) = 1|}{|w \in d_i|},$$

i.e. the fraction of words seen once in  $d_i$ .

We experimented with other smoothing methods, including Jelinek-Mercer and Dirichlet smoothing. A disadvantage of these latter two methods is that they have an additional tuning parameter to which their performance is highly sensitive, and even with optimal parameter settings neither consistently outperformed pseudo-Good-Turing. We also found no consistent improvement from using interpolation in place of backoff.

We also follow W&B in using Kullback-Leibler (KL) divergence as the similarity metric, since it outperformed both naive Bayes classification probability and cosine similarity:

$$KL(\theta_{d_i} || \theta_{d_j}) = \sum_k \theta_{d_i}(k) \log \frac{\theta_{d_i}(k)}{\theta_{d_j}(k)}.$$

The motivation for computing similarity with KL is that it is a measure of how well each document in the labeled set explains the word distribution found in the test document.

## 4 Collapsing Documents with an Adaptive Grid

In the previous section, we used the term “document” loosely when speaking of training documents. A simplistic approach might indeed involve comparing a test document to each training document. However, in the winner-takes-all model described above, we can rely only on the result of comparing with the single best training document, which may not contain enough information to make a good prediction.

A standard strategy to deal with this problem is to collapse groups of geographically nearby documents into larger pseudo-documents. This also has the advantage of reducing the computation time, as fewer training documents need to be compared against. Formally, this involves partitioning the training documents into a set of sets of documents  $G = \{g_1 \dots g_n\}$ . A collection  $\tilde{d}$  of pseudo-documents is formed from this set, such that the pseudo-document for a particular group  $g_i$  is simply the concatenation of the documents in the group:

$$\tilde{d}_{g_i} = \bigcup_{d_j \in g_i} d_j.$$

A location must be associated with each pseudo-document. This can be chosen based on the partitioning function itself or the locations of the documents in each group.

Both W&B and SMvZ use *uniform* grids consisting of cells of equal degree size to partition documents. We explore an alternative that uses  $k$ -d ( $k$ -dimensional) trees to construct a non-uniform grid that *adapts* to training sets of different sizes more gracefully. It ensures a roughly equal number of documents in each cell, which means that all pseudo-documents compete on similar footing with respect to the amount of training data.

W&B define the location for a cell to be its geographic *center*, while SMvZ only perform error analysis in terms of choosing the correct cell. We obtain consistently improved results using the *centroid* of the cell’s documents, which takes into account where the documents are concentrated.

### 4.1 $k$ -d Trees

A  $k$ -d tree is a space-partitioning data structure for storing points in  $k$ -dimensional space, which groups nearby points into buckets. As one moves down the tree, the space is split into smaller regions along chosen dimensions. In this way, it is a generalization of a binary search tree to multiple dimensions. The  $k$ -d tree was first introduced by Bentley (1975) and has since been applied to numerous problems, e.g. Barnes-Hut simulation (Anderson, 1999) and nearest-neighbors search (Friedman et al., 1977).

Partitioning geolocated documents using a  $k$ -d tree provides finer granularity in dense regions and coarser granularity elsewhere. For example, documents from Queens and Brooklyn may show significant cultural distinctions, while documents separated by the same distance in rural Montana may appear culturally identical. A uniform grid with large cells will mash Queens and Brooklyn together, while small cells will create unnecessarily sparse regions in Montana.

An important parameter for a  $k$ -d tree is its *bucket size*, which determines the maximum number of points (documents in our case) that a cell may contain. By varying the bucket size, the cells can be made fine- or coarse-grained.

### 4.2 Partitioning with a $k$ -d Tree

For geolocation, we consider the surface of earth to be a 2-dimensional space ( $k=2$ ) over latitude, longitude pairs. We form a  $k$ -d tree by a recursive procedure over the training data. Initially, all documents are placed in the root node of the tree. If the number of documents in the node exceeds the bucket size, the node is split into two nodes along a chosen split dimension and point. This procedure is recursively called on each of the new child nodes, and repeats until no node is overflowing. The resulting leaves of the  $k$ -d tree form a patchwork of rectangles which cover the entire earth.<sup>3</sup>

When splitting an overflowing node, the choice of splitting dimension and point can greatly impact the structure of the resulting  $k$ -d tree. Following Friedman et al. (1977), we choose to always split a node

<sup>3</sup>We note that the grid “rectangles” are actually trapezoids due to the nature of the latitude/longitude coordinate system. We assume the effect of this is negligible, since most documents are away from the poles, where distortion is the most extreme.

Figure 1: View of North America showing  $k$ -d leaves created from GEOWIKI with a bucket size of 600 and the MIDPOINT method, as visualized in Google Earth.

Figure 2:  $k$ -d leaves over the New York City and nearby areas from the same dataset and parameter settings as in Figure 1.

along the dimension exhibiting the greatest range of values. However, there still exist multiple methods for determining the split point, i.e. the point separating documents into “left” and “right” nodes. In this paper, we consider two possibilities for selecting this point: the **MIDPOINT** method, and the **FRIEDMAN** method. The latter splits at the median of all the points, resulting in an equal number of points in both the left and right nodes and a perfectly balanced  $k$ -d tree. The former splits at the midpoint between the two furthest points, allowing for a greater difference in the number of points in each bin. For geolocation, the FRIEDMAN splitting method will likely lead to less sparsity, and therefore more accurate cell selection. On the other hand, the MIDPOINT method is likely to draw more geographically desirable boundaries.

Figure 1 shows the leaves of the  $k$ -d tree formed over North America using the GEOWIKI dataset,

the MIDPOINT node division method, and a bucket size of 600. Figure 2 shows the leaves over New York City and its surrounding area for the same dataset and settings. More densely populated areas of the earth (which in turn tend to have more Wikipedia documents associated with them) contain smaller and more numerous leaf cells. The cells over Manhattan are significantly smaller than those of Queens, the Bronx, and East Jersey, even at such a coarse bucket size. Though the leaves of the  $k$ -d tree implicitly cover the entire surface of the earth, our illustrations limit the size of each box by its data, leaving gaps where no training documents exist.

### 4.3 Selecting a Representative Location

W&B use the geographic **center** of a cell as the geolocation for the pseudo-document it represents. However, this ignores the fact that many cells will have imbalances in the dispersion of the documents they contain – typically, they will be clumpy, with documents clustering around areas of high population or activity. An alternative is to select the **centroid** of the locations of all the documents contained within a cell. Uniform grids with small cells are not especially sensitive to this choice since the absolute distance between a center or centroid prediction will not be great, and empty cells are simply discarded. Nonetheless, using the centroid has the benefit of making a uniform grid less sensitive to cell size, such that larger cells can be used more reliably – especially important when there are few training documents.

In contrast, when choosing representative locations for the leaves of a  $k$ -d tree, it is quite important to use the centroid because the leaves necessarily span the entire earth and none are discarded (since all have a roughly similar number of documents in them). Some areas with low document density are thus assigned very large cells, such as those over the oceans, as seen in Figures 1 and 2. Using the centroid allows these large leaves to be in the mix, while still predicting the locations in them that have the greatest document density.

## 5 Experimental Setup

**Configurations.** We experiment with several configurations of grids and representative locations.

Figure 3: Development set comparisons for (a) GEOWIKI, (b) GEOTEXT, and (c) UTGEO2011-SMALL.

**W&B** refers to a uniform grid and geographic-center location selection, **UNIFCENTROID** to a uniform grid with centroid location selection, **KDCENTROID** to a  $k$ -d tree grid with centroid location selection, and **UNIFKDCENTROID** to the union of pseudo-documents constructed by **UNIFCENTROID** and **KDCENTROID**.

We also provide two baselines, both of which are based on a uniform grid with centroid location selection. **RANDOM** predicts a grid cell chosen at random uniformly; **MOSTCOMMONCELL** always predicts the grid cell containing the most training documents. Note that a most-common  $k$ -d leaf baseline does not make sense, as all  $k$ -d leaves contain approximately the same number of documents.

**Evaluation.** We use three metrics to measure geolocation performance. The output of each experiment is a predicted coordinate for each test document. For each prediction, we compute the error distance along the surface of the earth to the gold coordinate. We report the **mean** and **median** of all such distances as in W&B and Eisenstein et al. (2011). We also report the **fraction of error distances less than 161 km**, corresponding to Cheng et al. (2010)’s measure of predictions within 100 miles of the true location. This third measure can reveal differences between models not obvious from just mean and median.

## 6 Results

This section provides results for the datasets described previously: GEOWIKI, GEOTEXT, UTGEO2011-LARGE and UTGEO2011-SMALL.

We first give details for how we tuned parameters and algorithmic choices using the development sets, and then provide performance on the test sets based on these determinations.

### 6.1 Tuning

The specific parameters are (1) the partition location method; (2) the bucket size for  $k$ -d partitioning; (3) the node division method for  $k$ -d partitioning; (4) the degree size for uniform grid partitioning. We tune with respect to mean error, like W&B.

**Partition Location Method.** Development set results show that the centroid always performs better than the center for all datasets, typically by a wide margin (especially for large partition sizes). To save space, we do not provide details, but point the reader to the differences in test set results between W&B and **UNIFCENTROID** (which are identical except that the former uses the center and the latter uses the centroid) in Tables 1 and 2. All further parameter tuning is done using the centroid method.

**$k$ -d Tree Bucket Size.** Bucket size should not be too large as a proportion of the total number of training documents. Larger bucket sizes tend to produce larger leaves, so documents in a partition will have a higher average distance to the center or centroid point. This will result in predictions being made at too coarse a granularity, greatly limiting obtainable precision even when the correct leaf is chosen.

Conversely, small bucket sizes lead to fewer training documents per partition. A bucket size of one reduces to the situation where no pseudo-documents are used. While this might work well if location prediction is done using the kNNs for a test document, it

Test dataset	GEOWIKI				GEOTEXT			
Method	Parameters	Mean	Med.	Acc.	Parameters	Mean	Med.	Acc.
RANDOM	0.1°	7056	7145	0.3	5°	2008	1866	1.6
MOSTCOMMONCELL	0.1°	4265	2193	5.0	5°	1158	757	31.3
Eisenstein et al.	-	-	-	-	-	<b>845</b>	501	-
Wing & Baldrige	0.1°	221	11.8	-	5°	967	479	-
UNIFCENTROID	0.1°	181	<b>11.0</b>	<b>90.3</b>	5°	897	<b>432</b>	<b>35.9</b>
KDCENTROID	B100, MIDPT.	192	22.5	87.9	B530, FRIED.	958	549	35.3
UNIFKDCENTROID	0.1°, B100, MIDPT.	<b>176</b>	13.4	90.3	5°, B530, FRIED.	890	473	34.1

Table 1: Performance on the held-out test sets of GEOWIKI and GEOTEXT, comparing to the results of Wing and Baldrige (2011) and Eisenstein et al. (2011).

is likely to perform very poorly for the 1NN rule we adopt. It would also require efficient similarity comparisons, using techniques such as locality-sensitive hashing (Kulis and Grauman, 2009).

The graphs in Figure 3 show development set performance when varying bucket size. For GEOWIKI and UTGEO2011-LARGE (not shown), increments of 100 were used, but for the smaller GEOTEXT and UTGEO2011-SMALL, more fine-grained increments of 10 were used. In the case of plateaus, as was common with the FRIEDMAN method, we chose the middle of the plateau as the bucket size. Overall, we found optimal bucket sizes of 100 for GEOWIKI, 530 for GEOTEXT, 460 for UTGEO2011-SMALL, and 1050 for UTGEO2011-LARGE. That the Wikipedia data requires a smaller bucket size is unsurprising: the documents themselves are generally longer and there are many more of them, so a small bucket size provides good coverage and granularity without sacrificing the ability to estimate good language models for each partition.

**Node Division Method.** The graphs in Figure 3 also display the difference between the two splitting methods. MIDPOINT is clearly better for GEOWIKI, while FRIEDMAN is better for GEOTEXT in the range of bucket sizes producing the best results. FRIEDMAN is best for UTGEO2011-LARGE (not shown), but MIDPOINT is best for UTGEO2011-SMALL.

These results only partly confirm our expectations. We expected FRIEDMAN to perform better on smaller datasets, as it distributes the documents evenly and avoids many sparsity issues. We expected MIDPOINT to win on larger datasets, where all nodes receive plentiful data and the  $k$ -d

tree would choose more representative geographical boundaries.

**Cell Size.** Following W&B, we choose a cell degree size of 0.1° for GEOWIKI, and a cell degree size of 5.0° for GEOTEXT. For UTGEO2011-LARGE and UTGEO2011-SMALL, we follow the procedure of W&B, trying sizes 0.1°, 0.5°, 1.0°, 5.0°, and 10.0°, selecting the one which performed best on the development set. For UTGEO2011-SMALL, this resulted in coarse cells of 10.0°, while for UTGEO2011-LARGE, cell sizes of 0.1° were best.

With these tuned parameters, the average number of training tokens per  $k$ -d leaf was approximately 26k for GEOWIKI, 197k for GEOTEXT, 250k for UTGEO2011-SMALL, and 954k for UTGEO2011-LARGE.

## 6.2 Held-out Test Sets

Table 1 shows the performance on the test sets of GEOWIKI and GEOTEXT of the different configurations, along with that of W&B and Eisenstein et al. (2011) where possible. The results obtained by W&B on GEOWIKI are already very strong, but we do see a clear improvement by changing from the center-based locations for pseudo-documents they used to the centroid-based locations we employ: mean error drops from 221 km to 181 km, and median error from 11.8 km to 11.0 km. Also, we reduce the mean error further to 176 km for the configuration that combines the uniform grid and the  $k$ -d partitions, though at the cost of increasing median error somewhat. The 161 km accuracy is around 90% for all configurations, indicating that the general language modeling approach we employ is very

Test dataset	UTGEO2011

Wing & Baldrige	10°	1223	825	3.4	0.1°	956	570	30.9
UNIFCENTROID	10°	1147	782	12.3	0.1°	956	570	30.9
KDCENTROID	B460, MIDPT.	1098	733	<b>18.1</b>	B1050, FRIED.	<b>860</b>	<b>463</b>	<b>34.6</b>
UNIFKDCENTROID	10°, B460, MIDPT.	<b>1080</b>	<b>723</b>	<b>18.1</b>	0.1°, B1050, FRIED.	913	532	33.0

Table 2: Performance on the held-out test set of UTGEO2011 for different configurations trained on UTGEO2011-SMALL (comparable in size to GEOTEXT) and UTGEO2011-LARGE. The numbers given for W&B were produced from their implementation, and correspond to uniform grid partitioning with locations from centers rather than centroids.

robust for fact-oriented texts that are rich in explicit toponyms and geographically relevant named entities.

For GEOTEXT, the results show that the uniform grid with centroid locations is the most effective of our configurations. It improves on Eisenstein et al. (2011) by 69 km with respect to median error, but has 52 km worse performance than their model with respect to mean error. This indicates that our model is generally more accurate, but that it is comparatively more wildly off on some documents. Their model is a sophisticated one that attempts to build detailed models of the geographic linguistic variation found in the dataset. Dialectal cues are actually the most powerful ones in the GEOTEXT dataset, and it seems our general approach of winner-takes-all (1NN) hurts performance in this respect, especially with a very small training set.

Table 2 shows the performance on the test set of UTGEO2011 with the UTGEO2011-SMALL and UTGEO2011-LARGE training sets. (Performance for W&B is obtained from their code.<sup>4</sup>) With the small training set, error is worse than with GEOTEXT, reflecting the wider geographic scope of UTGEO2011. KDCENTROID is much more effective than the uniform grids, but combining it with the uniform grid in UNIFKDCENTROID edges it out by a small amount. More interestingly, KDCENTROID is the strongest on all measures when using the large training set, beating UNIFCENTROID by an even larger margin for mean and median error than with

the small training set. The bucket size used with the large training set is double that for the small one, but there are many more leaves created since there are 42 times more training documents. With the extra data, the model is able to adapt better to the dispersion of documents and still have strong language models for each leaf that work well even with our greedy winner-takes-all decision method.

Note that the accuracy measurements for all UTGEO2011 experiments are substantially lower than those reported by Cheng et al. (2010), who report a best accuracy within 100 miles of 51%. While UTGEO2011-LARGE contains a substantially larger number of tweets, Cheng et al. (2010) limit themselves to users with at least 1,000 tweets, while we have an average of 85 tweets per user. Their reported mean error distance of 862 km (versus our best mean of 860 km on UTGEO2011-LARGE) indicates that their performance is hurt by a relatively small number of extremely incorrect guesses, as ours appears to be.

Figure 4 provides a learning curve on UTGEO2011’s development set for KDCENTROID. Performance improves greatly with more data, indicating that GEOTEXT performance would also improve with more training data. Parameters, especially bucket size, need retuning as data increases, which we hope to estimate automatically in future work

Finally, we note that the KDCENTROID method was faster than other methods. While UNIFCENTROID took nearly 19 hours to complete the test run on GEOWIKI (approximately

<sup>4</sup><https://bitbucket.org/utcompling/textgrunder/wiki/WingBaldrige2011>

Figure 4: Learning curve of KDCENTROID on the UTGEO2011 development set.

1.38 seconds per test document), KDCENTROID took only 80 minutes (.078 s/doc). Similarly, UNIFCENTROID took about 67 minutes to run on UTGEO2011-LARGE (0.34 s/doc), but KDCENTROID took only 27 minutes (0.014 s/doc). Generally, the KDCENTROID partitioning results in fewer cells, and therefore fewer KL-divergence comparisons. As expected, the UNIFKDCENTROID model needs as much time as the two together, taking roughly 21 hours for GEOWIKI (1.52 s/doc) and 85 minutes for UTGEO2011-LARGE (0.36 s/doc).

## 7 Discussion

### 7.1 Error Analysis

We examine some of the greatest error distances to better understand and improve our models. In many cases, landmarks in Australia or New Zealand are predicted in European locations with similarly-named landmarks, or vice versa — e.g. the *Theatre Royal, Hobart* in Australia is predicted to be in London’s theater district, and the *Embassy of Australia, Paris* is predicted to be in the capital city of Australia. Thus, our model may be inadvertently capturing what Clements et al. (2010) call *wormholes*, places that are related but not necessarily adjacent.

Some of the other large errors stem from incorrect gold labels, in particular due to sign errors in latitude or longitude, which can place documents 10,000 or more km from their correct locations.

Word	Error	Word	Error
paramus	78	6100	130
ludlow	79	figueroa	133
355	99	dundas	138
ctfuuu	101	120th	139
74th	105	mississauga	140
5701	105	pulaski	144
bloomington	122	cucina	146
covina	133	56th	153
lawrenceville	122	403	157
ctfuuuu	124	428	161

Table 3: The 20 words with least average error (km) in the UTGEO2011 development set, trained on the UTGEO2011-SMALL training set, using the KDCENTROID approach with our best parameters. Only words that occur in at least 10 documents are shown.

Word	Error	Word	Error
seniorpastor	1.1	KS01	2.4
prebendary	1.6	Keio	2.5
Wornham	1.7	Vrah	2.5
Owings	1.9	overspill	2.5
Londoners	2.0	Oriel	2.5
Sandringham	2.1	Holywell	2.6
Sheffield’s	2.2	\’vr&h	2.6
Oxford’s	2.2	operetta	2.6
Belair	2.3	Supertram	2.6
Beckton	2.4	Chanel	2.7

Table 4: Top 20 words with the least average error (km) in the GEOWIKI development set, using the UNIFKDCENTROID approach with our best parameters. Only words occurring in at least 10 documents are shown.

### 7.2 Most Predictive Words

Our approach relies on the idea that the use of certain words correlates with a Twitter user or Wikipedia article’s location. To investigate which words tend to be good indicators of location, we computed, for each word in a development set, the average error distance of documents containing that word. Table 3 gives the 20 words with the least error, among those that occur in at least 10 documents (users), for the UTGEO2011 development set, trained on UTGEO2011-SMALL.

Many of the best words are town names (*paramus*, *ludlow*, *bloomington*), street names (*74th*, *figueroa*,

120th), area codes (403), and street numbers (5701, 6100). All are highly locatable terms, as we would expect. Many of the street addresses are due to check-ins with the location-based social networking service Foursquare (e.g. the tweet *I'm at Starbucks (7301 164th Ave NE, Redmond Town Center, Redmond)*), where the user is literally broadcasting his or her location. The token *ctfuuu(u)*—an elongation of the internet abbreviation *ctfu*, or *cracking the fuck up*—is a dialectal or stylistic feature highly indicative of the Washington, D.C. area.

Similarly, several place names (*Wornham, Belair, Holywell*) appear in GEOWIKI. *Operettas* are a cultural phenomenon largely associated with France, Germany, and England and particularly with specific theaters in these countries. However, other highly specific tokens such as *KS01* have a very low average error because they occur in few documents and are thus highly unambiguous indicators of location. Other terms, like *seniorpastor* and *\'vr&h*, are due to extraction errors in the dataset created by W&B, and are carried along because of a high correlation with specific documents.

## 8 Conclusion

We have shown how to construct an adaptive grid with  $k$ -d trees that enables robust text geolocation and scales well to large training sets. It will be interesting to consider how it interacts with other strategies for improving the IR-based approach. For example, the pseudo-document word distributions can be smoothed based on nearby documents or on the structure of the  $k$ -d tree itself. Integrating our system with topic models or Bayesian methods would likely provide more insight with regard to the most discriminative and geolocatable words. We also expect predicting locations based on multiple most similar documents (kNN) to be more effective in predicting document location, as the second and third most similar training documents together may sometimes be a better estimation of its distribution than just the first alone. Employing  $k$  Nearest Neighbors also allows for more sophisticated methods of location estimation than a single leaf's centroid. Other possibilities include constructing multiple  $k$ -d trees using random subsets of the training data to reduce sensitivity to the bucket size.

In this article, we have considered each user in isolation. However, Liben-Nowell et al. (2005) show that roughly 70% of social network links can be described using geographic information and that the probability of a social link is inversely proportional to geographic distance. Backstrom et al. (2010) verify these results on a much larger scale using geolocated Facebook profiles: their algorithm geolocates users with only the social graph and significantly outperforms IP-based geolocation systems. Given that both Twitter and Wikipedia have rich, linked document/user graphs, a natural extension to our work here will be to combine text and network prediction for geolocation. Sadilek et al. (2012) also show that a combination of textual and social data can accurately geolocate individual tweets when scope is limited to a single city.

Tweets are temporally ordered and the geographic distance between consecutive tweeting events is constrained by the author's movement. For tweet-level geolocation, it will be useful to build on work in geolocation that considers the temporal dimension (Chen and Grauman, 2011; Kalogerakis et al., 2009; Sadilek et al., 2012) to make better predictions for documents/images that are surrounded by others with excellent cues, but which are hard to resolve themselves.

## Abstract

Discriminative training in query spelling correction is difficult due to the complex internal structures of the data. Recent work on query spelling correction suggests a two stage approach a noisy channel model that is used to retrieve a number of candidate corrections, followed by discriminatively trained ranker applied to these candidates. The ranker, however, suffers from the fact the low recall of the first, suboptimal, search stage.

This paper proposes to directly optimize the search stage with a discriminative model based on latent structural SVM. In this model, we treat query spelling correction as a multi-class classification problem with structured input and output. The latent structural information is used to model the alignment of words in the spelling correction process. Experiment results show that as a standalone speller, our model outperforms all the baseline systems. It also attains a higher recall compared with the noisy channel model, and can therefore serve as a better filtering stage when combined with a ranker.

## 1 Introduction

Query spelling correction has become a crucial component in modern information systems. Particularly, search engine users rely heavily on the query correction mechanism to formulate effective queries. Given a user query  $q$ , which is potentially misspelled, the goal of query spelling correction is to find a correction of the query  $c$  that could lead to a

better search experience. A typical query spelling correction system employs a noisy channel model (Kernighan et al., 1990). The model assumes that the correct query  $c$  is formed in the user's mind before entering the noisy channels, e.g., typing, and get misspelled. Formally, the model maximizes the posterior probability  $p(c|q)$ :

$$\hat{c} = \arg \max_c p(c|q). \quad (1)$$

Applying Bayes rule, the formulation can be rewritten as:

$$\begin{aligned} \hat{c} &= \arg \max_c p(q|c)p(c) \\ &= \arg \max_c [\log p(q|c) + \log p(c)]. \end{aligned} \quad (2)$$

The model uses two probabilities. The prior probability  $p(c)$  represents how likely it is that  $c$  is the original correct query in the user's mind. The probability is usually modeled by a language model estimated from a sizable corpus. The transformation probability  $p(q|c)$  measures how likely it is that  $q$  is the output given that  $c$  has been formed by the user. This probability can be either heuristic-based (edit distance) or learned from samples of well aligned corrections. One problem with the noisy channel model is that there is no weighting for the two kinds of probabilities, and since they are estimated from different sources, there are usually issues regarding their scale and comparability, resulting in suboptimal performance (Gao et al., 2010). Another limitation of this generative model is that it is not able to take advantage of additional useful features.

A discriminative model may solve these problems by adding the flexibility of using features and applying weights. But training such a model is not easy. The difficulty is that the output space of query correction is enormous, as the candidate corrections for each a query term could be the entire vocabulary. This is even worse when word boundary errors (i.e. merging and splitting of words) exist. The problem is intractable with standard discriminative models as we cannot enumerate every candidate correction.

To solve the problem, (Gao et al., 2010) proposed a two stage approach. In this approach, a ranker is trained to score each candidate correction of a query. When a query is issued, the system first uses the noisy channel model with a standard search algorithm to find the 20 best candidates. Then the ranker is used to re-rank these candidates and find the best correction for the query. This ranker based system has one critical limitation, though. Since the ranking stage is decoupled from the search, it relies on the outsourced search algorithm to find the candidates. Because query spelling correction is an online operation, only a small number of candidates can enter the ranker due to efficiency concerns, thus limiting the ability of the ranker to the ceiling of recall set by the suboptimal search phase.

The research question we address here is whether we can directly optimize the search phase of query spelling correction using a discriminative model without loss of efficiency. More specifically, we want 1) a learning process that is aware of the search phase and interacts with its result; 2) an efficient search algorithm that is able to incorporate the learned model and guide the search to the target spelling correction.

In this paper, we propose a new discriminative model for query correction that maintains the advantage of a discriminative model in accommodating flexible combination of features and naturally incorporates an efficient search algorithm in learning and inference. Similarly to (Chang et al., 2010) we collapse a two stage process into a single discriminatively trained process, by considering the output of the first stage as an intermediate latent representation for the joint learning process. Specifically, we make use of the latent structural SVM (LS-SVM) (Yu and Joachims, 2009) formulation. We formulate the problem query spelling correction as a multi-

class classification problem on structured inputs and outputs. The advantage of the structural SVM model is that it allows task specific, customizable solutions for the inference problem. This allows us to adapt the model to make it work directly with the search algorithm we use for finding the best correction of the query. To account for word boundary errors, we model the word alignment between the query and the correction as a latent structural variable. The LS-SVM model allows us to jointly search over the output space and the latent structure space.

As the inference algorithm in the proposed discriminative model we use an algorithm that resembles a traditional noisy channel model. To adapt the LS-SVM model to enable the efficient search of query spelling correction, we study how features can be designed. We analyze the properties of features that can be used in the search algorithm and propose a criteria for selecting and designing new features. We demonstrate the use of the criteria by designing separate features for different types of spelling errors (e.g. splitting, merging). With the proposed discriminative model, we can directly optimize the search phase of query spelling correction without loss of efficiency. Our model can be used not only as a standalone speller with high accuracy, but also as a high recall candidate generation stage for a ranker based system.

Experiments verify the effectiveness of the discriminative model, as the accuracy of correction can be improved significantly over baseline systems including an award winning query spelling system. Even though the optimization is primarily based on the top correction, the weights trained by LS-SVM can be used to search for more candidate corrections. The improvement in recall at different levels over the noisy channel model demonstrates that our model is superior even when used in the two-stage approach..

## 2 Related Work

Spelling correction has a long history (Levenshtein, 1966). Traditional techniques were on small scale and depended on having a small trusted lexicons (Kukich, 1992). Later, statistical generative models were shown to be effective in spelling correction, where a source language model and an error model were identified as two major components

(Brill and Moore, 2000). Note that we are not dealing here with the standard models in context sensitive spelling (Golding and Roth, 1999) where the set of candidate correction is a known “confusion set”. Query spelling correction, a special form of the problem, has received much attention in recent years. Compared with traditional spelling correction task, query spelling deals with more complex types of misspellings and a much larger scale of language. Research in this direction includes utilizing large web corpora and query log (Chen et al., 2007; Cucerzan and Brill, 2004; Ahmad and Kondrak, 2005), employing large-scale n-gram models, training phrase-based error model from clickthrough data (Sun et al., 2010) and developing additional features (Gao et al., 2010).

Query alteration/refinement is a very relevant topic to query spelling correction. The goal of query alteration/refinement is to modify the ineffective query so that it could . Researches on this track include query expansion (Xu and Croft, 1996; Qiu and Frei, 1993; Mitra et al., 1998), query contraction (Kumaran and Allan, 2008; Bendersky and Croft, 2008; Kumaran and Carvalho, 2009) and other types of query reformulations for bridging the vocabulary gap (Wang and Zhai, 2008). (Guo et al., 2008) proposed a unified model to perform a broad set of query refinements including correction, segmentation and stemming. However, it has very limited ability in query correction. In this paper, we study the discriminative training of query spelling correction, which is potentially beneficial to many existing studies.

Noisy channel model (or source channel model) has been widely used in NLP. Many approaches have been proposed to perform discriminative training of the model (McCallum et al., 2000; Lafferty, 2001). However, these approaches mostly deal with a relatively small search space where the number of candidates at each step is limited (e.g. POS tagging). A typically used search algorithm is dynamic programming. In spelling correction, however, the search space is much bigger and the existing approaches featuring dynamic programming are difficult to be applied.

Structural learning and latent structural learning has been studied a lot in NLP in recent years (Chang et al., 2010; Dyer et al., 2011), and has been

shown to be useful in a range of NLP applications from Textual Entailment, Paraphrasing and Transliteration (Chang et al., 2010) to sentiment analysis (Yessenalina et al., 2010).

Work has also been done on integrating discriminative learning in search. Freitag and Khadivi used a perceptron algorithm to train for sequence alignment problem. A beam search algorithm was utilized in the search (Freitag and Khadivi, 2007). Daume et al. proposed the Searn framework for search based structural prediction (Daume et al., 2009). Our model differs from the Searn framework in that it learns to make global decisions rather than accumulating local decisions. The global decision was made possible by an efficient search algorithm.

Query spelling correction also shares many similarities with statistical machine translation (SMT). Sun et al. (2010) has formulated the problem within an SMT framework. However, SMT usually involves more complex alignments, while in query spelling correction search is the more challenging part. Our main contribution in this paper is a novel unified way to directly optimize the search phase of query spelling correction with the use of LS-SVM.

### 3 Discriminative Model for Query Spelling Correction Based on LS-SVM

In this section, we first present the discriminative formulation of the problem of query spelling correction. Then we introduce in detail the model we use for solving the problem.

#### 3.1 The Discriminative Form of Query Spelling Correction

In query spelling correction, given a user entered query  $q$ , which is potentially misspelled, the goal is to find a correction  $c$ , such that it could be a more effective query which improves the quality of search results. A general discriminative formulation of the problem is of the following form:

$$f(q) = \arg \max_{c \in \mathcal{V}^*} [w \cdot \Psi(q, c)], \quad (3)$$

where  $\Psi(q, c)$  is a vector of features and  $w$  is the model parameter. This discriminative formulation is more general compared to the noisy channel model. It has the flexibility of using features and applying

weights. The noisy channel model is a special case of the discriminative form where only two features, the source probability and the transformation probability, are used and uniform weightings are applied. However, this problem formulation does not give us much insight on how to proceed to design the model. Especially, it is unclear how  $\Psi(q, c)$  can be computed.

To enhance the formulation, we explore the fact that spelling correction follows a word-by-word procedure. Let us first consider a scenario where word boundary errors does not exist. In this scenario, each query term matches and only matches to a single term in the correction. Formally, let us denote  $q = q_1, \dots, q_n$  and  $c = c_1, \dots, c_m$  as structured objects from the space of  $\mathcal{V}^*$ , where  $\mathcal{V}$  is our vocabulary of words and  $\mathcal{V}^*$  is all possible phrases formed by words in  $\mathcal{V}$ . Both  $q$  and  $c$  have an intrinsic sequential structure. When no word boundary error exists,  $|c| = |q|$  holds for any candidate correction  $c$ .  $q_i$  and  $c_i$  establish a one-to-one mapping. In this case, we have a more detailed discriminative form:

$$f(q) = \arg \max_{c \in \mathcal{V}^{|q|}} [w \cdot (\Psi_0 + \sum_{i=1}^{|q|} \Psi_1(q_i, c_i))], \quad (4)$$

where  $\Psi_0$  is a vector of normalizing factors,  $\Psi_1(q_i, c_i)$  is the decomposed computation of  $\Psi(q, c)$  for each query term  $q_i$  and  $c_i$ , for  $i = 1$  to  $|q|$ .

Equation 4 is a clearer formulation. The major challenge of solving this discriminative problem is the complexity. Theoretically, each term has  $|\mathcal{V}|$  candidates and it is impossible to enumerate over all possible combinations. To make it even worse, merging and splitting errors are quite common in misspelling. As a result, the assumption of one-to-one mapping does not hold in practice.

To account for these word boundary errors and enhance the discriminative formulation, we introduce a latent variable  $a$  to model the unobserved structural information. More specifically,  $a = a_1, a_2, \dots, a_{|a|}$  is the alignment between  $q$  and  $c$ . Each alignment node  $a_t$  is a represented by a quadruple  $(q_{start}, q_{end}, c_{start}, c_{end})$ . Figure 1 shows a common merge error and its best alignment. The phrase "credit card", in this case, is incorrectly merged into one word "creditcard" by the user. Figure 2 shows

Figure 1: Example of Merge Error and Alignment

Figure 2: Example of Split Error and Alignment

the best alignment for a common split error, where the word "gamespot" is incorrectly split into a two word phrase "game spot".

Taking into consideration the latent variable, we arrive at our final discriminative form of query spelling correction:

$$\begin{aligned} f(q) &= \arg \max_{(c,a) \in \mathcal{V}^n \times \mathcal{A}} [w \cdot \Psi(q, c, a)] \\ &= \arg \max_{(c,a) \in \mathcal{V}^* \times \mathcal{A}} [w \cdot (\Psi_0 \\ &\quad + \sum_{t=0}^{|a|} \Psi_1(q_{a_t}, c_{a_t}, a_t))], \end{aligned} \quad (5)$$

The challenges of successfully applying a discriminative model to this problem formulation are 1) how can we design a learning algorithm to learn the model parameter  $w$  to directly optimize the maximization problem; 2) how can we solve the maximization efficiently without having to enumerate all candidates; 3) how can we design features to guarantee the correctness of the search algorithm. In the following subsections we introduce our solutions to the three challenges in detail.

### 3.2 Latent Structural SVM

We employ the latent structural SVM (LS-SVM) model for learning the discriminative model of query spelling correction. LS-SVM is a large margin method that deals with structured prediction problems with latent structural information (Yu and Joachims, 2009). LS-SVM has the merit of allowing

task specific, customizable solutions for the inference problem. This makes it easy to adapt to learning the model parameters for different problems. The following is a brief introduction of LS-SVM that largely mirrors the work by (Yu and Joachims, 2009).

Without loss of generality, let us aim at learning a prediction function  $f : \mathcal{X} \rightarrow \mathcal{Y}$  that maps input  $x \in \mathcal{X}$  to an output  $y \in \mathcal{Y}$  with latent structural information  $h \in \mathcal{H}$ . The decision function is of the following form:

$$f(x) = \arg \max_{(y,h) \in \mathcal{Y} \times \mathcal{H}} [w \cdot \Psi(x, y, h)], \quad (6)$$

where  $\Psi(x, y, h)$  is the set of feature functions defined jointly over the input  $x$ , the output  $y$  and the latent variable  $h$ .  $w$  is the parameter of the model. Given a set of training examples that consist of input and output pairs  $\{(x_1, y_1), \dots, (x_n, y_n)\} \in (\mathcal{X} \times \mathcal{Y})^n$ , the LS-SVM method solves the following optimization problem:

$$\begin{aligned} & \min_w \frac{1}{2} \|w\|^2 \\ & + C \sum_{i=1}^n \max_{(\hat{y}, \hat{h}) \in \mathcal{Y} \times \mathcal{H}} [w \cdot \Psi(x_i, \hat{y}, \hat{h}) + \Delta(y_i, \hat{y})] \\ & - C \sum_{i=1}^n \max_{h \in \mathcal{H}} [w \cdot \Psi(x_i, y_i, h)], \end{aligned} \quad (7)$$

where  $\Delta(y_i, \hat{y})$  is the loss function for the  $i$ th example. The details of the derivation is omitted in this paper. Readers who are interested can read more from (Yu and Joachims, 2009).

There are two maximization problems that are essential in Equation 7. The first one is the loss augmented decision function:

$$\max_{(\hat{y}, \hat{h}) \in \mathcal{Y} \times \mathcal{H}} [w \cdot \Psi(x_i, \hat{y}, \hat{h}) + \Delta(y_i, \hat{y})], \quad (8)$$

and the second is the inference of latent variable given the label of the training data:

$$\max_{h \in \mathcal{H}} [w \cdot \Psi(x_i, y_i, h)]. \quad (9)$$

The Latent Structural SVM framework does not specify how the maximization problems in Equation

8 and Equation 9 are solved, as well as the inference problem in 6. These maximization problems are task dependent. Being able to efficiently solve them is the key to successfully applying the Latent Structural SVM method. We will show in detail how we solve these maximization problems to make LS-SVM work for query spelling correction in the following subsection.

For training the LS-SVM model, a Concave-Convex Procedure (CCCP) was proposed to solve this optimization problem (Yu and Joachims, 2009). The method resembles the Expect-Maximization (EM) training method as it updates the model by iteratively recomputing the latent variable. However, rather than performing “sum-product” training as in EM where a distribution over the hidden variable is maintained, the CCCP method used for LS-SVM is more similar to the “max-product” paradigm where we “guess” the best hidden variable in each iteration, except here we “guess” by minimizing a regularized loss function instead of maximizing the likelihood.

### 3.3 Solving the Inference Problems

The essential inference problem is to find the correction that maximizes the scoring function according to the model (i.e., the decision function in Equation 6). For this purpose we design a best first search algorithm similar to the standard search algorithm in the noisy channel model. The essence of the search algorithm is to bound the score of each candidate so that we could evaluate the most promising candidates first. The algorithm is given in Algorithm 1.

Essentially, the algorithm maintains a priority queue of all search paths. Each time the best path is de-queued, it is expanded with up to  $m - 1$  words in  $q$  by searching over a vocabulary trie of up to  $m$ -gram. Each path is represented as a quadruple  $(pos, str, sc, a)$ , representing the current term position in query, the string of the path, the path’s score and the alignment so far. The priority queue is sorted according to the score of each path in descending order. The *GetSuggestions()* function retrieves the top  $n$  similar words to the given word with a vocabulary trie according to an error model.

Splitting errors are dealt with in Algorithm 1 by “looking forward”  $m$  words in the query when generating candidate words. Merging errors are accounted for by including up to  $m$ -gram in the vocab-

ulary trie. It is worth mentioning that performance of Algorithm 1 could be further improved by computing heuristic scores for each path.

---

**Algorithm 1: Best First Search Algorithm**

---

**Input:** Vocabulary Trie  $V$ , query  $q$ , output size  $k$ , max order  $m$ , candidate pool size  $n$   
**Output:** List  $l$  of top  $k$  corrections for  $q$

- 1 Initialize List  $l$ ;
- 2 Initialize PriorityQueue  $pq$ ;
- 3 Enqueue to  $pq$  a start path with position set to 0, string set to empty string, score set to  $w \cdot \Psi_0$ , and path alignment set to empty set;
- 4 **while**  $pq$  is not Empty **do**
- 5 Path  $\pi \leftarrow pq.Dequeue()$ ;
- 6 **if**  $\pi.pos < q.terms.length$  **then**
- 7 **for**  $i \leftarrow 0$  to  $m$  **do**
- 8  $ph \leftarrow q.terms[\pi.pos + 1 \dots \pi.pos + i]$ ;
- 9  $sug \leftarrow GetSuggestions(ph, V, n)$ ;
- 10 **foreach**  $s$  in  $sug$  **do**
- 11  $pos' \leftarrow \pi.pos + i$ ;
- 12  $str' \leftarrow concat(\pi.str, s.str)$ ;
- 13  $a' \leftarrow \pi.a \cup s.a$ ;
- 14  $sc' \leftarrow \pi.sc + w \cdot \Psi_1(q_{s.a}, c_{s.a}, s.a)$ ;
- 15 Enqueue  $pq$  with the new path  $(pos', str', sc', a')$ ;
- 16 **else**
- 17 Add suggestion string  $\pi.str$  to  $l$ ;
- 18 **if**  $l.Count > k$  **then return**  $l$ ;
- 19 **return**  $l$ ;

---

As Algorithm 1 originates from the noisy channel model, the two known features that work with the algorithm are  $\log p(c)$  and  $\log p(q|c)$  from the noisy channel model. However, it is unknown whether other features can work with the search algorithm and how we can develop new features to ensure it. After analyzing the properties of the features and the search algorithm, we find that a feature  $\psi$  has to satisfy the following monotonicity constraint in order to be used in Algorithm 1.

**Monotonicity Property.** Given query  $q$ , for any alignment  $A_t = A_{t-1} \cup \{a_t\}$  at time  $t$ ,  $\psi(q_{A_t}, c_{A_t}, A_t) \leq \psi(q_{A_{t-1}}, c_{A_{t-1}}, A_{t-1})$ , where  $q_{A_t}$  is the concatenation of  $q_{a_0}$  to  $q_{a_t}$  and  $c_{A_t}$  is the concatenation of  $c_{a_0}$  to  $c_{a_t}$ .

That is, the value of the feature (which is computed in an accumulative manner) cannot increase as the candidate is extended with a new term at

any search step. This ensures that the score of the best candidate at any search step is guaranteed to be higher than the score of any future candidates. It also implies  $\psi_t(q_{a_t}, c_{a_t}, a_t) \leq 0$  for any  $t \in T$ . The monotonicity feature ensures the correctness of Algorithm 1. We show how we design features with the guidance of the monotonicity constraint in Section 4.

The solution to the loss augmented inference depends on the loss function we use. In spelling correction, usually only one correction is valid for an input query. Therefore, we apply the 0-1 loss to our model:

$$\Delta(c, \hat{c}) = \begin{cases} 0 & c = \hat{c} \\ 1 & c \neq \hat{c} \end{cases} \quad (10)$$

Given this loss function, the loss augmented inference problem can be solved easily with an algorithm similar to Algorithm 1. This is done by initializing the loss to be 1 at the beginning of each search path. During the search procedure, we check if the loss decreases to 0 given the correction string so far. If this is the case, we decrease the score by 1 and add the path back to the priority queue. More advanced functions may also be used (Dreyer et al., 2006), which may lead to better training performance. We plan to further study different loss functions in our future work.

The inference of the latent alignment variable can be solved with dynamic programming, as the number of possible alignments is limited given the query and the correction.

## 4 Features

In the following discussions, we will describe how the features in our discriminative model are developed under the guidance of the monotonicity constraint.

### 4.1 Source Probability and Transformation Probability

We know from empirical experience that the source probability and the transformation probability are the two most important features in query spelling correction. We include them in our model in a normalized form. Taking the source probability for example, we define the following feature:

$$\begin{aligned}\psi(q, c, a) &= \frac{\mu + \sum_1^{|a|} \log p(c)}{\sum_1^{|a|} \frac{\log p(c)}{\mu}}, \\ &= 1 + \frac{\sum_1^{|a|} \log p(c)}{\mu},\end{aligned}\quad (11)$$

where  $\mu$  is a normalizing factor computed as:

$$\mu = -|q| \log p_{min}, \quad (12)$$

where  $p_{min}$  is the smallest probability we use in practice.

The formula fits the general form we define in 5 in that  $\psi_0 = 1$  and  $\psi_1(q_{a_t}, c_{a_t}, a_t) = \frac{\log p(c)}{\mu}$  for any  $t = 1$  to  $|a|$ .

Similarly, we have the follow feature for the transformation probability:

$$\begin{aligned}\psi'(q, c, a) &= \frac{\mu + \sum_1^{|a|} \log p(q|c)}{\sum_1^{|a|} \frac{\log p(q|c)}{\mu}}, \\ &= 1 + \frac{\sum_1^{|a|} \log p(q|c)}{\mu}.\end{aligned}\quad (13)$$

We use the web Microsoft n-gram model<sup>1</sup> to compute source model  $p(c)$ . We train the unigram transformation model for the transformation probability  $p(q|c)$  according to (Duan and Hsu, 2011).

In generative models, we treat transformation probabilities from merging and splitting errors in the same way as single word errors. In our discriminative model we can assign separate weight to the transformation probabilities resulted from different types of errors. This allows fine tuning of the query spelling correction system, making it more adaptive to environments where the ratio of different types of errors may vary. Moreover, the model also allows us to include language models trained over different resources, such as query log, title of webpages or anchor texts.

## 4.2 Local Heuristic Features

Despite the goal of query spelling correction is to deal with misspellings, in real world most queries are correctly spelled. A good query spelling correction system shall prevent as much as possible from misjudging an correctly spelled query as misspelled. With this idea in mind, we invent some heuristic functions to avoid misjudging.

<sup>1</sup><http://research.microsoft.com/en-us/collaboration/focus/cs/web-ngram.aspx>

**Local Heuristic 1.** When a query term is matched against trustable vocabulary, it increases the chance that the term is already in its correct form. For example, we extract a reliable vocabulary from the title field of Wikipedia<sup>2</sup>. We therefore design the following feature:

$$\phi(q, c, a) = 1 + \sum_{t=1}^{|a|} \phi_1(q_{a_t}, c_{a_t}, a_t), \quad (14)$$

where  $\phi_1(q_{a_t}, c_{a_t}, a_t)$  is defined as:

$$\phi_1(q_{a_t}, c_{a_t}, a_t) = \begin{cases} 0 & q_{a_t} \notin \mathcal{W} \\ 0 & q_{a_t} \in \mathcal{W}, q_{a_t} = c_t \\ -\frac{1}{|q|} & q_{a_t} \in \mathcal{W}, q_{a_t} \neq c_{a_t} \end{cases} \quad (15)$$

where  $\mathcal{W}$  is the vocabulary of Wikipedia titles. Since  $|q| > |a|$  always holds, the feature is normalized between 0 and 1.

**Local Heuristic 2.** Another heuristic is that words with numbers in it, despite usually not included in any vocabulary, should be treated carefully as they tend to be correct words. Such words could be a model, a serial number or a special entity name. Since the number keys on keyboard are away from the letter keys, they are more likely to be intentionally typed in if found in user queries. Similar to Heuristic 1, we design the following feature to capture this heuristic:

$$\phi'(q, c, a) = 1 + \sum_{t=1}^{|a|} \phi'_1(q_{a_t}, c_{a_t}, a_t), \quad (16)$$

where  $\phi'_1(q_{a_t}, c_{a_t}, a_t)$  is defined as:

$$\phi'_1(q_{a_t}, c_{a_t}, a_t) = \begin{cases} 0 & [0\dots9] \notin q_{a_t} \\ 0 & [0\dots9] \in q_{a_t}, q_{a_t} = c_{a_t} \\ -\frac{1}{|q|} & [0\dots9] \in q_{a_t}, q_{a_t} \neq c_{a_t} \end{cases} \quad (17)$$

## 4.3 Global Heuristic Features

Some global heuristics are also important in query spelling correction. For instance, the total number

<sup>2</sup><http://www.wikipedia.org>

of words being corrected in the query may be an indicator of whether the system has leaned towards overcorrecting. To account for this global heuristic, we design the following feature:

$$\varphi(q, c, a) = \begin{cases} 1 & wc(q, c, a) < wc_{max} \\ 0 & otherwise \end{cases} \quad (18)$$

where  $wc(q, c, a)$  is the number of word changes at step  $t$ ,  $wc_{max}$  is the maximum number of word changes we allow in our system (in a soft way). Similarly, other thresholded features can be designed such as the number of total edit operations. The use of global features is similar to the use of loss function in the search algorithm.

## 5 Experiments

In order to test the effectiveness and efficiency of our proposed discriminative training method, in this section we conduct extensive experiments on two web query spelling datasets. Below we first present the dataset and evaluation metrics, followed by the experiment results on query spelling correction.

### 5.1 Dataset Preparation

The experiments are conducted on two query spelling correction datasets. One is the TREC dataset based on the publicly available TREC queries (2008 Million Query Track). This dataset contains 5892 queries and the corresponding corrections annotated by the MSR Speller Challenge<sup>3</sup> organizers. There could be more than one plausible corrections for a query. In this dataset only 5.3% of queries are judged as misspelled.

We have also annotated another dataset that contains 4926 MSN queries, where for each query there is at most one correction. Three experts are involved in the annotation process. For each query, we consult the speller from two major search engines (i.e. Google and Bing). If they agree on the returned results (including the case if the query is just unchanged), we take it as the corrected form of the input query. If the results are not the same from the two, as least one human expert will manually annotate the most likely corrected form of the query. Finally, about 13% of queries are judged as misspelled

<sup>3</sup><http://web-ngram.research.microsoft.com/spellerchallenge/>

in this dataset, which is close to the error rate of real web queries. We've made this dataset publicly available to all researchers<sup>4</sup>.

Both the two datasets are split randomly into two equal subsets for training and testing.

### 5.2 Evaluation Metrics

We evaluate our system based on the evaluation metrics proposed in Microsoft Speller Challenge, including expected precision, expected recall and expected F1 measure.

Let  $q$  be a user query and  $C(q) = (c^1, c^2, \dots, c^k)$  be the set of system output with posterior probabilities  $P(c^i|q)$ . Let  $S(q)$  denote the set of plausible spelling variations annotated by the human experts for  $q$ . Expected Precision is computed as:

$$Precision = \frac{1}{|Q|} \sum_{q \in Q} \sum_{c \in C(q)} I_p(c, q) P(c|q), \quad (19)$$

where  $I_p(c, q) = 1$  if  $c \in S(q)$ , and 0 otherwise. And expected recall is defined as:

$$Recall = \frac{1}{|Q|} \sum_{q \in Q} \sum_{a \in S(q)} I_r(C(q), a) / |S(q)|, \quad (20)$$

where  $I_r(C(q), a) = 1$  if  $a \in C(q)$  for  $a \in S(q)$ , and 0 otherwise. We use R@N to denote recall for systems limited to output top N corrections.

Expected F1 measure can be computed as:

$$F1 = \frac{2 \cdot precision \cdot recall}{precision + recall} \quad (21)$$

### 5.3 Experiment Results

Table 1 compares the performance of our LS-SVM based model with two strong baseline systems. The first baseline system is an Echo system which simply echos the input. The echo system is usually considered as a strong baseline in query spelling correction as the majority of the queries are correctly spelled queries. The second baseline Lueck-2011 we use is a award winning speller system<sup>5</sup> (Luec, 2011), which was ranked at the first place in Microsoft Spelling Challenge 2011.

<sup>4</sup>[http://times.cs.uiuc.edu/duan9/msn\\_speller.tar.gz](http://times.cs.uiuc.edu/duan9/msn_speller.tar.gz)

<sup>5</sup><http://www.phraselink.com>

Table 1: LSSVM vs Baselines Serving as Standalone Speller

Dataset	Method	All Queries			Misspelled Queries		
		Precision	R@10	F1	Precision	R@10	F1
TREC	Echo	0.949	0.876	0.911	0	0	0
	Lueck-2011	<b>0.963</b>	0.932	0.947	<b>0.391</b>	0.479	0.430
	LS-SVM	0.955	<b>0.944</b>	<b>0.949</b>	0.331	<b>0.678<sup>†</sup></b>	<b>0.445<sup>†</sup></b>
MSN	Echo	0.869	0.869	0.869	0	0	0
	Lueck-2011	0.896	0.921	0.908	0.334	0.397	0.363
	LS-SVM	<b>0.903</b>	<b>0.953</b>	<b>0.928</b>	<b>0.353<sup>†</sup></b>	<b>0.662<sup>†</sup></b>	<b>0.461<sup>†</sup></b>

We show performances for the entire query sets as well as the query sets consisting only the misspelled queries. As we can see, our system outperforms both baseline systems on almost all metrics, except the precision of Lueck-2011 is better than ours on TREC dataset. We perform statistical test and measures where our system shows statistical significant improvement over both baseline systems are noted by <sup>†</sup>. It is theoretically impossible to achieve statistical significance in the entire query set as majority queries have almost identical performance in different systems due to the large amount of correct queries. But our method shows significant improvement in the dealing with the misspelled queries. This experiment verified the effectiveness of our proposed discriminative model. As a standalone speller, our system achieves very high accuracy.

Despite we are primarily focused on optimizing the top correction in our discriminative model, we can also use the trained system to output multiple candidate corrections. Table 2 compare our system with the noisy channel model (N-C) in terms of recall at different levels of cutoff. For all levels, we see that our system achieves higher recall than the noisy channel model. This indicates that when used together with a secondary ranker, our system serves as a better filtering method than the unoptimized noisy channel model. Since the ranker makes use of arbitrary features, it has the potential of further improving the accuracy of query spelling correction. We plan to further explore this idea as a future work.

In Table 3 we study the effect of treating the transformation probability of merging and splitting errors as separate features and including the local and global heuristic features (rich features). We see that

Table 2: LS-SVM vs Noisy Channel Model Serving as Filtering Method

Dataset	Method	R@5	R@10	R@20
TREC	N-C	0.896	0.899	0.901
	LS-SVM	<b>0.923</b>	<b>0.944</b>	<b>0.955</b>
MSN	N-C	0.870	0.873	0.876
	LS-SVM	<b>0.950</b>	<b>0.953</b>	<b>0.960</b>

the precision of query spelling correction can benefit from the use of rich features. However, it does not result in much improvement in recall. This is reasonable as the additional features are primarily designed to improve the accuracy of the top correction generated by the system. In doing so, it actually regularizes the ability of the system in retrieving diversified results. For instance, the global heuristic feature on the number of word change tries to prevent the system from returning candidates having more than a certain number of changed words. For the TREC collection where more than one corrections can be labeled for a query, this phenomena is aggravated.

Table 3: LSSVM w/ and w/o Rich Features

Dataset	Method	Precision	R@10	F1
TREC	w/o	0.942	<b>0.946</b>	0.944
	w/	<b>0.955</b>	0.944	<b>0.949</b>
MSN	w/o	0.898	0.952	0.924
	w/	<b>0.903</b>	<b>0.953</b>	<b>0.928</b>

## 6 Conclusions

In this paper, we present a novel discriminative model for query spelling correction. The paper made the following contributions:

First, to the best of our knowledge, this is a novel exploration of directly optimizing the search phase in query spelling correction with a discriminative model. By modeling word alignment as the latent structural information, our formulation also deals with word boundary errors. We propose to use LS-SVM for learning the discriminative model which naturally incorporates search in the learning process. Second, we develop an efficient search algorithm that solves the inference problems in the LS-SVM based model. We analyze the criteria for selecting and designing features to ensure the correctness and efficiency of the search algorithm. Third, we explore effective features to improve the accuracy of the model. Finally, experiments are conducted to verify the effectiveness of the proposed model. It is shown that as a standalone speller our system achieves high accuracy. When used in a two stage approach, it attains higher recall than the noisy channel model and can thus serve as a superior method for candidate generation. We also verify that through the use of rich features, we can further improve the accuracy of our query spelling correction system.

## Abstract

Much of the writing styles recognized in rhetorical and composition theories involve deep syntactic elements. However, most previous research for *computational* stylometric analysis has relied on shallow lexico-syntactic patterns. Some very recent work has shown that PCFG models can detect distributional difference in syntactic styles, but without offering much insights into exactly what constitute salient stylistic elements in sentence structure characterizing each authorship. In this paper, we present a comprehensive exploration of syntactic elements in writing styles, with particular emphasis on *interpretable characterization* of stylistic elements. We present analytic insights with respect to the authorship attribution task in two different domains.

## 1 Introduction

Much of the writing styles recognized in rhetorical and composition theories involve deep syntactic elements in style (e.g., Bain (1887), Kemper (1987) Strunk and White (2008)). However, previous research for automatic authorship attribution and computational stylometric analysis have relied mostly on shallow lexico-syntactic patterns (e.g., Mendenhall (1887), Mosteller and Wallace (1984), Stamatakos et al. (2001), Baayen et al. (2002), Koppel and Schler (2003), Zhao and Zobel (2007), Luyckx and Daelemans (2008)).

Some very recent works have shown that PCFG models can detect distributional difference in sentence structure in gender attribution (Sarawgi et al., 2011), authorship attribution (Raghavan et al., 2010), and native language identification (Wong and Dras, 2011). However, still very little has been understood exactly what constitutes salient stylistic elements in sentence structures that characterize each author. Although the work of Wong and Dras (2011) has extracted production rules with highest information gain, their analysis stops short of providing insight any deeper than what simple  $n$ -gram-level analysis could also provide.<sup>1</sup> One might even wonder whether PCFG models are hinging mostly on leaf production rules, and whether there are indeed deep syntactic differences at all. This paper attempts to answer these questions.

As an example of syntactic stylistic elements that have been much discussed in rhetorical theories, but have not been analyzed computationally, let us consider two contrasting sentence styles: *loose (cumulative)* and *periodic*:<sup>2</sup> a *loose* sentence places the main clause at the beginning, and then appends subordinate phrases and clauses to develop the main message. In contrast, a *periodic* sentence starts with subordinate phrases and clauses, suspending the most

<sup>1</sup>For instance, missing determiners in English text written by Chinese speakers, or simple  $n$ -gram anomaly such as frequent use of “according to” by Chinese speakers (Wong and Dras, 2011).

<sup>2</sup>*Periodic* sentences were favored in classical times, while *loose* sentences became more popular in the modern age.

Table 2: Loose/Periodic sentence with identical set of words and POS tags

important part to the end. The example in Table 2 highlights the difference:

Notice that these two sentences comprise of an identical set of words and part-of-speech. Hence, shallow lexico-syntactic analysis will not be able to catch the pronounced stylistic difference that is clear to a human reader.

One might wonder whether we could gain interesting insights simply by looking at the most discriminative production rules in PCFG trees. To address this question, Table 1 shows the top ten most discriminative production rules for authorship attribution for scientific articles,<sup>3</sup> ranked by LIBLINEAR (Fan et al., 2008).<sup>4</sup> Note that terminal production rules are excluded so as to focus directly on syntax.

It does provide some insights, but not to a satisfactory degree. For instance, Hobbs seems to favor inverted declarative sentences (SINV) and adverbs with prepositions (RB PP). While the latter can be easily obtained by simple part-of-

<sup>3</sup>See Section 2 for the description of the dataset.

<sup>4</sup>We use Berkeley PCFG parser (Petrov and Klein, 2007) for all experiments.

speech analysis, the former requires using parse trees. We can also observe that none of the top 10 most discriminative production rules for Hobbs includes SBAR tag, which represents subordinate clauses. But examining discriminative rules alone is limited in providing more comprehensive characterization of idiolects.

Can we unveil something more in deep syntactic structure that can characterize the collective syntactic difference between any two authors? For instance, what can we say about distributional difference between loose and periodic sentences discussed earlier for each author? As can be seen in Table 1, simply enumerating most discriminative rules does not readily answer questions such as above.

In general, production rules in CFGs do not directly map to a wide variety of stylistic elements in rhetorical and composition theories. This is only as expected however, partly because CFGs are not designed for stylometric analysis in the first place, and also because some syntactic elements can go beyond the scope of context free grammars.

As an attempt to reduce this gap between modern statistical parsers and cognitively recognizable stylistic elements, we explore two complementary approaches:

1. Translating some of the well known stylistic elements of rhetorical theories into PCFG analysis (Section 3).
2. Investigating different strategies of analyzing PCFG trees to extract author characteristics that are interesting as well as *interpretable* (Sections 4 & 5).

    if SBAR  $\notin \Omega(N_r)$  then
      return SIMPLE
    else
      return COMPLEX
return OTHER
```

---

We present analytic insights with respect to the authorship attribution task in two distinct domains.

## 2 Data

For the empirical analysis of authorship attribution, we use two different datasets described below. Sections 3, 4 & 5 provide the details of our stylometric analysis.

**Scientific Paper** We use the ACL Anthology Reference Corpus (Bird et al., 2008). Since it is nearly impossible to determine the gold-standard authorship of a paper written by multiple authors, we select 10 authors who have published at least 8 single-authored papers. We include 8 documents per author, and remove citations, tables, formulas from the text using simple heuristics.<sup>5</sup>

**Novels** We collect 5 novels from 5 English authors: Charles Dickens, Edward Bulwer-Lytton, Jane Austen, Thomas Hardy and Walter Scott. We select the first 3000 sentences from each novel and group every 50 consecutive sentences into 60 documents per novel per author.

---

<sup>5</sup>Some might question whether the size of the dataset used here is relatively small in comparison to typical dataset comprised of thousands of documents in conventional text categorization. We point out that authorship attribution is fundamentally different from text categorization in that it is often practically impossible to collect more than several documents for each author. Therefore, it is desirable that the attribution algorithms to detect the authors based on very small samples.

---

**Algorithm 2** Sentence Type-II Identification

---

**Input:** Parse tree  $t(N_r)$  of sentence  $s$ **Output:** Type of  $s$ .

```
 $k \leftarrow 1$ 
while  $k \leq \lambda$  do
  if  $L_k^{top} \neq VP$  then
    if  $s \in \Omega(L_k^{top})$  or SBAR  $\in \Omega(L_k^{top})$  then
      return PERIODIC
    else
      if  $s \in \Omega(L_k^{top})$  or SBAR  $\in \Omega(L_k^{top})$  then
        return LOOSE
return OTHER
```

## 3 Sentence Types

In this section, we examine well-known sentence types that are recognized in the literature, but have not been analyzed computationally.

**Type-I Identification – Simple/Complex/Compound/Complex-Compound:** PCFG trees do not provide this information directly, hence we must construct an algorithm to derive it. The key to identifying these sentences is the existence of *dependent* and *independent* clauses. For the former, we rely on the SBAR tag, while for the latter, we first define the sequence of nodes right below the root (e.g., [NP VP .] shown in the horizontal box in Figure 1). We call this the *top structural level*. We then check whether  $s$  (in addition to the root  $s$ ) appears in this sequence.

Formally, let  $L^{top} = \{N_i\}$  be the set of nodes in the top structural level, and  $\lambda = |L^{top}|$ . Let  $t(N_r)$  be the tree rooted at  $N_r$ , and  $\Omega(N_r)$  denote the set of nodes in  $t(N_r)$ . Algorithm 1 shows the procedure to determine the type-I class of a sentence based on its PCFG tree.<sup>6</sup>

**Type-II Identification – Loose/Periodic:**

A sentence can also be classified as loose or periodic, and we present Algorithm 2 for this identification. We perform a mini-evaluation on 20 previously unseen sentences for each type<sup>7</sup>. Our algorithm was able to perform type-I identification on all sentences correctly. In type-II

---

<sup>6</sup>Note that Algorithm 1 & 2 rely on the use of Berkeley parser (Petrov and Klein, 2007).

<sup>7</sup>These were gathered from several online quizzes for English learners. E.g., <http://grammar.about.com>, <http://a4esl.org>

Table 3: Sentence Types (%) in scientific data.

identification, it labeled all loose sentences correctly, and achieved 90% accuracy on periodic sentences.

**Discussion** Tables 3 & 4 show the sentence type distribution in scientific data and novels, respectively.<sup>8</sup> We see that different authors are characterized by different distribution of sentence types. For instance, in Table 3, Lin is a prolific user of simple sentences while McDon prefers employing complex sentences. McDon also uses complex-compound sentences quite often (15.5%), more than twice as frequently as Lin. Notice that all authors use loose sentences much more often than periodic sentences, a known trend in modern English.

In Table 4, we see the opposite trend among 19<sup>th</sup>-century novels: with the exception of Jane Austen, all authors utilize periodic sentences comparatively more often. We also notice that complex and complex-compound sentences abound, as expected from classic literary pros.

*Can we determine authorship solely based on the distribution of sentence types?*

We experiment with a SVM classifier using just 6 features (one feature for each sentence type in Table 3), and we achieve accuracy 36.0% with the scientific data. Given that a random baseline would achieve only about 10% accuracy, this demonstrates that the distribution of sentence types does characterize an idiolect to some degree.

<sup>8</sup>Due to space limitation, we present analyses based on 4 authors from the scientific data.

TYPE	DICKENS	B-LYT	AUSTEN	HARDY	SCOTT

## 4 Syntactic Elements Based on Production Rules

In this section, we examine three different aspects of syntactic elements based on production rules.

### 4.1 Syntactic Variations

We conjecture that the *variety* of syntactic structure, which most previous research in computational stylometry has not paid much attention to, provides an interesting insight into authorship. One way to quantify the degree of syntactic variations is to count the unique production rules. In Tables 5, we show the extent of syntactic variations employed by authors using the standard deviation  $\sigma$  and the *coverage* of an author:

$$C(a) := \frac{|\mathcal{R}(a)|}{|\cup_a \mathcal{R}(a)|} \times 100$$

where  $\mathcal{R}(a)$  denotes the set of unique production rules used by author  $a$ , and  $\cup_a$  iterates over all authors. In order to compare among authors, we also show these parameters normalized with respect to the highest value. Our default setting is to exclude all lexicalized rules in the productions to focus directly on the syntactic variations. In our experiments (Section 6), however, we do augment the rules with (a) ancestor nodes to capture deeper syntactic structure and (b) lexical (*leaf*) nodes.

As hypothesized, these statistics provide us new insights into the authorship. For instance, we find that McDon employs a wider variety of syntactic structure than others, while Lin’s writing exhibits relatively the least variation. Moreover, comparing Joshi and Hobbs, it is interesting to see the standard deviation differ a lot

	HOBBS	JOSHI	LIN	MCDON	DICKENS	B-LYT	AUSTEN	HARDY	SCOTT
$\mathcal{C}$	36.0	37.6	32.8	42.6	30.9	28.8	36.2	30.0	24.1
$\mathcal{C}_{\text{norm}}$	0.84	0.88	0.77	1.0	0.85	0.79	1.0	0.83	0.67
$\sigma$	51.5	39.2	63.3	44.4	88.3	81.6	98.0	125.3	114.7
$\sigma_{\text{norm}}$	0.81	0.62	1.0	0.7	0.7	0.65	0.78	1.0	0.92

Table 5: Syntactic variations of different authors in the scientific domain.

S → PP NP VP .	S → ADVP NP VP .	S → NP ADVP VP .	S → NP PP VP .

Table 6: Most discriminative sentence outlines in the scientific data.  $\#N$  shows the number of unique sentence outlines of each author.

(51.5 and 39.2), in spite of their  $\mathcal{C}$  scores being similar: 36.0% and 37.6%, respectively. This indicates that Hobbs tends to use a certain subset production rules much more frequently than Joshi. Lin exhibits the highest standard deviation in spite of having least syntactic variation, indicating that he uses a much smaller subset of productions regularly, while occasionally deviating to other rules.

Similarly, among novels, Jane Austen’s writing has the highest amount of variation, while Walter Scott’s writing style is the least varied. Even though authors from both datasets display similar  $\mathcal{C}$  scores (Table 5), the difference in  $\sigma$  is noteworthy. The significantly higher linguistic variation is to be expected in creative writing of such stature. It is interesting to note that the authors with highest coverage – Austen and Dickens – have much lower deviation in their syntactic structure when compared to Hardy and Scott. This indicates that while Austen and Dickens consistently employ a wider variety of sentence structures in their writing, Hardy and Scott follow a relatively more uniform style with sporadic forays into diverse syntactic constructs.

## 4.2 Sentence Outlines

Although the approach of Section 4.1 give us a better and more general insight into the characteristics of each author, its ability to provide insight on *deep* syntactic structure is still limited, as it covers production rules at all levels of

the tree. We thus shift our focus to the top level of the trees, e.g., the second level (marked in a horizontal box) in TREE (1) of Figure 1, which gives us a better sense of sentence outlines.

Tables 6 and 7 present the most discriminative sentence outlines of each author in the scientific data and novels, respectively. We find that McDon is a prolific user of subordinate clauses, indicating his bias towards using complex sentences. The rule “S → SBAR S CC S” shows his inclination towards complex-compound sentences as well. These inferences are further supported by the observations in Table 3. Another observation of possible interest is the tendency of Joshi and Lin to begin sentences with prepositional phrases.

In comparing Table 6 and Table 7, notice the significantly higher presence of complex and compound-complex structures in the latter<sup>9</sup>. The most discriminating sentence outlines for Jane Austen, for instance, are all indicative of complex-compound sentences. This is further supported by Table 4.

## 5 Syntactic Elements Based on Tree Topology

In this section, we investigate quantitative techniques to capture stylistic elements in the tree

<sup>9</sup>The presence of “FRAG” is not surprising. Intentional use of verbless sentence fragments, known as *scesis onomaton*, was often employed by authors such as Dickens and Bulwer-Lytton (Quinn, 1995).

DICKENS	BULWER-LYTTON	AUSTEN	HARDY	SCOTT

Table 8: Tree topology metrics for scientific data and novels.

topology. Figure 1 shows three different parse trees to accompany our discussion.<sup>10</sup> Notice that sentence (1) is a loose sentence, and sentence (2) is periodic. In general, loose sentences grow deep and unbalanced, while periodic sentences are relatively more balanced and wider.

For a tree  $t$  rooted at  $N_R$  with a height  $n$ , let  $\mathcal{T}$  be the set of leaf nodes, and let  $\mathcal{F}$  be the set of furcation nodes, and let  $\xi(N_i, N_j)$  denote the length of the shortest path from  $N_i$  to  $N_j$ . Inspired by the work of Shao (1990), we analyze tree topology with the following four measurements:

- LEAF HEIGHT ( $h^{\mathcal{T}} = \{h_i^{\mathcal{T}}, N_i \in \mathcal{T}\}$ ), where  $h_i^{\mathcal{T}} = \xi(N_i, N_R)$   $N_i \in \mathcal{T}$ . For instance, the leaf height of “free” of TREE (2) in Fig. 1 is 6.
- FURCATION HEIGHT ( $h^{\mathcal{F}} = \{h_i^{\mathcal{F}}, N_i \in \mathcal{F}\}$ ), where  $h_i^{\mathcal{F}}$  is the maximum leaf height within the subtree rooted at  $N_i$ . In Figure 1, for example, the furcation height of the VP in TREE (2) (marked in triangle) is 3.
- LEVEL WIDTH ( $w^L = \{w_l, 1 \leq l \leq n\}$ ), where  $w_l = |\{N_i : \xi(N_i, N_R) = l\}|$ . E.g.,  $w_4$  of TREE (1) in Figure 1 is 6.

<sup>10</sup>Example sentences are taken from Lin (1997), Joshi (1992), and Lin (1995).

- HORIZONTAL  $\sigma^H = \{\sigma_i^H, N_i \in \mathcal{F}\}$ , and VERTICAL IMBALANCE  $\sigma^S = \{\sigma_i^S, N_i \in \mathcal{F}\}$ . Let  $\mathcal{C}$  be the set of child nodes of  $N_k$ . If  $|\mathcal{C}| \geq 2$ , then

$$\sigma_k^H = \sqrt{\frac{1}{n} \sum_{i=1}^{|\mathcal{C}|} (h_i^{\mathcal{F}} - H)^2}$$

where  $H = \frac{1}{|\mathcal{C}|} \sum_{i=1}^{|\mathcal{C}|} h_i^{\mathcal{F}}$ . Similarly,

$$\sigma_k^S = \sqrt{\frac{1}{n} \sum_{i=1}^{|\mathcal{C}|} (s(N_i) - S)^2}$$

where  $S = \frac{1}{|\mathcal{C}|} \sum_{i=1}^{|\mathcal{C}|} s(N_i)$  and  $s(N_i)$  is the number of leaf nodes of tree rooted at  $N_i$ . As shown in Figure 1, the imbalance of the internal node VP in TREE (2) (marked in triangle) is 0.5 horizontally, and 0.5 vertically.

To give an intuition on the relation between these measurements and different tree structures, Table 9 provides the measurements of the three trees shown in Figure 1.

Note that all three sentences are of similar length but show different tree structures. TREE (1) and TREE (2) differ in that TREE (1) is highly unbalanced and grows deep, while TREE

Figure 1: Parsed trees

METRICS	TREE (1)	TREE (2)	TREE (3)
# of tokens	15	13	13
$\max_i \{h_i^T\}$	11	6	6
$\max_i \{w_i^L\}$	6	9	9
$\max_i \{\sigma_i^H\}$	4.97	1.6	1.7
$\max_i \{\sigma_i^S\}$	4	1.5	4.7

Table 9: Tree Topology Statistics for Figure 1.

(2) is much better balanced and grows shorter but wider. Comparing TREE (2) and TREE (3), they have the same max LEAF HEIGHT, LEVEL WIDTH, and HORIZONTAL IMBALANCE, but the latter has bigger VERTICAL IMBALANCE, which quantifies the imbalance in terms of the text span covered by subtrees.

We provide these topological metrics for authors from both datasets in Table 8.

## 6 Experiments & Evaluation

In our experiments, we utilize a set of features motivated by PCFG trees. These consist of simple production rules and other syntactic features based on tree-traversals. Table 10 describes these features with examples from TREE (2), using the portion marked by the triangle.

These sets of production rules and syntax fea-

tures are used to build SVM classifiers using LIBLINEAR (Fan et al., 2008), wherein all feature values are encoded as term-frequencies normalized by document size. We run 5-fold cross-validation with training and testing split first as 80%/20%, and then as 20%/80%.

We would like to point out that the latter configuration is of high practical importance in authorship attribution, since we may not always have sufficient training data in realistic situations, e.g., forensics (Luyckx and Daelemans, 2008).

Lexical tokens provide strong clues by creating features that are specific to each author: research topics in the scientific data, and proper nouns such as character names in novels. To lessen such topical bias, we lemmatize and rank words according to their frequency (in the entire dataset), and then consider the top 2,000 words only. Leaf-node productions with words outside this set are disregarded.

Our experimental results (Tables 11 & 12) show that not only do deep syntactic features perform well on their own, but they also significantly improve over lexical features. We also show that adding the  $STYLE_{11}$  features further improves performance.

FEATURES	
$pr$	Rules <i>excluding</i> terminal productions. E.g., $\mathbf{VP} \rightarrow \mathbf{VBG} \text{ NP}$
$syn_v$	Traversal from a non-leaf node to its grandparent (embedded rising). E.g., $\mathbf{VP} \hat{\ } \mathbf{S} \rightarrow \mathbf{PP}$
$syn_h$	Left-to-right traversal in the set of all non-leaf children of a node. E.g., $\mathbf{VBG} \rightarrow \mathbf{NP}$ (for node $\mathbf{VP}$ )
$syn_{v+h}$	$syn_v \cup syn_h$
$syn_0$	No tree traversal. Feature comprises interior nodes only.
$syn_{\downarrow}$	Union of all edges to child nodes, except when child is a leaf node. E.g., $\{\mathbf{VP} \rightarrow \mathbf{VBG}, \mathbf{VP} \rightarrow \mathbf{NP}\}$
$syn_{\uparrow}$	$syn_{\downarrow} \cup \{\text{edge to parent node}\}$
STYLE <sub>11</sub>	The set of 11 extra stylistic features. 6 values from the distribution of sentence types (Section 3), and 5 topological metrics (Section 5) characterizing the height, width and imbalance of a tree.

VARIATIONS	
$\hat{pr}$	Each production rule is augmented with the grandparent node.
*	Terminal ( <i>leaf</i> ) nodes are included.

Table 10: Features and their lexico-syntactic variations. *Illustration:*  $\hat{pr}^*$  denotes the set of production rules  $pr$  (including terminal productions) that are augmented with their grandparent nodes.

To quantify the amount of authorship information carried in the set STYLE<sub>11</sub>, we experiment with a SVM classifier using only 11 features (one for each metric), and achieve accuracy of 42.0% and 52.0% with scientific data and novels, respectively. Given that a random-guess baseline would achieve only 10% and 20% (resp.), and that the classification is based on just 11 features, this experiment demonstrates how effectively the tree topology statistics capture idiolects. In general, lexicalized features yield higher performance even after removing topical words. This is expected since tokens such as function words play an important role in determining authorship (e.g., Mosteller and Wallace (1984), Garcia and Martin (2007), Argamon et al. (2007)).

A more important observation, however, is that even after removing the leaf production rules, accuracy as high as 93% (scientific) and 92.2% (novels) are obtained using syntactic fea-

FEATURES	SCIENTIFIC		NOVELS	
		+STYLE <sub>11</sub>		+STYLE <sub>11</sub>
STYLE <sub>11</sub>	20.6	–	43.1	–
Unigram	56.9	–	69.3	–
$syn_h$	53.7	53.7	68.3	67.9
$syn_0$	22.9	<b>31.1</b>	57.8	<b>62.5</b>
$syn_{\downarrow}$	43.4	<b>44.0</b>	63.6	<b>65.7</b>
$syn_{\uparrow}$	51.1	<b>51.7</b>	71.3	<b>72.8</b>
$syn_{v+h}$	54.0	<b>55.7</b>	72.0	<b>73.2</b>
$syn_h^*$	63.1	<b>64.0</b>	72.1	<b>73.2</b>
$syn_0^*$	56.6	56.0	73.1	<b>74.1</b>
$syn_{\downarrow}^*$	56.3	<b>57.2</b>	74.0	<b>74.9</b>

$pr^*$	63.7	<b>65.1</b>	71.5	<b>73.2</b>
$\hat{pr}^*$	66.3	<b>69.4</b>	73.6	<b>74.9</b>

Table 11: Authorship attribution with **20% training data**. Improvement with addition of STYLE<sub>11</sub> shown in bold.

tures, which demonstrates that there are syntactic patterns unique to each author. Also notice that using only production rules, we achieve higher accuracy in novels (90.1%), but the addition of STYLE<sub>11</sub> features yields better results with scientific data (93.0%).

Using different amounts of training data provides insight about the influence of lexical clues. In the scientific dataset, increasing the amount of training data decreases the average performance difference between lexicalized and unlexicalized features: 13.5% to 11.6%. In novels, however, we see the opposite trend: 6.1% increases to 8.1%.

We further observe that with scientific data, increasing the amount of training data improves the average performance across all unlexicalized feature-sets from 50.0% to 82.9%, an improvement of 32.8%. For novels, the corresponding improvement is small in comparison: 17.0%.

This difference is expected. While authors such as Dickens or Hardy have their unique writing styles that a classifier can learn based on few documents, capturing idiolects in the more rigid domain of scientific writing is far from obvious with little training data.

FEATURES	SCIENTIFIC		NOVELS	
		+STYLE <sub>11</sub>		+STYLE <sub>11</sub>
STYLE <sub>11</sub>	42.0	–	52.0	–
Unigram	88.0	–	92.7	–
<i>syn<sub>h</sub></i>	85.0	85.0	87.6	<b>88.9</b>
<i>syn<sub>0</sub></i>	40.0	<b>53.0</b>	66.4	<b>72.3</b>
<i>syn<sub>↓</sub></i>	78.0	<b>82.0</b>	80.3	<b>82.3</b>
<i>syn<sub>↑</sub></i>	85.0	<b>92.0</b>	89.3	<b>92.2</b>
<i>syn<sub>v+h</sub></i>	89.0	<b>93.0</b>	90.1	<b>91.2</b>
<i>syn<sub>h</sub><sup>*</sup></i>	93.0	93.0	93.7	<b>93.9</b>
<i>syn<sub>0</sub><sup>*</sup></i>	92.0	<b>94.0</b>	92.1	<b>93.2</b>
<i>syn<sub>↓</sub><sup>*</sup></i>	93.0	<b>94.0</b>	93.4	<b>94.5</b>
<i>syn<sub>↑</sub><sup>*</sup></i>	93.0	<b>95.0</b>	94.9	<b>95.2</b>
<i>syn<sub>v+h</sub><sup>*</sup></i>	94.0	<b>96.0</b>	94.7	<b>94.8</b>
<i>pr</i>	85.0	<b>86.0</b>	86.7	86.7
<i>p<sup>∧</sup>r</i>	87.0	<b>89.0</b>	88.2	<b>89.3</b>
<i>pr<sup>*</sup></i>	93.0	<b>94.0</b>	92.1	<b>93.2</b>
<i>p<sup>∧</sup>r<sup>*</sup></i>	94.0	<b>95.0</b>	94.5	<b>95.1</b>

Table 12: Authorship attribution with **80% training data**.

Turning to lexicalized features, we note that with more training data, lexical cues perform better in scientific domain than in novels. With 80% data used for training, the average performance of lexicalized feature-sets with science data is 94.4%, and slightly lower at 94.3% for novels. With less training data, however, these figures are 63.5% and 74.3% respectively.

Finally, we point out that adding the style features derived from sentence types and tree topologies almost always improves the performance. In scientific data, *syn<sub>v+h</sub><sup>\*</sup>* with STYLE<sub>11</sub> features shows the best performance (96%), while *syn<sub>↓</sub><sup>\*</sup>* yields the best results for novels (95.2%). For unlexicalized features, adding STYLE<sub>11</sub> to *syn<sub>v+h</sub>* and *syn<sub>↑</sub>* yields respective improvements of 4.0% and 2.9% in the two datasets.

## 7 Related Work

There are several hurdles in authorship attribution. First and foremost, writing style is extremely domain-dependent. Much of previous research has focused on several domains of writing, such as informal modern writing in blogs and online messages (Zheng et al., 2006), rela-

tively formal contemporary texts such as news articles (Raghavan et al., 2010), or classical literature like novels and proses (e.g., (Burrows, 2002), (Hoover, 2004)).

The nature of these features have also varied considerably. Character level *n*-grams have been used by several researchers; most notably by Peng et al. (2003), by Houvardas and Stamatatos (2006) for feature selection, and by Stamatatos (2006) in ensemble learning. Keselj et al. (2003) employed frequency measures on *n*-grams for authorship attribution.

Others, such as Zhao and Zobel (2005), Argamon and Levitan (2004), Garcia and Martin (2007), have used word-level approaches instead, incorporating the differential use of function words by authors.

More sophisticated linguistic cues have been explored as well: parts-of-speech *n*-grams (Diederich et al., 2003), word-level statistics together with POS-sequences (Luyckx and Daelemans, 2008), syntactic labels from partial parsing (Hirst and Feiguina, 2007), etc. The use of syntactic features from parse trees in authorship attribution was initiated by Baayen et al. (1996), and more recently, Raghavan et al. (2010) have directly employed PCFG language models in this area.

Syntactic features from PCFG parse trees have also been used for gender attribution (Sarawgi et al., 2011), genre identification (Stamatatos et al., 2000), native language identification (Wong and Dras, 2011) and readability assessment (Pitler and Nenkova, 2008). The primary focus of most previous research, however, was to attain better classification accuracy, rather than providing linguistic interpretations of individual authorship and their stylistic elements.

Our work is the first to attempt authorship attribution of scientific papers, a contemporary domain where language is very formal, and the stylistic variations have limited scope. In addition to exploring this new domain, we also present a comparative study expounding the role of syntactic features for authorship attribution in classical literature. Furthermore, our work is also the first to utilize tree topological

features (Chan et al., 2010) in the context of stylometric analysis.

## 8 Conclusion

In this paper, we have presented a comprehensive exploration of syntactic elements in writing styles, with particular emphasis on interpretable characterization of stylistic elements, thus distinguishing our work from other recent work on syntactic stylometric analysis. Our analytical study provides novel statistically supported insights into stylistic elements that have not been computationally analyzed in previous literature. In the future, we plan to investigate the use of syntactic feature generators for text categorization (e.g., Collins and Duffy (2002), Moschitti (2008), Pighin and Moschitti (2009)) for stylometry analysis.
