The major advantage of embedding over co-training is that it produces where the two different types of objects, entity-pairs and relation expressions, are treated in the exactly the same vector space. Therefore, we can easily gather a set of relation expressions relevant to a given prototype entity pair of a relation. In this experiment, instead of representative relation expressions, we gave entity pairs which are prototypical examples of certain relations. As in the previous experiment, we used the shortest paths as relation expressions, and ignored relation expressions with frequency under 10.

Table 5 shows the list of relation expressions for two prototypical entity-pairs used in the ENT dataset, ⟨charlie chaplin, london⟩ as a representative entity-pair for BIRTHPLACE and ⟨facebook inc, mark zuckerberg⟩ as CEO relation semantics. The table shows that the top-10 frequently co-occurring relation expressions. While many noisy relation expressions (i.e. ambiguous expressions) appear by extracting expressions based on their co-occurrence frequency with ⟨charlie chaplin, london⟩, these ambiguous expressions disappear in the proximity of the entity-pair in the common space. Moreover, the result of ⟨facebook inc. mark zuckerberg⟩ shows that some relation expressions that do not co-occur with the prototype entity-pair were successfully extracted, such as {'s executive ,}.

5 Related Work

Bollegala et al. (2010) proposed a simple sequential co-clustering framework of entity-pairs and relation expressions for objects sharing the same semantic relation to be clustered. Our definition of primal-dual

⟨charlie chaplin, london⟩		⟨facebook inc, mark zuckerberg⟩	
Embedded	Co-occurrence	Embedded	Co-occurrence
{bear walworth}	{bear}	{'s executive ,}	{, ceo}
{bear april}	{'s " arrangement while lay orchestra}	{ceo be}	{, ceo (}
{play}	{,}	{ceo}	{founder and}
{bear}	{reception}	{,}	{everything , ceo}
{bear}	{'s}	{'s president ,}	{andceo}
{bear woolsthorpe ,}	{'s}	{have say}	{ceo ,}
{bear woolthrope}	{be when}	{, ceo ,}	{-}
{be member parliament}	{and}	{, ceo}	N/A
{bear woolsthorpe}	{bear april street , walworth ,}	{ceo become}	N/A
{'s}	{walk ,}	{buy}	N/A

Table 5: Relation expressions gathered by prototype entity-pairs on the ENT dataset. This table shows the top-10 ranked relation expressions that are closest to the representative entity-pairs ⟨charlie chaplin, london⟩ as BIRTHPLACE and ⟨facebook inc, mark zuckerberg⟩ as CEO. ⟨facebook inc, mark zuckerberg⟩ co-occurred with only seven discrete relation expressions.

semantic space and common space embedding approach can be viewed as extensions of their work by introducing feature spaces as characterizations. This extension enables to utilize each space's characterizations and calculate similarity between different types of objects. Baroni and Lenci (2010) proposed a framework that analyze triplets as a third-order tensor, called "distributional memory". By matricizing the tensor to second-order tensors, that is matrices, this framework can utilize the relationship between entity-pairs and relation expressions. They also propose the procedure for generating continuous vector representations of entities and relation expressions through the tensor decomposition techniques. However, this framework cannot use semantic spaces independently defined, therefore it is difficult to incorporate the similarity information between entity-pairs or similarities between relation expressions into the decomposition procedure in contract to our framework based on MVPLS. Lin and Pantel (2001) proposed a weakly supervised framework of mining paraphrases based on shortest paths as basic units to be mined. Our work can be viewed as an extension by mixing entity-pair characterizations with the extended distributional hypothesis by embedding.

Many other previous work have been proposed to construct a knowledge base, including relation expressions (Carlson et al., 2010; Fader et al., 2011; Nakashole et al., 2012). However, they cannot interactively predict semantic meanings of objects through labeled objects of the other space.

As for treatment of ambiguity, some previous work has focused on triplet clustering to disambiguate each triplet object known as relation extraction. Unlike other mining tasks, this task requires a system to disambiguate the meaning of a relation expression r in $\langle r, e_1, e_2 \rangle$ which appears in a specific context. We did not treat this task in this paper, however, our framework would discharge the burden by showing the insight of ambiguities of each relation expression and entity-pair. Yao et al. (2011; 2012) proposed a new triplet clustering method through a generative probabilistic model. The model used surrounding contexts as features in both a sentence and document level to identify the meaning of each triplet. They demonstrated the effectiveness of their models compared with USP (Poon and Domingos, 2009) or DIRT (Lin and Pantel, 2001). Min et al. (2012) provided a simple and scalable triplet clustering algorithm in an unsupervised way and enables to incorporate various resources about entity and relation expressions. Chen et al. (2006) proposed a label propagation algorithm for relation extraction as a semi-supervised learning method by utilizing the information of parsing.

6 Conclusion

We propose a common space embedding framework which constructs a semantic space in which both entity-pairs and relation expressions are represented. We showed that our framework is effective to construct the extension set and the manifestation set of a relation R in this space. The results of experiments showed that the common space is further refined for tasks such as relation and relation expression mining, compared with the original two spaces. Moreover, we showed relation expressions collected from a small set of entity-pairs through the common space, which share the same semantics as being relevant.

There are several interesting future topics:

- how to iteratively collect objects from a dual object, like bootstrapping
- how to reduce surface diversities of relation expressions which are not abstracted away by simple method or shortest paths (by using methods such as SOL Pattern Model (Nakashole et al., 2012))
- How to combine a ground truth and non-textual knowledge stored in knowledge bases for characterizing entity-pairs with our framework
- How to extend the framework in order to deal with n-ary relations

Abstract

This paper describes a new Word Sense Disambiguation (WSD) algorithm which extends two well-known variations of the Lesk WSD method. Given a word and its context, Lesk algorithm exploits the idea of maximum number of shared words (maximum overlaps) between the context of a word and each definition of its senses (gloss) in order to select the proper meaning. The main contribution of our approach relies on the use of a word similarity function defined on a distributional semantic space to compute the gloss-context overlap. As sense inventory we adopt BabelNet, a large multilingual semantic network built exploiting both WordNet and Wikipedia. Besides linguistic knowledge, BabelNet also represents encyclopedic concepts coming from Wikipedia. The evaluation performed on SemEval-2013 Multilingual Word Sense Disambiguation shows that our algorithm goes beyond the most frequent sense baseline and the simplified version of the Lesk algorithm. Moreover, when compared with the other participants in SemEval-2013 task, our approach is able to outperform the best system for English.

1 Introduction

Unsupervised Word Sense Disambiguation (WSD) algorithms aim at resolving word ambiguity without the use of annotated corpora. Among these, two categories of knowledge-based algorithms gained popularity: overlap- and graph-based methods. The former owes its success to the simple intuition underlying that family of algorithms, while the diffusion of the latter started growing after the development of semantic networks.

The overlap-based algorithms stem from the Lesk (1986) one, which inspired a whole family of methods that exploit the number of common words in two sense definitions (*glosses*) to select the proper meaning in a context. Glosses play a key role in Lesk algorithm, which exploits only two types of information: 1) the set of dictionary entries, one for each possible word meaning, and 2) the information about the context in which the word occurs. The idea is simple: given two words, the algorithm selects those senses whose definitions have the maximum overlap, i.e. the highest number of common words in the definition of the senses. In order to extract definitions, Lesk adopted the *Oxford Advanced Learner's* dictionary. This approach suffers from two problems: 1) complexity, the number of comparisons increases combinatorially with the number of words in a text; and 2) definition expressiveness, the overlap is based only on word co-occurrences in glosses. The first problem was tackled by a "simplified" version of Lesk algorithm (Kilgarriff and Rosenzweig, 2000), which disambiguated each word separately. Given a word, the meaning whose gloss shows the maximum overlap with the current context, represented by the surrounding words, is selected. The simplified Lesk significantly outperforms the original Lesk algorithm as proved by Vasilescu et al. (2004). The second problem was faced by Banerjee and Pedersen (2002), who proposed an "adapted" Lesk algorithm. The adapted variation exploits relationships among meanings: each gloss is extended by the definitions of semantically related meanings. Banerjee and Pedersen adopt WordNet as semantic network and their algorithm takes into account several relations:

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1591–1600, Dublin, Ireland, August 23-29 2014.

hypernym, hyponym, holonym, meronym, troponym and attribute relation. The adapted algorithm outperforms the Lesk one in disambiguating nouns in SensEval-2 English task. Despite these improvements, overlap-based algorithms failed to stand the pace with figures achieved by graph approaches. Their ability to disambiguate all words in a sequence at once, meanwhile exploiting the existing interconnections (edges) between senses (nodes), has made these algorithms more principled than methods that use the sense definition overlaps. Moreover, the success of PageRank in web search has inspired a new vein of algorithms for sense disambiguation that blossomed during the past years. Although graph-based algorithms have taken advantage of the rich set of relationships available in dictionaries like WordNet, they completely neglected the role of glosses in the disambiguation process.

From our standpoint, glosses are an important piece of information since they extensionally define a word meaning. In this paper we propose a revised version of the simplified and adapted Lesk variations that overcomes limits due to the definition expressiveness. Our method replaces the concept of overlap with that of similarity. Similarity is computed on a Distributional Semantic Space (DSS) in order to account for semantic relationships between words occurring in the definition and context, for as they emerge from the use in the language. Indeed, Distributional Semantics Models (DSM) exploit the geometric metaphor of meanings, which are represented through points into a space where distance is a measure of semantic similarity. The point representation inherits information about all co-occurring context words, and then it is suitable for computing the overlap where no exact word matching can occur. In addition, we introduce two functions: the former assigns an inverse gloss frequency (IGF) score to each term occurring in the extended gloss, the latter exploits information about sense frequencies extracted from an annotated corpus.

We choose BabelNet (Navigli and Ponzetto, 2012) as sense inventory. BabelNet is a very large semantic network built up exploiting both WordNet and Wikipedia. Besides linguistic knowledge, it also represents encyclopedic concepts coming from Wikipedia and information about named entities. This makes our approach inherently multilingual and suitable for tasks such as named entity disambiguation. The evaluation on SemEval-2013 Multilingual Word Sense Disambiguation (Navigli et al., 2013) proves that our method is able to outperform both baselines (simplified Lesk and most frequent sense) and, for English language, also the best SemEval-2013 participant.

The paper is structured as follows. Section 2 provides a brief introduction to Distributional Semantic Models, while Section 3 describes the proposed methodology. Evaluation and details about the algorithm implementation are reported in Section 4, while related work is described in Section 5. Finally, conclusions close the paper.

2 Distributional Semantic Models

Semantic (or *Word*) *Spaces* are geometrical spaces of words where vectors express concepts, and their proximity is a measure of the semantic relatedness. One of their greatest virtues is that they can be built using entirely unsupervised analysis of free text. Moreover, they make few language-specific assumptions since only tokenized text is needed. *WordSpace*s are inspired by the *distributional hypothesis* (Harris, 1968) whereby the meaning of a word is determined by the rules of its use in the context of ordinary and concrete language behaviour. This means that words are semantically similar if they share *contexts* (surrounding words). Building a *WordSpace* involves the definition of a distributional model, that is a quadruple (Lowe, 2001) consisting of: the space basis (word vectors) and dimension; the function that takes into account word co-occurrences and how these are represented in the final vector; a similarity function defined over vectors; and eventually a map that transforms the vector space.

Our idea is to apply DSMs to WSD for computing the overlap between the gloss of the meaning and the context as a similarity measure between their corresponding vector representations in a *SemanticSpace*. In this paper we build a *SemanticSpace* (co-occurrences matrix M) by analysing the distribution of words in a large corpus, then M is reduced using Latent Semantic Analysis (LSA) (Landauer and Dumais, 1997). LSA collects the text data in a co-occurrence matrix, which is then decomposed into smaller matrices with Singular-Value Decomposition (SVD). Hence, LSA represents high-dimensional vectors in a lower-dimensional space while capturing latent semantic structures in the text data.

Given the vector representation of two words, DSMs usually compute their similarity as the cosine of the angle between them. In our case, the gloss and the context are composed by several terms, so in order to compute their similarity we need a method to compose the words occurring in these sentences. It is possible to combine words through vector addition (+) that corresponds to the point-wise sum of vector components. For each set of terms, phrase or sentence, we build its vector representation by adding the vectors associated to the words it is composed of. Then, the similarity measure is computed as the cosine similarity between the two phrases/sentences. More formally, if $g = g_1 g_2 ... g_n$ and $c = c_1 c_2 ... c_m$ are the gloss and the context respectively, we build their vector representation $\mathbf{g}$ and $\mathbf{c}$ in the *SemanticSpace* through addition of word vectors belonging to them:

$$\begin{aligned} \mathbf{g} &= \mathbf{g_1} + \mathbf{g_2} + \ldots + \mathbf{g_n} \\ \mathbf{c} &= \mathbf{c_1} + \mathbf{c_2} \ldots + \mathbf{c_m} \end{aligned} \tag{1}$$

The cosine similarity between $\mathbf{g}$ and $\mathbf{c}$ is a measure of the similarity of the two sentences that we consider as a score associated to the candidate meaning with respect to the context.

3 Methodology

At the heart of our approach there is the simplified Lesk algorithm. Given a text $w_1 w_2 ... w_n$ of n words, we disambiguate one at a time taking into account the similarity between the gloss associated to each sense of the target word w_i and the context. The meaning whose gloss has the highest similarity is selected. The context could be represented by a subset of surrounding words or the whole text where the word occurs. Moreover, taking into account the idea of the Banerjee's adaptation, we expand each gloss with those of related meanings.

Our sense inventory is BabelNet, a very large multilingual semantic network built relying on both WordNet and Wikipedia. In BabelNet linguistic knowledge is enriched with encyclopedic concepts coming from Wikipedia. WordNet synsets and Wikipedia concepts (pages) are connected in an automatic way. We choose BabelNet for three reasons: 1) glosses are richer and contain text from Wikipedia, 2) it is multilingual, thus the proposed algorithm can be applied to several languages, and 3) it also contains information about named entities, thus an algorithm using BabelNet could be potentially used to disambiguate entities.

Our algorithm consists of five steps:

1. **Look-up**. For each word w_i, the set of possible word meanings is retrieved from BabelNet. First, we look for senses coming from WordNet (or WordNet translated into languages different from English). If no sense is found, we retrieve senses from Wikipedia. We adopt this strategy because mixing up all senses from Wikipedia and WordNet results in worse performance. Conversely, if a word does not occur in WordNet it is probably a named entity, thus Wikipedia could provide useful information to disambiguate it.

2. **Building the context**. The context C is represented by the l words to the left and to the right of w_i. We also adopt a particular configuration in which the context is represented by all the words that occur in the text.

3. **Gloss expansion**. We indicate with s_{ij} the j-th sense associated to the target word w_i. We expand the gloss g_{ij} that describes the j-th sense using the function "getRelatedMap" provided by BabelNet API. This method returns all the meanings related to a particular sense. For each related meaning, we retrieve its gloss and concatenate it to the original gloss g_{ij} of s_{ij}. During this step we remove glosses belonging to synsets related by the "antonym" relationship. The result of this step is an extended gloss denoted by g^*_{ij}. In order to give more importance to terms occurring in the original gloss, the words in the expanded gloss are weighed taking into account both the distance between s_{ij} and the related synsets and the word frequencies. More details about term scoring are reported in Subsection 3.2.

4. **Building semantic vectors**. Exploiting the DSM described in Section 2, we build the vector representation for each gloss g^*_{ij} associated with the senses of w_i and the context C.

5. **Selecting the correct meaning**. For each gloss g^*_{ij}, the algorithm computes the cosine similarity between its vector representation and context vector C. The similarity is linearly combined with the probability $p(s_{ij}|w_i)$ that takes into account the sense distribution of s_{ij} given the word w_i; details are reported in Subsection 3.1. The sense with the highest similarity is chosen.

In order to compare our approach to the simplified Lesk algorithm, we developed a variation of our method in which, rather than building the semantic vectors, we count the common words between each extended gloss g^*_{ij} and the context C. In this case, we apply stemming to maximize the overlap.

3.1 Sense Distribution

The selection of the correct meaning takes also into account the senses distribution of the word w_i. We retrieve information about sense occurrences from WordNet (Fellbaum, 1998), which reports for each word w_i its sense inventory S_i with the number of times that the word w_i was tagged with s_{ij} in SemCor. SemCor is a collection of 352 documents manually annotated with WordNet synsets. We introduce the sense distribution factor in order to consider the probability that a word w_i can be tagged with the sense s_{ij}. Moreover, since some synsets do not occur in SemCor and can cause zero probabilities, we adopt an additive smoothing (also called Laplace smoothing). Finally the probability is computed as follow:

$$p(s_{ij}|w_i) = \frac{t(w_i, s_{ij}) + 1}{\#w_i + |S_i|} \tag{2}$$

where $t(w_i, s_{ij})$ is the number of times the word w_i is tagged with s_{ij} and $\#w_i$ is the number of occurrences of w_i in SemCor.

3.2 Gloss Term Scoring

The extended gloss conflates words from the gloss directly associated with the synset s_{ij} with those of the glosses appearing in the related synsets. When we add words to the extended gloss, we weigh them by a factor inversely proportional to the distance in the graph (number of edges) between s_{ij} and the related synsets so to reflect their different origin. Let d be that distance, then the weight is computed as $\frac{1}{1+d}$. Finally, we re-weigh words using a strategy similar to the inverse document frequency (IDF) that we call inverse gloss frequency (IGF). The idea is that if a word occurs in all the extended glosses associated with a word, then it poorly characterizes the meaning description. Let gf^*_k be the number of extended glosses that contain a word w_k, then IGF is computed as follow:

$$IGF_k = 1 + log_2 \frac{|S_i|}{gf^*_k} \tag{3}$$

This approach is similar to the idea proposed by Vasilescu et al. (2004), where TF-IDF of terms is computed taking into account the glosses in the whole WordNet, while we compute IGF considering only the glosses associated to each word. Finally, the weight for the word w_k appearing h times in the extended gloss g^*_{ij} is given by:

$$weight(w_k, g^*_{ij}) = h \times IGF_k \times \frac{1}{1+d} \tag{4}$$

4 Evaluation

The evaluation is performed using the dataset provided by the organizers of the Task-12 of SemEval-2013. The task concerns Multilingual Word Sense Disambiguation, a traditional WSD "all-words" experiment in which systems are expected to assign the correct BabelNet synset to all occurrences of noun phrases (which refer to both disambiguated nouns and named entities) within arbitrary texts in different languages.

The goal of our evaluation is twofold: to prove that our strategy outperforms the simplified Lesk approach, and then to compare our system with respect to the other task participants.

In both the experiments we consider two languages, English and Italian, to evaluate performance in a multilingual setting. It is important to underline that in our approach only stemming and the corpus used to build the distributional model are language dependent.

4.1 System Setup

Our method[1] is completely developed in JAVA using BabelNet API 1.1.1 provided by the authors[2]. We adopt the standard Lucene analyzer to tokenize both glosses and the context, while Snowball library[3] is used for stemming in several European languages. The *SemanticSpace*s for the two languages are built using proprietary code relying on two Lucene indexes, which contain documents from British National Corpus (BNC) for English, and from Wikipedia dump for Italian, respectively. For each language, the co-occurrences matrix M contains information about the top 100,000 most frequent words in the corpus. M is reduced by LSA using the SVDLIBC tool[4] and setting a reduced dimension equal to 200. The result of the SVD decomposition is stored in a binary format used by our algorithm implementation.

It is important to underline that BabelNet Italian glosses are taken from MultiWordNet, which does not contain glosses for all the synsets. Then, we replace each missing gloss by the words that belong to the synset.

We evaluate our system by setting two parameters: 1) the context size (3, 5, 10, 20 and the whole text); 2) the use of information about sense distribution (see Formula (2) in Subsection 3.1).

The gloss term scoring function is always applied, since it provides better results. The synset distance d used to expand the gloss is fixed to 1; we experimented with a distance d set to 2 without any improvement. The sense distribution is linearly combined with the cosine similarity score through a coefficient set to 0.5.

Some notes about sense frequency: by using only sense distribution to select a sense we obtain an algorithm that performs like the most frequent sense (MFS). In other words, the algorithm always assigns the most probable meaning. It is well known that this approach obtains very good performance and it is hard to be outperformed especially by unsupervised approaches.

4.2 English Evaluation

Table 1 reports results of our algorithm (DSM) compared with the best simplified Lesk approaches (LESK) in terms of precision (P), recall (R), F-measure (F) and attempt (A). Attempt is the percentage of words disambiguated by the algorithm. $SenseDistr.$ column reports the information about when the sense distribution formula (see Subsection 3.1) is used (Y) or not (N); it is also important to point out that MSF produces the same results of using only sense distribution i.e. the first sense is the most likely one. We have experimented different context sizes also for the Lesk algorithm, although for the sake of readability we report only the best Lesk with and without sense distribution.

All our runs always obtain an attempt of 100%; thus the precision and recall values are always the same. The run **EN.DSM.10** obtains the best result using both sense distribution information and the whole text (W) as context. Another important outcome is the result obtained by the run **EN.DSM.5** that, without information about sense distribution, is able to overcome the MFS baseline. To the best of our knowledge, this is the first completely unsupervised system able to overcome the MFS baseline without using sense frequency. Both results (**EN.DSM.10** and **EN.DSM.5**) suggest that the vector representation of the whole text helps the system to achieve the best performance.

Considering the Lesk method, generally, the best size for the context is 3, then a larger set of surrounding words results in worse performance, differently to what happens in the distributional approach. This is probably due to the fact that words distant from the target one match some incorrect glosses. It is important to note that no simplified Lesk run is able to overcome the MFS baseline.

Table 1: Results of the English evaluation.

Comparing DSM-based with simplified Lesk approaches, the former consistently outperform Lesk-based algorithms when considering the use (or not) of sense distribution.

4.3 Italian Evaluation

Table 2 reports results of our algorithm for the Italian language. In this case we still obtain the best result (**IT.DSM.10**) using DSM and sense distribution. As for English, the systems without sense distribution overcome the MFS baseline. However, in this case simplified Lesk with sense distribution is able to outperform the MFS. We ascribe this different behaviour to the problem of missing glosses that we solved by adding the words in the synset.

4.4 Task Results

In this subsection, we report our best performance (Table 3) with respect to the other participants in the SemEval-2013 Task-12 on multilingual Word Sense Disambiguation, for both English (Table 3a) and Italian (Table 3b).

Regarding the English language, our best methods are able to outperform all the systems. It is important to underline that our method without knowledge about sense distribution (**EN.DSM.5**) outperforms both the MFS and all the task participants. This is a very important outcome because generally

System	F
EN.DSM.10	**0.715**
EN.DSM.5	**0.687**
UMCC-DLSI-2	0.685
UMCC-DLSI-3	0.680
UMCC-DLSI-1	0.677
MFS	*0.656*
DAEBAK	0.604
GETALP-BN-1	0.263
GETALP-BN-2	0.266

(a) English

System	F
UMCC-DLSI-2	0.658
UMCC-DLSI-1	0.657
IT.DSM.10	**0.641**
IT.DSM.5	**0.633**
DAEBAK	0.613
MFS	*0.572*
GETALP-BN-2	0.325
GETALP-BN-1	0.324

(b) Italian

Table 3: Results of our best systems with respect to the Semeval-2013 participants.

knowledge-base approaches without information about sense frequencies obtain low results. For example, the UMCC-DLSI system (Gutiérrez et al., 2013) exploits sense frequency to modify prior probability of synset nodes in the PageRank, and DAEBAK system (Manion and Sainudiin, 2013) uses MFS when it is not able to select a meaning. Our experiments show that a dictionary-based approach and the adoption of a distributional semantic model for computing the similarity are enough to obtain good results. Moreover, by adding information about sense frequencies we are able to boost our performance and obtain over 70% of F-measure.

For Italian, our systems are not able to reach the same performance as for English, although they still outperform the MFS and two task participants. We think that these results are due to the same problem observed for the Italian evaluation (Subsection 4.3), that is to say, the poor quality of glosses.

5 Related Work

WSD has been an active area of NLP whose roots stem from early work in Machine Translation. Ambiguity resolution has been pursued as a way to improve retrieval systems, and generally to get better information access. Despite its ancient roots and perceived importance, this task is still far from being resolved.

Our WSD method relies on both the Lesk algorithm and its two variants: simplified (Kilgarriff and Rosenzweig, 2000) and adapted (Banerjee and Pedersen, 2002). Several approaches have modified the Lesk algorithm to reduce is exponential complexity, like the one based on Simulated Annealing (Cowie et al., 1992). Basile et al. (2007) adopted the simplified Lesk algorithm to disambiguate adjectives and adverbs, combining it with other two methods for nouns and verbs: the combination of different approaches for each part-of-speech resulted in better performance with respect to the use of a single strategy. More recently, Schwab et al. (2013) proposed GETALP, another unsupervised WSD algorithm inspired by Lesk. Their approach computes a local similarity using the classical Lesk measure (overlap between glosses), and then the local similarity is propagated to the whole text (global similarity) using an algorithm inspired by the Ant Colony. This approach got the lowest results during the SemEval-2013 Task 12 evaluation due to a bug in the system. However, the correct implementation achieves 0.583 of F-measure for English and 0.528 for Italian.

Another problem with the Lesk-based approaches is to maximize the chances of overlap between glosses or between the gloss and the context. To solve this problem, Ponzetto and Navigli (2010) extended WordNet with Wikipedia pages (WordNet++) in order to produce a richer lexical resource, obtaining the English portion of BabelNet. The simple Lesk algorithm built over WordNet++ outperformed the WordNet-base version, although it was not successful in overtaking the MFS baseline. Our approach tries to extend glosses using related synsets and adopts distributional semantics to address the problem of data sparsity. A different perspective has been recently proposed by Wang and Hirst (2014), where the limits of the exact string matching between glosses and context are overcome by a Naive Bayes-based similarity measure.

Other unsupervised approaches rely on graph algorithms that exploit the graph generated by a semantic network where the senses are connected through semantic relations. For example, DAEBAK (Manion and Sainudiin, 2013) adopts a sub-graph of BabelNet generated taking into account the surrounding words of the target word. A measure of connectivity computed on the sub-graph is used to extract the most probable sense. The MFS is used when the algorithm is not able to choose any sense. Also Navigli and Lapata (2010) exploit the idea of graph connectivity measures for identifying the most important node (sense) in the graph. Experiments conducted on SemCor show that the Degree Centrality provides best results compared to other well known techniques, such as PageRank, HITS, Key Player Problem and Betweenness Centrality. Graph-based methods also showed their validity during the SemEval 2013 Multilingual Word Sense Disambiguation task. The best system, UMCC-DLSI (Gutiérrez et al., 2013), builds a graph using several resources: WordNet, WordNet Domains and the eXtended WordNet. Then, the best sense is selected using the PageRank algorithm where the a priori probability of senses is estimated according to the sense frequencies. This is an extension of UBK algorithm (Agirre and Soroa, 2009), the first application of personalized PageRank to the WSD problem.

On the distributional side, Brody and Lapata (2008) use distributional similarity to automatically annotate a corpus for training a supervised method. Each target word in the corpus is paired with a list of neighbours selected via distributional similarity. A neighbour is linked to a sense in WordNet and then it is used for the annotation. Differently from our approach, distributional similarity is used to automatically annotate a training corpus rather than directly disambiguate terms. Miller et al. (2012) exploit a distributional thesaurus to expand both glosses and the context, then they apply the classical word overlap adopted in the simplified Lesk. This approach is strongly related to our, although our approach directly computes the overlap in the geometric space that implements the distributional semantic model. In particular, we build a vector representation for both the gloss and the context. In recent years, other approaches have tried to solve unsupervised WSD relying on distributional information. Gliozzo et al. (2005) build a matrix taking into account words and WordNet domains. The matrix is reduced using LSA and then it is combined in a kernel exploited in a supervised approach. Martinez et al. (2008) propose a method based on topic signatures automatically constructed using the Web, while Li et al. (2010) adopt Latent Dirichlet Allocation (LDA) to compute a conditional probability between a sense and the context. In this model, a sense is represented by its paraphrases used to build the LDA model.

6 Conclusions and Future Work

In this paper we describe an unsupervised WSD approach which selects the best sense according to the distributional similarity with respect to the context. In particular, the similarity is computed representing both the gloss and the context as vectors in a geometric space generated by a distributional semantic model based on LSA. The evaluation, conducted on the Task-12 of SemEval-2013, shows promising results: our method is able to overcome both the most frequent sense baseline and, for English, also the other task participants. We provide two implementations of our approach, with and without exploiting sense frequencies. For English, both implementations outperform the SemEval-2013 participants and the MFS. Differently, for Italian both implementations do not reach the figures of the best participant, but they are able to defeat the MFS. As future work, we plan to extend our evaluation to other languages, and to investigate how to adapt our approach to a specific domain. In particular, distributional models built upon a domain corpus, and sense frequencies extracted from the same corpus, could result in a domain adaptation of our algorithm.

Abstract

Word Sense Induction is a task of automatically finding word senses from large scale texts. It is generally considered as an unsupervised clustering problem. This paper introduces a hypergraph model in which nodes represent instances of contexts where a target word occurs and hyperedges represent higher-order semantic relatedness among instances. A lexical chain based method is used for discovering the hyperedges, and hypergraph clustering methods are used for finding word senses among the context instances. Experiments show that this model outperforms other methods in supervised evaluation and achieves comparable performance with other methods in unsupervised evaluation.

1 Introduction

Word sense induction (WSI) aims to automatically find senses of a given target word (Yarowsky, 1995) from large scale texts. Compared with existing manual word sense resources, WSI techniques use clustering algorithms to determine the possible senses for a word.

Word sense induction is generally considered as an unsupervised clustering problem. The input for the clustering algorithm is context instances of a target word, represented by word bags or co-occurrence vectors, and the output is a grouping of these instances into classes, each corresponding to an induced sense.

Traditional methods in WSI tend to adopt the vector space model, in which the context of each instance of a target word is represented as a vector of features based on frequency statistics and probability distributions, e.g., first-order or second-order vector (Schütze, 1998; Purandare and Pedersen, 2004; Cruys et al., 2011). These vectors are clustered and the resulting clusters represent the induced senses. Another family of employed approach is graph-based methods (Widdows and Dorow, 2002; Véronis, 2004; Agirre et al., 2006; Klapaftis and Manandhar, 2007; Di Marco and Navigli, 2011; Hope and Keller, 2013), which have been recently explored successfully to some extent. Graph-based methods are considering the notion of a co-occurrence graph, assuming a binary relatedness between co-occurring words.

One of the key challenges in WSI is learning the higher-order semantic relatedness among multiple context instances. Previous approaches (Klapaftis and Manandhar. 2007; Bordag, 2006) for WSI are used to construct higher-order relatedness by counting co-occurrence frequency or collocation of mutiwords, regardless of global semantic similarity.

Lexical chain (Morris and Hirst, 1991) is defined as a sequence of semantically related words in text and provides important clues about the text structure and topic. It can be viewed as a global counterpart of the measures of semantic similarity (Navigli, 2009). For example, Figure 1 gives three context instances containing Apple.

Figure 1. Context instances of Apple

Obviously, four Apples in Figure 1 all refer to the Apple Company. We can directly group three instances by the lexical chain: *iPod-iTunes-hardware and software product-Inc*. This lexical chain represents a higher-order semantic relatedness among the three instances.

In this paper, we propose a hypergraph model from a *global* perspective, in which nodes represent instances of contexts where a target word occurs and hyperedges denote higher-order semantic relatedness among instances. A lexical chain based method is used for identifying the hyperedges. This method for lexical chain extraction is a knowledge-free method based on LDA topic model (Remus and Biemann, 2013).

The remainder of this paper is structured as follows. Section 2 presents an overview of the related work. Section 3 describes our model in details. Section 4 provides a quantitative evaluation and comparison with other algorithms in the SemEval-2013 word sense induction task. Finally, section 5 draws conclusions and lays out some future research directions.

2 Related Work

2.1 Word sense induction

A number of diverse approaches to WSI have been proposed so far. Context features are often represented in a variety of forms such as co-occurrence of words within phrases (Pantel and Lin, 2002; Dorow and Widdows, 2003), parts of speeches (Purandare and Pedersen, 2004), and grammatical relations (Pantel and Lin, 2002; Dorow and Widdows, 2003). The size of the context window also varies, such as two words before and after the target word, the sentence or even larger paragraph within which contains the target word.

Most of the work in WSI is the vector space model, such as context-based vector algorithm (Schütze, 1998; Ide et al., 2001; Van de Cruys et al., 2011), substitute-based vector algorithm (Yatbaz et al., 2012; Baskaya et al., 2013). In this model, the context of each instance of a target word is represented as a vector of features based on frequency statistics or probability distributions (e.g., first-order or second-order vector). These vectors are clustered by various algorithms and the resulting clusters represent the induced senses.

Another family of employed approach is graph-based methods, which have been successfully applied in the sense induction task with some better results achieved. In this framework words are represented as nodes in the graph and vertices are drawn between the target word and its co-occurrences. The co-occurrences between words can be obtained on the basis of grammatical (Widdows and Dorow, 2002) or collocational relations (Véronis, 2004). Senses are induced by identifying highly dense sub-graphs (hubs) in the co-occurrence graph.

Klapaftis (2007) uses hypergraph model for WSI, in which co-occurrences of two or more words are represented by using weighted hyperedges. This model fully exploits the existence of collocations or terms consisting of more than two words. In fact, the method converts the sense induction problem to the clustering of the contextual words, and the result relies on local word co-occurrence frequency. Our hypergraph model is constructed from a global perspective, where the whole context instance is regarded as a node.

WSI evaluation also is an important issue in WSI tasks. Previous WSI evaluations in SemEval (Agirre and Soroa, 2007; Manandhar et al., 2010) have approached sense induction in terms of finding the single most salient sense of a target word given its context. However, as shown in Erk and McCarthy (2009), multiple senses of the target word may be perceived by readers from different angles and a graded notion of sense labeling may be considered as the most appropriate. The SemEval-2013 WSI evaluation is designed to explore the possibility of finding all perceived senses of a target word in a single context instance. Our model is evaluated and verified on the SemEval-2013 WSI task.

Algorithm 1. lexical chains extraction algorithm

Input: training set D of target word, hyper-parameters of LDA model; semantic threshold γ.
Output: lexical chain set S

```
θ,φ,Z ← LDA (D)
for each topic z
  lc =""              // lc denotes a lexical chain
  for each doc d
    for each word w in doc d
      if ( z_w = z and p(w,d|z) > γ )
        lc.add (w)
S.add (lc)
return S
```

2.2 Lexical chain extraction

The Lexical chain method is an important technique in natural language processing. A lexical chain is a sequence of semantic related words in text and provides important clues about the text structure and topic. It has formed a theoretically well-founded building block in a lot of applications, such as word sense disambiguation (Manabu and Takeo, 1994), malapropism detection and correction (Hirst and St-Onge, 1998), summarization (Barzilay et al., 1997), topic tracking (Carthy, 2004), text segmentation (Stokes et al., 2004), and others.

There are mainly two approaches for lexical chain extraction. One focuses on the use of knowledge resources like WordNet (Hirst and St-Onge, 1998) or thesauri (Morris and Hirst, 1991) as background information in order to quantify semantic relations between words. A major disadvantage of this strategy is that it relies on the resource, which has a direct impact on the quality of lexical chains. Another approach is based on statistical methods (Remus and Biemann, 2013). In this paper, we follow Remus and Biemann (2013) to automatically extract lexical chain by using LDA topic model.

3 Hypergraph model

In general, lexical chain based hypergraph model contains the following steps:

i) Automatically extracting lexical chains based on topic model;
ii) Constructing hypergraph with lexical chains;
iii) Inducing word sense by hypergraph clustering.

3.1 Lexical chain extraction

The extraction technique of lexical chains is based on LDA topic model. LDA topic model (Blei et al., 2003) is a probabilistic model of text generation designed for revealing some hidden structure in large data collections. The key idea is that each document can be represented as a probability distribution over a fixed set of topics where each topic can be represented as a probability distribution over words. We use LDA topic model for estimating the semantic closeness of lexical terms, and explore a way of utilizing LDA's topic information in constructing lexical chains automatically. In our model, document is replaced with context instance of a target word.

We adopt the idea of interpreting lexical chains as topics and placing all word tokens that share the same topic into the same chain. Lexical chains are usually extracted from the same paragraph or text, whose topic distributions are identical. However, in our experiment the context instances of a target word for WSI are derived from different articles, whose topic distributions are varied. Therefore both lexical and contextual topics are modeled. After training the LDA model, we use the information of the per-document topic distribution $\theta_d = p(z|d)$, the per-topic word distribution $\phi_w = p(w|z)$ and the sampling topic of a word z_w.

The key work lies in how to assign a word to a topic in training LDA model. Since single samples of topics per word may exhibit a large variance (Riedl and Biemann, 2012), we sample several times and use the mode (most frequently assigned) topic ID per word as the topic assignment.

d_1. WOMEN are half the population but only 15% of board members at big American firms, and 10% in Europe.

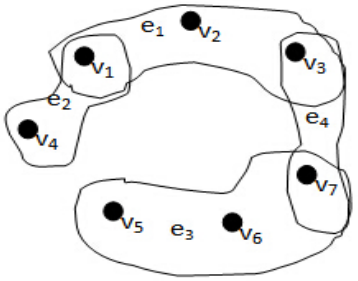
Chain 2: (firms#d_1, candidates#d_4)

Chain 3: (nails#d_5, ropes#d_6, wood#d_7)

Chain 4: (skirt#d_3, neck#d_7)

(b)



(c)

Figure 2. An example of hypergraph creation. (a). seven context instances of **board**; (b). four lexical chains extracted; (c). the created hypergraph. The d_i in (a) corresponds to the v_i in (c) and the chain i in (b) corresponds to the e_i in (c).

The extraction algorithm is shown in algorithm 1. In order to improve the quality of identified lexical chains, a threshold γ is set to filter those invalid words whose generating probability of sampling topics in the document is lower than γ.

$$p(w,d \mid z) \approx p(z \mid d)p(w \mid z) > \gamma \qquad (1)$$

The threshold γ is essential for the quality of lexical chains, which directly impacts on the performance of the model. Detailed analysis for the threshold γ will be given in section 4.5.

3.2 Hypergraph creation

A hypergraph $H = (V, E)$ is a generalization of a graph whose edge can connect more than two vertices. Just as graphs represent many kinds of information in mathematical and computer science problems, hypergraphs also arise in important practical problems, including circuit layout, boolean satisfiability, numerical linear algebra, complex network and article co-citation, etc.

Figure 2 shows an example of hypergraph creation in our model. We represent each context instance as a vertex and connect those context instances with a lexical chain across them by a hyperedge. A hyperedge weight equals to the weight of the corresponding lexical chain, defined as follows:

$$w(e) = \frac{\sum_{w_i \in C} p(z \mid \mathrm{d}_i)p(\mathrm{w}_i \mid z)}{|C|} \qquad (2)$$

where lexical chain C corresponds to hyperedge e, $|C|$ is the number of words in C, and z is the sampling topic of C.

3.3 Hypergraph clustering

For hypergraph clustering, the hypergraph is usually transformed into induced graph. There are two transformation strategies: one is vertex expansions (2006; Zhou et al., 2006), i.e., clique expansion or star expansion, in which a hyperedge is transformed into a clique; the other is called hyperedge expansion (Pu and Faltings, 2012) based on a network flow technique, in which hyperedges are projected back to vertices through the adjacency information between hyperedges and vertices.

Hypergraph clustering algorithm can be divided into two classes: one is based on minimal normalized cut, and the other is based on maximal density. We use three general hypergraph clustering algorithms to identify the context instance clusters. The three algorithms are simply shown in figure 3 and described as the follows.

1) Normalized Hypergraph Cut (NHC)

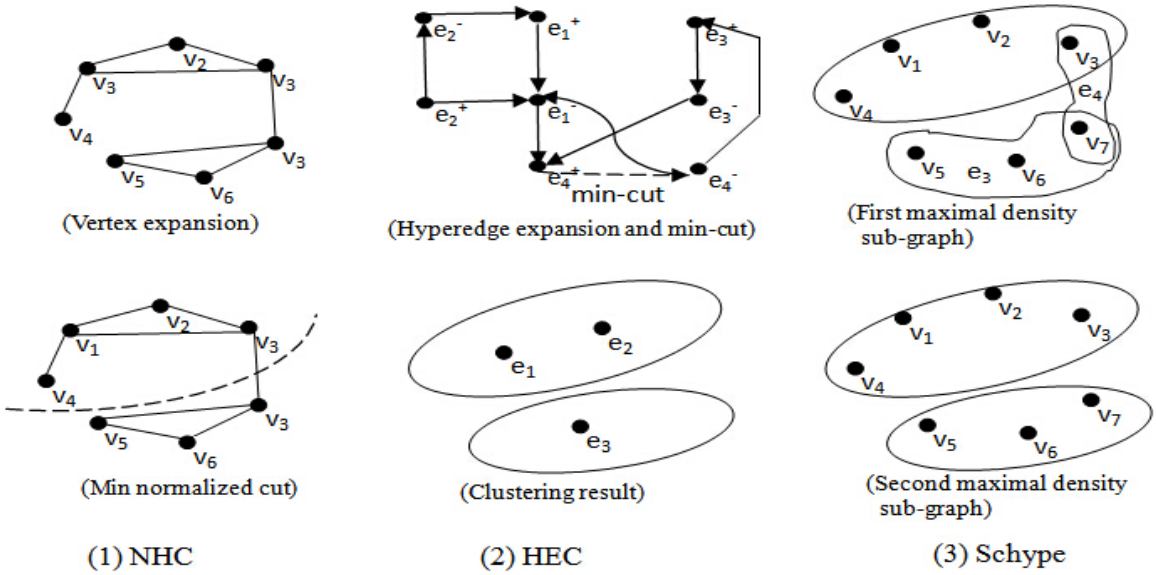


Figure 3. The clustering processes of three algorithms for the hypergraph created in figure 2.

The NHC algorithm (Zhou et al., 2006) is a typical approach based on vertex expansion. The objective is to obtain a partition in which the connection among the vertices in the same cluster is dense while the connection between two clusters is sparse. The main steps include transforming the hypergraph into an induced graph first, and then adopting the normalized Laplacian to spectral partitioning.

2) Hyperedge Expansion Clustering (HEC)

Some works (e.g., Shashua et al., 2006; Bulo and Pelillo, 2012) have shown that the pairwise affinity relations after the projection to the induced graph would introduce information loss, and working directly on the hypergraph could produce better performance.

The hyperedge expansion works as follows. It constructs a directed graph $G = (V, E)$ that includes two vertices $e+$ and $e-$ for each hyperedge e in the original hypergraph. Note that the vertices in G correspond to the hyperedges, but not the vertices in the original hypergraph. A directed edge is placed from $e+$ to $e-$ with weight $w(e)$ where w is the weighting function in the hypergraph. For every pair of overlapping hyperedges e_1 and e_2, two directed edges (e_1^-, e_2^+) and (e_2^-, e_1^+) are added to G with weights $w(e_2)$ and $w(e_1)$. After hypergraph expansion, it adopts spectral method for clustering.

3) Schype

The Schype (Michoel and Nachtergaele, 2012) is a maximal density cluster algorithm. According to the generalization of the Perron-Frobenius theorem, there exists a unique, positive vector, called the dominant eigenvector, over the set of vertices of the hypergraph, which produces a maximal density sub-graph with linear time. The procedure is as follow:

i) Finding maximal density sub-graph by computing the dominant eigenvector.
ii) Removing all vertices and hyperedges of the sub-graph from hypergraph.
iii) Repeating above steps until no vertex in hypergraph occurs.

This algorithm tends to generate many fine-grained clusters. We follow Tan and Kumar (2006) to merge clusters using two measures: cohesion and separation. The cohesion of a cluster C_i is defined as:

$$cohesion(\mathrm{C}_i) = \frac{\sum_{x \in C_i, y \in C_i} \#(e \mid x, y \in e)}{|\mathrm{C}_i|} \qquad (3)$$

where $\#(e \mid x, y \in e)$ is the number of hyperedges containing nodes x and y in C and $|C_i|$ is the number of vertices in C_i. Separation between two clusters C_i, C_j is defined as:

$$separation(\mathrm{C}_i, \mathrm{C}_j) = 1 - \left(\frac{\sum_{x \in C_i, y \in C_j} \#(e \mid x, y \in e)}{|\mathrm{C}_i| \times |\mathrm{C}_j|}\right) \qquad (4)$$

We merge cluster pairs with high cohesion and low separation. The intuition is that context instances in such pairs will maintain a relatively high degree of semantic similarity. High cohesion is defined as greater than average cohesion of all clusters. Low separation is defined as a reciprocal relationship between two clusters: if a cluster C_i has the lowest separations to a cluster C_j and C_j has the lowest separation to C_i, then the two (high cohesion) clusters are merged. This merging process is iterated until it converges.

4 Experiment and Evaluation

4.1 Dataset

Our WSI evaluation is based on the dataset provided by the SemEval-2013 shared 13th task. Test data was drawn from the Open American National Corpus (OANC) (Ide and Suderman, 2004) across a variety of genres and from both the spoken and written portions of the corpus. It consists of 4,806 instances of 50 target words: 20 verbs, 20 nouns and 10 adjectives. Due to the unsupervised nature of the task, participants were not provided with sense-labeled training data. However, WSI systems were provided with the ukWac corpus (Baroni et al., 2009) to use in inducing senses. Additionally, we used the SemEval-2013 lexical trial data sets as development sets to tune parameters.

4.2 Implementation details

The training data is extracted from uKWac corpus. For each target word, we extracted 10K context instances, and each instance is a sentence window containing the target word. Additionally, we randomly selected 10K sentences as common auxiliary corpus, including none of the target word. The training data are tagged with POS tags and lemmatized with TreeTagger (Schmid, 1994). Removing stop words, nouns are taken as features. Meanwhile, we also removed words that co-occur with the target of word less than 50 times over the whole ukWac data.

The training data in the model contains 20K instances: 10K instances of target word, 10K auxiliary instances. Specifically, we used the JGibbLDA[1] framework for topic model estimation and inference, and examined the following LDA parameters: number of topics K, dirichlet hyperparameters for document-topic distribution α and topic-term distribution β. We tested combinations in the ranges K=1000, 1500, 2000, α=5/K..50/K and β=0.001..0.1. The highest performance of the WSI system was found for K = 2000, α =0.025, β = 0.001. Similar to tuning the dirichlet hyperparameters of LDA, the best parameter γ in lexical chain extraction is 0.0001 in the ranges γ =0.01.. 0.000001.

We adopt the three clustering algorithms to cluster hypergraph[2]. The number of clusters is set as 10 for NHC and HEC, while Schype algorithm generates the number of the clusters (but requiring the edge-vertex ratio to be pre-defined), whose average number of senses is 31.8 after clusters are merged. Additionally, For Schype algorithm, we used the default values of parameters, except that the "min-clustscore" parameter, a minimal score to output a cluster, being tuned to 0.1.

The sense inventory acquired from the induction step can be used for disambiguation of individual instances. Each sense is represented as a vector, whose element is a word and the value of element is co-occurrence frequency with target word in the training set. Each test instance is also represented as a vector. The similarity between the instance and the induced sense is computed by using cosine function. For each test instance, it is compared with each sense separately, and finally the sense is selected if the cosine value is greater than a certain threshold λ. In experiment, λ is 0.04 for NHC and HEC, and is 0.1 for schype.

4.3 Evaluation measures

Evaluation in the SemEval-2013 WSI task can be divided into two categories:

1. A traditional WSD task for unsupervised WSD and WSI systems,
2. A clustering comparison setting that evaluates the similarity of the sense inventories for WSI systems.

[1] http://sourceforge.net/projects/jgibblda/

[2] The Hypergraph Analysis Toolbox (HAT) for NHC and HEC: http://lia.epfl.ch/index.php/research/relational-learning and the Schype's code: http://www.roslin.ed.ac.uk/tom-michoel/software/

In the first evaluation, we adopt a WSD task with three objectives: (1) detecting which senses are applicable, (2) ranking senses by their applicability, and (3) measuring agreement in applicability ratings with human annotators. Each objective uses a specific measurement:

i): Jaccard Index: given two sets of sense labels for an instance, X and Y, the Jaccard Index is used to measure the agreement: $\frac{X \cap Y}{X \cup Y}$. The Jaccard Index is maximized when X and Y use identical labels, and is minimized when the sets of sense labels are disjoint.

ii): Positionally-weighted Kendall's τ similarity: for graded sense evaluation, we consider an ranking scoring based on Kumar and Vassilvitskii(2010), which weights the penalty of reordering the lower positions less than the penalty of reordering the first ranks.

iii): Weighted Normalized Discounted Cumulative Gain (WNDCG): NDCG (Moffat and Zobel, 2008) normally compares the rankings of two lists. It is extended to weighting the DCG by considering the relative difference in the two weights.

Because the induced senses will likely vary in number and nature between systems, the WSD evaluation has to incorporate a sense alignment step, in which it performs by splitting the test in-stances into two sets: a mapping set and an evaluation set. The optimal mapping from induced senses to gold-standard senses is learned from the mapping set, and the sense alignment is used to map the predictions of the WSI system to pre-defined senses for the evaluation set. The particular split we use to calculate WSD effectiveness in this paper is 80%/20% (mapping/test), averaged across 5 random splits.

In the clustering evaluation, similarity between participant's clusters and the gold standard clusters is measured by way of two metrics.

i): Fuzzy Normalised Mutual information (NMI): it extends the method of (Lancichinetti et al., 2009) to compute NMI between overlapping clusters. Fuzzy NMI captures the alignment of the two clusters independent of the cluster sizes and therefore serves as an effective measure of the ability of an approach to accurately model rare senses.

ii): Fuzzy B-Cubed: it adapts the overlapping B-Cubed measured defined in Amigo et al. (2009) to the fuzzy clustering setting, and provides an item-based evaluation that is sensitive to the cluster size skew and effectively captures the expected performance of the system on a dataset where the cluster distribution would be equivalent.

4.4 Results

We compared our models with four baselines and three benchmark systems from the SemEval-2013 task. Four baselines are described as follows.

- Baseline MFS — most frequent sense baseline, assigning all test instances to the MFS in the test data (regardless of what applicability rating it was given).
- One sense — labels each instance with the same induced sense.
- One sense per instance (1clinst) — labels each instance with its own induced.
- Baseline Random-n — randomly assigns each test instance to one of n randomly selected induced senses, where n is the number of senses for the target word in WordNet 3.1.

Three benchmark systems as the following are those which achieved better results in the original SemEval-2013 task.

- AI-KU is based on a lexical substitution method.
- UoS uses dependency-parsed features from the corpus, which are then clustered into senses using the MaxMax algorithm (Hope and Keller, 2013).
- Unimelb is a non-parameter topic model which uses a Hierarchical Dirichlet Process (Teh et al., 2006) to automatically infer the number of senses from contextual and positional features.

4.4.1 Supervised evaluation

In the supervised evaluation, the automatically induced clusters are mapped to gold standard senses, using one part of the test set. The obtained mapping is used to label the other part of test set with gold standard tags, which means that the methods are evaluated in a standard WSD task. In experiment, we follow the 80/20 setup: 80% for mapping and 20% for test.

Table 1 shows the results of our systems on test data using all instances (including verbs, nouns and adjectives) for the WSD evaluation. As in previous WSD tasks, the MFS baseline on Jaccard Index measures is quite competitive, outperforming all systems in detecting which senses are applicable.

System	JI-F1	WKT-F1	WNDCG-F1
NHC	0.325	0.692	0.375
HEC	0.327	0.693	**0.376**
Schype	**0.376**	**0.753**	0.345
AI-KU	0.244	0.642	0.332
UNIMELB	0.213	0.62	0.371
UoS	0.232	0.625	0.374
MFS	0.455	0.465	0.339
One sense	0.192	0.609	0.288
1c1inst	0.0	0.095	0.0
Random-n	0.29	0.638	0.286

Table 1. The supervised results over the SemEval-2013 dataset.

System	FNMI	FBC
NHC	0.046	0.406
HEC	0.037	0.400
Schype	0.042	0.377
AI-KU	0.039	0.451
UNIMELB	**0.056**	**0.459**
UoS	0.045	0.448
MFS	-	-
One sense	0	0.632
1c1inst	0.071	0
Random-n	0.016	0.245

Table 2. The unsupervised results over the SemEval-2013 dataset.

However, most systems in this task were able to outperform the MFS baseline in ranking senses and quantifying their applicability.

On the other hand, it also indicates that our three systems achieve better or comparable scores And the Schype gets the highest scores in detecting senses and ranking senses over all systems.

4.4.2 Unsupervised evaluation

Unsupervised evaluation aims to measure the similarity of the induced sense inventories for WSI systems. Unlike supervised metrics, it avoids potential loss of sense information since this setting does not require any sense mapping procedure to convert induced senses to WordNet senses.

Table 2 shows the performance of our systems, benchmarks and baselines. It shows that the NMI-measure is biased towards the **one sense per instance** baseline and the FBC-measure **one sense** baseline. However, systems are capable of performing well in both the Fuzzy NMI and Fuzzy B-Cubed measures, thereby avoiding the extreme performance of either baseline. Generally, the performance of our model gets balanced scores.

4.5 Discussion

Topic models, such as LDA and HDP (Brody and Lapata, 2009; Lau et al., 2012), have been successfully adopted for WSI, in which one topic is viewed as one sense. Our work is motivated by lexical chain that represents the intrinsic semantic relatedness among context instances on the viewpoint of linguistics. Topic model is used to find lexical chains which are interpreted as topics. We have compared the Unimelb (Lau et al., 2013), a HDP topic model, with our model in the experiments. Additionally, we also follow Lau et al. (2012) to train a LDA model with a fixed number of topics based on our training data for WSI[3]. Table 3 shows the supervised result compared to the Schype.

These experiments show promising performance for our model, which captures richer semantic relatedness by using lexical chains. Lexical chains play a key role for the performance of our model. Intuitively, when lexical chains are too long, the higher-order relatedness would be mixed with some noises, while when lexical chains are too short, some higher-order relatedness will be missed. In order to verify the effectiveness of lexical chains, we tune the parameter γ in lexical chain extraction procedure and the results are shown in Figure 4.

Another issue is the impact of POS labels of word for WSI task. The test data in SemeVal-2013 WSI task contain nouns, verbs and adjectives. We also test the performance based on different POS labels. Table 4 gives the supervised evaluation performance of our three systems on adjectives, verbs and nouns respectively. We found that the performance for adjectives in sense detection is the best, verbs followed and nouns worst, whereas it's reversed in sense ranking. The probable interpretation is

[3] The LDA model parameters are set as follows: K=10, α =0.025, β = 0.001.

Table 4. The supervised performance of three algorithms respectively on nouns, verbs and adjectives.

that adjective's average sense number is the lowest, and the sense granularity is greater than verbs and nouns over the test data[4].

5 Conclusions and future work

In this paper, we present a hypergraph model in which a node represents an instance and a hyperedge represents higher-order semantic relatedness among instances. Compared with other strategies based on binary local comparison, the model captures complex semantic relatedness among the instances from a global perspective.

The evaluation results indicate that our model outperforms or reaches competitive performance comparable to other systems for the SemEval-2013 word sense induction task. Additionally, the experiments also show that both sense number and sense granularity of a target word affect the performance of WSI.

For future work, we would like to explore better ways to extract and evaluate lexical chain for WSI task. In addition, for the three clustering algorithms, they generally require the number of clusters or edge-vertex ratio to be pre-defined, so we will seek more effective hypergraph clustering algorithms to automatically determine the parameters. Finally, the hypergraph model proposed in this work is not specific to the sense induction task, and can be adapted for other applications, such as document classification and clustering, information retrieval, etc.

Minimally Supervised Classification to Semantic Categories using Automatically Acquired Symmetric Patterns

Abstract

Classifying nouns into semantic categories (e.g., animals, food) is an important line of research in both cognitive science and natural language processing. We present a minimally supervised model for noun classification, which uses symmetric patterns (e.g., "X and Y") and an iterative variant of the k-Nearest Neighbors algorithm. Unlike most previous works, we do not use a predefined set of symmetric patterns, but extract them automatically from plain text, in an unsupervised manner. We experiment with four semantic categories and show that symmetric patterns constitute much better classification features compared to leading word embedding methods. We further demonstrate that our simple k-Nearest Neighbors algorithm outperforms two state-of-the-art label propagation alternatives for this task. In experiments, our model obtains 82%-94% accuracy using as few as four labeled examples per category, emphasizing the effectiveness of simple search and representation techniques for this task.

1 Introduction

The role of language is to express meaning. In the field of NLP, there has been an increasingly growing number of approaches that deal with semantics. Among these are vector space models (Turney and Pantel, 2010; Baroni and Lenci, 2010), lexical acquisition (Hearst, 1992; Dorow et al., 2005; Davidov and Rappoport, 2006), universal cognitive conceptual annotation (Abend and Rappoport, 2013) and automatic induction of feature representations (Collobert et al., 2011). In this paper, we utilize extremely weak supervision to classify words into fundamental cognitive semantic categories.

There are several types of semantic categories expressed by languages, e.g., objects, actions, and properties. We follow human development, acquiring coarse-grained categories and distinctions before detailed ones (Mandler, 2004). Specifically, we focus on the major class of concrete "*things*" (Langacker, 2008, Ch. 4), roughly corresponding to nouns – the main participants in linguistic clauses – that are universally present in the semantics of virtually all languages (Dixon, 2005).

Most works on noun classification to semantic categories require large amounts of human annotation to build training corpora for supervised algorithms (Bowman and Chopra, 2012; Moore et al., 2013) or rely on language-specific resources such as WordNet (Evans and Orăsan, 2000; Orăsan and Evans, 2007). Such heavy supervision is labor intensive and makes these models domain and language dependent.

Our reasoning is that weak supervision is highly valuable for semantic categorization, as it can compensate for the lack of input from the senses in text corpora. Our model therefore performs semantic category classification using only a small number of labeled seed words per category. The experiments we conduct show that such weak supervision is sufficient to construct a high quality classifier.

A key component of our model is the application of symmetric patterns. We define patterns to be sequences of words and wildcards (e.g., "X is a dog", "both X and Y", etc.). Accordingly, *symmetric* patterns are patterns that contain exactly two wildcards, where both wildcards are interchangeable. Examples of symmetric patterns include "X and Y", "X as well as Y" and "neither X nor Y".

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1612–1623, Dublin, Ireland, August 23-29 2014.

Works that apply symmetric patterns in their model generally require expert knowledge in the form of a pre-compiled set of patterns (Widdows and Dorow, 2002; Kozareva et al., 2008). In this work, we extract symmetric patterns in an unsupervised manner using the (Davidov and Rappoport, 2006) algorithm. This algorithm automatically extracts a set of symmetric patterns from plain text using simple statistics about high and low frequency word co-occurrences. The unsupervised nature of our approach makes it domain and language independent.

Our model addresses semantic classification in a transductive setup. It takes advantage of word similarity scores that are computed based on symmetric pattern features, and propagates information from concepts with known classes to the rest of the concepts. For this aim we apply an iterative variant of the k-Nearest Neighbors algorithm (denoted with I-k-NN) to a graph in which vertices correspond to nouns and word pairs are connected with edges based on their participation in symmetric patterns.

We experiment with a subset of 450 nouns from the CSLB dataset (Devereux et al., 2013), which were annotated with semantic categories by thirty human subjects. From the set of semantic categories in this dataset, we select categories that are both frequent and have a high inter-annotator agreement (Section 2). This results in a set of four semantic categories – *animacy, edibility, is_a_tool* and *is_worn*.

Our experiments show that our model performs very well even when only a small number of labeled seed words are available. For example, on the task of binary classification with respect to a single category, when using as few as four labeled seed words, classification accuracy reaches 82%-94%.

Furthermore, our model outperforms several strong baselines for this task. First, we compare our model against a model that uses a deep neural network word embedding baseline (Collobert et al., 2011) instead of our symmetric pattern based features, and applies the exact same I-k-NN algorithm. In recent years, deep networks word embeddings obtained state-of-the-art results in several NLP tasks (Collobert and Weston, 2008; Socher et al., 2013). However, in our task, features based on simple, intuitive and easy to compute symmetric patterns, lead to substantially better performance (average improvement of 0.15 F1 points). Second, our model outperforms two baseline models that utilize the same symmetric pattern classification features as in our model, but replace our simple I-k-NN algorithm with two leading label propagation alternatives (the normalized graph cut (N-Cut) algorithm (Yu and Shi, 2003) and the Modified Adsorption (MAD) algorithm (Talukdar and Crammer, 2009)). The average improvement over these two baselines is 0.21 and 0.03 F1 points .

The rest of the paper is organized as follows. Section 2 describes our semantic classification task and, particularly, the semantic classes that we aim to learn. Section 3 presents our method for automatic symmetric patterns acquisition. Sections 4, 5 and 6 describe our model, experimental setup and results, respectively. Related work is finally surveyed in Section 7.

2 Task Definition

The task we tackle in this paper is the classification of nouns into semantic categories. This section defines the categories we address and the dataset we use.

Semantic Categorization of Concrete Nouns. We focus on concrete "*things*" (Langacker, 2008), which correspond to *noun* categories. Nouns are interesting because they are the most basic lexical semantic categories. Specifically, children acquire nouns before any other category (Clark, 2009). Moreover, noun categories are generally not subjective. For example, it is hard to argue that a dog is not an animal, or that an apple is inedible, in most reasonable contexts. The context independent nature of nouns makes them appropriate for a type level classification task, such as the one we tackle. In order to provide a better description of the categories we aim to predict, we now turn to discuss the CSLB dataset, with which we experiment.

Dataset. We experiment with the CSLB property norms dataset (Devereux et al., 2013). In order to prepare this data set, thirty human subjects were presented with 638 concrete nouns and were asked to write the categories associated with each concept. Table 1 presents the top five categories for the nouns *apple* and *horse*.

Noun	Categories
Apple	is_a_fruit, does_grow_on_trees, is_green, is_red, has_pips_seeds
Horse	is_ridden, is_an_animal, has_four_legs, has_legs, has_hooves

Table 1: Five most frequent semantic categories for the words *apple* and *horse* in the CSLB dataset.

Category Selection. The CSLB dataset consists of a total of 2725 semantic categories. We apply a selection mechanism that provides us with a dataset in which (1) only noun categories (*things*) are included; and (2) only semantic categories that are prominent across humans are considered. For this, we apply the following filtering stages. First, since the vast majority of annotated categories are rare (for example, 1691 categories are assigned to a single noun only), we set a minimum threshold of 35 nouns per category (5% of the nouns). After removing highly infrequent categories, 28 are left. We then apply an inter-annotator agreement criterion: for each semantic category c, we compute the average number of human annotators that associated this category with a given noun, across the nouns annotated with c. We select the category c only if the value of this statistic is higher than 10 subjects ($1/3$ of the subjects), which results in a semantic category set of size 18. Finally, we discard categories, such as *color* and *size*, that do not correspond to *things*. We are left with four noun semantic categories: *animacy* (animals), *edibility* (food items), *is_a_tool* (tools), and *is_worn* (clothes).

Interestingly, the resulting semantic categories can also be justified from a cognitive perspective. There is a large body of work indicating that our categories relate to brain organization principles. For example, Just et al. (2010) showed that food products and tools arouse different brain activation patterns. Moreover, a number of works showed that both animate objects and tools are represented in specific brain regions. These works used neuroimaging methods such as functional magnetic resonance imaging (fMRI) (Naselaris et al., 2012), electroencephalography (EEG) (Chan et al., 2011) and magnetoencephalography (MEG) (Sudre et al., 2012). See (Martin, 2007) for a detailed survey. This parallel evidence to the prominence of our categories provides substance for intriguing future research.

3 Symmetric Patterns

Patterns. In this work, patterns are combinations of words and wildcards, which provide a structural phrase representation. Examples of patterns include "*X and Y*", "*X such as Y*", "*X is a country*", etc. Patterns can be used to extract various relations between words. For example, patterns such as "X of a Y" ("basement *of a* building") can be useful for detecting the meronymy (part-of) relation (Berland and Charniak, 1999). Symmetric patterns (e.g., "X *and* Y", "France *and* Holland"), which we use in this paper, can be used to detect semantic similarity between words (Widdows and Dorow, 2002).

Symmetric Patterns. *Symmetric* patterns are patterns that contain exactly two wildcards, and where these wildcards are interchangeable. Examples of symmetric patterns include "X *and* Y", "X *or* Y" and "X *as well as* Y". Previous works have shown that word pairs that participate in symmetric patterns bare strong semantic resemblance, and consequently, that these patterns can be used to cluster words into semantic categories, where a high precision, but low coverage (recall) solution is good enough (Dorow et al., 2005; Davidov and Rappoport, 2006). A key observation of this paper is that symmetric patterns can be also used for semantic classification, where recall is as important as precision.

Flexible Patterns. It has been shown in previous work (Davidov and Rappoport, 2006; Turney, 2008; Tsur et al., 2010; Schwartz et al., 2013) that patterns can be extracted from plain text in a fully unsupervised manner. The key idea that makes this procedure possible is the concept of "flexible patterns", which are composed of high frequency words (HFW) and content words (CW). Every word in the language is defined as either HFW or CW, based on the number of times this word appears in a large corpus. This clustering procedure is applied by traversing a large corpus, and marking words that appear with corpus frequency higher than a predefined threshold t_1 as HFWs, and words with corpus frequency lower than t_2 as CWs.[1]

[1]We follow (Davidov and Rappoport, 2006) and set $t_1 = 10^{-5}, t_2 = 10^{-3}$. Note that some words are marked both as HFW and as CW. See (Davidov and Rappoport, 2008) for discussion.

The resulting clusters have a desired property: HFWs are comprised mostly of function words (prepositions, determiners, etc.) while CWs are comprised mostly of content words (nouns, verbs, adjectives and adverbs). This coarse grained clustering is useful for pattern extraction from plain text, since language patterns tend to use fixed function words, while content words change from one instance of the pattern to another (Davidov and Rappoport, 2006).

Flexible patterns are extracted by traversing a large corpus and, based on the clustering of words to CWs and HFWs, extracting all pattern instances. An extracted pattern instance consists of CW wildcards and the actual words replacing the HFWs in the pattern type. Consider the sentence "*The boy is happy and joyful*". Replacing the content words with the CW wildcard results in "*The* CW *is* CW *and* CW". From this intermediate representation, we extract word sequences of a given length constraint and denote them as flexible patterns.[2] The flexible patterns of length 5 extracted from this sentence are "*The* CW *is* CW *and*" and "CW *is* CW *and* CW". The reader is referred to (Davidov and Rappoport, 2006) for more details.

Automatically Extracted Symmetric Patterns. Most models that incorporate symmetric patterns use a predefined set of patterns (Widdows and Dorow, 2002; Kozareva et al., 2008). In this work, we apply an automatic, completely unsupervised procedure for symmetric pattern extraction. This procedure, described in Algorithm 1, is adopted from (Davidov and Rappoport, 2006).

The procedure first extracts flexible patterns that contain exactly two CW wildcards. It then selects those flexible patterns in which both CWs are interchangeable. That is, it selects a pattern p if every word pair CW_1, CW_2 that participates in p indicates with high probability that the word pair C_2, C_1 also participates in p. For example, for the symmetric pattern "CW *and* CW", both "cats *and* dogs" and "dogs *and* cats" are semantically plausible expressions, and are therefore likely to appear in a large corpus. On the other hand, the flexible pattern "CW *such as* CW" is asymmetric, as exemplified in expressions like "countries *such as* France", where replacing the CWs does not result in a semantically plausible expression (# "France *such as* countries"). The selection process is done by computing the proportion of CW_1, CW_2 pairs that participate in p for which CW_2, CW_1 also participates in p. Patterns for which this proportion exceed a certain threshold are selected.

We apply Algorithm 1 on the google books 5-gram corpus (Michel et al., 2011)[3] and extract 20 symmetric patterns. Some of the more interesting symmetric patterns extracted using this algorithm include "CW *and the* CW", "*from* CW *to* CW", "CW *rather than* CW" and "CW *versus* CW". In the next section we present our approach to semantic classification, which makes use of automatically acquired symmetric patterns for word similarity computations.

4 Model

In this section we present our model for binary word classification according to a single semantic category in a minimally-supervised, transductive setup. Given a set of words, we label a small number of words with their correct label according to the category at hand (+1 for words that belong to the category, -1 for words that do not belong to it). Our model is based on an undirected weighted graph, in which vertices correspond to words, and edges correspond to relations between words. Our goal is to classify the unlabeled words (vertices) in the graph through a label propagation process. We now turn to describe our model in detail.

Graph Construction. We construct our graph such that an edge is added between two words (vertices) if both words participate in a symmetric pattern. The edge generation process is performed as follows. We first apply our symmetric pattern extraction procedure (Algorithm 1), and denote the set of selected symmetric patterns with P. We then traverse a large corpus[4] and extract all word pairs that participate in any pattern $p \in P$. We denote the number of occurrences of a word pair (w_1, w_2) in such patterns with f_{w_1,w_2}. Finally, we select all word pairs (w_1, w_2) for which $min(f_{w_1,w_2}, f_{w_2,w_1}) > \alpha$. Each such

[2] We set the maximal flexible pattern length to be 5.

[3] `https://books.google.com/ngrams`

[4] We use google books 5-grams (Michel et al., 2011).

Algorithm 1 Symmetric pattern extraction

procedure EXTRACT_SYMMETRIC_PATTERNS(C, W)
  ▷ C is a large corpus, W is a lexicon
  ▷ Traverse C and extract all flexible patterns of length 3-5 that appear in C and contain exactly two content words
  $P \leftarrow$ extract_flexible_patterns(C, W)
  for $p \in P$ **do**
    if p appears in $<10^{-6}$ of the sentences in C **then**
      Discard p and continue
    end if
    $G_p \leftarrow$ a directed graph s.t. $V(G_p) \leftarrow W$, $E(G_p) \leftarrow \{(w_1, w_2) \in W^2 : w_1, w_2$ participate in at least one instance of $p\}$
    ▷ An undirected graph based on the bidirectional edges of the G_p
    $symG_p \leftarrow$ an undirected graph: $\{(w_1), (w_1, w_2) : (w_1, w_2) \in E(G_p) \wedge (w_2, w_1) \in E(G_p)\}$
    ▷ Two measures of symmetry
    $M_1 \leftarrow \frac{|V(symG_p)|}{|V(G_p)|}, M_2 \leftarrow \frac{|E(symG_p)|}{|E(G_p)|}$
    ▷ Symmetric pattern candidates are those with high M_1 and M_2 values
    if $\min(M_1, M_2) < 0.05$ **then**
      Discard p
    end if
  end for
  for $p \in P$ **do**
    ▷ E.g., "CW and CW" is contained in "both **CW and CW**"
    if $\exists p' \in P$ s.t. p' is contained in p **then**
      Discard p
    end if
  end for
  return The top 20 members of P with the highest M_1 value
end procedure

pair is connected with an edge e_{w_1,w_2} in the graph, where the edge weight (denoted with w_{w_1,w_2}) is the geometric mean between f_{w_1,w_2} and f_{w_2,w_1}.

Label Propagation. Given a small number of annotated words (vertices), our goal is to propagate the information these words convey to other words in the graph. To do so, we apply an iterative variant of the k-Nearest Neighbors algorithm (I-k-NN). This iterative variant is required due to graph sparsity; when starting with a small set of labeled vertices, most unlabeled vertices do not have any labeled neighbor, and thus running the standard k-NN algorithm would result in classifying a very small number of vertices. Our approach is to run iterations of the k-NN algorithm, and thus propagate information to additional vertices at each iteration. At each k-NN step, the algorithm selects words that have at least one labeled neighbor. From this set, only the words that have the highest ratio of neighbors with the same label are selected, and are assigned with this label.

Consider a simple example. Say we have three candidate vertices a, b and c, where a has one neighbor with label +1 ($ratio(a) = 1/1 = 1.0$), b has two neighbors with label -1 ($ratio(b) = 2/2 = 1.0$) and c has three neighbors with label +1 and one neighbor with label -1 ($ratio(c) = max(3, 1)/4 = 3/4$). Then, a and b are selected and are assigned with $+1$ and -1, respectively.

Seed Expansion. In minimally supervised setups like ours, the model is initialized with a small set of labeled seed examples. A natural approach in such settings is to apply a seed expansion step, in order to obtain a larger set of labeled seeds. Our method uses the same graph construction procedure described above, but uses a larger edge generation threshold $\beta >> \alpha$.[5] We then apply an iterative procedure that labels a vertex v with a label l if either (a) v is directly connected to γ of the vertices labeled with l or (b) v is connected to δ_l of the neighbors of vertices labeled with l.[6] This procedure is run iteratively until no more vertices meet any of the criteria (a) or (b).

[5] Using a larger threshold results in a sparser graph. Nevertheless, each edge in this graph is more likely to represent a real semantic relation.

[6] γ and δ_l are hyperparameters tuned on our development set (see Section 5.2).

5 Experimental Setup

5.1 Baselines

We compare our model to two types of baselines. The first (Classification Features Baselines) utilizes the I-k-NN algorithm, along with a different set of classification features. The second (Label Propagation Baselines) utilizes the same classification features as we do, but replaces I-k-NN with a more sophisticated label propagation algorithm.

5.1.1 Classification Features Baselines

In this set of baselines, we use different methods for building our graph. Concretely, instead of adding edges for pairs of words that appear in the same symmetric pattern, we use word similarity measures based on different feature sets as described below. The process of building the graph using the baseline word similarity measures is described in Section 5.2.

SENNA. Deep neural networks have gained recognition as leading feature extraction methods for word representation (Collobert and Weston, 2008; Socher et al., 2013). We use SENNA,[7] a deep network based word embedding method, which has been used to produce state-of-the-art results in several NLP tasks, including POS tagging, chunking, NER, parsing and SRL (Collobert et al., 2011). We use the cosine similarity between two word embeddings as a word similarity measure.

Brown. This baseline is derived from the clustering induced by the Brown algorithm (Brown et al., 1992).[8] This clustering, in which words share a cluster if they tend to appear in the same lexical context, has shown useful for several NLP tasks, including POS tagging (Clark, 2000), NER (Miller et al., 2004) and dependency parsing (Koo et al., 2008). We use it in order to control for the possibility that a simple contextual preference similarity correlates with similarity in semantic categorization better than symmetric pattern features.

The Brown algorithm builds a binary tree, where words are located at leaf nodes. We use the graph distance between two words u, v (i.e., the shortest path length between u, v in the tree) as a word similarity measure for building our graph.

5.1.2 Label Propagation Baselines

In this type of baselines, we replace I-k-NN with a different label propagation algorithm, while still using the symmetric pattern features for word similarity computations.

N-Cut. This baseline applies the normalized graph cut algorithm (Yu and Shi, 2003)[9] for label propagation. Given a graph $G = (V, E)$ and two sets of vertices $A, B \subseteq V$, this algorithm defines $links(A, B)$ to be the sum of edge weights between A and B. The objective of the algorithm is to find the clusters $A, V \setminus A$ that minimize $\frac{links(A,V \setminus A)}{links(A,V)}$. The algorithm of (Yu and Shi, 2003) is particularly efficient for this problem as it avoids eigenvector computations which may become computationally prohibitive for large graphs (for more details, see their paper). In order to encode information about our labeled seed words, we hard-code a large negative value (-100000) to the weights of edges between seed words with different labels (positive and negative).

MAD. The Modified Adsorption (MAD) algorithm (Talukdar and Crammer, 2009)[10] is an extension of the Adsorption algorithm (Baluja et al., 2008). MAD is a stochastic graph-based label propagation algorithm which has shown to have a number of attractive theoretical properties and demonstrated good experimental results.

[7] The word embeddings were downloaded from `http://ml.nec-labs.com/senna/`

[8] We use the clusters induced by (Koo et al., 2008), who applied the Brown algorithm implementation of (Liang, 2005) to the BLLIP corpus (Charniak et al., 2000). `http://www.people.csail.mit.edu/maestro/papers/bllip-clusters.gz`

[10] `http://github.com/parthatalukdar/junto`

5.2 Experiments

Graph Construction. We experiment with the CSLB dataset (Devereux et al., 2013), consisting of 638 nouns, annotated with their semantic categories by thirty human subjects. We first omit all nouns that are annotated as having more than one sense, and use the remaining 603 nouns to build our graph. From these nouns, 146 nouns are annotated as animate, 115 as edible, 50 as wearable and 35 as tools.[11] We then discard nouns that have less than two neighbors, which results in a final set of 450 nouns (vertices).

The graphs used in the classification features baselines are different than those used by the models that use our symmetric pattern classification features, since the features define the graph structure (Section 4). In order to provide a meaningful comparison, we build graphs with the same number of vertices for each of these baselines. We do so by selecting the n edges with the highest weight, together with the set of vertices connected by these edges, such that the resulting graph has 450 vertices. Working with these sets of vertices is the optimal setting for these baselines, as the resulting graphs are the ones with the highest possible edge weights for graphs with 450 vertices.[12]

Parameter Tuning. In order to avoid adding additional labeled examples for the sake of parameter tuning, we set the hyperparameter values to the ones for which each model performs best on an auxiliary semantic classification task. Concretely, we experiment with a fifth semantic category (*audibility*),[13] which is not part of our evaluation setting, for parameter tuning. Note that this results in our model having the same hyperparamter values for all four classification tasks.

In order to ensure that the models assign all participating words with labels, we set α=3, where α is the minimal number of times a word pair should appear in the same symmetric pattern in order to have an edge in our graph (See Section 4). In our seed expansion procedure, where we search for seeds whose label is predicted with high confidence, only word pairs that appear at least β=50 times in the same symmetric pattern are assigned an edge in the graph. We set the seed expansion procedure parameters to be $\gamma = 0.6$, $\delta_{+1} = 0.5, \delta_{-1} = 0.2$.

Evaluation. For each classification task, we run experiments with 4, 10, 20 and 40 labeled seed words. In each setting, half of the labeled seed words are assigned a positive label and the other half are assigned a negative label. For each semantic category and labeled seed set size, we repeat our experiment 1000 times, each of which with a different set of randomly selected labeled seed examples, and report the average results. We report both accuracy (number of correct labels divided by number of vertices in the graph) and F1 score, which is the harmonic mean of p (the average precision across labels) and r (average recall across labels).

These two measures represent complementary aspects of our results. On the one hand, accuracy is the most natural classification performance measure. On the other hand, the number of positive labels is substantially smaller than the number of negative labels,[14] and thus this measure can be manipulated: a dummy model that always assigns the negative label gets a high accuracy. The F1 score controls against such models by assigning them low scores.

6 Results

Our experiments are designed to explore two main questions: (a) the value of symmetric patterns as semantic classification features, compared to state-of-the-art word clustering and embedding methods; and (b) the required complexity of an algorithm that can propagate information about semantic similarity. Particularly, we test the value of our simple I-k-NN algorithm compared to more sophisticated alternatives.

A Minimally Supervised Setting. Our first set of experiments is in a minimally supervised setting where only two positive and two negative examples are available for each binary classification task. This

[11] Some words are classified as belonging to more than one category (e.g., "chicken" is both animate and edible).

[12] The resulting graphs are actually denser than the symmetric patterns-based graph: 14K and 9K edges for the Brown and SENNA graphs, respectively, compared to $<$ 5K edges in the symmetric patterns graph.

[13] We used four labeled seed words in these experiments.

[14] Only 6-25% of the nouns have a positive label.

		Animacy			Edibility			is_worn			is_a_tool		
		SP	SENNA	Brown	SP	SENNA	Brown	SP	SENNA	Brown	SP	SENNA	Brown

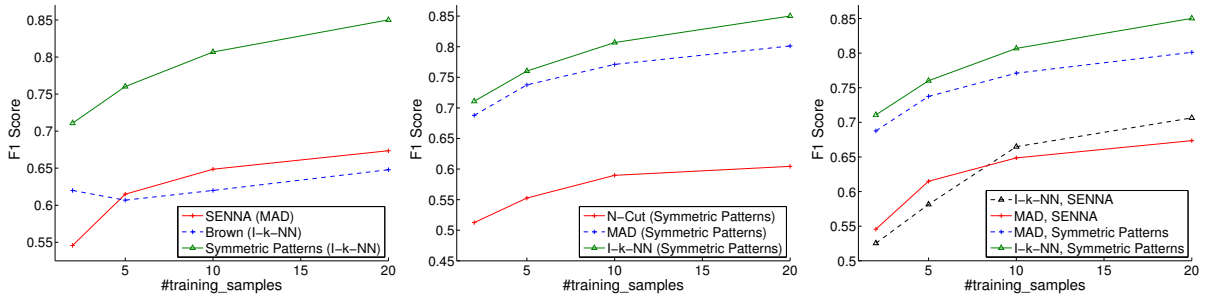
Table 2: Accuracy and F1 score comparison between our model and the baselines. The columns correspond to the type of classification features used by the model: SP – symmetric patterns, SENNA – word embeddings extracted using deep networks (Collobert et al., 2011), Brown – Brown word clustering (Brown et al., 1992). The rows correspond to the algorithms applied by the model: N-Cut – the normalized graph cut algorithm (Yu and Shi, 2003), MAD – the modified adsorption algorithm (Talukdar and Crammer, 2009), I-k-NN – our iterative k-NN algorithm. Our model (I-k-NN + SP) is superior in all cases, except for the accuracy of the "is_a_tool" semantic category, where it is second only to N-Cut+SP.



(a) Classification Features Comparison (b) Algorithm Comparison (c) Top four Best Models

Figure 1: (a) Comparison of the different classification features. The figure shows the F1 scores of the best model that uses each of the feature sets (the label propagation algorithm used in each model appears in parentheses). (b) Comparison of the different label propagation algorithms. The figure shows the F1 scores of the best model that uses each of the algorithms (the classification feature sets used in each model appears in parentheses. It is always symmetric patterns). (c) The four best overall models (algorithm + classification feature set). The figures show that the symmetric pattern feature set is superior to the other feature sets, and that I-k-NN is superior or comparable to the other label propagation algorithms.

setup enables us to explore the performance of our model when the amounts of labeled training data is taken to the possible minimum.

Table 2 presents our results. With respect to objective (a), the table clearly demonstrates that symmetric patterns lead to much better results compared to the alternatives. Particularly, for all four semantic categories, and across both evaluation measures, it is a model that utilizes symmetric pattern classification features that achieves the best results. The average difference between the best model that uses symmetric patterns and the best model that does not is 12.5% accuracy and 0.13 F1 points. The dominance of symmetric pattern classification features is further demonstrated by the fact that a model that uses these features always performs better than a model that uses the same algorithm but different features.

With respect to objective (b) the table shows that I-k-NN provides a large improvement in seven out of eight (*category* $\times$ *evaluation measure*) settings. The average difference between the best model that utilizes I-k-NN and the best model that applies a different algorithm is 5.4% accuracy and 0.06 F1 points.

Analysis of Labeled Seed Set Size. In order to get a wider perspective on our model, we repeated our experiments with various sizes of the labeled seed set: 5,10 and 20 positive and negative labeled examples per semantic category. For brevity, only the F1 score results of the edibility category are presented. The trends observed on the other semantic categories (as well as when using the accuracy measure) are very similar.

Figure 1a compares the different classification features. For each feature f, results of the best performing model that uses f are shown. The results reveal that symmetric patterns clearly outperform the other features. The average differences between the best symmetric patterns-based model and the best

models that use the other features are 0.15 (SENNA) and 0.16 (Brown) F1 points.

Figure 1b compares the different label propagation algorithms. For each algorithm a, results for the best performing model that uses a are presented. The results reveal that the I-k-NN algorithm outperforms both algorithms by 0.03 (MAD) and 0.21 (N-Cut) F1 points. The results also show that for all algorithms, the best performing model uses symmetric patterns classification features, which further demonstrates the dominance of these features.

Finally, Figure 1c presents the four top performing models (algorithm + classification feature). In accordance with the other findings presented in this section, the top two models, which outperform the other models by a large margin, apply symmetric pattern classification features.

Seed Expansion Effect. Our model uses a seed expansion procedure in order to expand a small set of labeled seed words to a larger set (see Section 4). In order to assess the quality of this procedure we compute, for each semantic category, the average size of the expanded set and the accuracy of the new seeds (i.e., the proportion of new seeds that are labeled correctly). Results show that the initial set is increased from four seeds (two positive + two negative) to 48-52, and that the accuracy of the new seeds is as high as 88-99%. Our experiments also show that this procedure provides a substantial performance boost to our I-k-NN algorithm, which obtains a 7.2% accuracy and 0.05 F1 points improvement (averaged over the four semantic categories) when applied with the expanded set of labeled seed words compared to the original set of size four.

7 Related Work

Classification into Semantic Categories. Several works tackled the task of semantic classification, mostly focusing on animacy, concreteness and countability. The vast majority of these works are either supervised (Hatzivassiloglou and McKeown, 1997; Baldwin and Bond, 2003; Peng and Araki, 2005; Øvrelid, 2005; Nagata et al., 2006; Xing et al., 2010; Kwong, 2011; Bowman and Chopra, 2012) or make use of external, language-specific resources such as WordNet (Orăsan and Evans, 2001; Orăsan and Evans, 2007; Moore et al., 2013). Our work, in contrast, is minimally supervised, requiring only a small set of labeled seed words.

Ji and Lin (2009) classified words into the gender and animacy categories, based on their occurrences in instances of hand-crafted patterns such as "X *who* Y" and "X *and his* Y". While their model uses patterns that are tailored to the animacy and gender categories, our model uses automatically induced patterns and is thus applicable to a range of semantic categories.

Finally, Turney et al. (2011) built a label propagation model that utilizes LSA (Landauer and Dumais, 1997) based classification features. They used their model to classify nouns into the concrete/abstract category using 40 labeled seed words . Unlike our model, which requires only a small set of labeled seeds, their algorithm is actually heavily supervised, requiring thousands of labeled examples for selecting the seed set of labeled words that are used for propagation. Our model, on the other hand, does not require any seed selection procedure, and utilizes a randomly selected set of labeled seed words.

Lexical Acquisition. Another line of work focused on the acquisition of semantic categories. In this setup, a model aims to find a core seed of words belonging to a given category, sacrificing recall for precision. Our model tackles a different task, namely the classification of words according to a given category where both recall and precision are to be optimized.

Lexical acquisition models are either supervised (Snow et al., 2006), unsupervised, making use of symmetric patterns (Davidov and Rappoport, 2006), or lightly supervised, requiring expert, language specific knowledge for compiling a set of hand-crafted patterns (Widdows and Dorow, 2002; Kozareva et al., 2008; Wang and Cohen, 2009). Other models require syntactic annotation derived from a supervised parser to extract coordination phrases (Riloff and Shepherd, 1997; Dorow et al., 2005). Our model automatically induces symmetric patterns, obtaining high quality results without relying on any type of language specific knowledge or annotation. Moreover, some of the works mentioned above (Riloff and Shepherd, 1997; Widdows and Dorow, 2002; Kozareva et al., 2008) also require manually selected label

seeds to achieve good performance; in contrast, our work performs very well with a randomly selected set of labeled seed words.

8 Conclusion

We presented a minimally supervised model for noun classification into coarse grained semantic categories. Our model obtains 82%-94% accuracy on four semantic categories even when using only four labeled seed words per category. We showed that our modeling decisions – using symmetric patterns as classification features and a simple iterative k-NN algorithm for label propagation – lead to a substantial performance gain compared to state-of-the-art, more sophisticated, alternatives. Our results demonstrate the applicability of minimally supervised methods for semantic classification tasks. Future work will include modifying our model to support other, more fine-grained types of semantic categories, including adjectival categories (*properties*). We also plan to work on token-level word classification, and thus support multi-sense words, as well as demonstrate the power of unsupervised patterns acquisition for multilingual setups.

Abstract

Automatic lexical acquisition has been an active area of research in computational linguistics for over two decades, but the automatic identification of new word-senses has received attention only very recently. Previous work on this topic has been limited by the availability of appropriate evaluation resources. In this paper we present the largest corpus-based dataset of diachronic sense differences to date, which we believe will encourage further work in this area. We then describe several extensions to a state-of-the-art topic modelling approach for identifying new word-senses. This adapted method shows superior performance on our dataset of two different corpus pairs to that of the original method for both: (a) types having taken on a novel sense over time; and (b) the token instances of such novel senses.

1 Novel word-senses

The meanings of words change over time with, in particular, established words taking on new senses. For example, the usages of *drop*, *wall*, and *blow up* in the following sentences correspond to relatively-recent senses of these words that appear to be quite common in text related to popular culture, but are not listed in many dictionaries; for example, they are all missing from WordNet 3.0 (Fellbaum, 1998).

1. *The reissue album drops March 27 and is an extension of Perry's huge 2010 Teenage Dream.* [*drops* = "comes out", "is released"]

2. *On Facebook, you can plainly see much of the data the site has on you, because it's posted to your wall.* [*wall* = "Facebook wall", "personal electronic noticeboard"]

3. *Why would I give him my number so he can blow up my phone the way he does my inbox.* [*blow up* = "overwhelm with messages"]

Computational lexicons are an essential component of systems for a variety of natural language processing (NLP) tasks. The success of such systems, therefore, depends on the quality of the lexicons they use, and (semi-)automatic techniques for identifying new word-senses could benefit applied NLP by helping to keep lexicons up-to-date. In revising dictionaries, lexicographers must identify new word-senses, in addition to new words themselves; methods which identify new word-senses could therefore also help to keep dictionaries current.

In this paper, because of the need for lexicon maintenance, we focus on relatively-new word-senses. Specifically, we consider the identification of word-senses that are not attested in a *reference corpus*, taken to represent standard usage, but that are attested in a *focus corpus* of newer texts.

Lau et al. (2012) introduced the task of novel sense identification. They presented a method for identifying novel word-senses — described here in Section 4 — and evaluated this method on a very small dataset consisting of just five lemmas having a novel sense in a single corpus pair. Cook et al. (2013) extended the method of Lau et al. to incorporate knowledge of the expected domains of new word-senses, but did not conduct a rigorous empirical evaluation. The remainder of this paper is structured

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1624–1635, Dublin, Ireland, August 23-29 2014.

as follows. After discussing related work in Section 2, we present a substantially-expanded evaluation dataset in Section 3, that is based on a second corpus pair and consists of many more lemmas with a novel sense. We describe the models used by Lau et al. and Cook et al., and our new extensions to them, in Section 4. In Section 5 we analyse the results of novel sense identification, and consider a new baseline for this task. We demonstrate that the extended methods give an improvement over the original method of Lau et al. We conclude by discussing some previously-unexplored variations on novel sense identification, and limitations of the approaches considered.

The primary contributions of this paper are: (1) development of a novel sense detection dataset much larger than has been used in research to date; (2) development and evaluation of a new baseline for novel sense detection, reformulations of the method of Lau et al., and a method that incorporates only the expected domain(s) of novel senses; (3) empirical evaluation of the method of Cook et al.; and (4) extension of the novel sense detection method of Cook et al. to automatically acquire information about the expected domain(s) of novel senses.

2 Related work

Identifying diachronic changes in word-sense is a challenge that has only been considered rather recently in computational linguistics. Sagi et al. (2009) and Cook and Stevenson (2010) propose methods to identify specific types of semantic change — widening and narrowing, and amelioration and pejoration, respectively — based on specific properties of these phenomena. Gulordava and Baroni (2011) identify diachronic sense change in an n-gram database, but using a model that is not restricted to any particular type of semantic change. Cook and Hirst (2011) consider the impact of sense frequency on methods for identifying novel senses. Crucially, all of the aforementioned approaches are type-based: they are able to identify words that have undergone a change in meaning, but not the token instances which give rise to these sense differences.

Bamman and Crane (2011) use a parallel Latin–English corpus to induce word senses and build a WSD system, which they then apply to study diachronic variation in sense frequency. Rohrdantz et al. (2011) present a system for visualizing changes in word usage over time. Crucially, in these token-based approaches there is a clear connection between (induced) word-senses and tokens, making it possible to identify usages of a specific (new) sense.

Other work has focused on sense differences between dialects and domains. Peirsman et al. (2010) consider the identification of words that are typical of Belgian and Netherlandic Dutch, due to either marked frequency or sense. McCarthy et al. (2007) consider the identification of predominant word-senses in corpora, including differences between domains. However, this approach does not identify new senses as it relies on a pre-existing sense inventory. Carpuat et al. (2013) identify words in a domain-specific parallel corpus with novel translations.

The method proposed by Lau et al. (2012), and extended by Cook et al. (2013), identifies novel word-senses using a state-of-the-art word-sense induction (WSI) system. This token-based approach offers a natural account of polysemy and not only identifies word types that have a novel sense, but identifies the token instances of the hypothesized novel senses, without reliance on parallel text or a pre-existing sense inventory. We therefore adopt this method for evaluation on our new dataset, and propose further extensions to this method.

3 Datasets

Evaluating approaches to identifying semantic change is a challenge due to the lack of appropriate evaluation resources (i.e., corpora for the appropriate time periods, known to exhibit particular sense changes); indeed, most previous approaches have used very small datasets (e.g., Sagi et al., 2009; Cook and Stevenson, 2010; Bamman and Crane, 2011). In this study we consider two datasets of relatively newly-coined word-senses: (1) an extended version of the dataset based on the BNC (Burnard, 2000) and ukWaC (Ferraresi et al., 2008) used by Lau et al. (2012); and (2) a new dataset based on the SiBol/Port Corpus.[1] This

[1] http://www3.lingue.unibo.it/blog/clb/?page_id=8

is the largest dataset for evaluating approaches to identifying diachronic semantic change constructed from corpus evidence to be presented to date.

3.1 BNC–ukWaC

Lau et al. (2012) take the written portion of the BNC (approximately 87 million words of British English from the late 20th century) as the reference corpus, and a similarly-sized random sample of documents from the ukWaC (a Web corpus built from the `.uk` domain in 2007) as the focus corpus. They used TreeTagger (Schmid, 1994) to tokenise and lemmatise both corpora.

A set of words that has acquired a new sense between the late 20th and early 21st centuries — the time periods of the reference and focus corpora — is required. The Concise Oxford English Dictionary aims to document contemporary usage, and has been published in numerous editions including Thompson (1995, COD95) and Soanes and Stevenson (2005, COD08), enabling the identification of new senses amongst the entries in COD08 relative to COD95. Manually searching these dictionaries for new senses would be time intensive, but new words often correspond to concepts that are culturally salient (Ayto, 2006), and one can leverage this observation to speed up the process of finding some candidate words with novel senses.[2]

Between the time periods of the reference and focus corpora, computers and the Internet have become much more mainstream in society. Lau et al. therefore extracted all headwords in COD08 whose entries contain the word *computing*. They then carefully annotated these lemmas to identify those that indeed exhibit the novel sense indicated in the dictionary in the corpora. Here, we expand Lau et al.'s dataset by extracting all headwords including any of the following words *code*, *computer*, *internet*, *network*, *online*, *program*, *web*, and *website*. We then follow a similar annotation process to Lau et al.

An annotator read the entries for the selected lexical items in COD95 and COD08, and identified those which have a clear sense related to computers or the Internet in COD08 that is not present in COD95; such senses are referred to as *novel senses*. This process, along with all the annotation in this section (including Section 3.2), is carried out by native English-speaking authors of this paper and graduate students in computational linguistics.

To ensure that the words identified from the dictionaries do in fact have a new sense in the ukWaC sample compared to the BNC, we examine word sketches (Kilgarriff et al., 2004)[3] for each of these lemmas in the BNC and ukWaC for collocates that likely correspond to the novel sense; we exclude any lemma for which we find evidence of the novel sense in the BNC, or fail to find evidence of the novel sense in the ukWaC sample.[4]

We further examine the usage of these words in the corpora. We extract a random sample of 100 usages of each lemma from the BNC and ukWaC sample, and annotate these usages as to whether they correspond to the novel sense or not. This binary distinction is easier than fine-grained sense annotation, and since we do not use these annotations for formal evaluation — only for selecting items for our dataset — we do not carry out an inter-annotator agreement study here. We eliminate any lemma for which we find evidence of the novel sense in the usages from the BNC, or for which we do not find evidence of the novel sense in the ukWaC sample usages.[5]

This process resulted in the identification of two lemmas not in the dataset of Lau et al., with frequency greater than 1000 in the ukWaC sample, and having a novel sense in the ukWaC compared to the BNC (*feed* (n) and *visit* (v)). Combining these new lemmas with the dataset of Lau et al. gives an expanded dataset consisting of seven lemmas. For both of the two new lemmas, a second annotator annotated the sample of 100 usages from the ukWaC. The observed agreement and unweighted Kappa for this annotation task for all seven lemmas is 97.4% and 0.93, respectively, indicating that this is indeed a relatively easy annotation task. The annotators discussed the small number of disagreements to reach

[2]We access the dictionaries in the same way as Lau et al., namely we use COD08 online via `http://oxfordreference.com`, and the paper version of COD95.

[3]`http://www.sketchengine.co.uk/`

[4]We examine word sketches for the full ukWaC because this version of the corpus is available through the Sketch Engine.

[5]We use the IMS Open Corpus Workbench (`http://cwb.sourceforge.net/`) to extract usages of our target lemmas from the corpora. This extraction process fails in a number of cases, and so we also eliminate such items from our dataset.

Table 1: Lemmas in the BNC–ukWaC and SiBol/Port datasets. For each lemma, the frequency of its novel sense in the annotated sample of usages from the focus corpus, and a definition of its novel sense, are shown.

consensus. The seven lemmas in this dataset are shown in Table 1, along with definitions of their novel senses, and the frequencies of their novel senses in the focus corpus.

Lau et al. compared the novelty of the lemmas with a novel sense to that of a same-size set of distractor lemmas not having a novel sense. Here we consider a much larger set of 50 distractors — 25 nouns and 25 verbs — randomly sampled from a similar frequency range as the items with a novel sense.

One shortcoming of this dataset (and indeed the subset of it used by Lau et al.) is that text types are represented to different extents in the BNC and ukWaC, with, for example, texts related to the Internet being much more common in the ukWaC. Such differences in corpus composition are a noted challenge for approaches to identifying lexical semantic differences between corpora (Peirsman et al., 2010). In the following subsection we therefore consider the creation of a new dataset from more-comparable corpora.

3.2 SiBol/Port

The SiBol/Port Corpus consists of texts from several British newspapers for the years 1993, 2005, and 2010; we use the 1993 and 2010 portions of this corpus — referred to as SP1993 and SP2010 — as our reference and focus corpora, respectively. SP1993 and SP2010 contain approximately 93M and 99M words, respectively. In contrast to BNC–ukWaC, our reference and focus corpora are now comparable, in that they both consist of texts from British newspapers but they differ with respect to the specific year.

The novel word-senses in the BNC–ukWaC dataset are all related to computers and the Internet, but there has been recent lexical semantic change unrelated to technology as well (e.g., *sick* can be used to mean "excellent"). In an effort to include such non-technical novel senses in this new dataset, we obtain a list of headwords for which a sense was added to the Macmillan English Dictionary for Advanced

Learners (MEDAL)[6] since its first edition (Rundell and Fox, 2002), courtesy of Macmillan Dictionaries. Beginning with these candidates from MEDAL, and the items extracted from COD from Section 3.1, we discard any lemma whose frequency is less than 1000 in SP1993 or SP2010.

As for the BNC–ukWaC dataset, an annotator examined word sketches for these lemmas. However, it is possible that the novel sense for a lemma is present in a corpus, but that we fail to find evidence for it in that lemma's word sketch. We therefore also obtain judgements from two annotators as to whether each novel sense is expected to be very infrequent (or unattested) in SP2010. To reduce subsequent annotation effort, we discard any lemma for which its novel sense is believed to be infrequent in SP2010 by both judges, and is not found in the word sketch from SP2010.

Annotators then annotate a random sample of 100 usages of each lemma in the reference and focus corpora as before, and again eliminate any lemma for which we find evidence of its novel sense in the reference corpus, or fail to find evidence of that sense in the focus corpus. We identify thirteen lemmas having a novel sense in SP2010 relative to SP1993. These lemmas are also shown in Table 1.

We obtain a second set of annotations for the usages of these lemmas in the sample from SP2010, with each lemma being annotated by a different annotator than before. The observed agreement and unweighted Kappa between the two sets of annotations is 96.2% and 0.81, respectively. In cases of disagreement, a final annotation is again reached through discussion.

We randomly select 164 lemmas (116 nouns and 48 verbs) from a similar frequency range as the lemmas having a novel sense, to serve as distractors.

Both the BNC–ukWaC and SiBol/Port datasets have been made available.[7]

4 The WSI-based approach to novel word-sense detection

In this section we describe the WSI-based method of Lau et al. (2012) for detecting novel senses, and an extension of this method from Cook et al. (2013). We then present new extensions of this method.

The Lau et al. (2012) WSI model is based on a Hierarchical Dirichlet Process (HDP, Teh et al., 2006), which is a non-parametric variant of a topic model that, like the commonly-used Latent Dirichlet Allocation (LDA, Blei et al., 2003), learns topics (in the form of multinomial probability distributions over words) and per-document topic assignments (in the form of multinomial probability distributions over topics) for a collection of documents; unlike LDA, however, it also optimises the number of topics in an unsupervised data-driven manner. In the context of WSI, by creating "documents" that consist of sentences containing a target word, we can view the topics learnt by topic models as the sense representation of the target word. Indeed, topic models have been previously applied to WSI (e.g., Brody and Lapata, 2009; Yao and Van Durme, 2011).

To generate the input for the topic model, the documents are tokenised (in this case, a "document" is a short context, typically 1–3 sentences, containing a target word) into a bag of words. All words are lemmatised, and stopwords and low frequency terms are removed. Positional word features — commonly used in WSI — for each of the three words to the left and right of the target word are also included.

To induce the senses of a target word w from a given set of usages of w, HDP is run on those usages (represented according to the features described above) to induce topics; these topics are then interpreted as representing the senses of w (one topic per sense). To determine the sense assigned to each instance, the system aggregates over the topic assignments for each word in the context of w, and selects the topic with the highest aggregated probability, i.e., $\text{argmax}_z P(t = z|d)$, where d is a document and t is a topic.

Recently, Lau et al. (2013a,b) found this method to give the overall best performance on two WSI shared tasks (Jurgens and Klapaftis, 2013; Navigli and Vannella, 2013), demonstrating that the method is competitive with the state-of-the-art in WSI, and appropriate as the basis for a method for identifying novel word-senses.

[7] http://www.csse.unimelb.edu.au/~tim/etc/novel-sense-dataset.tgz

4.1 Novel Sense Detection

Following Lau et al. (2012), to detect novel senses of a target word using this WSI method, we *jointly* topic model two corpora: a reference corpus — taken to represent standard usage — and a focus corpus of newer texts potentially containing novel senses. In other words, we extract usages of a target word w from both corpora, and then topic model the pooled instances of w. Under this approach, the discovered topics are applicable to both corpora, so there is no need to reconcile two different sets of topics. For the experiments in this paper, we extract three sentences of context for each usage, one sentence to either side of the usage of the target word.

As each usage is given a sense assignment, we can identify novel senses — senses present in the focus corpus, but unattested in the reference corpus — based on differences in the sense distribution for a given word between the two corpora. Lau et al. present a Novelty score which is proportional to the following:

$$\text{Novelty}_{\text{Ratio}}(s) = \frac{p_f(s)}{p_r(s)} \tag{1}$$

where $p_f(s)$ and $p_r(s)$ are the proportion of usages of a given word corresponding to sense s in the focus corpus and reference corpus, respectively, calculated using smoothed maximum likelihood estimates. The score for a given lemma is the maximum score for any of its induced senses. We refer to the *novel sense* for a lemma as the induced sense corresponding to this maximum.

4.2 Alternative Formulations of Novelty

The WSI system underlying the approach of Lau et al. labels each usage of a target lemma with an induced sense. Therefore, any approach to identifying keywords — words that are substantially more frequent in one corpus than another — can potentially be applied to identify novel senses, by viewing "words" as (word,sense) tuples. We consider a version of Novelty based on the difference in relative frequency of an induced sense in the focus and reference corpora, as below:

$$\text{Novelty}_{\text{Diff}}(s) = p_f(s) - p_r(s) \tag{2}$$

We consider a further new variant of Novelty based on the log-likelihood ratio of an induced sense in the two corpora, referred to as $\text{Novelty}_{\text{LLR}}$.

4.3 Incorporating knowledge of expected topics of novel senses

Cook et al. (2013) extended Lau et al.'s method by incorporating the observation that many neologisms are related to topics that are culturally salient (e.g., Ayto, 2006); nowadays we see many neologisms related to computing and the Internet. Indeed this observation was used to construct the gold-standard dataset for this study. Cook et al. identified a set of words, W, related to computing and the Internet, based on manual analysis of keywords for the corpora they considered. They then formulated the Relevance of an induced sense s for a given word as follows:

$$\text{Relevance}_{\text{Manual}}(s) = \sum_{w \in W} p(w|s) \tag{3}$$

For a given lemma, $\text{Relevance}_{\text{Manual}}$ is the maximum of this score for any of its induced senses, similar to Novelty.

Following Cook et al., we calculate Relevance and Novelty for each induced sense of each lemma, and then rank all the induced senses by these measures independently. We then compute the rank sum of each induced sense of each lemma under these two rankings. The final score for a given lemma is then the rank sum of its highest-ranked sense, and this sense is taken as that lemma's novel sense. We refer to this new method as "Rank Sum". Cook et al. only considered Novelty and Rank Sum; here we additionally consider Relevance on its own.

For the keywords, we manually construct a set of words related to computing and the Internet, the topics for which we expect to observe many novel senses in both of our datasets, in a similar way to Cook et al. In order to minimize annotation effort, we concentrate on words that are more-frequent in the

focus corpus than the reference corpus. For a given corpus pair, we begin by computing the keywords for those corpora using Kilgarriff's (2009) method.[8] Two annotators — both computational linguists and not authors of this paper — independently scanned the top-1000 keywords for the focus corpus, and selected those that were, based on their intuition, related to computing and the Internet. We then took the topically-relevant words for a given corpus pair to be those in the intersection of the sets of words selected by the two annotators. For BNC–ukWaC and SiBol/Port this gives 102 and 30 topically-relevant words, respectively. This annotation required, on average, 23 minutes per annotator per corpus pair to complete. Examples of the keywords selected for SiBol/Port include *broadband*, *click*, *device*, *online*, and *tweet*.

4.4 Automatically-extracting keywords

We propose a new fully-automated method for identifying a set of topically-relevant keywords. Because of the differences in corpus composition, the BNC–ukWaC keywords are often related to computing and the Internet. To automatically obtain topically-relevant words, we take the top-1000 keywords for the ukWaC relative to the BNC (i.e., the same keywords annotated for the BNC–ukWaC in Section 4.3). The keywords for SiBol/Port are less-clearly related to the topics of interest, so we therefore use the topically-relevant keywords from BNC–ukWaC for both datasets.

5 Results

In the following subsections we consider results at the type and then token level.

5.1 Type-level results

In these experiments we rank all items — lemmas with a novel sense, and distractors — by the various Novelty, Relevance and Rank Sum methods for the BNC–ukWaC and SiBol/Port datasets. When a lemma takes on a new sense, it might also increase in frequency. We therefore also consider a baseline in which we rank the lemmas by the ratio of their frequency in the focus corpus and the reference corpus. This baseline has not been previously considered by Lau et al. (2012) or Cook et al. (2013).

To compare approaches, we examine precision–recall curves in Figures 1 and 2. In an applied setting, we envision these ranked lists being manually examined; we are therefore primarily interested in the highly-ranked items, i.e., the left portion of the precision–recall curves.

For BNC–ukWaC (Figure 1), $\text{Novelty}_{\text{Diff}}$ and $\text{Novelty}_{\text{Ratio}}$ perform much better than $\text{Novelty}_{\text{LLR}}$, but not better than the frequency ratio baseline, at least for the left-most portion of the precision–recall curve. Surprisingly, for Relevance, $\text{Relevance}_{\text{Auto}}$ outperforms $\text{Relevance}_{\text{Manual}}$. This could be because the focus corpus exhibits a clear topical bias towards computing and the Internet (the expected domain of many neologisms in the focus corpus), and therefore a larger set of potentially noisy keywords is more informative than a smaller, hand-selected set. All of the measures including the baseline, except for $\text{Novelty}_{\text{LLR}}$, assign higher scores to lemmas with a gold-standard novel sense than the distractors, according to a one-sided Wilcoxon rank sum test ($p < 0.05$ in each case).

Turning to SiBol/Port in Figure 2, the frequency ratio baseline is much less effective here; the frequency of the gold-standard novel senses is much lower overall than for BNC–ukWaC. All of the Novelty and Relevance methods outperform the baseline, and — with the exception of $\text{Novelty}_{\text{Ratio}}$ — rank the lemmas with a gold-standard novel sense higher than the distractors (again using a one-sided Wilcoxon rank sum test and $p < 0.05$). Furthermore, in this case, $\text{Relevance}_{\text{Manual}}$ outperforms $\text{Relevance}_{\text{Auto}}$, as expected.

In terms of the three Novelty measures, only $\text{Novelty}_{\text{Diff}}$ ranked items with a novel sense higher than the distractors for both datasets. We therefore also show results for the Rank Sum approach combining $\text{Novelty}_{\text{Diff}}$ and each of $\text{Relevance}_{\text{Manual}}$ and $\text{Relevance}_{\text{Auto}}$, denoted $\text{Rank Sum}_{\text{Diff,manual}}$ and $\text{Rank Sum}_{\text{Diff,auto}}$, respectively, in Figures 1 and 2. For both BNC–ukWaC and SiBol/Port, $\text{Rank Sum}_{\text{Diff,manual}}$

[8] Using this method, the keywordness score for a given word is simply the ratio of its frequency per million words, plus a constant, in two corpora; we set the constant to 100, the value recommended by Kilgarriff.

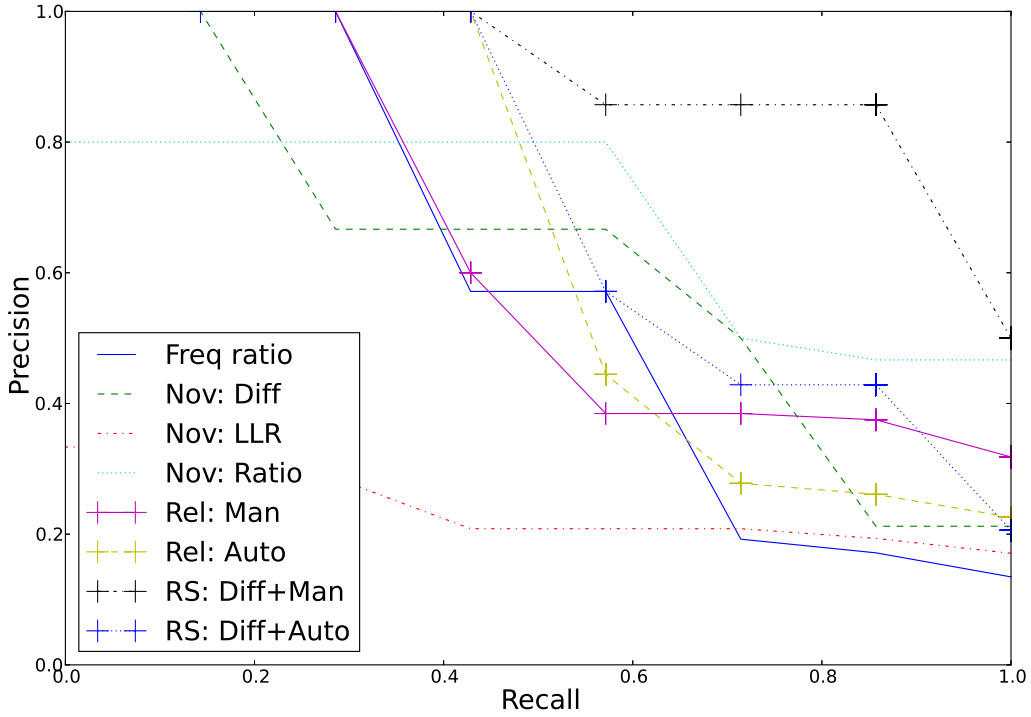

Figure 1: Precision–recall curve for the BNC–ukWaC dataset.

gives the best performance, and is a clear improvement over either of the individual methods. As expected, the performance of Rank $\text{Sum}_{\text{Diff,auto}}$ is not as good, but is nevertheless an improvement over the frequency ratio baseline for both datasets and provides an alternative to manual scrutiny of the keywords.

To further examine the potential of incorporating knowledge of the expected domains of novel senses to improve novel sense identification, we consider the case of *cloud* (n) from the SiBol/Port dataset. The highest-probability words for the topic with highest $\text{Novelty}_{\text{Diff}}$ are the following: *ash*, *volcanic*, *flight*, *@card@*,[9] *travel*, *airline*, *volcano*, *airport*, *air*, *cloud*. This sense appears to be related to the eruption of the Eyjafjallajökull volcano, a major event in 2010 (the year from which the SiBol/Port focus corpus is taken). Such topical differences, which do not correspond to a novel sense, are a problem for any approach to identifying lexical semantic differences between two corpora based on differences in the lexical context of a target word, and indeed observations such as this motivated our use of the methods incorporating Relevance. The highest probability words for the topic with highest $\text{Relevance}_{\text{Auto}}$ are the following: *cloud*, *@card@*, *company*, *service*, *business*, *computing*, *market*, *security*, *datum*, *need*. This topic appears to correspond to the expected novel sense of Internet-based computational resources, demonstrating the potential to improve a system for identifying novel word-senses by incorporating knowledge of the expected domains of neologisms. Moreover, incorporating Relevance is particularly powerful for avoiding false positives. For example, the distractor *clause* (n) is the lemma with the sixth-highest $\text{Novelty}_{\text{Diff}}$ for SiBol/Port. The highest probability words for the corresponding topic are the following: *contract*, *@card@*, *club*, *player*, *million*, *england*, *capello*, *manager*, *sign*, *deal*. This induced sense appears to be related to clauses in Fabio Capello's contract as manager of the England national football team, and is not a novel sense of *clause*. However, none of the induced senses of *clause* have high $\text{Relevance}_{\text{Auto}}$ or $\text{Relevance}_{\text{Manual}}$, and so incorporating information from Relevance can avoid incorrectly identifying this lemma as having a novel sense.

[9] A generic token signifying a cardinal number.

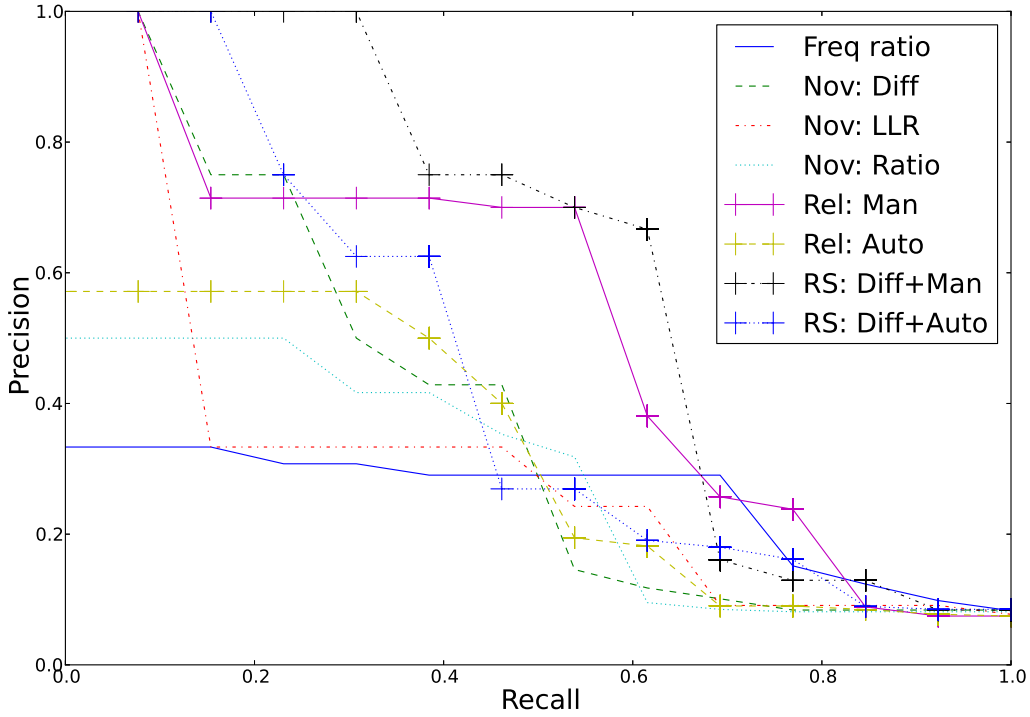

Figure 2: Precision–recall curve for the SiBol/Port dataset.

5.2 Token-level results

In this section, we consider the token-level identification of instances of the gold-standard novel senses. We compare Novelty, Relevance, and Rank Sum to a baseline that assigns all usages of a lemma to a single topic which is selected as the novel sense; in this case recall is 1, and precision is proportional to the frequency of the novel sense. We further consider the theoretical upper-bound of a method which selects a single topic as the novel sense, based on the output of the HDP-based WSI method; this oracle selects the best topic in terms of F-score as the novel sense. Results are presented in Table 2.

Each variant of Novelty and Relevance is an improvement over the baseline, although the Relevance measures don't perform as well as the Novelty ones, despite this dataset only containing novel senses related to computing (despite our efforts to include non-technical novel senses). For consistency with the presentation of the type-level results, we again consider Rank Sum using $\text{Novelty}_{\text{Diff}}$, even though it doesn't perform as well as $\text{Novelty}_{\text{LLR}}$ or $\text{Novelty}_{\text{Ratio}}$ on BNC–ukWaC. Using either automatically- or manually-obtained keywords, the performance of Rank Sum on BNC–ukWaC is remarkably on par with the upper-bound, although for SiBol/Port there is little or no improvement over $\text{Novelty}_{\text{Diff}}$. Nevertheless, these findings are further indication that novel sense identification can be improved by incorporating information about the topics for which we expect to see novel senses. However, this approach is particularly helpful at the type-level, where information about the expected topics of novel senses prevents lemmas not having a novel sense (i.e., the distractors) from being assigned high novelty.

6 Discussion and conclusion

The methods considered in this paper could be applied to any corpus pair, and potentially to identify lexical semantic differences between, for example, domains or language varieties. The focus of this study is English; sufficiently-large comparable corpora of national varieties of English (e.g., British and American English), are not readily-available, but could potentially be inexpensively constructed in the future (Cook and Hirst, 2012). We conducted some preliminary experiments using domain-specific sports

Method	F-score	
	BNC–ukWaC	SiBol/Port
$\text{Novelty}_{\text{Diff}}$	0.57	0.29
$\text{Novelty}_{\text{LLR}}$	0.67	0.28
$\text{Novelty}_{\text{Ratio}}$	0.66	0.28
$\text{Relevance}_{\text{Auto}}$	0.48	0.24
$\text{Relevance}_{\text{Manual}}$	0.45	0.27
$\text{Rank Sum}_{\text{Diff,auto}}$	0.72	0.30
$\text{Rank Sum}_{\text{Diff,manual}}$	0.72	0.29
Upper-bound	0.72	0.42
Baseline	0.36	0.20

and finance corpora (Koeling et al., 2005) and the BNC. However, in these experiments we observed very high $\text{Novelty}_{\text{Ratio}}$ for many distractors (selected in a similar way to our other experiments). Unlike the case of time difference, in corpora from different domains, an arbitrarily chosen word will tend to cooccur with very different words in the corpora, and $\text{Novelty}_{\text{Ratio}}$ will consequently be high. To address vocabulary differences between corpora, in their experiments on identifying lexical semantic differences between Dutch dialects, Peirsman et al. (2010) restricted the context words used to represent a target word to those with moderate frequency in each of the two corpora used. We considered a similar restriction in experiments on SiBol/Port, but did not see an overall improvement in performance.

We demonstrated that the performance of a method for identifying novel word-senses can be improved by incorporating information — acquired manually or automatically — about the expected topics of novel senses, which tend to be related to culturally-salient concepts. In future work, we intend to consider improved approaches for automatically identifying topically-relevant words by incorporating information about the top keywords of a corpus harvested from the Web for the domain of interest (e.g., PVS et al., 2012). We also believe that topic models could be useful for identifying emerging or changing domains themselves given the reference and focus corpus, and related work in this area (e.g., Wang and McCallum, 2006; Blei and Lafferty, 2007).

To conclude, we have presented the largest type- and token-level dataset of diachronic sense differences to date, drawing on two pairs of corpora, and have made this dataset available. We applied a recently-proposed WSI-based method to the task of finding sense differences in this data. We demonstrated that, while the method shows promise, on a type-based task it is comparable to a a simple frequency baseline, which had not been previously considered for this task. We carried out the first empirical evaluation of a recently-proposed extension of this method that incorporates manually-acquired knowledge of the expected domains of new senses, and found it to have superior performance at both the type and token level. We further proposed and evaluated an approach that only uses this domain knowledge, and a method for automating its acquisition.

Acknowledgments

We thank Michael Rundell and Macmillan Dictionaries for providing the list of headwords added to MEDAL since its first edition, and Charlotte Taylor for providing us with early access to SiBol/Port. We also thank Richard Fothergill, Karl Grieser, and Andrew Mackinlay for their help in annotation. This research was supported in part by funding from the Australian Research Council.

Abstract

We cast multi-sentence compression as a structured prediction problem. Related sentences are represented by a word graph so that summaries constitute paths in the graph (Filippova, 2010). We devise a parameterised shortest path algorithm that can be written as a generalised linear model in a joint space of word graphs and compressions. We use a large-margin approach to adapt parameterised edge weights to the data such that the shortest path is identical to the desired summary. Decoding during training is performed in polynomial time using loss augmented inference. Empirically, we compare our approach to the state-of-the-art in graph-based multi-sentence compression and observe significant improvements of about 7% in ROUGE F-measure and 8% in BLEU score, respectively.

1 Introduction

Automatic text summarisation is one of oldest forms of natural language processing (Luhn, 1958; Baxendale, 1958). The goal is to extract the most important part of the content from either a single document or a collection of documents (Mani, 2001; Roussinov and Chen, 2001; McKeown *et al.*, 2005).

Frequently, the information of interest is contained in only a part of a sentence or may be distributed across parts of several sentences. Identifying the content carrying part(s) constitutes an essential technique not only for single- and multi-document extractive summarisation but also text simplification in general. Generating a simplified version of a text traditionally has many applications in question answering (Hermjakob *et al.*, 2002) and speech synthesis (Kaji *et al.*, 2004). Due to limited display sizes of mobile devices, recent applications also deal with summarising/simplifying news articles, social media, emails, or websites (Corston-Oliver, 2001).

Multi-sentence compression (MSC) unifies many of the mentioned characteristics and challenges and can be seen as a key to text summarisation and simplification (Jing and McKeown, 2000). The task in multi-sentence compression is to map a collection of related sentences to a grammatical short sentence that preserves the most important part of the content. Sentence compression methods have been devised using manually crafted rules (Dorr *et al.*, 2003), language models (Hori *et al.*, 2003; Clarke and Lapata, 2008), or syntactical representations (Barzilay and Lee, 2003; Galley and McKeown, 2007; Filippova and Strube, 2008). Filippova (2010) introduces an elegant graph-based approach to multi-sentence compression that simply relies on the words of the sentences and efficient dynamic programming. Her approach implements the observation that the frequency of words influences their appearance in human summaries (Nenkova *et al.*, 2006). Although being an intuitive rule that does work well in practice, frequency-based strategies often remain heuristic.

In this paper we propose a structured learning-based approach to multi-sentence compression. In analogy to Filippova (2010), related sentences are represented by a word graph (the *input*). Words are identified with vertices and directed edges connect adjacent words in at least one sentence, so that the summarising sentence (the *output*) is contained as a path in the graph. Generally, learning mappings between complex structured and interdependent inputs and outputs challenges the standard model of

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1636–1647, Dublin, Ireland, August 23-29 2014.

learning a mapping from independently drawn instances to a small set of labels. To capture the involved dependencies we represent input graphs $\mathcal{G}$ and output paths p jointly by a (possibly rich) feature representation $\Phi(\mathcal{G}, p)$. The goal is to find a linear function $f(\mathcal{G}, p) = \lambda^\top \Phi(\mathcal{G}, p)$ in joint space such that

$$p = \operatorname*{argmin}_{\tilde{p}} f(\mathcal{G}, \tilde{p}) \tag{1}$$

is the desired summary for the collection $\mathcal{G}$. Our approach can therefore be seen as translating the work by Filippova (2010) into the structured prediction framework (Tsochantaridis *et al.*, 2005; Taskar *et al.*, 2004). Instead of applying heuristics, we adapt the decoding machinery to the data by parameterising a shortest path algorithm. The latter admits a representation as a generalised linear model in joint input output space. We devise a structural support vector machine (SVM) (Tsochantaridis *et al.*, 2005) to learn the shortest path in possibly high dimensional joint feature spaces and propose a generalised, loss-augmented decoding algorithm that is solved exactly by an integer linear program in polynomial time. Empirically, we evaluate the structural support vector machine on a real world news headline summarisation task. Our experiments show that a very rudimentary set of five features already suffices to significantly improve the state-of-the-art in graph-based multi-sentence compression. We observe an increase of 7% in in ROUGE F-measure and 8% in BLEU score, respectively.

The remainder of the paper is organised as follows. Section 2 reviews related work and Section 3 introduces word graphs and shortest paths. Our technical contribution is presented in Section 4. We report on empirical results in Section 5 and Section 6 concludes.

2 Related Work

The goal of automatic text summarisation is to produce a summary of a given text (or text collection) that preserves the most important information (Luhn, 1958; Edmundson, 1969). Summarisation systems usually rely on clues or features that help to identify key elements such as the main topic of a document (Salton *et al.*, 1994). Such features may be extracted from sentences (e.g., the length of a sentence, its position in the text), words (e.g., frequency of a word, relative position in sentence) as well as from style and structure elements (Kupiec *et al.*, 1995; Teufel and Moens, 1997; Marcu, 1997).

A special case of text summarisation is sentence compression; given a sentence, the task is to produce a summary of the input that preserves the most important information and is grammatically correct (Jing, 2000). Sentence compression is thus relevant for many NLP tasks including question answering, machine translation, text simplification, speech synthesis applications and multi-sentence compression (e.g., Lin (2003)).

Multi-sentence compression extends sentence compression to collections of related sentences that are to be summarised in a single output sentence. Traditionally, contributions to multi-sentence compression exploit linguistic properties based on lexical information and syntactic dependencies. Dorr *et al.* (2003) for instance propose a headline generation system based on linguistically-motivated, hand-crafted heuristics. Barzilay and Lee (2003) study sentence compression with dependency trees. The aligned trees are represented by a lattice from which a summary is extracted by an entropy-based criterion over all possible traversals of the lattice. Similarly, Barzilay and McKeown (2005) combine syntactic trees of similar sentences by a multi-sequence alignment candidate selection and summary generation. Wan (2007) deploys a language model in combination with maximum spanning trees to rank candidate aggregations satisfying grammatical constraints. Hori *et al.* (2003) propose a statistical model for automatic speech summarisation without using parallel data or syntactic information. Instead they focus on language models to provide a scoring function and use dynamic programming for searching the compression with the highest score. Clarke and Lapata (2008) cast sentence compression as an optimisation problem. They use linguistically motivated constraints and integer linear programming to infer globally optimal compressions.

Recently, graph-based approaches to multi-sentence compression have been proposed. The underlying idea is that syntax may help to find important content. Thus, instead of using hand-crafted rules, parsers, or language models, a simple and robust graph-based method can be used to generate reasonable summaries. Graph-based multi-sentence compression approaches identify the summary with the

shortest path in word graphs (Filippova, 2010). Shortest paths of unweighted word graphs however do not necessarily lead to satisfying summaries. As a remedy, Filippova (2010) introduces heuristic edge weights based on normalised frequencies of the connected words. Boudin and Morin (2013) propose an additional re-ranking scheme to identify summarisations that contain key phrases. The underlying idea is that particular key phrases give rise to certain topics and thus lead to more informative aggregations.

In this paper, we parameterise the graph-based framework by Filippova (2010) such that the shortest path algorithm is adapted to labeled data at hand. Adapting the dynamic programming to the data renders the use of heuristics unnecessary. Instead, word graphs and compressions are embedded in a (possibly high-dimensional) joint feature space where a generalised linear scoring function learns to separate between compressions of different quality. We develop a generalised, loss-augmented shortest path algorithm that is solved exactly by a (relaxed) integer linear program in polynomial time.

3 Preliminaries

3.1 Word Graphs

In a nutshell, word graphs represent collections of sentences efficiently in a graph by mapping identical words to a single vertex while the graph structure preserves the local neighbourhood of words.

From a collection of related sentences a word graph is constructed as follows: Initially, every sentence is augmented by a preceding start token $\langle S \rangle$ and a terminal end symbol $\langle E \rangle$ so that beginning and end of the sentences are preserved in the final graph. Starting with the empty graph, sentences are added one after another. The first word of the first sentence is the auxiliary $\langle S \rangle$ that is converted into the first vertex $v_{\langle S \rangle}$. The second word of the first sentence also becomes a vertex v and the two vertices are connected with a directed edge $v_{\langle S \rangle} \rightarrow v$. The procedure continues with the third word and so on until the end symbol $\langle E \rangle$ is reached. The other sentences are incorporated analogously. A special case arises if the graph already contains a vertex v that is identical to the word that is just to be added. Instead of adding a redundant vertex, the already existing vertex v is used and, if $v \neq v_{\langle S \rangle}$, connected to the respective predecessor as before. In that case, the vertex v has an in-degree of (at least) two and is used as the predecessor for the next word to be added. The procedure continues until all n sentences are incorporated in the graph.

Note that merging nodes to the same vertex requires an appropriate preprocessing of the sentences. Simple lower- or upper-case representations of words often suffice but more complex preprocessing schemas are also possible such as merging vertices carrying synonyms or words possessing small WordNet distances (Miller, 1995; Fellbaum, 1998). As word graphs are a condensed representation of the input sentences, word graphs are also known as compression graphs. The described construction gives us a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ is the set of unique words in the sentences and $\mathcal{E}$ the set of neighbouring words. An exemplary word graph is shown in Figure 1.

3.2 Shortest Path Algorithms

Given a directed weighted graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, cost)$ where $\mathcal{V}$ is the set of vertices and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ the set of edges. The function $cost : (v, v') \mapsto \Re^+$ assigns positive weights to every edge $(v, v') \in \mathcal{E}$. A path p from a vertex $v_s \in \mathcal{V}$ to a vertex $v_e \in \mathcal{V}$ is a sequence of edges connecting vertices of $\mathcal{G}$. We write $\mathcal{P}(v_s, v_e)$ to denote the set of all possible paths starting in v_s and terminating in v_e. The cost of a path is given by the sum of the weights of the edges on the path.

The *shortest path* from a start vertex $v_s \in \mathcal{V}$ to an end vertex $v_e \in \mathcal{V}$ is defined as the path in G from v_s to v_e with the lowest costs. Introducing auxiliary binary variables $p_{(v,v')}$ indicating whether an edge $(v, v') \in \mathcal{E}$ lies on the path ($p_{v,v'} = 1$) or not ($p_{v,v'} = 0$) the shortest path can be computed by the following optimisation problem

$$p^* = \operatorname*{argmin}_{p} \sum_{(v,v') \in \mathcal{E}} p_{v,v'} \, cost(v, v') \quad \text{s.t.} \quad p \in \mathcal{P}(v_s, v_e). \tag{2}$$

There exist many algorithms for computing shortest paths efficiently (Bellman, 1958; Ford, 1956; Dijkstra, 1959). Usually, these methods are based on dynamic programming or (relaxed) integer program-

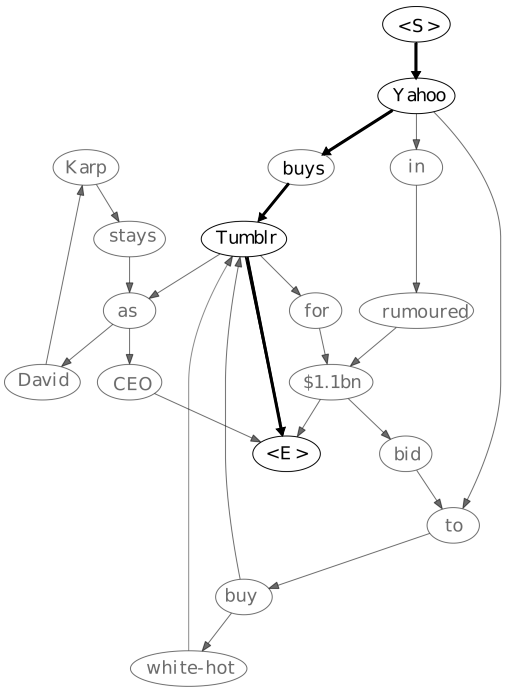

Figure 1: The word graph constructed from the sentences: "Yahoo in rumoured $1.1bn bid to buy white-hot Tumblr", "Yahoo buys Tumblr as David Karp stays as CEO", "Yahoo to buy Tumblr for $1.1bn". The shortest path is highlighted.

ming, where an approximation of the exact quantity is iteratively updated until it converges to the correct solution, which is achieved in polynomial time. A prominent algorithm for computing the k-shortest paths is Yen's algorithm (Yen, 1971). Intuitively, the approach recursively computes the second best solution by considering deviations from the shortest path, the third best solution from the previous two solutions, and so on. Figure 1 visualises the shortest path for the displayed compression graph.

4 Learning to Summarise Related Sentences

4.1 Problem Setting

Given a word graph $\mathcal{G}$, we aim to find a ranking function $f(\mathcal{G}, p)$ that assigns the lowest score to the best summary p^*, that is, $p^* \stackrel{!}{=} \operatorname{argmin}_p f(\mathcal{G}, p)$. Note that f is defined jointly on $\mathcal{G}$ and p to allow for exploiting dependencies between word graph and summary. Our approach can thus be seen as an instance of structured prediction models. The quality of f is measured by the Hamming loss Δ, $\Delta(p^*, \hat{p}) = \frac{1}{2}\sum_{(v_i,v_j)\in\mathcal{V}}[[p^*_{ij} \neq \hat{p}_{ij}]]$, that details differences between the best summary p^* and the prediction $\hat{p}$, where $[[z]]$ is the indicator function returning one if z is true and zero otherwise. The generalisation error is given by

$$R[f] = \int \Delta\left(p, \operatorname*{argmin}_{\tilde{p}} f(\mathcal{G}, \tilde{p})\right) dP(\mathcal{G}, p)$$

and approximated by its empirical counterpart

$$\hat{R}[f] = \sum_{i=1}^{m} \Delta\left(p_i, \operatorname*{argmin}_{\tilde{p}} f(\mathcal{G}_i, \tilde{p})\right) \tag{3}$$

on a finite m-sample of pairs $\{(\mathcal{G}_i, p_i)\}_{i=1}^m$ where $\mathcal{G}_i$ is a word graph and p_i the best summarising sentence. However, minimising the empirical risk directly leads to an ill-posed optimisation problem as

there generally exist many indistinguishable but equally well solutions realising an empirical loss of zero. We thus focus on the minimisation of the regularised empirical risk

$$\hat{R}_{reg}[f] = \Omega(f) + \sum_{i=1}^{m} \Delta\left(p_i, \operatorname*{argmin}_{\tilde{p}} f(\mathcal{G}_i, \tilde{p})\right).$$

The additive regularisation $\Omega(f)$ acts like a prior on f, e.g. to enforce smooth solutions. In the remainder we use $\Omega(f) = \|f\|^2$.

4.2 Representation

The idea of our approach is as follows: We adapt the cost function of the graph to the training sample such that the shortest path of the compression graph is identical to the desired summary. Recall the general form of the cost function of Section 3.2. Instead of a constant or hand-crafted function (Filippova, 2010), we deploy a linear mixture of features ϕ_i, parameterised by λ,

$$cost(v, v') = \sum\nolimits_i \lambda_i \phi_i(v, v') = \lambda^\top \phi(v, v').$$

Features $\phi_i(v, v')$ are drawn from adjacent vertices v, v' in the word graph to capture local dependencies of the connecting edge. Examples for feature functions are frequency-based counts or indicators such as POS-transitions of the form $\phi_{234}(v, v') = [[v \text{ is a noun} \wedge v' \text{ is a verb}]]$. Note that complex features using the context of the edge are straight forward by extending the feature representation to the input graph $\phi(v, v', \mathcal{G})$. The final feature vector is obtained by stacking-up all feature functions, that is, $\phi(v, v') = (\ldots, \phi_i(v, v'), \ldots)^\top$.

Using the parameterised costs in the computation of the shortest path in Equation (2) yields the following objective function (ignoring the constraints for a moment) that can be rewritten as a generalised linear model in joint input output space

$$\sum_{(v_i,v_j)\in\mathcal{V}} p_{ij}\, \lambda^\top \phi(v_i, v_j) = \lambda^\top \underbrace{\left(\sum_{(v_i,v_j)\in\mathcal{V}} p_{ij} \phi(v_i, v_j)\right)}_{\equiv \Phi(\mathcal{G}, p)} = \lambda^\top \Phi(\mathcal{G}, p) = f(\mathcal{G}, p)$$

where the joint feature representation is given by

$$\Phi(\mathcal{G}, p) \equiv \left(\sum_{(v_i,v_j)\in\mathcal{V}} p_{ij} \phi(v_i, v_j)\right).$$

Decoding the shortest path $\hat{p}$ for a fixed parameter vector λ can now be computed by

$$\hat{p} = \operatorname*{argmin}_{p} f(\mathcal{G}, p) \quad s.t.\ p \in \mathcal{P}(\langle S\rangle, \langle E\rangle)$$

using standard shortest path algorithms (Yen, 1971). In addition, reformulating the objective as a generalised linear model allows to adapt the parameters λ to the data to identify shortest paths with summaries.

4.3 Optimisation

Recall that the goal of the optimisation is to find the ranking function $f(\mathcal{G}, p)$ that takes the smallest value for the best summary. That is, for the i-th training instance $(\mathcal{G}_i, p_i)$, we aim at fulfilling the constraints

$$\lambda^\top \Phi(\mathcal{G}_i, p) - \lambda^\top \Phi(\mathcal{G}_i, p_i) > 0 \tag{4}$$

for all $p \in \mathcal{P}(\langle S\rangle, \langle E\rangle) \backslash p_i$. We extend the constraints in Equation (4) by a term that induces a margin between the best path p_i and all alternative paths. A common technique is called margin-rescaling and implies to scale the margin with the actual loss that is induced by decoding $\tilde{p}$ instead of p_i. Thus,

rescaling the margin by the loss implements the intuition that the confidence of rejecting a mistaken output is proportional to its error. In the context of learning shortest paths, margin-rescaling gives us the following constraints

$$\lambda^\top \Phi(\mathcal{G}_i, \tilde{p}) - \lambda^\top \Phi(\mathcal{G}_i, p_i) > \Delta(p_i, \tilde{p}) - \xi_i$$

for all $p \in \mathcal{P}(\langle S \rangle, \langle E \rangle) \backslash p_i$. The non-negative $\xi_i \geq 0$ is a slack-variable that allows point-wise relaxations of the margin. Solving the equation for ξ_i shows that margin rescaling also effects the hinge loss that now augments the structural loss Δ,

$$\ell_\Delta(\mathcal{G}_i, p_i, f) = \max \left[\min_{\tilde{p}} \left[\Delta(p_i, \tilde{p}) - f(\mathcal{G}_i, \tilde{p}) + f(\mathcal{G}_i, p_i) \right] \right].$$

The effective hinge loss upper bounds the structural loss Δ for every pair $(\mathcal{G}_i, p_i)$ and trivially also

$$\sum_{i=1}^{m} \ell_\Delta(\mathcal{G}_i, p_i, f) \geq \sum_{i=1}^{m} \Delta(p_i, \operatorname*{argmin}_{\tilde{p}} f(\mathcal{G}_i, \tilde{p}))$$

holds. A max-margin approach to learning shortest paths therefore leads to the following optimisation problem that is also known as structural support vector machine (Tsochantaridis *et al.*, 2005)

$$\min_{\lambda, \xi \geq 0} \ \|\lambda\|^2 + C \sum_{i=1}^{m} \xi_i \quad s.t. \quad \forall i \, \forall \tilde{p} \in P \backslash p_i : \ f(\tilde{p}) - f(p_i) > \Delta(p_i, \tilde{p}) - \xi_i. \tag{5}$$

The parameter C trades-off margin maximisation and error minimisation and needs to be adjusted by the user. The above optimisation problem can be solved efficiently by cutting plane methods. The idea behind cutting planes is to instantiate only a minimal subset of the exponentially many constraints. That is, for the i-th training example, we decode the shortest path $\hat{p}$ given our current model and consider two cases: (i) For $\hat{p} \neq p_i$ the prediction is erroneous and $\hat{p}$ is called the most strongly violated constraint as it realises the smallest function value and $f(\mathcal{G}_i, \hat{p}) < f(\mathcal{G}_i, p)$ holds for all $p \neq \hat{p}$. Consequentially, the respective constraint of the above optimisation problem is instantiated and influences the subsequent iterations. (ii) If instead the prediction is correct, that is $\hat{p} = p_i$, we need to verify that the runner-up $\hat{p}^{(2)}$ fulfils the margin constraint. If so, we proceed with the next training example, otherwise we instantiate the corresponding constraint, analogously to case (i). Luckily, we do not need to rely on an expensive two-best shortest path algorithm but can compute the most strongly violated constraint directly via the cost function

$$Q(\tilde{p}) = \Delta(p_i, \tilde{p}) - \lambda^\top \Phi(\mathcal{G}_i, \tilde{p}) + \lambda^\top \Phi(\mathcal{G}_i, p_i) \tag{6}$$

that has to be maximised wrt $\tilde{p}$. The following proposition shows that we can equivalently solve a shortest path problem for finding the maximiser of Q.

Proposition 1. *The argmax $\tilde{p}$ of Q in Equation* (6) *can be computed by minimising a shortest path problem with cost function $cost(v_i, v_j) = p_{ij} + \lambda^\top \phi(v_i, v_j)$.*

Proof. We treat the ground truth paths p as graphs and write $\mathcal{V}(p)$ for the set of nodes on the path and $\mathcal{E}(p)$ to denote the set of edges that lie on the path. If, for instance, an element of the binary adjacency matrix representing path p equals one, e.g., $p_{ij} = 1$, we write $p_i, p_j \in \mathcal{V}(p)$ and $(p_i, p_j) \in \mathcal{E}(p)$. First, note that the Hamming loss can be rewritten as

$$\Delta(p, \tilde{p}) = \sum_{(p_i, p_j) \in \mathcal{E}(p)} (1 - p_{ij} \tilde{p}_{ij}) \, .$$

We have

$$\begin{aligned}
\hat{p} &= \operatorname*{argmax}_{\tilde{p}} \Delta(p,\tilde{p}) + \lambda^\top \Phi(\mathcal{G}_i, p) - \lambda^\top \Phi(\mathcal{G}_i, \tilde{p}) \\
&= \operatorname*{argmax}_{\tilde{p}} \Delta(p,\tilde{p}) - \lambda^\top \Phi(\mathcal{G}_i, \tilde{p}) \\
&= \operatorname*{argmax}_{\tilde{p}} \sum_{(p_i,p_j)\in\mathcal{E}(p)} (1 - p_{ij}\tilde{p}_{ij}) - \lambda^\top \Phi(\mathcal{G}_i, \tilde{p}) \\
&= \operatorname*{argmax}_{\tilde{p}} -\sum_{(p_i,p_j)\in\mathcal{E}(p)} p_{ij}\tilde{p}_{ij} - \lambda^\top \Phi(\mathcal{G}_i, \tilde{p}) \\
&= \operatorname*{argmin}_{\tilde{p}} \sum_{(p_i,p_j)\in\mathcal{E}(p)} p_{ij}\tilde{p}_{ij} + \lambda^\top \Phi(\mathcal{G}_i, \tilde{p}) \\
&= \operatorname*{argmin}_{\tilde{p}} \sum_{(p_i,p_j)\in\mathcal{E}(p)} p_{ij}\tilde{p}_{ij} + \lambda^\top \Big[\sum_{(x_i,x_j)\in E(\mathcal{G})} \tilde{p}_{ij}\phi(v_i,v_j)\Big] \\
&= \operatorname*{argmin}_{\tilde{p}} \sum_{(v_i,v_j)\in\mathcal{E}(\mathcal{G})} p_{ij}\tilde{p}_{ij} + \lambda^\top \Big[\sum_{(x_i,x_j)\in E(\mathcal{G})} \tilde{p}_{ij}\phi(v_i,v_j)\Big] \\
&= \operatorname*{argmin}_{\tilde{p}} \sum_{(v_i,v_j)\in\mathcal{E}(\mathcal{G})} \Big[p_{ij} + \lambda^\top \phi(v_i,v_j)\Big]\tilde{p}_{ij}
\end{aligned}$$

The output $\hat{p}$ is the shortest path with costs given by $p_{ij} + \lambda^\top \phi(v_i, v_j)$. □

Using this result, the following lemma shows that we can compute the most strongly violated constraint directly by a linear program.

Lemma 1. *The maximizer $\tilde{p}$ of function Q in Equation* (6) *and thus the shortest path of Proposition 1 can be computed in polynomial time by the following linear program*

$$\min_{\tilde{p}} \sum_{ij} \Big(p_{ij} + \lambda^\top \phi(v_i,v_j)\Big)\,\tilde{p}_{ij}$$

subject to the constraints

$$\begin{aligned}
\forall k \in \mathcal{V}(\mathcal{G})\backslash\{\langle S\rangle, \langle E\rangle\}: \ \sum_j \tilde{p}_{kj} - \sum_i \tilde{p}_{ik} \le 0 \ \wedge \ -\sum_j \tilde{p}_{kj} + \sum_i \tilde{p}_{ik} \le 0 \\
\sum_j \tilde{p}_{\langle S\rangle,j} - \sum_i \tilde{p}_{i,\langle S\rangle} \le 1 \ \wedge \ -\sum_j \tilde{p}_{\langle S\rangle,j} + \sum_i \tilde{p}_{i,\langle S\rangle} \le -1 \\
\sum_i \tilde{p}_{i,\langle E\rangle} - \sum_j \tilde{p}_{\langle E\rangle,j} \le 1 \ \wedge \ -\sum_i \tilde{p}_{i,\langle E\rangle} + \sum_j \tilde{p}_{\langle E\rangle,j} \le -1 \\
\forall (i,j): \ \tilde{p}_{ij} \le \mathcal{G}_{(i,j)} \ \wedge \ \forall (i,j): \ \tilde{p}_{ij} \in \{0,1\}.
\end{aligned}$$

Proof. For lack of space, we only motivate the constraints. The first line of constraints guarantees that every inner node of the path has exactly as many incoming as outgoing edges, the second line forces the path to start in $v_{\langle S\rangle}$ and, analogously, the third line ensures that it terminates in $v_{\langle E\rangle}$. The last line of constraints requires the edges of the path $\tilde{p}$ to adhere to existing paths of $\mathcal{G}$. □

4.4 Parallelisation

Using the result by Zinkevich *et al.* (2011) the proposed approach can easily be distributed on several machines. Note that cutting planes treat one input $(\mathcal{G}, p)$ at a time. Thus, several models can be trained independently in parallel on disjoint subsets of the data. A subsequent merging process aggregates the models where each models impact is proportional to the amount of data it has been trained on. Note that the described parallelisation can easily be realised by the MapReduce/Hadoop framework. Processing training instances and updating local models is performed by (one or more) mappers while the merge operation is carried out by a reduce task.

5 Empirical Results

5.1 Data Preparation

We crawl RSS feeds of 6 major news sites and harvest news headlines of a predefined set of categories including sports, technology, and business. The headlines are processed automatically by a spectral clustering. The data is thus transformed into a fully connected graph where vertices correspond to headlines and edges are weighted by the number of shared non-stopwords. The clustering is performed for each category on a daily basis. Resulting clusters are headlines that belong (with high probability) to the same event and form our related input sentences. Groups with less than five sentences are discarded.

To identify the best summaries, we conduct a crowd sourcing experiment on Crowdflower[1]. Every annotator is given a group of related sentences together with 10 possible summaries generated by a 10-best Yen's algorithm (Yen, 1971). The task of the annotator is to pick the best summary or mark the collection as inappropriate. Each collection is labeled by at least 10 annotators. The group is discarded if the majority of the annotators mark the group as inappropriate. Otherwise, the three most frequent summaries are extracted, ties are broken by the authors. The most frequent summary is used as the ground-truth annotation in the learning phase, the other two are used additionally in the evaluation. The described process leaves us with 1024 sentences that are divided into 164 annotated groups of related sentences. Table 1 shows an exemplary collection of related sentences (left) and a selection of summaries together with the number of votes from the annotators. The overall distribution of votes is displayed in Figure 2. The figure shows the mean value per rank of all 164 normalised and sorted histograms. The best summary receives on average 8% more votes than the runner-up (not shown).

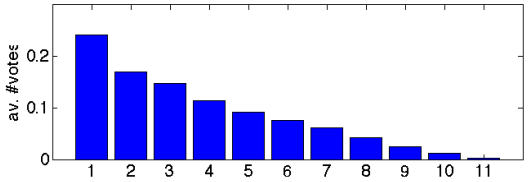

Figure 2: Distribution of annotations.

5.2 Baselines and Features

We compare our learning approach to graph-based sentence compression techniques proposed by Filippova (2010), Boudin and Morin (2013). The two baselines construct word graphs as presented in Section 3.1 and output the weighted shortest path. Filippova (2010) uses a frequency-based heuristic for edges weights and Boudin and Morin incorporate a keyphrase detection framework to re-rank summaries according to the number and importance of keyphrases found. In addition, we also include an unweighted shortest path strategy which is a straight forward application of Yen's algorithm (Yen, 1971) and trivially returns the shortest path in terms of the number of edges. Additional straw men are a random (Random) input sentence and the shortest input sentence (Shortest).

In our learning-based approach, every edge between vertices v and v' is associated with a feature vector. Let $w = \#(v)$ the frequency of word v, w' the analogue for v', $e = \#(v, v')$ the frequency of the edge, and $n = |\mathcal{V}|$ the number of vertices in the graph. The feature vector $\phi(v, v')$ of

the edge $v \rightarrow v'$ consists of the normalised joint frequency $\phi_1(w, w') = \frac{e}{n}$, the maximal word frequency $\phi_2(w, w') = \max\left\{\frac{w}{n}, \frac{w'}{n}\right\}$, the lexical relevance $\phi_3(w, w') = \frac{2}{n}\frac{w \cdot w'}{w + w'}$, the normalised PMI $\phi_4(w, w') = (\log \frac{e}{w \cdot w'})/ - \log \frac{e}{n}$ (Bouma, 2009), and ϕ_5 captures the average location of the phrase in the input sentences (Turney, 2000),

$$\phi_5(w, \tilde{w}) = \begin{cases} 1.0 & : & [0-10]\% \\ 0.4 & : & [10-30]\% \\ 0.8 & : & [30-60]\% \\ 0.6 & : & [60-80]\% \\ 1.0 & : & [80-100]\%. \end{cases}$$

Note that $\phi_i \in [0, 1]$ holds for $1 \leq i \leq 5$. Also note that ϕ denotes a rudimentary set of features. Elaborate representations could for instance also contain POS-tags or named entities.

5.3 Experimental Setup and Results

For the news headline experiment, we draw $m \in \{22, 35, 48, 61, 74, 87, 100\}$ training instances without replacement at random from the collected data. The remaining instances are split randomly into equally sized holdout and test sets. We perform model selection for adjusting the trade-off parameter of the support vector machine on the interval $C \in [2^{-10}, 2^{12}]$. We report average ROUGE F-measures (Lin, 2004) and BLEU scores (Papineni *et al.*, 2012) over 10 repetitions with distinct training, holdout, and test sets. In each repetition, all algorithms are trained and/or evaluated on identical data splits.

ROUGE measures the concordance of system and human generated summaries by determining n-gram, word sequence, and word pair matches. We use unigrams (R1), bigrams (R2), and the weighted longest common subsequence (RW1.2) to evaluate compressions. Note that R1 has been found to correlate well with human evaluations based on various statistical metrics (Lin and Hovy, 2003). Moreover, R1 and R2 emulate human pyramid and responsiveness scores (Owczarzak *et al.*, 2012).

Table 2 shows the resulting ROUGE scores for the news headline experiment. Significant results are marked in bold face according to a paired t-test using a significance level of 5%. For small training sets, the structural support vector machine performs only slightly better than the unweighted application of Yen's algorithm and is clearly outperformed by the unsupervised baselines. However, the SVM improves

continuously with increasing training set sizes and outperforms the baselines significantly for more than 50 training examples. The unsupervised baselines cannot utilise the valuable annotations of the data and remain constant. For 100 training instances, we observe performance improvements of about 5-7% for all three ROUGE F-measures.

The BLEU metric computes scores for individual segments, then averages these scores over the whole corpus for a final score. For our experiments we use BLEU-1, BLEU-2 and BLEU-3 to evaluate compressions. Table 3 shows the corresponding results, significant results are again marked in bold face according to a paired t-test with a significance level of 5%. The table draws a similar picture than the previous one. The SVM continuously improves the performance with increasing training set sizes and beats the baselines again at about 50 training examples significantly. For 100 training instances, all three BLEU scores are improved by about 7-8%, respectively.

5.4 Analysis

The Pearson correlation between BLEU scores per instance and the number of vertices is -0.1886. The negative correlation implies that summarising larger word-graphs is more challenging. A negative correlation of -0.1267 is also observed for the lexical diversity of the collection; diverse groups of sentences are thus more difficult to summarise. A possible remedy could be features that are not frequency-based, such as POS-transitions. By contrast, the density of the graph given by $|\mathcal{E}|/|\mathcal{V}|(|\mathcal{V}|-1)$ shows a positive correlation of 0.1851. The more dense a graph, the more edges interconnect vertices and there exist more paths. These paths however frequently pass through the same vertices and as a consequence the lexical diversity is low. A positive correlation of graph density is therefore closely connected to a negative correlation of lexical diversity.

6 Conclusion

We proposed to learn shortest paths in word graphs for multi-sentence compression. A shortest path algorithm is parameterised and adapted to labeled data at hand using the structured prediction framework. Word graphs and summaries are embedded in a joint feature space where a generalised linear scoring function learns to separate between compressions of different quality. Decoding is performed

by a generalised, loss-augmented shortest path algorithm that can be solved by an integer linear program in polynomial time. Empirically, we observe that a very rudimentary set of five features suffices to significantly improve the state-of-the-art in graph-based multi-sentence compression.

Abstract

In this paper we introduce a novel single-document summarization method based on a hidden semi-Markov model. This model can naturally model single-document summarization as the optimization problem of selecting the best sequence from among the sentences in the input document under the given objective function and knapsack constraint. This advantage makes it possible for sentence selection to take the coherence of the summary into account. In addition our model can also incorporate sentence compression into the summarization process. To demonstrate the effectiveness of our method, we conduct an experimental evaluation with a large-scale corpus consisting of 12,748 pairs of a document and its reference. The results show that our method significantly outperforms the competitive baselines in terms of ROUGE evaluation, and the linguistic quality of summaries is also improved. Our method successfully mimicked the reference summaries, about 20 percent of the summaries generated by our method were completely identical to their references. Moreover, we show that large-scale training samples are quite effective for training a summarizer.

1 Introduction

Single-document summarization is attracting much more attention as a key technology in providing better information access in a commercial context. The Financial Times and CNN have been providing summaries of articles in their websites to attract users, and Summly, which has been acquired by Yahoo!, provided the service of automatically summarizing articles on the Internet. Given the cost of manual summarization, we can greatly improve the information access of Internet users by creating an automatic summarizer that can approach the summarization quality of humans.

To mimic manually-written summaries, one important aspect is coherence (Nenkova and McKeown, 2011). Although coherence has been studied widely in a field of multi-document summarization (Karamanis et al., 2004; Barzilay and Lapata, 2005; Nishikawa et al., 2010; Christensen et al., 2013), it has not been studied enough in the context of single-document summarization. In this paper, we revisit the problem of coherence and employ it to produce both informative and linguistically high-quality summaries.

To obtain such summaries, we introduce a novel summarization method based on a hidden semi-Markov model. The method has the properties of both the popular single-document summarization model, the knapsack problem, which packs the sentences into the given length and the hidden Markov model, which takes summary coherence into account by determining sentence context when selecting sentences. By leveraging this, we can build a summarizer that naturally achieves coherence.

We state the novelty and contributions of this paper as follows:

- We regard single-document summarization as a combinatorial optimization problem modeled by a hidden semi-Markov model and propose an efficient decoding algorithm for the problem.
- We introduce various features related to coherence in a combinatorial formulation. We extend a hidden semi-Markov model to achieve discrimination, so our method can take advantage of many features for predicting coherence.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1648–1659, Dublin, Ireland, August 23-29 2014.

- We show that our large-scale corpus greatly improves the performance of summarization.

This paper is organized as follows. In Section 2, we describe related work. In Section 3, we detail our proposed model. We also explain how the parameters in our model are optimized and how sentences are compressed. In Section 4, we explain how variants of the original sentences are generated. In Section 5, we explain the decoding algorithm for our method. In Section 6, we explain the settings of our experiments, our corpus, and compared methods. In Section 7, we show results of the experiments conducted to evaluate our method. In Section 8, we conclude this paper.

2 Related Work

2.1 Single-Document Summarization

Basically, single-document summarization can be done through sentence selection (Nenkova and McKeown, 2011) . The document to be summarized is decomposed into a set of sentences and then the summarizer selects a subset of the sentences as a summary.

McDonald (2007) pointed out that single-document summarization can be formulated as a well-known combinatorial optimization problem, the knapsack problem. Given a set of sentences together with their lengths and values, the summarizer packs them into a summary so that the total value is as large as possible but the total length is less than or equal to a given maximum summary length. Interestingly, a hidden semi-Markov model (Yu, 2010) can be regarded as a natural extension of the knapsack problem, we take advantage of this property for single-document summarization. We elaborate the relation between the knapsack problem and the hidden semi-Markov model in Section 3.

To generate coherent summaries in single-document summarization, there are two types of approaches[1] : tree-based approaches (Marcu, 1997; Daume and Marcu, 2002; Hirao et al., 2013) and sequence-based approaches (Barzilay and Lee, 2004; Shen et al., 2007). The former rely on the tree representation of a document based on the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). Basically, the former approaches (Marcu, 1997; Daume and Marcu, 2002; Hirao et al., 2013) trim the tree representation of a document by making use of nucleus-satellite relations among sentences. The advantage of RST-based approaches is that they can take advantage of global information about the documents. However, a drawback is that they depend heavily on the RST parser that is used. Performance is remarkably sensitive to the accuracy of RST parsing, and hence we have to build a good RST parser. Instead of making use of the global structure of the document, the sequence-based methods rely on and take advantage of the local coherence of sentences. As one advantage over the tree-based approaches, the sequence-based approaches do not require tools as RST parsers, and hence they are more robust. For this reason, this paper focuses on sequence-based approaches.

The previous works most closely related to our method are those proposed by Barzilay and Lee (2004) and Shen et al. (2007). Barzilay and Lee built a hidden Markov model to capture the content structure of documents and used it to identify the important sentences. Shen et al. (2007) extended the HMM-based approach to make it discriminative by making use of conditional random fields (Lafferty et al., 2001). Conditional random fields can incorporate various features to identify the importance of a sentence and they showed its effectiveness. A shortcoming of these approaches is that their model only classifies sentences into two classes, it cannot take account of output length directly. This deficiency is problematic because in practical usage the maximum length of a summary is specified by the user; hence, the summarizer should be able to control output length. In contrast to their method, our approach naturally takes the maximum summary length into account when summarizing a document.

2.2 Coherence

In the context of multi-document summarization, coherence has been studied widely. In multi-document summarization, sentences are selected from different documents, and hence some way of ordering the sentences is required. Sentence ordering (Barzilay et al., 2002; Althaus et al., 2004; Karamanis et al.,

[1]As an interesting related work, Clarke and Lapata (2007) compresses documents by making use of Centering Theory (Grosz et al., 1995). However, in their approach, the desired length of an output summary could not be specified and hence they said their method was compression rather than summarization.

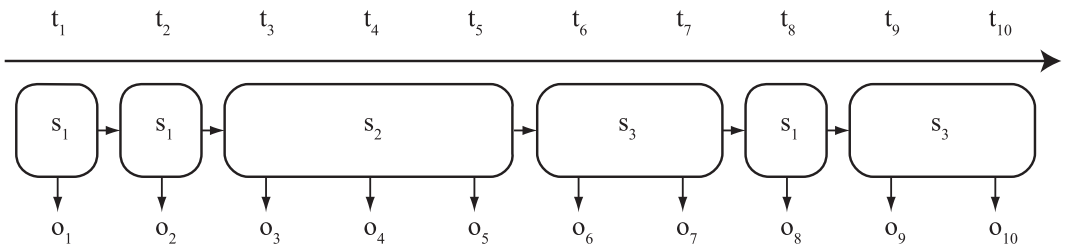

Figure 1: An example of the hidden semi-Markov model. The system observes a sequence consisting of 10 symbols $o_1...o_{10}$ over time $t_1...t_{10}$ and transitions between states $s_1...s_3$. Unlike the basic hidden Markov model, states can persist for a non-unit length. In this figure, state s_2 and state s_3 persist for non-unit lengths. Hence, the system traverses only 6 states despite observing 10 symbols.

2004; Okazaki et al., 2004) is a task to order extracted sentences and is closely related to coherence (Lapata, 2003; Barzilay and Lapata, 2005; Nenkova et al., 2010; Pitler et al., 2010; Louis and Nenkova, 2012). Many effective features have been found out to capture coherence and we utilize these features.

Some work proposed a model that could jointly taking the content of the summary and its coherence into account (Nishikawa et al., 2010; Christensen et al., 2013). Since extracted sentences in multi-document summarization must be ordered, a task that is NP-hard, they relied on integer linear programming (Nishikawa et al., 2010) or a local search strategy (Christensen et al., 2013). The former can locate the optimal solution at a heavy computation cost, while the latter runs quickly but there is no guarantee of locating the optimal solution. In contrast to their trade-off, our proposed algorithm, based on dynamic programming, can locate the optimal solution quickly because the single-document summarization can skip the ordering operation by reproducing the original order of the input sentences.

In this paper, we show that coherence also takes an important role in single-document summarization. We model the coherence between adjacent sentences in the summary by leveraging the hidden semi-Markov model, which can naturally capture the coherence between sentences.

3 Summarization with Hidden Semi-Markov Model

We first introduce the knapsack problem, which can naturally model single-document summarization. Next, we explain the hidden semi-Markov model and show its relationship to the knapsack problem. Then, we elaborate our summarization method.

3.1 Knapsack Problem

The knapsack problem is a type of combinatorial optimization problem (Korte and Vygen, 2008). Given a set of elements, each of which has a score and size, the problem is formulated as the task of finding the best subset in terms of maximizing the sum of their scores under the size limitation. As mentioned above, single-document summarization can be regarded as an instance of the knapsack problem. The best combination of input sentences can be found by calculating the value of each sentence and packing them into a summary through the dynamic programming knapsack algorithm.

3.2 Hidden Semi-Markov Model

The hidden semi-Markov model (HSMM) is an extension of the hidden Markov model (HMM) (Yu, 2010). In the popular hidden Markov model, each state persists for only one unit length. For example, if a system observes 10 discrete symbols, it outputs 10 hidden states. In the HSMM, each state can persist for some unit lengths through the concept of duration. For example, if a system observes 10 discrete symbols and each state persists for two unit lengths, i.e., their duration is 2, the system outputs 5 hidden states. We show an example in Figure 1. The system observes a sequence consisting of 10 symbols $o_1...o_{10}$ over time $t_1...t_{10}$ and transitions between states $s_1...s_3$. Unlike the basic HMM, states can persist for a non-unit length. In this figure, state s_2 and state s_3 persist for a non-unit length. Hence, the system traverses 6 states even though it observes 10 symbols. This property has been utilized for

sequential tagging, such as named entity recognition (Sarawagi and Cohen, 2004), scene text recognition (Weinman et al., 2008) and phonetic recognition (Kim et al., 2011).

The hidden semi-Markov model is closely related to the knapsack problem. The length, K, of the observed symbols can be regarded as a knapsack constraint. We can consider that the system tries to *pack* the states of the model into the observed sequence of symbols by transitioning over the states under the knapsack constraint so as to maximize the likelihood. Therefore, the hidden semi-Markov can naturally be used for single-document summarization. Suppose that the document to be summarized consists of 10 sentences and the length of each of them is measured by the number of words. In this case, the system transitions over 10 states corresponding to the 10 sentences until it cannot select any further sentence due to the given length requirement. Since each state persists for the length of the corresponding sentence, the remaining length decreases every time the system transitions to a new state.

While an HMM is basically a generative model, Collins (2002) extended it to create a discriminative model. An HSMM can also be extended to become discriminative model (Sarawagi and Cohen, 2004). Our discriminative HSMM learns through the application of max-margin training.

3.3 Formulation

We consider there are n input sentences $s_1, s_2, ..., s_n$. These sentences have lengths $\ell_1, \ell_2, ..., \ell_n$ and weights $w_1, w_2, ..., w_n$. We assume that a sentence that has a high weight should be present in the output summary. We also consider each sentence, s_i, has m_i variants $s_{i,1}, s_{i,2}, ..., s_{i,m}$, each produced by some sort of sentence compression or paraphrase module. These variants also have lengths $\ell_{i,1}, \ell_{i,2}, ..., \ell_{i,m_i}$ and weights $w_{i,1}, w_{i,2}, ..., w_{i,m_i}$. For simplicity, we hereinafter note the original sentences $s_1, s_2, ..., s_n$ as $s_{1,0}, s_{2,0}, ..., s_{n,0}$. Hence we have original sentence $s_{i,0}$ and variants $s_{i,1}, s_{i,2}, ..., s_{i,m}$. Let $s_{0,0}$ and $s_{n+1,0}$ be special symbols indicating the beginning of a document and the end of a document, respectively. We define coherence $c_{g,h,i,j}$ as the coherence between sentence $s_{g,h}$ and sentence $s_{i,j}$. An output summary is described as a sequence of input sentences, g. Let G be the entire set of sequences that can be constructed from the input sentences, i.e., $g \in G$. Finally, let K be the maximum length of the summary desired. With these notations, our proposed method can be formulated as the following optimization problem:

$$g^* = \underset{g \in G}{\operatorname{argmax}} \sum_{s_{i,j} \in sent(g)} w_{i,j} + \sum_{(s_{g,h}, s_{i,j}) \in adj(g)} c_{g,h,i,j} \tag{1}$$

$$s.t. \sum_{s_{i,j} \in sent(g)} \ell_{i,j} \leq K, \tag{2}$$

where $sent(g)$ and $adj(g)$ indicate a set of sentences in g and a set of adjacent sentences in g, respectively. That is, our model tries to find the best sequence of sentences under the knapsack constraint so as to maximize the sum of weights and sentence coherence. In contrast to the common knapsack problem which cannot take the variants and sentence coherence into account, our method, based on the hidden semi-Markov model, does so naturally.

3.4 Parameter Optimization

Here we elaborate how parameters in the model are optimized to achieve the desired summaries. The goal is to determine the value of $w_{i,j}$ for all i, j and $c_{g,h,i,j}$ for all g, h, i, j. We define $w_{i,j}$ and $c_{g,h,i,j}$ as follows:

$$w_{i,j} = \mathbf{w}_w \cdot \mathbf{f}_w(s_{i,j}) \tag{3}$$

$$c_{g,h,i,j} = \mathbf{w}_c \cdot \mathbf{f}_c(s_{g,h}, s_{i,j}), \tag{4}$$

where $\mathbf{f}_w$ and $\mathbf{f}_c$ are d_w-dimensional and d_c-dimensional feature vectors for sentences and sentence pairs, respectively, and $\mathbf{w}_w$ and $\mathbf{w}_c$ are d_w-dimensional and d_c-dimensional parameter vectors for sentences and sentence pairs, respectively. The goal of optimization is to determine the values of both vector $\mathbf{w}_w$ and

$\mathbf{w}_c$, given feature function $\mathbf{f}_w$ and $\mathbf{f}_c$. For simplicity, let $\mathbf{s}$ be a summary, let $\mathbf{f} = \langle \mathbf{f}_w, \mathbf{f}_c \rangle$ be a $(d_w + d_c)$-dimensional feature function for the whole summary and let $\mathbf{w} = \langle \mathbf{w}_w, \mathbf{w}_c \rangle$ be a $(d_w + d_c)$-dimensional weight vector. The value that the objective function outputs for summary $\mathbf{s}$ is $\mathbf{w} \cdot \mathbf{f}(\mathbf{s})$.

To optimize the parameter, we employ the Passive-Aggressive algorithm (Crammer, 2006), a widely-used structured learning method. Since the algorithm offers online learning, it can learn the parameter quickly and is easy to implement. To learn the parameter so that the output summary is optimized to the evaluation criteria popular in document summarization research, ROUGE (Lin, 2004), we introduce ROUGE as the loss function. The parameter is estimated by solving the following formula iteratively[2]:

$$\mathbf{w}^{new} = \underset{\mathbf{w}}{\operatorname{argmin}} \frac{1}{2} ||\mathbf{w} - \mathbf{w}^{old}||^2 \tag{5}$$

$$s.t.\ \ \mathbf{w} \cdot \mathbf{f}(\mathbf{r}) - \mathbf{w} \cdot \mathbf{f}(\mathbf{s}) \geq \mathrm{loss}(\mathbf{s}; \mathbf{r}),$$

where $\mathbf{w}^{new}$ is the parameter vector after update, $\mathbf{w}^{old}$ is the parameter vector before update, $\mathbf{r}$ is a reference summary, and loss is the loss function. We define loss as $1 - \mathrm{ROUGE}(\mathbf{s}; \mathbf{r})$. Among the variants of ROUGE, we used ROUGE-1 for the loss function.

3.4.1 Sentence Feature

The features introduced in this section are used to calculate the weights of sentences, $w_{i,j}$.

Term Frequency: Term frequency is a classic feature in document summarization (Luhn, 1958). We calculate the total number of times each content word occurs in the document and then, for each sentence, sum the totals of the content words that appear in the sentence as the value of this feature.
Word: We also use the words and parts-of-speech as features.
Named Entity: Named entities such as a name of person or organization are important. We use named entities and classes as features.
Length: The length of a sentence may indicate the information value of its content. We use the length of a sentence, measured by character number, as a feature.
Position: The position of a sentence is a classically important feature. We use the position of a sentence, the relative position of a sentence, whether the sentence is the first in the document and whether the sentence is the first in a paragraph, the position of the paragraph in which the sentence is, as features.

3.4.2 Coherence Feature

The features introduced in this section are used to calculate sentence coherence, $c_{g,h,i,h}$.

Lexical Transition: Lapata (2003) showed that the structure of the document can be captured by word-pairs consisting of words of two adjacent sentences. We use this feature for capturing the links between two sentences[3]. We build a set of word pairs where one occurs in a precedent sentence and the other occurs in a succeeding one, and use the elements of the set as a feature.
Lexical Cohesion: Pitler et al. (2010) showed that the similarity of two sentences is one of the strongest features for predicting coherence. We reproduce this feature for generating coherent summaries. We calculate cosine similarity between two sentences and use its value as a feature.
Entity Grid: Previous studies showed that Entity Grid (Barzilay and Lapata, 2005) is a strong feature for predicting coherence (Pitler et al., 2010). We also employ this feature for summarization. While the entity vector made from the entity grid was originally defined for whole documents, we build the entity vector for each pair of two sentences because our model is based on the Markovian assumption, and hence the coherence score is defined between two sentences.

[2]As we explain later in Section 5, computation complexity of our algorithm is pseudo-polynomial, and hence the best solution of our model can be located quickly. This is also advantageous in the learning phase because to learn parameters using structured learning, the learner has to generate a summary to calculate the loss. Since our algorithm can quickly find the best solution and generate a summary, it can also contribute to shortening the time required for learning.

[3]It is expected that this feature will also contribute to sentence selection. Barzilay and Elhadad (1997) showed that a closely related word-pair was a good indicator for sentence selection. This feature captures this property by learning.

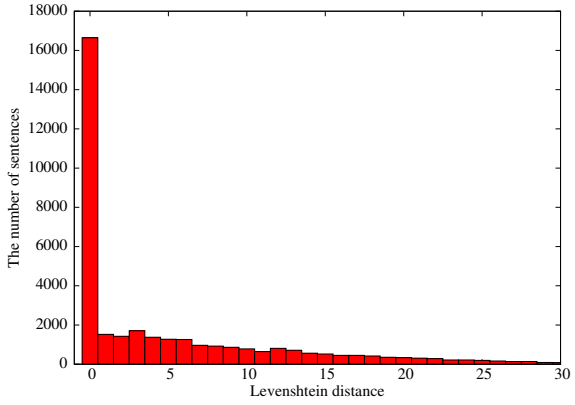

Figure 2: Distribution of Levenshtein distance in the aligned sentences. Among the 36,413 sentences in the references, 16,643 were identical (Levenshtein distance is 0) to the aligned sentences in the input documents.

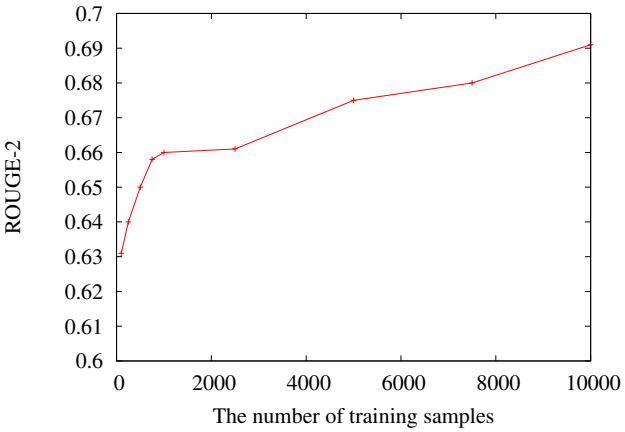

Figure 3: Learning curve of HSMM.

4 Generating Sentence Variants

Since our model can take the variants of an original sentence in the input document as in the multi-candidate reduction framework (Zajic et al., 2007), we incorporate sentence compression.

We generate a few variants of each original sentence by trimming the dependency tree of the sentence; this simple operation is sufficient for reproducing reference summaries. By aligning sentences in a reference summary with those in the corresponding input document[4], we found that human summaries were quite conservative. Among the 36,413 sentences in the references, 16,643 were identical to the aligned sentences in the input documents. Furthermore, most remaining sentences were virtually identical to the original sentences; revisions were minor, and can be reproduced by simple operations. Few sentences exhibited paraphrasing or more sophisticated operations. We plot the distribution of Levenshtein distance in the aligned sentences in Figure 2. According to this observation, we produce the following types of variants by sentence compression:

1. Removing information in parentheses. Some sentences contain parentheses containing additional information for readers. The first type of variant deletes text in parentheses.

2. Shortening sentences by trimming their dependency trees. Basically this method follows the sentence trimmer proposed by Nomoto (2008). While using his method, we keep the predicate and its obligatory arguments in the sentences to keep the sentences grammatical. If a predicate is trimmed, its obligatory arguments are also trimmed and vice versa. Since there are an exponential number of subtrees in one tree, we use only n-best subtrees by ranking them according to n-gram language likelihood and dependency-based language likelihood. We used the dependency parser proposed by Imamura et al (Imamura et al., 2007) to acquire the dependency tree.

5 Decoding with Dynamic Programming

To solve Equation 1 under the constraints of Equation 2, we use dynamic programming. Algorithm 1 shows the pseudo code of the decoding algorithm. Line 1 to Line 7 initializes the variables used in the algorithm. Vector $\mathbf{x} = \langle x_0, ..., x_{n+1} \rangle$ stores which sentence and which variants are included in the output summary. If $x_3 = 2$, $s_{3,2}$ is included in the summary. V, P and S are two-dimensional arrays, each of which is used as a dynamic programming table. They store the process of dynamic programming.

[4]Alignment proceeds in two steps: first, we calculate the Levenshtein distance between sentences in the document and its reference, and then we align sentences so as to minimize the distance between them.

Algorithm 1 Decoding Algorithm: Filling Table

1: $\mathbf{x} = \langle x_0, ..., x_{n+1} \rangle$
2: **for** $i = 0$ to $n + 1$ **do**
3: $x_i = -1$
4: $V[0][i] \leftarrow -1$
5: $P[0][i] \leftarrow -1$
6: $S[0][i] \leftarrow 0$
7: $V[0][0] = 0$
8: **for** $k = 1$ to K **do**
9: **for** $i = 1$ to n **do**
10: $V[k][i] \leftarrow V[k-1][i]$
11: $P[k][i] \leftarrow P[k-1][i]$
12: $S[k][i] \leftarrow S[k-1][i]$
13: **for** $v = 0$ to m_i **do**
14: **if** $\ell_{i,v} \leq k$ **then**
15: **for** $h = 0$ to $i - 1$ **do**
16: $u = V[k - \ell_{i,v}][h]$
17: **if** $u \neq -1 \wedge S[k - \ell_{i,v}][h] + w_{i,v} + c_{h,u,i,v} \geq S[k][i]$ **then**
18: $V[k][i] \leftarrow v$
19: $P[k][i] \leftarrow h$
20: $S[k][i] \leftarrow S[k - \ell_{i,v}][h] + w_{i,v} + c_{h,u,i,v}$
21: $V[K+1][n+1] \leftarrow 0$
22: $P[K+1][n+1] \leftarrow 0$
23: $S[K+1][n+1] \leftarrow 0$
24: **for** $h = 1$ to n **do**
25: $u = V[K][h]$
26: **if** $S[K][h] + c_{h,u,n+1,0} \geq S[K+1][n+1]$ **then**
27: $P[K+1][n+1] \leftarrow h$
28: $S[K+1][n+1] \leftarrow S[K][h] + c_{h,u,n+1,0}$

	Document	Reference
Avg. # of characters	476.2	142.0
Avg. # of words	298.6	88.3
Avg. # of sentences	9.7	2.9

Table 1: The statistics of our corpus.

$V[k][i]$ stores which variants are used at time k, i. If $V[k][i] = 0$, original sentence $s_{i,0}$ is selected at time k, i. If $V[k][i] = -1$, no sentence is selected at time k, i. $P[k][i]$ stores a pointer to the sentence connected to the front of the current sentence. $S[k][i]$ stores the value of the objective function at time k, i. Line 8 to Line 36 locates the best sequence of sentences based on the following recurrence formula:

$$S[k][i] = \begin{cases} \max_{h=0...i-1, v=0...m} S[k - \ell_{i,v}][h] + w_{i,v} + c_{h,V[k-\ell_{i,v}][h],i,v} & \text{(A)} \\ S[k-1][i] & \text{(B)}, \end{cases} \quad (6)$$

where case A is: $\ell_{i,v} \leq k \ \wedge S[k-1][i] \leq S[k - \ell_{i,v}][h] + w_{i,v} + c_{h,V[k-\ell_{i,v}][h],i,v}$ and case B is: $otherwise$. This recurrence formula means that at time k, i the best variant to be selected as can be determined at time $k - \ell_{i,v}, h$. Hence, for all $k \in 1...K$ and $i \in 1...n$, the algorithm finds the best sequence of sentences at time k, i. After Algorithm 1 locates the best sequence of sentences by filling the tables, the best sequence can be restored by backtracing along the pointers stored in P. Finally, the algorithm outputs $\mathbf{x}$, which stores which sentences and variants are used in the best sequence. Since this algorithm is based on a dynamic programming knapsack algorithm (Korte and Vygen, 2008), it runs in pseudo-polynomial time. This is a significant advantage over the methods that rely on integer linear programming solvers due to their substantial computation cost.

6 Experiments

6.1 Data

We prepared 12,748 pairs of Japanese newspaper articles and their manually-written reference summaries. This is one of the largest corpus available for single-document summarization research. The length of all references is within 150 characters. All references in the corpus were written by a specialist staff in a Japanese newspaper company and the company sold these summaries for commercial purposes.

We list the statistics of our corpus in Table 1. As shown, the task is to summarize the document in about a third of its original length in terms of the number of words.

6.2 Evaluation Criteria

ROUGE; ROUGE is an automatic evaluation method for automatic summarization proposed by Lin (2004). We used ROUGE-1 and ROUGE-2 to evaluate the summaries. Since our document-reference pairs are written in Japanese, we segmented the sentences into words using the Japanese morphological analyzer developed by Fuchi and Takagi (1998). When calculating the ROUGE score, we used only content words (i.e. nouns, verbs and adjectives) and so excluded function words as stop words.
Linguistic Quality: To evaluate the linguistic quality of the summaries generated by our method, we performed a manual evaluation according to quality questions proposed by the National Institute of Standards and Technology (NIST) (2007)[5]. We randomly sampled 100 summaries from the outputs of each method described below and asked 7 subjects to evaluate the summaries according to the questions. All subjects were Japanese native and none were among the authors. Since the quality questions by NIST (2007) were designed for multi-document summarization, we used 3 of the 5 NIST questions for single-document summarization: grammaticality, referential clarity, and structure/coherence. We also asked the subjects to evaluate overall summary quality.

6.3 Compared Methods

We compared the following 8 methods.

Random: Random method selects sentences in the input document randomly.
Lead: Lead method is a classic baseline in single-document summarization. It only extracts the words from the beginning of the document until the extracted words reach the given length. We simply extracted 150 characters from the beginning of each document.
Knapsack: The knapsack problem can be used as a single-document summarization model (McDonald, 2007). In this baseline, the weight of each sentence was calculated based on the average probabilities of the words in the sentence (Nenkova and Vanderwende, 2005). Then, a summary was generated by solving the knapsack problem.
Knapsack with Supervision: Instead of the average word probabilities used in the above baseline, we used only sentence features $\mathbf{f}_w$ to weigh a sentence.
Conditional Random Fields: Conditional random fields can be used to weigh sentences (Shen et al., 2007). Since CRFs required binary labels in learning, we aligned sentences in an input document with the sentences in its reference as explained in Section 4. We used the probabilities of sentences from CRFs as the weights of the knapsack problem.
Hidden Semi-Markov Model: This is our proposed method without variants of the original sentences. It selected sentences only from the set of original sentences.
Hidden Semi-Markov Model with Compression: This is our proposed method with variants of the original sentences. It selected from among the variants and the original ones.
Human: In the linguistic quality evaluation, we added references to the summaries generated by the above methods to show the upper bound.

When learning, we did 10-fold cross validation. In the experiments, statistical significance was checked by Wilcoxon signed-rank test (Wilcoxon, 1945). To counteract the problem of multiple comparisons, we used the Holm-Bonferroni method (Holm, 1979) to adjust the significance level, α.

7 Results and Discussion

We show the results of our experiment in Table 2 and Table 3. In this section, first we discuss the results of the ROUGE evaluation, and then we discuss the results of the linguistic quality evaluation.

In the ROUGE evaluation, all the compared methods except for RANDOM showed good performance. This is because, as shown in Section 4, many references consisted of sentences identical to the original

[5]Some recent studies have tried to predict the readability of the text automatically (Pitler et al., 2010).

Method	R-1	R-2	Idt.
RANDOM	0.417	0.291	1.2%
LEAD	$0.779^{\mathrm{C,S,U,R}}$	$0.727^{\mathrm{C,S,U,R}}$	4.4%
KP	0.704^{R}	0.611^{R}	9.3%
KP(S)	$0.729^{\mathrm{U,R}}$	$0.647^{\mathrm{U,R}}$	10.4%
CRFs	$0.741^{\mathrm{U,R}}$	$0.675^{\mathrm{S,U,R}}$	11.3%
HSMM	$0.769^{\mathrm{C,S,U,R}}$	$0.703^{\mathrm{C,S,U,R}}$	15.2%
HSMM(C)	$0.785^{\mathrm{C,S,U,R}}$	$0.722^{\mathrm{C,S,U,R}}$	20.4%

Table 2: Results of the ROUGE evaluation. "R-1" and "R-2" correspond to ROUGE-1 and ROUGE-2, respectively. The values in the column of "Idt." are the percentage of summaries completely-identical to the corresponding references. In the table, $^{\mathrm{C,S,U,L,R}}$ indicate statistical significance against CRFs, KP(S), KP, LEAD, RANDOM, respectively.

Method	Gram.	Ref.	S./C.	Overall
LEAD	1.9	3.9	2.5	2.1
KP	4.1^{L}	3.7	3.4	3.5
KP(S)	4.2^{L}	3.6	3.5	3.6^{L}
CRFs	4.1^{L}	3.9	3.7^{L}	3.6^{L}
HSMM	4.3^{L}	4.0	4.1^{L}	4.0^{L}
HSMM(C)	4.0^{L}	3.9	4.0^{L}	3.9^{L}
HUMAN	4.7^{L}	4.5	4.7^{L}	4.8^{L}

Table 3: Results of the linguistic quality evaluation. The values ranged from 1 (very poor) to 5 (very good) (National Institute of Standards and Technology, 2007). We show statistical significance with the same notations as Table 2.

ones, and hence the references can be reproduced if important sentences are identified. Since the compression rate in our corpus was relatively light, it made important information easy to identify. Among the compared methods, both LEAD and our proposed method, HSMM(C), achieved the best result. There was no significant difference between LEAD and HSMM(C). This surprising performance of LEAD was due to the ROUGE evaluation. The words in the document leads were likely to be important, and LEAD drew on this property. However, as we mentioned later, it sacrificed the linguistic quality to achieve the high ROUGE score. Furthermore, it failed to yield summaries identical to the reference. In contrast to LEAD, almost 20% of the summaries generated by HSMM(C) were identical to the references. This shows that our method successfully mimicked human assessments. HSMM followed the best models. There was a statistically significant difference between HSMM(C) and HSMM. Since some sentences, especially the first sentence in the document, were long and the first sentence was particularly important to summarize the document, sentence compression yielded a significant improvement. As shown in Table 2, employing compression greatly improved the percentage of identical summaries. HSMM significantly outperformed all of the baseline extractive methods except LEAD. While CRFs can take advantage of all features used in HSMM, CRFs cannot take the evaluation measure such as ROUGE and the knapsack constraint into account in learning. HSMM also significantly outperformed KP(S). This difference is particularly important, and shows the usefulness of features related to coherence. While KP(S) used only features about sentences, HSMM successfully mimicked the references as it drew on the features related to coherence.

We show the learning curve of HSMM in Figure 3. We fixed 2,748 pairs for testing, and learned parameters from 100, 250, 500, 1,000, 2,500, 5,000, 7,500 and 10,000 pairs. The curve in the figure clearly shows the effectiveness of our large-scale corpus in learning. It seems that the curve does not saturate and hence HSMM performance can be improved by more training samples. As in the results recently shown by Filippova (2013), this result implies that large-scale data is important in the field of document summarization as in other fields of computational linguistics. Past studies in document summarization relied on relatively small datasets consisting of a few dozen or at most a few hundred pairs of a document and its reference in learning. In contrast to the past studies, there are over 10,000 pairs in our dataset and the results show its effectiveness.

Second, we discuss the result of the linguistic quality evaluation. Unlike the ROUGE evaluation, HSMM achieved the best result. As previous studies have pointed out (Nenkova and McKeown, 2011), sentence compression commonly tends to degrade the linguistic quality of a summary while improving its content. As shown in Table 3, the grammaticality of HSMM(C) is lower than that of HSMM, but the

difference is not significant. Although we could not observe any significant difference between HSMM and other extractive baselines, our proposals, HSMM and HSMM(C), yielded the best result in terms of structure/coherence. By making use of the features related to coherence, we successfully improved summary quality. In contrast to the surprising performance of LEAD in the ROUGE evaluation, in the linguistic quality evaluation, LEAD yielded the worst performance. Since LEAD had to cut the sentences when it reached the given length, it create ungrammatical fragments.

Finally, we touch on the balance between the quality of content and linguistic quality. Comparing Table 2 to 3, we can see the correlation between the quality of content and linguistic quality. This result is reasonable because we can extract much more information from grammatical and well-organized sentences. Although we optimized the parameter to maximize the ROUGE score, it also yielded improvements in linguistic quality. This is because the manually-generated reference summaries are basically grammatical and well-organized and the parameter is learnt to mimic them. However, there is an inherent trade-off between the quality of content and linguistic quality. For example, under stricter length limitations, instead of cohesive devices such as conjunctions, which can improve the coherence of sentences, content words would be preferred for summary inclusion to augment information. Balancing them to maximize reader satisfaction is an interesting problem.

8 Conclusions

In this paper we presented a novel single-document summarization method based on the hidden semi-Markov model, which is a natural extension of the knapsack problem. Our model naturally takes account of sentence context when identifying important sentences. This property is particularly important to ensure the coherence of output summaries and to produce informative and linguistically high-quality summaries. We also proposed an algorithm based on dynamic programming so the best solution can be located quickly. Experiments on a very large-scale single-document summarization corpus showed that our proposed method significantly outperforms competitive baselines.

As future work, we plan to tackle on the summarization task where higher compression is demanded. To generate shorter summaries, we plan to employ more sophisticated approaches, such as paraphrasing.

Acknowledgement

The corpus used in this paper is owned by The Mainichi Newspapers Co., Ltd. and is leased to Nippon Telegraph and Telephone Corporation. We sincerely appreciate their consideration. We also appreciate the insightful comments from reviewers. Their comments greatly improved the quality of this paper.

Abstract

We present a submodular function-based framework for query-focused opinion summarization. Within our framework, relevance ordering produced by a statistical ranker, and information coverage with respect to topic distribution and diverse viewpoints are both encoded as submodular functions. Dispersion functions are utilized to minimize the redundancy. We are the first to evaluate different metrics of text similarity for submodularity-based summarization methods. By experimenting on community QA and blog summarization, we show that our system outperforms state-of-the-art approaches in both automatic evaluation and human evaluation. A human evaluation task is conducted on Amazon Mechanical Turk with scale, and shows that our systems are able to generate summaries of high overall quality and information diversity.

1 Introduction

Social media forums, such as social networks, blogs, newsgroups, and community question answering (QA), offer avenues for people to express their opinions as well collect other people's thoughts on topics as diverse as health, politics and software (Liu et al., 2008). However, digesting the large amount of information in long threads on newsgroups, or even knowing which threads to pay attention to, can be overwhelming. A text-based summary that highlights the diversity of opinions on a given topic can lighten this information overload. In this work, we design a submodular function-based framework for opinion summarization on community question answering and blog data.

Question: What is the long term effect of piracy on the music and film industry?

Best Answer: Rising costs for movies and music. ... If they sell less, they need to raise the price to make up for what they lost. The other thing will be music and movies with less quality. ...
Other Answers:
Ans1: Its bad... really bad. (Just watch this movie and you will find out ... Piracy causes rappers to appear on your computer).
Ans2: By removing the profitability of music & film companies, piracy takes away their motivation to produce new music & movies. If they can't protect their copyrights, they can't continue to do business. ...
Ans4: *It is forcing them to rework their business model, which is a good thing.* In short, I don't think the music industry in particular will ever enjoy the huge profits of the 90's. ...
Ans6: Please-People in those businesses make millions of dollars as it is!! I don't think piracy hurts them at all!!!

Figure 1: Example discussion on Yahoo! Answers. Besides the best answer, other answers also contain relevant information (in *italics*). For example, the sentence in blue has a contrasting viewpoint compared to the other answers.

Opinion summarization has previously been applied to restricted domains, such as product reviews (Hu and Liu, 2004; Lerman et al., 2009) and news (Stoyanov and Cardie, 2006), where the output summary is either presented in a structured way with respect to each aspect of the product or organized along contrastive viewpoints. Unlike those works, we address user generated online data: community QA and blogs. These forums use a substantially less formal language than news articles, and at the same time address a much broader spectrum of topics than product reviews. As a result, they present new challenges for automatic summarization. For example, Figure 1 illustrates a sample question from Yahoo! Answers[1] along with the answers from different users. The question receives more than one answer, and one of them is selected as the "best answer" by the asker or other participants. In general, answers from other users also provide relevant information. While community QA successfully pools rich knowledge from the wisdom of the crowd, users might need to seine through numerous posts to extract the information

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1660–1669, Dublin, Ireland, August 23-29 2014.

they need. Hence, it would be beneficial to summarize answers automatically and present the summaries to users who ask similar questions in the future. In this work, we aim to return a summary that encapsulates different perspectives for a given opinion question and a set of relevant answers or documents.

In our work we assume that there is a central topic (or query) on which a user is seeking diverse opinions. We predict query-relevance through automatically learned statistical rankers. Our ranking function not only aims to find sentences that are on the topic of the query but also ones that are "opinionated" through the use of several features that indicate subjectivity and sentiment. The relevance score is encoded in a submodular function. Diversity is accounted for by a dispersion function that maximizes the pairwise distance between the pairs of sentences selected.

Our chief contributions are:
(1) We develop a submodular function-based framework for query-focused opinion summarization. To the best of our knowledge, this is the first time that submodular functions have been used to support opinion summarization. We test our framework on two tasks: summarizing opinionated sentences in community QA (Yahoo! Answers) and blogs (TAC-2008 corpus). Human evaluation using Amazon Mechanical Turk shows that our system generates the best summary 57.1% of the time. On the other hand, the best answer picked by Yahoo! users is chosen only 31.9% of the time. We also obtain significant higher Pyramid F1 score on the blog task as compared to the system of Lin and Bilmes (2011).
(2) Within our summarization framework, the statistically learned sentence relevance is included as part of our objective function, whereas previous work on submodular summarization (Lin and Bilmes, 2011) only uses ngram overlap for query relevance. Additionally, we use Latent Dirichlet Allocation (Blei et al., 2003) to model the topic structure of the sentences, and induce clusterings according to the learned topics. Therefore, our system is capable of generating summaries with broader topic coverage.
(3) Furthermore, we are the first to study how different metrics for computing text similarity or dissimilarity affect the quality of submodularity-based summarization methods. We show empirically that lexical representation-based similarity, such as TFIDF scores, uniformly outperforms semantic similarity computed with WordNet. Moreover, when measuring the summary diversity, topical representation is marginally better than lexical representation, and both of them beats semantic representation.

2 Related Work

Our work falls in the realm of query-focused summarization, where a user asks a question and the system generates a summary of the answers containing pertinent and diverse information. A wide range of methods have been investigated, where relevance is often estimated through TF-IDF similarity (Carbonell and Goldstein, 1998), topic signature words (Lin and Hovy, 2000) or by learning a Bayesian model over queries and documents (Daumé and Marcu, 2006). Most work only implicitly penalizes summary redundancy, e.g. by downweighting the importance of words that are already selected.

Encouraging diversity of a summary has recently been addressed through submodular functions, which have been applied for multi-document summarization in newswire (Lin and Bilmes, 2011; Sipos et al., 2012), and comments summarization (Dasgupta et al., 2013). However, these works either ignore the query information (when available) or else use simple ngram matching between the query and sentences. In contrast, we propose to optimize an objective function that addresses both relevance and diversity.

Previous work on generating opinion summaries mainly considers product reviews (Hu and Liu, 2004; Lerman et al., 2009), and formal texts such as news articles (Stoyanov and Cardie, 2006) or editorials (Paul et al., 2010). Mostly, there is no query information, and summaries are formulated in a structured way based on product features or contrastive standpoints. Our work is more related to opinion summarization on user-generated content, such as community QA. Liu et al. (2008) manually construct taxonomies for questions in community QA. Summaries are generated by clustering sentences according to their polarity based on a small dictionary. Tomasoni and Huang (2010) introduce coverage and quality constraints on the sentences, and utilize an integer linear programming framework to select sentences.

3 Submodular Opinion Summarization

In this section, we describe how query-focused opinion summarization can be addressed by submodular functions combined with dispersion functions. We first define our problem. Then we introduce the

Basic Features	Sentiment Features
- answer position in all answers/sentence position in blog - length of the answer/sentence - length is less than 5 words	- number/portion of sentiment words from a lexicon (Section 3.2) - if contains sentiment words with the same polarity as sentiment words in query
Query-Sentence Overlap Features	**Query-Independent Features**
- unigram/bigram TF/TFIDF similarity with query - number of key phrases in the query that appear in the sentence. A model similar to that described in (Luo et al., 2013) was applied to detect key phrases.	- unigram/bigram TFIDF similarity with cluster centroid - sumBasic score (Nenkova and Vanderwende, 2005) - number of topic signature words (Lin and Hovy, 2000) - JS divergence with cluster

Table 1: Features used for candidate ranking. We use them for ranking answers in both community QA and blogs.

components of our objective function (Sections 3.1–3.3). The full objective function is presented in Section 3.4. Lastly, we describe a greedy algorithm with constant factor approximation to the optimal solution for generating summaries (Section 3.5).

A set of documents or answers to be summarized are first split into a set of individual sentences $V = \{s_1, \cdots, s_n\}$. Our problem is to select a subset $S \subseteq V$ that maximizes a given objective function $f : 2^V \rightarrow \mathbb{R}$ within a length constraint: $S^* = \arg\max_{S \subseteq V} f(S)$, subject to $\mid S \mid \leq c$. $\mid S \mid$ is the length of the summary S, and c is the length limit.

Definition 1 *A function $f : 2^V \rightarrow \mathbb{R}$ is submodular iff for all $s \in V$ and every $S \subseteq S' \subseteq V$, it satisfies $f(S \cup \{s\}) - f(S) \geq f(S' \cup \{s\}) - f(S')$.*

Previous submodularity-based summarization work assumes this diminishing return property makes submodular functions a natural fit for summarization and achieves state-of-the-art results on various datasets. In this paper, we follow the same assumption and work with non-decreasing submodular functions. Nevertheless, they have limitations, one of which is that functions well suited to modeling diversity are not submodular. Recently, Dasgupta et al. (2013) proved that diversity can nonetheless be encoded in well-designed *dispersion functions* which still maintain a constant factor approximation when solved by a greedy algorithm.

Based on these considerations, we propose an objective function $f(S)$ mainly considering three aspects: *relevance* (Section 3.1), *coverage* (Section 3.2), and *non-redundancy* (Section 3.3). Relevance and coverage are encoded in a non-decreasing submodular function, and non-redundancy is enforced by maximizing the dispersion function.

3.1 Relevance Function

We first utilize statistical rankers to produce a preference ordering of the candidate answers or sentences. We choose ListNet (Cao et al., 2007), which has been shown to be effective in many information retrieval tasks, as our ranker. We use the implementation from Ranklib (Dang, 2011).

Features used in the ranking algorithm are summarized in Table 1. All features are normalized by standardization. Due to the length limit, we cannot provide the full results on feature evaluation. Nevertheless, we find that ranking candidates by TFIDF similarity or key phrases overlapping with the query can produce comparable results with using the full feature set (see Section 5).

We take the ranks output by the ranker, and define the relevance of the current summary S as: $r(S) = \sum_i^{|S|} \sqrt{rank_i^{-1}}$, where $rank_i$ is the rank of sentence s_i in V. For QA answer ranking, sentences from the same answer have the same ranking. The function $r(S)$ is our first submodular function.

3.2 Coverage Functions

Topic Coverage. This function is designed to capture the idea that a comprehensive opinion summary should provide thoughts on distinct aspects. Topic models such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and its variants are able to discover hidden topics or aspects of document collections, and thus afford a natural way to cluster texts according to their topics. Recent work (Xie and Xing, 2013) shows the effectiveness of utilizing topic models for newsgroup document clustering. We first learn an LDA model from the data, and treat each topic as a cluster. We estimate a sentence-topic distribution $\vec{\theta}$ for each sentence, and assign the sentence to the cluster k corresponding to the mode of the distribution (i.e., $k = \arg\max_i \theta_i$). This naive approach produces comparable clustering performance to the state-of-the-art according to (Xie and Xing, 2013). $\mathcal{T}$ is defined as the clustering induced by our algorithm on the set V. The topic coverage of the current summary S is defined as $t(S) = \sum_{T \in \mathcal{T}} \sqrt{|S \cap T|}$.

From the concavity of the square root it follows that sets S with uniform coverages of topics are preferred to sets with skewed coverage.

Authorship Coverage. This term encourages the summarization algorithm to select sentences from different authors. Let $\mathcal{A}$ be the clustering induced by the sentence to author relation. In community QA, sentences from the answers given by the same user belong to the same cluster. Similarly, sentences from blogs with the same author are in the same cluster. The authorship score is defined as $a(S) = \sum_{A \in \mathcal{A}} \sqrt{|S \cap A|}$.

Polarity Coverage. The polarity score encourages the selection of summaries that cover both positive and negative opinions. We categorize each sentence simply by counting the number of polarized words given by our lexicon. A sentence belongs to a positive cluster if it has more positive words than negative ones, and vice versa. If any negator co-occurs with a sentiment word (e.g. within a window of size 5), the sentiment is reversed.[2] The polarity clustering $\mathcal{P}$ thus have two clusters corresponding to positive and negative opinions. The score is defined as $p(S) = \sum_{P \in \mathcal{P}} \sqrt{| S \cap P |}$. Our lexicon consists of MPQA lexicon (Wilson et al., 2005), General Inquirer (Stone et al., 1966), and SentiWordNet (Esuli and Sebastiani, 2006). Words with conflicting sentiments from different lexicons are removed.

Content Coverage. Similarly to Lin and Bilmes (2011) and Dasgupta et al. (2013), we use the following function to measure content coverage of the current summary S: $c(S) = \sum_{v \in V} \min(cov(v, S), \theta \cdot cov(v, V))$, where $cov(v, S) = \sum_{u \in S} sim(v, u)$. We experiment with two types of similarity functions. One is a Cosine TFIDF similarity score. The other is a WordNet-based semantic similarity score between pairwise dependency relations from two sentences (Dasgupta et al., 2013). Specifically, $sim_{Sem}(v, u) = \sum_{rel_i \in v, rel_j \in u} WN(a_i, a_j) \times WN(b_i, b_j)$, where $rel_i = (a_i, b_i), rel_j = (a_j, b_j)$, $WN(w_i, w_j)$ is the shortest path length. All scores are scaled onto $[0, 1]$.

3.3 Dispersion Function

Summaries should contain as little redundant information as possible. We achieve this by adding an additional term to the objective function, encoded by a dispersion function. Given a set of sentences S, a complete graph is constructed with each sentence in S as a node. The weight of each edge (u, v) is their dissimilarity $d'(u, v)$. Then the distance between any pair of u and v, $d(u, v)$, is defined as the total weight of the shortest path connecting u and v.[3] We experiment with two forms of dispersion function (Dasgupta et al., 2013): (1) $h_{sum} = \sum_{u,v \in V, u \neq v} d(u, v)$, and (2) $h_{min} = \min_{u,v \in V, u \neq v} d(u, v)$.

Then we need to define the dissimilarity function $d'(\cdot, \cdot)$. There are different ways to measure the dissimilarity between sentences (Mihalcea et al., 2006; Agirre et al., 2012). In this work, we experiment with three types of dissimilarity functions.

Lexical Dissimilarity. This function is based on the well-known Cosine similarity score using TFIDF weights. Let $sim_{tfidf}(u, v)$ be the Cosine similarity between u and v, then we have $d'_{Lex}(u, v) = 1 - sim_{tfidf}(u, v)$.

Semantic Dissimilarity. This function is based on the semantic meaning embedded in the dependency relations. $d'_{Sem}(u, v) = 1 - sim_{Sem}(v, u)$, where $sim_{Sem}(v, u)$ is the semantic similarity used in content coverage measurement in Section 3.2.

Topical Dissimilarity. We propose a novel dissimilarity measure based on topic models. Celikyilmaz et al. (2010) show that estimating the similarity between query and passages by using topic structures can help improve the retrieval performance. As discussed in the topic coverage in Section 3.2, each sentence is represented by its sentence-topic distributions estimated by LDA. For candidate sentence u and v, let their topic distributions be P_u and P_v. Then the dissimilarity between u and v can be defined as: $d'_{Topic}(u, v) = JSD(P_u || P_v) = \frac{1}{2}(\sum_i P_u(i) \log_2 \frac{P_u(i)}{P_a(i)} + \sum_i P_v(i) \log_2 \frac{P_v(i)}{P_a(i)})$ where $P_a(i) = \frac{1}{2}(P_u(i) + P_v(i))$.

3.4 Full Objective Function

The objective function takes the interpolation of the submodular functions and dispersion function:

$$\mathcal{F}(S) = r(S) + \alpha t(S) + \beta a(S) + \gamma p(S) + \eta c(S) + \delta h(S). \quad (1)$$

[2] There exists a large amount of work on determining the polarity of a sentence (Pang and Lee, 2008) which can be employed for polarity clustering in this work. We decide to focus on summarization, and estimate sentence polarity through sentiment word summation (Yu and Hatzivassiloglou, 2003), though we do not distinguish different sentiment words.

[3] This definition of distance is used to produce theoretical guarantees for the greedy algorithm described in Section 3.5.

The coefficients $\alpha, \beta, \gamma, \eta, \delta$ are non-negative real numbers and can be tuned on a development set.[4] Notice that each summand except $h(S)$ is a non-decreasing, non-negative, and submodular function, and summation preserves monotonicity, non-negativity, and submodularity. Dispersion function $h(s)$ is either h_{sum} or h_{min} as introduced previously.

3.5 Summary Generation via Greedy Algorithm

Generating the summary that maximizes our objective function in Equation 1 is NP-hard (Chandra and Halldórsson, 1996). We choose to use a greedy algorithm that guarantees to obtain a constant factor approximation to the optimal solution (Nemhauser et al., 1978; Dasgupta et al., 2013). Concretely, starting with an empty set, for each iteration, we add a new sentence so that the current summary achieves the maximum value of the objective function. In addition to the theoretical guarantee, existing work (McDonald, 2007) has empirically shown that classical greedy algorithms usually works near-optimally.

4 Experimental Setup

4.1 Opinion Question Identification

We first build a classifier to automatically detect opinion oriented questions in Community QA; questions in the blog dataset are all opinionated. Our opinion question classifier is trained on two opinion question datasets: (1) the first, from Li et al. (2008a), contains 646 opinionated and 332 objective questions; (2) the second dataset, from Amiri et al. (2013), consists of 317 implicit opinion questions, such as "*What can you do to help environment?*", and 317 objective questions. We train a RBF kernel based SVM classifier to identify opinion questions, which achieves F1 scores of 0.79 and 0.80 on the two datasets when evaluated using 10-fold cross-validation (the best F1 scores reported are 0.75 and 0.79).

4.2 Datasets

Community QA Summarization: Yahoo! Answers. We use the Yahoo! Answers dataset from Yahoo! *Webscope*^{TM} program,[5] which contains 3,895,407 questions. We first run the opinion question classifier to identify the opinion questions. For summarization purpose, we require each question having at least 5 answers, with the average length of answers larger than 20 words. This results in 130,609 questions.

To make a compelling task, we reserve questions with an average length of answers larger than 50 words as our test set for both ranking and summarization; all the other questions are used for training. As a result, we have 92,109 questions in the training set for learning the statistical ranker, and 38,500 in the test set. The category distribution of training and test questions (Yahoo! Answers organizes the questions into predefined categories) are similar. 10,000 questions from the training set are further reserved as the development set. Each question in the Yahoo! Answers dataset has a user-voted best answer. These best answers are used to train the statistical ranker that predicts relevance. Separate topic models are learned for each category, where the category tag is provided by Yahoo! Answer.

Blog Summarization: TAC 2008. We use the TAC 2008 corpus (Dang, 2008), which consists of 25 topics. 23 of them are provided with human labeled nuggets, which TAC used in human evaluation. TAC also provides snippets (i.e., sentences) that are frequently retrieved by participant systems or identified as relevant by human annotators. We do not assume those snippets are known to any of our systems.

4.3 Comparisons

For both opinion summarization tasks, we compare with (1) the approach by Dasgupta et al. (2013), and (2) the systems from Lin and Bilmes (2011) with and without query information. The sentence clustering process in Lin and Bilmes (2011) is done by using CLUTO (Karypis, 2003). For the implementation of systems in Lin and Bilmes (2011) and Dasgupta et al. (2013), we always use the parameters reported to have the best performance in their work.

For cQA summarization, we use the **best answer** voted by the user as a baseline. Note that this is a strong baseline since all the other systems are unaware of which answer is the best. For blog summarization, we have three additional baselines – the **best systems** in TAC 2008 (Kim et al., 2008; Li et al., 2008b), top sentences returned by our **ranker**, a baseline produced by TFIDF similarity and a lexicon

[4] The values for the coefficients are $5.0, 1.0, 10.0, 5.0, 10.0$ for $\alpha, \beta, \gamma, \eta, \delta$, respectively, as tuned on the development set.

[5] `http://sandbox.yahoo.com/`

(henceforth called **TFIDF+Lexicon**). In TFIDF+Lexicon, sentences are ranked by the TFIDF similarity with the query, and then sentences with sentiment words are selected in sequence. This baseline aims to show the performance when we only have access to lexicons without using a learning algorithm.

5 Results

5.1 Evaluating the Ranker

We evaluate our ranker (described in Section 3.1) on the task of best answer prediction. Table 2 compares the average precision and mean reciprocal rank (MRR) of our method to those of three baselines, (1) where answers are ranked randomly (**Baseline (Random)**), (2) by length (**Baseline (Length)**), and (3) by Jensen Shannon Divergence (**JSD**) with all answers. We expect that the best answer is the one that covers the most information, which is likely to have a smaller JSD. Therefore, we use JSD to rank answers in the ascending order. Table 2 manifests that our ranker outperforms all the other methods.

	Baseline (Random)	**Baseline (Length)**	**JSD**	**Ranker (ListNet)**
Avg Precision	0.1305	0.2834	0.4000	**0.5336**
MRR	0.3403	0.4889	0.5909	**0.6496**

Table 2: Performance for best answer prediction. Our ranker outperforms the three baselines.

5.2 Community QA Summarization

Automatic Evaluation. Since human written abstracts are not available for the Yahoo! Answers dataset, we adopt the Jensen-Shannon divergence (JSD) to measure the summary quality. Intuitively, a smaller JSD implies that the summary covers more of the content in the answer set. Louis and Nenkova (2013) report that JSD has a strong negative correlation (Spearman correlation $= -0.737$) with the overall summary quality for multi-document summarization (MDS) on news articles and blogs. Our task is similar to MDS. Meanwhile, the average JSD of the best answers in our test set is smaller than that of the other answers (0.39 vs. 0.49), with an average length of 103 words compared with 67 words for the other answers. Also, on the blog task (Section 5.3), the top two systems by JSD also have the top two ROUGE scores (a common metric for summarization evaluation when human-constructed summaries are available). Thus, we conjecture that JSD is a good metric for community QA summaries.

Table 3 (left) shows that our system using a content coverage function based on Cosine using TFIDF weights, and a dispersion function (h_{sum}) based on lexicon dissimilarity and 100 topics, outperforms all of the compared approaches (paired-t test, $p < 0.05$). The topic number is tuned on the development set, and we find that varying the number of topics does not impact performance too much. Meanwhile, both our system and Dasgupta et al. (2013) produce better JSD scores than the two variants of the Lin and Bilmes (2011) system, which implies the effectiveness of the dispersion function. We further examine the effectiveness of each component that contributes to the objective function (Section 3.4), and the results are shown in Table 3 (right).

	Length	
	100	200
Best answer	0.3858	-
Lin and Bilmes (2011)	0.3398	0.2008
Lin and Bilmes (2011) + q	0.3379	0.1988
Dasgupta et al. (2013)	0.3316	0.1939
Our system	**0.3017**	**0.1758**

	JSD$_{100}$	**JSD$_{200}$**
Rel(evance)	0.3424	0.2053
Rel + Aut(hor)	0.3375	0.2040

Rel + Aut + TM + Pol + Cont(ent Coverage)	0.3102	0.1851
Rel + Aut + TM + Pol + Cont + Disp(ersion)	**0.3017**	**0.1758**

Table 3: [**Left**] Summaries evaluated by Jensen-Shannon divergence (JSD) on Yahoo Answer for summaries of 100 words and 200 words. The average length of the best answer is 102.70. [**Right**] Value addition of each component in the objective function. The JSD on each line is statistically significantly lower than the JSD on the previous ($\alpha = 0.05$).

Human Evaluation. Human evaluation for Yahoo! Answers is carried out on Amazon Mechanical Turk[6] with carefully designed tasks (or "HITs"). Turkers are presented summaries from different systems in a random order, and asked to provide two rankings, one for overall quality and the other for information diversity. We indicate that informativeness and non-redundancy are desirable for quality; however, Turkers are allowed to consider other desiderata, such as coherence or responsiveness, and write down those when they submit the answers. Here we believe that ranking the summaries is easier than evaluating each summary in isolation (Lerman et al., 2009).

[6] https://www.mturk.com/mturk/

We randomly select 100 questions from our test set, each of which is evaluated by 4 distinct Turkers located in United States. 40 HITs are thus created, each containing 10 different questions. Four system summaries (best answer, Dasgupta et al. (2013), and our system with 100 and 200 words respectively) are displayed along with one noisy summary (i.e. irrelevant to the question) per question in random order.[7] We reject Turkers' HITs if they rank the noisy summary higher than any other. Two duplicate questions are added to test intra-annotator agreement. We reject HITs if Turkers produced inconsistent rankings for both duplicate questions. A total of 137 submissions of which 40 HITs pass the above quality filters.

Turkers of all accepted submissions report themselves as native English speakers. An inter-rater agreement of Fleiss' κ of 0.28 (fair agreement (Landis and Koch, 1977)) is computed for quality ranking and κ is 0.43 (moderate agreement) for diversity ranking. Table 4 shows the percentage of times a particular method is picked as the best summary, and the macro-/micro-average rank of a method, for both overall quality and information diversity. Macro-average is computed by first averaging the ranks per question and then averaging across all questions.

For overall quality, our system with a 200 word limit is selected as the best in 44.6% of the evaluations. It outperforms the best answer (31.9%) significantly, which suggests that our system summary covers relevant information that is not contained in the best answer. Our system with a length constraint of 100 words is chosen as the best for quality 12.5% times while that of Dasgupta et al. (2013) is chosen 11.0% of the time. Our system is also voted as the best summary for diversity in 78.7% of the evaluations. More interestingly, both of our systems, with 100 words and 200 words, outperform the best answer and Dasgupta et al. (2013) for average ranking (both overall quality and information diversity) significantly by using Wilcoxon signed-rank test ($p < 0.05$). When we check the reasons given by Turkers, we found that people usually prefer our summaries due to "helpful suggestions that covered many options" or being "balanced with different opinions". When Turks prefer the best answers, they mostly stress on coherence and responsiveness. Sample summaries from all the systems are displayed in Figure 2.

	Length of Summary	**Overall Quality**			**Information Diversity**		
		% Best	Average Rank Macro	Micro	% Best	Average Rank Macro	Micro
Best answer	102.70	31.9%	2.68	2.69	9.6%	3.27	3.29
Dasgupta et al. (2013)	100	11.0%	2.84	2.83	5.0%	2.95	2.94
Our system		12.5%	**2.50***	**2.50***	6.7%	**2.43***	**2.43***
Our system	200	**44.6%**	**1.98***	**1.98***	**78.7%**	**1.35***	**1.34***

Table 4: Human evaluation on Yahoo! Answer Data. **Boldface** implies statistically significance compared to other results in the same columns using paired-t test. Both of our systems are ranked higher (i.e. numbers in **bold** with *) than the best answers voted by Yahoo! users and system summaries from Dasgupta et al. (2013).

Question: What is the long term effect of piracy on the music and film industry?

Dasgupta et al. (2013) (Qty Rank=2.75 Div. Rank=2.5):
- In short, I don't think the music industry in particular will ever enjoy the huge profits of the 90's.
- Please-People in those businesses make millions of dollars as it is !! I don't think piracy hurts them at all !!!
- The other thing will be music and movies with less quality.
- Its a big gray area, I dont see anything wrong with burning a mix cd or a cd for a friend so long as youre not selling them for profit.
- By removing the profitability of music & film companies, piracy takes away their motivation to produce new music & movies.

Our system (100 words) (Qty Rank=2.25 Div. Rank=2.25):
- Rising costs for movies and music. The other thing will be music and movies with less quality.
- Now, with piracy, there isn't the willingness to take chances.
- But it's also like the person put the effort into it and they aren't getting paid. It's a big gray area, I don't see anything wrong with burning a mix cd or a cd for a friend so long as you're not selling them for profit.
- It is forcing them to rework their business model, which is a good thing.

Our system (200 words) (Qty. Rank=2.25, Div Rank=1.25):
- Rising costs for movies and music. The other thing will be music and movies with less quality.
- Now, with piracy, there isn't the willingness to take chances. American Idol is the result of this. .... The real problem here is that the mainstream music will become even tighter. Record labels will not won't to go far from what is currently like by the majority.
- I hate when people who have billions of dollars whine about not having more money. But it's also like the person put the effort into it and they aren't getting paid ... I don't see anything wrong with burning a mix cd or a cd for a friend ....
- It is forcing them to rework their business model, which is a good thing.
- By removing the profitability of music & film companies, piracy takes away their motivation to produce new music & movies.

Figure 2: Sample summaries from Dasgupta et al. (2013), and our systems (100 words and 200 words). Sentences from separate bullets (•) are partial answers from different users.

[7]Note that we aim to compare results with the gold-standard best answers of about 100 words. The evaluation of the 200-word summaries is provided only as an additional data-point.

5.3 Blog Summarization

Automatic Evaluation. We use the ROUGE (Lin and Hovy, 2003) software with standard options to automatically evaluate summaries with reference to the human labeled nuggets as those are available for this task. ROUGE-2 measures bigram overlap and ROUGE-SU4 measures the overlap of unigram and skip-bigram separated by up to four words. We use the ranker trained on Yahoo! data to produce relevance ordering, and adopt the system parameters from Section 5.2. Table 5 (left) shows that our system outperforms the best system in TAC'08 with highest ROUGE-2 score (Kim et al., 2008), the two baselines (TFIDF+Lexicon, and our ranker), Lin and Bilmes (2011), and Dasgupta et al. (2013).

	ROUGE-2	**ROUGE-SU4**	**JSD**
Best system in TAC'08	0.2923	0.3766	0.3286
TFIDF + Lexicon	0.3069	0.3876	0.2429
Ranker (ListNet)	0.3200	0.3960	0.2293
Lin and Bilmes (2011)	0.2732	0.3582	0.2330
Lin and Bilmes (2011) + q	0.2852	0.3700	0.2349
Dasgupta et al. (2013)	0.2618	0.3500	0.2370
Our system	**0.3234**	**0.3978**	*0.2258*

	Pyramid F-score
Best system in TAC'08	0.2225
Lin and Bilmes (2011)	0.2790
Our system	**0.3620**

Table 5: Results on TAC'08 dataset. [**Left**] Our system has significant better ROUGE scores than all the other systems except our ranker (paired-t test, $p < 0.05$). We also achieve the best JS divergence. [**Right**] Human evaluation with Pyramid F-score. Our system significantly outperforms the others.

Human Evaluation. For human evaluation, we use the standard Pyramid F-score used in the TAC'08 opinion summarization track with $\beta = 3$ (Dang, 2008). In the TAC task, systems are allowed to return up to 7,000 non-white characters for each question. Since the TAC metric favors recall we do not produce summaries shorter than 7,000 characters. We ask two human judges to evaluate our system along with the one that got the highest Pyramid F-score in the TAC'08 and Lin and Bilmes (2011). Cohen's κ for inter-annotator agreement is 0.68 (substantial). While we did not explicitly evaluate non-redundancy, both of our judges report that our system summaries contain less redundant information.

5.4 Further Discussion

Yahoo! Answer				
	DISPERSION$_{sum}$		DISPERSION$_{min}$	
DISSIMI	Cont$_{tfidf}$	Cont$_{sem}$	Cont$_{tfidf}$	Cont$_{sem}$
Semantic	0.3143	0.324 3	0.3129	0.3232
Topical	0.3101	0.3202	0.3106	0.3209
Lexical	**0.3017**	0.3147	0.3071	0.3172

TAC 2008				
	DISPERSION$_{sum}$		DISPERSION$_{min}$	
DISSIMI	Cont$_{tfidf}$	Cont$_{sem}$	Cont$_{tfidf}$	Cont$_{sem}$
Semantic	0.2216	0.2169	0.2772	0.2579
Topical	0.2128	0.2090	**0.3234**	0.3056
Lexical	0.2167	0.2129	0.3117	0.3160

Table 6: Effect of different dispersion functions, content coverage, and dissimilarity metrics on our system. [**Left**] JSD values for different combinations on Yahoo! data, using LDA with 100 topics. All systems are significantly different from each other at significance level $\alpha = 0.05$. Systems using summation of distances for dispersion function (h_{sum}) uniformly outperform the ones using minimum distance (h_{min}). [**Right**] ROUGE scores of different choices for TAC 2008 data. All systems use LDA with 40 topics. The parameters of our systems are adopted from the ones tuned on Yahoo! Answers.

Given that the text similarity metrics and dispersion functions play important roles in the framework, we further study the effectiveness of different content coverage functions (Cosine using TFIDF vs. Semantic), dispersion functions (h_{sum} vs. h_{min}), and dissimilarity metrics used in dispersion functions (Semantic vs. Topical vs. Lexical). Results on Yahoo! Answer (Table 6 (left)) show that systems using summation of distances for dispersion functions (h_{sum}) uniformly outperform the ones using minimum distance (h_{min}). Meanwhile, Cosine using TFIDF is better at measuring content coverage than WordNet-based semantic measurement, and this may due to the limited coverage of WordNet on verbs. This is also true for dissimilarity metrics. Results on blog data (Table 6 (right)), however, show that using minimum distance for dispersion produces better results. This indicates that optimal dispersion function varies by genre. Topical-based dissimilarity also marginally outperforms the other two metrics in blog data.

6 Conclusion

We propose a submodular function-based opinion summarization framework. Tested on community QA and blog summarization, our approach outperforms state-of-the-art methods that are also based on submodularity in both automatic evaluation and human evaluation. Our framework is capable of including statistically learned sentence relevance and encouraging the summary to cover diverse topics. We also study different metrics on text similarity estimation and their effect on summarization.

Abstract

In this paper we study how to summarize travel-related information in forum threads to generate supplementary travel guides. Such summaries presumably can provide additional and more up-to-date information to tourists. Existing multi-document summarization methods have limitations for this task because (1) they do not generate structured summaries but travel guides usually follow a certain template, and (2) they do not put emphasis on named entities but travel guides often recommend points of interest to travelers. To overcome these limitations, we propose to use a latent variable model to align forum threads with the section structure of well-written travel guides. The model also assigns section labels to named entities in forum threads. We then propose to modify an ILP-based summarization method to generate section-specific summaries. Evaluation on threads from Yahoo! Answers shows that our proposed method is able to generate better summaries compared with a number of baselines based on ROUGE scores and coverage of named entities.

1 Introduction

Online forums and community question answering (CQA) sites contain much useful information from ordinary users, such as their personal experience, opinions, suggestions and recommendations. Extracting and summarizing information from these rich information sources has a wide range of applications. In this work, we study how to tap into user-generated content in forums such as Yahoo! Answers to generate supplementary city travel guides. Travel guides published by well-known publishers such as Lonely Planet are written by a small number of authors based on their travel experience. Presumably if we could summarize the large amount of information given by ordinary users about a city, such a summary could supplement the official travel guide and cover more up-to-date information.

However, social media content is diverse and noisy because it is contributed by many different authors. Directly applying existing multi-document summarization methods to forum and CQA threads may not produce good travel guides for the following reasons: (1) Summaries produced by standard summarization methods are not structured, but travel guides usually follow a template structure. (2) Travel guides put much emphasis on points of interest, which are usually location entities, but standard text summarization methods are not entity-oriented.

To illustrate our points, in Table 1 we show (i) the overall structure of a travel guide for Sydney from Lonely Planet, (ii) an excerpt from a summary generated by a state-of-the-art ILP-based summarization method (Gillick and Favre, 2009) from a set of threads related to Sydney, and (iii) excerpts of a structured summary generated by our proposed method. The comparison shows that the summary generated by the standard ILP method mixes information on different topics together and does not mention many

Table 1: Comparison of different travel guides about Sydney. Top: excerpts from Lonely Planet. Bottom left: excerpt from a summary generated by standard ILP. Bottom right: excerpts from summary generated by our method. Named entities are highlighted in bold font.

interesting places to visit. The summary by our proposed method, in contrast, organizes the information into sections and has a high coverage of places a tourist can visit.

To generate the kind of summaries as shown in the bottom right of Table 1, we propose to first leverage the section structure of well-written travel guides and use a latent variable model to align forum threads with the different sections from these travel guides. Moreover, observing that points of interest are organized by sections in these travel guides, we also identify location names from user-generated content and try to uncover their underlying section labels. We then treat the remaining problem as a multi-document summarization task. We modify an Integer Linear Programming (ILP)-based extractive summarization framework (Gillick and Favre, 2009) to select sentences from forum threads to generate section-specific summaries, where we specifically emphasize the inclusion of potential points of interest for each section. Experiments using threads from Yahoo! Answers show that our proposed method generates better summaries than a number of baselines in terms of ROUGE scores and coverage of named entities.

Our work makes the following contributions. First, we study a new problem of summarizing multiple forum threads to generate city travel guides based on known template structure from well-written travel guides. Second, we propose a principled approach based on latent variable models and Integer Linear Programming. Third, we evaluate our method using real forum threads and human generated model summaries, and the results are positive.

2 Overview of Our Method

Our task is to summarize travel-related information from forum threads for potential tourists. In order to inject some structure into the generated summaries, we assume that we have a set of I well-written travel guides that correspond to I different cities and have the same structure. We refer to these travel guides as official travel guides. Each official travel guide consists of a fixed set of S sections such as *restaurants* and *shopping*, and this section structure will be used to organize our generated summaries. We further assume that each section of an official travel guide consists of a list of points of interest, each with a name and a short description, as illustrated in Figure 1. We believe that this is a fairly common structure followed by many if not all travel guides.

Given a target city, we assume that we can collect a set of threads about this city from travel-related forums. In this paper we use threads from Yahoo! Answers, but our solution does not use any CQA properties of the threads, so threads from other general forums can also be used. Our goal is to generate a text summary with S sections from these threads, where each section has a length limit.

As we have mentioned, we treat the problem as a multi-document summarization task. However, different from standard text summarization, our generated summaries should contain S sections. To achieve this goal, we first select a set of relevant threads for each section and then perform section-specific summarization from the selected threads.

Thread selection: To select relevant threads given a section, a naive solution is to rank the threads based on their relevance to the section, where relevance can be measured by, for example, cosine similarity between a thread and all the text in the given travel guides belonging to the section. But we observe that the language used in forum threads could be very different from that in the official travel guides, making it hard to measure relevance purely based on lexical overlap. For example, in the *entertainment* section, forum threads may contain words such as "djs," "Xmas," "b'day" and "anni.", but these words do not occur in the official travel guides. To overcome this difficulty, we propose to use a latent variable model that jointly models official travel guides and forum threads. We treat the S sections as S latent factors that govern the generation of the forum threads. With the latent factors observed in the official travel guides, we receive some supervision; and yet by jointly modeling both the official travel guides and the forum threads, we allow the latent factors to adapt to the lexical variations in user-generated content. In the end, the learned latent factors can help us align forum threads with the sections and subsequently select the most relevant ones for each section.

Section-specific summarization: Given the selected relevant threads for a section, we adopt an ILP-based extractive summarization framework that has been shown to be effective (Gillick and Favre, 2009). We modify the objective function in this framework to consider two factors: (1) Since not every sentence in the selected threads is highly relevant to the section, we want to give preference to those more relevant sentences in the objective function, where relevance can be measured using word distributions learned by the latent variable model. (2) Since travel guides are expected to recommend points of interest to readers, we try to maximize the coverage of section-specific location entities in the objective function.

3 Joint City Section Model

3.1 Model

In this section we present our Joint City Section Model (JCSM), which links official travel guides and forum threads. The model is a typical extension of LDA, where a number of latent topics (i.e. latent factors) are assumed to have generated the observed text. First of all, for each pre-defined section there is a latent topic. These explain words such as "food" and "menu" for *restaurants* and "store" and "mall" for *shopping*. In addition, in both travel guides and forum threads, some words are more related to the city being discussed than any specific section. For example, when New York City is being discussed, words such as "NYC" and "Manhattan" may frequently show up in any section. We therefore further assume that for each city there is a city-specific topic. A switch variable is used to determine whether a word comes from a city-specific or section-specific topic.

A special design of our model that differs from many existing LDA extensions is the treatment of named entities. We first use a named entity recognizer to identify potential names of locations from forum threads. We assume that each of these entities belongs to a section, which is indicated by a latent variable. We then assume that the section labels of the non-entity words in forum threads are dependent on the section labels of these entities. By doing so, we emphasize the importance of associating potential points of interest with sections, which will be useful when we generate summaries.

We now formally present JCSM. To simplify the model description, we assume that we work with I cities, each of which has a given, well-written travel guide and a set of forum threads. Note that in practice this model can be easily extended such that a target city with forum threads does not need to have a given travel guide to begin with. Let ϕ_i denote the word distribution for the city-specific latent topic associated with city i. Let ψ_s denote the word distribution for the section-specific latent topic for section s. Let $d_{i,s,n}$ denote the n-th word in the s-th section of the i-th city's travel guide. Here $1 \leq d_{i,s,n} \leq V$ is an index into the vocabulary with size V. Let $x_{i,s,n}$ be a switch variable associated with $d_{i,s,n}$ to indicate whether this word is city-specific or section-specific. For the j-th forum thread related to the i-th city, we assume there is a distribution over sections, denoted as $\theta_{i,j}$. For the l-th location entity in the k-th post

of this thread, we assume a latent variable $c_{i,j,k,l}$ ($1 \leq c_{i,j,k,l} \leq S$) that indicates the section label of this entity. Then for the m-th word in this post, we first use a switch variable $y_{i,j,k,m}$ to determine whether the word is city-specific or section-specific. If it is section-specific, we then choose one of the entities in the same post, denoted as $z_{i,j,k,m}$, and its corresponding section label as the section for this word.

All the binary switch variables follow a global Bernoulli distribution parameterized by π. There are hyperparameters α, β, β' and γ that define the prior distributions. The complete model is depicted in Figure 1. The generative process of JCSM is also described as follows.

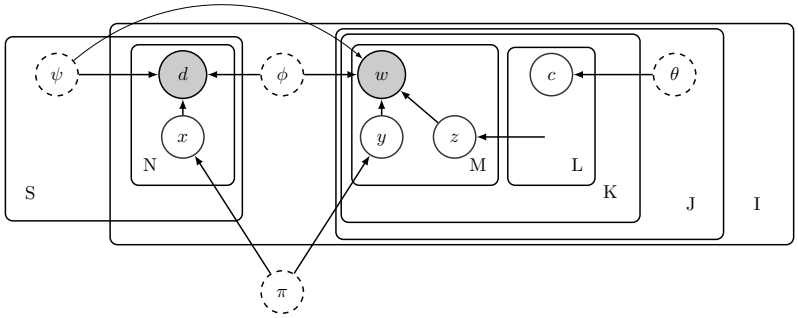

Figure 1: The plate notation of the Joint City Section Model (JCSM). Dashed variables will be integrated out in Gibbs sampling. For clarity, the Dirichlet and Beta priors are omitted. The arrow pointing to z indicates that z is drawn from a uniform distribution over the integers from 1 to L.

- For each city i, ($i = 1, 2, \cdots, I$), draw a city-specific word distribution $\phi_i \sim \text{Dir}(\beta')$
- For each section s, ($s = 1, 2, \cdots, S$), draw a section-specific word distribution $\psi_s \sim \text{Dir}(\beta)$
- Draw a switch distribution $\pi \sim \text{Beta}(\gamma)$
- For each city i ($i = 1, 2, \cdots, I$)
  - For each section s ($s = 1, 2, \cdots, S$)
    - For the n-th word in the given travel guide
      - Draw $x_{i,s,n} \sim \text{Bernoulli}(\pi)$
      - If $x_{i,s,n} = 1$, draw $d_{i,s,n} \sim \text{Multi}(\psi_s)$; otherwise, draw $d_{i,s,n} \sim \text{Multi}(\phi_i)$.
  - For the j-th thread
    - Draw a thread specific section distribution $\theta_j \sim \text{Dir}(\alpha)$
    - For the k-th post
      - For the l-th entity, draw $c_{i,j,k,l} \sim \text{Multi}(\theta_j)$
      - For the m-th word, draw $y_{i,j,k,m} \sim \text{Bernoulli}(\pi)$. If $y_{i,j,k,m} = 1$, draw $z_{i,j,k,m} \sim \text{Uniform}(1, \cdots, L_{i,j,k})$ and then draw $w_{i,j,k,m} \sim \text{Multi}(\psi_{c_{i,j,k,z_{i,j,k,m}}})$; otherwise, draw $w_{i,j,k,m} \sim \text{Multi}(\phi_i)$.

3.2 Inference

We use collapsed Gibbs sampling to estimate the parameters in the model. The problem is to compute the Gibbs update rules for sampling $x_{i,s,n}$, $c_{i,j,k,l}$, $z_{i,j,k,m}$, $y_{i,j,k,m}$.

Sample entity topic $c_{i,j,k,l}$

Let b denote $\{i, j, k, l\}$ and u denote $\{i, j, k\}$. We can derive the Gibbs update rule for sampling entity topic $c_{i,j,k,l}$ as follows:

$$p(c_b = s|\mathbf{C}_{\neg_b}, \mathbf{W}, \mathbf{D}, \mathbf{X}, \mathbf{Y}, \mathbf{Z}) = \frac{n^s_{i,j,\neg_b} + \alpha}{\sum_{s'=1}^{S} n^{s'}_{i,j,\neg_b} + S\alpha} \cdot \frac{\prod_{w=1}^{V} \prod_{i'=1}^{n^w_{u,y=1,z=l}} (n^w_{y=1,z=l,\neg_u} + \beta + i' - 1)}{\prod_{j'=1}^{n^{\mathbf{w}}_{y=1,z=l,u}} (\sum_{w=1}^{V} n^w_{y=1,z=l,\neg_u} + V\beta + j' - 1)},$$

where $n^s_{i,j,\neg_b}$ denotes the number of entities whose topic assignments are s in thread $\{i, j\}$ without consideration of entity $\{i, j, k, l\}$. $n^w_{u,y=1,z=l}$ denotes the number of times term w occurs in the post $\{i, j, k\}$ with the constraint that $y = 1$ and $z = l$. $n^w_{y=1,z=l,\neg_u}$ is the number of times term w occurs in all posts except the post $\{i, j, k\}$ with the constraint that $y = 1$ and $z = l$.

Sample switch label $x_{i,s,n}$

We can derive the Gibbs update rule for sampling $x_{i,s,n}$ in a similar way. Note that the sampling of $x_{i,s,n}$ is in travel guide word level. Let g denote$\{i, s, n\}$, the Gibbs update rule for sampling $x_{i,s,n}$ is as follows:

$$p(x_g = 0|\mathbf{C}, \mathbf{W}, \mathbf{D}_{\neg_g}, \mathbf{X}_{\neg_g}, \mathbf{Y}, \mathbf{Z}) = \frac{n^{x=0}_{\neg_g} + \gamma}{\sum_{x=0}^{1} n^{x}_{\neg_g} + 2\gamma} \cdot \frac{n^{w_g}_{x=0,i,\neg_g} + \beta'}{\sum_{w=1}^{V} n^{w}_{x=0,i,\neg_g} + V\beta'}$$

$$p(x_g = 1|\mathbf{C}, \mathbf{W}, \mathbf{D}_{\neg_g}, \mathbf{X}_{\neg_g}, \mathbf{Y}, \mathbf{Z}) = \frac{n^{x=1}_{\neg_g} + \gamma}{\sum_{x=0}^{1} n^{x}_{\neg_g} + 2\gamma} \cdot \frac{n^{w_g}_{x=1,s,\neg_g} + \beta}{\sum_{w=1}^{V} n^{w}_{x=1,s,\neg_g} + V\beta}$$

Sample post word topic $z_{i,j,k,m}$ and switch label $y_{i,j,k,m}$

For words in the thread posts, We can derive the Gibbs update rule for sampling post word topic $z_{i,j,k,m}$ and switch label $y_{i,j,k,m}$. Note that the sampling of $z_{i,j,k,m}$ and $y_{i,j,k,m}$ is in post word level. Let f denote$\{i, j, k, m\}$. The Gibbs update rule for sampling $z_{i,j,k,m}$ and $y_{i,j,k,m}$ is as follows:

$$p(z_f = s|\mathbf{C}, \mathbf{W}_{\neg_f}, \mathbf{D}, \mathbf{X}, \mathbf{Y}_{\neg_f}, \mathbf{Z}_{\neg_f}) = \frac{n^{w_f}_{y=1,s',\neg_f} + \beta}{\sum_{w=1}^{V} n^{w}_{y=1,s',\neg_f} + V\beta} \cdot \frac{1}{L_{i,j,k}}$$

$$p(y_f = 0|\mathbf{C}, \mathbf{W}_{\neg_f}, \mathbf{D}, \mathbf{X}, \mathbf{Y}_{\neg_f}, \mathbf{Z}_{\neg_f}) = \frac{n^{y=0}_{\neg_f} + \gamma}{\sum_{y=0}^{1} n^{y}_{\neg_f} + 2\gamma} \cdot \frac{n^{w_f}_{y=0,i,\neg_f} + \beta'}{\sum_{w=1}^{V} n^{w}_{y=0,i,\neg_f} + V\beta'}$$

$$p(y_f = 1|\mathbf{C}, \mathbf{W}_{\neg_f}, \mathbf{D}, \mathbf{X}, \mathbf{Y}_{\neg_f}, \mathbf{Z}_{\neg_f}) = \frac{n^{y=1}_{\neg_f} + \gamma}{\sum_{y=0}^{1} n^{y}_{\neg_f} + 2\gamma} \cdot \frac{n^{w_f}_{y=1,s',\neg_f} + \beta}{\sum_{w=1}^{V} n^{w}_{y=1,s',\neg_f} + V\beta}$$

where $s' = c_{i,j,k,l}$ which is the topic index of the associated entity of this word.

Parameter estimation

After Gibbs Sampling, we can make the following parameter estimation:

$$\theta_{i,j,s} = \frac{n^{s}_{i,j} + \alpha}{\sum_{s'=1}^{S} n^{s'}_{i,j} + S\alpha}. \quad \text{thread-section distribution.}$$

$$\psi_{s,w} = \frac{n^{w}_{s,y=1} + \beta}{\sum_{w'=1}^{V} n^{w'}_{s,y=1} + V\beta}. \quad \text{section-word distribution.}$$

$$\phi_{i,w} = \frac{n^{w}_{i,y=0} + \beta'}{\sum_{w'=1}^{V} n^{w'}_{i,y=0} + V\beta'}. \quad \text{city-word distribution.}$$

$$\pi_{y} = \frac{n^{y}_{(.)} + \gamma}{\sum_{y'=0}^{1} n^{y'}_{(.)} + 2\gamma}. \quad \text{switch distribution.}$$

4 Generating Section-specific Summaries

With the JCSM model presented in the last section, we can learn a word distribution for each section, which can help us find more relevant content for the section. For each section, we rank the forum threads by how likely the words inside a thread is generated from the corresponding section-specific word distribution. We select the top-K threads for each section to perform section-specific summarization.

Extractive summarization has been well studied and many algorithms have been proposed. We choose to build our solution on top of an ILP-based framework proposed by Gillick and Favre (2009), partly because our experiments comparing this ILP framework and other existing methods show its advantage on our data sets (see Section 5). Below we first briefly review this ILP-based summarization framework and then present our proposed improvements.

The idea behind the ILP framework by Gillick and Favre (2009) is to maximize the coverage of so-called "concepts" from the original corpus in the generated summary. In practice, bigrams are used as concepts. Specifically, let us use i to index all the concepts from the original corpus. Let w_i denote the weight of the i-th concept computed based on its frequency and $b_i \in \{0, 1\}$ denote the absence or

presence of the concept. The framework aims to maximize $\sum_i w_i b_i$, i.e. the total weighted coverage of the concepts, subject to the following constraints:

$$\begin{array}{rcl} & \sum_j l_j s_j \leq L, & (l_j \text{ is the length of the } j\text{-th sentence in terms of words, and } L \text{ is the length limit of the summary.}) \\ \forall i,j: & s_j o_{i,j} \leq b_i, & (s_j \in \{0,1\} \text{ denotes the absence or presence of the } j\text{-th sentence.}) \\ \forall i: & \sum_j s_j o_{i,j} \geq b_i. & (o_{i,j} \in \{0,1\} \text{ denotes whether concept } i \text{ occurs in sentence } j.) \end{array}$$

Although this framework works well for standard summarization, our task is different. We propose the following changes to this framework:

Favoring relevant sentences: Recall that although we select presumably the most relevant threads for each section, we cannot guarantee that each sentence in these threads is related to the section. For example, we observe that the *things-to-do* section is often mixed with content from *restaurants*, *sights*, *transport* and *entertainment* sections. Also, some sentences are less relevant to the target city than others. In order to select the more relevant sentences in the summary, we propose to add the second term in Eqn. 1 below. Here j is used to index all the candidate sentences and u_j is a weight for sentence j based on its relevance.

We measure relevance with respect to both the city and the section. Let $\text{LL}(j, \psi)$ denote the log likelihood of generating sentence j from the section-specific topic ψ and $\text{LL}(j, \phi)$ denote the log likelihood of generating sentence j from the city-specific topic ϕ. We define u_j as follows:

$$u_j \quad \propto \quad \exp\left(\rho \text{LL}(j,\psi) + (1-\rho)\text{LL}(j,\phi)\right).$$

u_j are then normalized to be between 0 and 1. Note that here ρ is a manually defined parameter used to control the tradeoff between city-specific relevance and section-specific relevance. As we will show in Section 5, both relevance factors turn out to be useful.

Covering section-specific points of interest: We hypothesize that a good summary travel guide should mention potential points of interest to the reader. To this end, the last term in Eqn. 1 is added. Specifically, k is an index for unique location names we find that have been labeled as belonging to section s according to the JCSM model. $e_k \in \{0,1\}$ denotes whether the k-th entity is present in the selected sentences, and v_k denotes the weight for this entity based on its frequency.

Eventually, the summarization task is formulated as the following optimization problem:

$$\begin{array}{ll} \text{Maximize:} & \lambda_1 \sum_i w_i b_i + \lambda_2 \sum_j u_j s_j + (1-\lambda_1-\lambda_2) \sum_k v_k e_k \\ \text{Subject to:} & \sum_j l_j s_j \leq L, \\ & \forall i: \sum_j s_j o_{i,j} \geq b_i, \qquad \forall i,j: s_j o_{i,j} \leq b_i, \\ & \forall j: \sum_k s_j p_{j,k} \geq e_k, \qquad \forall j,k: s_j p_{j,k} \leq e_k. \end{array} \tag{1}$$

Here $o_{i,j}$ denotes whether concept i occurs in sentence j, and $p_{j,k}$ denotes whether entity k occurs in sentence j. For the weights w_i and v_k, we normalize them using the total occurrences of bigrams/entities to ensure their values are between 0 and 1. We solve the above optimization problem using the IBM ILOG CPLEX Optimizer[1].

5 Experiments

5.1 Data and Experimental Setup

We use real data from Yahoo! Answers and Lonely Planet for evaluation. We first crawl the travel guides for 10 cities from Lonely Planet, where each travel guide has 8 sections. We then crawl the top 60000 Q&A threads ranked by number of posts related to these 10 cities (6000 for each city) from Yahoo! Answers under the "travel" category where all questions have been grouped by cities. We filter out trivial factoid questions using features used by Tomasoni and Huang (2010). We then use the Stanford

Table 2: Comparison of the summarization results. ‡ means the result is better than others except ILP-BL in the same column at 5% significance level measured by Wilcoxon signed rank test. Note that only the average scores are tested for statistical significance based on the 32 summarization tasks in total.

NER tool to recognize named entities in these threads. Since we notice that sometimes entities tagged as PER are also possible points of interest, we include all entities of LOC, ORG and PER types. In order to use higher quality threads for evaluation, for each city we pick the top 600 threads that have the most overlapping points of interest with the Lonely Planet travel guides. On average, each thread contains 5.0 posts and 618.1 words. These 600×10 threads are used to train the JCSM model.

We need human generated model summaries for evaluation. Since it is too time consuming to ask human annotators to look through 600 threads and generate structured summaries, we instead opt to first retrieve the top 30 relevant threads per section per city based on the JCSM results and then ask human annotators to summarize these 30 threads to generate a section-specific summary. Our summarization method as well as the baselines are also applied to these 30 threads per section per city for fair comparison. We randomly select 4 cities for human annotation, giving us $8 \times 4 = 32$ section-specific summarization tasks. For each task, we ask four annotators to read all 30 threads and write a summary as model summaries in our experiments[2].

We use the following baseline algorithms for comparison: (1) **Random**, which randomly picks summary sentences. (2) **Centroid** (Radev et al., 2004), which selects sentences according to several features like tfidf, cluster centroid and position. (3) **LexRank** (Erkan and Radev, 2004b)., which applies a graph-based algorithm . (4) **DivRank** (Mei et al., 2010), which employs a time-variant random walk to enhance diversity. (5) **GMDS** (Wan, 2008), which incorporates the document-level information and the sentence-to-document relationship into the ranking process. (6) **ILP-BL**, which is the method proposed by Gillick and Favre (2009).

We empirically set Dirichlet hyperparameters $\alpha = 0.5, \beta = 0.01, \gamma = 0.01, \beta' = 0.1$. We run JCSM with 400 iterations of Gibbs sampling. For the weight parameters in the ILP model, we empirically set $\lambda_1 = 0.7, \lambda_2 = 0.1, \rho = 0.7$ after we conduct multiple experiments to determine the best values of them from 0.1 to 0.9.

5.2 Summarization Results

To compare the summaries generated by our method with those generated by the baselines, we first compute their ROUGE scores against the human generated model summaries. ROUGE scores have been widely used for evaluation of summarization systems (Lin and Hovy, 2003). We use the ROUGE toolkit[3], which provides multiple kinds of ROUGE metrics including ROUGE-N, ROUGE-L, ROUGE-W and ROUGE-SU4. In the experiment results we report three ROUGE F-measure scores, namely, ROUGE-1, ROUGE-2 and ROUGE-SU4. The higher the ROUGE scores, the better a summary is.

In Table 2 we show the summarization results of our method (with the optimal parameter setting) and the baseline methods. For each city, the scores we show are averaged over the 8 sections. The overall average scores on the right hand side are averaged over the 4 cities. We have the following findings from the table: (1) Compared with the other baselines, the ILP-based baseline clearly shows its advantage, justifying our our design choice of adopting an ILP-based framework as the basis of our method. (2) Our method performs slightly better than ILP-BL based on the overall scores, but the difference is not statistically significant.

[2]The summary dataset can be found at `https://sites.google.com/site/liuyang198908/code-data`.

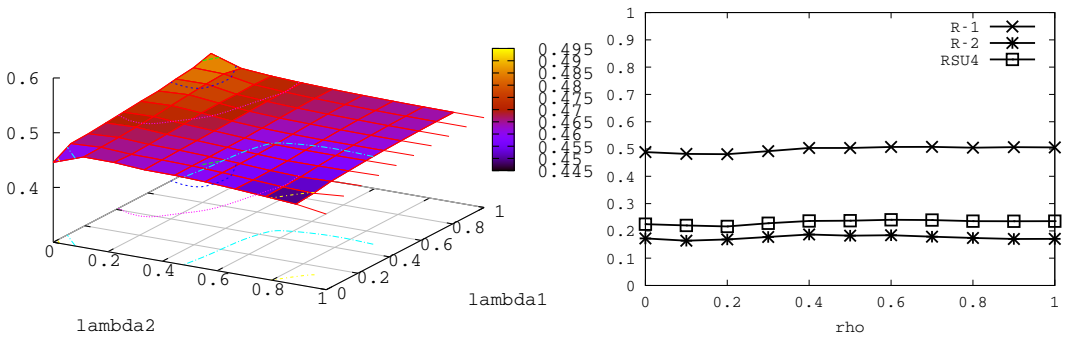
Table 4: Summarization results of the degenerate versions of our method. "−" means removing this component from our complete method. The table shows the average results over data sets of all cites.

Considering that an importance difference between our method and ILP-BL is our focus on points of interest, we further compared ILP-BL and our method using a different metric. The objective is to test the coverage of points of interest in our generated summaries versus the summaries generated by ILP-BL. To this end, we first identify all the named entities in the model summaries using the Stanford NER tool. We then check the percentage of these named entities covered in the generated summaries and report these recall scores in Table 3. We can see that for majority of the 32 section-specific summaries, our method clearly has a higher recall score than ILP-BL, showing that our method generates summaries with more potential points of interest.

To further understand whether all the components of our improved ILP method have contributed to the performance improvement, we compare our overall method with a few degenerate versions of our method. In each degenerate version, we remove a single component of the objective function. The results are shown in Table 4, where −EC removes the consideration of entity coverage (i.e. setting $\lambda_1 + \lambda_2 = 1$), −SR removes the consideration of sentence relevance (i.e. setting $\lambda_2 = 0$), −SecRel removes only the section-specific relevance of the sentences (i.e. setting $\rho = 0$), and −CityRel removes only the city-specific relevance of the sentences (i.e. setting $\rho = 1$). We can see that each degenerate version of our method performs worse than the complete method, which shows that all components of the objective function are useful. In particular, entity coverage and section-specific relevance seem to be the more important components.



(a) R-1(λ_1, λ_2) (b) ρ

Figure 2: Summarization performance of our method by varying the value of the parameters λ_1, λ_2 and ρ.

5.3 Analysis of Topic Words

We show some further analysis of our results. To begin with, we analyze the learning results of JCSM. The top words in city-specific word distributions and section-specific word distributions learnt by JCSM are presented in Table 5 and Table 6. Generally we observe clean top words for each city and each section. For each city, city-specific words are those associated with the corresponding city. For example, for Singapore, we see words such as "s$" (Singapore dollars), "sentosa" (an island resort in Singapore), "orchard" (a boulevard that is the retail and entertainment hub of Singapore) and "bugis" (a popular shopping place). For New York City, we see "square", "times" and "manhattan". For each section, section-specific words are those words which frequently appear when people discuss about this section, such as "menu", "dishes" and " seafood" for the restaurant section and "train", "bus" and "station" for the transport section.

5.4 Parameter Sensitivity Analysis

We further give parameter sensitivity analysis for our proposed method. We show how sensitive our results are with respect to the parameters λ_1, λ_2 and ρ. We choose the Sydney data set to perform parameter sensitivity analysis. In Figure 2(a), we show how ROUGE-1 varies with respect to λ_1 and λ_2. We can see that the performance fluctuates within a limited range as we vary λ_1 and λ_2. We find the trend for ROUGE-2 and ROUGE-SU4 is similar so we leave out the figures for them. In Figure 2(b) we see that the performance is pretty stable as we vary ρ.

5.5 Sample Output and Case Study

Finally, we show a sample travel guide our method generates for Sydney in Table 7. We can see that first of all the sentences selected by our method have high relevance to the corresponding sections. Second, through observation we find that humans tend to select sentences containing more points of interest as summary. Our summary sentences contain many points of interest as highlighted, showing the advantage of our method.

Sample Summary Sentences Generated from Yahoo! Answers by Our Method for Sydney
Hotel
Sorry can not recommend you a hotels as I have no idea of pricing , but if you want a nice area , check hotels in **Bondi** and **Manly Beaches** . As for the **Acer Arena** , that is in the **Homebush Olympic Park** and you can choose to live in either **Parramatta** or the city . You need to live in one of the surrounding residential suburbs , close to a train line . Try **Alexandria** , **Newtown** , **Surry hills** for inner suburbs . . . .
Sights
You can walk around the harbor area to the **Opera House** and you can see the beautiful **Harbor Bridge** . All this is apart from the **Opera House** and the **Botanical Gardens** . Visit the **Custom House Circular Quay** and see a model of **Sydney**. You must also do a day trip to the **Blue Mountains** . **Harbour Wedding** is one of the major attraction in **Sydney** . . . .
Entertainment
George Street has a number of bars . All the bars around the harbour are really good day and night . If you want to stay in a hotel where there is entertainment at night , you could look at **Woolloomooloo** , **Darlinghurst** , **Surry Hills** , **Kings Cross** or **Potts Point** . **Newtown** is good for bars . Get them to see a theatre show or something at the **Opera House** . . . .
Things-to-do
If you are going out for the day , starting with a walk to the city will be most enjoyable . Take a public ferry from **Circular Quay** to **Darling Harbour** , about 15 minutes across the harbour and under the bridge , when you get to **Darling Harbour** go and see the **Chinese Gardens** . There are lots of interesting things to see and do in and around **Sydney** . . . .
Activities
They have good markets at the weekend and great views of the **Opera House** . The **Opera House** is free to have a look at , if you like art then walk through the **Botanical Gardens** and go and see the art gallery . If you 're feeling brave , you can do a **Harbour Bridge** walk , though I think it may be a little pricey . . . .

Table 7: Excerpts from the summary generated from Yahoo! Answers by our method for Sydney. We show summaries for the 5 sections other than the 3 sections shown in Table1. Named entities are highlighted in bold font.

6 Related Work

Multi-document summarization is a process to generate a text summary by reducing documents in size while retaining the main points of the original documents. It has been extensively studied in the NLP community, with most efforts on extractive summarization. Our work is also based on extractive summarization. Extractive summarization essentially selects a set of sentences from the original documents to form a summary.

To select sentences, different features and ranking strategies have been studied. Early work focuses on finding good features to select summary sentences. Radev et al. (2004) proposed a centroid-based summarizer which combines several pre-defined features like tfidf, cluster centroid and position to score sentences. Lin and Hovy (2002) built the NeATS multi-document summarization system using term frequency, sentence position, stigma words and simplified Maximal Marginal Relecvance (MMR). Nenkova et al. (2006) proved that high-frequency words were significant in reflecting the focus of documents. Ouyang et al. (2010) studied the influence of different word positions in summarization. Later, graph-based ranking algorithms have been successfully applied to summarization. LexPageRank (Erkan and Radev, 2004a) is a representative one based on the PageRank algorithm (Page et al., 1999). Later extensions include ToPageRank (Pei et al., 2012), which incorporates topic information into the propagation mechanism, the manifold-ranking based method for topic-focused summarization (Wan et al., 2007) and DivRank (Mei et al., 2010), which introduces a time-variant matrix into a reinforced random walk to balance prestige and diversity.

More recently, Integer Linear Programming (ILP) based framework was introduced as a global inference algorithm for multi-document summarization by McDonald (2007), which considers information and redundancy at the sentence level. Gillick and Favre (2009) studied information and redundancy at a sub-sentence, "concept" level, modeling the value of a summary as a function of the concepts it covers. In our work we also model concept level coverage of the summaries. Li et al. (2013) proposed a regression model to estimate the frequency of bigrams in the reference summary and analyzed the impact of bigram selection, weight estimation and ILP setup. Haghighi and Vanderwende (2009) constructed a sequence of generative probabilistic models for multi-document summarization, exhibiting ROUGE gains along the way. Sauper and Barzilay (2009) investigated an approach for creating a comprehensive textual overview of subject composed of information drawn from the Internet and applied ILP to optimize both local fit of information into each topic and global coherence across the entire overview. Li et al. (2011) developed an entity-aspect LDA model to cluster sentences into aspects and then extend LexRank algorithm to rank sentences. Hu and Wan (2013) proposed to use SVR model and ILP method to generate presentation slides for academic papers.

Our work is different from standard ILP-based multi-document summarization. We designed a latent variable model to first separate the threads to be summarized into sections based on model gravel guides.

We also emphasized the inclusion of potential points of interest in formulating the ILP optimization problem.

Our work is also closely related to previous work on answer summarization in community-based QA sites. Previous work on summarizing answers is mainly based on query focused multi-document summarization techniques to summarize multiple answer documents given a single question. Liu et al. (2008) proposed a CQA question taxonomy to classify questions in CQA and question-type oriented answer summarization for better reuse of answers. Tomasoni and Huang (2010) proposed two concept-scoring functions to combine quality, coverage, relevance and novelty measures for answer summary in response to a question and showed that their summarized answers constitute a solid complement to best answers voted by CQA users. Chan et al. (2012) presented an answer summarization method for complex multi-sentence questions. For our work, we study a new problem of summarizing multiple threads to automatically generate city travel guides based on known template structure from well-written travel guides, which is different from the setting of single Q&A thread summarization in the previous related studies.

7 Conclusion and Future Work

In this paper we proposed a summarization framework to generate well structured supplementary travel guides from social media based on a latent variable model and integer linear programming. The latent variable model could align forum threads with the section structure of well-written travel guides. Compared to standard concept based ILP methods, our method additionally tries to cover more named entities as points of interest and maximizes sentence relevance scores measured by section-specific and city-specific word distributions learnt by the latent variable model. Extensive experiments with real data from Yahoo! Answers show that our proposed method is able to generate better summaries compared with a number of multi-document summarization baselines measured by ROUGE scores.

Currently our generated summaries may have overlap with the well-written model travel guides. In the future, we plan to improve our method to emphasize the selection of *additional* information from social media compared with the model travel guides. We will also look into the problem of how to summarize information that does not fit into the template structure derived from model travel guides.

Abstract

Despite the successes of distant supervision approaches to relation extraction in the news domain, the lack of a comprehensive ontology of medical relations makes it difficult to apply such approaches to relation classification in the medical domain. In light of this difficulty, we propose an ensemble approach to this task where we exploit human-supplied knowledge to guide the design of members of the ensemble. Results on the 2010 i2b2/VA Challenge corpus show that our ensemble approach yields a 19.8% relative error reduction over a state-of-the-art baseline.

1 Introduction

Medical relation (MR) classification, an information extraction task in the clinical domain that was recently defined in the 2010 i2b2/VA Challenge (Uzuner et al., 2011), involves determining the relation between a pair of medical concepts (problems, treatments, or tests). The ability to classify MRs is indispensable to sound automatic analysis of patient health records.

While MR classification is a relatively new task, there has been a lot of work on extracting semantic relations from news articles. *Supervised approaches* train classifiers on data annotated with the target relation types, typically using a rich feature set (Zhou et al., 2005; Surdeanu and Ciaramita, 2007; Zhou et al., 2007). Since obtaining annotated data is a time-consuming and labor-intensive process, researchers have considered *unsupervised approaches* (Shinyama and Sekine, 2006; Banko et al., 2007). While unsupervised approaches can use a large amount of unannotated data and extract a large number of relations, it may not be easy to map the resulting relations to those needed for a given knowledge base. One way to mitigate this problem is *semi-supervised learning*: starting from a given set of seed instances, a bootstrapping algorithm is used to iteratively learn extraction patterns and extract instances (Brin, 1999; Riloff and Jones, 1999; Agichtein and Gravano, 2000; Ravichandran and Hovy, 2002; Etzioni et al., 2005; Pantel and Pennacchiotti, 2006; Bunescu and Mooney, 2007; Rozenfeld and Feldman, 2008). However, the resulting patterns often suffer from semantic drift and low precision. Recent years have seen a surge of interest in *distant supervision* for relation extraction (Mintz et al., 2009; Nguyen and Moschitti, 2011; Krause et al., 2012; Min et al., 2013). The idea is to automatically create annotated relation instances by extracting their labels from relation instances in a knowledge base such as Freebase (Bollacker et al., 2008) and YAGO (Suchanek et al., 2007).

Our goal in this paper is to advance the state of the art in MR classification. One of the major challenges in MR classification is the scarcity of labeled data. At first glance, we can mitigate this problem using distant supervision approaches. However, there is difficulty in applying these approaches to MR classification: only one of the relation types defined in the 2010 i2b2 Challenge is represented in the Unified Medical Language System[1], the most comprehensive medical ontology available to date.

In light of this difficulty, we propose an *ensemble* approach to MR classification, where we exploit *human-supplied knowledge* to guide the design of different members of the ensemble. Unlike state-of-the-art supervised approaches to this task, which represent contextual information largely as *flat* (i.e.,

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1682–1693, Dublin, Ireland, August 23-29 2014.

discrete- or real-valued) features (de Bruijn et al., 2011; Rink et al., 2011) or *structured tree* features (Zhu et al., 2013), we represent contexts as *sequences*, specifically *word* sequences and *dependency* sequences, and use them to derive lexical and dependency patterns. Our ensemble approach exploits human-supplied knowledge in three ways. First, while existing approaches employ similarity functions already defined in off-the-shelf learning algorithms (e.g., linear kernel (Rink et al., 2011), tree kernel (Zhu et al., 2013)) to compute the similarity between two relation instances, we define functions to compare the similarity between two patterns. Second, to complement the automatically induced patterns, we hand-craft patterns based on manual observations made on the training set, specifically by having a human identify the contexts of two concepts that are strongly indicative of a medical relation class. Finally, we employ human knowledge to identify the *constraints* on the classification of different relation instances, and enforce the resulting constraints in an integer linear programming (ILP) framework. Evaluation results on the 2010 i2b2/VA Challenge corpus (henceforth the *i2b2 corpus*) show that our ensemble approach yields a 19.8% relative error reduction over a state-of-the-art system.

The rest of the paper is organized as follows. Section 2 provides an overview of the i2b2 corpus. Section 3 describes the baseline systems. Sections 4 and 5 describe our new components and our ensemble approach. Section 6 discusses our constraints for enforcing global consistency. We present evaluation results in Section 7, conduct an error analysis in Section 8, and conclude in Section 9.

2 Corpus

For evaluation, we use the i2b2 corpus, which comprises 426 de-identified discharge summaries. We adopt the i2b2 organizers' partition of the 426 summaries into a training set (170 summaries) and a test set (256 summaries). As many of the algorithms in our approach require parameter tuning, we reserve 30 of the 170 summaries in the training set for development purposes.

In each discharge summary, the *concepts* and the *medical relation* between each pair of concepts are marked up. Each concept is annotated with a type attribute that indicates whether it is a TEST, a PROBLEM, or a TREATMENT. In addition, a PROBLEM concept has an *assertion* attribute, which specifies whether the problem was present, absent, or possible in the patient, conditionally present in the patient under certain circumstances, hypothetically present in the patient at some future point, or mentioned in the patient report but associated with someone other than the patient.

Eleven types of intra-sentential pairwise relations are annotated. A brief description of these relation types and the relevant statistics are provided in Table 1. As we can see from the table, each medical relation has a *type* and is defined only on *intra-sentence* TREATMENT-PROBLEM, TEST-PROBLEM, and PROBLEM-PROBLEM concept pairs. Also, while there are 11 relation types, three of them, namely Relations 6, 9, and 11, denote the *absence* of a medical relation between the corresponding concepts. The purpose of having "no relation" classes is to ensure that every pair of TEST/PROBLEM/TREATMENT concepts is annotated, whether or not a medical relation exists between them.

3 Baseline MR Classification Systems

We employ two supervised MR classification systems as baselines. The first baseline is a state-of-the-art system that achieved the best performance in the official 2010 i2b2 evaluation. The second baseline is a tree kernel-based system, motivated by the fact that tree kernels are frequently used in relation extraction (e.g., Zhou et al. (2007), Zhu et al. (2013)).

3.1 SVM with Flat Features

Our first baseline, Rink et al.'s (2011) system, employs an SVM classifier trained on a set of *flat* features (i.e., features that are discrete- or real-valued).

Following Rink et al., we create training instances as follows. First, we form training instances between every pair of (PROBLEM, TEST, and TREATMENT) concepts in the training documents, labeling an instance with its relation type. Since the instances belonging to the three "no relation" classes significantly outnumber those belonging to the remaining eight classes, we reduce data skew by downsampling

Id	Relation	Example	Total	(%)
1	**TrIP**: Treatment improves medical problem	*Her pain* resolved after *surgery*	203	(0.6)
2	**TrWP**: Treatment worsens medical problem	treated with *Zofran* with *no relief*	133	(0.4)
3	**TrCP**: Treatment causes medical problem	*Transdermal nitroglycerin* caused *headache*	526	(1.8)
4	**TrAP**: Treatment is administered for medical problem	start on *Decadron* 4 mg q6 to prevent *swelling*	2613	(8.9)
5	**TrNAP**: Treatment is not administered because of medical problem	*His Avandia* was discontinued secondary to *the side effect profile*	174	(0.6)
6	**NTrP**: No relation between treatment and problem	with *sutures* intact and no *erythema* or purulence noted .	4462	(15.2)
7	**TeRP**: Test reveals medical problem	*A postoperative MRI* revealed no *remarkable findings*	3051	(10.4)
8	**TeCP**: Test conducted to investigate medical problem	*An ultrasound* was done to rule out *cholestasis*	504	(1.7)
9	**NTeP**: No relation between test and problem	Throughout the stay *his labs* remained normal and *his pain* controlled .	2964	(10.1)
10	**PIP**: Medical problem indicates medical problem	with *a moderate-sized , dense , fixed inferior defect* indicative of *scar*	2202	(7.5)
11	**NPP**: No relation between paired medical problems	He is somewhat *cantankerous* and *demanding* of the nurses .	12503	(42.6)

Table 1: The 11 relation types for medical relation classification. Each relation type is defined on an ordered pair where concepts in the pair are as specified by the relation. The "Total" and "%" columns show the number and percentage of instances annotated with the corresponding relation type over all 426 discharge summaries, respectively.

instances belonging to the three "no relation" classes.[2] Specifically, we downsample the instances belonging to the three "no relation" classes (i.e., **NTrP**, **NTeP**, and **NPP**) by ensuring that (1) the ratio of the number of **NTrP** instances to the number of TREATMENT-PROBLEM instances is 0.06; (2) the ratio of the number of **NTeP** instances to the number of TEST-PROBLEM instances is 0.03; and (3) the ratio of the number of **NPP** instances to the number of PROBLEM-PROBLEM instances is 0.5. These ratios are selected using our 30-summary development set, as described in Section 2. As mentioned above, each instance corresponds to a pair of concepts, c_1 and c_2, and is represented using 37 groups of features that can be divided into five categories:[3]

Context (13 groups). The words, the POS tags, the bigrams, the string of words, the sequence of phrase chunk types, and the concept types used between c_1 and c_2; the word preceding c_1/c_2; any of the three words succeeding c_1/c_2; the predicates associated with c_1/c_2; the predicates associated with both concepts; and a feature that indicates whether a conjunction regular expression matched the string of words between c_1 and c_2.

Similarity (5 groups). We find the concept pairs in the training set that are most similar to the (c_1,c_2) pair (i.e., its nearest neighbors), and create features that encode the statistics collected from these nearest neighbors. To find the nearest neighbors, we (1) represent each pair in the training set as a sequence; (2) define the number of nearest neighbors to use; and (3) define a similarity metric to compute the similarity of two sequences.

Following Rink et al. (2011), we employ five methods to represent a pair. The five methods are: (1) as a sequence of POS tags for the entire sentence containing the pair; (2) as a phrase chunk sequence between the two concepts; (3) as a word lemma sequence beginning the two words before the first concept, up to and including the second word following the second concept in the pair; (4) as a concept type sequence for all the concepts found in the sentence containing the pair; and (5) as a shortest dependency path sequence connecting the two concepts. Table 2 shows an example of these five methods of generating sequences from the TEST concept *her exam* and the PROBLEM concept *her hyperreflexia* in the sentence

[2]Other methods for addressing class imbalance, such as over-sampling (Chawla et al., 2002) and cost-sensitive learning (Turney, 1995), can also be employed.

[3]To compute the features, we use (1) the Stanford CoreNLP tool (Manning et al., 2014) to obtain POS tags, word lemmas, and dependency structures; (2) GENIA (`http://www.nactem.ac.uk/tsujii/GENIA/tagger`) to obtain phrase chunks; and (3) SENNA (Collobert et al., 2011) to obtain predicate-argument structures.

Generation Method	Sequence
(1)	RB VB , test$_{c1}$ RB VBD RB IN problem$_{c2}$.
(2)	ADVP VP ADVP PP
(3)	postop , test$_{c1}$ only improve slightly in problem$_{c2}$.
(4)	test$_{c1}$ problem$_{c2}$
(5)	test$_{c1}$–nsubj–> prep <–pobj–problem$_{c2}$

Table 2: Examples of the five methods of sequence generation.

Postop, her exam only improved slightly in her hyperreflexia . Note that for better generalization, the two concepts are replaced with their concept type (i.e., *her exam* and *her hyperreflexia* are replaced with test$_{c1}$ and problem$_{c2}$ respectively) before sequence generation. Like Rink et al., we seek different numbers of nearest neighbors for the five methods of generating sequences. For the first method, we use 100 nearest neighbors; for the second method, 15 neighbors; for the third method, 20 neighbors; for the fourth method, 100 neighbors; and for the fifth method, 20 neighbors. We use the Levenshtein distance (Levenshtein, 1966) as the similarity metric.

After finding the nearest neighbors for each of the five methods of sequence representation, we create features as follows. For each method, we compute the percentage of nearest neighbors belonging to each of the 11 relation types, and then create 11 features whose values are these 11 numbers.

Single concept (11 groups). Any word lemma from c_1/c_2; any word used to describe c_1/c_2; the concept type for c_1/c_2; the string of words in c_1/c_2; the concatenation of assertion types for both concepts; and the sentiment category (i.e., positive or negative) of c_1/c_2 obtained from the General Inquirer lexicon (Stone et al., 1968).

Wikipedia (6 groups). Six features are computed based on the Wikipedia articles, their categories, and the links between them. The first feature encodes whether neither c_1 nor c_2 contains any substring that may be matched against the title of an article. The second feature encodes whether the links between the articles retrieved based on the two concepts are absent. The next two features encode whether a link exists from the article pertaining to c_1 (c_2) to the article pertaining to c_2 (c_1). The fifth feature encodes whether there are links between the articles pertaining to both concepts. The last feature encodes whether both concepts have the same concept type according to their Wikipedia categories.

Vicinity (2 groups). The concatenation of the type of c_1 and the type of the closest concept preceding c_1; and the concatenation of the type of c_2 and the type of the closest concept succeeding c_2.

After creating the training instances, we train a 11-class classifier on them using SVM^{multiclass} (Tsochantaridis et al., 2004). We set C, the regularization parameter, to 10,000, since preliminary experiments indicate that preferring generalization to overfitting (by setting C to a small value) tends to yield poorer classification performance. The remaining learning parameters are set to their default values. After training, we use the resulting classifier to make predictions on the test instances, which are generated in the same way as the training instances.

3.2 SVM with Structured Feature

In this framework, each instance is represented using a single structured feature computed from the parse tree of the sentence containing the concept pair. Since publicly available SVM learners capable of handling structured features can only make binary predictions, we train 11 SVM classifiers, one for representing each medical relation. In each classifier's training data, a positive instance is one whose class value matches the medical relation class value of the classifier, and a negative instance is one with other class values applicable to the given concept pair. Since the negative instances significantly outnumber the positive instances in each of these binary classifiers, we reduce data skew by downsampling the negative instances. Following the order of the 11 relations listed in Table 1, the optimal ratios of negative-to-positive instances according to our 30-summary development set are 0.2, 0.2, 0.06, 0.2, 0.5, 1, 1, 0.3, 0.06, 0.06, and 0.09, respectively. We set C to 100 based on the development data.

While we want to use a parse tree directly as a feature for representing an instance, we do *not* want to use the *entire* parse tree as a feature. Specifically, while using the entire parse tree enables a richer

representation of the syntactic context of the two concepts than using a *partial* parse tree, the increased complexity of the tree also makes it more difficult for the SVM learner to make generalizations.

To strike a better balance between having a rich representation of the context and improving the learner's ability to generalize, we extract a subtree from a parse tree and use it as the value of the structured feature of an instance. Specifically, given two concepts in an instance and the associated syntactic parse tree T, we retain as our subtree the portion of T that covers (1) all the nodes lying on the shortest path between the two entities, and (2) all the immediate children of these nodes that are not the leaves of T. This subtree is known as a simple expansion tree.

After training the 11 tree kernel-based relation classifiers, we can apply them to classify a test instance. The class value of an instance is determined based on the classifier with the maximum classification confidence, where the confidence value of an instance is its signed distance from the SVM hyperplane.

4 Exploiting Sequences for MR Classification

Unlike the two baselines, which exploit flat features and parse-based structured features for MR classification, in this section we describe three MR classification systems that exploit sequences.

4.1 Dependency-Based Sequences

The first system is based on sequences of *dependency* relations. To see why dependency relations could be useful for MR classification, consider the sentences in Table 3:

(1)	nsubjpass$_{e1}$ prep$_{e2}$ pobj$_{e2}$ *His pain* was well controlled with *oral medication* at this time .
(2)	nsubjpass$_{e1}$ prep$_{e2}$ pobj$_{e2}$ conj$_{e2}$ *The patient's pain* from his catheters was controlled with Oxycodone and *Motrin* .

Table 3: Example dependency paths.

In sentences (1) and (2), the PROBLEM concepts *His pain* and *The patient's pain* occur as the subject of the verb controlled and the TREATMENT concepts *oral medication* and *Motrin* occur as objects of the prepositional with modifier of the same verb controlled. In other words, intuitively, the verb controlled cues that the PROBLEM concept is being controlled, and together with the preposition with it cues that the TREATMENT concept is doing the controlling. Note that in each case the relation between the PROBLEM and TREATMENT is **TrIP**, which can now be easily inferred given the dependency relations of the concept pairs with the verb controlled. These examples suggest that the verb closest to each of the two concepts is an important word as it cues the relation.

Given the usefulness of dependency structures and the verb closest to each concept for MR classification, we represent each training/test instance as a paired dependency sequence with separate dependency paths traced from each concept in the pair to its closest verb. To reduce data sparsity, for the argument words found in a dependency path, we replace them with their POS tags. For example, given sentence (1), the path extracted from *His pain* is "nsubjpass (controlled NN)" and from *oral medication* is "prep (controlled with) pobj (with NN)".[4]

Next, we describe how to classify a test instance *inst*. First, we identify the set of training instances T that satisfy two conditions: (a) the ancestor verb pair in the training instance is the same as that in *inst*, and (b) each of the two dependency sequences in the training instance either is the same as, or contains, or is contained in the corresponding dependency sequences in *inst*. Second, we find for *inst* its nearest neighbor in T by employing the following similarity function:

$$Similarity(train, test) = cosine(path_{train_{c_1}}, path_{test_{c_1}}) \cdot cosine(path_{train_{c_2}}, path_{test_{c_2}}) \quad (1)$$

[4]Note that sometimes a dependency path cannot be traced (e.g., a verb does not exist, which is not uncommon in a discharge report) for a given concept pair. If this happens, no instance will be generated from the concept pair.

where $cosine(x, y)$ is a function that computes the cosine similarity of x and y.[5] Finally, if the similarity between *inst* and its nearest neighbor in T is greater than a threshold, we classify *inst* using the class value of its nearest neighbor.[6] Otherwise, this system will leave *inst* unclassified. In other words, this system is precision-oriented, classifying only those instances it can classify confidently.

4.2 Lexical Patterns

In our second system, we represent each concept pair as a lexical pattern. Specifically, we employ Generation Method 3 as described in the Similarity features in Section 3.1 to generate a lexical pattern from a concept pair. To classify a test instance *inst*, we employ the one-nearest-neighbor algorithm. To identify the nearest neighbor of *inst*, we employ the Levenshtein distance as the similarity metric.

Two questions naturally arise. First, since these lexical patterns have already been used to generate features in the flat-feature baseline, why do we still employ them in a separate system? To answer this question, note that although these lexical patterns were used to generate features for training the flat-feature baseline classifier, we have no control over whether these features are deemed useful by the learning algorithm and are subsequently used by the resulting classifier. Having a separate system that employs these patterns ensures that they will be used when making the final classification decision.

Second, given that we described five methods to generate sequences in Section 3.1, why do we employ Generation Method 3 but not the remaining methods? In principle, we can employ the remaining four generation methods for generating lexical patterns as well: all we need to do is to create four additional systems, each of which makes use of the patterns created by exactly one of the four methods. In practice, however, not all generation methods are equally good: if a method does not generate patterns that adequately capture context, then employing the resulting patterns may yield poor-performing systems. Consequently, we employ only the system corresponding to the generation method that yields the best performance on the development data, which turns out to be the system corresponding to Method 3.

4.3 Rules

In the previous subsection, we employ automatically induced patterns. In contrast, our third system employs patterns that are *hand-crafted* based on manual observations made on the *training* set. Specifically, we ask a human to identify the contexts of two concepts that are strongly indicative of a relation class. Like the automatically induced patterns, each hand-crafted pattern is composed of the types of the two concepts involved and the context in which they occur. For example, in the pattern *due to* PROBLEM *by* TREATMENT, the TREATMENT is likely to cause the PROBLEM and therefore it will be labeled as **TrCP**. As another example, in the pattern *attributed to* PROBLEM *as a result of* PROBLEM, the two PROBLEMs are likely to have an indicative relation and therefore it will be labeled as **PIP**. At the end of this process, we end up with 136 manually labeled patterns, which we will subsequently refer to as a *ruleset*.

Next, we order these rules in decreasing order of accuracy, where the accuracy of a rule is defined as the number of times it yields the correct MR type divided by the number of times it is applied, as measured on the training set.

Given this ruleset, we can classify a test instance using the first applicable rule in it. If no rules are applicable, the test instance will remain unclassified.[7]

5 The Ensemble

In the previous section, we described three systems for MR classification. Together with the two baseline systems, we have five systems for MR classification. A natural way to make use of all of them for MR classification is to include them in an ensemble. The question, then, is: how do we classify a test instance using this ensemble? The simplest approach is perhaps majority voting, but that presumes that each

[5] To apply cosine similarity, we represent each path as a frequency-count vector, where each dimension in the vector corresponds to a dependency type or an argument word appearing in the path.

[6] Based on development set experiments, the similarity threshold values for each concept pair type are: $T_{Treatment-Problem}$ = 0.85; $T_{Test-Problem}$ = 0.75; and $T_{Problem-Problem}$ = 0.75.

[7] Space limitations preclude a complete listing of these rules. See our website at `https://www.hlt.utdallas.edu/~jld082000/medical-relations/` for the complete list of rules.

member of the ensemble is equally important. In practice, however, some members are more important than the others, so the votes cast by these members should have higher weights.

To model this observation, we combine the (probabilistic) votes of the members in a weighted fashion using the following formula:

$$P_{combined}(c) = w_1 \cdot P_{tree}(c) + w_2 \cdot P_{flat}(c) + w_3 \cdot P_{dependency}(c) + w_4 \cdot P_{word}(c) + w_5 \cdot P_{rules}(c) \quad (2)$$

where w_i ($i = 1, \ldots, 5$) is a combination weight, and $P_x(c)$ is the probability that the test instance belongs to class c according to system x.

Two questions naturally arise. First, how can the combination weights be determined? We perform an exhaustive search on held-out development data to find the combination of weights that jointly maximizes overall accuracy on the development set. We allow each weight to vary between 0 and 1 in steps of 0.1, subject to the constraint that the five weights sum to 1.

Second, how can $P_x(c)$ be computed? In other words, how can each system compute the probability that a given test instance belongs to a certain class? To answer this question, we have to convert the output of each system for each test instance into a 11-element probability vector, which is used to encode the probability that the given test instance belongs to each of the 11 relation types.

We perform the conversion as follows. For the two baseline systems, the SVM outputs a confidence value for each class. Hence, to obtain the probability vector, we first normalize the confidence value associated with each class so that it falls within the [0,1] range, and then normalize the resulting values so that they sum to 1. For the systems employing lexical patterns and dependency-based sequences, the class chosen by each system receives a probability of 0.6, and each of the other classes applicable to the test instance under consideration receives an equal share of the remaining probability mass. For the rule-based system, we take the rule that is used to classify the test instance and apply this rule to each instance in the training set to estimate the probability that the rule is correct with respect to each of the 11 classes. We can then use the resulting 11 probabilities to create the 11-element probability vector.

Finally, recall that some of these systems are not applicable to all of the test instances. If this happens, the corresponding system(s) will return a vector in which all of its elements are set to 0.

6 Enforcing Global Consistency

So far we have had an ensemble that, given a test instance, returns the probability that it belongs to each of the 11 classes. Since the test instances are classified independently of each other, there is no guarantee that the resulting classifications are globally *consistent*. To enforce global consistency, we employ global constraints implemented in the Integer Linear Programming (ILP) framework (Roth and Yih, 2004).

Since our constraints are intra-sentential, we formulate one ILP program for each sentence s in each training summary. Each ILP program contains $11 \times N_s$ variables, where N_s is the number of test instances formed from the concept pairs in s. In other words, there is one binary indicator variable $x_{i,j,r}$ for each relation class r of each test instance *inst* formed from concept i and concept j, which will be set to 1 by the ILP solver if and only if it thinks *inst* should belong to class r.

Our objective is to maximize the linear combination of these variables and their corresponding probabilities given by the ensemble (see (3) below) subject to two types of constraints, the *integrity* constraints and the *consistency* constraints. The integrity constraints ensure that each concept pair is assigned exactly one relation type (see the equality constraint in (4)). The consistency constraints ensure consistency between the predictions made for different instances in the same sentence.

Maximize:

$$\sum_{(i,j) \in R} \sum_{r \in L} p_{i,j,r} x_{i,j,r} \quad (3)$$

subject to:

$$\sum_{r \in L} x_{i,j,r} = 1 \;\; \forall \, (i,j) \in R \quad (4)$$

Relation	Relations in Conflict
TrIP(tr$_i$,p$_j$)	**TrWP(tr$_i$,p$_k$),TrCP(tr$_i$,p$_m$),TrNAP(tr$_i$,p$_n$)**
TrWP(tr$_i$,p$_j$)	**TrIP(tr$_i$,p$_k$),TrCP(tr$_i$,p$_m$),TrNAP(tr$_i$,p$_n$)**
TrCP(tr$_i$,p$_j$)	**TrIP(tr$_i$,p$_k$),TrWP(tr$_i$,p$_m$),TrNAP(tr$_i$,p$_n$)**
TrAP(tr$_i$,p$_j$)	**TrNAP(tr$_i$,p$_k$)**
TrNAP(tr$_i$,p$_j$)	**TrAP(tr$_i$,p$_k$),TrIP(tr$_i$,p$_m$),TrWP(tr$_i$,p$_n$),TrCP(tr$_i$,p$_o$)**
TeRP(te$_i$,p$_j$)	**TeCP(te$_i$,p$_k$)**
TeCP(te$_i$,p$_j$)	**TeRP(te$_i$,p$_k$)**

Table 4: Constraints on relation types.

and consistency constraints.

Note that (1) $p_{i,j,r}$ is the probability that the instance formed from concept i and concept j belongs to relation type r according to the ensemble; (2) L denotes the set of unique relation types; and (3) R is the set of instances in the sentence under consideration.

The consistency constraints are listed in Table 4. Each row of the table represents a constraint and can be interpreted as follows. If the relation in the first column holds, then none of the relations in the second column can hold. Consider, for instance, the constraint in the first row of the table, which says that if TREATMENT tr_i improves PROBLEM p_j, then tr_i cannot worsen, cause, or be administered for any other PROBLEM. At first glance, it may not seem intuitive that a treatment that improves one problem cannot also worsen or cause other problems. This can be attributed to the way a patient discharge summary is written: while the constraint can be violated for concept pairs in *different* sentences, there is no case in which the constraint is violated for concept pairs in the *same* sentence in the training set. These constraints can be implemented as linear constraints in ILP. For example, the constraint "if TREATMENT tr_i improves PROBLEM p_j, then tr_i cannot worsen PROBLEM p_k" can be implemented as follows.

$$x_{i,j,\text{TrIP}} \leq 1 - x_{i,k,\text{TrWP}} \tag{5}$$

7 Evaluation

7.1 Experimental Setup

Following the 2010 i2b2/VA evaluation scheme, we assume that (1) gold concepts and their types are given, and (2) a medical relation classification system is evaluated on all but the "no relation" types. In other words, a system will not be *directly* rewarded if it correctly identifies a "no relation" instance, but will be penalized if it misclassifies a "no relation" instance as one of the eight relation types.

As mentioned before, we use 170 training summaries from the 2010 i2b2/VA corpus for classifier training and reserve 256 test summaries for evaluating system performance. Thirty training summaries are used for development purposes in all experiments that require parameter tuning.

7.2 Results and Discussion

Table 5 shows the 8-class classification results for our MR classification task, where results are expressed in terms of recall (R), precision (P), and micro F-score (F).

Row 1 and row 2 show the results of the flat-feature baseline and the structured-feature baseline, respectively. As we can see, the flat-feature baseline performs significantly better than the structured-feature baseline.[8] It is worth mentioning that since the dataset available to the research community which we are using contains a subset of the summaries from the dataset that was available to the shared task participants, we were unable to directly compare our system's performance with theirs. Nevertheless, we believe that the results of our reimplementation of Rink et al.'s (2011) system in row 1 can be taken to be roughly the state of the art results on this dataset.

Rows 3–5 show the results of the three systems we introduced. As we can see from row 3, by using simple lexical patterns in combination with the Levenshtein similarity metric, we achieve an F-score that is significantly better than that of the structured-feature baseline but significantly worse (at $p < 0.01$) than

[8] All statistical significance tests are paired t-tests with $p < 0.05$ unless otherwise stated.

	Individual System	R	P	F
1	Flat	66.7	58.1	62.1
2	Tree	64.3	55.6	59.6
3	Lexical Patterns	63.9	59.2	61.4

20	Bagging$_{(1+2+3+4+5)}$ + ILP	59.2	75.5	66.4

Table 5: Medical relation classification results.

that of the flat-feature baseline. On the other hand, the remaining two systems are precision-oriented: they classify an instance only if they can do so confidently, thus resulting in poor recall.

Rows 6–10 show the results of our ensemble approach when the individual MR classification systems are added *incrementally* to the flat-feature baseline. Except for the addition of the dependency-based system and the hand-crafted rules, which yielded insignificant improvements in F-score, the addition of all other components yielded significant improvements. In fact, every significant improvement in F-score is accompanied by a simultaneous rise in recall and precision. The best-performing system is the one that comprises all of our components, achieving an F-score of 69.6. This translates to a relative error reduction of 19.8% and a highly significant improvement ($p < 0.001$) over our reimplementation of Rink et al.'s (2011) state-of-the-art baseline. The weights learned for the members of the ensemble are indeed different: both baselines have a weight of 0.3, the rule-based system and the lexical patterns have a weight of 0.1, and the remaining weight goes to the dependency-based component.

7.3 Additional Comparisons

Given the above results, a natural question is: is an ensemble approach ever needed to combine the knowledge sources exploited by different systems in order to obtain these improvements? In other words, can we achieve similar performance by training a *single* classifier using a feature set containing all the features currently exploited by different members of the ensemble?

To answer this question, we repeat the experiments in rows 6–10 of Table 5, except that in each experiment we train a single classifier on a feature set formed from the union of those features employed by all the members of the corresponding ensemble. Results are shown in rows 11–15 of Table 5. In each of these five experiments the F-score obtained by our ensemble approach is significantly better than that achieved by the corresponding single-classifier approach. In addition, although we see improvements in F-score as we add the individual extensions (including ILP) incrementally to the flat-feature baseline, none of these improvements is statistically significant. Nevertheless, when applied in combination, these extensions yield a system that is significantly better than the flat-feature baseline. Overall, these results provide suggestive evidence that to achieve the same level of performance we cannot replace our ensemble approach with a simpler setup that relies on a single classifier.

Given that our ensemble approach performs better than a single-classifier approach, a relevant question is: do we have to use *our* ensemble approach, or can we still achieve similar performance by replacing it with a generic ensemble learning method such as *bagging* (Breiman, 1996)?

To answer this question, we repeat the experiments in rows 6-10 of Table 5, except that we train a committee of classifiers using bagging. Recall that in bagging each classifier in the committee is trained on a *bootstrap sample* created by randomly sampling instances with replacement from the training data until the size of the bootstrap sample is equal to that of the training data. In our implementation, we train 20 multi-class SVM classifiers using SVM^{multiclass}. Given a test instance, each member of the committee will independently cast a probabilistic vote, and the class that receives the largest number of probabilistic votes from the committee members will be assigned to the test instance. Results are shown in rows 16–20 of Table 5. In each of these five experiments, the F-score obtained by bagging

is significantly worse that that achieved by our ensemble approach. In fact, comparing bagging and the single-classifier approach, their results are statistically indistinguishable in all but one case (row 11 vs. row 16), where bagging achieves significantly better performance. Like in the single-classifier experiments, in the bagging experiments we see improvements in F-score as we add the individual extensions (including ILP) incrementally to the flat-feature baseline, although the improvements are significant only with the addition of ILP and the dependency-based system. Nevertheless, when applied in combination, these extensions yield a system that is significantly better than the flat-feature baseline. Overall, these results provide suggestive evidence that to achieve the same level of performance we cannot replace our ensemble approach with bagging.

8 Error Analysis

To gain additional insights into our ensemble approach and to provide directions for future work, we conduct an error analysis of our best-performing system.

NTeP confused as TeRP. This is a frequent type of confusion where 34% of the TEST–PROBLEM pairs that do not have a relation are misclassified as having a "Test Reveals Problem" relation. Below are two subcategories of errors commonly made by the system in this confusion category.

- TEST **with numeric results followed by** PROBLEM **concepts in written text**

The following example illustrates this confusion:
. . . [$_{test}$ *mean gradient*] 33 mm , [$_{problem}$ *decreased disc motion*] , [$_{problem}$ *mobile mass in LVOT*] , [$_{problem}$ *mild AI*] , [$_{problem}$ *mild to moderate MR*] . . .

In sentences like the one above where a TEST concept has a numeric result (result of TEST *mean gradient* is *33 mm*), since the TEST concept is already associated with its result, it has no relation with any other concepts in the sentence. While in some cases the system is able to correctly classify the relation between the TEST concept and the first following PROBLEM concept, in almost all cases, it fails to propagate this no relation class down through the other PROBLEMs listed in a series following the TEST concept. For the sentence above, it incorrectly classifies the relation between TEST concept *mean gradient* and each of the PROBLEM concepts *mobile mass in LVOT*, *mild AI*, and *mild to moderate MR* as **TeRP** instead of **NTeP**.

- TEST **reveals** PROBLEM **that is consistent with other** PROBLEM

This is a common error where a TEST concept is classified as revealing two consistent PROBLEM concepts when in actuality it only reveals one of the PROBLEMs. Consider the following sentence:
[$_{test}$*Radiograph*] revealed [$_{problem}$ *bilateral diffuse granular pattern*] consistent with [$_{problem}$ *surfactant deficiency*] .

In this sentence, PROBLEM concept *bilateral diffuse granular pattern* is described as being consistent with another PROBLEM concept *surfactant deficiency*. While the system correctly classifies the pair (*Radiograph*, *bilateral diffuse granular pattern*) as **TeRP**, it misclassifies the pair (*Radiograph*, *surfactant deficiency*) as **TeRP**. In case of the second pair, the TEST concept has no relation with the PROBLEM concept. From this common error type, an insight one can derive is that the system is currently missing knowledge of the association of the two PROBLEMs w.r.t. each other, and thus in turn cannot make an informed decision of which of the two PROBLEMs the TEST concept actually reveals.

PIP confused as NPP. The second major confusion in the system's output concerns misclassifying PROBLEM concept pairs that are indicative of each other as having "no relation". We observe that 39.5% of the **PIP** instances get classified as **NPP**.

- PROBLEM **without another** PROBLEM

In a sentence, if a PROBLEM concept is actually said to be without another PROBLEM, then such a pair is commonly misclassified by the classifier into the no-relation class **NPP** instead of the has-relation class **PIP**. An example of this can be found in the sentence "[$_{problem}$ *Angio site*] was clean , dry , and intact without [$_{problem}$ *bleeding*] or [$_{problem}$ *drainage*] .", where PROBLEM *Angio site* is classified as **NPP** with

both concepts *bleeding* and *drainage*, respectively. Such cases call for domain-specific knowledge that can aid in identifying attributes of PROBLEMs, like that the PROBLEM concepts *bleeding* and *drainage* are commonly associated attributes of the PROBLEM concept *Angio site*. With this information the system is better equipped to recognize that PROBLEM *Angio site* is related to its attributes.

9 Conclusion

We investigated a new approach to the medical relation classification task, where we employed human-supplied knowledge to assist the construction of relation classification systems based on sequences, combined them via an ensemble, and then enforced global consistency using constraints in an ILP framework. Experimental results on the i2b2 corpus show a significant relative error reduction of 19.8% over a state-of-the-art baseline.

Abstract

This paper presents the first experiments on identifying implicit discourse relations (i.e., relations lacking an overt discourse connective) in French. Given the little amount of annotated data for this task, our system resorts to additional data automatically labeled using unambiguous connectives, a method introduced by (Marcu and Echihabi, 2002). We first show that a system trained solely on these artificial data does not generalize well to natural implicit examples, thus echoing the conclusion made by (Sporleder and Lascarides, 2008) for English. We then explain these initial results by analyzing the different types of distribution difference between natural and artificial implicit data. This finally leads us to propose a number of very simple methods, all inspired from work on domain adaptation, for combining the two types of data. Through various experiments on the French ANNODIS corpus, we show that our best system achieves an accuracy of 41.7%, corresponding to a 4.4% significant gain over a system solely trained on manually labeled data.

1 Introduction

An important bottleneck for automatic discourse understanding is the proper identification of implicit relations between discourse units. What makes these relations difficult is that they lack strong surface cues like a discourse marker. This point is illustrated in the French examples (1) and (2).[1] In (1), the connective *mais* (*but*) triggers a relation of *contrast*, whereas in (2), there is no explicit connective to signal the *explanation* relation, and the relation has to be inferred through other ways (in this case, a causal relation between having injured players and loosing).

(1) La hulotte est un rapace nocturne, **mais** elle peut vivre le jour.
*The tawny owl is a nocturnal bird of prey, **but** it can live in the daytime.*

(2) L'équipe a perdu lamentablement hier. Elle avait trop de blessés.
The team lost miserably yesterday. It had too many injured players.

Implicit relations are very widespread in naturally-occurring data. Thus, they make up between 39.5% and 54% of the annotated examples in the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008), depending on the relation types used.[2] A quick look at other discourse corpora suggests that the problem is as pervasive (if not more) in other languages. The French ANNODIS corpus does not annotate the distinction between explicit and implicit relations, but a projection of a French connective lexicon on the data gives a proportion of 47.4 to 71% of implicit relations, depending on the set of relations.[3] For the German discourse corpus of (Gastel et al., 2011), (Versley, 2013) report 65% of implicit relations.

In this paper, we tackle the problem of automatically identifying implicit discourse relations in French. To date, the large majority of studies on this task have focused on English, and to a lesser extent on German. Performance remain relatively low compared to explicit relations, due to the lack of strong

[1] All our examples are taken from the ANNODIS corpus: http://redac.univ-tlse2.fr/corpus/annodis/.

[2] The former count does not include *AltLex*, *EntRel* and *NoRel* as implicit examples, whereas the latter does.

[3] The first count does not include *attribution*, *e-elaboration* and *frame* examples.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1694–1705, Dublin, Ireland, August 23-29 2014.

predictors. Because it relies on more complex, interacting factors, the identification of implicit relations requires a lot of data. But the available annotated for French is scarce: while the PDTB contains about $40,000$ examples, the French ANNODIS only has about $3,000$ examples. An additional challenge for building such a system for French compared to English is the lack of external lexical ressources (e.g., semantic verb classification, polarity database).

A natural approach to deal with the lack of annotated implicit data is to resort to additional data automatically obtained from explicit examples in which the connective is removed (Marcu and Echihabi, 2002). Provided that one could reliably identify discourse connectives, this approach makes it possible to create large amounts of additional implicit data from raw texts. Unfortunately, (Sporleder and Lascarides, 2008) show that a system trained on this type of artificially generated data does not generalize well, leading to important performance degradation compared to a system solely trained on natural data.

The central question we address in this paper is how to better leverage the large amount of automatically generated data. We first show that the bad generalization performance of the system trained on artificial data lies in important distribution differences between the two datasets. This analysis in turn leads us to investigate various simple schemes for combining natural and artificial data methods inspired from the field of domain adaptation. Our best combined system yields a significant improvement of 4.4% over a system solely trained on the available manually annotated data.

The rest of this paper is organized as follows. Section 2 summarizes previous works on implicit relation identification. In section 3, we describe the problems introduced by the use of artificial data and the methods we develop to deal with them. In section 4, we give a description of the data used, and in section 5, we detail our feature set. Our experiments are then summarized in section 6.

2 Related Work

To date, there have been only a few attempts at building full document-based discourse parsers. On the RST-DT (Carlson et al., 2001), the best performing system is (Joty et al., 2013), who report an F_1 score of 55.71 for labeled stuctures (with 23 relations). On the same corpus, (Sagae, 2009) and (Hernault et al., 2010) report F_1 scores of 44.5 and 47.3, respectively. On the PDTB, the parser of Lin et al. (2010) obtains an F_1 score of 33 (16 explicit relations, 11 implicit relations). On the ANNODIS corpus, Muller et al. (2012) reports F_1 scores of 36.1 (17 relations) and 46.8 (4 relations).

These still modest performance are due to wrong attachment decisions, as well as to errors in relation labeling. Most of these latter errors are mostly imputable to wrong classifications of implicit relations. Thus, the current best accuracy performance on explicit PDTB relations are 94.15% on 4 relations (Pitler and Nenkova, 2009), and 86.77% on 16 relations (Lin et al., 2010). By contrast, the best identification system for implicit PDTB relations obtains an accuracy of 65.4% on 4 relations in (Pitler et al., 2009), and down to 40.2% for 11 of the level 2 relations of PDTB (Lin et al., 2009). For German, Versley (2013)'s study on implicit relations reports 42.5 in F_1 for 5 relations and 18.7 for 21 relations. For French, Muller et al. (2012) report an accuracy score of 63.6% for their relation labeling system (over 17 relations), but they do not provide separate scores for explicit vs. implicit relations.

This performance drop reflects the difficulty of identifying a rhetorical relation in the absence of an explicit discourse marker. As shown by (Park and Cardie, 2012), the identification of implicit relations relies on more diverse and noisy predictors from syntax (in the form of prediction rules) and (lexical) semantics (e.g., polarity, semantic classes and fine-grained semantic tags for verbs). Unfortunately, most of the semantic resources used to derive features for English (polarity database, Inquirer tags) are not available for French. Zhou et al. (2010) try to predict the implicit connectives annotated in the PDTB as a way of predicting the relation, a method only possible with this corpus. They obtain results lower than those reported by (Park and Cardie, 2012). In another context, Sporleder (2008) shows that using WordNet is less effective than lemmatisation for capturing semantic generalization, and (Wang et al., 2010) use tree kernels in order to better capture important syntactic information. In another context, Sporleder (2008) shows that using WordNet is less effective than lemmatisation for capturing semantic generalization, and (Wang et al., 2010) use tree kernels in order to better capture important syntactic information.

Another set of studies we directly build upon explore the idea that many connectives unambiguously trigger a unique relation, thus allowing to construct massive amount of (artificially) labelled implicit examples from raw data. Marcu and Echihabi (2002) were the first to use this method: they were mainly interested in showing that a removed connective could be recovered from its linguistic context. In turn, they only tested their approach on examples that were also generated automatically, and not on manually annotated implicit examples. In this setting, they report an accuracy of 49.7 (6 classes), significantly above luck. Reusing the same approach, Sporleder and Lascarides (2008) then showed that a system trained on a large amount of artificial examples (72000 examples) performs much worse than the same system trained on a much smaller amount of natural examples ($1,051$ examples) implicit examples, with accuracies of 25.8 and 40.3, respectively.

Marcu and Echihabi's (2002) original approach was based on the idea of finding pairs of semantically related words that together trigger a relation (such as "nocturne/jour" ("nocturnal/daytime") in example 1 of *contrast*). Interestingly, Pitler et al. (2009) showed that word pairs extracted from artificial data are not helpful for implicit relation identification and, moreover, that the most informative word pairs are not semantically related. Blair-Goldensohn et al. (2007) showed that, for *cause* and *contrast* at least, results can be enhanced by improving the quality of the artificial data. Finally, Wang et al. (2012) propose a first approach that exploits both natural and artificial data. Specifically, they select the most informative training points among natural and artificial examples, both coming from the PDTB or the RST DT. They define deterministic rules for identifying so-called "typical" examples of a relation, the "seed" sets that are then expanded using a simple clustering algorithm. They report performance results well over those of (Pitler et al., 2009), but using a different evaluation protocole. [4] Also, their method is not easy to repoduce, especially for French, where we can not define the same deterministic rules as some of these depend on polarity information, for which we do not have external resources. Furthermore, their approach only extracts 1 to 5% of the data as seed examples, which would represent too few examples on our corpus. Finally, we are interested in finer-grained relations, thus more difficult to discriminate using these kind of rules.

3 Proposed Approach

Our approach builds upon and extends the method of (Marcu and Echihabi, 2002) and (Sporleder and Lascarides, 2008) by investigating different strategies for combining natural and artificial examples of implicit discourse relations. These different combination schemes are inspired from domain adaptation and are motivated by the fact that artificial and natural examples follow different probability distributions.

3.1 Distribution Differences

Most machine learning algorithms are based on the assumption that data from training and test samples are independently and identically distributed (i.e., the i.i.d. sampling assumption). Yet, it seems that the use of artificial data clearly undermines this assumption. There is indeed no guarantee that our artificial examples should follow a distribution similar to that of the manual examples. This leads to the problem of learning from non-iid data, a problem that has attracted growing attention these last years in machine learning and NLP (Sogaard, 2013), (Hand, 2006).

In this particular context, we have two sets of data with the same output space (i.e., the discourse relations), and the same kind of inputs space (i.e., spans of text). But our data samples can differ in a number of ways. Following the terminology in (Moreno-Torres et al., 2012), we may encounter all the different kinds of *shift* that can appear in a classification problem.

Prior Probability Shift This shift describes changes in the marginal distribution of the *output* (i.e., the relations). The artificial data do not have the same class distribution as the natural ones (see section 4). Neither do they have the same distribution as the natural explicit, because of the automatic extraction. This problem can be easily handled by resampling artificial data (see section 4).

[4] Wang et al. (2012) only use the first annotated relation and ignore the *Entity* relation, whereas Pitler et al. (2009) keep all the annotations and map *Entity* examples to the *Expansion* class.

Covariate Shift This shift describes changes in the marginal distribution of the *input* (i.e., the pairs of spans of text). Artifical examples are originally explicit examples minus their connective, so it is reasonnable to think that these examples will have a different distribution from the natural implicit examples. Moreover, it is possible that, by removing the connective, we have made these examples semantically unfelicitous or even ungrammatical. Segmentation is another issue, since it is automatic and based on heuristics (see section 4). For example, artificial examples can not be multi-sentential whereas it can be the case for natural ones.

Concept Shift This shift describes changes in the *joint* distribution of inputs and outputs. Consider for instance the occurrences of relations within inter- and intra-sentential contexts. The proportion of inter-sentential examples in natural and artificial datasets is the same for *contrast* (57.1%), it is similar for *result* (resp. 45.7% and 39.8%), but very different for *continuation* (resp. 70% and 96.5%) and for *explanation* (resp. 21.4% and 53.0%). Moreover, the extraction method is prone to errors, and it may be the case that we wrongly identify a word form as a discourse connective. Thus, we may produce examples annotated with a wrong relation or that do not involve any discourse relation at all. Finally, deleting a connective can make the discourse ackward or even incoherent (Asher and Lascarides, 2003). We can actually witness this with example (1). As shown by (Sporleder and Lascarides, 2008), deleting the connective can also change the inferred relation. They found examples of *explanation* in which an implicit relation becomes the only one inferable after removing the explicit marker.The deletion can also change the inferred relation (Sporleder and Lascarides, 2008). We found an even worse effect in our French corpus. In example (3), the connective *puisqu(e)* (*because*) triggers an *explanation*, thus the events are ordered following the causal law. The cause, "migrer" ("migrate"), comes before the effect, "deviennent" ("becomes"). But when we delete the connective, the order of the events seems to be reversed. Keeping the first clause as the first argument, we then obtain a *result* relation in this sentence.

(3) Les Amorrites deviennent à la période suivante de sérieux adversaires des souverains d'Ur, **puisqu**'ils commencent alors à migrer en grand nombre vers la Mésopotamie.
In the next period, Amorrites become severe opponents of the sovereigns of Ur, ***because*** *they then begin to migrate in large numbers to Mesopotamia.*

3.2 Methods Inspired by Domain Adaptation

A way to deal with all the distribution differences observed is to reframe our problem within the framework of domain adaptation. Informally, the task of domain adaptation is to port some system from one domain, the *source*, to another, the *target*. Informally, we have a distribution D_s for the source data and a distribution D_t for the target data. The goal of the classifier is to build a good approximation of D_t. If one uses data following the distribution D_s in order to build this approximation, then the performance will depend of the similarity between D_s and D_t. If these distributions are too dissimilar, the approximation will be bad and so will be the performance. It is the case in particular when the domains (e.g., text genres) are different. The goal of domain adaptation is precisely to deal with data from different distributions (Jiang, 2008), (Mansour et al., 2009). We are not exactly in the same setting, but we can regard the artificial data as the *source*, and the natural data, on which we evaluate, as the *target*.

As a first step, we decided to investigate the simplest domain adaptation methods there is, such as those described in (Daumé III, 2007). These methods either combine directly the data or the models built on each set of data. Performance of all these systems will be compared to the base systems trained on only one set of data, in section 6.

Data combination The first possibility is to combine the data. The first model is trained on all natural *and* artificial data together (UNION). This method does not allow us to control the importance of the two sets of data nor to evaluate their influence on the system. We thus refine it in two ways. First, we only add to the manual data randomly selected samples from the artificial data (ARTSUB). Alternatively, we keep all the artificial examples but reweight (or, equivalently, duplicate) the manual examples (NATW). Both these schemes allow us to avoid a massive imbalance between the two kinds of data.

Model combination The second strategy consists in combining the models. A first set of methods involve adding new features. That is, we train a model on the artificial data, then run it on the natural examples. We use these predictions as new attributes for the natural model (ADDPRED). The parameter associated to the attribute therefore measures the importance to be given to the predictions made by the model trained on artificial data. We propose a variation of this method by adding the probabilities of each prediction as supplementary attributes (ADDPROB). The intuition is that even if the classifier is wrong, it could still be consistent in its errors. Yet another model combination consists in using the parameters of the artificial model as initial values for the manual model parameters (ARTINIT). This method allows to give an initial information to the natural model rather than a random intialization. Finally, we also build a model by linearly interpolating the two basic models (LININT).

In addition to these combination schemes, we also add a method to automatically select examples among the artificial set based on the confidence of the artificial model. Its aim is to filter out noisy examples, our hypothesis being that the more confident the model, the less noisy the example.

4 Data

In this work, we choose to focus on 4 relations, *contrast*, *result*, *continuation* and *explanation*, each of which can be either explicit or implicit. These are the same as the relations used in (Sporleder and Lascarides, 2008), allowing for easy comparison across languages, with the exception of the relation *summary* which does not appear in the ANNODIS corpus. Although it is difficult to map these relations onto the relation set of the PDTB, we can say that our relations are closer to level 2 and level 3 (i.e., fine-grained) PDTB relations than level 1 (i.e., coarse-grained) ones.

4.1 Manually Annotated Data: ANNODIS

Our natural implicit examples are taken from the ANNODIS corpus, which is to date the only available French corpus annotated at the discourse level. Its annotations are based on the SDRT framework (Asher and Lascarides, 2003). It consists of 86 newspaper and Wikipedia articles. 3,339 examples have been annotated using 17 relations. In way of comparison, note that the PDTB has roughly 12 times more annotated relations than ANNODIS. Documents are segmented in Elementary Discourse Units (EDUs) which can be clauses, prepositionnal phrases and some adverbials and parentheticals if the span of text describes an event. The relations link EDUs and complex segments, adjacent or not. The connectives are not annotated, which means that the examples of implicit relations had to be extracted automatically.

The corpus has been pre-processed using the MELt tagger (Denis and Sagot, 2009) for POS-tagging, lemmatization and morphological markings. Then, the documents have been parsed using the the MST-Parser (McDonald and Pereira, 2006) trained for French by (Candito et al., 2010). In order to identify implicit examples, we used the French lexicon of connectives (LexConn) developed by Roze et al. (2012). We simply matched all possible connective forms associated with the annotated relations (discarding *à*, which is too ambiguous). We did not add constraints on the connective position, as we wanted to be sure to exclude all explicit examples, this method led us to miss a few implicit examples. Out of 1,108 examples annotated with one of the 4 relations considered, 494 were found to be implicit (see table 2).

4.2 Automatically Annotated Data

The artificial data are automatically extracted from raw data using heuristic rules. We use LexConn to mine explicit instances in the corpus Est Républicain composed of newspaper articles (9M sentences), with the same pre-processings as ANNODIS. LexConn contains 329 connectives, among them, 131 are unambiguous for our 4 relations. We grouped pragmatic relations (i.e., the relation is between speech acts) and non pragmatic relations (i.e., the relation is between facts) relations, assuming they involve the same kind of predictors, and the 3 contrastive relations, as only one type of *contrast* is annotated in ANNODIS. We did not take into account 3 connectives corresponding to unknown part-of-speech. Our first evaluation led us to delete 6 connectives, very ambiguous between discourse and non discourse readings, such as "maintenant" ("now"). We eventually settled on 122 connectives, among which 100 were seen in the corpus in a configuration matching one of our pre-defined patterns. As a comparison, (Sporleder

and Lascarides, 2008) only had 50 such connectives. We finally use 122 connectives, among which 100 were seen in a correct configuration in the corpus. As a comparison, 50 were used in (Sporleder and Lascarides, 2008).

Position	Part-of-speech	Patterns	Examples
Inter-sentential	All POS	A1. **C**(,) A2.	A1. **Malheureusement**(,) A2 A1. **Surtout**, A2.
	Adv.	A1. beg-A2(,) **C**(,) end-A2. A1. A2, **C**.	A1. beg-A2, **de plus**, end-A2. A1. beg-A2(,) **en outre**(,) end-A2. A1. A2, **remarque**.
Intra-sentential	All POS	A1, **C**(,) A2.	A1, **de plus**(,) A2. A1(,) **donc**(,) A2.
	SC and Prep.	**C** A1, A2.	**Preuve que** A1, A2. **Puisque** A1, A2.
	Adv.	A1, beg-A2(,) **C** (,) end-A2. A1, A2, **C**.	A1, beg-A2, **de plus**, end-A2. A1, beg-A2(,) **en outre**(,) A2. A1, A2, **réflexion faite**.

Table 1: Defined patterns with some examples. "A1" stands for the first argument, "A2" for the second and "**C**" stands for the connective ; "beg" and "end" stand resp. for the beginning and the end of an argument ; "(x)" indicates that "x" is not necessary, depending on the connective form. Some patterns are only possible for some sets of connectives based on their part-of-speech (Subordinating Conjunction (SC), Preposition (Prep.), Averbials (Adv.)).

The heuristic used to extract the examples has two main steps. First, we search forms used in discourse readings using patterns (see table 1) that were manually defined for each connective based on its position, its part-of-speechand the punctuation around it. Second, we identify the connectives arguments using the same information. We make the same simplifying assumptions as in the previous studies: an argument covers at most one sentence, and we have at most 2 EDUs within a sentence. As additional constraint, we also require the presence of a verb in each relation argument. When two connectives occur in the same segment, it is possible that one modifies the other. In turn, a naive extraction could produce two examples with different relations but the same arguments. To avoid the creation of spurious examples, we extract two examples in these cases only if one is inter- and the other intra-sentential according to our extraction patterns.

	Natural dataset		Artificial dataset		
Relation	Explicit	Implicit	Available	Training	Test
contrast	100	42	252 793	23 409	2 926
result	52	110	50 297	23 409	2 926
continuation	404	272	29 261	23 409	2 926
explanation	58	70	59 909	23 409	2 926
All	614	494	392 260	93 636	11 704

Table 2: Number of examples in our corpora, for the natural dataset, only the implicit examples are used.

This simple method allows to quickly generate a large amount of data. In total, we extracted $392,260$ examples (see table 2). This initial dataset was rebalanced in a way to keep the maximum number of available examples (thus dealing with the prior probability shift). We used 80% of the data as training set, and 10% the development and test set. Note that there are some important differences in the label distributions between natural and artificial data. For instance, the most represented relation in the natural data (*continuation*) is the least represented in the artificial data. This is because the connectives that trigger this relation are highly ambiguous between discourse and non-discourse readings. Finally, this method generates some noise: out of 250 random examples, we found 37 errors in span boudaries and

18 cases in which the connective form does not have a discourse reading.

5 Features

We adapted various features used in previous studies. The lack of ressources for French prevented us from using them all, especially the semantic ones. These features correspond to surface information and others more linguistic. As a comparison, (Marcu and Echihabi, 2002) only used pairs of words.

Sporleder and Lascarides (2008) used various linguistic features but no syntaxic ones. (Wang et al., 2012) used semantic, syntaxic and lexical information. We used lexico-syntaxic information. Finally, note that our goal is to evaluate the efficiency of data combinations. Thus we did not try to optimize this feature set, as it would have introduced another parameter in our model.

Indication of syntactic complexity: we compute the number of nominal, verbal, prepositional, adjectival and adverbial phrases.

Information concerning the heads of the arguments: we keep the lemma of negative element linked to the head, we also get some temporal/aspectual information (number of auxiliaries dependent of the head, tense, person, number of the auxiliaries), information about the heads dependents (if an object, a by-object or a modifier is present ; if a preposition dependent of the head, subject or object is present ; part-of-speech of the modifiers and prepositional dependents of the head, subject and object) and some morphological information (tense and person of the head if verbal, gender if non verbal, number of the head, precise part-of-speech, "VPP", and simplified,"V"). We also add features pairing the tenses for verbal heads and the heads numbers.

Position: we add a feature indicating if the example is inter or intra-sentential.

Indication of thematic continuity: we compute general lemma overlap and lemma overlap for open class words.

6 Experiments

Our main objective is to assess whether one can use the artificial data to improve the performance of a system solely based on data manually annotated only available in small amount. We therefore test the methods described in section 3.

We experimented with a maximum entropy classifier from the MegaM[5] package, in multiclass classification, with a maximum of 100 iterations. We did not try to optimize the regularization parameter which is then equal to 1.

We rebalance the corpus of manually annotated data to a maximum of 70 examples per relation.[6] We have too few annotated examples to be able to construct a separate test set sufficiently large to make statistical significance test. Thus, we decided to make a stratified nested cross-validation. It has been shown that this method provides an estimate of the error that is very close to that one could obtain on an independent evaluation set ((Varma and Simon, 2006), (Scheffer, 1999)), as it prevents us from optimizing our hyper-parameters and performing evaluation on the same data. Specifically, there are two cross-validation loops: the inner loop is used for tuning the hyper-parameters (as described in section 6.2) and the outer loop estimates the generalization error. The data are first split into N folds. We take the fold k (with $1 \leq k \leq N$) as the current evaluation set. The $N-1$ other folds are used as training data and split into M folds used for model fitting. The best model is then evaluated on the fold k. Finally, we report performance on the N folds. We used two 5-fold cross-validation in order to select and evaluate the best models for the systems described in section 3.2. We have no guarantee to select the best models at each test step, but this procedure allows to evaluate the stability of the system with respect to the hyper-parameters (i.e. the chosen values should not be too scattered), the overfitting (i.e. inner and

[5] http://www.umiacs.umd.edu/~hal/megam/version0_3/

[6] Our focus is on the methodology of data combination, so we left for future work the issue of dealing with the highly imbalanced relation distribution of the natural data. Incidentally, note that this setting prevents us from getting a system solely performing well on highly frequent relations.

outer estimations should be close) and the stability of the models (i.e. variance in the predictive capacity, between the results on the outer folds).

As in the previous studies, we report performance using micro-averaged accuracy and F_1 score per relation. In order to evaluate the statistical significance of our results, we use the Student's t-test (with p-value < 0.05) which has been proved to work with very small sample (see (de Winter, 2013)) if the effect size (computed using the Cohen coefficient) and the correlation between the sample are large enough, while, as noted in (de Winter, 2013), the Wilcoxon signed rank test (that we initially tried) could lead to overestimated p-value with such small sample. The results of the most relevant systems are presented in table 3.

	Without selection				With selection	
	NATONLY	ARTONLY	ADDPRED	ARTINIT	ADDPRED+SELEC	NATW+selec
Accuracy	37.3	23.0	39.3	40.1	**41.7***	41.3
contrast	15.0	23.2	16.0	16.9	20.8	19.2
result	47.6	15.7	50.6	45.9	51.0	48.3
continuation	28.1	32.1	31.9	34.0	31.2	32.4
explanation	47.9	22.4	46.7	52.2	53.9	53.4

Table 3: Most relevant systems, with or without selection of examples, overall accuracy and F_1 score per relation, * corresponds to a significant improvement over NATONLY.

6.1 Basic Models

In the first set of experiments, we trained two classifiers. The first one is trained on the natural implicit data (NATONLY, 252 examples), and the second one on the artificial implicit data (ARTONLY, 93,636 examples). We test both models on natural implicit data.

The overall accuracy of the NATONLY model is 37.3 with F_1 score ranging from 15.0 for *contrast* to 47.9 for *explanation*. The performance on *contrast* is fairly low, probably because this relation is the least frequent in our training set. Note that the overall accuracy obtained is quite close to the 40.3 obtained for English by (Sporleder and Lascarides, 2008).

The overall accuracy of the ARTONLY model is 47.8 when evaluated on the same type of data, that is, artificial ones (11,704 test examples), but only 23.0 when evaluated on natural data. This significant drop in performance has been observed in the previous studies on English. It can be attributed to the distribution differences described in section 3. We can observe that the use of the artificial data lowers the F_1 score for *result* and *explanation* while, for *contrast*, F_1 score is raised by about 10 points.

6.2 Models with Combinations

In this section, we present the results for the systems using both natural and artificial data. We either directly combine the data or use the data to build separate models that are then combined. Some of these models use hyper-parameters. When weighting the natural examples, we test weights $c \in [0.5, 1, 5]$ and $c \in [10; 2000]$ with an increment of 10 until 100, of 50 until 1000 and of 500 until 2000. When adding random subsets of artificial data, we add each time k times the number of natural examples artificial examples with $k \in [0.1; 600]$ with an increment of 0.1 until 1, of 10 until 100 and of 50 until 600. Finally, when taking a linear interpolation of the models, we build a new model by weighting the artificial model by $\alpha \in [0.1; 0.9]$ with increments of 0.1.

In general, we observe that most of the systems lead to similar or higher accuracy than NATONLY, but none of the improvements is statistically significant. The best system is ARTINIT (accuracy 40.1, p-value of 0.18 and a small effect size, 0.39). Two other systems get an accuracy score better than 39, that is ADDPRED (39.3) and LININT (39.3), but not significantly better than NATONLY. The system ADDPROB, similar to ADDPRED, leads to lower accuracy, showing that adding the probabilities decrease the performance. For these systems, the scores on each of the outer folds are close[7], specially for ADDPRED,

[7] ARTINIT : standard deviation (sd) = 0.074, mean = 40.1 ; ADDPRED : sd = 0.037, ADDPROB sd = 0.061, mean $\simeq$ 39

revealing a high model stability. The other systems allow to evaluate the impact of the artificial data on the final results.

The only method leading to lower results is when training on the union of the data sets (UNION), the accuracy (22.6) is similar to ARTONLY. This was expected, as the natural data are about 372 times less numerous than the artificial ones, the new model is thus more influenced by the latter. Note that Wang et al. (2012) also experiment this setting but do not observe such a gap, maybe because their artificial data are based on manually annotated explicit examples, which are likely to be less noisy.

When directly combining the data, either by adding random subsets of the artificial data (ARTSUB, accuracy 34.5) or by weighting the natural examples (NATW, accuracy 38.9), we observe, on the inner folds, an inverse trend. As expected, the accuracy increases as the influence of the artificial data decreases, that is, decreasing the coefficients for ARTSUB and increasing the weights for NATW. Observing the results in the inner folds reveals a same trend about the relative importance of the two kinds of data: natural data have to be around 2.5 times more important than the artificial ones. We also observe this effect with LININT, with the mean of the choosen α values equals to 0.3. We also note that the variance for the values of the hyper-parameter for ARTSUB is pretty high, probably caused by the randomness of the subsamples selection. It is a bit lower for NATW and LININT showing that these methods are more robust. Nevertheless, the strategy does not give an *a priori* good value for the hyper-parameter but restricts the space of values (1020 plus or minus 272 for NATW and 0.3 plus or minus 0.18 for LININT).

6.3 Models with Automatic Selection of Examples

Previous experiments showed that adding artificial data mostly improves the performance but still not significantly. We assume that a lot of the artificial data are noisy, which could hurt the systems. The method of selection of examples thus aims at eliminating potentially noisy examples. The artificial model is used on the training set, and we keep the examples that are predicted with a probability higher than a threshold $s \in [0.3; 0.85]$ with an increment of 0.1 until 0.5 and of 0.05 until 0.85. If the model is confident enough about its prediction, the example might not correspond to noise, that is, a word form that does not have a discourse readings and/or a segmentation error. We also check whether the connective is redundant. For each threshold, we rebalance the data based on the least represented relation (+SELEC systems).

The automatic selection of examples allows to improve previous results. The accuracy of the ARTONLY model moves from 23.0 to 25.0 with selection, and the system UNION move from 22.6 to 40.1 with selection.

The best results are obtained when we use artificial data to create new features but when we add only the relation predicted by the artificial model (ADDPRED+SELEC). With this system, we observe a clear tendency toward significance (accuracy 41.7 with a large effect size, 0.756, and a high correlation, 0.842). The F_1 scores for all classes are improved : 20.8 for *contrast*, 51.0 for *result*, 31.2 for *continuation* and 53.9 for *explanation*. Two other systems get an accuracy over 40: NATW+SELEC (accuracy 41.3, with a trend toward significance[8]) and UNION+SELEC (no significantly higher than NATONLY). We note that ADDPRED corresponds to the best baseline in (Daumé III and Marcu, 2006), which shows the relevance of dealing with the distributions differences in our data through domain adaptation methods.

The automatic selection step allows a more important weight on the informations provided by the artificial data. For LININT+SELEC, the best results are obtained with an almost equal influence of the two models. In the same way, the mean of the choosen values for the coefficient for NATW+SELEC is much lower, and it increases a lot for ARTSUB+SELEC allowing for larger subsamples. Even if the choosen values are widly scattered, these observations tend to prove that the selection improves the quality of our artificial corpus. Regarding the choosen values for the thresholds, the mean over all the systems is 0.7, with a variable standard deviation but always greater than 0.1. This deviation is pretty high, this hyper-parameter probably needs a better optimisation, by repeating the inner loop for example, but these experiments will allow to reduce the search space.

[8] p-value $= 0.077$, large effect size, 0.68 and high correlation, 0.67

The automatic selection of examples leads to one system, namely ADDPRED+SELEC, significantly improving the accuracy of NATONLY. This shows that the artificial data, when rightly integrated, can thus be used to improve a system identifying implicit relations, especially if their influence is low, the model is driven towards the good distribution.

6.4 Effects on the Identification of the Relations

Looking at the F_1 score per relation, we observed that these systems have dissimilar behaviors. A larger influence of the artificial model allows improvements for *contrast*: the best result for this relation is obtained when only the artificial data are used for training (at best, 28.8 F_1 score with ARTONLY+SELEC). The identification of the relation *continuation* seems to be also improved by the influence of the artificial data. We can observe it with the linear interpolation of the models: the mean of the F_1 score increases with the increasing of the α coefficient for these relations. For *continuation*, however, the best mean F_1 is obtained with $\alpha = 0.8$, this relation needs a certain degree of influence from the natural data. Some support for this proposition can be found in the fact that the best result for this relation is obtained with NATW (at best, 44.7 F_1 score). For the other relations, a large weight on the artificial data clearly decreases the F_1 score. However, the identification of *explanation* is improved when we add the predictions of the artificial model (at best, ADDPRED+SELEC, 53.9 F_1 score). Improvement is fairly low for *result* (at best, 51.0 with ADDPRED+SELEC).

The relation *contrast* might take advantage of less noisy artificial data as most of the examples are extracted using the connective *mais* (*but*) always in discourse readings. For *explanation*, predictions of the artificial model could be quiet coherent as most of the artificial examples correspond to the pragmatic relation *explanation**. Moreover, if we look at the feature distribution (850 features overall), we observe a gap of more than 30% for 2 and 5 features for *result* and *explanation* that is not observed for *contrast* and *continuation*, the relations that make the most of the artificial data.

7 Conclusion

We have presented the first system that identifies implicit discourse relations for French. This kind of relation is difficult to identify because of the lack of specific predictors. In the previous studies on English, the performance on this task are fairly low despite the use of complex features, probably because of a lack of manually annotated data. To deal with this issue, even more crucial for French, our system also resorts to additional data, automatically annotated using discourse connectives. These new data, however, do not generalize well to natural implicit data, because of distribution differences. We thus test methods inspired by domain adaptation in order to combine natural and artificial data. We add an automatic selection of examples among the artificial data to deal with noise generated by the method of automatic annotation. We manage to get significant improvement over a system solely trained using available data manually annotated by using automatic selection and the addition of features corresponding to the predictions of the artificial model.

In future work, we will explore more sophisticated methods to deal with data samples that follow different distributions. We will also explore ways to deal with imbalanced data and use our methods on all the relations annotated in our French corpus. Finally, we will test these methods on English corpora, in order to compare their efficiency with previous studies.

Reinforcement Learning of Cooperative Persuasive Dialogue Policies using Framing

Abstract

In this paper, we apply reinforcement learning for automatically learning cooperative persuasive dialogue system policies using framing, the use of emotionally charged statements common in persuasive dialogue between humans. In order to apply reinforcement learning, we describe a method to construct user simulators and reward functions specifically tailored to persuasive dialogue based on a corpus of persuasive dialogues between human interlocutors. Then, we evaluate the learned policy and the effect of framing through experiments both with a user simulator and with real users. The experimental evaluation indicates that applying reinforcement learning is effective for construction of cooperative persuasive dialogue systems which use framing.

1 Introduction

With the basic technology supporting dialogue systems maturing, there has been more interest in recent years about dialogue systems that move beyond the traditional task-based or chatter bot frameworks. In particular there has been increasing interest in dialogue systems that engage in persuasion or negotiation (Georgila and Traum, 2011; Georgila, 2013; Paruchuri et al., 2009; Heeman, 2009; Mazzotta and de Rosis, 2006; Mazzotta et al., 2007; Nguyen et al., 2007; Guerini et al., 2003). We concern ourselves with *cooperative* persuasive dialogue systems (Hiraoka et al., 2013), which try to satisfy both the user and system goals. For these types of systems, creating a system policy that both has persuasive power and is able to ensure that the user is satisfied is the key to the system's success.

In recent years, reinforcement learning has gained much attention in the dialogue research community as an approach for automatically learning optimal dialogue policies. The most popular framework for reinforcement learning in dialogue models is based on Markov decision processes (MDP) and partially observable Markov decision processes (POMDP). In these frameworks, the system gets a reward representing the degree of success of the dialogue. Reinforcement learning enables the system to learn a policy maximizing the reward. Traditional reinforcement learning requires thousands of dialogues, which are difficult to collect with real users. Therefore, a user simulator which simulates the behavior of real users is used for generating training dialogues. Most research in reinforcement learning for dialogue system policies has been done in slot-filling dialogue, where the system elicits information required to provide appropriate services for the user (Levin et al., 2000; Williams and Young, 2007).

There is also ongoing research on applying reinforcement learning to persuasion and negotiation dialogues, which are different from slot-filling dialogue (Georgila and Traum, 2011; Georgila, 2013; Paruchuri et al., 2009; Heeman, 2009). In slot-filling dialogue, the system is required to perform the dialogue to achieve the user goal, eliciting some information from a user to provide an appropriate service. A reward corresponding to the achievement of the user's goal is given to the system. In contrast, in persuasive dialogue, the system convinces the user to take some action achieving the system goal. Thus, in this setting, reward corresponding to the achievement of both the user's and the system's goal is given to the system. The importance of each goal will vary depending on the use case of the system. For

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1706–1717, Dublin, Ireland, August 23-29 2014.

example, a selfish system could be rewarded with an emphasis on only achievement of the system goal, and a cooperative system could be rewarded with an emphasis on achievement of both of the goals. In addition, negotiation dialogue could be considered as a kind of the persuasive dialogue where the user also tries to convince the system to achieve the user's goal.

In this paper, our research purpose is learning better policies for cooperative persuasive dialogue systems using *framing*. We focus on learning a policy that tries to satisfy both the user and system goals. In particular, two elements in this work set it apart from previous works:

- We introduce framing (Irwin et al., 2013), which is known to be important for persuasion and a key concept of this paper, as a system action. Framing uses emotionally charged words to explain particular alternatives. In the context of research that applies reinforcement learning to persuasive (or negotiation) dialogue, this is the first work that considers framing as a system action.
- We use a human-to-human persuasive dialogue corpus of Hiraoka et al. (2014) to train predictive models for achievement of a human persuadee's and a human persuader's goals, and introduce these models to reward calculation to enable the system to learn a policy reflecting knowledge of human persuasion.

To achieve our research purpose, we construct a POMDP where the reward function and user simulator are learned from a corpus of human persuasive dialogue. We define system actions based on framing and general dialogue acts. In addition, the system dialogue state (namely, belief state) is defined for tracking the system's rewards. Then, we evaluate the effect of framing and learning a system policy. Experimental evaluation is done through a user simulator and real users.

2 Reinforcement learning

Reinforcement learning is a machine learning technique for learning a system policy. The policy is a mapping function from a dialogue state to a particular system action. In reinforcement learning, the policy is learned by maximizing the reward function. Reinforcement learning is often applied to models based on the framework of MDP or POMDP.

In this paper, we follow a POMDP-based approach. A POMDP is defined as a tuple $\langle S, A, P, R, O, Z, \gamma, b_0 \rangle$ where S is the set of states (representing different contexts) which the system may be in (the system's world), A is the set of actions of the system, $P : S \times A \rightarrow P(S, A)$ is the set of transition probabilities between states after taking an action, $R : S \times A \rightarrow \Re$ is the reward function, O is a set of observations that the system can receive about the world, Z is a set of observation probabilities $Z : S \times A \rightarrow Z(S, A)$, and γ a discount factor weighting longterm rewards. At any given time step i the world is in some unobserved state $s_i \in S$. Because s_i is not known exactly, we keep a distribution over states called a belief state b, thus $b(s_i)$ is the probability of being in state s_i, with initial belief state b_0. When the system performs an action $\alpha_i \in A$ based on b, following a policy $\pi : S \rightarrow A$, it receives a reward $r_i(s_i, \alpha_i) \in \Re$ and transitions to state s_{i+1} according to $P(s_{i+1}|s_i, \alpha_i) \in P$. The system then receives an observation o_{i+1} according to $P(o_{i+1}|s_{i+1}, \alpha_i)$. The quality of the policy π followed by the agent is measured by the expected future reward also called Q-function, $Q^\pi : S \times A \rightarrow \Re$.

In this framework, it is critical to be able to learn a good policy function. In order to do so, we use Neural fitted Q Iteration (Riedmiller, 2005) for learning the system policy. Neural fitted Q Iteration is an offline value-based method, and optimizes the parameters to approximate the Q-function. Neural fitted Q Iteration repeatedly performs 1) sampling training experience using a POMDP through interaction and 2) training a Q-function approximator using training experience. Neural fitted Q Iteration uses a multi-layered perceptron as the Q-function approximator. Thus, even if the Q-function is complex, Neural fitted Q Iteration can approximate the Q-function better than using a linear approximation function[1].

3 Persuasive dialogue corpus

In this section, we give a brief overview of Hiraoka et al. (2014)'s persuasive dialogue corpus between human participants that we will use to estimate the models described in later sections.

[1]In a preliminary experiment, we found that Neural fitted Q Iteration had high performance compared to using the linear approximation of the Q-function in this domain.

Table 1: The beginning of a dialogue from the corpus (translated from Japanese)

Speaker	Transcription	GPF Tag
Cust	Well, I am looking for a camera, do you have camera B?	PROPQ
Sales	Yes, we have camera B.	ANSWER
Sales	Did you already take a look at it somewhere?	PROPQ
Cust	Yes. On the Internet.	ANSWER
Sales	It is very nice. Don't you think?	PROPQ
Cust	Yes, that's right, yes.	INFORM

SetQ	Commisive	Directive	

Table 3: An example of positive framing

(Camera A is) able to achieve performance of comparable single-lens cameras and can fit in your pocket, this is a point.

3.1 Outline of persuasive dialogue corpus

As a typical example of persuasive dialogue, the corpus consists of dialogues between a salesperson (persuader) and customer (persuadee). The salesperson attempts to convince the customer to purchase a particular product (decision) from a number of alternatives (decision candidates). This type of dialogue is defined as "sales dialogue." More concretely, the corpus assumes a situation where the customer is in an appliance store looking for a camera, and the customer must decide which camera to purchase from 5 alternatives.

Prior to recording, the salesperson is given the description of the 5 cameras and instructed to try to convince the customer to purchase a specific camera (the persuasive target). In this corpus, the persuasive target is camera A, and this persuasive target is invariant over all subjects. The customer is also instructed to select one preferred camera from the catalog of the cameras, and choose one aspect of the camera that is particularly important in making their decision (the determinant). During recording, the customer and the salesperson converse and refer to the information in the camera catalog as support for their dialogues. The customer can close the dialogue whenever they want, and choose to buy a camera, not buy a camera, or reserve their decision for a later date.

The corpus includes a role-playing dialogue with participants consisting of 3 salespeople from 30 to 40 years of age and 19 customers from 20 to 40 years of age. All salespeople have experience working in an appliance store. The total number of dialogues is 34, and the total time is about 340 minutes. Table 1 show an example transcript of the beginning of one dialogue. Further examples are shown in Table 8 in the appendix.

3.2 Annotated dialogue acts

Each utterance is annotated with two varieties of tags, the first covering dialogue acts in general, and the rest covering framing.

As a tag set to represent traditional dialogue acts, we use the general-purpose functions (GPF) defined by the ISO international standard for dialogue act annotation (ISO24617-2, 2010). All annotated GPF tags are defined to be one of the tags in this set (Table 2).

More relevant to this work is the *framing* annotation. Framing uses emotionally charged words to explain particular alternatives. It has been suggested that humans generally evaluate decision candidates by selecting based on several determinants weighted by the user's preference, and that framing is an effective way of increasing persuasive power. This corpus focuses on negative/positive framing (Irwin et al., 2013; Mazzotta and de Rosis, 2006), with negative framing using negative words and positive framing using positive words.

In the corpus, framing is defined as a tuple $\langle a, p, r \rangle$ where a represents the target alternative, p takes value NEG if the framing is negative, and POS if the framing is positive, and r represents whether the framings contains a reference to the persuadees preferred determinant (for example, the performance or price of a camera), taking the value TRUE if contained, and FALSE if not contained. The user's preferred determinant is annotated based on the results of a questionnaire.

Table 3 shows an example of positive framing (p=POS) about the performance of Camera A (a=A). In this example, the customer answered that his preference is the price of camera, and this utterance does

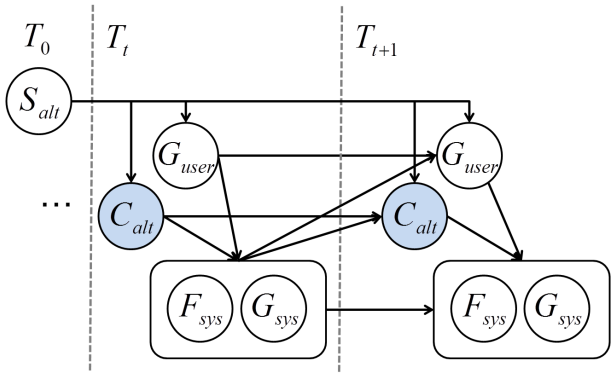

Figure 1: Dynamic Bayesian network of the user simulator. Each node represents a variable, and each edge represents a probabilistic dependency. The system cannot observe the shaded variables.

not contain any description of price. Thus, r=NO is annotated. Further examples of positive and negative framing are shown in Tables 9 and 10 in the appendix.

In this paper, we re-perform annotation of the framing tags and evaluate inter-annotator agreement, which is slightly improved from Hiraoka et al. (2014). Two annotators are given the description and examples of tags (e.g. what a positive word is), and practice with these manuscripts prior to annotation. In corpus annotation, at first, each annotator independently chooses the framing sentences. Then, framing tags are independently annotated to all utterances chosen by the two annotators. The inter-annotator agreement of framing polarity is 96.9% (kappa=0.903).

4 User simulator

In this section, we describe a statistical dialogue model for the user (customer in Section 3). This model is used to simulate the system's conversational partner in applying reinforcement learning.

The user simulator estimates two aspects of the conversation:

1. The user's general dialogue act.
2. Whether the preferred determinant has been conveyed to the user (conveyed preferred determinant; CPD).

The users' general dialogue act is represented by using GPF. For example, in Table 1, PROPQ, ANSWER, and INFORM appear as the user's dialogue act. In our research, the user simulator chooses one GPF described in Table 2 or $None$ representing no response at each turn. CPD represents that the user has been convinced that the determinant in the persuader's framing satisfies the user's preference. For example, in Table 3, the "performance" is contained in the clerk's positive framing for camera A. If the persuadee is convinced that the decision candidate satisfies his/her preference based on this framing, we say that CPD has occurred (r=YES)[2]. In our research, the user simulator models CPD for each of the 5 cameras. This information is required to calculate reward described in the following Section 5.1. Specifically, GPF and CPD are used for calculating naturalness and persuasion success, which are part of the reward function.

The user simulator is based on an order one Markov chain, and Figure 1 shows its dynamic Bayesian network. The user's GPF G^{t+1}_{user} and CPD C^{t+1}_{alt} at turn $t+1$ are calculated by the following equations.

$$P(G^{t+1}_{user}|G^t_{user}, F^t_{sys}, G^t_{sys}, S_{alt}) \quad (1)$$

$$P(C^{t+1}_{alt}|C^t_{alt}, F^t_{sys}, G^t_{sys}, S_{alt}) \quad (2)$$

G^t_{sys} represents the system GPF at time t. F^t_{sys} represents the system framing at t. These two variables correspond to system actions, and are explained in Section 5.2. G^t_{user} represents the user's GPF at t. C^t_{alt} represents the CPD at t. S_{alt} represents the users's original evaluation of the alternatives. In our

[2]Note that the persuader does not necessarily know if r=YES because the persuader is not certain of the user's preferred determinants.

research, this is the camera that the user selected as a preferred camera at the beginning of the dialogue[3]. We use the persuasive dialogue corpus described in Section 3 for training the user simulator, considering the customer in the corpus as the user and the salesperson in the corpus as the system. In addition, we use logistic regression for learning Equations (1) and (2).

5 Learning cooperative persuasion policies

Now that we have introduced the user model, we describe the system's dialogue management. In particular, we describe the reward, system action, and belief state, which are required for reinforcement learning.

5.1 Reward

We follow Hiraoka et al. (2014) in defining a reward function according to three factors: user satisfaction, system persuasion success, and naturalness. As described in Section 1, we focus on developing cooperative persuasive dialogue systems. Therefore, the system must perform dialogue to achieve both the system and user goals. In our research, we define three elements of the reward function as follows:

Satisfaction The user's goal is represented by subjective user satisfaction. The reason why we use satisfaction is that the user's goal is not necessarily clear for the system (and system creator) in persuasive dialogue. For example, some users may want the system to recommend appropriate alternatives, while some users may want the system not to recommend, but only give information upon the user's request. As the goal is different for each user, we use abstract satisfaction as a measure, and leave it to each user how to evaluate achievement of the goal.

Persuasive success The system goal is represented by persuasion success. Persuasion success represents whether the persuadee finally chooses the persuasive target (in this paper, camera A) at the end of the dialogue. Persuasion success takes the value SUCCESS when the customer decides to purchase the persuasive target at the end of dialogue, and FAILURE otherwise.

Naturalness In addition, we use naturalness as one of the rewards. This factor is known to enhance the learned policy performance for real users (Meguro et al., 2011).

The reward at each turn t is calculated with the following equation[4].

$$r_t = (Sat^t_{user} + PS^t_{sys} + N^t)/3 \quad (3)$$

Sat^t_{user} represents a 5 level score of the user's subjective satisfaction (1: Not satisfied, 3: Neutral, 5: Satisfied) at turn t scaled into the range between 0 and 1. PS^t_{sys} represents persuasion success (1: SUCCESS, 0: FAILURE) at turn t. N_t represents bi-gram likelihood of the dialogue between system and user at turn t as follows.

$$N_t = P(F^t_{sys}, G^t_{sys}, G^t_{user} | F^{t-1}_{sys}, G^{t-1}_{sys}, G^{t-1}_{user}) \quad (4)$$

In our research, Sat and PS are calculated with a predictive model constructed from the human persuasion dialogue corpus described in Section 3. In constructing these predictive models, the persuasion results (i.e. persuasion success and persuadee's satisfaction) at the end of dialogue are given as the supervisory signal, and the dialogue features in Table 4 are given as the input. In the reward calculation, the dialogue features used by the predictive model are calculated by information generated from the dialogue of the user simulator and the system. Table 4 shows all features used for reward calculation at each turn[5]. Note that, for the calculating TOTAL TIME, average speaking time corresponding to speakers and dialogue acts is added at each turn.

[3]Preliminary experiments indicated that the user behaved differently depending on the first selection of the camera, thus we introduce this variable to the user simulator.

[4]We also optimized the policy in the case where the reward (Equation (3)) is given only when dialogue is closed. However, the convergence of the learning was much longer, and the performance was relatively bad.

[5]Originally, there are more dialogue features for the predictive model. However as in previous research, we choose significant dialogue features by step-wise feature selection (Terrell and Bilge, 2012).

Table 4: Features for calculating reward. These features are also used as the system belief state.

Sat_{user}	Frequency of system commisive
	Frequency of system question
PS_{sys}	Total time
	C_{alt} (for each 6 cameras)
	S_{alt} (for each 6 cameras)
N	System and user current GPF
	System and user previous GPF
	System framing

Table 5: System framing. Pos represents positive framing and Neg represents negative framing. A, B, C, D, E represent camera names.

<Pos B, Answer>	<Pos E, Inform>
<None, Inform>	<None, Answer>
<None, Question>	<None, Commissive>
<None, Directive>	

5.2 Action

The system's action $\langle F_{sys}, G_{sys} \rangle$ is a framing/GPF pair. These pairs represent the dialogue act of the salesperson, and are required for reward calculation (Section 5.1). There are 11 types of framing (Table 5), and 9 types of GPF which are expanded by adding RELEASETURN and CLOSEDIALOGUE to the original GPF sets (Table 2). The number of all possible GPF/framing pairs is 99, and some pairs have not appeared in the original corpus. Therefore, we reduce the number of actions by filtering. We construct a unigram model of the salesperson's dialogue acts $P(F_{sales}, G_{sales})$ from the original corpus, then exclude pairs for which the likelihood is below 0.005[6]. As a result, the 13 pairs shown in Table 6 remained[7]. We use these pairs as the system actions.

5.3 Belief state

The current system belief state is represented by the features used for reward calculation (Table 4) and the reward calculated at previous turn. Namely, the features for the reward calculation and calculated reward are also used as the next input of the system policy. Note that the system cannot directly observe C_{alt}, thus the system estimates it through the dialogue by using the following equation.

$$P(\hat{C_{alt}^{t+1}} | \hat{C_{alt}^{t}}, F_{sys}^{t}, G_{sys}^{t}, S_{alt}) \tag{5}$$

where $\hat{C_{alt}^{t+1}}$ represents the estimated CPD at $t+1$. $\hat{C_{alt}^{t}}$ represents the estimated CPD at t. The other variables are the same as those in Equation (2). In contrast, we assume that the system can observe G_{user} and S_{alt}. G_{user} is not usually observable because traditional dialogue systems have automatic speech recognition/Spoken language understanding errors. However, in this work, we use Wizard of Oz in place of automatic speech recognition/Spoken language understanding (Section 6.2). Thus, we can ignore these factors[8].

6 Experimental evaluation

In this section, we describe the evaluation of the proposed method for learning cooperative persuasive dialogue policies. Especially, we focus on examining how the learned policy with framing is effective for persuasive dialogue. The evaluation is done both using a user simulator and real users.

[6]We chose this threshold by trying values from 0.001 to 0.01 with incrementation of 0.001. We select the threshold that resulted in the number of actions closest to previous work (Georgila, 2013).

[7]Cameras C and D are not popular, and don't appear frequently in the human persuasive dialogue corpus, and are therefore excluded in filtering.

[8]In addition to this reason, the G_{user} is not so essential to our research (GPF is general dialogue act), and we want to focus the CPD. This is the other reason that we assume that G_{user} is observable.

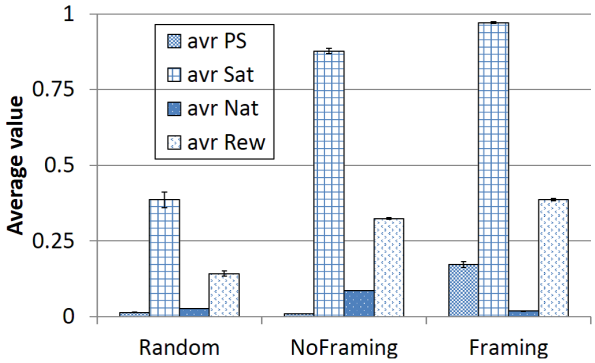

Figure 2: Average reward of each system. Error bars represents 95% confidence intervals. Rew represents the reward, Sat represents the user satisfaction, PS represents persuasion success, and Nat represents naturalness.

6.1 Policy learning and evaluation using the user simulator

For evaluating the effectiveness of framing and learning the policy through the user simulator, we prepare the following 3 policies.

Random A baseline where the action is randomly output from all possible actions.

NoFraming A baseline where the action is output based on the policy which is learned using only GPFs. For constructing the actions, we remove actions whose framing is not $None$ from the actions described in Section 5.2. The policy is a greedy policy, and selects the action with the highest Q-value.

Framing The proposed method where the action is output based on the policy learned with all actions described in Section 5.2 including framing. The policy is also a greedy policy.

For learning the policy, we use Neural fitted Q Iteration (Section 2). For applying Neural fitted Q Iteration, we use the Pybrain library (Schaul et al., 2010). We set the discount factor γ of learning to 0.9, and the number of nodes in the hidden layer of the neural network for approximating the Q-function to the sum of number of belief states and actions (i.e. Framing: 53, NoFraming: 47). The policy in learning is the ϵ-greedy policy ($\epsilon = 0.3$). These conditions follow the default Pybrain settings. We consider 50 dialogues as one epoch, and update the parameters of the neural network at each epoch. Learning is finished when number of epochs reaches 200 (10000 dialogues), and the policy with the highest average reward is used for evaluation.

We evaluate the system on the basis of average reward per dialogue with the user simulator. For calculating average reward, 1000 dialogues are performed with each policy.

Experimental results (Figure 2) indicate that 1) performance is greatly improved by learning and 2) framing is somewhat effective for the user simulator. Learned policies (Framing, NoFraming) get a higher reward than Random. Particularly, both of the learned policies better achieve user satisfaction than Random. On the other hand, only Framing is able to achieve better persuasion success than Random. This result indicates that framing is effective for persuasive success. In contrast, naturalness of Framing is not improved from Random. One of the reasons for this is that variance of Nat is smaller than those of the other factors, and the optimization algorithm favored the other two factors which had a higher variance.

6.2 Real user evaluation based on Wizard of Oz

To test whether the gains shown on the user simulator will carry over to an actual dialogue scenario, we perform an experiment with real human users. In addition to the policies described in Section 6.1, we add the following policy.

Human An oracle where the action is output based on human selection. In this research, the first author (who has no formal sales experience, but experience of about 1 year in analysis of camera sales dialogue) selects the action.

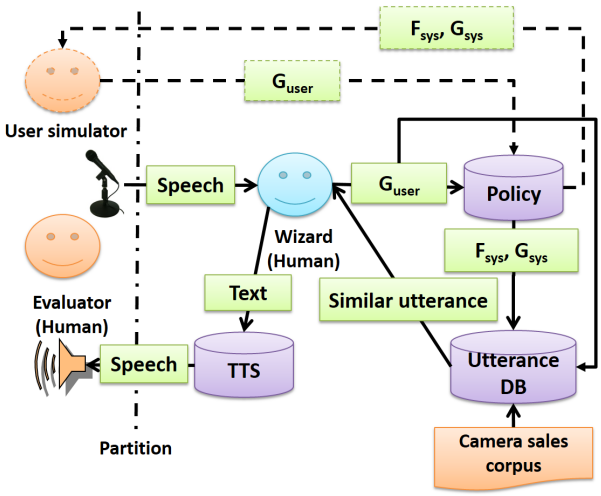

Figure 3: The experimental environment based on Wizard of Oz. The rectangle represents information, and the cylinder represents a system module. The information flow (dashed line) in the experiment through the user simulator is also shown for comparison.

Experimental evaluation is conducted, based on the Wizard of Oz framework. In the experiment, the wizard plays the salesperson, and the evaluator plays the customer. Dialogue is performed between the wizard and the evaluator. The wizard and evaluator are divided by a partition, and the evaluator cannot see or detect what the wizard is doing. The evaluator selects his/her preferred camera from the catalog before starting evaluation. Then, the evaluator starts the dialogue with the wizard who is obeying one of the policies (Figure 3). In particular, dialogue between wizard and evaluator proceeds based on the following steps.

1. The evaluator talks to the wizard using the mic. In this step, the evaluators can close the dialogue if they want.
2. The wizard listens to the evaluator's utterance, translating the utterance into the appropriate G_{user}. Then, the wizard inputs G_{user} to the policy module.
3. The policy module decides action sequences (F_{sys}, G_{sys}) based on G_{user}, then outputs the action to the utterance database module. This module is constructed from the camera sales corpus (Section 3).
4. The utterance database module searches for similar sentences that match the history of input actions and G_{user} so far, then outputs the top 6 similar utterances to the wizard.
5. The wizard generates the system utterance (Text) using the retrieved sentences. The wizard selects one sentence which best matches the context[9]. If the wizard determines the sentence is hard to understand, the wizard can correct the sentence to be more natural.
6. The wizard inputs the system utterance to text-to-speech, then waits for the next evaluator utterance (back to step 1).

Finally, the evaluator answers the following questionnaire for calculating the evaluation measures in Section 5.1.

Satisfaction The evaluator's subjective satisfaction defined as a 5 level score of customer satisfaction (1: Not satisfied, 3: Neutral, 5: Satisfied).

Final decision The camera that the customer finally wants to buy.

We use SofTalk (cncc, 2010) as text-to-speech software.

Evaluation criteria are basically same to those of previous section (described in Section 5.1). Note that in the previous section, Sat_{user} and PS_{sys} are estimated from the simulated dialogue. In contrast to the previous section, Sat_{user} and PS_{sys} are calculated from the result of the real user's questionnaire

[9]Note that the wizard is not allowed to create the utterance with complete freedom, and selects an utterance from the utterance database even when Human policy is used.

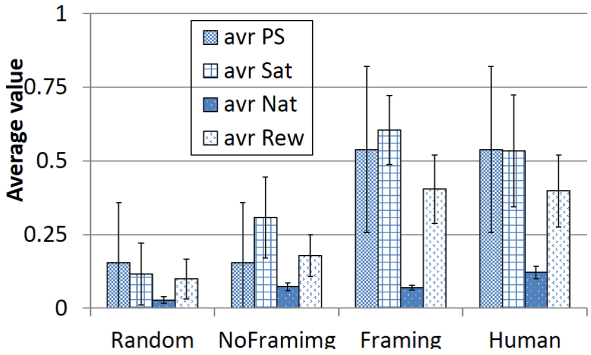

Figure 4: Evaluation results for real users. Error bars represent 95% confidence intervals. Rew represents the reward, Sat represents the user satisfaction, PS represents persuasion success, and Nat represents naturalness.

Eva	I think B sounds good.		ANSWER
Wiz	Yes, B is popular with zoom,	Pos B	INFORM
Wiz	But, A has extremely good performance. Camera A has almost the same parts as a single lens camera, and is more reasonably priced than a single lens-camera.	Pos A	ANSWER
Wiz	How about it?		RELEASET

(described in the previous paragraph)[10] based on the definition of Sat_{user} and Sat_{user} in Section 6.1. The naturalness is automatically calculated by the system, in the same manner as described in the previous section. Finally, reward is calculated considering Sat_{user}, PS_{sys} and naturalness according to Equation 3.

Participants consist of 13 evaluators (3 female, 10 male) and one wizard. Evaluators perform one dialogue with the wizard obeying each policy (a total of 4 dialogues) in random order.

Experimental results (Figure 4) indicate that framing is effective in persuasive dialogues with real users, and that the reward of Framing is higher than NoFraming and Random, and almost equal to Human. In addition, the score of NoFraming is almost equal to Random. This indicates that despite the fact that it performed relatively well in the simulation experiment, NoFraming is not an effective policy for real users. In addition, the score of NoFraming is lower than the score given by the user simulator. In particular, persuasion success is drastically decreased. This indicates that framing is important for persuasion.

We can see that some features in human persuasive dialogue appear in the dialogue between users and the wizard using the Framing policy. An example of a typical dialogue of Framing is shown in Table 7. The first feature is that the system also recommends camera B when the system does positive framing of camera A, which is the persuasive target. This feature was found by Hiraoka et al. (2014) to be an indicator of persuasion success in the camera sales corpus. The second feature is that the system asks the user about the user's profile at the first stage of the dialogue. This feature is often found when user satisfaction is high. The second feature also appeared in the dialogue with NoFraming. However, NoFraming does not use framing, and asks the user to make a decision (DIRECTIVE). An example utterance from the DIRECTIVE class is "Please, decide (which camera you want to buy) after seeing the catalog".

Considering the evaluation result of the previous section, we can see that Sat and PS differ between the user simulator and the real users ($p < .05$). While the general trend of showing improvements for

[10]Note that, though systems estimate the satisfaction and evaluator's decision at each turn for the belief state, the human evaluator answers the questionnaire only when the dialogue is closed.

satisfaction and persuasive success is identical in Figures 2 and 4, the systems are given excessively high Sat in simulation. In addition, systems (especially Framing) are given underestimated PS in simulation. One of the reasons for this is that the property of dialogue features for the predictive model for reward differs from previous research (Hiraoka et al., 2014). In this paper, dialogue features for the predictive model are calculated at each turn. In addition, persuasion success and user satisfaction are successively calculated at each turn. In contrast, in previous research, the predictive model was constructed with dialogue features calculated at end of the dialogue. Therefore, it is not guaranteed that the predictive model estimates appropriate persuasion success and user satisfaction at each turn. Another reason is that the simulator is not sufficiently accurate to use for reflecting real user's behavior. Compared to other works (Meguro et al., 2010; Misu et al., 2012), we are using a relatively small sized corpus for training the user simulator. Therefore, the user simulator cannot be trained to accurately imitate real user behavior. Improving the user simulator is an important challenge for future work.

7 Related work

There are a number of related works that apply reinforcement learning to persuasion and negotiation dialogue. Georgila and Traum (2011) apply reinforcement learning to negotiation dialogue using user simulators divided into three types representing individualist, collectivist, and altruist. Dialogue between a florist and a grocer are assumed as an example of negotiation dialogue. In addition, Georgila (2013) also applies reinforcement learning to two-issue negotiation dialogue where participants have a party, and decide both the date and food type. A handcrafted user simulator is used for learning the policy of each participant. Heeman (2009) models negotiation dialogue, assuming a furniture layout task, and Paruchuri et al. (2009) model negotiation dialogue, assuming the dialogue between a seller and buyer.

Our research differs from these in three major ways. The first is that we use framing, positive or negative statements about the particular item, which is known to be important for persuasion (Irwin et al., 2013). By considering framing, the system has the potential to be more persuasive. While there is one previous example of persuasive dialogue using framing (Mazzotta et al., 2007), this system does not use an automatically learned policy, relying on handcrafted rules. In contrast, in our research, we apply reinforcement learning to learn the system policy automatically.

In addition, in these previous works, rewards and belief states are defined with heuristics. In contrast, in our research, reward is defined on the basis of knowledge of human persuasive dialogue. In particular, we calculate the reward and belief state using the predictive model of Hiraoka et al. (2014) for estimating persuasion success and user satisfaction using dialogue features. In the real world, it is unclear what factors are important for achieving the dialogue goal in many persuasive situations. By considering these predictions as knowledge of human persuasion, the system can identify the important factors in human persuasion and can track the achievement of the goal based on these.

Finally, these works do not evaluate the learned policy, or evaluate only in simulation. In contrast, we evaluate the learned policy with real users.

8 Conclusion

We apply reinforcement learning for learning cooperative persuasive dialogue system policies using framing. In order to apply reinforcement learning, a user simulator and reward function is constructed based on a human persuasive dialogue corpus. Then, we evaluate the learned policy and effect of framing using a user simulator and real users. Experimental evaluation indicates that applying reinforcement learning is effective for construction of cooperative persuasive dialogue systems that use framing.

In the future, we plan to construct a fully automatic persuasive dialogue system using framing. In this research, automatic speech recognition, spoken language understanding and natural language generation are performed by a human Wizard. We plan to implement these modules and evaluate system performance. In addition, in this research, corpus collection and evaluation are done in a role-playing situation. Therefore, we plan to evaluate the system policies in a more realistic situation. We also plan to consider non-verbal information (Nouri et al., 2013) for estimating persuasive success and user satisfaction.

Customer	Hello.	INFORM
Customer	I'm looking for a camera for traveling. Do you have any recommendations?	PROPQ
Clerk	What kind of pictures do you want to take?	SETQ
Customer	Well, I'm the member of a tennis club, and want to take a picture of landscapes or tennis.	ANSWER
Clerk	O.K. You want the camera which can take both far and near. Don't you?	PROPQ
Clerk	Well, have you used a camera before?	PROPQ
Customer	I have used a digital camera. But the camera was cheap and low resolution.	ANSWER
Clerk	I see. I see. Camera A is a high resolution camera. A has extremely good resolution compared with other cameras. Although this camera does not have a strong zoom, its sensor is is almost the same as a single-lens camera.	INFORM
Customer	I see.	INFORM
Clerk	For a single lens camera, buying only the lens can cost 100 thousand yen. Compared to this, this camera is a bargain.	INFORM
Customer	Ah, I see.	INFORM
Customer	But, it's a little expensive. right?	PROPQ
Customer	Well, I think, camera B is good at price.	INFORM
Clerk	Hahaha, yes, camera B is reasonably priced.	ANSWER
Clerk	But its performance is low compared with camera A.	INFORM
Customer	If I use the two cameras will I be able to tell the difference?	PROPQ
Clerk	Once you compare the pictures taken by these cameras, you will understand the difference immediately. The picture itself is very high quality. But, camera B and E are lower resolution, and the picture is a little bit lower quality.	ANSWER
Customer	Is there also difference in normal size pictures?	PROPQ
Clerk	Yes, whether the picture is small or large, there is a difference	ANSWER
Customer	Considering A has single-lens level performance, it is surely reasonable.	INFORM
Clerk	I think so too.	INFORM
Clerk	The general price of a single-lens is about 100 or 200 thousand yen. Considering these prices, camera A is a good choice.	INFORM
Customer	Certainly, I'm interested in this camera.	INFORM
Clerk	Considering its performance, it is a bargain.	INFORM
Customer	I think I'll go home, compare the pictures, and think a little more.	COMMISIVE
Clerk	I see. Thank you.	DIRECTIVE

Table 9: Example positive framing of a salesperson's utterance $\langle a_i = \mathrm{B}, p_i = \textsc{pos}, r_i = \textsc{yes}\rangle$. In this example, the customer has indicated price as the preferred determinant.

Hahaha, yes, camera B is reasonably priced.

Table 10: Example negative framing of a salesperson's utterance $\langle a_i = \mathrm{B}, p_i = \textsc{neg}, r_i = \textsc{no}\rangle$. In this example, the customer has indicated price as the preferred determinant.

But, considering the long term usage, you might care about picture quality. You might change your mind if you only buy a small camera (Camera B).

Towards multimodal modeling of physicians' diagnostic confidence and self-awareness using medical narratives

Abstract

Misdiagnosis is a problem in the medical field, often related to physicians' cognitive errors. Overconfidence is considered a major cause of such errors. Intelligent diagnostic support systems could benefit from understanding how aware physicians are of their performance when they estimate their confidence in a diagnosis (i.e. a physician's *diagnostic self-awareness*). Shedding light on the cognitive processes related to such awareness could also help improve medical education. We use a multimodal dataset of medical narratives to computationally model diagnostic confidence and self-awareness based on physicians' linguistic and eye movement behaviors. Dermatologists viewed images of cutaneous conditions, providing a description, diagnosis, and certainty level for each image case, while their speech and eye movements were recorded. We define both a generalized and a personalized approach to binning confidence levels, used in classification experiments. We also introduce truly multimodal features, which focus on combining linguistic and eye movement data into multimodal attributes. Results indicate that combinations of multiple modalities can outperform their constituent modalities in isolation for these problems.

1 Introduction

Misdiagnosis in the medical field is estimated to be as high as 10%-15% (Berner and Graber, 2008; Croskerry, 2009). Such errors can result in incorrect or delayed treatment, causing patients to experience additional suffering. Graber et al. (2002) describe three types of diagnostic errors: *no-fault* errors, resulting from atypical disease presentation or limitations of medical knowledge; *system* errors, resulting from problems with the health care system; and *cognitive* errors, resulting from biases or faulty interpretation on the part of a physician. Cognitive errors in particular have potential for substantial reduction through education and training aimed at developing clinicians' metacognitive skills. Understanding the cognitive processes of physicians during diagnosis is also of critical importance for building human-centered diagnostic support systems, which could help detect and flag problematic diagnostic self-awareness cases. Examples of cognitive errors include settling on a final diagnosis too early, without ever considering the correct diagnosis (Berner and Graber, 2008), or confirmation bias, in which only evidence to confirm a diagnostic hypothesis is considered (Croskerry, 2003). Overconfidence is generally thought to be a major cause of such errors (Berner and Graber, 2008; Croskerry, 2008). For example, an overconfident physician may not question her original thoughts or explore alternative diagnoses until later in the treatment process. In general, overconfidence may be a systemic problem, reinforced by patients' preferences for confident doctors, and by a professional environment that favors decisive actions (Katz, 1984). Similarly, underconfidence can erode patients' trust in their providers. In this study, we view the interplay between confidence[1] and correctness as a two-dimensional problem (see Figure 1). Ideally, physicians would have high confidence when correct and low confidence when incorrect, indicated by the upper-left and lower-right quadrants in Figure 1.

[1]For consistency, this paper uses the term *confidence*, treated as interchangeable with *certainty* and similar synonymous expressions which may have been used by clinicians in the medical narratives, such as *sure*, *certain*, *confident*, etc.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1718–1727, Dublin, Ireland, August 23-29 2014.

	Correct	Incorrect
Confident	Appropriate Confidence	Overconfidence
Not confident	Underconfidence	Appropriate Confidence

Figure 1: Two-dimensional view of the confidence and correctness relationship as it relates to *diagnostic self-awareness*. A similar conceptual model is presented by Pon-Barry and Shieber (2011). Ideally, physicians should have high confidence when they are correct and low confidence when incorrect.

Contribution Diagnostic self-awareness is an important phenomenon with implications for clinical training and practice, yet has received little focus from a computational perspective. We report on computational modeling for predicting the confidence and correctness interplay in diagnosis using features of physicians' speech, eye movements, and combinations thereof, as dermatologists performed medical image inspection tasks while narrating their diagnostic thought process. In dermatology, visual expertise and clinical knowledge are both important. A motivation behind our multimodal approach is that medical image inspection relies on both the physician's visual perceptual expertise and conceptual knowledge base, each of which can be regarded as expressed by eye movement behavior and linguistic behavior, respectively. We aim to apply this decision modeling to intelligent diagnostic support and clinical tutoring systems. Here we solve a foundational problem by successfully modeling the complex relationship between physicians' confidence in and correctness of their diagnoses. We also make contributions in multimodal and linguistic feature analysis: carefully assessing feature modalities that represent physicians' behaviors, and introducing a novel multimodal feature type that focuses on fusing eye movement and verbal data.

2 Previous Work

Although there are many causes of diagnostic errors (Graber et al., 2005), those resulting from cognitive errors may be the most challenging to reduce (Croskerry, 2003; Graber et al., 2002), while their reduction provides high impact. Examples of such errors include flawed perception, biased heuristics, and settling on a final diagnosis too early (Graber et al., 2002), all of which can be caused by overconfidence (Berner and Graber, 2008; Croskerry, 2008). Underconfidence may also be a problem if it prevents a physician from pursuing a correct diagnosis (Friedman et al., 2005).

There is evidence for links between speech and confidence in terms of prosodic features, such as pitch and loudness (Scherer et al., 1973; Pon-Barry and Shieber, 2011; Kimble and Seidel, 1991), as well as other characteristics of spoken language, such as speech disfluencies (Womack et al., 2012) and hedges (Smith and Clark, 1993). Prosodic features have been identified and successfully used in intelligent tutoring systems (Liscombe et al., 2005), where a student's confidence (or lack thereof) can play a key role in effective system response. In medical diagnosis, prosodic and lexical features have been useful indicators of physicians' confidence and diagnostic correctness, individually (Womack et al., 2013; McCoy et al., 2012). Other potentially useful information may be evident in speech as well. In a study by Womack et al. (2012) on a similar dataset, the authors found a relationship between speech characteristics and physician experience: attending (experienced) physicians used more filled pauses and spoke more than resident (in-training) physicians. Additionally, verbal features may expose differences in diagnostic reasoning that may be useful predictors of confidence. Rogers (1996) analyzed a dataset of spoken chest X-ray examinations by radiologists, remarking that reasoning styles influence physicians' expectations, and confirmations or contradictions of those expectations can affect their self-reported confidence levels.

Most relevant literature focuses on linguistic features. Language, as the primary form of human expression, is certainly critical. However, analyzing meaning may require going beyond linguistic inference, depending on the context or application. Previous studies have successfully incorporated multiple expressive modalities when examining linguistic and cognitive processes, such as facial expressions for video sentiment analysis (Pérez-Rosas et al., 2013) and pointing gestures for referring actions (Gatt and Paggio, 2013). In such studies, the additional modalities were carefully chosen based on the nature of the performed tasks. Here, we deal with experts (dermatologists) inspecting images (skin conditions) for diagnostic purposes, a task that heavily involves their use of visual perceptual expertise, in addition to conceptual domain knowledge. For this reason, we incorporate features of their eye movements in our study. There is evidence for ties between perceptual expertise and eye movements during image inspection tasks (Li et al., 2012b), and we explore if such ties may also relate to a physician's confidence and diagnostic self-awareness.

Integrating different expressive modalities is challenging. Previous work involving multimodality has predominantly treated each in isolation. We further address this challenge by identifying and exploring truly *multimodal* features that focus on combining verbal and eye movement data into complex multimodal attributes, as it seems reasonable that the two modalities together could be more informative if linked, and that such complex features represent a natural interactive extension of multimodal semantics. Evidence for ties between speech and eye movements specifically was found by Li et al. (2012a), in which sequences of fixations and saccadic eye movements were identified to predominantly align with particular conceptual units of thought (e.g. primary lesion type) expressed verbally in medical narratives.

3 Data Description and Analysis

This study takes advantage of a dataset previously reported on by Womack et al. (2013), which is briefly described here for clarity, as Womack et al.'s work ignored the eye movement data. A group of 29 dermatologists (11 attending physicians, 18 residents) were each shown a series of 30 images of dermatological conditions in random order and asked to narrate their diagnosis of each condition. They were asked to provide a description of the case, a list of differential diagnoses to consider, a final diagnosis, and their certainty of their final diagnosis, as a percentage. The physicians' verbal descriptions were recorded as audio and later manually transcribed in detail, including pauses, disfluencies, and other speech phenomena.[2] During this process, the physicians' eye movements were also tracked. Each image was displayed on a 22" LCD monitor (1650x1050 pixels) with an attached 250Hz SensoMotoric Instruments RED remote eye-tracker while IViewX software was recording the eye movements.

In this study, the time-aligned pair of verbal description and eye movements for one physician viewing one image is henceforth called a *narrative*. Figure 2a shows an example of a verbal description for one narrative and Figure 2b shows a visualization of the corresponding eye movements. The correct diagnoses for all images were known for the experiment and each narrative was assigned a binary label of *correct* or *incorrect*.[3] For the purposes of this multimodal study, 238 of the 870 narratives were excluded due to technical issues that had occurred with the eye tracking or audio capture equipment, or because the physicians had provided no confidence values for their diagnoses. The remaining 632 narratives were used for the analysis and experimentation reported on in this paper.

3.1 Case Studies towards Understanding Physicians' Confidence and Correctness

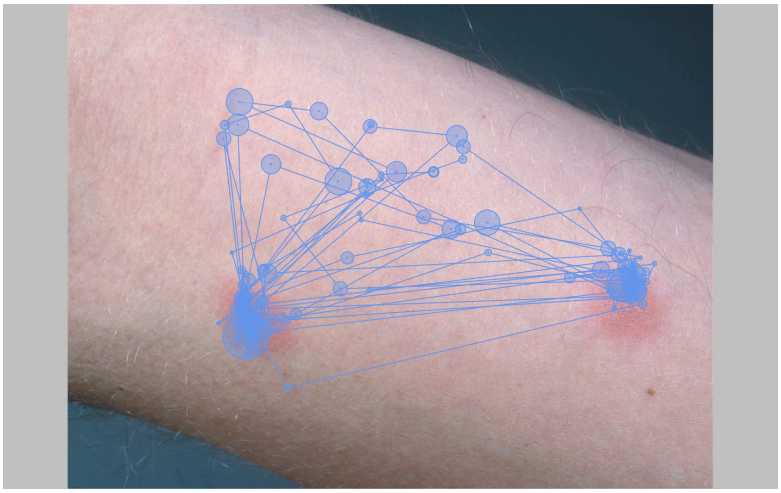
The physicians tended to evaluate their confidence towards the upper end of the spectrum, with a median of 70% confident over all narratives. But diagnostic confidence may be affected by many factors, including professional experience, case difficulty, and personality. We examine both individual images and physicians at the extremes of confidence to gain insight into the relationship between confidence and correctness in the dataset. Table 1 summarizes information for the three image cases that received the

[2] Some transcription imperfections may occur.

[3] A limited number of narratives in the dataset were labeled *half* correct if one of two final diagnoses given was correct, and *partially* correct if the final diagnosis was too broad. Here, we consider *half* to be correct, because in such cases the correct diagnosis was still identified, but *partial* to be incorrect, because the correct diagnosis was technically not identified.

... um two ... pa- ... pink to purple macules ... on the ... volar wrist differential diagnosis ... um fixed drug eruption ... bites ... urticaria ... uh ... diagnosis fixed drug eruption percent certainty fifty percent next ...

(a) Sample verbal description. Ellipses ("...") show pauses.



(b) Sample eye movement visualization. Circles represent *fixations*, where the center is the point of fixation and the radius is proportional to the time fixating at that point. Lines represent *saccades* (movements) between fixation points.

Figure 2: Sample verbal description and eye movements for one narrative. The final diagnosis is correct and the physician was 50% confident.

Confidence	Conf.	% Correct	Rank
Highest	100	100	2
	90	100	5
	90	100	1
Lowest	50	24	25
	50	35	29
	45	0	20

Confidence	Conf.	% Correct	Exp.
Highest	90	53	R
	85	50	A
	85	41	R
Lowest	38	39	A
	30	48	R
	15	37	R

Table 2: Most and least confident physicians by median confidence values given over all images. The last column shows experience level: experienced attending (A) or resident (R) physician.

highest median confidence values and the three that received the lowest. A domain expert (dermatologist and clinical educator) who was not a subject in the experiment gave each image a unique difficulty ranking from 1 to 30, where the image ranked number 1 was considered the easiest to support a correct diagnosis, and 30 the most difficult. As expected, the highest confidence images were among the easiest, and vice versa. Accordingly, the higher confidence images were correctly diagnosed by every physician, while those receiving the lowest confidence were correctly diagnosed much less often. The negative correlation between image difficulty and median physician confidence was significant using Spearman's rank correlation ($r_s = -0.544$, $p < 0.005$). In other words, higher levels of case difficulty were associated with lower levels of physician confidence. In contrast, examination of the most and least confident physicians yields less intuitive results. The physicians with the highest and lowest median confidence values are shown in the top and bottom halves of Table 2, respectively. Notably, each of the two groups contained both resident dermatologists-in-training and attending physicians with careers spanning multiple decades. Also, the most confident physicians were only correct roughly half of the time, and the least confident physicians' correctness appears quite similar. While this may reflect the sample size, the observation is interesting nonetheless. Clearly, this points to how complicated diagnostic self-awareness is, and how potentially useful it would be to computationally infer a physician's self-awareness for diagnostic cases based on their behaviors.

3.2 Confidence Binning

Nearly all confidence values given were multiples of five, or simply numbers close to 100, such as 99%.[4] This makes discretization preferable to using real-numbered values for confidence. Additionally, the analyses in Section 3.1 revealed patterns of over- or underconfidence in individual physicians. What this indicates is that "high" and "low" confidence involve different numerical values in the minds of different physicians. This subjectivity could be problematic in doctor-patient interactions and it adds complexity for predictive modeling involving confidence. To explore the impact, we devise two alternative binary binning schemes: *generalized* bins, based on the performance of all physicians in the dataset, and *personalized* bins, based on each individual physician's performance in the training data only. In terms of application, consider a diagnostic support system which could establish a history for each physician who uses it. Such a system could implement a generalized binning scheme and predictive model for new users, and later, after learning from repeated exposure to a given physician, switch to a model based on that physician's individual performance. In addition, binning choice may be influenced by context: in a clinical tutoring system, it may be preferable to compare learners to experienced physicians as a target population. For the *generalized* binning scheme, a confidence value greater than or equal to the median over all physicians is considered *high*, while a value below is considered *low*. This results in a slight imbalance towards *high* confidence (56% of narratives).[5] We construct the *personalized* binning scheme similarly, but using a given physician's own median confidence in the training data as the dividing line. In this case, *high* confidence accounts for 58% of the narratives, similar to that of the generalized bins. Calling a physician's median confidence *high* lets us better distinguish the problem cases: cases of underconfidence should be strictly less than their "typical" confidence, while cases of overconfidence should be at or above typical. The binning scheme used does not affect the correctness value for each narrative, but it does change the distribution of high and low confidence, with the *generalized* scheme favoring over- and underconfidence, and the *personalized* scheme favoring appropriate confidence. Arguably, the latter is a better reflection of the expected: over- and underconfidence as the minority classes.

4 Approach and Methodology

There are many ways to approach the problem of predicting physicians' diagnostic self-awareness. Here we formulate two classification problems, each tested under both binning schemes, yielding a total of four classification models. We also outline the performance evaluation experiments for the models.

4.1 Classification Problems

We define two classification problems based on the chart in Figure 1 (above). First, we define *Confidence Only*, which ignores correctness (the horizontal dimension of Figure 1) and predicts only confidence as a binary *high* or *low*. Intuitively, low confidence might be considered a warning sign for a diagnosis, alerting a physician to seek additional insight or information.[6] This first problem was used as a stepping stone to explore and better understand confidence, before incorporating correctness. Next, we define *Confidence & Correctness*, which relates confidence with the correctness of the diagnosis (considering all four quadrants in Figure 1, individually) to better address the more problematic, but interesting, cases. Distinguishing these four classes could be of use to intelligent tutoring or clinical support systems, which could respond differently to over- or underconfident users. In general, the full separation of these classes could ultimately allow for deeper analysis of physician self-awareness.

4.2 Model Evaluation

Before any development took place, the 632 narratives were randomly divided into three subsets: 442 (70%) for training (*dev-train*), 95 (15%) for testing during development and tuning (*dev-test*), and 95

[4]There were only a few exceptions: one physician gave three values of 3%, another gave a 33% and a 66% (rounded down from "two-thirds"), and a third gave a 33%. The latter three cases could also seem intuitive depending on how many conditions were listed in the differential diagnosis. For example, 66% might indicate that one disease seemed twice as likely as a another.

[5]Other simple binning schemes dividing up the 0-100% range were explored, but this binary version allowed for a more systematic approach to both generalized and personalized binning, without sacrificing performance.

[6]Normally, a physician would likely administer tests after the differential diagnosis, before reaching a final diagnosis.

(15%) for final summative evaluation after all development was completed (*heldout-test*). All three subsets have similar class distributions. Each of the four classification models were evaluated in two ways: (1) by training the model on the union of the *dev-train* and *dev-test* sets and testing on the *heldout-test* set, and (2) by running 50 randomized iterations of 10-fold cross-validation on the entire collection of 632 narratives. The first evaluation experiment addresses the problem of overfitting by excluding the *heldout-test* set from all development, while the second addresses the problem of sampling bias in the initial set divisions. The results are described in Section 5.2.

5 Models and Results

Here we describe the development and performance of each of the four computational models outlined in Section 4. We report on logistic regression, which had the best performance in all metrics for all experiments, after dimensionality reduction (see Section 5.1). The feature selection and modeling was implemented in Python with the `scikit-learn` machine learning library (Pedregosa et al., 2011).

5.1 Feature Extraction and Selection

A total of 60 features were examined (see Table 3). The features represented three modalities, motivated by the task the physicians performed and knowledge about dimensions of clinical expertise in this domain: *verbal*, composed of lexical, prosodic, and structural features of the narratives; *eye movement*, consisting of features of fixations and saccadic eye movements; and truly *multimodal* features, consisting of overlapping or simultaneously occurring features from the other two modalities, to reflect integrated multimodal semantics. Continuing with the theme of personalization, we also created a fourth category of *personal* features, with demographics of the physician and statistics about their confidence and correctness in the training data, in order to model their "past" performance. The latter simulates how a system could learn from experience with a particular physician.

As discussed in Section 2, verbal features of confidence have been studied before, and many of the verbal features used here are inspired by previous work. Some verbal features are based on word choice, such as *amplifiers* (e.g. *definitely*, *sure*) and *modals* (e.g. *could*, *might*),[7] while other have to do with silences (or pauses) or prosody. The eye movement and multimodal features are mostly concerned with fixations, as it seems intuitive that fixation may be associated with thoughtfulness about a particular area of the image, which may in turn reflect a physician's confidence.

Initial feature selection was performed on the development data (*dev-train* and *dev-test*) using `scikit-learn`'s random forest ensemble classifier. This allowed for human-friendly inspection of useful features. Random forests (Breiman, 2001) are an ensemble method in which numerous decision trees are constructed, each trained on a randomized subset of the development data, which allows for the utility of features to be evaluated on many sub-distributions of the data. The importance of a feature can then be approximated as the sum of the error reduction at each node that splits on that feature, weighted by the population size at that node. This reflects the fact that features used near the root of the tree often handle a larger number of individuals. The importance values for all features will sum to 1. We consider any feature that appeared in the top 20 of the ranked features for any model to be important, and all such types of features are marked in bold in Table 3. Interestingly, the useful features for all classification models were almost the same, with a few transpositions in the ordering. The exception was *past confidence*, which was useful under generalized, but disappeared under personalized, as expected, since the personalized scheme effectively normalizes each physician's confidence values.

Interpreting the results for the verbal features, *silence duration* (statistics about the durations of all silences) and the *duration of narrative* were most useful. Intuitively, this may relate to thoughtfulness or contemplation. Additionally, *words per second*, or speech rate, was also useful, again perhaps relating to more careful or thorough inspection/diagnosis. As discussed earlier, ties between speech and confidence have been well-studied, while eye movements are underreported. It seems intuitive that eye movement

[7] Such word-choice features were mostly based on lexical lists, and some overlap may occur. The *cutaneous conditions* feature contained multiword expressions. These could be improved by using resources such as UMLS (`http://www.nlm.nih.gov/research/umls/`) or WordNet (`http://wordnet.princeton.edu/`).

Verbal (29)		Multimodal (14)
Duration of narrative	Pronouns 1st (n, %)	**% of initial silence time fixating**
Number of silences	Pronouns 3rd (n, %)	**% of total silent time fixating**
Silence duration ($\underline{\Sigma}$, $\underline{\mu}$, $\underline{\sigma}$)	Modals (n, %)	**% of total fixation time silent**
Duration of initial silence	Amplifier words (n, %)	Words per second during fixation
Number of filled pauses	Speculative words (n, %)	**Pitch during fixations** ($\underline{\mu}$, $range$)
Word type-token ratio	Negations (n, %)	**Intensity during fixations** ($\underline{\mu}$, $range$)
Words per second	**Pitch** ($\underline{m}$, M, μ)	Pitch of filled pauses (m, M, μ)
Cutaneous conditions (n, %)	Intensity (m, M, μ)	Intensity of filled pauses (m, M, μ)

Eye movement (11)		Personal (6)	
Fixation duration ($\underline{\Sigma}$, μ, σ)	**Number of fixations**	Attending vs. Resident	Past correctness
Saccade duration ($\underline{\Sigma}$, $\underline{\mu}$, $\underline{\sigma}$)	**% image area fixated**	Years of experience	
Saccade amplitude ($\underline{\Sigma}$, $\underline{\mu}$, $\underline{\sigma}$)		**Past confidence** ($\underline{m}$, M, μ)	

Table 3: Features examined for classification (60 total), grouped by modality. Symbols in parentheses indicate statistics over all occurrences of a feature in a narrative: raw count (n), raw count divided by the total number of words (%), sum (Σ), mean (μ), standard deviation (σ), min (m), max (M), range ($range$). Useful features are boldfaced. If a feature has multiple statistics, the useful ones are underlined.

features may be more related to correctness. For example, the most useful eye movement feature was *% image area fixated*, computed using a grid overlaid onto the image. If more of the image was fixated upon, then it may have contained more areas of interest, or more visual evidence may have been sought, which may also be related to case difficulty. Similarly, features of *saccade amplitude* (the angle of a saccadic eye movement) may reflect physicians feeling a need to explore additional visual evidence by switching focus between distant areas in an image. It is not surprising that the useful individual features from verbal and eye movement modalities were also useful when combined as multimodal features. In particular, simultaneous silence and fixation were the most useful, which again might indicate contemplation and analytical cognitive processing. This suggests that expression of confidence and diagnostic self-awareness is at least partially a multimodal phenomenon.

Although the random forest method could be used for dimensionality reduction, we instead use Principle Component Analysis (PCA) in evaluation below, as it gave better performance gains in development. The purpose of the random forest method was to examine which verbal, eye movement, and multimodal features were most informative for classification, as we are interested in understanding how these modalities relate to confidence and correctness. The latent features resulting from PCA are linear combinations of the features, and thus would not allow for such inspection. The number of PCA components was optimized for classification accuracy in cross-validation for each of the four classification models. Each problem had a different number of principal components, indicating that both the binning scheme and the classification problem type affected which features were identified as more collectively discriminative by PCA.

5.2 Results and Evaluation

Heldout narratives We addressed the problem of overfitting by withholding 15% ($n = 95$) of the narratives as an unseen final evaluation set. All predictive models performed well above their respective majority class baselines (see Table 4). The Confidence Only models were able to reach higher accuracy, precision, and recall than the joint Confidence & Correctness models. The exception is the accuracy relative to baseline for personalized Confidence Only, which may be due to its higher baseline. As mentioned in Section 3.2, the generalized binning scheme is biased towards over- and underconfidence, and the personalized towards appropriate confidence. The per-class metrics (not shown here) reflect this fact, with overconfidence having higher precision and recall under generalized binning than under personalized. Additionally, under the personalized scheme underconfidence is particularly underrepresented and thus more difficult to predict.

Binning	Problem	N	Majority Class	% BL	% Acc.	P	R
Generalized	Conf. Only	2	High Confidence	53	76 (+23)	0.76	0.76
	Conf. & Corr.	4	Overconfidence	37	53 (+16)	0.42	0.42
Personalized	Conf. Only	2	High Confidence	65	77 (+12)	0.75	0.73
	Conf. & Corr.	4	Appropriate High	37	53 (+16)	0.38	0.42

Table 4: Performance metrics for the *heldout-test* set under each binning scheme with logistic regression and PCA. All four models performed well above the majority class baselines (% BL) of their respective problems (each with N many class labels). Precision (P) and recall (R) are each macro-averaged.

Random cross-validation A potential drawback of the initial development strategy used here is that the initial random splits may bias classification models. To address this problem, after the heldout testing, 50 randomized iterations of 10-fold cross-validation were performed on the total collection of narratives, the results of which are in Table 5. The personalized binning scheme was designed to mimic a system that could adapt to a physician's performance history, and thus the statistics used for personalized confidence binning were recomputed on the training data within each individual cross-validation fold. It is therefore not possible to establish a baseline for the personalized confidence binning outside of a given fold. Instead, we take the mean of the percent accuracy *above baseline* from each test fold ($\frac{1}{k}\sum_{i=1}^{k}(accuracy_i - baseline_i)$). All models performed well above their respective baselines, which is in line with observations from heldout testing.

Binning	Generalized		Personalized	
Problem	C.O.	C&C	C.O.	C&C
Acc. above baseline	+14	+9	+13	+12
Precision	0.70	0.25	0.69	0.32
Recall	0.70	0.38	0.57	0.37

Table 5: Performance metrics for logistic regression with 50 randomized iterations of cross-validation using all narratives for Confidence Only (C.O.) and Confidence & Correctness (C&C). We average the accuracy above baseline from each individual fold. Precision and recall are each macro-averaged for each problem.

Feature modality	Generalized		Personalized	
	C.O.	C&C	C.O.	C&C
V	+13	+9	+12	+11
E	+7	+6	+11	+10
MM	+7	+4	+6	+5
V+E	+13	+9	+13	+11
V+MM	+14	+8	+11	+11
E+MM	+10	+6	+13	+11
V+E+MM	+14	+9	+13	+12

Table 6: Modality study with cross-validation for Verbal (V), Eye movement (E), and Multimodal (MM) features, measured in accuracy above respective baselines, averaged over all folds. Most modality combinations equaled or slightly improved on constituent modalities in isolation.

Modality study We also performed a study within the cross-validation testing to investigate the impact of different feature modality combinations on classification (see Table 6). Importantly, the verbal modality alone was more powerful than the eye movement or multimodal features, but most combinations of modalities resulted in slightly higher or equal accuracy compared to their isolated constituent modalities. This suggests that, as we projected, considering multiple modalities of a physician's behavior can help reveal their confidence and self-awareness, but also that verbal features are the most informative, likely since verbal expression is the primary means to tap into physicians' rich and tacit conceptual understanding of a diagnostic case. The multimodal features, which focused on combining verbal and eye movement data, did not improve performance over baselines as much as the simple combination of the individual verbal and eye movement features. One reason for this could be that a person's speech and eye movements are not perfectly temporally aligned (Vaidyanathan et al., 2012), and this asynchronous relationship may affect the meaningfulness of our multimodal feature measurements. Additionally, these eye movement features may be at a much finer spatial or temporal scale than the verbal features.

6 Conclusions

This study examined a dataset of medical narratives consisting of verbal descriptions, eye movements, and self-reported confidence values, and used it to model physicians' confidence in diagnosis, as well as their diagnostic self-awareness. The Confidence Only problem involves the expression of confidence based on clinicians' belief, but it is important to understand the relationship to clinicians' actual diagnostic performance. This distinction is key because, while predicting confidence alone is a stepping stone, self-awareness is the ability to additionally align one's confidence with unknown correctness, which involves human intuitive and analytical reasoning (another topic of interest to the medical field, see Hochberg et al. (2014)). Case studies of the most and least confident physicians revealed a complex relationship between confidence and correctness, and highlighted the need for exploring clinical self-awareness. We also defined a personalized binning scheme for physician confidence levels, taking into account a physician's past confidence when drawing the line between high and low confidence, and compared this to a generalized binning scheme based on performance of all physicians. In tandem, these approaches to confidence binning could be used by an intelligent diagnostic support system.

We incorporated previously unused eye movement information from this dataset, and introduced truly multimodal features which directly combined physicians' verbal and eye movement behaviors. While physicians' eye movement and multimodal features were not individually as powerful as verbal features, combinations of the three groups mostly produced classification improvements that were slightly better than, or at least as good as, their constituent feature groups in isolation. The best performance for the majority of models was achieved by considering features from all three modalities. This suggests that eye movements help convey confidence and diagnostic self-awareness. The multimodal features did not help as much, which we believe is explained by the more flexible temporal relationship between speech and eye movements in the human mind. We leave the multimodal alignment challenge to future work. Some pitch features implemented without speaker-dependent analysis were useful for classification, but future work may benefit from pitch feature representations that adapt to demographic variation. Another area for future work beyond the scope of this study includes examining alternative ways of combining confidence and correctness classes, such as merging the diagonals of Figure 1 into a binary classification of appropriate vs. inappropriate (i.e. the union of over- and underconfidence). Such alternatives may present additional challenges for classification, but could also provide benefits for simpler clinical support applications that may not be concerned with differentiating all four classes.

Abstract

Derivationally related lemmas like *friend*$_N$ – *friendly*$_A$ – *friendship*$_N$ are derived from a common stem. Frequently, their meanings are also systematically related. However, there are also many examples of derivationally related lemma pairs whose meanings differ substantially, e.g., *object*$_N$ – *objective*$_N$. Most broad-coverage derivational lexicons do not reflect this distinction, mixing up semantically related and unrelated word pairs.

In this paper, we investigate strategies to recover the above distinction by recognizing semantically related lemma pairs, a process we call *semantic validation*. We make two main contributions: First, we perform a detailed data analysis on the basis of a large German derivational lexicon. It reveals two promising sources of information (distributional semantics and structural information about derivational rules), but also systematic problems with these sources. Second, we develop a classification model for the task that reflects the noisy nature of the data. It achieves an improvement of 13.6% in precision and 5.8% in F1-score over a strong majority class baseline. Our experiments confirm that both information sources contribute to semantic validation, and that they are complementary enough that the best results are obtained from a combined model.

1 Introduction

Morphological processing forms the first step of virtually all linguistic processing toolchains in natural language processing (NLP) and precedes other analyses such as part of speech tagging, parsing, or named entity recognition. There are three major types of morphological processes: (a) *Inflection* modifies word forms according to the grammatical context; (b) *derivation* constructs new words from individual existing words, typically through affixation; (c) *composition* combines multiple words into new lexical items. Computational treatment of morphology is often restricted to normalization, such as *lemmatization* (covering inflection only) or *stemming* (covering inflection and derivation heuristically, Porter (1980)).

An important reason is that English is morphologically a relatively simple language. Composition is not marked morphologically (*zoo gate*) and an important derivational pattern is *zero derivation* where the input and output terms are identical surface forms (*a fish / to fish*). Thus, lemmatization or stemming go a long way towards treating the aspects of English morphology relevant for NLP. The situation is different for languages with a complex morphology that calls for explicit treatment. In fact, recent years have seen a growing body of computational work in particular on derivation, which is a very productive process of word formation in Slavic languages but also in languages more closely related to English, like German (Štekauer and Lieber, 2005).

Derivation comprises a large number of distinct patterns, many of which cross part of speech boundaries (nominalization, verbalization, adjectivization), but some of which do not (gender indicators like *master / mistress*, approximations like *red / reddish*). A simple way to conceptualize derivation is that it partitions a language's vocabulary into *derivational families* of derivationally related lemmas (cf. Zeller et al. (2013), Gaussier (1999)). In WordNet, this type of information has been included to some extent by so-called "morpho-semantic" relations (Fellbaum et al., 2009), and the approach has been applied to languages other

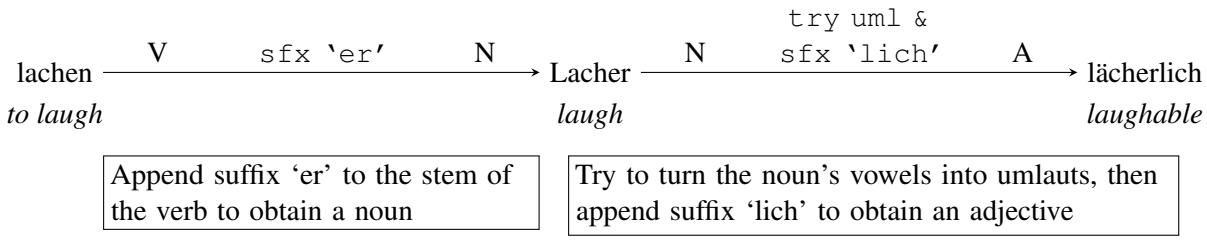

Figure 1: (Part of) a derivational family from DERIVBASE including derivational rules

than English (Bilgin et al., 2004; Pala and Hlaváčková, 2007). Another source of derivational information are stand-alone derivational lexicons such as CatVar (Habash and Dorr, 2003) for English, DERIVBASE (Zeller et al., 2013) for German, or the multilingual CELEX (Baayen et al., 1996).

Recent work has demonstrated that NLP can benefit from derivational knowledge. Shnarch et al. (2011) employ derivational knowledge in recognizing English textual entailment to better gauge the semantic similarity of text and hypothesis. Padó et al. (2013) improve the prediction of German semantic similarity judgments for lemma pairs by backing off to derivational families for infrequent lemmas. Luong et al. (2013) and Lazaridou et al. (2013) improve distributional semantic representations.

Note that all of these applications make use of derivational knowledge to address various *semantic* tasks, working on the assumption that derivationally related words, as represented in derivational lexicons, are strongly semantically related. This assumption is not completely warranted, though. The development of wide-coverage derivational lexicons is generally driven by morphological information, using for example finite-state technology (Karttunen and Beesley, 2005) to characterize known derivational patterns in terms of string transformations. Even though there is a strong correlation in derivation between morphology and semantics, it is not perfect. The absence of (synchronic) semantic relatedness can have a number of reasons, including accidental instantiation of derivational patterns (*corn – corner*) and diachronic meaning drift (*dog* (*animal*) – *dogged* (*determined*)). In other words, a substantial number of the lemma pairs in those lexicons are false positives regarding the level of semantic relatedness.

Our goal in this paper is to ameliorate this situation by developing strategies for the *semantic validation* of derivational lexicons, i.e., methods to determine, for lemma pairs that are derivationally related at the morphological level, whether they are in fact semantically related. We base our study on the German derivational lexicon DERIVBASE, and start by assessing which strategies can be used for its semantic validation (Section 2). In Sections 3 and 4, we analyze the contributions of semantic information (distributional semantics) as well as structural information (derivational rules). On the basis of our observations, we train a classifier that is able to semantically validate DERIVBASE at 89.9% F_1-score (Section 5), significantly outperforming a majority-class baseline of 84.1%. Section 6 reviews related work. Section 7 concludes the paper and outlines future work.

2 A Lexicon for German Derivation

2.1 DERIVBASE

DERIVBASE (Zeller et al., 2013) is a freely available derivational lexicon for German.[1] We used a rule-based framework to define derivation rules that cover suffixation, prefixation, and zero derivation as well as stem changes. Following the work of Šnajder and Dalbelo Bašić (2010), derivational processes are defined using derivational rules and higher-order string transformation functions. The only requirements for this method are (a) a comprehensive set of lemmas and (b) knowledge about admissible derivational rules, which can be gathered, for example, from linguistics textbooks.

Figure 1 shows a small sample from a derivational family with three lemmas and two derivational rules, one turning a verb into the corresponding event noun (in this case a semelfactive), and one turning the event into an adjective associated with it. Note that there are two perspectives on such a family: It can

[1] http://www.cl.uni-heidelberg.de/~zeller/res/derivbase/

DERIVBASE release	"Positive" class	Precision %	Recall %
1.2 (Zeller et al., 2013)[3]	R and M	83.0	71.0
1.4 (our analysis)	R and M	85.1	91.4
1.4 (our analysis)	R only	76.7	93.8

Table 1: DERIVBASE evaluation across releases on the DERIVBASE release 1.2 P and R samples

either be seen as a set of lemmas, or as a set of (independent) lemma pairs. We will assume the latter perspective in this paper, leaving questions of global coherence for future work.

DERIVBASE is a good example for the problems sketched in Section 1. It is defined purely on morphological grounds, without semantic validation of derivational families. Consequently, it contains a substantial number of words that are not semantically related.

2.2 Morphological and Semantic Relatedness in DERIVBASE

Our original evaluation of the quality of DERIVBASE in Zeller et al. (2013) was based on manually classified samples of lemma pairs. We introduce two samples, the "R sample", drawn from a large population of lemma pairs with high string similarity, in order to calculate recall, and the "P sample", drawn from the DERIVBASE families, in order to compute precision. Each lemma pair was classified into one of five categories (**R**: morphologically and semantically related; **M**: only morphologically related; **N**: not related; **L**: lemmatization errors; **C**: compounds) and inter-annotator agreement was checked to be substantial.[2] The overall best model (L123) showed 83% precision and 71% recall. However, this evaluation is limited in two important respects. First, it refers to DERIVBASE release 1.2 from 2013. Since then, we have extended DERIVBASE, e.g., with rules covering particle verbs, a very productive area of German derivation. Secondly, and more seriously, the previous evaluation considered all instances of **R** *and* **M** as true positives. In other words, in Zeller et al. (2013) we only evaluated the morphological relatedness of the lemma pairs but not the semantic relatedness.

We therefore start by presenting an evaluation of DERIVBASE focusing on the **R** instances in Table 1, reusing the DERIVBASE 1.2 "P" and "R" samples introduced in Zeller et al. (2013, see there for evaluation details). Between DERIVBASE 1.2 and 1.4, precision increased marginally and recall substantially, due mainly to the inclusion of rules that cover particle verbs. However, the numbers change substantially when only **R** (truly semantically related pairs) are counted as true positives. Recall increases by about 2.5%, but precision drops about 8.5%. Almost one quarter of all pairs in the lexicon are *not* semantically related.

A possible confounder of this analysis is that the "P sample" was drawn on DERIVBASE 1.2 and therefore does not include the novel items in DERIVBASE 1.4. We therefore created a novel DERIVBASE *1.4 extended sample* by combining the existing "P sample" with those pairs from the "R sample" that are in the coverage of a DERIVBASE rule as of DERIVBASE 1.4, resulting in 2,545 lemma pairs.

This DERIVBASE 1.4 extended sample will form the basis of all our analyses in this paper. The class distribution in the new sample is similar, but not identical, to the old P sample, as shown in Table 2. The relative frequency of **R** drops another 2%. Since this number also corresponds to the precision of the resource, the precision of the extended sample is 74.6%.

There are almost no compound errors **C**, which is not surprising given the rule-based construction of the lexicon, and only a relatively small number (about 5%) of lemmatization errors **L**, which fall outside the scope of our work. In contrast, both **N** and **M** occur with substantial frequency: Each class accounts for around 10% of the pairs. An analysis of **N** shows many cases of rule overgeneration: These are often pairs of lemmas whose stems are sufficiently similar that they might be related, e.g., by stem-changing derivation rules. Although such rules are valid in other contexts ($Verkauf_N$ – $Verkäufer_N$ (*selling – seller*)),

[2] Although we believe semantic relatedness to be fundamentally a graded scale, we adopt a binary notion of it as a convenient operational simplification that is supported by the good inter-annotator agreement for manual labeling in DERIVBASE.

[3] DERIVBASE 1.2 corresponds to DERIVBASE "L123" in (Zeller et al., 2013, p. 1207).

	R	M	N	L	C
Frequency	1899	265	240	131	8
Percentage overall	74.6	10.4	9.5	5.2	0.3
Percentage on dev. set	75.5	10.3	9.0	4.8	0.3
Percentage of test set	72.6	10.6	10.6	5.9	0.3

Table 2: Class distribution in our new DERIVBASE 1.4 extended sample

erroneous application leads to **N** cases like *Blase*$_N$ – *Bläser*$_N$ (*bubble – blower*). Also, we find false matches of common noun rules with named entities (*Empire*$_N$ – *Empirismus*$_N$ (*Empire – empiricism*)).

In contrast, many cases of **M** (as sketched in Section 1) refer to different senses of the same stem. As an example, consider *beruhen*$_V$ – *unruhig*$_A$ (*to rest on – restless*), both related to *Ruhe*$_N$ *(rest)*. In other cases, one of the two lemmas appears to have undergone a meaning shift (*Rappel*$_N$ – *rappeln*$_V$ (*craze – to rattle*)). This is particularly prominent for particle verbs (*bauen*$_V$ – *erbaulich*$_A$ (*build – edifying*)).

We divide the DERIVBASE 1.4 extended sample into a development and a test partition (70:30 ratio); the subsequent analyses consider only the development set.

2.3 Hypotheses for Semantic Validation

The preceding analysis of DERIVBASE has established that the lexicon contains a substantial number (around one fourth) of lemma pairs that are not semantically related. Therefore, it is in need of *semantic validation*, i.e., a computational procedure that can filter out semantically unrelated words.

In this paper, we frame semantic validation as a binary classification task that classifies all lemma pairs within one derivational family as either semantically related or unrelated. We consider this a first step towards splitting the current, morphologically motivated, DERIVBASE families into smaller, semantically coherent, families. We base our work on two general hypotheses about the types of information that might be helpful in this endeavor.

Hypothesis 1. *Distributional similarity indicates semantic relatedness between derivationally related words.* The instances of polysemy and meaning shift that we observe, in particular in the **M** class, motivate the use of distributional similarity (Turney and Pantel, 2010) since we expect these lemma pairs to be distributionally less related than cases of true semantic relatedness.

Hypothesis 2. *Derivational rules differ in their reliability.* Both the evidence from **M** and **N** indicate that some rules are more meaning-preserving than others. We expect this to be tied to both lexical properties of the rules (particle verbs are more likely than diminutives to radically change meaning) as well as structural properties (more specific rules are presumably more precise than generic rules).

In the two following Sections, we will operationalize these hypotheses and analyze the development set of the DERIVBASE 1.4 extended sample with respect to their empirical adequacy.

3 Analysis 1: Distributional Similarity for Semantic Validation

3.1 Measuring Distributional Similarity

We examine semantic similarities as predicted by simple bag-of-words semantic space models built from the lemmatized SDeWaC (Faaß et al., 2010), a large German web corpus containing about 880 million words. We compute vectors for all words covered in DERIVBASE using a window of $\pm$5 words within sentence boundaries and considering the 10k most frequent lemma-part of speech combinations of nouns, verbs, and adjectives in SDeWaC as contexts. Distributional vectors are built from co-occurrences which are measured with Local Mutual Information (Evert, 2005). The semantic similarity is measured by the cosine similarity between the vectors. Despite the size of the corpus, many lemmas from DERIVBASE occur very infrequently, and due to the inflection in German, it is important to retrieve as many occurrences of each lemma as possible.

We therefore use a very permissive two-step lemmatization scheme that starts from lemmas from the lexicon-based TreeTagger (Schmid, 1994), which provides reliable lemmas but with relatively low coverage, and supplements them with lemmas and parts of speech produced by the probabilistic MATE toolkit (Bohnet, 2010) when TreeTagger abstains.

3.2 Frequency Considerations

The advantage of the string transformation-based construction of DERIVBASE is its ability to include infrequent lemmas in the lexicon, and in fact DERIVBASE includes more than 250,000 content lemmas, some of which occur not more than three times in SDeWaC. However, this is a potential problem when we build distributional representations for all lemmas in DERIVBASE since it is known from the literature that similarity predictions for infrequent lemmas are often unreliable (Bullinaria and Levy, 2007).

Our data conform to expectations in this regard – infrequent lemmas are indeed problematic for validating the semantic relatedness of lemma pairs. More specifically, the semantic similarity of *related* lemmas (**R**) is systematically underestimated, because the lemma pairs from our sample are often too infrequent to share any dimensions. Consequently, they receive a low or zero cosine even when they are semantically strongly related. For example, each of the lemmas *Drogenverkauf*$_N$ – *Drogenverkäufer*$_N$ (*drug selling – drug seller*) has only nine lemmas as dimensions, and those are completely disjoint. This underestimation constitutes a general trend. The model assigns cosine scores below 0.1 to 64% of the related pairs in the development set, cosines below 0.2 to 81%, and cosines below 0.3 to 87%. Such low scores are problematic for separating related from unrelated pairs.

Two-step lemmatization is important for the proper handling of infrequent words. Compared to just using TreeTagger, the TreeTagger+MATE vectors for *auferstehen*$_V$ – *auferstehend*$_A$ (*to resurrect – resurrecting*) share seven more dimensions, including *Jesus*, *Lord*, *myth*, and *suffering*. Correspondingly, the cosine value of this pair rises by 50%. Generally, the amount of zero cosines in the DERIVBASE 1.4 extended sample drops by 45% using two-step lemmatization compared to one-step TreeTagger lemmatization.

3.3 Conceptual Considerations

In addition to the frequency considerations discussed above, we find three conceptual phenomena that affect distributional similarity independently of the frequency aspects.

The first one is the influence of *parts of speech*. Derivational rules often change the part of speech of the input lemma, and the parts of speech of its context words change as well. This decreases context overlap. For example, *Überschätzung*$_N$ – *überschätzt*$_A$ (*overestimate – overestimated*) is assigned a cosine of merely 0.09. The upper half of Table 3 shows the top ten individual and shared context words for this pair, ranked by LMI. The context words of the noun are mainly nominal heads of genitive complements (*overestimation of possibility/force/...*), while the context words of the adjective comprise many adverbs (*totally, widely, ...*). None of the shared contexts rank among of the top ten for both target lemmas. This is even more surprising considering that German adjectives and adverbs have the same surface realization (as opposed to English) and are more likely to form matching context words.

The second phenomenon that we identified as influencing semantic similarity is *markedness* (Battistella, 1996). A considerable number of derivational rules systematically produce marked terms. A striking example is the feminine suffix "*-in*" as in *Entertainer*$_N$ – *Entertainerin*$_N$: Although the lemmas are intuitively very similar, their cosine is as low as 0.1. The reason is that the female versions tend to be used in contexts where the gender of the entertainer is relevant. This is illustrated in the lower half of Table 3. The first two contexts for both words (*actor, singer*) stem from frequent enumerations (*actor and entertainer X*) and are almost identical, but again the female versions are marked for gender. We also find two female given names. As a result, the target lemmas receive a low distributional similarity.

The third example are cases of mild meaning shifts that were tagged by the annotators as **R**. These are lemmas where the semantic relatedness is intuitively clearly recognizable but may be accompanied by pretty substantial changes in the distribution of contexts. Consider the semantically related pair *Absteiger*$_N$ – *absteigend*$_A$ (*descender (person) – descending/decreasing*). It achieves only a cosine of

word pair (l_1, l_2)	context(l_1)	context(l_2)	shared contexts(l_1, l_2)
Überschätzung – überschätzt (*overestimation – overestimated*), $cos = 0.09$	eigen (*own*) warnen (*to alert*) Möglichkeit (*possibility*) führen (*to lead*) Kraft (*force*) Bedeutung (*meaning*) Fähigkeit (*ability*) Leistungsfähigkeit (*performance*) neigen (*to tend*) Einfluß (*influence*)	völlig (*totally*) Problem (*problem*) Gefahr (*danger*) Autor (*author*) weit (*widely*) total (*totally*) ernst (*seriously*) überhöht (*excessive*) gnadenlos (*mercilessly*) Hollywood (*Hollywood*)	völlig (*totally*) Möglichkeit (*possibility*) Bedeutung (*meaning*) Gefahr (*danger*) Einfluß (*influence*) überhöht (*excessive*) Macht (*power*) gnadenlos (*mercilessly*) Kraft (*force*) häufig (*frequent*)
Entertainer – Entertainerin (*entertainer – female entertainer*), $cos = 0.1$	Sänger (*singer*) Schauspieler (*actor*) Musiker (*musician*) Harald (*male given name*) Moderator (*anchorman*) Schmidt (*surname*) groß (*big*) Künstler (*artist*) Talent (*talent*) gut (*good*)	Sängerin (*female singer*) Schauspielerin (*actress*) Helga (*female given name*) Mutter (*mother*) berühmt (*famous*) brillant (*brilliant*) Lisa (*female given name*) Künstlerin (*female artist*) verstorben (*deceased*) Talent (*talent*)	Schauspieler (*actor*) Musiker (*musician*) **Talent** (*talent*) bekannt (*well-known*) Sängerin (*female singer*) beliebt (*popular*) groß (*big*) berühmt (*famous*) Sportler (*sportsman*) Schauspielerin (*actress*)

Table 3: Top ten individual and shared context words for *Überschätzung*$_N$ *– überschätzt*$_A$ (*overestimation – overestimated*) and *Entertainer*$_N$ *– Entertainerin*$_N$. Individual context words are ranked by LMI, shared context words by the product of their LMIs for the two target words. Shared context words that occur in the top ten contexts for both words are marked in **boldface**.

0.005, because *Absteiger* is almost exclusively used to refer to relegated sport teams while *absteigend* is used as a general verb of scalar change.

3.4 Ranking of Distributional Information

Given the results reported above, the standard distributional approach of using plain cosine scores to measure the absolute amount of co-occurrences does not seem very promising, due to the low absolute numbers of shared dimensions of the two lemmas. We expect other similarity measures, e.g., the Lin measure (Lin, 1998), to perform equally poorly since they do not change the fundamental approach. Also, although using a large corpus for semantic space construction might ameliorate the situation, we would prefer to make improvements on the modeling side of semantic validation.

We follow the ideas of Hare et al. (2009) and Lapesa and Evert (2013) who propose to consider semantic similarity in terms of ranks rather than absolute values. The advantage of rank-based similarity is that it takes the density of regions in the semantic space into account. That is, a low cosine value does not necessarily indicate low semantic relatedness – provided that the two words are located in a "sparse" region. Conversely, a high cosine value can be meaningless in a densely populated region. A second conceptual benefit of rank-based similarity is that it is directed: It is possible to distinguish the "forward" rank (the rank of l_1 in the neighborhood of l_2) and the "backward" rank (the rank of l_2 in the neighborhood of l_1). The previous studies found rank-based similarity to be beneficial for the prediction of priming results. In our case, it suggests a refined version of our Hypothesis 1:

Hypothesis 1'. *High* rank-based *distributional similarity indicates semantic relatedness between derivationally related words.*

4 Analysis 2: Derivational Rules for Semantic Validation

As discussed in Section 2.3, a second source of information that should be able to complement the problematic distributional similarity is provided by the derivational rules that are encoded in DERIVBASE (cf. the arrows in Figure 1). Our intuition is that some rules are "semantically stable", meaning that they reliably connect semantically similar lemmas, while other rules tend to cause semantic drifts. To examine

this situation, we perform a qualitative analysis on all lemma pairs connected by rule paths of length one ("simplex paths"), which are easy to analyze. Longer paths ("complex paths") are considered below.

We find that rules indeed behave differently. For example, the "*-in*" female marking rule from Section 3.3 is very reliable: every lemma pair connected by this rule is semantically related. At the other end of the scale, there are rules that consistently lead to semantically unrelated lemmas, e.g., the *"ver-"* noun-verb prefixation: *Zweifel*$_N$ – *verzweifeln*$_V$ (*doubt – to despair*). Foreign suffixes like "*-ktiv*" in *instruieren*$_V$ – *instruktiv*$_A$ (*to instruct – instructive*) retain semantic relatedness in most cases, but sometimes link actually unrelated lemmas (**N**, **C**, **L**). For example, *Objektiv*$_N$ – *Objektivismus*$_N$ (*lens – objectivism*), is an **N** pair for the suffix "*-ismus*". Finally, zero derivations and very short suffixes are less reliable: Since they easily match, they are often applied to incorrectly lemmatized words (**L**). For example, the "*-n*" suffix, which relates nationalities with countries (*Schwede*$_N$ – *Schweden*$_N$ (*Swede – Sweden*)). It matches many wrongly lemmatized nouns due to its syncretism with the plural dative/accusative suffix *-n*, as in *Schweineschnitzel*$_N$ – *Schweineschnitzeln*$_N$ (*pork cutlet – pork cutlets*$_{dat/acc\text{-}pl}$). This suggests that *rule-specific reliability* is a promising feature for semantic validation. Fortunately, due to its construction, DERIVBASE provides a rule chain for each lemma pair so that these reliabilities can be "read off". For other rules, however, the variance of the individual lemma pairs that instantiate the rule is large, and the applicability of the rule is influenced by the particular combination of rule and lemma pair. Such cases suggest that distributional knowledge and structural rule information should be combined, a direction that we will pursue in the next section.

On word pairs that are linked by "complex paths", i.e., more than one rule (*lachen*$_V$ – *lächerlich*$_A$ in Figure 1), our main observation in this respect is that rule paths show a clear "weakest link" property. One unreliable rule can be sufficient to cause a semantic drift, and only a sequence of reliable rules is likely to link two semantically related words. We will act on this observation in the next section.

5 A Machine Learning Model for Semantic Validation

5.1 Classification

The findings of our analyses suggest that the decision to classify lemma pairs as semantically related or unrelated can draw on a range of considerations. We therefore decided to adopt a machine learning approach and phrase semantic validation as a binary classification task, using the analyses we performed in Sections 3 and 4 as motivation for feature definition.

We train a classifier on the development portion of the DERIVBASE 1.4 extended sample (1,780 training instances, cf. Section 2.2). We learn a binary decision: Semantic relatedness (**R**) vs. non-semantic relatedness (**M**, **N**, **C**, **L**) within derivationally related pairs. For classification, we use a nonlinear model: Support Vector Machine (SVM) with a Radial Basis Function (RBF) kernel. Using the RBF kernel allows us to capture the non-linear dependencies between the features.[4] We rely on LIBSVM (Chang and Lin, 2011), a well-known SVM implementation. We optimize the C and γ hyperparameters of the SVM model using 3-fold cross-validation on the training data (i.e., the development portion of the extended sample).

5.2 Features

Our analyses motivate three feature groups comprising 35 individual features: Distributional, derivation rule-based ("structural"), and hybrid features. Table 4 gives a list.

Distributional features. All distributional features apply to the lemma or pair level. They are calculated from our BOW model with permissive lemmatization (Section 3.1). We use absolute and rank-based cosine similarity (Section 3.4) as well as the number of shared contexts (computed with LMI, cf. Section 3.3) and lemma frequency. To speed up processing, we compute the forward rank similarity for a lemma pair (l_1, l_2) not on the complete vocabulary but by pairing l_1 with a random sample of 1,000 lemmas from DERIVBASE (plus l_2 if it is not included). We do the computation analogously for the backward rank.

[4]The nonlinear SVM model outperforms a linear SVM. The difference is 0.8% F-Score, statistically significant at p=0.05.

Feature group (# features)	Type	Feature name (# features)	Description
Distributional (6)	l	Lemma frequency (2)	Normalized SDeWaC corpus lemma frequencies
	p	Cosine similarity	Standard cosine lemma similarity
	p	Dimensions shared	Number of shared context words
	p	Cos. rank similarity (2)	Rank-based forward and backward similarity
Structural (25)	r	Rule identity (11)	Indicator features for the top ten rules in the dev set + one aggregate feature for the rest
	r	Rule reliability	Percentage of rule applications on **R** pairs among all applications of the rule in dev set
	r	Rule frequency rank (2)	Rank-based rule frequency in DERIVBASE
	r	Avg. string distance (2)	Avg. Levenshtein distance for all rule instances
	p	POS combinations (6)	Indicator features for lemma POS combinations
	p	Path length	Length of the shortest path between the lemmas
	p	String distance (2)	Dice bigram coefficient; Levenshtein distance
Hybrid (4)	r	Average rank sim (2)	Frequency-weighted average rank similarity of rules on shortest path
	p	Rank sim deviation (2)	Difference between lemma pair rank similarity and average rule rank similarity

Table 4: Features used to characterize derivationally related lemma pairs. "Type" indicates the level at which each feature applies: *l* lemma level, *p* pair level, *r* rule level.

Structural features. The structural features encode properties of the rules and paths in DERIVBASE. Most features apply to the level of derivation rules. This includes the identity of the rule; its reliability (estimated as the ratio of its application on **R** pairs among all its applications on the dev set); its frequency rank among all rules (as a measure of specificity)[5]; and the average Levenshtein distance between the input and output lemmas (estimating rule complexity by measuring the amount of string modification).

For lemma pairs linked by complex paths (i.e., more than one rule, cf. Figure 1), the question arises how the rule-level features should be computed. Following our observations on "weakest link" behavior in Section 4, we always combine the feature values for the individual rules adopting the most pessimistic combination function (e.g., minimum in the case of reliability, maximum in the case of frequency rank).

Three more structural features are computed directly at the lemma pair level: their part of speech combination (e.g., *"NV"* for $oxide_N - oxidate_V$), the length of the shortest path connecting them, and the Levenshtein and Dice string distances between the two lemmas.

Hybrid features. Hybrid features combine rule-based and distributional information to avoid their respective shortcomings. We work with two hybrid features, one at rule level and one at pair level. The rule-level feature models the reliability of the rule. It is the average rank similarity for each rule (computed as a log frequency-weighted average over rule instances). This feature is a counterpart to rule reliability that is unsupervised in that it does not require class labels. We compute it by randomly drawing 200 lemma pairs for each rule from DERIVBASE (less if the rule has fewer instances). The pair-level feature is the difference between the rule's average rank similarity and the rank similarity for the current pair. It measures the rank of a pair relative to the rule's "baseline" rank and indicates how similar and dissimilar lemma pairs are compared to the rule average. In parallel to the structural features, values for complex rule paths are computed by minimum. Since the rank similarity is directional, we compute both hybrid features in two variants, one for each direction.[6]

[5]We compute this feature once only on simplex paths and once on all instances of the rule in DERIVBASE, trading reliability against noise.

[6]We also tested hybrid features based on raw cosine; however, this yielded worse results than the rank-based hybrid features.

Validation method	Precision	Recall	F_1	Accuracy
Majority baseline	72.6	**100**	84.1	72.6
Classifier, *only "cosine similarity" feature*	72.6	100	84.1	72.6
Classifier *only "similarity rank" feature*	80.3	90.3	85.0	76.8
Classifier, *only "rule identity" feature*	73.7	99.5	84.6	73.8
Classifier, *hybrid group*	80.4	95.3	87.2	79.7
Classifier, *distributional group*	80.5	96.6	87.8	80.5
Classifier, *structural group*	82.7	93.1	87.6	80.9

Classifier, *hybrid + structural groups*	84.9	93.7	89.1	83.4
Classifier, *distributional + structural groups*	85.3	94.6	89.7	84.3
Classifier, *all features*	**86.2**	93.9	**89.9**	**84.7**

Table 5: Accuracy, precision, recall, and F_1 on the test portion of the DERIVBASE 1.4 extended sample.

5.3 Results and Discussion

We applied the trained classifier to the test portion of the DERIVBASE 1.4 extended sample (cf. Section 2.2). Table 5 summarizes precision, recall, and F_1-score of the classifier for various combinations of features and feature groups. Recall that since our motivation is semantic validation, i.e., the removal of false positives, we are in particular interested in improving the *precision* of our predictions. We test significance of F_1 differences among models with bootstrap resampling (Efron and Tibshirani, 1993).

Our baseline is the majority class in the sample, **R**. Due to the sample's skewed class distribution (cf. Table 2), the frequency baseline is quite high (precision 72.6, F_1-score 84.1). We next consider the three most prominent individual features: Distributional similarity measured as cosine, distributional similarity measured as similarity rank, and rule identity. As expected from our analyses, the cosine similarity on its own is not reliable; in fact, it performs at baseline level. The rank-based similarity already leads to a considerable gain (precision +7.7%), but only a slight F_1-score increase of 0.9% that is not statistically significant at p=0.05. These results provide good empirical evidence for Hypothesis 1' (Section 3.4) and underscore that 1' is a more accurate statement than Hypothesis 1 (Section 2.3). On the structural side, rule identity alone improves the precision by 1.1%, with an F_1-score increase in 0.5% (again not significant).

We now proceed to complete feature groups, all of which perform at least 3% F_1-score better than the baseline, proving that the features within these groups are complementary. The hybrid feature group is the worst among the three. The distributional feature group is able to improve only slightly over the individual rank-based similarity feature in precision (80.5 vs. 80.3), but gains 6.3% in recall. This is sufficient for a significant improvement in F_1 (+3.7%, significant at p=0.01). The structural feature group performs surprisingly well, given that these features are very simple and most are computed only on the relatively small training set. It yields by far the highest precision (82.7), and its F_1-score is only slightly lower than the one of the distributional group (87.6 vs. 87.8). We take this as further evidence for the usefulness of structural information, as expressed by Hypothesis 2 (cf. Section 2.3).

Ultimately, all three feature groups turn out to be complementary. We obtain an improvement in F_1-score for two out of the three feature group combinations, and a clear improvement in precision in all cases. Finally, the best overall result is shown by the combination of all three feature groups. It attains an F_1-score of 89.9, an improvement of 5.8% over the baseline and 2.1% over the best feature group (both differences significant at p=0.01). Crucially, this model gains over 13% in precision while losing only 6% of recall compared to the baseline. This corresponds to a reduction of false positives in the sample by about half (from 27% to 14%) while the true positives were reduced only by 5% (from 73% to 68%).

Table 6 shows a breakdown of the predictions by the best model in terms of the five gold standard classes

	R	M	N	L	C	total
Gold annotation	554	81	81	45	2	763
Classified as **R**	520	36	16	29	2	603
Classified as **not R**	34	45	65	16	0	160

Table 6: Predictions on the test set of the *all features* Classifier per annotation class.

(**R**, **M**, **N**, **L**, **C**). Ignoring compounds (**C**), of which there are too few cases to analyze, we first find that the classifier achieves a high **R** recall. It is also very good in filtering out unrelated cases (**N**), of which it discards around 80%. The model recognizes morphologically but not semantically related word pairs (**M**) fairly well and manages to remove more than half of these. It has the hardest time with lemmatization errors (**L**), of which only about 35% were removed. However, this is not surprising: Lemmatization errors do not form a coherent category that would be easy to retrieve with the kinds of features that we have developed. We believe that such errors should be handled in an earlier stage, i.e., during preprocessing.

6 Related Work

Given that many derivational lexicons were only developed in recent years, we are only aware of one study (Jacquemin, 2010) that semantically validates the output of an existing derivational lexicon (Gaussier, 1999) to apply it to Question Answering. In contrast to our study, it requires elaborate dictionary information to look up which derivations are permitted for a specific lemma, as well as word sense disambiguation to determine the meaning of ambiguous words in context. Other related work comes from two areas: unsupervised morphology induction and semantic clustering.

Unsupervised morphology induction is concerned with the automatic identification of morphological relations (cf. Hammarström and Borin (2011) for an overview). Most approaches in this area do not differentiate between the inflectional and derivational level of morphology (Gaussier (1999) is an exception) and restrict themselves to the string level. Only a small number of studies (Schone and Jurafsky, 2000; Baroni et al., 2002) take distributional information into account.

Semantic clustering is the task of inducing semantic classes from (broadly speaking) distributional information (Turney and Pantel, 2010; im Walde, 2006). Boleda et al. (2012) include derivational properties in their feature set to learn Catalan adjective classes. However, the input to such studies is almost always a set of words from the same part of speech with no prior morphological constraints, while our input lemmas are morphologically preselected (via derivational rules), are often extremely infrequent, and exhibit systematical variation in parts of speech. To our knowledge, this challenging situation has not been addressed in previous studies.

Recent work has also considered the opposite problem, namely using derivational morphology for improving distributional similarity predictions. Luong et al. (2013) use recursive neural networks to learn representations of morphologically complex words and demonstrate the usefulness of their approach on word similarity tasks across different datasets. Similarly, Lazaridou et al. (2013) improve the word representations of derivationally related words by composing vector space representations of stems and derivational suffixes.

7 Conclusions

Almost all existing derivational lexicons do not distinguish between only morphologically related words on one hand and words that are both morphologically and semantically related words on the other hand. In this paper, we have addressed the task of recovering this distinction and called it *semantic validation*. We have used DERIVBASE, a German derivation lexicon, as the basis of our investigation.

We have made two contributions: (a) providing a detailed analysis of the types of information available for this task (distributional similarity as well as structural information about derivation rules) and the problems associated with each information type; and (b) training a machine learning classifier on linguistically

motivated features. The classifier, although not perfect, can substantially improve the precision of the word pairs in DERIVBASE and thus help to filter the derivational families in the lexicon. We are making this semantic validation information available in the DERIVBASE lexicon by attaching a probability for the class **R** to each lemma pair (see footnote 1 for the DERIVBASE URL).

The approach that we have described should transfer straightforwardly to other derivational lexicons and other languages on the conceptual level. The practical requirements are an appropriate corpus (for the distributional features) and derivational rule information (for the structural features).

There are two clear directions for future work. First, we plan to broaden our attention from word pairs to clusters and use the relatedness probabilities to cluster the derivational families in DERIVBASE into semantically coherent subfamilies. Second, we will demonstrate the impact of semantic validation on applications of derivational knowledge such as derivation-driven smoothing of distributional models (Padó et al., 2013).

Abstract

We describe a novel approach to error detection in adjective–noun combinations. We present and release a new dataset of annotated errors where the examples are extracted from learner texts and annotated with error types. We show how compositional distributional semantic approaches can be applied to discriminate between correct and incorrect word combinations from learner data. Finally, we show how the output of the compositional distributional semantic models can be used as features in a classifier yielding good precision and accuracy.

1 Introduction

The task of error detection and correction (henceforth, EDC) in non-native writing in English has been a focus of research in recent years. However, usually research in this area focuses on EDC in the use of function words, such as articles or prepositions (Leacock et al., 2010; Dale et al., 2012), while much less attention has been paid to errors in the choice of content words.

Errors in function words are some of the most common error types in learner writing (Dalgish, 1985; Leacock et al., 2010), so it is important for any EDC system to be able to deal with such errors. Certain properties of these errors facilitate their detection and correction. As function words belong to closed classes, the set of possible corrections is limited by the size of the function word set. Since errors in function words are systematic and highly recurrent, in practice, each article or preposition has an even smaller number of appropriate alternatives. We illustrate this point with the following examples on (1) article and (2) preposition errors:

(1) I am *0*/a* student.

(2) Last October, I came *in*/to* Tokyo.

In (1) an EDC system would consider {*a, an, the*} as possible corrections for the missing article. To correct the preposition *in* in (2), an EDC system would consider the most frequent prepositions {*on, from, for, of, about, to, at, with, by*}, among which *at* or *to* would have a higher chance to be appropriate corrections as these are most often confused with *in*. Confusion sets can be learnt from learner texts, and probabilities can be set up according to the distribution of the confusions (Rozovskaya and Roth, 2011).

EDC is usually cast as a multi-class classification task, with the number of classes equal to the number of target corrections. Detection and correction can occur simultaneously: an error is detected when an EDC system suggests using a word different from the one originally used by the learner, and the suggested word can be used as a correction. Each occurrence of a function word is represented with a feature vector, where features are derived from the surrounding context. This is usually highly informative for function words: for example, a context of *I am* and *student* or a similar noun requires the use of an indefinite article, while the only correct preposition to relate a verb of movement like *come* to a locative like *Tokyo* is *to*.

In this work, however, we focus on errors in the choice of content words, which have received much less attention in spite of being the third most frequent error type in learner writing (Leacock et al., 2010). Errors in content words are more challenging than errors in function words, since the number of possible

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1740–1751, Dublin, Ireland, August 23-29 2014.

confusions and corrections cannot be reduced to a finite set. For example, consider incorrect choice of adjectives in the following sentences extracted from learner data:

(3) A *big*/great* damage has been made to the environment.

(4) I have tried a rock'n'roll dance and a *classic*/classical* dance already.

The confusion in (3) is caused by semantic similarity of the adjectives *big* and *great*, while in (4) it is due to similarity in form between *classic* and *classical*. It is much harder to cast the EDC in content words as multi-class classification, unless we consider the full set of English adjectives as possible classes. The surrounding contexts are much sparser and less informative, and in addition to that, often contain further errors. In this work, we address error detection and focus on adjective-noun combinations (ANs), which are representative of the more general task of EDC in content word combinations and are a frequent error type in learner text.

We have created a dataset of ANs, where the combinations are extracted from learner texts and manually error-coded using a novel annotation scheme. This scheme is motivated by observations about typical learner confusions in the choice of adjectives and nouns – for example, semantically-related or form-related confusions. Since errors in content words are related to semantics, we derive semantically-motivated features through models of compositional distributional semantics and use these features for error detection. We treat error detection as a binary classification task, following the usual convention in EDC.

The original contributions of this paper are that we:

- present and release an error-annotated AN dataset extracted from learner data;
- show how compositional distributional semantic models can be applied to detect semantic anomalies in this dataset;
- demonstrate that the output of these models can be used to derive features for error detection in AN combinations.

2 Previous work

2.1 Error Detection in Content Words

Previous work on EDC for content words has either focused on correction alone assuming that errors are already detected (Liu et al., 2009; Dahlmeier and Ng, 2011), or has reformulated the task as *writing improvement* (Shei and Pain, 2000; Wible et al., 2003; Chang et al., 2008; Futagi et al., 2008; Park et al., 2008; Yi et al., 2008; Östling and Knutsson, 2009).

In the first case, the task is reduced to the search for the most suitable correction among the alternatives typically composed of synonyms, homophones or L1-related paraphrases (Dahlmeier and Ng, 2011), while the more challenging error detection step is omitted. In the second case, error detection is integrated into suggestion of alternatives and their comparison to the originally used word combination according to some metric of collocational strength. Such approaches aim to improve the fluency of non-native texts by correcting erroneous idioms or collocations, where low frequency or low collocational strength clearly signifies an error.

These approaches might be useful for correcting collocations, but they are less suitable for error detection in free word combinations. As they compare original word combinations to their alternatives using corpus statistics, they are not applicable to unseen word combinations, while learner texts contain many previously unseen combinations, not all of which are errors. Moreover, some word combinations may be correct even though less fluent than some of their alternatives. For example, *appropriate concern*, though it is correct, would have lower collocational strength than its alternative *proper concern*, and would, according to this approach, be tagged as an error. From the educational point of view, tagging an acceptable combination as an error is misleading for language learners and should be avoided.

We implement a baseline model inspired by such comparison-based approaches and demonstrate that it cannot be usefully applied to error detection in content word combinations. Then we present an approach that is capable of dealing with unseen data and does not rely on direct corpus-based comparison.

2.2 Semantic Anomaly Detection

Learner errors in content words often result from a semantic mismatch between the chosen words. A similar problem of semantic anomaly detection in content word combinations has been addressed with compositional distributional semantic models.

These models are based on distributional representations for words which are then composed to derive phrase representations. They rely on the assumption that a word meaning can be approximated by its distribution across its contexts of use. Words are represented as vectors in a high-dimensional space with each dimension encoding a word's co-occurrence with one of its contextual elements. Distributional models are less suitable for representing content word combinations directly since these will be very sparse and will often remain unattested even in an extremely large corpus.

A promising solution is provided by compositional distributional semantic models, which combine distributional vectors for the component words using some function over such vectors. Compositional distributional semantic representations have been previously used to detect semantic anomaly in AN combinations (Vecchi et al., 2011). Vecchi *et al.* have applied the *additive* and *multiplicative* models of Mitchell and Lapata (2008) and *adjective-specific linear maps* of Baroni and Zamparelli (2010) to a set of corpus-unattested ANs. They show that there is a distinguishable difference in the compositional semantic representations for the semantically acceptable and anomalous combinations, suggesting that compositional distributional models can be used to detect semantic anomaly without relying directly on corpus statistics.

Kochmar and Briscoe (2013) have applied the same models of semantic composition to distinguish between correct and incorrect ANs extracted from learner texts. Their results support the assumption that there is a distinguishable difference between the composite vectors for the correct and incorrect ANs, but they did not address the question of how to integrate these semantic models into an error detection system.

Recent work by Lazaridou *et al.* (2013) has shown that measures used for quantifying the degree of semantic anomaly in phrases derived from their compositional distributional semantic representations can be used as features by a classifier to help resolve syntactic ambiguities.

Our goals are to test, using a new and larger AN dataset, whether semantic models can distinguish between correct and incorrect AN combinations, which cannot be dealt with using simpler error detection approaches, and to implement an error detection system using these semantically-based features.

3 Data Annotation

We present and release a dataset of AN combinations which, on the one hand, exemplify the typical errors committed by language learners in the choice of content words within such combinations, and, on the other hand, are challenging for an EDC system.

For that, we examined the publicly available CLC-FCE dataset (Yannakoudakis et al., 2011), used the error annotation (Nicholls, 2003), and analysed the typical errors in AN combinations committed by language learners. We have compiled a list of 61 adjectives that are most problematic for learners.

Most typically, learners confuse semantically related words: for example, they are unable to distinguish between synonyms, near-synonyms or co-hyponyms and choose an appropriate one from the set. Our list of adjectives contains some frequent ones that are confused with each other due to their similarity in meaning. For example, the adjectives within the set {*big, large, great*} are frequently confused with each other as in:

(5) *big*/large* quantity

(6) *big*/great* importance

Another common source of error related to the high-frequency adjectives involves using them instead of more specific ones: in such cases, learners are unable to distinguish between the more specific terms and they choose the most frequent adjective, usually encompassing a variety of related meanings, to represent the whole class of similar words. For example, adjectives *big* and *large* encompass a variety of meanings including those of *high*, *wide* or *broad*. As learners often lack intuitions about which of these

more specific adjectives should be chosen, they use the ones with more general meaning. This results in errors like:

(7) *big*/long* history

(8) *bigger*/wider* variety

(9) *greatest*/highest* revenue

(10) *large*/broad* knowledge

The reverse of this – an incorrect selection of a more specific term instead of the more general one – also leads to learner errors.

Form-related confusions represent another typical source of learner errors, and we have included pairs of adjectives such as *classic* and *classical*, *economic* and *economical* and the like in our dataset:

(11) *classic*/classical* dance

(12) *economical*/economic* crisis

Using this set of 61 adjectives, we have extracted AN combinations from the Cambridge Learner Corpus (CLC),[1] a large corpus of texts produced by English language learners, sitting Cambridge Assessment's examinations.[2] We have focused on AN combinations previously unseen in a native English corpus, as we hypothesise that they would have a higher chance of containing an error. Such combinations are more challenging for EDC algorithms since:

- these ANs cannot be effectively handled with simple comparison-based approaches like the ones overviewed in section 2.1;
- language learners are creative in their writing, so there is a substantial number of such previously unseen combinations;
- as no corpus could cover all possible acceptable content word combinations in language, the fact that these combinations are not seen in the corpus cannot be used as definitive evidence of incorrectness.

To summarise, it is important for an EDC algorithm to handle such combinations, but their absence in a native corpus of English makes it impossible to rely on simpler approaches and suggests that semantic analysis of such combinations would be more effective. In our research, we used the British National Corpus (BNC)[3] to select the corpus-unattested combinations.

We have compiled a set of 798 AN combinations.[4] An annotation scheme has been devised to annotate these examples as correct or incorrect, and for the incorrect combinations, to identify the locus of error (adjective, noun or both) and the type of confusion (incorrect synonym, form-related word, or non-related word). The most appropriate corrections are included in the dataset.

We also distinguish between *out-of-context* (*OOC*) and *in-context* (*IC*) annotation. The motivation behind this distinction is as follows: some combinations may appear to be correct when considered out of their original context of use, because there might be other contexts where the same combination would be appropriate. For example, *classic dance* is annotated as correct out of context because one could imagine using it in a context where it would denote some typical dance like:

(13) They performed a *classic Ceilidh dance*.

However, in practice, the AN *classical dance* is used much more frequently, and *classic dance* is most often errorful in context, as in (4) above.

Some ANs in our dataset are represented with more than one context of use, and in that case the *in-context* annotation can be conditioned on each context, or used to derive the most typical annotation for the AN. Both types of information are useful, as EDC systems which make use of the surrounding context should rely on the annotation in each particular context of use and, for example, be able to detect

Table 1: Distribution of correct (cor.) and incorrect (incor.) ANs in the dataset.

that *classic dance* is correct in one specific context, while in others it is incorrect. EDC systems that do not make use of the context can simply rely on the most frequent *in-context* annotation and detect that *classic dance* is typically an error in learner writing.

To create the two-level annotation, the annotators were first presented with an AN combination and asked to tag each word as correct or incorrect depending on whether they can think of some appropriate contexts of use for it. Next, the same combination was presented in its context of use from the CLC and the annotators were asked to annotate it with respect to its context.

The dataset was primarily annotated by a professional linguist. To ensure that the annotation scheme is clear and efficient, the dataset was split into 100 and 698 ANs, and the 100 ANs were first annotated by the same professional annotator and three other annotators. We have measured the inter-annotator agreement for the two levels of annotation using the mean values for the observed agreement within each pair of annotators, as well as mean Cohen's *kappa* value (Cohen, 1960). In Table 1 we report the mean inter-annotator agreement for the correct versus incorrect combinations at the two annotation levels, which represents the upper bound (*UB*) in our experiments. We have obtained the mean *kappa* values of 0.65 and 0.49 at the two levels of annotation, which are interpreted as substantial and medium agreement between annotators and confirm that the annotation scheme is clear.[5] Table 1 presents the distribution of ANs and the majority class baseline which we further use as a lower bound (*LB*).

4 Semantic Models for Error Detection

We replicate the semantic approaches, which have previously shown promising results in detecting semantic anomaly and content word errors (Vecchi et al., 2011; Kochmar and Briscoe, 2013), and test their performance on our dataset of corpus-unattested correct and incorrect AN combinations.

4.1 Experimental Setting

We use the *additive* (*add*) and *multiplicative* (*mult*) models of Mitchell and Lapata (2008), and the *adjective-specific linear maps* (*alm*) of Baroni and Zamparelli (2010).

The first two models derive the composite phrase vector through addition and multiplication of the components of the word vectors. These models have a clear mathematical interpretation and require no training. Their principal weakness is that they are symmetric, and fail to represent the difference in grammatical function of the component words. The *alm* model provides a theoretically more appropriate way of representing ANs based on this asymmetry: nouns are represented by their distributional vectors, while attributive adjectives are functions mapping from noun meanings to a composite noun-like vector for the ANs. Adjectives are represented as weight matrices which are learned from corpus-attested examples of noun–AN mappings, and composition is defined by matrix-by-vector multiplication.

We use the experimental setting previously described (Vecchi et al., 2011; Kochmar and Briscoe, 2013) and populate the semantic space with the constituent nouns and adjectives from the test ANs, frequent nouns and adjectives from the BNC and the AN combinations containing these frequent words. We use about $8K$ nouns, $4K$ adjectives and $64K$ ANs following Kochmar and Briscoe (2013). The semantic space is represented by a matrix encoding word co-occurrences, where the rows represent the $76K$ elements mentioned above, and the columns represent a selected set of $10K$ context elements. The $10K$ context elements include the most frequent nouns, adjectives and verbs from the corpus. The word co-occurrence counts are estimated using the BNC. The corpora have been lemmatized, tagged and parsed with the RASP system (Briscoe et al., 2006; Andersen et al., 2008; Yannakoudakis et al., 2011), and all statistics are extracted at the lemma level.

[5] Further details of the annotation experiment are described in the dataset release.

We transform the raw sentence-internal co-occurrence counts into Local Mutual Information scores (Baroni and Zamparelli, 2010; Evert, 2005), and perform dimensionality reduction applying Singular Value Decomposition to the noun and adjective matrix rows, projecting the AN rows onto the same reduced space following Baroni and Zamparelli (2010). The original $76K \times 10K$ matrix is reduced to a $76K \times 300$ matrix. This allows us to perform training and other calculations in the semantic space more efficiently.

The weight coefficients for the *alm* model are estimated with multivariate partial least squares regression using the RPLS package (Mevik and Wehrens, 2007). The weight matrix is learned for each adjective separately.

4.2 Semantic Cues

In previous work (Vecchi et al., 2011; Kochmar and Briscoe, 2013) several semantic measures for detecting semantic anomaly have been introduced. We reimplement these measures (1 to 8), but also test some additional measures (9 to 13) that we hypothesise can also help distinguish between correct and incorrect word combinations:

1. **Vector length (*VLen*)**: vectors for correct and incorrect combinations may differ with respect to their length, and the latter are expected to be shorter;
2. **Cosine to the input noun (*cosN*)**: the distance between the model-generated AN vector and the input noun vector is expected to be greater for the incorrect combinations, as the noun meaning is typically 'distorted';
3. **Cosine to the input adjective (*cosA*)**: analogical to *cosN* measure, the adjective meaning might be 'distorted' as well, especially as two of the composition functions are symmetric;
4. **Density of the neighbourhood populated by** 10 **nearest neighbours (*dens*)** is calculated as the average distance from the model-generated vector to the 10 nearest neighbours in the original semantic space, and is expected to be higher for the correct ANs;
5. **Density among the** 10 **nearest neighbours (*densAll*)** is a modification of *dens*, which is estimated as an average for the 11 density values calculated for each member within the set consisting of the AN vector and its 10 neighbours;
6. **Ranked density in close proximity (*Rdens*)** relies on the notion of *close proximity*, which is defined as a neighbourhood populated by some very close neighbours (for example, within a distance of ≥ 0.8). It is calculated as: $RDens = \sum_{i=1}^{N} rank_i distance_i$ with N being the total number of close neighbours within close proximity, each with its rank and distance;
7. **Number of neighbours within close proximity (*num*)** is used as another measure, and is assumed to be lower for incorrect combinations, which are expected to be more isolated in the semantic space;
8. **Overlap between the** 10 **nearest neighbours and constituent noun/adjective (*OverAN*)** assumes correct ANs should be surrounded by similar words and combinations. It is calculated as the proportion of the 10 nearest neighbours containing the same constituent words as in the tested ANs;
9. **Overlap between the** 10 **nearest neighbours and input noun (*OverN*)** is a variant of the *OverAN* with only the noun considered;
10. **Overlap between the** 10 **nearest neighbours and input adjective (*OverA*)** is a variant of the *OverAN* with only the adjective considered;
11. **Overlap between the** 10 **nearest neighbours for the AN and constituent noun/adjective (*NOverAN*)** assumes that correct ANs and their constituent words should be placed in similar neighbourhoods. It is calculated as the proportion of the common neighbours among the 10 nearest neighbours for the model-generated AN and the constituent words;

4.3 Results

We evaluate the models and report the results following the procedure that has been used before in Vecchi *et al.* (2011) and Kochmar and Briscoe (2013). For each model and semantic measure, we report the p value denoting statistical significance of the difference between the groups of correct and incorrect ANs. The statistical significance is reported at the $p<0.05$ level, and if a measure applied to the two groups of ANs shows statistically significant difference we interpret that as an ability of this measure to distinguish the correct ANs from the incorrect ones in general. The results for the out-of-context annotation are reported in Table 2, and those for the in-context annotation in Table 3.

The results show that the difference between the vector representations for the correct and incorrect AN combinations can be reliably detected with a number of the proposed measures. Measures which show statistically significant results with at least one model are marked in bold. These results also suggest that the values for the semantic measures can be used to derive discriminative features for a classifier.

5 Error Detection as Classification Task

5.1 Baseline System

We implement a simple comparison-based baseline system inspired by previous work on error detection in content words (see section 2.1). For every AN, we create a set of possible alternatives crossing the confusion set for the adjective with that for the noun, and compare the collocational strength of the original combination with that for each of the alternatives. If an alternative has higher collocational strength than the original combination, the original combination is tagged as an error and the alternative is chosen as a correction. Since semantically related confusions are a rich source of learner errors in content word combinations, we include adjective synonyms in the confusion set for an adjective, and noun synonyms and hyponyms in the confusion set for a noun. All synonyms and hyponyms are retrieved using WordNet 3.0 without word sense disambiguation.

We measure collocational strength using *normalized pointwise mutual information (npmi)* of the adjective a and noun n, which is defined as:

$$npmi(a,n) = \frac{pmi(a,n)}{-log[p(a,n)]} \quad (1) \qquad pmi(a,n) = log\frac{p(a,n)}{p(a)p(n)} \quad (2)$$

All probabilities are estimated from the BNC. This approach performs poorly on the unseen ANs in our dataset, since any alternative AN seen in the BNC would be preferred by this system over the original unseen AN. This ensures that less fluent (in this case, unseen) word combinations are substituted with more fluent (seen) ones. As a result, even though an original AN *important conversation* in our dataset is correct, it is still "corrected" by this system to *serious conversation*. At the same time, some incorrect combinations are not recognised if no appropriate alternative is found (e.g., **high shyness*). It shows that this approach lacks deeper semantic analysis and is also too dependent on the set of alternatives found for a word combination.

We measure *accuracy (acc)* as the proportion of true positives (*TP*) and true negatives (*TN*) to the total number of test items:

$$Acc = \frac{TP + TN}{TP + FP + TN + FN} \quad (3)$$

Accuracy reflects how often an error detection system correctly identifies that an AN is correct or incorrect. We compare the results to the lower and upper bounds set as the majority class distribution and inter-annotator agreement, respectively (see section 3).

With this approach we get quite low accuracy of 0.3897 on the out-of-context annotation since most of the test items are correct out of context (LB=0.7932), and the baseline system overcorrects many of those. Accuracy of the baseline system on the in-context annotation is 0.5147, which is slightly above the lower bound of 0.5063. These results are used as a baseline and included in Table 4.

Type	Accuracy	Baseline	LB	UB
OOC	**0.8113** $\pm$ 0.0149	0.3897	0.7932	0.8650
IC	**0.6535** $\pm$ 0.0189	0.5147	0.5063	0.7467

Table 4: *Decision Tree* classification results

Type	P (correct)	P (incorrect)
OOC	0.8193	0.7500
IC	0.6241	0.6850

Table 5: Classification precision

5.2 Classification

We implement a supervised classifier which uses output of the semantic models as features. We have tested a number of classifier models but the best results so far have been obtained with the *Decision Tree* classifier using $NLTK$ (Bird et al., 2009). We assume that this classifier effectively learns the inter-dependencies between the features within the small feature set that we use in our experiments. We use feature binning where the whole range of feature values is divided into 10 bins according to the distribution of values for each feature. This feature representation technique combined with the classifier helps generalise over feature values, reducing feature space dimensionality. The order of the feature application to the data is determined by the classifier on the basis of the information gain for the features and their values.

We apply 5-fold cross-validation and report average accuracy over the folds. The 798 ANs are split into 5 subsets with 80% in each of the splits used for training and 20% for testing. We keep the AN error rate in the training and test sets, as well as for each adjective, approximately the same across the splits to avoid any bias. Error detection is cast as a binary classification task. The output of the semantic models is used to derive numeric features for the classifier. Most values are in the range of $[0, 1]$, and we apply normalisation to *VLen*, *RDens* and *num* which originally have a different range.

The full feature set contains 14 features, with 13 features derived from the semantic measures, and 1 feature representing adjective identity. We hypothesise that introduction of this feature might help classifier learn that, for example, an AN containing an adjective *classic* has a higher chance of being incorrect, as most of the ANs with this adjective in the learner data are incorrect and involve confusions with *classical*. We also hypothesise that it facilitates learning correlations between the adjective and other

feature values: it might be the case that ANs with an adjective adj_1, on the average, have higher *cosN* values than ANs with an adjective adj_2. This feature helps the classifier establish such dependencies between the adjective and the values of the semantic measures. For instance, in our data ANs with the adjective *true* have significantly higher cosine between AN vectors and vectors for their constituent nouns than ANs with the adjective *false*: this is in accordance with an intuition that, for example, *true happiness* is more similar to *happiness* than *false happiness* is.

The best results in our experiments have been obtained with the *mult* model. We have performed ablation tests incrementally removing features that did not improve classifier performance in order to find an optimal feature set. The best-performing feature set we found for the *mult* model on the out-of-context annotation uses *adjective*, *cosN* and *RDens* features, while for the in-context annotation the best-performing feature set found uses a combination of features including *adjective*, *VLen*, *densAll*, *NOverA*, *NOverN*, *RDens* and *num* features.

We note that the sets of best performing features in the classification experiments do not coincide with the semantic measures that showed the highest statistically significant difference (Tables 2 and 3). We conclude that although the p values reported in Tables 2 and 3 show that some semantic measures can distinguish one group of ANs from another on the basis of the statistically significant difference between the means of the two groups, when the measures are used as features for a classifier the results depend on how these features interact with each other as well as on their individual discriminativeness across the test dataset. For example, Figure 1 illustrates a small part of the decision tree constructed using the best performing feature set on the in-context annotation:

```
...
    if (num=1.0) == False:
    ...
        if (adjective is 'large') == True:
            if (0.002<=VLen<0.003) == False: return '1' [e.g., 'large jeans']
            if (0.002<=VLen<0.003) == True: return '-1' [e.g., 'large knowledge']
    if (num=1.0) == True: return '1'
...
```

Figure 1: *Decision Tree* classifier pseudocode.

Figure 1 shows how interaction of feature values for *num* and *VLen* in combination with the adjective identity feature can help classify the two ANs containing adjective *large* as correct (`1`) or incorrect (`-1`).

In Table 4 we report results for the *out-of-context* (*OOC*) and *in-context* (*IC*) annotation. The accuracy is reported with its mean $\pm$ standard deviation over the 5 data splits. We compare the *Decision Tree* classifier results to those obtained with the baseline system, as well as to the lower and upper bounds set as before (see section 3). The results show that a classifier that uses output of the semantic models as features outperforms the comparison-based baseline system by a large margin.

6 Discussion

In the previous section, we showed that a classifier that uses output of the semantic models as features outperforms the comparison-based baseline system and shows good accuracy. In this section, we analyse the classifier's performance in more detail.

We note that, from an educational point of view, it is important for an EDC system to have high precision. For example, it has been shown that grammatical error detection systems with high precision maximize learning effect, and that systems with high precision but lower recall are more useful in language learning than systems with high recall and lower precision (Nagata and Nakatani, 2010). This suggests that learners might be misled and confused if they are frequently notified by a system that something is an error when it is not.

Since precision is measured as the proportion of true positives (*TP*) to the sum of true positives and false positives (*FP*):

$$P = \frac{TP}{TP + FP} \tag{4}$$

an EDC system that achieves precision less than 0.5 is, in fact, misleading for language learners: for example, precision of less than 0.5 on the class of errors means that the system misidentifies correct use as an error more frequently than it correctly detects an error.

Our classifier achieves good precision values with respect to both out-of-context and in-context annotations, on correct and incorrect examples. Precision (P) values are reported in Table 5. As precision figures are higher than 0.5 in each case, it shows that the implemented error detection system would, on balance, help guide a learner to text regions in need of reformulation.

With respect to the out-of-context annotation, the error detection system has good precision and recall on correct examples ($P = 0.8193$, $R = 0.9762$). Precision on the incorrect examples is also high ($P = 0.7500$). This is a very encouraging result, suggesting the system would rarely misidentify an originally correct AN combination as an error.

For the in-context annotation, both precision and recall on correct and incorrect examples are quite high: $P = 0.6241$ and $R = 0.7169$ on the correct examples, and $P = 0.6850$ and $R = 0.5849$ on the incorrect examples.

Error analysis on the classifier's output shows that the majority of the incorrect examples misclassified as correct (*missed errors*) contain semantically-related confusions. It appears that the classifier relying on semantically-motivated features misses a number of cases where the original AN and its correction are semantically similar: for example, it misses the errors in *big*/great anger*, *biggest*/greatest painter* and *small*/short speech*. Since the ANs in these pairs are semantically similar, the features based on their semantic representations might not be discriminative enough. In contrast, the classifier is more effective in detecting errors in cases where the original AN and its correction are only similar in form, or not related to each other.

7 Conclusion

We have presented and released a dataset of learner errors in ANs, which has been extracted from learner texts and annotated with error types and corrections. The dataset contains examples not seen in a native corpus of English, and error annotation shows that a substantial number of such examples are correct. Error detection in this dataset is a challenging task, since absence of the ANs in a corpus of English cannot be used as definitive evidence of incorrectness. We have implemented a simple baseline system inspired by previous work on improving content word combinations and shown that such a system would not be effective for error detection in our dataset.

We have cast error detection as a binary classification task and implemented a supervised classifier that uses semantically-motivated features. The features are derived from the compositional distributional semantic representations of the AN combinations. We use a number of semantic measures that describe and distinguish between semantic representations for correct and incorrect combinations. We have introduced new semantic measures in addition to the ones used in previous work and show that they can be effectively applied to this task.

The best results in our experiments are obtained with a *Decision Tree* classifier, and we show that the resulting error detection system can identify errors with high precision and accuracy. We aim to extend this system to perform error correction on ANs, as well as error detection and correction on other types of content word combinations.

Acknowledgments

We are grateful to Cambridge English Language Assessment and Cambridge University Press for supporting this research and for granting us access to the CLC for research purposes. We would like to thank Øistein Andersen for providing us with the annotation tool, Diane Nicholls for undertaking the bulk of the annotation work, and Helen Yannakoudakis and the anonymous reviewers for their valuable comments.

A Novel Distributional Approach to Multilingual Conceptual Metaphor Recognition

Abstract

We present a novel approach to the problem of multilingual conceptual metaphor recognition. Our approach extends recent work in conceptual metaphor discovery by combining a complex methodology for facet-based concept induction with a distributional vector space model of linguistic and conceptual metaphor. In the evaluation of our system in English, Spanish, Russian, and Farsi, we experiment with several state-of-the-art vector space models and demonstrate a clear benefit to the fine-grained concept representation that forms the basis of our methodology for conceptual metaphor recognition.

1 Introduction

The role of metaphor in language has been defined by Lakoff et al. (1980; 1993) as a cognitive phenomenon which operates at the level of mental processes, whereby one concept or domain is viewed systematically in terms of another. For example, the phrase "to cure poverty" is a metaphor which subtly conveys a wide variety of information to the listener. In order to mentally process this phrase, we must first recognize that a metaphor is being used and that "cure" (as a medical term) is being used figuratively. Then, we assume some relationship between "poverty" and "things that can be medically cured" which leads to the conceptual mapping "POVERTY as DISEASE." This conceptual mapping enables the listener to transfer a variety of properties and associations between the two concepts, such as their association with a feeling of helplessness, the existence of sustained efforts to end them, the potential for them to spread, and their mutual relationship with ill-health and death. Therefore, by identifying the conceptual domains associated with this linguistic metaphor, we are able to reason about the target domain (POVERTY) using concepts and terms associated with the source domain (DISEASE).

Any natural language processing system capable of processing metaphor in text with human-level competence must, therefore, overcome three problems in sequence:

1. the identification of metaphorical expressions (also known as linguistic metaphors (LMs))
2. the discovery of a conceptual domain mapping or conceptual metaphor (CM) which consists of
   (a) the conceptual domain of the metaphor target (e.g., POVERTY); and
   (b) the conceptual domain of the metaphor source (e.g., DISEASE)
3. the real-world interpretation of the metaphorical text which uses the conceptual metaphor framework to transfer knowledge between the source and target domains.

While a significant amount of recent work has presented interesting and promising methodologies for multilingual LM identification (Shutova and Sun, 2013; Wilks et al., 2013; Strzalkowski et al., 2013), the work presented in this paper is focused on (2), the problem of multilingual CM recognition, which will be made to serve as the foundation for a more fine-grained interpretation of metaphor.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1752–1763, Dublin, Ireland, August 23-29 2014.

We cast the CM recognition process as a two-part methodology which (a) selects the target domain associated with a particular LM that has been detected; and (b) determines the source domain to which it should be mapped in order to produce a satisfactory interpretation. In this work, we assume that the target domains are known and belong to one of the following conceptual spaces: POVERTY, WEALTH, or TAXATION. Pragmatically speaking, research in CM recognition presupposes some methodology for LM identification, and to this end, we have employed an existing state-of-the-art LM identification system which has been developed to detect linguistic metaphors in four languages: English, Spanish, Russian, and Farsi (Bracewell et al., 2014).

In order to generate a CM which can serve as the basis for an interpretation of an LM, we have developed an approach that is based on the following hypotheses:

> CONCEPTUAL HYPOTHESIS: When an LM has been identified as a pair of lexical items that represent the source (e.g., "cure") and the target (e.g., "poverty"), we can generate a conceptual mapping by selecting the conceptual domains that are, *a priori*, the most likely for the source and target lexemes.[1]
>
> DISTRIBUTIONAL HYPOTHESIS: It is possible to decide which conceptual space better represents a given lexeme by
>
> 1. expanding the lexical space with additional terms (which we call "grammatical co-occurrents") that are strongly associated with the lexeme through grammatical relations such as AGENT, PATIENT, INSTRUMENT, and ATTRIBUTE;
> 2. using these lexical expansions to produce distributional vectors; and
> 3. uncovering the *selectional constraints* of particular domain facets by clustering the distributional vectors within a semantic space.
>
> DOMAIN HYPOTHESIS: The grammatical co-occurrents of the LM are themselves very likely to belong to the same conceptual domain as the lexeme (e.g., "cure patient", "cured of AIDS", and "doctor cured").
>
> MAPPING HYPOTHESIS: The semantic space representations of both the LM source and its grammatically associated terms can be used to produce mappings into a high dimensional space in which source domains are known to exist.

While other computational linguistics research in metaphor has made use of the CONCEPTUAL and DISTRIBUTIONAL hypotheses, to our knowledge the DOMAIN and MAPPING hypotheses have not yet been explored in combination with a distributional approach.

The remainder of this work is organized as follows. In Section 2, we discuss related work in the field of metaphor interpretation and unsupervised concept induction. In Section 3, we introduce the overall architecture of our CM recognition system. In Section 4, we describe our method for representing lexical items and conceptual metaphors in a distributional vector space. Then, in Section 5, we explain our methodology for creating and ranking clusters of LM co-occurrents which are then mapped to conceptual metaphors within our vector space. In Section 6, we describe our experimental setup and provide the results of our experiments. Finally, in Section 7 we present our conclusions.

2 Related Work

Research in metaphor processing can broadly be divided into two categories: metaphor identification and metaphor interpretation. Although some recent work on metaphor interpretation has skirted the issue of conceptual metaphor entirely by casting the problem of metaphor interpretation as an instance of lexical paraphrase (Shutova, 2010; Bollegala and Shutova, 2013) or textual entailment (Mohler et al., 2013), the mapping and modeling of conceptual metaphors has historically served as an important foundation for

[1] If the target domains are pre-selected, this hypotheses is reduced to selecting only the most likely source domain.

more robust interpretation of metaphor. Indeed, a significant amount of research in metaphor interpretation has been concentrated on the development of highly-structured, manually curated representations of both the CM source and CM target domains. Notable in this regard are the KARMA system (Feldman and Narayanan, 2004) which was designed to simulate neurological modeling of verbs – both abstract and metaphorical – and the ISOMETA system (Beust et al., 2003) which made use of differential tables of CM domain lexical items to drive their metaphor interpretation process. The CorMet system (Mason, 2004) sought to model conceptual metaphors by detecting individual source-target mappings that provide evidence for a known CM by quantifying the overlap between clusters of terms with a strong selectional preference to the most representative verbs within the source and target domains. After a manual inspection of the source/target cluster pairs across domains, the directionality and the systematicity of these underlying conceptual mappings were quantified in order to produce an overall confidence in the mapping. As part of their development of the Hamburg Metaphor Database (HMD), Reining and Lönneker-Rodman (2007) performed a a manual categorization of lexical items into conceptual source domains with a facet-level granularity and enriched their domains using a WordNet-based lexical expansion. In the same vein, Chung et al. (2005) chose to model source domains by expanding their lexical items by exploiting the links between WordNet glosses and the SUMO ontology.

In recent years, however, research has focused on automating the modeling and classification of conceptual metaphors as much as possible in order to encourage the scaling up of metaphor research in general. Veale and Hao (2008), as part of the Talking Points system, developed what they refer to as a Slipnet which defines linked chains of meaning that connect a source to a target through shared (or related) attributes and actions. As a step in this process, they combined WordNet relations with pragmatic relations extracted from text and clustered nouns according to their relation (and attribute) similarity in order to define a weak conceptual mapping within the clusters. In a similar way, Shutova et al. (2010), beginning with a seed set of noun/verb linguistic metaphor pairs, performed spectral clustering on a large set of nouns and verbs in order to predict metaphors which participate in the same conceptual metaphor mapping. In particular, she modeled verbs according to their subcategorization frames parameterized by a model of their selectional preferences, while nouns were modeled according to the verbs with which they frequently co-occurred in a dependency relation.

More recently, Gandy et al. (2013) approached the CM discovery problem as a set covering problem. For a given nominal target lexeme, they began by finding all facets (i.e., verbs/adjectives) that share a positive PMI with the target. Then, they would find the set of nouns that also have a positive PMI with those facets, compute their confidence in each association, and heuristically select pairs of concepts (defined as rooted WordNet synset trees) which subsume a large percentage of those nouns and cover a large portion of the overlapping facets. Similarly, Shutova and Sun (2013) detect conceptual mappings by performing hierarchical graph factorization clustering on a graph in which the vertices are defined to be nouns (i.e., concepts) and the edges are weighted using Jensen-Shannon Divergence. For a given input LM source, its likely conceptual metaphors are then discovered by determining its non-literal cluster membership. Finally, Strzalkowski et al. (2013) discovered terms (literal and metaphoric) which often co-occur with an LM source in a corpus and clustered those terms using WordNet and corpus statistics to form "ProtoSources" which could be further inspected to define CM source concepts.

Two vector-based approaches to concept representation are of particular interest in understanding the present work. In the first of these, Schütze (1998) described an approach to word sense identification using second-order co-occurrence vectors which were used to cluster first-order vectors of the in-context terms into senses.[2] Lin (1998), in developing a methodology for evaluating the quality of thesauri, defined a word vector space that moved beyond simple co-occurrence by integrating information about the relations between the word and its co-occurrents. In particular, a word's vector was defined by the number of times that word occurred within a set of (*word, relation, word*) tuples. Our DepVec space represents an extension to Lin's space insofar as we incorporate additional information about relational (i.e., selectional) preference.

[2]While context is critical in word sense disambiguation, we hasten to point out that one mark of metaphoricity is its disconnect from the surrounding literal context.

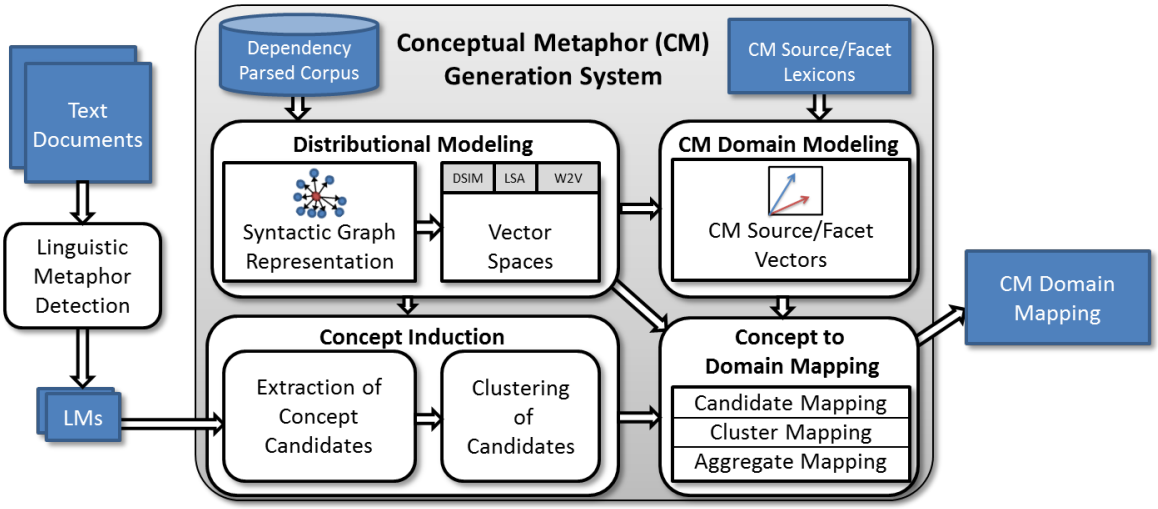

Figure 1: The architecture of our conceptual metaphor recognition system. This system takes a linguistic metaphor as input, induces potential concepts using vector-space clustering, and maps these clusters onto a conceptual metaphor domain.

3 A New Methodology for Conceptual Metaphor Recognition

Figure 1 shows the overall flow of our metaphor processing architecture. We begin with a set of documents gathered from a variety of online news-wire sources. These documents are fed to our state-of-the-art LM detection system which employs a binary logistic regression classifier using a variety of feature modules including imageability and concreteness estimation, topicality modeling, pattern matching, semantic categorization, selectional preference violation, and source/target vector space similarity. The methodology used in this system is beyond the scope of this work, but it is described in detail by Bracewell et al. (2014). The LMs provided by the detection system are validated by a group of native-language experts before being sent for CM recognition system for concept-level interpretation.

Once the LMs have been collected and validated, the CM recognition system begins by extracting, weighting, and clustering the common grammatical contexts of the LM source term. By grammatical context, we refer to the syntactic relations (along with their arguments) which have been found to frequently co-occur with the LM source term in open text. In order to model this grammatical context, we have syntactically parsed a wide collection of documents in each of our focus languages: English, Spanish, Russian, and Farsi. From these parsed documents, we have extracted the most common grammatical co-occurrents of each word in the corpus along with the relation that connects them and the number of times they are connected by that relation. For a given word, we refer to the set of its grammatical co-occurrents as the "concept candidates" associated with that word, as they represent potential concepts within the same conceptual domain as the given word (the DOMAIN HYPOTHESIS). For example, grammatical co-occurrents of the noun "battle" would include many WAR concepts such as "fought", "died in", "waged", "naval", and "losing".

Since a conceptual domain is made up of several interacting concepts, we perform a clustering over the grammatical co-occurrents to produce groups of terms which are likely to represent individual concepts within a domain. The clustering is performed within a high-dimensional, distributional vector space which we describe in Section 4. The clusters are then merged and aligned with a set of 51 predefined source concept domains (see Table 1) that have been found to occur frequently in conceptual metaphors about POVERTY, WEALTH, or TAXATION. For each of these known conceptual domains, we have amassed a collection of lexical items for the purpose of modeling the domains and aligning them to our automatically discovered domains. The collection of lexical items associated with each domain have been further partitioned into three to five *facets* which provide a more fine-grained representation of the domain. For instance, the conceptual domain of ABYSS as been subdivided into facets representing

Full Source Concept List					
A GOD	COMPETITION	ENSLAVEMENT	LIGHT	NATURAL PHYSICAL FORCE	PORTAL
A RIGHT	CONFINEMENT	FOOD	LOW POINT	OBESITY	RESOURCE
ABYSS	CRIME	FORCEFUL EXTRACTION	MACHINE	PARASITE	SCHISM

DEPTH (e.g., "deep", "bottomless"), ENTRANCE (e.g., "plunged into", "falling into"), and EXIT (e.g., "climb out of").

3.1 Motivating Example

Table 2 shows a sample of the concept candidates associated with the word "cure" along with the relation that connects them. Our methodology for extracting these terms is discussed in Section 5.1.

nsubj	NIH, WHO, therapist, doctor, vaccine, drug, medicine, *chef, butcher*	prep_of	cancer, AIDS, HIV, malaria, influenza, seizures, allergies
dobj	cancer, polio, Goji Berries, man, genetic defects, aging, infant, woman, depression, *meat, fish, garlic*	prep_by	bone marrow transplant, spleen cells, acupuncture, *smoking, salting,* doxycycline, *drying, burying, dipping*
prep_without	surgery, operation, suppuration, *salt* chemotherapy, injections	prep_to^{-1}	need, project, *brine, mineral,* coalition, run, walk, *salt, nitrite*
prep_in	mice, children, baby, *spices, salt,* monkeys, drug trial, breakthrough, *brine, smokehouse, basement, fridge*	prep_for	*grinding, smoking, voyages, lox, transportation, preservation, jerky, sausages, bacon, sale*

Table 2: Terms that are frequently a part of the grammatical context of "cure" along with their associated relations

It is clear from the concept candidates shown that there are at least two coarse-grained senses of "cure" present – corresponding to the domains of MEDICINE and FOOD. Table 3 shows a sample result of clustering these concept candidates. These clusters are organized according to their domain with MEDICINE-related clusters in the left grouping, FOOD-related clusters in the top-right grouping, and clusters not strongly related to either domain in the bottom-right grouping. Each row of the table represents a single cluster. In addition, it can be observed that these clusters correspond to particular semantic facets of the conceptual domain. For instance, there is a cluster that defines "procedures which result in medical cures" ("acupuncture", "surgery", "operation", etc.), one that defines "individuals who cure food products" ("chef", "butcher"), and one that defines "diseases that can (potentially) be cured" ("cancer", "polio", "AIDS", etc.). Our methodology for automatically inducing such clusters is described in Section 5.2.

Once the clusters have been identified, they can be used to define a mapping from the original LM ("cure") onto a pre-defined set of CM source domains (the MAPPING HYPOTHESIS). In particular, individual concept candidates are mapped to CM domains by calculating the distance between the candidate and one or more vectors representing each domain in a high-dimensional distributional vector space.

4 Distributional Representations

Our method for identifying conceptual metaphor domains relies on determining when multiple words should be grouped as belonging to the same conceptual class (the DISTRIBUTIONAL HYPOTHESIS). Previous work in semantic similarity has shown two types of approaches to work well: (a) hand-coded knowledge such as WordNet or SUMO, and (b) distributional approaches which rely on statistics of

NIH, WHO, therapist, doctor	chef, butcher
vaccine, drug, medicine, doxycycline	project, coalition
spleen cells, bone marrow transplant	meat, fish, sausages, jerky, bacon, lox
acupuncture, surgery, operation	garlic, Goji Berries
chemotherapy, injections, suppuration	smoking, salting, drying, dipping
HIV, malaria, influenza	burying
cancer, polio, AIDS	salt, brine, spices, nitrite, mineral
genetic defects, aging, depression	smokehouse, basement, fridge
seizures, allergies	run, walk
drug trial, breakthrough	voyages, transportation
infant, man, woman, children, baby	mice, monkeys

Table 3: Terms from Table 2 grouped into conceptual clusters – one per line. These clusters are organized according to their domain association: MEDICINE (left), FOOD (top-right), unclear (bottom-right).

word usage in corpora. We adopt the distributional approach in order to facilitate research in languages (such as Farsi) for which coverage of existing knowledge bases is limited. The only requirements for our approach are a corpus with documents written in that language and a syntactic parser for the language. We use the Malt dependency parser to obtain syntactic parses for web documents in each language.

Table 2 of Section 3.1 shows some of the words which participate regularly with the word "cure" in a dependency relation. These syntactic contexts of the word "cure" form the basis for one semantic representation we use to find other similar words, which we will call *DepVec*. All of the dependency relations for a word are used to form a vector-based distributional representation for that word. This representation projects words which are semantically similar to one another onto vectors which are near to each other in the vector space. In the following subsection, we describe DepVec along with LSA and word2vec which are alternative vector space models of word meaning. These vector spaces are then used to calculate similarities between words in order to cluster them and to align them with lexicons which model our existing conceptual spaces.

4.1 Dependency Vectors (DepVec) space

In our DepVec vector space model, each word is represented by a vector whose elements correspond to syntactic contexts of the word. Each element of the vector for word w corresponds to the frequency of a unique dependency relation (w, r, w') seen in the corpus. For example, if the relation $(whale, nsubj^{-1}, swim)$ is extracted once, then the vector for "whale" contains a 1 in the element for $(nsubj^{-1}, swim)$, and the vector for "swim" contains a 1 for the element $(nsubj, whale)$. This representation corresponds that proposed by Lin (1998).

However, the use of raw frequency counts in these vectors leads to a situation in which words that are more frequent in the corpus (e.g., "of", "the", "one") will have higher frequencies in the vectors by chance alone, and so a high co-occurrence count for those words is not indicative of a significant relation to the word. We overcome this limitation by replacing the raw frequency counts in each vector with their corresponding G-test scores. The G-test is a measure of statistical significance for proportions, similar to the Chi-square test, which measures the degree to which a particular triple (w, r, w') was found to occur more frequently than expected given all relations (w'', r, w'). If w' occurs far more often with w than it does with other words, then it will receive a high G-test score for w. In particular, the G-test score is computed according to the following equation:

$$G = 2 \sum_i O_i \cdot ln(O_i / E_i)$$

where the index i ranges over the four cells of a 2x2 contingency table, O_i is the observed count in cell i, and E_i is the expected count in the same cell.

Language	Source	# Documents	Language	Source	# Documents

Russian	ruWac	1,173,590	Farsi	Online news sites	835,588

Table 4: Statistics of the corpora used to construct the vector space models

4.2 Latent Semantic Analysis (LSA)

While the DepVec model provides information about the immediate contexts a word can be expected to occur in, it does not directly capture information about the broader contexts typical of that word, such as topical information. Latent Semantic Analysis (LSA) is a well-studied model (Landauer and Dumais, 1997) which does capture such topical information. The LSA model utilizes a singular value decomposition of a TF-IDF weighted matrix representation of the term-document co-occurrences. Terms and documents are then represented in a reduced dimensionality space using only the information from the eigenvectors with the k largest eigenvalues.

4.3 Continuous skip-gram model (W2V)

Mikolov et al. (2013) recently presented a new method for determining distributional word representations based on a shallow neural network model. The values of the latent vector for each word are trained to optimize prediction of the words within a 10 token window. This prediction is performed using the term's latent vector as the input to a series of log-linear classifiers with outputs which correspond to probability distributions over the tokens within the context window. Each position in the context window is assigned its own classifier weights, so that the model used for making predictions about words immediately following the input term is different than the model which makes predictions about the words two tokens after the term, and so on. Because these latent vector representations are in a low dimensionality space (300 dimensions in our case), the training process will tend to move the representations for similar words closer together in this space in order to maximize the predictive accuracy of their contexts.

One benefit of the continuous skip-gram model is that it creates representations which capture some local context as in the DepVec model, which is required to make predictions about the previous and next tokens. However, it must also encode some topical knowledge in order to make accurate predictions about the words seven tokens away. Therefore, using the latent term representations from the continuous skip-gram model as a vector space puts it in a convenient position in between the two others we presented.

4.4 Corpus Processing

The vector models described above were developed using web-scale corpora collected from a combination of frequently used NLP corpora and web crawls on news websites. Table 4 indicates the number of documents used for each language along with their source. These corpora were part-of-speech tagged with in-house POS taggers for English and Spanish, TreeTagger[3] for Russian, and hunpos[4] for Farsi. The open-source MaltParser was used to produce dependency parses for all four languages (Nivre, 2003). Dependency counts for all words occurring fewer than 40 times and for triples occurring fewer than three times were discarded to minimize noise.

5 Concept Induction and CM Recognition

In Section 4, we described our DepVec representation of terms as vectors in a high-dimensional distributional space. These vector representations encode both the dominant grammatical contexts of a term as well as the selectional preference information associated with it in the form of G-test scores. In this section, we describe our methodology for inducing conceptual domains for a linguistic metaphor by adapting techniques for unsupervised word-sense induction (Erk and Padó, 2008; Korkontzelos and Manandhar, 2010; Hope and Keller, 2013). In particular, we induce conceptual domains in an unconstrained manner by extracting the grammatical co-occurrents of an LM source term (i.e., the 'concept candidates') and clustering them into semantically-related concept clusters. Both the clusters and our

[3] http://www.cis.uni-muenchen.de/~schmid/tools/TreeTagger/

[4] http://code.google.com/p/hunpos/

given source domains are then mapped into a distributional vector space, allowing us to compute cluster-to-domain scores. Finally, each source domain is assigned a score based on its affinity to each individual cluster with these affinity scores weighted according to cluster quality. This results in an overall weighted ranking of the given source conceptual domains for the linguistic metaphor.

5.1 Extracting Concept Candidates

Given a linguistic metaphor which consists of a metaphor source, s (e.g., "cure"), and a metaphor target, t (e.g., "poverty"), our system extracts a set of terms (i.e., "concept candidates") from the typical grammatical contexts of s as found in the web-scale corpus described in Section 4.4. In order to extract these candidates, we first determine the syntactic relation, r, which exists between s and t. This relation is the key point of interaction between the domains of the source and the target for the given LM and, as such, it provides an indication of which terms will contribute the most to our understanding of the underlying conceptual mapping. In addition, we make use of a predefined set of relations that are semantically meaningful – specifically the subjects and objects of verbs (i.e., "nsubj", "nsubjpass", and "dobj"),[5] attributes and verbs associated with nouns (i.e., "amod", "dobj^{-1}", "nsubj^{-1}", and "nsubjpass^{-1}"), the terms modified by adjectives or adverbs (i.e., "advmod^{-1}" and "amod^{-1}"), and prepositional relations (e.g., "prep_by", "prep_of", "prep_for"). Using this set of relations, R, we extract the set of candidate terms, X, that have been found to co-occur with the term s within some relation $r_i \in R$ in the preprocessed, web-scale corpus described in Section 4.4 such that $X = \{x|(s, r_i, x)\text{exists in the corpus}\}$.

To improve the quality of our extracted candidates, we apply three criteria to isolate those that best exemplify the underlying non-metaphorical senses of s. First, we anticipate that any term in X which does not co-occur with s at least k times will not be informative,[6] and so we remove such terms from further processing. Next, we predict that poorly imageable terms (i.e., highly abstract terms) are likely to represent metaphorical usages of s and so are unlikely to be integral to a given literal source domain, so these are filtered out as well.[7] Finally, to improve our ability to map these candidates into a conceptual domain, we remove terms that are not significantly related to any of our provided source domains (i.e., those that are off-topic) along with terms that are strongly related to multiple source domains (i.e., those that are ambiguous) as these provide little evidence to distinguish the most appropriate concept for the given LM.[8] We determine the relatedness of a term to a source domain by measuring the similarity of the term and domain vectors in our distributional space as described in Section 5.3.

5.2 Clustering Concept Candidates

Once the candidates have been extracted, they are clustered using a hierarchical agglomerative clustering algorithm with the distance metric defined as the cosine distance between the vectors within one of our distributional vector spaces. Each cluster is then assigned a quality score based on its size (to prefer large clusters with a large amount of semantic evidence), average internal distance (to prefer tighter clusters), and co-occurrence frequency with the LM source (to prefer more closely related terms). Formally, we define the weight associated with a given cluster using the following equation:

$$w(C) = (1 - IDIST(C)) * (S2(C) + FREQ(C) * (1 + S2(C)))$$

$$S2(C) = \frac{\max(SIZE(C)^2, k)}{k}$$

where $IDIST(C)$ represents the average vector distance between all pairs of terms in cluster C, $FREQ(C)$ represents the total co-occurrence frequency of the terms in C with the original LM,

[5] These dependency relation types come from the MaltParser.

[6] We empirically set k to 3.

[7] We estimate candidate imageability by combining the scores of the candidate's most distributionally similar words for which an imageability score is available in the MRC psycholinguistics database (Coltheart, 1981) using the ranked weighting methodology described in Mohler et al. (2014).

[8] Note that filtering by conceptual domain relatedness is only necessary when mapping the induced concepts to a predefined set of source concepts.

$SIZE(C)$ represents the number of unique terms in C, and k is a tuning parameter meant to favor large clusters.[9] Singleton clusters are discarded.

5.3 Assigning Domain Scores to Concept Candidates

We propose two methods for calculating domain scores for candidates – one which attempts to compare candidate vectors to a source domain directly, and and another which attempts to compare them to individual facets of the domain. These two methods rely on representing sources [CentS], or facets [CentF], as centroids which take the average of the vectors of each the lexemes assigned to that source (or facet). Our three vector spaces – DepVec, W2V, and LSA – along with our two methods for mapping terms to domains – CentS and CentF – correspond to six approaches to modeling a CM domain in some vector space.

In each case, the result for a given candidate is a distribution over all source domain scores. This distribution is then normalized by subtracting the mean score between the candidate vector and any of the source concepts. Formally, we define the normalized distribution for concept candidate x as:

$$S(x, D_y) = (1 - DIST(x, D_y)) - \frac{\sum_{D_k \in D} (1 - DIST(x, D_k))}{|D|}$$

where D is defined as the set of all known source domains and $DIST(x, d)$ is the cosine distance from x to a CM domain d in one of our vector spaces.

5.3.1 Assigning Domain Scores to Clusters

Within a given cluster (found as described in Section 5.2), the individual concept domain scores can then be combined to produce cluster-level domain scores. For a given cluster C_x, the score associated with a particular source domain D_y is defined as follows:

$$S(C_x, D_y) = \sum_{i=1}^{N} \frac{S(C_{xi}, D_y)}{\alpha^i}$$

where N represents the number of concepts in C_x with a positive score for the domain D_y, C_{xi} is the i-th highest score associated with any candidate in the cluster, and α is a tuning parameter which bounds the growth of the cluster-level score.[10] Any cluster with a maximum domain score that does not exceed a threshold is discarded as being weakly related to any CM source domain.

5.3.2 Assigning Domain Scores to the Linguistic Metaphor

We then sum the cluster-level source domain scores, scaling each by its associated cluster quality weight $w(c)$ as computed in Section 5.2. By scaling cluster domain scores in this way, we ensure that the most pure and discriminating clusters contribute the most to the overall LM domain scores. The final result measuring the association between the given LM and the source domain D_y is then defined as:

$$S(D_y) = \sum_{C_x \in C} w(C_x) * S(C_x, D_y)$$

Applied across all known domains, we therefore produce a ranked and scored list of CM source domains (i.e., a mapping) that are associated with the given linguistic metaphor and can be used to drive more robust interpretation of the metaphor.

6 Evaluation

We evaluate two aspects of our end-to-end CM recognition system. First, we analyze the impact of our choice of vector space. Specifically, we compare the use of our DepVec space to link concept candidates

[9] In our experiments, k is set to 5.

[10] We have used a value of $\alpha = 2$ which ensures that the result remains within the bounds [0.0,1.0].

with source domains against two off-the-shelf vector space models – the continuous skip-gram model [W2V] (Mikolov et al., 2013) [11] and latent semantic analysis [LSA] (Landauer and Dumais, 1997). Both alternative models were trained over the same corpus as in our DepVec space using a predefined number of dimensions (300 for W2V; 400 for LSA). Second, we have experimented with two different metrics for calculating the distance between a vector and a source concept – the cosine distance to the source-level centroid (CentS) and the cosine distance to the facet-level centroid (CentF).

Our evaluation dataset consists of a held out, unseen set of documents taken from a variety of news articles, opinion pages, and blogs on the open web. These documents consist of 3 to 5 sentences each and cover four of our focus languages.[12] They were then annotated by two native-proficiency speakers in the following way. For each LM, they were instructed to choose the most closely related source concept from our list of 51 provided. Any source concepts selected by at least one annotator were considered correct. Since our CM recognition system produces a ranked list of source concepts, we report both the accuracy associated with our top-ranked concept and the accuracy of the system when allowed to select two.

		Cluster Linking							
		English		Spanish		Russian		Farsi	
Vector Space	**Distance**	Acc@1	Acc@2	Acc@1	Acc@2	Acc@1	Acc@2	Acc@1	Acc@2
DepVec	CentS	28.0%	44.1%	33.3%	43.4%	24.4%	32.6%	16.5%	27.5%
	CentF	25.8%	40.9%	33.3%	49.4%	25.6%	34.9%	26.4%	40.7%

	CentF	28.0%	44.1%	**46.0%**	**58.6%**	**34.9%**	**48.8%**	**35.2%**	**48.4%**

Table 5: The accuracy of our conceptual interpretation system. We experiment with three vector spaces (LSA, W2V, and DepVec) and two source concept centroid representations – source-level (CentS) and facet-level (CentF).

These results indicate that the continuous skip-gram vector space [W2V] is well suited to the task of cluster-level concept mapping, consistently and significantly outperforming both the LSA space and the DepVec space in every language but English. We believe that this is a result of its probabilistic representation of local context which implicitly collects many of the same relations as the DepVec model while incorporating the advantages associated with dimensionality reduction which has not been incorporated into our DepVec model.[13] We further observe an unmistakable dominance of the facet-level centroid representation over the source-level representation. Based on these results, we believe that we have successfully demonstrated the contribution of our system's vector-space clustering component which groups concept candidates at a facet-level granularity.

7 Conclusion

In this paper, we have presented a novel approach to the problem of multilingual conceptual metaphor recognition which combines facet-based concept induction with a distributional vector space representation of metaphor. We have experimentally demonstrated the advantage of our fine-grained concept induction approach within a variety of vector space models, including our novel DepVec space. Taken together, we hypothesize that a facet-level conceptual model represented in a relational context vector space will serve as a reliable foundation enabling high-quality metaphoric interpretation in future metaphor research. Future work includes expanding the set of concept candidates through higher-order dependency contexts, improved clustering techniques, and evaluating the induced clusters directly.

[11] We make use of the implementation included as part of the gensim python package: `http://radimrehurek.com/gensim/`

[12] This dataset consists of the following counts of documents: English (92), Spanish (86), Russian (85), Farsi (90).

[13] During our pilot experiments, we applied singular value decomposition (SVD) to the DepVec space without any significant improvement to system performance.

Abstract

In the context of Social Media Analytics, Natural Language Processing tools face new challenges on on-line conversational text, such as microblogs, chat, or text messages, because of the specificity of the language used in these channels. This work addresses the problem of Part-Of-Speech tagging (initially for French but also for English) on noisy language usage from the popular social media services like Twitter, Facebook and forums. We employ a linear-chain conditional random fields (CRFs) model, enriched with several morphological, orthographic, lexical and large-scale word clustering features. Our experiments used different feature configurations to train the model. We achieved a higher tagging performance with these features, compared to baseline results on French social media bank. Moreover, experiments on English social media content show that our model improves over previous works on these data.

1 Introduction

There are many challenges inherent to applying standard natural language analysis techniques to social media. On-line conversational texts, such as tweets are quite challenging for text mining tools, and in particular for opinion mining, as they contain very little contextual information and assume too much implicit knowledge. They expose much more language variation and tend to be less grammatical than regular texts such as news articles or books. Furthermore, they contain unusual capitalization, and make frequent use of emoticons, abbreviations and hash-tags, which can form an important part of their inner meaning (Maynard et al., 2012). Conventional natural language processing tools for regular texts have achieved reasonably high accuracy thanks to machine learning techniques on large annotated data set. However, "off the shelf" language processing systems fail to work on social media data and their performance on this domain degrade very fast. For example, in English Part-Of-Speech tagging, the accuracy of the Stanford tagger (Toutanova et al., 2003) falls from 97% on Wall Street Journal text to 85% accuracy on Twitter (Gimpel et al., 2011), similarly the MElt POS tagger (Denis and Sagot, 2012) drops from 97.7% on the French Treebank (called the FTB-UC by (Candito and Crabbé, 2009)) to 85.2% on on-line conversational texts (Seddah et al., 2012). In Named Entity Recognition, the CoNLL-trained Stanford recognizer achieves 44% F-measure (Ritter et al., 2011), down from 86% on the CoNLL test set (Finkel et al., 2005); regarding parsing, see for example (Foster et al., 2011; Seddah et al., 2012), poor performances have been reported for different state-of-the-art parsers applied to English and French social media content.

The main objective of this work is to implement a dedicated Part-Of-Speech (POS) tagger for French social media content such as Twitter, Facebook, blogs, forums and customer reviews. We used the first user-generated content resource for French presented by Seddah et al. (2012), which contains a fine-grained tag set and has been extracted from various social media contents. We have designed and implemented a POS tagger considering one of the well-known *discriminative* type of sequence-based methods; Conditional Random Fields (CRF) (Lafferty et al., 2001). To deal with sparsity and unknown

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1764–1772, Dublin, Ireland, August 23-29 2014.

words, we have applied unsupervised techniques to enrich the feature set. Finally, we have evaluated our tagger performance with different configurations on annotated corpora from French social media.

We will first present related work in Part-Of-Speech tagging (Section 2) on noisy data like social media content. In Section 3, the annotated dataset and its characteristics (e.g., tag set) are described. Section 4 presents the result of applying the MElt POS tagger to user generated text as our baseline (Seddah et al., 2012). In Section 5, we explain how we design and implement our POS tagger. Section 6 is devoted to experiments and performance of our tagger. Section 7 describes the evaluation of the new tagger on English social media texts. Conclusion and future work are given in Section 8.

2 Related work

Online conversational texts, typified by micro-blogs, chat, and text messages, are a challenge for natural language processing. Unlike the highly edited genres for which conventional NLP tools have been developed, conversational texts contain many non-standard lexical items and syntactic patterns. These are the result of unintentional errors, dialectal variation, conversational ellipsis, topic diversity, and creative use of language and orthography (Eisenstein, 2013)

The language technology research community proposes two approaches to deal with noisy texts, namely normalization and domain adaptation, which are briefly described here.

2.1 Normalization

One way to deal with ill-formed language is to turn it into a well-formed language as a pre-processing task: "normalizing" social media or SMS messages to better conform to the language that the technology expects. For example, (Han and Baldwin, 2011) propose the lexical normalization of short text messages, such as tweets, based on string and distributional similarity. They describe a method to identify and normalize ill-formed words. Word similarity and context are exploited to select the best candidate for noisy tokens.

2.2 Domain adaptation

The other approach is instead to adapt the tools to fit the text. A series of papers has followed the mold of "NLP for Twitter," including POS tagging (Gimpel et al., 2011; Owoputi et al., 2013), named entity recognition (Finin et al., 2010; Ritter et al., 2011; Xiaohua et al., 2011), parsing (Foster et al., 2011), dialog modeling (Ritter et al., 2010) and summarization (Hutton and Kalita, 2010). These works adapt various parts of the natural language processing pipeline for social media text, and make use of a range of techniques (Preprocessing, New labeled data, New annotation schemes, Self training, Distributional features, Distance supervision) (Eisenstein, 2013).

Recently, Seddah et al. (2012) followed the second approach on French social media content and provided new labeled data and annotation schemes. They applied the MElt POS tagger (Denis and Sagot, 2012) embedded within text normalization and correction to noisy user generated texts and presented baseline POS tagging and statistical constituency parsing results.

3 Annotated Dataset

A set of 1,700 sentences (38k tokens) has been extracted from various types of French Web 2.0 user generated content (Facebook, Twitter, Video games and medical web forums) by Seddah et al. (2012). They selected these corpora through direct examination of various search queries and ranked the texts according to their distance from the French Treebank style, by measuring noisiness using the kullback-Leibler divergence between the distribution of trigrams of characters in given corpus and the distribution of trigrams of characters in the French Treebank reference. Some properties of this corpora are shown in Table 1.

They targeted the annotation scheme of the FTB-UC in order to annotate the French social media bank. The tagset includes 28 POS tags from FTB-UC and compound tags with additional categories specific to social media, including **HT** for Twitter hashtags and **META** for meta-textual tokens, such as

Twitter's "RT". Twitter at-mention as well as URLs and e-mail addresses have been tagged **NPP** which is the main difference with other works on on-line conversational texts. The inter-annotator agreement rate in this corpora range between 93.4% for **F**ACEBOOK data and 97.44% for **J**EUX**V**IDEOS.COM (Table 1) which indicates an almost perfect agreement on the corpus (Landis and Koch, 1977).

Corpus Name	**# sent.**	**# tokens**	Inter Annotator Agreement %
TWITTER	216	2465	95.40
FACEBOOK	452	4200	93.40
JEUX**V**IDEOS.COM	199	3058	97.44
DOCTISSIMO	771	10834	95.05

Table 1: Annotated datasets

4 Baseline

This section presents the performance of a state-of-the-art POS tagger for French, conducted by Seddah et al. (2012). They used FTB-UC as training, development and test data. First, they applied several correction processes in order to wrap the POS tagger to tag a sequence of tokens as close as possible to standard French and training corpus. Then, the MElt tagger has been used with a set of 15 language-independent rules, that aim at assigning the correct POS to tokens that belong to categories not found in training corpus (e.g., URLs, e-mail addresses, emoticons). The preliminary evaluation experiments with normalization and correction wrapper showed *84.72%* and *85.28%* token accuracy over annotated development and test set respectively.

5 New POS Tagger Development

Conversational style context and 140-character limitation in micro-blogs require users to express their thought or reply to others' messages within a short text. Therefore, without being ambiguous, some words are usually abbreviated with a special spelling. For example, *c t* usually means c'était (it was); *qil* denotes qu' il (that it/he).

Our tagger is based on sequence labeling models (CRF), enabling arbitrary local features to be integrated into a log-linear model. We employed three categories of feature templates to deal with syntactic variations on social media contents and alleviating the data sparseness problem.

5.1 Basic Feature Templates

The feature templates we use here are a superset of the largely language independent features used by (Ratnaparkhi, 1996; Toutanova and Manning, 2000; Toutanova et al., 2003). These features fall into two main categories. A first set of features tries to capture the *lexical form* of the word being tagged: it includes prefixes and suffixes (of at most 10 characters) from the current word, together with binary features based on the presence of special characters such as numbers, hyphens, and uppercase letters, within w_i. A second set of features directly models the context of the current word and tag: it includes the previous tag, surrounding word forms in a 5 tokens window. The detailed list of feature templates we used in this category is shown in Table 2.[1]

Context	
$w_i = X$,$i \in [-2,-1,0,1,2]$	& $t_0 = T$
$w_i w_j = XY$, $(i,j) \in \{(-1,0),(0,1),(-2,0),(0,2)\}$	& $t_0 = T$
$w_i w_j w_k = XYZ$, $(i,j,k) \in \{(-2,-1,0),(0,1,2),(-1,0,1)\}$	& $t_0 = T$
$w_i w_j w_k w_l w_m$=$XYZPQ$, (i,j,k,l,m) =$(-2,-1,0,1,2)$	& $t_0 = T$
t_{-1}	& $t_0 = T$
Lexical and Orthographic	
$f(w_i)$,$i \in [-1,0,1]$,$f \in F$	& $t_0 = T$
$m(w_i)$, $i \in [-1,0,1]$, $m \in M$	& $t_0 = T$

Table 2: Basic Feature Templates

[1] w_0 means the token at the current position while w_{-1} means the previous token.

The model generates the feature space by scanning each pair in the training data with the feature templates given in Table 2. For example, if we consider the following tweet from the training set, the generated features based on the first template can be seen in Table 3, in which the current word is "vous" (position 6) .

Sample tweet : "@Marie Je vais tener De vous produire la vidéo *-* "

word:	@Marie	Je	vais	tener	De	vous	produire	la	vidéo	*-*
Tag:	NPP	CLS-SUJ	V	VINF	P	CLO-A_OBJ	VINF	DET	NC	I
Position:	1	2	3	4	5	6	7	8	9	10

w_0=**vous**	$\&t_0$=**O**
w_{-1}=**De**	$\&t_0$=**O**
w_{-2}=**tener**	$\&t_0$=**O**
w_{+1}=**produire**	$\&t_0$=**O**
w_{+2}=**la**	$\&t_0$=**O**

Table 3: Generated features with template :
$w_i = X$,$i \in [-2, -1, 0, 1, 2]$ $\quad \&t_0 = T$

We defined two sets of operations, F and M. Each operation maps tokens to equivalence classes.
F is a set of regular expression rules that detect specific patterns on w_i and return binary values. The functions $f(w_i) \in F$ include the rules as detailed in the following list (List 1):

List 1: Set of regular expression rules (F)

- ▷ Return "$True$" if the w_i contains Punctuation marks otherwise return "$False$"
- ▷ Return "$True$" if the w_i is list of Punctuation marks otherwise return "$False$"
- ▷ Return "$True$" if the w_i contains digits otherwise return "$False$"
- ▷ Return "$True$" if the w_i number otherwise return "$False$"
- ▷ Return "$True$" if all letters of w_i are capitalized otherwise return "$False$" allNumber
- ▷ Return "$True$" if the w_i starts with capital letter otherwise return "$False$"
- ▷ Return "$True$" if the w_i has"URL" pattern otherwise return "$False$"
- ▷ Return "$True$" if the w_i has "Email" pattern otherwise return "$False$"
- ▷ Return "$True$" if the w_i has "Abbreviation" pattern otherwise return "$False$"
- ▷ Return "$True$" if the w_i has "Arrow" pattern otherwise return "$False$"
- ▷ Return "$True$" if the w_i has "Time " pattern otherwise return "$False$"
- ▷ Return "$True$" if the w_i has "NumberWithCommas" pattern otherwise return "$False$"
- ▷ Return "$True$" if the w_i has symbol representing "RT:retweeting" form otherwise return "$False$"
- ▷ Return "$True$" if the w_i has symbol representing "At-Mention" form otherwise return "$False$"
- ▷ Return "$True$" if the w_i has symbol representing "hash-tagh" form otherwise return "$False$"

M is a set of orthographic transformations that maps a string to another string via a simple surface level transformation. The functions $m(w_i) \in M$ are given in List 2 :

List 2: Set of orthographic transformation (M)

- ▷ Return capitalized type of w_i ,These types are (allCap, shortCap, longCap, noCap, initCap, mixCap)
(e.g.,"Plus-tard" → "initCap" ,"RT" →"allCap,longCap")

- ▷ Return the *type* of w_i, obtained by replacing $[a-z]$ with x, $[A-Z]$ with X, and $[0-9]$ with 9
(e.g.,., "@DJRyan1der" → "@XXXxxx9xxx")

- ▷ Return a vector of Unicode matching of the string w_i
(e.g., "@DJRyan1der" → "$[64-68-74-82-121-97-110-49-100-101-114]$")

- ▷ Return the first n character of x (n-gram prefix), where $1 \leq n \leq 10$
- ▷ Return the last n character of x (n-gram suffix), where $1 \leq n \leq 10$

5.2 Word Clustering Feature Templates

To bridge the gap between high and low frequency words, we employed word clustering to acquire knowledge about paradigmatic lexical relations from large-scale texts. Our work is inspired by the suc-

cessful application of word clustering in supervised NLP models (Miller et al., 2004; Turian et al., 2010; Ritter et al., 2011; Owoputi et al., 2013).

Various clustering techniques have been proposed, some of which, for example, perform automatic word clustering optimizing a maximum likelihood criterion with iterative clustering algorithms. In this work, we focus on distributional word clustering, based on the assumption that the words that appear in similar contexts (especially surrounding words) tend to have similar meanings.

5.2.1 Brown Clustering

We used our unlabeled Twitter corpus (4M tweets) to improve our tagger performance. This corpus has been extracted in the framework of a French government funded ANR project called Imagiweb, whose goal is to develop tools to analyse the brand image of entities (persons or companies) on social media. More specifically, one of the focus of the project is to analyse the brand image of politicians on Twitter. Therefore, data about the two main candidates (F. Hollande and N. Sarkozy) in the last French presidential election in May 2012 have been crawled from Twitter, using Twitter API, from 6 months before to 6 months after the elections. Our unlabeled Twitter data is a sub-set of this corpus.

We obtained hierarchical word clusters via Brown Clustering (Brown et al., 1992) on a large set of unlabeled tweets. This algorithm generates a hard clustering, each word belongs to exactly one cluster. The input to the algorithm is a sequence of words $w_i, \ldots, w_n$. Initially, the algorithm starts with each word in its own cluster. As long as there are at least two clusters left, the algorithm merges the two clusters that maximize the resulting cluster quality. The quality is defined on the class-based bigram language model as follows, where C maps a word w to its class $C(w)$.

$$p(w_i|w_1, \ldots, w_{i-1}) = p(C(w_i)|C(w_{i-1}))p(w_i|C(w_i))$$

We ended up with 500 clusters (the optimal number of clusters according to the performance of the tagger among different number of clusters) with 222,788 word types by keeping the words appearing 10 or more times. Since Brown clustering creates hierarchical clusters in a binary tree, we used the feature template which maps the word w_i to the cluster at depths $2, 4, \ldots, 16$ containing w_i. If w_i was not seen while constructing the clusters and thus does not belong to any cluster we tried to find similar words by computing *Jaro-Winkler distance* (Philips, 1990; Winkler, 2006) and mapped the best match to the cluster depths. Nevertheless, if we couldn't find the best match (the threshold of the similarity score is 0.9), we mapped it to a special $NULL$ cluster. The detailed list of feature templates we used in this category is shown in Table 5.[2]

5.2.2 MKCLS Clustering

We also did some experiments, using another popular clustering method based on the exchange algorithm (Kneser and Ney, 1993). The objective function maximizes the likelihood $\prod_{i=1}^{n} P(w_i|w_1, \ldots, w_{i-1})$ of the training data given a partially class-based bigram model of the form as follows:

$$p(w_i|w_1, \ldots, w_{i-1}) \approx p(C(w_i)|w_{i-1})p(w_i|C(w_i))$$

We use the publicly available implementation MKCLS [3] to train this model on our French Twitter data (4M tweets). This algorithm provides us with 500 word clusters with 2,768,297 different words.

Word Cluster	
$c(w_i) = X$,$i \in [-2, -1, 0, 1, 2]$ and $c \in C$	& $t_0 = T$
$c(w_i)c(w_j) = XY$, $(i, j) \in \{(-1, 0), (0, 1)\}$ and $c \in C$	& $t_0 = T$
$c(w_i)C(w_j)c(w_k) = XYZ$, $(i, j, k) \in \{(-2, -1, 0), (0, 1, 2), (-1, 0, 1)\}$ and $c \in C$	& $t_0 = T$
$c(w_i)c(w_j)c(w_k)c(w_l)c(w_m)$=$XYZPQ$, (i, j, k, l, m) =$(-2, -1, 0, 1, 2)$ and $c \in C$	& $t_0 = T$

Table 5: Word Clustering Feature Templates

[2] $c(w_i) \in C$ map the word w_i to the clusters at depths $2, 4, \ldots, 16$

6 Experiments

For the implementation of discriminative sequential model, we chose the *Wapiti* [4] toolkit (Lavergne et al., 2010). Wapiti is a very fast toolkit for segmenting and labeling sequences with discriminative models. It is based on maxent models, maximum entropy Markov models and linear-chain CRF and proposes various optimization and regularization methods to improve both the computational complexity and the prediction performance of standard models. Wapiti has been ranked first on the sequence tagging task for more than a year on MLcomp[5] web site.

6.1 Training and parameter regularization

In the training of log-linear models, regularization is normally required to prevent the model from over fitting on the training data. The two most common regularization methods are called L1 and L2 regularization (Tsuruoka et al., 2009). *Wapiti* uses the elastic-net penalty of the form:

$$\rho_1 * |\theta|_1 + \frac{\rho_2}{2} * ||\theta||_2^2$$

and it is implemented with 3 different algorithms: *Orthant-Wise Limited-memory Quasi-Newton* (OWL-QN: L-BFGS), *Stochastic Gradient Descent* (SGD) and *Block Coordinate Descent*. We trained with *L-BFGS*, a classical Quasi-Newton optimization algorithm with limited memory which minimizes the regularized objective and uses elastic net regularization. Using even a very small L1 penalty excludes many irrelevant or highly noisy features. We carried out a grid search for the regularization values, assessing with F-measure and accuracy. We conducted a first order linear chain CRF model on the French corpora with classical setting (training set: 80%, development set: 10% and test set: 10%) for $L1 \in \{0, 0.0625, 0.125, 0.25, 0.5, 1, 2, 4, 8, 16\}$ and $L2 \in \{0, 0.0325, 0.0625, 0.125, 0.25, 0.5, 1, 2, 4, 8, 16\}$ (Owoputi et al., 2013). In any experiment, the result of the regularization values were close to each other, therefore we selected L1,L2=$(0.25, 0.5)$ achieving 80.4% and 90.6% F-measure and accuracy on the corpora respectively.

6.2 Performance

In order to assess how the results of our tagger based on the current limited corpora could be generalized to an independent data set, a set of 10-fold cross validation experiments has been performed. We investigated the effect of each feature template on the tagging. We used *"c: compact"* option in *Wapiti* which enables model compaction at the end of the training. This removes all inactive observations from the model, leading to a much smaller model when an L1-penalty is used.
Table 6 shows the result of each experiment, measured by token and sentence accuracy. It shows that word clustering is a very strong source of lexical knowledge and significantly increases the performance of our tagger.

Feature Templates	Token Accuracy %	Sentence Accuracy %
B	88.2	45.8
B+C1	90.8	49.9
B+C2	90.3	50.3
B+C1+C2	91.9	51.1

B: Basic Feature Templates
C1: Brown word-Clustering Feature Templates
C2: MKCLS word-Clustering Feature Templates

Table 6: Performance of new tagger based on CRF with different configurations

The CRF model with all set of features (B+C1+C2) is the best model with 91.9% and 51.1% token and sentence accuracy on 10-fold cross validation. All of these tagging accuracies are significantly above previous results on the French social bank (baseline).

[5] http://mlcomp.org/

7 Evaluation on English social media Content

In order to implement a tagger for English dedicated to social media content, we used the publicly available clusters data set (Owoputi et al., 2013) to build Brown clustering features. Moreover we performed the same process as in Section 5.2.2 in order to provide MKCLS clustering features with English Twitter data (1 million tweets obtained from [6]).

We applied our tagger with the best configuration to the annotated dataset provided by Ritter et al. (2011). This dataset contains 800 tweets that have been annotated with the Penn Treebank (PTB) tagset (Marcus et al., 1993). We trained and test our system with 10-fold cross validation. Table 7 shows our tagger performance compared to other state-of-art taggers on this data set.

Tagger	Accuracy%
Our new tagger, CRF with B+C1+C2 configuration	90.1
Ritter et al. (Ritter et al., 2011), CRF tagger	88.3
Owoputi et al. (Owoputi et al., 2013), MEMM tagger	90± 0.5

Table 7: Evaluation on Twitter data with PTB tags

In addition, we evaluated the tagger performance on another English social media data: NPS chat ("Chat with PTB tags" (Forsythand and Martell, 2007)). Due to the large number of tokens (50 K), we trained and tested our tagger with a 5-fold cross validation setup. Our new tagger performance as well as the other taggers results are given in Table 8.

Tagger	Accuracy%
Our new tagger, CRF with B+C1+C2 configuration	92.7
Forsythand and Martell (Forsythand and Martell, 2007), HMM tagger	90.8
Owoputi et al. (Owoputi et al., 2013), MEMM tagger	93.4± 0.3

Table 8: Evaluation on Chat data with PTB tags

8 Conclusion and Future Work

In this paper, we have presented an innovative work on POS tagging for French social media noisy input. Because of the specific phenomena encountered in such data and also because of the lack of large training corpus, we proposed a discriminative sequence labeling model (CRF) enhanced with several type of features. After experimenting different configurations of features, we achieved 91.9% token accuracy on target corpus. Moreover, experiments on English social media contents show that our model obtains further improvement over previous works on these data and could be reproduced for other languages. In the future, we plan to pursue this work in two main directions: (a) Integrate the new tagger with a robust syntactic parser and investigate its impact on dependency parsing applied to social media and (b) evaluate the impact of POS tagging on opinion mining on micro-blogs, since this parser is the core component of an opinion mining system applied in different social-media analytics projects.

Morphological Analysis for Japanese Noisy Text Based on Character-level and Word-level Normalization

Abstract

Social media texts are often written in a non-standard style and include many lexical variants such as insertions, phonetic substitutions, abbreviations that mimic spoken language. The normalization of such a variety of non-standard tokens is one promising solution for handling noisy text. A normalization task is very difficult to conduct in Japanese morphological analysis because there are no explicit boundaries between words. To address this issue, in this paper we propose a novel method for normalizing and morphologically analyzing Japanese noisy text. We generate both character-level and word-level normalization candidates and use discriminative methods to formulate a cost function. Experimental results show that the proposed method achieves acceptable levels in both accuracy and recall for word segmentation, POS tagging, and normalization. These levels exceed those achieved with the conventional rule-based system.

1 Introduction

Social media texts attract a lot of attention in the fields of information extraction and text mining. Although texts of this type contain a lot of information, such as one's reputation or emotions, they often contain non-standard tokens (lexical variants) that are considered out-of-Vocabulary (OOV) terms. We define an OOV as a word that does not exist in the dictionary. Texts in micro-blogging services such as Twitter are particularly apt to contain words written in a non-standard style, e.g., by lengthening them ("goooood" for "good") or abbreviating them ("thinkin' " for "thinking"). This is also seen in the Japanese language, which has standard word forms and variants of them that are often used in social media texts. To take one word as an example, the standard form is おいしい (*oishii*, "It is delicious") and its variants include おいしい いいい(*oishiiii*), おいし ぃ(*oishii*), and おいし ー(*oishii*), where the underlined characters are the differences from the standard form. Such non-standard tokens often degrade the accuracy of existing language processing systems, which are trained using a clean corpus.

Almost all text normalization tasks for languages other than Japanese (e.g., English), aim to replace the non-standard tokens that are explicitly segmented using the context-appropriate standard words (Han et al. (2012), Han and Baldwin (2011), Hassan and Menezes (2013), Li and Liu (2012), Liu et al. (2012), Liu et al. (2011), Pennell and Liu (2011), Cook and Stevenson (2009), Aw et al. (2006)). On the other hand, the problem is more complicated in Japanese morphological analysis because Japanese words are not segmented by explicit delimiters. In traditional Japanese morphological analysis, word segmentation and part-of-speech (POS) tagging are simultaneously estimated. Therefore, we have to simultaneously analyze normalization, word segmentation, and POS tagging to estimate the normalized form using the context information. For example, the input パンケーキぉぃしーぃ(*pan-keiki oishiiii*, "This pancake tastes good") written in the standard form is パンケーキおいしい (*pan-keiki oishii*). The result obtained with the conventional Japanese morphological analyzer MeCab (Kudo (2005)) for this input is **パンケーキ (pancake, noun)**/**おいし (unk)**/**ー (unk)**/**ぃ(unk)**/, where slashes indicate the word segmentations and "unk" means an unknown word. As this result shows, Japanese morphological analyzers often fail to

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1773–1782, Dublin, Ireland, August 23-29 2014.

correctly estimate the word segmentation if there are unknown words, so the pipeline method (e.g., first estimating the word segmentations and then estimating the normalization forms) is unsuitable.

Moreover, Japanese has several writing scripts, the main ones being Kanji, Hiragana, and Katakana. Each word has its own formal written script (e.g., 教科書 (*kyoukasyo*, "textbook") as formally written in Kanji), but in noisy text, there are many words that are intentionally written in a different script (e.g., きょうかしょ (*kyoukasyo*, "textbook") is the Hiragana form of 教科書). These tokens written in different script also degrade the performance of existing systems because dictionaries basically include only the standard script. Unlike the character-level variation we described above, this type of variation occurs on a word—level one. Therefore, there are both character-level and word-level non-standard tokens in Japanese informal written text. Several normalization approaches have been applied to Japanese text. Sasano et al. (2013) and Oka et al. (2011) introduced simple character level derivational rules for Japanese morphological analysis that are used to normalize specific patterns of non-standard tokens, such as for word lengthening and lower-case substitution. Although these approaches handle Japanese noisy text fairly effectively, they can handle only limited kinds of non-standard tokens.

We propose a novel method of normalization in this study that can handle both character- and word-level lexical variations in one model. Since it automatically extracts character-level transformation patterns in character-level normalization, it can handle many types of character-level transformations. It uses two steps (character- and word-level) to generate normalization candidates, and then formulates a cost function of the word sequences as a discriminative model. The contributions this research makes can be summarized by citing three points. First, the proposed system can analyze a wider variety of non-standard token patterns than the conventional system by using our two-step normalization candidate generation algorithms. Second, it can largely improve the accuracy of Japanese morphological analysis for non-standard written text by simultaneously performing the normalization and morphological analyses. Third, it can automatically extract character alignments and in so doing reduces the cost of manually creating many types of transformation patterns. The rest of this paper is organized as follows. Section 2 describes the background to our research, including Japanese traditional morphological analysis, related work, and data collection methods. Section 3 introduces the proposed approach, which includes lattice generation and formulation, as a discriminative model. Section 4 discusses experiments we performed and our analyses of the experimental results. Section 5 concludes the paper with a brief summary and a mention of future work.

2 Background

2.1 Japanese Morphological Analysis

Many approaches to joint word segmentation and POS tagging including Japanese Morphological analysis can be interpreted as re-ranking while using a word lattice (Kaji and Kitsuregawa (2013)). There are two points to consider in the analysis procedure: how to generate the word lattice and how to formulate the cost of each path. In Japanese morphological analysis, the dictionary-based approach has been widely used to generate the word lattice (Kudo et al. (2004), Kurohashi et al. (1994)). In a traditional approach, an optimal path is sought by using the sum of the two types of costs for the path: the cost for a candidate word that reflects the word's occurrence probability, and the cost for a pair of adjacent POS that reflects the probability of an adjacent occurrence of the pair (Kudo et al. (2004), Kurohashi et al. (1994)). A greater cost means less probability. The Viterbi algorithm is usually used for finding the optimal path.

2.2 Related Work

Several studies have been conducted on Japanese morphological analysis in the normalized form. The approach proposed by Sasano et al. (2013) aims to develop heuristics to flexibly search by using a simple, manually created derivational rule. Their system generates normalized character sequence based on the derivational rule, and adding new nodes that are generated from normalized character sequence when generating the word lattice using dictionary lookup. Figure 1 presents an example of this approach. If the non-standard written sentence すーごく楽しぃ (*suugoku tanoshii*, "It is such fun") is input, the

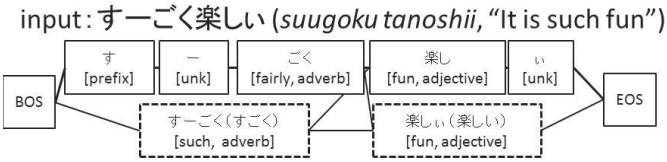

Figure 1: Example of Japanese morphological analysis and normalization

type	non-standard form	standard form
(1) Insertion	ありがと ーー う (*arigatoou*)	ありがとう (*arigatou*, "Thank you")
(2) Deletion	さむ _ (*samu*)	さむい (*samui*, "cold")
(3) Substitution with phonetic variation	かわ ええ (*kawaee*)	かわいい (*kawaii*, "cute")
(4) Substitution with lowercases and uppercases	ぁりがと ぅ (*arigatou*)	ありがとう (*arigatou*, "Thank you")
(5) Hiragana substitution	あいでぃー (*aidei*)	ID (*aidei*, "identification card")
(6) Katakana substitution	アリガトウ (*arigatou*)	ありがとう (*arigatou*, "Thank you")
(7) Any combination of (1) to (6)	かぅんたー (*kaunta*)	カウンター (*kaunta*, "counter")
	あ っ つ ぃ (*attsui*)	あつい (*atsui*, "hot")

Table 1: Types of non-standard tokens and examples of annotated data

traditional dictionary-based system generates Nodes that are described using solid lines, as shown in Fig. 1. Since "すーごく" (*suugoku*, "such") and "楽しぃ" (*tanoshii*, "fun") are OOVs, the traditional system cannot generate the correct word segments or POS tags. However, their system generates additional nodes for the OOVs, shown as broken line rectangles in Fig. 1. In this case, derivational rules that substitute "ー" with "null" and "ぃ" (*i*) with "い" (*i*) are used and the system can generate the standard forms "すごく" (*sugoku*, "such") and "楽しい" (*tanoshii*, "fun") and their POS tags. If we can generate sufficiently appropriate rules, these approaches seem to be effective. However, there are many types of derivational patterns in SNS text and it is difficult to cover all of them by hand. Moreover, it becomes a serious problem how to set the path cost for appropriately re-ranking the word lattice when the number of candidates increases. Our approach is also based on the dictionary-based approach, however, our approach is significantly dissimilar from their approach in two ways. First, we automatically generate derivational patterns (we call them transformation tables) based on the character-level alignment between non-standard tokens and their standard forms. Compared to generating the rules by hand, our approach can generate broad coverage rules. Second, we use discriminative methods to formulate a cost function. Jiang et al. (2008), Kaji and Kitsuregawa (2013) introduce several features to appropriately re-rank the added nodes. This enables our system to perform well even when the number of candidates increases.

On the other hand, several studies have applied a statistical approach. For example, Sasaki et al. (2013) proposed a character-level sequential labeling method for normalization. However, it handles only one-to-one character transformations and does not take the word-level context into account. The proposed method can handle many-to-many character transformations and takes word-level context into account, so the scope for handling non-standard tokens is different. Many studies have been done on text normalization for English; for example Han and Baldwin (2011) classifies whether or not OOVs are non-standard tokens and estimates standard forms on the basis of contextual, string, and phonetic similarities. In these studies it was assumed that clear word segmentations existed. However, since Japanese is an unsegmented language the normalization problem needs to be treated as a joint normalization, word segmentation, and POS tagging problem.

2.3 Data Collection and Analysis of Non-standard Tokens

In previous studies (Hassan and Menezes (2013), Ling et al. (2013), Liu et al. (2011)), the researchers proposed unsupervised ways to extract non-standard tokens and their standard forms. For Japanese text, however, it is very difficult to extract word pairs in an unsupervised way because there is no clear word segmentation. To address this problem we first extracted non-standard tokens from Twitter text and blog

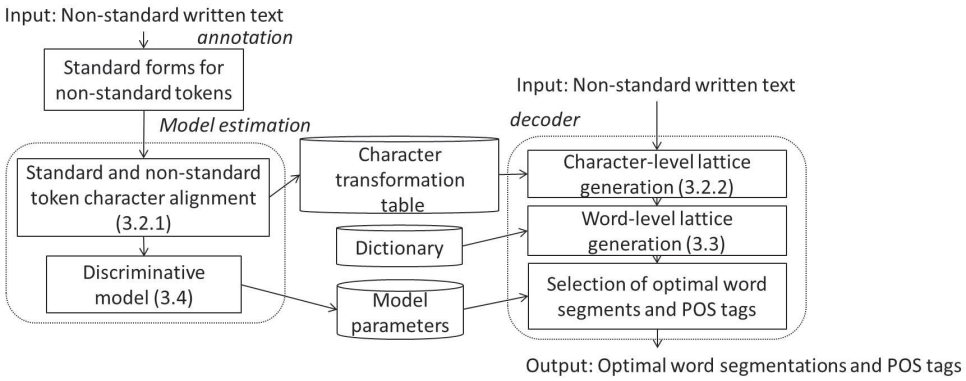

Figure 2: Structure of proposed system

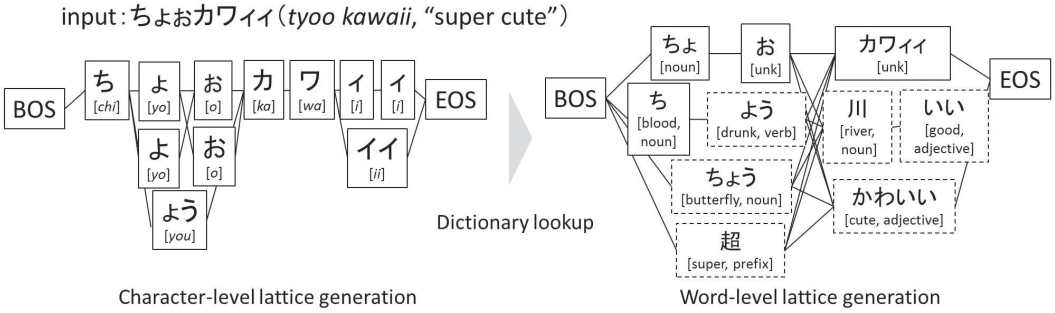

Figure 3: Example of candidate generation

text and manually annotated their standard (dictionary) forms. In total, we annotated 4808 tweets and 8023 blog text sentences. Table 1 lists the types of non-standard tokens that we targeted in this study and examples of the annotated data. Types (1), (2), (3) and (4) are similar to English transform patterns. Types (5) and (6) are distinctive patterns in Japanese. As previously mentioned Japanese has several kinds of scripts, the main ones being Kanji, Hiragana, and Katakana. These scripts can be used to write the same word in several ways. For example, the dictionary entry 先生 (*sensei*, "teacher") can also be written in Hiragana form せんせい (*sensei*) or Katakana form センセイ (*sensei*). Most words are normally written in the standard form, but in informal written text (e.g., Twitter text), these same words are often written in a non-standard form. In examining Twitter data for such non-standard tokens, we found that 55.0% of them were types (1) to (3) in Table 1, 4.5% were type (4), 20.1% were types (5) to (6), 2.7% were type (7), and the rest did not fall under any of these types since they were the result of dialects, typos, and other factors. In other words, a large majority of the non-standard tokens fell under types (1) to (7). We excluded those that did not as targets in this study because our proposed method cannot easily handle them. Types (1) to (4) occur at character-level and so can be learned from character-level alignment, but types (5) to (6) occur at word-level and it is inefficient to learn them on a character—level basis. Accordingly, we considered generating candidates and features on two levels: character-level and word-level.

3 Proposed Method

3.1 Overview of Proposed System

We showed the structure of the proposed system in Fig. 2. Our approach adds possible normalization candidates to a word lattice and finds the best sequence using a Viterbi decoder based on a discriminative model. We introduced several features that can be used to appropriately evaluate the confidence of the added nodes as normalization candidates. We generate normalization candidates as indicated in Fig. 3.

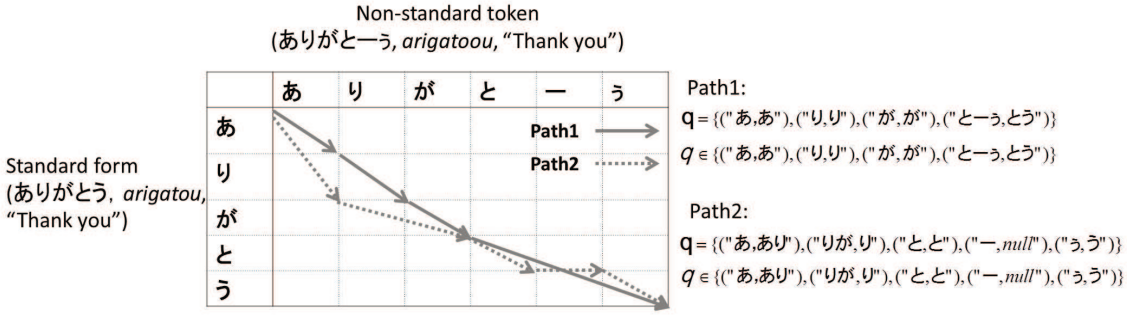

Figure 4: Example of character alignment

We describe the details in the following section.

3.2 Character-level Lattice

3.2.1 Character Alignment between Non-standard Tokens and Their Normalized Forms

We have to create a character-level transformation table to generate the character-level lattice. We used the joint multigram model proposed by Sittichai et al. (2007) to create the transformation table because this model can handle many-to-many character alignments between two character sequences. In observing non-standard tokens and their standard forms, we find there are not only one-to-one character transformations but also many-to-many character transformations. Furthermore, unlike in translation, there is no character reordering so the problems that arise are similar to those in transliteration. Accordingly, we adopted a joint multigram model that is widely used for transliteration problems. The optimal alignment can be formulated as $\hat{\mathbf{q}} = \arg\max_{\mathbf{q} \in K_d} \prod_{q \in \mathbf{q}} p(q)$, where d is a pair of non-standard tokens and its standard form (e.g., d is ありがとーぅ (*arigatoou*), ありがとう (*arigatou*). Here, q is a partial character alignment in d (e.g., q is "とーぅ, とう"), $\mathbf{q}$ is the character alignment q set in d (e.g., $\mathbf{q}$ of path 1 in Fig. 4 is {("あ, あ"), ("り, り"), ("が, が"), ("とーぅ, とう")}. K_d is the possible character alignment sequence candidates generated from d. We generate n-best optimal path for K_d in this study. The maximum likelihood training can be performed using the EM algorithm derivated in Bisani and Ney (2008) and Kubo et al. (2011) to estimate $p(q)$. $p(q)$ can be formulated as follow:

$$p(q) = \gamma_q / \sum_{q \in Q} \gamma_q \tag{1}$$

$$\gamma_q = \sum_{d \in D} \sum_{\mathbf{q} \in K_d} p(\mathbf{q}) n_q(\mathbf{q}) = \sum_{d \in D} \sum_{\mathbf{q} \in K_d} \frac{\prod_{q \in \mathbf{q}} \bar{p}(q)}{\sum_{\mathbf{q} \in K_d q \in \mathbf{q}} \prod \bar{p}(q)} n_q(\mathbf{q}),$$

and where D is the number of the d pair, Q is the set of q, and $n_q(\mathbf{q})$ is the count of q that occurred in $\mathbf{q}$. In our system, we allow for standard form deletions (i.e., mapping of a non-standard character to a null standard character) but not non-standard token deletions. Since we use this alignment as the transformation table when generating a character-level lattice, the lattice size becomes unnecessarily large if we allow for non-standard form deletions. In the calculation step of the EM algorithm, we calculate the expectation (partial counts) γ_q of each alignment in the E-step, calculate the joint probability $p(q)$ that maximizes the likelihood function in the M-step as described before, and repeat these steps until convergence occurs. $\bar{p}(q)$ indicates the result of $p(q)$ calculated in the previous step over the iteration. When generating the character-level lattice, we used alignments that were expected to exceed a predefined threshold. We used γ_q ($q = (c_t, c_v)$) and $r(c_t, c_v)$ as thereshold, where c_t and c_v are the partial character sequence of non-standard token and it's standard form respectively. $r(c_t, c_v)$ is calculated by $r(c_t, c_v) = \gamma_q / n_{c_v}$., where n_{c_v} is the number of occurrences of c_v in the training data. We set the threshold $\gamma_{q\_thres} = 0.5$, and $r(c_t, c_v)_{thres} = 0.0001$ in this study. We also used $r(c_t, c_v)$ as a feature of cost

function in subsection. 3.4.2. When calculating initial value, we set $p(c_t, c_v)$ high if the character c_t and c_v are the same character and the length of each character is 1. We also give the limitation that a Kanji character does not change to a different character and is aligned with same character in the calculation step of the character alignment.

3.2.2 Generation of Character-level Lattice Based on Transformation Table

First, repetitions of more than one letter of "ー", "〜", "-", and "っ" are reduced back to one letter (e.g., ありがと ーーー う (*arigatooooou*, "Thank you") is reduced to ありがと ー う (*arigatoou*)) for the input text. In addition, repetitions of more than three letters other than "ー", "〜", "-", and "っ" are reduced back to three letters (e.g., うれし いいいいい (*uresiiiiii*, "I'm happy") is reduced back to うれし いいい (*uresiii*)). These preprocessing rules are inspired by Han and Baldwin (2011) and determined by taking the Japanese characteristics into consideration. We also used these rules when we estimated the alignments of the non-standard tokens and their standard forms. Next, we generate the character-level normalization candidates if they match the key transformation table in the input text. For example, if the transformation table contains (q, log$p(q)$)= ("よお (*yoo*), よう (*you*)", -8.39), ("お (*o*), お (*o*)", -7.56), and the input text includes the character sequence "ちよお" (*tyoo*), we generate a new sequence "ちょう" (*tyou*) and "ちょお" (*tyoo*). In other words, we add new nodes "ょう" (*you*) and "お" (*o*) in the position of "よお" (*yoo*) and "お" (*o*), respectively (see Fig. 3).

3.3 Generation of Word-level Lattice

We generate the word lattice based on the generated character-level lattice using dictionary lookup. We exploit dictionary lookup by using the possible character sequence of the character-level lattice while the traditional approach exploits it by using only the input character sequence. For example, we exploit dictionary lookup for character sequences such as "ちよおカワィィ" (*tyoo kawaii*) and "ちょう カワィィ" (*tyou kawaii*) and "ち よおカワィィ" (*chiyou kawaii*) and "ちよおカワ イイ" (*tyoo kawaii*) (see Fig. 3)

Furthermore, we use the phonetic information of the dictionary to generate the normalization candidates for Hiragana and Katakana substitution. For example, assume "超" (*tyou*, "super") and "かわいい" (*kawaii*, "cute") are the dictionary words. Then, if the input text contains the character sequences "ちょう" (*tyo*) (which is written in Hiragana) and "カワイイ" (*kawaii*) (which is written in Katakana), we add "超" (*tyo*, "super") and "かわいい" (*kawaii*, "cute") to the word lattice as the normalization candidates since the two character sequences are pronounced identically. By using this two-step algorithm, we can handle any combinational derivational patterns, such as Katakana substitutions or substitutions of lowercases like "カワィィ" (*kawaii*) → "カワイイ" (*kawaii*) → "かわいい" (*kawaii*, "cute") (see Fig. 3). Note that we filtered candidates on the basis of a predefined threshold to prevent the generation of unnecessary candidates. The threshold was defined on the basis of the character sequence cost of normalization, which is described in subsection 3.4.2. Furthermore, we limited the number of character transformations to two per word.

3.4 Decoder

3.4.1 Objective Function

The decoder selects the optimal sequence $\hat{y}$ from $L(s)$ when given the candidate set $L(s)$ for sentence s. This is formulated as $\hat{y} = \arg\min_{y \in L(s)} \mathbf{w} \cdot \mathbf{f}(y)$ (Jiang et al. (2008), Kaji and Kitsuregawa (2013)), where $\hat{y}$ is the optimal path, $L(s)$ is the lattice created for sentence s, and $\mathbf{w} \cdot \mathbf{f}(y)$ is the dot product between weight vector $\mathbf{w}$ and feature vector $\mathbf{f}(y)$. The optimal path is selected according to the $\mathbf{w} \cdot \mathbf{f}(y)$ value.

3.4.2 Features

The proposed lattice generation algorithm generates a lattice larger than that generated in traditional dictionary-based lattice generation. Therefore, we need to introduce an appropriate normalization cost into the objective function. We listed the features we used in Table 2. Let w_i be the ith word candidate and p_i be the POS tag of w_i. p_{i-1} and w_{i-1} are adjacent POS tag and word respectively. We also used the word unigram cost $f_{w_i p_i}$, the cost for a pair of adjacent POS f_{p_{i-1}, p_i} that are quoted from MeCab (Kudo,

Name	Feature
Word unigram cost	$f_{w_i p_i}$
POS bi-gram cost	f_{p_{i-1},p_i}
Word-POS bi-gram cost	$-\log p_{w_{i-1}p_{i-1},w_i p_i}$
Character sequence cost	$\log(p'_s/p'_{t_i})$
	where, $p'_x = p_x^{1/length(x)}$, $p_x = \prod_{j=1}^{n} p(c_j \mid c_{j-5}^{j-1})$, $x \in \{s, t_i\}$
Character transformation cost	$\phi_{trans_i} \cdot (-\log r(c_t, c_v))$
Hiragana substitution cost	$\phi_{h_i} \cdot f_{w_i p_i}$
Katakana substitution cost	$\phi_{k_i} \cdot f_{w_i p_i}$

Table 2: Feature list of the decoder. ϕ_{trans_i} is 1 if w_i is generated by character transformation, otherwise 0. ϕ_{h_i} is 1 if w_i is generated by Hiragana substitution, otherwise 0. ϕ_{k_i} is 1 if w_i is generated by Katakana substitution, otherwise 0.

2005), and five additional types of costs. These are the word-pos bi-gram cost $-\log p_{w_{i-1}p_{i-1},w_i p_i}$ of a blog corpus; the character transformation cost $\phi_{trans_i} \cdot (-\log r(c_t, c_v))$, which is calculated in Section3.2, for nodes generated by character transformation; the Hiragana substitution cost $\phi_{h_i} \cdot f_{w_i p_i}$ for nodes generated by Hiragana substitution; the Katakana substitution cost $\phi_{k_i} \cdot f_{w_i p_i}$ for nodes generated by Katakana substitution; and the character sequence cost $\log(p'_s/p'_{t_i})$ for all the normalized nodes. The character sequence cost reflects the character sequence probability of the normalization candidates. Here, s and t_i are input string and transformed string respectively. (e.g., In Fig. 3, for the normalized node "かわいい" (cute, adjective), s is "ちよおカワイイ" and t_i is "ちよおかわいい"). Then p_s and p_{t_i} are calculated by using the character 5-gram of a blog corpus, which is formulated by $p_s = p(c_1 \cdots c_n) = \prod_{j=1}^{n} p(c_j \mid c_{j-5}^{j-1})$, where c_j is the j th character of character sequence s. p'_{t_i} and p'_s are normalized by using the length of each string s and t_i as $p'_{t_i} = p_{t_i}^{1/length(t_i)}$. We set the threshold $(p'_s/p'_{t_i})_{thres} = 1.5$ for generating a Hiragana or Katakana normalization candidate in this study. Since all those features can be factorized, the optimal path is searched for by using the Viterbi algorithm.

3.4.3 Training

We formulated the objective function for tuning weights $\mathbf{w}$ by using Eq. 2. The weights $\mathbf{w}$ are trained by using the minimum error rate training (MERT) Machery et al. (2008). We defined the error function as the differences between the reference word segmentations and the POS tags of the reference sequence y_{ref} and the system output $\arg\min_{y \in L(s)} \mathbf{w} \cdot \mathbf{f}(y)$.

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w} \in \mathbf{W}} \sum_{i=1}^{N} \mathrm{error}(y_{ref}, \arg\min_{y \in L(s)} \mathbf{w} \cdot \mathbf{f}(y)) \quad (2)$$

4 Experiments

4.1 Dataset and Estimated Transformation Table

We conducted experiments to confirm the effectiveness of the proposed method, in which we annotated corpora of a Japanese blog and Twitter. The Twitter corpus was split into three parts: the training, development, and test sets. The test data comprised 300 tweets, development data comprised 500 sentences and the training data comprised 4208 tweets. We randomly selected the test data which contained at least one non-standard token. The test data comprised 4635 words, 403 words of them are non-standard token and are orthographically transformed into normalized form and POS tags. The blog corpus comprised 8023 sentences and all of them were used as training data. Training data was used for extracting character transformation table and development data was used for estimating parameters of discriminative model. We used the IPA dictionary provided by MeCab to generate the word-level lattice and extracted the dictionary-based features. We itemized the estimated character transformation patterns in Table 3. There were 5228 transformation patterns that were learned from the training data and we used 3268 of them, which meets the predefined condition. The learned patterns cover most of the previously pro-

posed rules. In addition, our method can learn more of the variational patterns that are difficult to create manually.

4.2 Baseline and Evaluation Metrics

We compared the five methods listed in Table 4 in our experiments. Traditional means that which generates no normalization candidates and only uses the word cost and the cost for a pair of adjacent POS, so we can consider it as a traditional Japanese morphological analysis. We compared three baselines, Baseline1, Baseline2 and Baseline3. Baseline1 is the conventional rule-based method (considering insertion of long sound symbols and lowercases, and substitution with long sound symbols and lowercases), which was proposed by Sasano et al. (2013). In Baseline2, 3, and Proposed, we basically use the proposed discriminative model and features, but there are several differences. Baseline2 only generates character-level normalization candidates. Baseline3 uses our two-step normalization candidate generation algorithms, but the character transformation cost of all the normalization candidates that are generated by character normalization is the same. Proposed generates the character-level and Hiragana and Katakana normalization candidates and use all features we proposed.

We evaluated each method on the basis of precision and recall and the F-value for the overall system accuracy. Since Japanese morphological analysis simultaneously estimates the word segmentation and POS tagging, we have to check whether or not our system is negatively affected by anything other than the non-standard tokens. We also evaluated the recall with considering only normalized words. That value directly reflects the performance of our normalization method. We registered emoticons that occurred in the test data in the dictionary so that they would not negatively affect the systems' performance.

4.3 Results and Discussion

The results are classified in Table 4. As the table shows, the proposed methods performed statistically significantly better than the baselines and the traditional method in both precision and recall ($p < 0.01$), where the precision was greatly improved. This indicates that our method can not only correctly analyze the non-standard tokens, but can also reduce the number of wrong words generated. Baseline1 also improved the accuracy and recall compared to the traditional method, but the effect was limited. When we compare Proposed with Baseline2, we find the F-value is improved when we take the Hiragana and Katakana substitution into consideration. Baseline3 also improved the F-value but its performance is inferior to proposed method.This proves that even if we can generate sufficient normalization candidates, the results worsen if the weight parameter of each normalization candidate is not appropriately tuned. The column of "recall*" in Table 4 specifies the improvement rates of the non-standard tokens. The proposed methods improve about seven times when using Baseline1 while preventing degradation. These results prove that we have to generate appropriate and sufficient normalization candidates and appropriately tune the cost of each candidate to improve both the precision and recall.

We show examples of the system output in Table 5. In the table, slashes indicate the position of the estimated word segmentations and the words that were correctly analyzed are written in bold font. Examples (1) to (5) are examples improved by using the proposed method. Examples (6) to (7) are examples that were not improved and example (8) is an example that was degraded. Examples (1) to (3) include phonetic variations and example (4) is a Hiragana substitution. Example (5) is a combinational trans-

Table 5: System output examples

formation pattern of a phonetic variation and Hiragana substitution. We can see our system can analyze such variational non-standard tokens for all these examples. Two types of errors were identified. The first occurred as the result of a lack of a character transformation pattern and the second was search errors. Example (6) shows an example of a case in which our system couldn’t generate correct normalization candidate because there was not corresponding character transformation pattern, even though there was a similar phonetic transformation pattern. To ensure there will be no lack of transformation patterns, we should either increase the parallel corpus size to enable the learning of more patterns or derive new transformation patterns from the learned patterns. Example (7) shows an example of a case in which a normalized candidate was generated but a search failed to locate it. Example (8) shows an example of a case in which the result was degraded. Our system can control the degradation well, but there are several degradation caused by normalization. We will need to develop a more complicated model or introduce other features into the current model to reduce the number of search errors.

5 Conclusion and Future Work

We introduced a text normalization approach into joint Japanese morphological analysis and showed that our two-step lattice generation algorithm and formulation using discriminative methods outperforms the previous method. In future work, we plan to extend this approach by introducing an unsupervised or semi-supervised parallel corpus extraction for learning character alignments to generate more patterns at a reduced cost. We also plan to improve our model’s structure and features and implement it with a decoding method to reduce the number of search errors. In addition, we should consider adding other types of unknown words (such as named entities) to the morphological analysis system to improve its overall performance.

Abstract

We experiment with using different sources of distant supervision to guide unsupervised and semi-supervised adaptation of part-of-speech (POS) and named entity taggers (NER) to Twitter. We show that a particularly good source of not-so-distant supervision is linked websites. Specifically, with this source of supervision we are able to improve over the state-of-the-art for Twitter POS tagging (89.76% accuracy, 8% error reduction) and NER (F1=79.4%, 10% error reduction).

1 Introduction

Twitter contains a vast amount of information, including first stories and breaking news (Petrovic et al., 2010), fingerprints of public opinions (Jiang et al., 2011) and recommendations of relevance to potentially very small target groups (Benson et al., 2011). In order to automatically extract this information, we need to be able to analyze tweets, e.g., determine the part-of-speech (POS) of words and recognize named entities. Tweets, however, are notoriously hard to analyze (Foster et al., 2011; Eisenstein, 2013; Baldwin et al., 2013). The challenges include dealing with variations in spelling, specific conventions for commenting and retweeting, frequent use of abbreviations and emoticons, non-standard syntax, fragmented or mixed language, etc.

Gimpel et al. (2011) showed that we can induce POS tagging models with high accuracy on in-sample Twitter data with relatively little annotation effort. Learning taggers for Twitter data from small amounts of labeled data has also been explored by others (Ritter et al., 2011; Owoputi et al., 2013; Derczynski et al., 2013). Hovy et al. (2014), on the other hand, showed that these models overfit their respective samples and suffer severe drops when evaluated on out-of-sample Twitter data, sometimes performing even worse than newswire models. This may be due to drift on Twitter (Eisenstein, 2013) or simply due to the heterogeneous nature of Twitter, which makes small samples biased. So while existing systems perform well on their own (in-sample) data sets, they over-fit the samples they were induced from, and suffer on other (out-of-sample) Twitter data sets. This bias can, at least in theory, be corrected by learning from additional unlabeled tweets. This is the hypothesis we explore in this paper.

We present a semi-supervised learning method that does not require additional labeled in-domain data to correct sample bias, but rather leverages pools of unlabeled Twitter data. However, since taggers trained on newswire perform poorly on Twitter data, we need additional guidance when utilizing the unlabeled data. This paper proposes distant supervision to help our models learn from unlabeled data. Distant supervision is a weakly supervised learning paradigm, where a knowledge resource is exploited to gather (possible noisy) training instances (Mintz et al., 2009). Our basic idea is to can use linguistic analysis of linked websites as a novel kind of distant supervision for learning how to analyze tweets. We explore standard sources of distant supervision, such as Wiktionary for POS tagging, but we also propose to use the linked websites of tweets with URLs as supervision. The intuition is that we can use websites to provide a richer linguistic context for our tagging decisions. We exploit the fact that tweets with URLs provide a one-to-one map between an unlabeled instance and the source of supervision, making this

less distant supervision. Note that we use linked websites only for semi-supervised learning, but do *not* require them at test time.

Our semi-supervised learning method enables us to learn POS tagging and NER models that perform more robustly across different samples of tweets than existing approaches. We consider both the scenario where a small sample of labeled Twitter data is available, and the scenario where only newswire data is available. Training on a mixture of out-of-domain (WSJ) and in-domain (Twitter) data as well as unlabeled data, we get the best reported results in the literature for both POS tagging and NER on Twitter. Our tagging models are publicly available at `https://bitbucket.org/lowlands/ttagger-nsd`

2 Tagging with not-so-distant supervision

We assume that our labeled data is highly biased by domain differences (Jiang and Zhai, 2007), population drift (Hand, 2006), or by our sample size simply being too small. To correct this bias, we want to use unlabeled Twitter data. It is well-known that semi-supervised learning algorithms such as self-training sometimes effectively correct model biases (McClosky et al., 2006; Huang et al., 2009). This paper presents an augmented self-training algorithm that corrects model bias by exploiting unlabeled data and not-so-distant supervision. More specifically, the idea is to use hyperlinks to condition tagging decisions in tweets on a richer linguistic context than what is available in the tweets. This semi-supervised approach gives state-of-the-art performance across available Twitter POS and NER data sets.

The overall semi-supervised learning algorithm is presented in Figure 1. The aim is to correct model bias by predicting tag sequences on small pools of unlabeled tweets, and re-training the model across several iterations to gradually correct model bias. Since information from hyperlinks will be important, the unlabeled data U is a corpus of tweets containing URLs. We present a baseline and four system proposals that only differ in their treatment of the **predict()** function.

In the SELF-TRAINING baseline, **predict()** corresponds to standard Viterbi inference on the unlabeled Twitter data. This means, the current model $\mathbf{v}$ is applied to the tweets by disregarding the websites in the tweet-website pairs, i.e., tagging $\mathbf{x}$ without considering w. Then the automatically tagged tweets are added to the current pool of labeled data and the procedure is iterated (line 7-11 in Figure 1).

In the WEB method, we additionally use the information from the websites. The current model $\mathbf{v}$ is used to predict tags for the pooled tweets *and* the website they linked to. For all the words that occur both in a tweet and on the corresponding website, we then project the tag most frequently assigned to those words on the website to their occurrences in the tweet. This enables us to basically condition the tag decision for each such word on its accumulated context on the website. The assumption of course being that the word in the tweet has the part-of-speech it most often has on the website linked to.

Example Here is an example of a tweet that contains a URL:

(1) #Localization #job: Supplier / Project Manager - Localisation Vendor - NY, NY, United States http://bit.ly/16KigBg #nlppeople

The words in the tweet are all common words, but they occur without linguistic context that could help a tagging model to infer whether these words are nouns, verbs, named entities, etc. However, on the website that the tweet refers to, all of these words occur in context:

(2) The Supplier/Project Manager performs the selection and maintenance ...

For illustration, the Urbana-Champaign POS tagger[1] incorrectly tags *Supplier* in (1) as an adjective. In (2), however, it gets the same word right and tags it as a noun. The tagging of (2) could potentially help us infer that *Supplier* is also a noun in (1).

Obviously, the superimposition of tags in the WEB method may change the tag of a tweet word such that it results in an unlikely tag sequence, as we will discuss later. Therefore we also implemented type-constrained decoding (Täckström et al., 2013), i.e., prune the lattice such that the tweet words observed on the website have *one of* the tags they were labeled with on the website (soft constraints), or, alternatively, were forced during decoding to have the most frequent tags they were labeled with (hard constraint decoding), thereby focusing on licensed sequences. However, none of these approaches performed significantly better than the simple WEB approach on held-out data. This suggests that sequential dependencies are less important for tagging Twitter data, which is of rather fragmented nature. Also, the WEB approach allows us to override transitional probabilities that are biased by the observations we made about the distribution of tags in our out-of-domain data.

Furthermore, we combine the not-so-distant supervision from linked websites (WEB) with supervision from dictionaries (DICT). The idea here is to exploit the fact that many word types in a dictionary are actually unambiguous, i.e., contain only a single tag. In particular, 93% of the word types in Wiktionary[2] are unambiguous. Wiktionary is a crowdsourced tag dictionary that has previously been used for minimally supervised POS tagging (Li et al., 2012; Täckström et al., 2013). In the case of NER, we use a gazetteer that combines information on PER, LOC and ORG from the KnownLists of the Illinois tagger.[3] For this gazetteer, 79% of the word types contained only a single named entity tag.

We experiment with a model that uses the dictionary only (DICT) and two ways to combine the two sources. In the former setup, the current model is first applied to tag the tweets, then any token that appears in the dictionary and is unambiguous is projected back to the tweet. The next two methods are combinations of WEB and DICT: either first project the predicted tags from the website and then, in case of conflicts, overrule predictions by the dictionary (WEB$\prec$DICT), or the other way around (DICT$\prec$WEB).

The intuition behind the idea of using linked websites as not-so-distant supervision is that while tweets are hard to analyze (even for humans) because of the limited context available in 140 character messages, tweets relate to real-world events, and Twitter users often use hyperlinks to websites to indicate what real-world events their comments address. In fact, we observed that about 20% of tweets contain URLs. The websites they link to are often newswire sites that provide more context and are written in a more canonical language, and are therefore easier to process. Our analysis of the websites can then potentially inform our analysis of the tweets. The tweets with the improved analyses can then be used to bootstrap our tagging models using a self-training mechanism. Note that our method *does not* require tweets to contain URLs at test time, but rather uses unlabeled tweets with URLs during training to build better tagging models for tweets in general. At test time, these models can be applied to any tweet.

3 Experiments

3.1 Model

In our experiments we use a publicly available implementation of conditional random fields (CRF) (Lafferty et al., 2001).[4] We use the features proposed by Gimpel et al. (2011), in particular features for word tokens, a set of features that check for the presence of hyphens, digits, single quotes, upper/lowercase, 3 character prefix and suffix information. Moreover, we add Brown word cluster features that use 2^i for $i \in 1, ..., 4$ bitstring prefixes estimated from a large Twitter corpus (Owoputi et al., 2013), which is publicly available.[5] We use a pool size of 1000 tweets. We experimented with other pool sizes {500,2000} showing similar performance. The number of iterations i is set on the development data.

For NER on websites, we use the Stanford NER system (Finkel et al., 2005)[6] with POS tags from the LAPOS tagger (Tsuruoka et al., 2011).[7] For POS we found it to be superior to use the current POS model for re-tagging websites; for NER it was slightly better to use the Stanford NER tagger and thus off-line NER tagging rather than retagging the websites in every iteration.

3.2 Data

In our experiments, we consider two scenarios, sometimes referred to as unsupervised and semi-supervised domain adaptation (DA), respectively (Daumé et al., 2010; Plank, 2011). In unsupervised DA, we assume only (labeled) newswire data, in semi-supervised DA, we assume labeled data from both domains, besides unlabeled target data, but the amount of labeled target data is much smaller than the labeled source data. Most annotated corpora for English are newswire corpora. Some annotated Twitter data sets have been made available recently, described next.

	POS	**NER**
train	WSJ (700k)	REUTER-CONLL (Tjong Kim Sang and De Meulder, 2003) (200k)

Table 1: Overview of data sets. Number in parenthesis: size in number of tokens.

Training data. An overview of the different data sets is given in Table 3.2. In our experiments, we use the SANCL shared task[8] splits of the OntoNotes 4.0 distribution of the WSJ newswire annotations as newswire training data for POS tagging.[9] For NER, we use the CoNLL 2003 data sets of annotated newswire from the Reuters corpus.[10] The in-domain training POS data comes from Gimpel et al. (2011), and the in-domain NER data comes from Finin et al. (2010) (FININ-TRAIN). These data sets are added to the newswire sets when doing semi-supervised DA. Note that for NER, we thus do not rely on expert-annotated Twitter data, but rely on crowdsourced annotations. We use MACE[11] (Hovy et al., 2013) to resolve inter-annotator conflicts between turkers (50 iterations, 10 restarts, no confidence threshold). We believe relying on crowdsourced annotations makes our set-up more robust across different samples of Twitter data.

Development and test data. We use several evaluation sets for both tasks to prevent overfitting to a specific sample. We use the (out-of-sample) development data sets from Ritter et al. (2011) and Foster

et al. (2011). For NER, we simply use the parameters from our POS tagging experiments and thus do not assume to have access to further development data. For both POS tagging and NER, we have three test sets. For POS tagging, the ones used in Foster et al. (2011) (FOSTER-TEST) and Ritter et al. (2011) (RITTER-TEST),[12] as well as the one presented in Hovy et al. (2014) (HOVY-TEST). For NER, we use the data set from Ritter et al. (2011) and the two data sets from Fromreide et al. (2014) as test sets. One is a manual correction of a held-out portion of FININ-TRAIN, named FININ-TEST; the other one is referred to as FROMREIDE-TEST. Since the different POS corpora use different tag sets, we map all of them corpora onto the universal POS tag set by Petrov et al. (2012). The data sets also differ in a few annotation conventions, e.g., some annotate URLs as NOUN, some as X. Moreover, our newswire tagger baselines tend to get Twitter-specific symbols such as URLs, hashtags and user accounts wrong. Instead of making annotations more consistent across data sets, we follow Ritter et al. (2011) in using a few post-processing rules to deterministically assign Twitter-specific symbols to their correct tags. The major difference between the NER data sets is whether Twitter user accounts are annotated as PER. We follow Finin et al. (2010) in doing so.

Unlabeled data We downloaded 200k tweet-website pairs from the Twitter search API over a period of one week in August 2013 by searching for tweets that contain the string *http* and downloading the content of the websites they linked to. We filter out duplicate tweets and restrict ourselves to websites that contain more than one sentence (after removing boilerplate text, scripts, HTML, etc).[13] We also require website and tweet to have at least one matching word that is not a stopword (as defined by the NLTK stopword list).[14] Finally we restrict ourselves to pairs where the website is a subsite, because website head pages tend to contain mixed content that is constantly updated. The resulting files are all tokenized using the Twokenize tool.[15] Tweets were treated as one sentence, similar to the approaches in Gimpel et al. (2011) and Owoputi et al. (2013); websites were processed by applying the Moses sentence splitter.[16]

The out-of-vocabulary (OOV) rates in Figure 2 show that in-domain training data reduces the number of unseen words considerably, especially in the NER data sets. They also suggest that some evaluation data sets share more vocabulary with our training data than others. In particular, we would expect better performance on FOSTER-TEST than on RITTER-TEST and HOVY-TEST in POS tagging, as well as better performance on FININ-TEST than on the other two NER test sets. In POS tagging, we actually do see better results with FOSTER-TEST across the board, but in NER, FININ-TEST actually turns out to be the hardest data set.

4 Results

4.1 POS results

Baselines We use three supervised CRF models as baselines (cf. the first part of Table 2). The first supervised model is trained only on WSJ. This model does very well on FOSTER-DEV and FOSTER-TEST, presumably because of the low OOV rates (Figure 2). The second supervised model is trained only on GIMPEL-TRAIN; the third on the concatenation of WSJ and GIMPEL-TRAIN. While the second baseline performs well on held-out data from its own sample (90.3% on GIMPEL-DEV), it performs poorly across our out-of-sample test and development sets. Thus, it seems to overfit the sample of tweets described in Gimpel et al. (2011). The third model trained on the concatenation of WSJ and GIMPEL-TRAIN achieves the overall best baseline performance (88.4% macro-average accuracy). We note that this is around one percentage point better than the best available off-the-shelf system for Twitter (Owoputi et al., 2013) with an average accuracy of 87.5%.

[12] Actually (Ritter et al., 2011) do cross-validation over this data, but we use the splits of Derczynski et al. (2013) for POS.

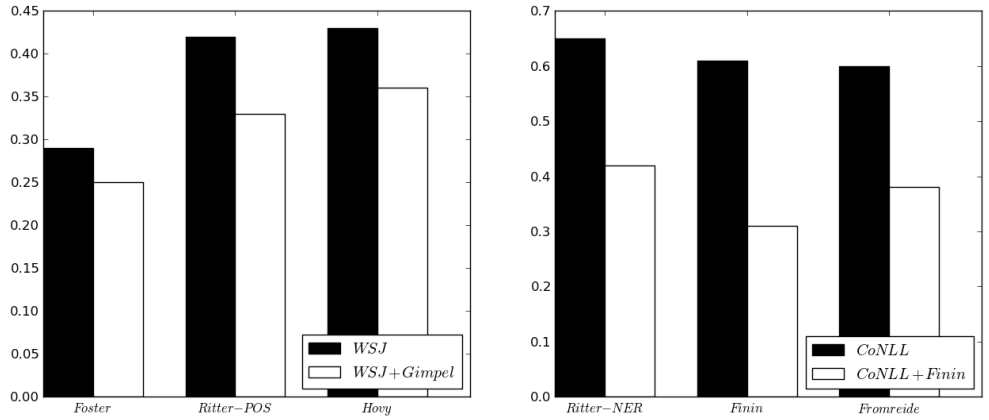

Figure 2: Test set (type-level) OOV rates for POS (left) and NER (right).

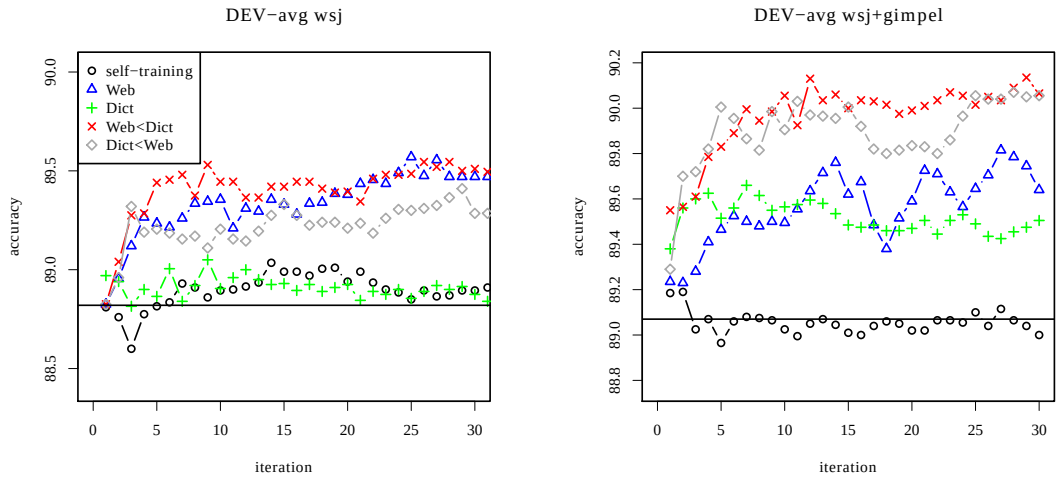

Figure 3: Learning curves on DEV-avg for systems trained on WSJ (left) and WSJ+GIMPEL (right) used to set the hyperparameter i.

Learning with URLs The results of our approaches are presented in Table 2. The hyperparameter i was set on the development data (cf. Figure 3). Note, again, that they do not require the test data to contain URLs. First of all, naive self-training does not work: accuracy declines or is just around baseline performance (Table 2 and Figure 3). In contrast, our augmented self-training methods with WEB or DICT reach large improvements. In case we assume no target training data (train on WSJ only, i.e. unsupervised DA), we obtain improvements of up to 9.1% error reduction. Overall the system improves from 88.42% to 89.07%. This also holds for the second scenario, i.e. training on WSJ+GIMPEL-TRAIN (semi-supervised DA, i.e., the case where we have some labeled target data, besides the pool of unlabeled tweets) where we reach error reductions of up to 10%. Our technique, in other words, improves the robustness of taggers, leading to much better performance on new samples of tweets.

4.2 NER results

For our NER results, cf. Table 3, we used the same feature models and parameter settings as those used for POS tagging, except conditioning also on POS information. It is conceivable that other parameter settings would have led to better results, but we did not want to assume the existence of in-domain development data for this task. Our baselines are again supervised systems, as well as off-the-shelf systems. Our in-

house supervised baselines perform better than the available off-the-shelf systems, including the system provided by Ritter et al. (2011) (TEST-avg of 54.2%). We report micro-average F_1-scores over entity types, computed using the publicly available evaluation script.[17] Our approaches again lead to substantial error reductions of 8–13% across our NER evaluation data sets.

5 Error analysis

The majority of cases where our taggers improve on the ARK tagger (Owoputi et al., 2013) seem to relate to richer linguistic context. The ARK tagger incorrectly tags the sequence *Man Utd* as PRT-NOUN, whereas our taggers correctly predict NOUN-NOUN. In a similar vein, our taggers correctly predict the tag sequence NOUN-NOUN for *Radio Edit*, while the ARK tagger predicts NOUN-VERB.

However, some differences seem arbitrary. For example, the ARK tagger tags the sequence *Nokia*

[17] http://www.cnts.ua.ac.be/conll2000/chunking/

D5000 in FOSTER-TEST as NOUN-NUM. Our systems correctly predict NOUN-NOUN, but it is not clear which analysis is better in linguistic terms. Our systems predict a sequence such as *Love his version* to be VERB-PRON-NOUN, whereas the ARK tagger predicts VERB-DET-NOUN. Both choices seem linguistically motivated.

Finally, some errors are made by all systems. For example, the word *please* in *please, do that*, for example, is tagged as VERB by all systems. In FOSTER-TEST, this is annotated as X (which in the PTB style was tagged as interjection UH). Obviously, *please* often acts as a verb, and while its part-of-speech in this case may be debatable, we see *please* annotated as a verb in similar contexts in the PTB, e.g.:

(3) Please/VERB make/VERB me/PRON ...

It is interesting to look at the tags that are projected from the websites to the tweets. Several of the observed projections support the intuition that coupling tweets and the websites they link to enables us to condition our tagging decisions on a richer linguistic context. Consider, for example *Salmon-Safe*, initially predicted to be a NOUN, but after projection correctly analyzed as an ADJ:

Word	Context	Initial tag	Projected tag
Salmon-Safe	... parks	NOUN	ADJ
Snohomish	... Bakery	ADJ	NOUN
toxic	ppl r ...	NOUN	ADJ

One of the most frequent projections is analyzing *you're*, correctly, as a VERB rather than an ADV (if the string is not split by tokenization).

One obvious limitation of the WEB-based models is that the projections apply to all occurrences of a word. In rare cases, some words occur with different parts of speech in a single tweet, e.g., *wish* in:

(4) If I gave you one **wish** that will become true . What's your **wish** ?... ? i **wish** i'll get <num> wishes from you :p <url>

In this case, our models enforce all occurrences of *wish* to, incorrectly, be verbs.

6 Related work

Previous work on tagging tweets has assumed labeled training data (Ritter et al., 2011; Gimpel et al., 2011; Owoputi et al., 2013; Derczynski et al., 2013). Strictly supervised approaches to analyzing Twitter has the weakness that labeled data quickly becomes unrepresentative of what people write on Twitter. This paper presents results using no in-domain labeled data that are significantly better than several off-the-shelf systems, as well as results leveraging a mixture of out-of-domain and in-domain labeled data to reach new highs across several data sets.

Type-constrained POS tagging using tag dictionaries has been explored in weakly supervised settings (Li et al., 2012), as well as for cross-language learning (Das and Petrov, 2011; Täckström et al., 2013). Our type constraints in POS tagging come from tag dictionaries, but also from linked websites. The idea of using linked websites as distant supervision is similar in spirit to the idea presented in Ganchev et al. (2012) for search query tagging.

Ganchev et al. (2012), considering the problem of POS tagging search queries, tag search queries and the associated snippets provided by the search engine, projecting tags from the snippets to the queries, guided by click-through data. They do not incorporate tag dictionaries, but consider a slightly more advanced matching of snippets and search queries, giving priority to n-gram matches with larger n. Search queries contain limited contexts, like tweets, but are generally much shorter and exhibit less spelling variation than tweets.

In NER, it is common to use gazetteers, but also dictionaries as distant supervision (Kazama and Torisawa, 2007; Cucerzan, 2007). Rüd et al. (2011) consider using search engines for distant supervision of NER of search queries. Their set-up is very similar to Ganchev et al. (2012), except they do not use click-through data. They use the search engine snippets to generate feature representations rather than projections. Want et al. (2013) also use distant supervision for NER, i.e., Wikipedia page view counts,

applying their model to Twitter data, but their results are considerably below the state of the art. Also, their source of supervision is not linked to the individual tweets in the way mentioned websites are.

In sum, our method is the first successful application of distant supervision to POS tagging and NER for Twitter. Moreover, it is, to the best of our knowledge, the first paper that addresses both problems using the same technique. Finally, our results are significantly better than state-of-the-art results in both POS tagging and NER.

7 Conclusion

We presented a semi-supervised approach to POS tagging and NER for Twitter data that uses dictionaries and linked websites as a source of not-so-distant (or linked) supervision to guide the bootstrapping. Our approach outperforms off-the-shelf taggers when evaluated across various data sets, achieving average error reductions across data sets of 5% on POS tagging and 10% on NER over state-of-the-art baselines.

Interpolated Dirichlet Class Language Model for Speech Recognition Incorporating Long-distance N-grams

Md. Akmal Haidar and Douglas O'Shaughnessy

Abstract

We propose a language modeling (LM) approach incorporating interpolated distanced n-grams in a Dirichlet class language model (DCLM) (Chien and Chueh, 2011) for speech recognition. The DCLM relaxes the bag-of-words assumption and documents topic extraction of latent Dirichlet allocation (LDA). The latent variable of DCLM reflects the class information of an n-gram event rather than the topic in LDA. The DCLM model uses default background n-grams where class information is extracted from the $(n$-$1)$ history words through Dirichlet distribution in calculating n-gram probabilities. The model does not capture the long-range information from outside of the n-gram window that can improve the language modeling performance. In this paper, we present an interpolated DCLM (IDCLM) by using different distanced n-grams. Here, the class information is exploited from $(n$-$1)$ history words through the Dirichlet distribution using interpolated distanced n-grams. A variational Bayesian procedure is introduced to estimate the IDCLM parameters. We carried out experiments on a continuous speech recognition (CSR) task using the Wall Street Journal (WSJ) corpus. The proposed approach shows significant perplexity and word error rate (WER) reductions over the other approach.

1 Introduction

Statistical n-gram LMs have been successfully used for speech recognition and many other applications. They suffer from insufficiencies of training data and long-distance information, which limit the model generalization (Chien, 2006). The data sparseness problem is usually solved by backoff smoothing using lower-order language models (Katz, 1987; Kneser and Ney, 1995). The class-based language model was investigated where the class n-grams were calculated by considering the generation of concatenated classes rather than words (Brown et al., 1992). By incorporating the multidimensional word classes and considering the classes from various positions of left and right contextual information (Bai et al., 1998), the class n-gram can be improved (Yamamoto et al., 2003). A neural network language model (NNLM) was trained by linearly projecting the history words of an n-gram event into a continuous space (Bengio et al., 2003; Schwenk, 2007). Later, a recurrent neural network-based LM was investigated that shows better results than NNLM (Mikolov et al., 2010; Mikolov et al., 2011). Unsupervised class-based language models such as Random Forest LM (Xu and Jelinek, 2007), Model M (Chen, 2008) have been investigated that outperform a word-based LM. However, the long-distance information is captured by using a cache-based LM that takes advantage of the fact that a word observed earlier in a document could occur again. This helps to increase the probability of the seen words when predicting the next word (Kuhn and Mori, 1990).

To compensate for the weakness of the n-gram models, latent topic analysis has been used broadly. Several techniques such as Latent Semantic Analysis (LSA) (Deerwester et al., 1990; Bellegarda, 2000), probabilistic LSA (PLSA) (Hofmann, 1999; Gildea and Hofmann, 1999), and Latent Dirichlet Allocation (LDA) (Blei et al., 2003) have been studied to extract the latent semantic information from a training

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1793–1802, Dublin, Ireland, August 23-29 2014.

corpus. The LSA, PLSA and LDA models have been used successfully in recent research work for LM adaptation (Bellegarda, 2000; Gildea and Hofmann, 1999; Mrva and Woodland, 2004; Tam and Schultz, 2005; Tam and Schultz, 2006; Haidar and O'Shaughnessy, 2011; Haidar and O'Shaughnessy, 2012b; Haidar and O'Shaughnessy, 2012a). Even so, the extracted topic information is not directly useful for speech recognition, where the latent topic of n-gram events should be of concern. In (chien and Chueh, 2008), a latent Dirichlet language model (LDLM) was proposed where the latent topic information was exploited from (n-1) history words through the Dirichlet distribution in calculating the n-gram probabilities. A topic cache language model was proposed where the topic information was obtained from long-distance history through multinomial distributions (Chueh and Chien, 2010). Topic-dependent-class-based n-gram LM was proposed where the LSA method was used to reveal latent topic information from noun-noun relations (Naptali et al., 2012). In (Bassiou and Kotropoulos, 2010), a PLSA technique enhanced with long-distance bigrams was used to incorporate the long-term word dependencies in determining word clusters. This technique was used in (Haidar and O'Shaughnessy, 2013b) and (Haidar and O'Shaughnessy, 2013a) for the PLSA and LDLM models respectively where the long-distance information was captured by using interpolated distanced n-grams and their parameters were estimated by using an expectation maximization (EM) procedure (Dempster et al., 1977). In (Chien and Chueh, 2011), the DCLM model was proposed to tackle the data sparseness and to extract the large-span information for the n-gram model. In this model, the topic structure in LDA is assumed to derive the hidden classes of histories in calculating the language model. A Bayesian class-based language model was presented where a variational Bayes-EM procedure was used to compute the model parameters. Also, a cache DCLM model was proposed to capture the long-distance information beyond the n-gram window. However, in the DCLM model (Chien and Chueh, 2011), the class information of the history words was obtained from the n-gram events of the corpus. Here, the long-range information outside the n-gram window is not captured. In this paper, we present an IDCLM model to capture the long-range information in the DCLM using the interpolated distanced n-grams. The n-gram probabilities of the proposed IDCLM model are computed by mixing the component distanced word probabilities for classes and the interpolated class information for histories. Similar to the DCLM model, the parameters of the IDCLM model are computed by using the variational Bayesian-EM procedure.

The rest of this paper is organized as follows. Section 2 is used for reviewing the DCLM model. The proposed IDCLM model is described in section 3. The comparison of the IDCLM and the DCLM models is described in section 4. The experimental details are described in section 5. Finally, the conclusions and future work are described in section 6.

2 DCLM

LDA is used to compute the document probability by using the topic structure at the document level, which is inconsistent with the language model for speech recognition where the n-gram regularities are characterized (Chien and Chueh, 2011). The DCLM was developed to model the n-gram events of the corpus for speech recognition. In the DCLM, the class structure is described by Dirichlet densities and estimated from n-gram events. The graphical model of the DCLM for a text corpus that comprises n-gram events $\{w_{i-n+1}^{i-1}, w_i\}$ is described in Figure 1. Here, H and N_h represent the number of history events w_{i-n+1}^{i-1} and the number of collected words that occur following the history w_{i-n+1}^{i-1}, respectively. The (n-1) history words w_{i-n+1}^{i-1} are represented by a (n-1)V $\times$ 1 vector $\mathbf{h}$, consisting of n-1 block subvectors, with the entries of the seen words assigned to ones and those of unseen words assigned to zeros (Chien and Chueh, 2011). Here, V represents the size of the vocabulary. The vector $\mathbf{h}$ is then projected into a C-dimensional continuous class space using a class-dependent linear discriminant function:

$$g_c(\mathbf{h}) = \mathbf{a}_c^T \mathbf{h} \tag{1}$$

where $\mathbf{a}_c^T$ is the c^{th} row vector of matrix $\mathbf{A} = [\mathbf{a}_1, \cdots, \mathbf{a}_C]$ (Chien and Chueh, 2011). The function $g_c(\mathbf{h})$ describes the class posterior probability $p(c|\mathbf{h})$, which is used in predicting the class information for an unseen history (Chien and Chueh, 2011). The model can be described as:

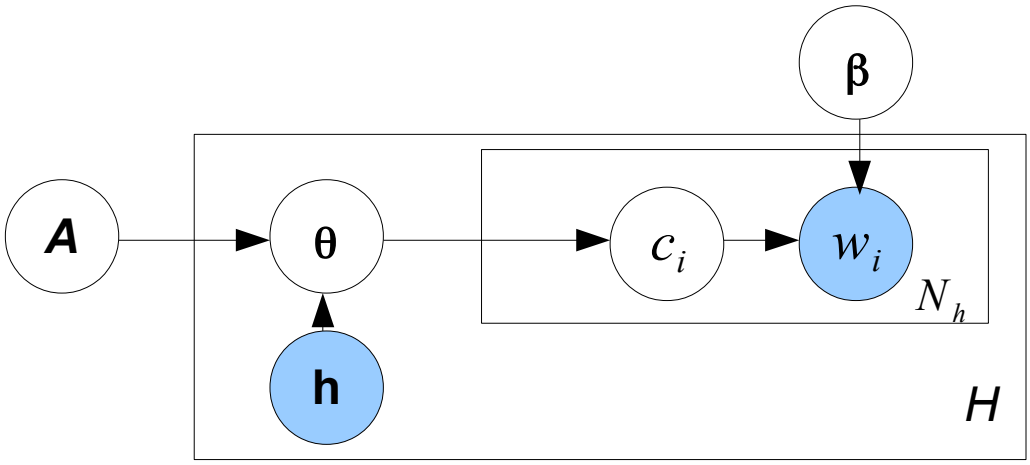

Figure 1: The graphical model of the DCLM. Shaded circles represent observed variables.

- For each history vector $\mathbf{h}$, the class information c is drawn from a history-dependent Dirichlet prior $\boldsymbol{\theta}$, which is related to a global projection matrix $\mathbf{A}$:

$$p(\boldsymbol{\theta}|\mathbf{h},\mathbf{A}) \propto \prod_{c=1}^{C} \theta_c^{g_c(\mathbf{h})-1}, \tag{2}$$

- For each predicted word w_i of the n-gram events from a multinomial distribution with parameter $\boldsymbol{\beta}$, the associated class c_i is chosen by using a multinomial distribution with parameter $\boldsymbol{\theta}$. The joint probability of the variable $\boldsymbol{\theta}$, c_i, and w_i conditioned on $\mathbf{h}$ can be computed as:

$$p(\boldsymbol{\theta}, c_i, w_i|\mathbf{h},\mathbf{A},\boldsymbol{\beta}) = p(\boldsymbol{\theta}|\mathbf{h},\mathbf{A})p(c_i|\boldsymbol{\theta})p(w_i|c_i,\boldsymbol{\beta}) \tag{3}$$

- The conditional probability in the n-gram language model can thus be obtained as:

$$p(w_i|\mathbf{h},\mathbf{A},\boldsymbol{\beta}) = \int p(\boldsymbol{\theta}|\mathbf{h},\mathbf{A}) \sum_{c_i=1}^{C} p(c_i|\boldsymbol{\theta})p(w_i|c_i,\boldsymbol{\beta})d\boldsymbol{\theta}, \tag{4}$$

  where the integral is computed as:

$$p(c_i|\mathbf{h},\mathbf{A}) = \int p(\boldsymbol{\theta}|\mathbf{h},\mathbf{A})p(c_i|\boldsymbol{\theta})d\boldsymbol{\theta} = \frac{g_{c_i}(\mathbf{h})}{\sum_{j=1}^{C} g_j(\mathbf{h})}. \tag{5}$$

  which is an expectation of a Dirichlet distribution of latent class c_i (Chien and Chueh, 2011).

Therefore, the probability of an n-gram event using the DCLM (Equation 4 and 5) can be written as (Chien and Chueh, 2011):

$$p(w_i|\mathbf{h},\mathbf{A},\boldsymbol{\beta}) = \sum_{c=1}^{C} p(w_i|c,\boldsymbol{\beta}) \frac{g_c(\mathbf{h})}{\sum_{j=1}^{C} g_j(\mathbf{h})} \tag{6}$$

The parameters ($\mathbf{A}$,$\boldsymbol{\beta}$) of the model are computed by using the variational bayesian EM (VB-EM) procedure (Chien and Chueh, 2011).

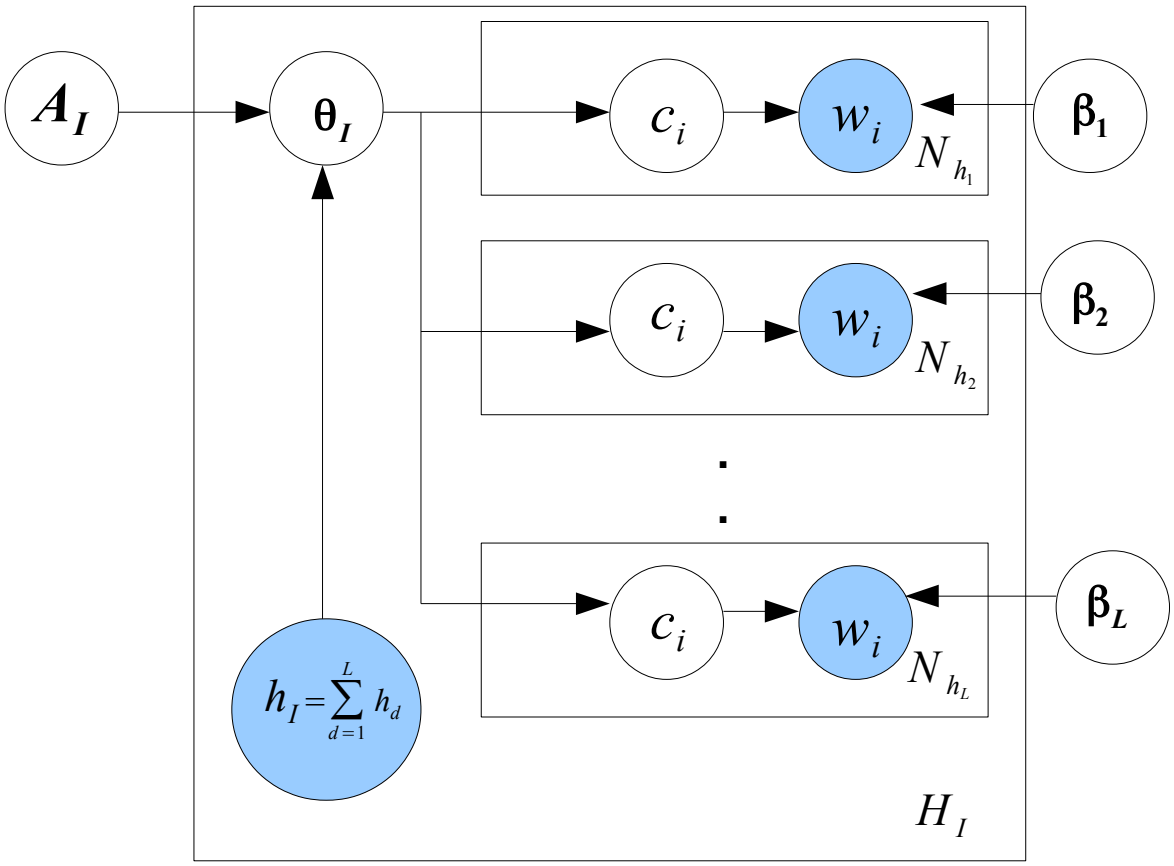

Figure 2: The graphical model of the IDCLM. Shaded circles represent observed variables.

3 Proposed IDCLM

The DCLM does not capture the long-range information from outside of the n-gram window (Chien and Chueh, 2011). To incorporate the long-range information into the DCLM, we propose an IDCLM where the class information is extracted from interpolated distance n-gram histories through a Dirichlet distribution in calculating the language model probability. In this model, we interpolate the distanced n-gram events into the original n-gram events of the DCLM. The graphical model of the IDCLM is described in Figure 2. In Figure 2, H_I contains the histories of all the distanced d n-grams, d represents the distance between words in the n-gram events, and L describes the maximum length of distance d. When d = 1, the n-grams are the default background n-grams. For example, the distanced tri-grams of the phrase "Interpolated Dirichlet Class Language Model for Speech Recognition" are described in Table 1 for the distance $d = 1, 2, 3$. Here, the (n-1)V dimensional discrete history vector $\mathbf{h}_I$ is projected

d	Trigrams

Table 1: *Distanced tri-grams for the phrase "Interpolated Dirichlet Class Language Model for Speech Recognition"*

into a C-dimensional continuous class space using a class-dependent linear discriminant function:

$$g_c(\mathbf{h}_I) = \mathbf{a}_{c,I}^T \mathbf{h}_I \tag{7}$$

where $\mathbf{h}_I$ is the combined histories of all the distanced histories $\mathbf{h}_d$ and is defined as $\mathbf{h}_I = \sum_{d=1}^{L} \mathbf{h}_d$. Here, $\sum$ represents the logical OR operator. $\mathbf{a}_{c,I}^T$ is the c^{th} row vector of the matrix $\mathbf{A}_I$ and $g_c(\mathbf{h}_I)$ describes the class posterior probability $p(c|\mathbf{h}_I)$.

The n-gram probability of the IDCLM model is computed as:

$$\begin{aligned} p_I(w_i|\mathbf{h}_I, \mathbf{A}_I, \boldsymbol{\beta}_d) &= \sum_{c_i=1}^{C} \left\{ \Big[\sum_d \lambda_d p_d(w_i|c_i, \boldsymbol{\beta}_d) \Big] \times \int p(\boldsymbol{\theta}_I|\mathbf{h}_I, \mathbf{A}_I) p(c_i|\boldsymbol{\theta}_I) d\boldsymbol{\theta}_I \right\} \\ &= \sum_{c=1}^{C} \Big[\sum_d \lambda_d \beta_{d,ic} \Big] \frac{g_c(\mathbf{h}_I)}{\sum_{j=1}^{C} g_j(\mathbf{h}_I)} \end{aligned} \tag{8}$$

where λ_d are the weights for each component probability estimated on the held-out data using the EM algorithm (Bassiou and Kotropoulos, 2010; Dempster et al., 1977).

The parameters of the IDCLM model are computed using the variational Bayes EM (VB-EM) procedure by maximizing the marginal distribution of the training data that contains a set of n-gram events $D = \{w_{i-n+1}^{i-1}, w_i\}$:

$$\begin{aligned} \log p(D|\mathbf{A}_I, \boldsymbol{\beta}_d) &= \sum_{(w_i, \mathbf{h}_I) \in D} \log p_I(w_i|\mathbf{h}_I, \mathbf{A}_I, \boldsymbol{\beta}_d) \\ &= \sum_{\mathbf{h}_I} \log \left\{ \int p(\boldsymbol{\theta}_I|\mathbf{h}_I, \mathbf{A}_I) \times \left[\sum_d \prod_{j=1}^{N_{h_d}} \sum_{c_j=1}^{C} \lambda_d p_d(w_j|c_j, \boldsymbol{\beta}_d) p(c_j|\boldsymbol{\theta}_I) \right] d\boldsymbol{\theta}_I \right\} \end{aligned} \tag{9}$$

where D contains all the distanced n-gram events, N_{h_d} represents the number of collected words that occur following the history $\mathbf{h}_d$ in d-distanced n-grams. In Equation 9, the summation is over all possible histories in training samples D. However, directly optimizing the Equation 9 is intractable (Chien and Chueh, 2011). A variational IDCLM is introduced where the marginal likelihood is approximated by maximizing the lower bound of Equation 9. The VB-EM procedure is required since the parameter estimation involves the latent variables of $\{\boldsymbol{\theta}_I, \mathbf{c}_{h_d} = \{c_i\}_{i=1}^{N_{h_d}}\}$.

The lower bound $L(\mathbf{A}_I, \boldsymbol{\beta}_d; \hat{\boldsymbol{\gamma}}_I, \hat{\boldsymbol{\phi}}_d)$ is given by:

$$\begin{aligned} &\sum_{\mathbf{h}_I} \left\{ \log \Gamma\Big(\sum_{c=1}^{C} g_c(\mathbf{h}_I) \Big) - \sum_{c=1}^{C} \log \Gamma(g_c(\mathbf{h}_I)) + \sum_{c=1}^{C} (g_c(\mathbf{h}_I) - 1) \times \Big(\Psi(\gamma_{h_I,c}) - \Psi\Big(\sum_{j=1}^{C} \gamma_{h_I,j} \Big) \Big) \right\} \\ &\qquad + \sum_d \sum_{\mathbf{h}_d} \sum_{i=1}^{N_{h_d}} \sum_{c=1}^{C} \lambda_d \phi_{h_d,ic} \Big(\Psi(\gamma_{h_I,c}) - \Psi\Big(\sum_{j=1}^{C} \gamma_{h_I,j} \Big) \Big) \\ &+ \sum_d \sum_{\mathbf{h}_d} \sum_{i=1}^{N_{h_d}} \sum_{c=1}^{C} \sum_{v=1}^{V} \lambda_d \phi_{h_d,ic} \delta(w_v, w_i) \log \beta_{d,vc} - \sum_{\mathbf{h}_I} \left\{ \log \Gamma\Big(\sum_{c=1}^{C} \gamma_{h_I,c} \Big) - \sum_{c=1}^{C} \log \Gamma(\gamma_{h_I,c}) \right. \\ &\qquad \left. + \sum_{c=1}^{C} (\gamma_{h_I,c} - 1) \Big(\Psi(\gamma_{h_I,c}) - \Psi\Big(\sum_{j=1}^{C} \gamma_{h_I,j} \Big) \Big) \right\} - \sum_d \sum_{\mathbf{h}_d} \sum_{i=1}^{N_{h_d}} \sum_{c=1}^{C} \lambda_d \phi_{h_d,ic} \log \phi_{h_d,ic} \end{aligned}$$

where $\Psi(.)$ is the derivative of the log gamma function, and is known as a digamma function (Chien and Chueh, 2011). The history-dependent variational parameters $\{\hat{\boldsymbol{\gamma}}_{h_I} = \hat{\gamma}_{h_I,c}, \hat{\boldsymbol{\phi}}_{h_d} = \hat{\phi}_{h_d,vc}\}$, corresponding to the latent variables $\boldsymbol{\theta}_I, \mathbf{c}_{h,d}$, are then estimated in the VB-E step by setting the differentials $(\partial L(\boldsymbol{\gamma}))/(\partial \gamma_{h_I,c})$ and $(\partial L(\boldsymbol{\phi}))/(\partial \phi_{h_d,ic})$ to zero respectively (Chien and Chueh, 2011):

$$\hat{\gamma}_{h_I,c} = g_c(\mathbf{h}_I) + \sum_d \sum_{i=1}^{N_{h_d}} \lambda_d \phi_{h_d,ic} \tag{10}$$

$$\hat{\phi}_{h_d,ic} = \frac{\beta_{d,ic} \exp\left[\Psi(\gamma_{h_I,c}) - \Psi(\sum_{j=1}^{C} \gamma_{h_I,j})\right]}{\sum_{l=1}^{C} \beta_{d,il} \exp\left[\Psi(\gamma_{h_I,l}) - \Psi(\sum_{j=1}^{C} \gamma_{h_I,j})\right]} \tag{11}$$

In computing $\hat{\phi}_{h_d,ic}$ the corresponding $\gamma_{h_d,c}$ is used in Equation 11. With the updated $\hat{\boldsymbol{\gamma}}_{h_I}, \hat{\boldsymbol{\phi}}_{h_d}$ in the VB-E step, the IDCLM parameters $\{\mathbf{A}_I,\boldsymbol{\beta}_d\}$ are estimated in the VB-M step as (Chien and Chueh, 2011):

$$\hat{\beta}_{d,vc} = \frac{\sum_{\mathbf{h}_d} \sum_{i=1}^{N_{h_d}} \lambda_d \hat{\phi}_{h_d,ic} \delta(w_v, w_i)}{\sum_{m=1}^{V} \sum_{\mathbf{h}_d} \sum_{i=1}^{N_{h_d}} \lambda_d \hat{\phi}_{h_d,ic} \delta(w_m, w_i)} \tag{12}$$

where $\sum_{v=1}^{V} \beta_{d,vc}$=1 and $\delta(w_v, w_i)$ is the Kronecker delta function that equals one when vocabulary word w_v is identical to the predicted word w_i and equals zero otherwise. The gradient ascent algorithm is used to calculate the parameters $\hat{\mathbf{A}}_I = [\hat{\mathbf{a}}_{1,I}, \cdots, \hat{\mathbf{a}}_{C,I}]$ by updating the gradient $\bigtriangledown_{\mathbf{a}_{c,I}}$as (Chien and Chueh, 2011):

$$\bigtriangledown_{\mathbf{a}_{c,I}} \leftarrow \bigtriangledown_{\mathbf{a}_{c,I}} + \sum_{\mathbf{h}_I} \left[\Psi\Big(\sum_{j=1}^{C} g_j(\mathbf{h}_I) \Big) - \Psi(g_c(\mathbf{h}_I)) + \Psi(\hat{\gamma}_{h_I,c}) - \Psi\Big(\sum_{j=1}^{C} \hat{\gamma}_{h_I,j} \Big) \right] . \mathbf{h}_I \tag{13}$$

The n-gram probabilities $p_t(w_i, \mathbf{h}_t, \mathbf{A}_I, \boldsymbol{\beta}_d)$ of the test document t are then computed using Equation 8. To capture the local lexical regularities, the model $p_t(w_i|\mathbf{h}_t, \mathbf{A}_I, \boldsymbol{\beta}_d)$ is then interpolated with the background trigram model as:

$$p_{Interpolated}(w_i|\mathbf{h}) = \mu p_{Background}(w_i|\mathbf{h}) + (1-\mu) p_t(w_i|\mathbf{h}_t, \mathbf{A}_I, \boldsymbol{\beta}_d) \tag{14}$$

4 Comparison of DCLM and IDCLM Models

In the DCLM model, the class information for the $(n-1)$ history words is obtained by using the n-gram counts in the corpus. The current word is predicted from the history-dependent Dirichlet parameter, which is controlled by a matrix $\mathbf{A}$ and corpus-based histories $\mathbf{h}$ (Chien and Chueh, 2011). In contrast, the IDCLM model captures long-range information by incorporating distanced n-grams. Here, the class information is exploited for the interpolated $(n-1)$ history words $\mathbf{h_I}$ that are obtained from all the distanced n-gram events. Both the DCLM and IDCLM exploit the word distribution given the history words. They perform the history clustering of the corpus. For the DCLM model, the number of parameters $\{\mathbf{A},\boldsymbol{\beta}\}$ increases linearly with the number of history words and is given by $(n-1)CV + CV$. For the IDCLM model, the number of parameters $\{\mathbf{A}_I,\boldsymbol{\beta}_d\}$ increases linearly with the number of history words and distance d and is given by $((n-1)CV + CVd)$. The time complexity of DCLM and IDCLM are $O(HVC)$ and $O(H_IVCd)$ with H corpus-based histories, H_I corpus-based interpolated histories, V vocabulary words, d distances and C classes.

5 Experiments

5.1 Data and experimental setup

The LM approaches are evaluated using the Wall Street Journal (WSJ) corpus (Paul and Baker, 1992). The SRILM toolkit (Stolcke, 2002) and the HTK toolkit (Young et al., 2013) are used for generating the LMs and computing the WER respectively. The '87-89 WSJ corpus is used to train language models. The background trigrams are trained using the back-off version of the Witten-Bell smoothing; the 5K non-verbalized punctuation closed vocabulary. We train the trigram IDCLM model using $L = 2$ and $L = 3$. Ten EM iterations in the VB-EM procedure were used. The initial values of the entries in the matrix $\boldsymbol{\beta}$,$\boldsymbol{\beta}_d$ were set to be $1/V$ and those in $\mathbf{A}, \mathbf{A}_I$ were randomly set in the range [0,1]. To update the variational parameters in the VB-E step, one iteration was used. The VB-M step was executed to update the parameters $\mathbf{A}, \mathbf{A}_I$ by three iterations (Chien and Chueh, 2011). To capture the local lexical regularity, trigrams of various methods are interpolated with the background trigrams. The acoustic model from (Vertanen, 2013) is used in our experiments. The acoustic model is trained by using all WSJ and TIMIT (Garofolo et al., 1993) training data, the 40-phone set of the CMU dictionary (-, 2013),

approximately 10000 tied-states, 32 Gaussians per state and 64 Gaussians per silence state. The acoustic waveforms are parameterized into a 39-dimensional feature vector consisting of 12 cepstral coefficients plus the 0^{th} cepstral, delta and delta delta coefficients, normalized using cepstral mean subtraction $(MFCC_{0-D-A-Z})$. We evaluated the cross-word models. The values of the word insertion penalty, beam width, and the language model scale factor are -4.0, 350.0, and 15.0 respectively (Vertanen, 2013). The interpolation weights λ_d and μ are computed by optimizing on the held-out data according to the metric of perplexity. The experiments are evaluated on the evaluation test, which is a total of 330 test utterances from the November 1992 ARPA CSR benchmark test data for vocabularies of 5K words (Paul and Baker, 1992; Woodland et al., 1994).

5.2 Experimental Results

Due to the higher memory and training time requirements for the IDCLM model, we trained the DCLM and IDCLM models for class sizes of 10 and 20. The perplexity and WER results are described in Table 2 and Figure 3 respectively.

Language Model	10 Classes	20 Classes
Background (B)	109.41	109.41
B+Class	106.65	106.97
B+DCLM	100.20	100.45
B+IDCLM (L=2)	98.01	97.94
B+IDCLM (L=3)	95.63	95.43

Table 2: Perplexity results of the models

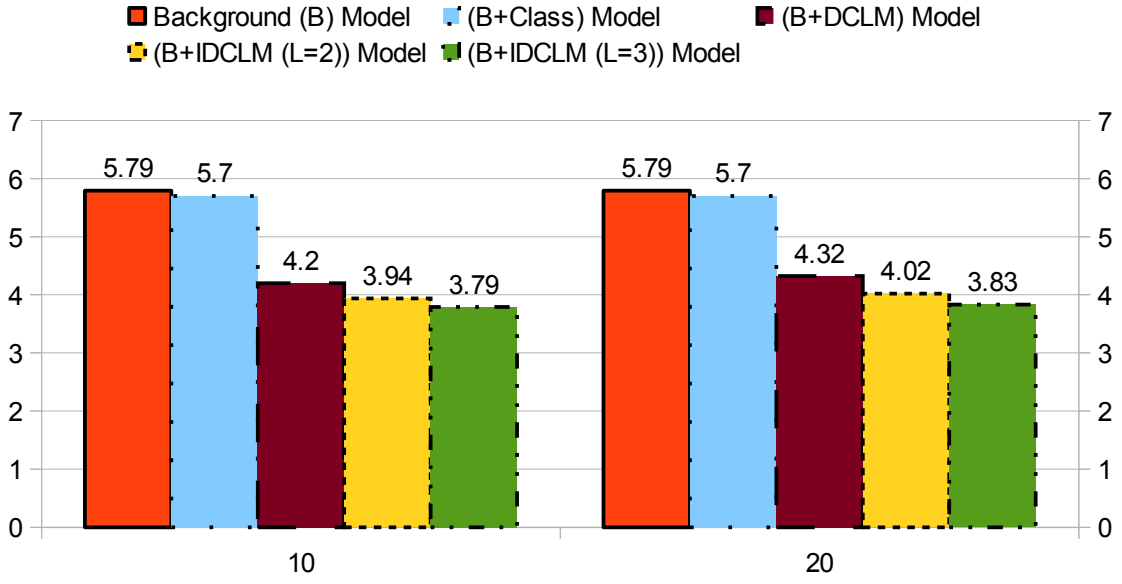

Figure 3: WER results for different class sizes

From Table 2, we can note the proposed IDCLM model outperforms the other models for all class sizes. The performance of IDCLM improves with more distances ($L = 3$).

We evaluated the WER experiments using lattice rescoring. In the first pass decoding, we used the background trigram for lattice generation. In the second pass, we applied the interpolated model for lattice rescoring. The WER results are described in Figure 3. From Figure 3, we can note that the proposed IDCLM ($L = 3$) model yields a WER reduction of about 34.54% (5.79% to 3.79%), 33.5% (5.7% to 3.79%), and 9.76% (4.2% to 3.79%) for 10 classes and about 33.85% (5.79% to 3.83%), 32.8%

(5.7% to 3.83%), and 11.34% (4.32% to 3.83%) over the background trigram, class trigram (Brown et al., 1992), and the DCLM (Chien and Chueh, 2011) approaches respectively. The significance improvement in WER is done by using a match-pair-test where the misrecognized words in each test utterance are counted. The p-values are described in Table 3. From Table 3, we can note that the IDCLM ($L = 2$)

Language Model	10 Classes	20 Classes
B+Class & B+IDCLM (L=2)	3.8E-10	4.3E-10
B+Class & B+IDCLM (L=3)	4.7E-12	4.7E-12
B+DCLM & B+IDCLM (L=2)	0.04	0.01
B+DCLM & B+IDCLM (L=3)	0.004	0.006

Table 3: p-values obtained from the match-pair test on the WER results

is statistically significant to the class-based LM (Brown et al., 1992) and DCLM (Chien and Chueh, 2011) at a significance level of 0.01 and 0.05 respectively. However, the IDCLM ($L = 3$) model is statistically significant to the above models at a significance level of 0.01. We have also seen that the cache DCLM model also gives the same results as DCLM (Chien and Chueh, 2011) for smaller number of classes (Chien and Chueh, 2011).

6 Conclusions and Future Work

In this paper, we proposed an integration of distanced n-grams into the original DCLM model (Chien and Chueh, 2011). The DCLM model (Chien and Chueh, 2011) extracted the class information from the $(n$-1) history words through a Dirichlet distribution in calculating the n-gram probabilities. However, it does not capture the long-range semantic information from outside of the n-gram events. The proposed IDCLM overcomes the shortcomings of DCLM by incorporating the interpolated long-distance n-grams that capture the long-term word dependencies. Using the IDCLM, the class information for the histories is trained using the interpolated distanced n-grams. The IDCLM yields better results with including more distances ($L = 3$). The model probabilities are computed by weighting the component word probabilities for classes and the interpolated class information for histories. A variational Bayesian EM (VB-EM) procedure is presented to estimate the model parameters.

For future work, we will evaluate the proposed approach with neural network-based language models and exponential class-based language models. Furthermore, we will find out a way to perform the experiments for higher numbers of classes.

Abstract

A common site of language use is interactive dialogue between two people situated together in shared time and space. In this paper, we present a statistical model for understanding natural human language that works incrementally (i.e., does not wait until the end of an utterance to begin processing), and is grounded by linking semantic entities with objects in a shared space. We describe our model, show how a semantic meaning representation is grounded with properties of real-world objects, and further show that it can ground with embodied, interactive cues such as pointing gestures or eye gaze.

1 Introduction

Dialogue between co-located participants is possibly the most common form of language use (Clark, 1996). It is highly interactive (time is shared between two participants), interlocutors can refer to objects in their visual field (space is also shared), and visual cues such as gaze or pointing gestures often play a role (shared time *and* space). Most computational dialogue research focuses only one of these constraints.

In this paper, we present a model that processes incrementally (i.e., can potentially work interactively), can make use of the visual world by symbolically representing objects in a scene, and incorporate gaze and gestures. The model can learn from conversational data and can potentially be used in an application for a situated dialogue system, such as an autonomous robot.

In the following section we will provide background and present related work. That will be followed by a description of the task and the model. In Section 4 we will show how our model performs in two experiments, the first uses speech and a visual scene, the second incorporates visual cues.

2 Background and Related Work

2.1 Background: Incremental Dialogue Processing

Dialogue systems that process incrementally produce behavior that is perceived by human users to be more natural than systems that use a turn-based approach (Aist et al., 2006; Skantze and Schlangen, 2009; Skantze and Hjalmarsson, 2010). Incremental dialogue has seen improvements in speech recognition (Baumann et al., 2009), speech synthesis (Buschmeier et al., 2012), and dialogue management (Buß et al., 2010; Selfridge et al., 2012). Futhermore, architectures for incremental dialogue systems have been proposed (Schlangen and Skantze, 2009; Schlangen and Skantze, 2011) and incremental toolkits are also available (Baumann and Schlangen, 2012).

In this paper, we approach *natural language understanding* (NLU), which aims to map an utterance to an *intention*, as a component in the incremental model of dialogue processing as described in (Schlangen and Skantze, 2011; Schlangen and Skantze, 2009), where incremental systems consist of a network of processing *modules*. Each module has a *left buffer* and a *right buffer*, where a typical module takes input

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1803–1812, Dublin, Ireland, August 23-29 2014.

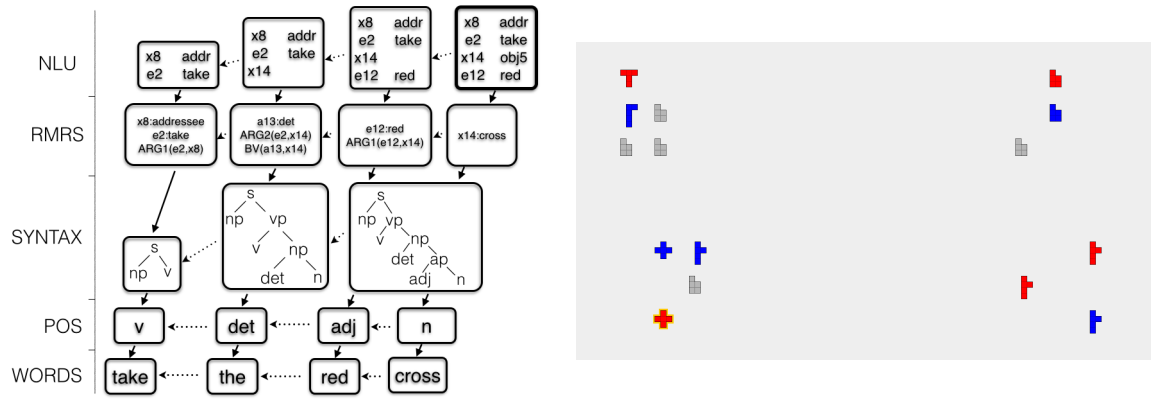

Figure 1: Example of an IU network composed of words, parts of speech (POS), a semtic representation (*Robust Minimal Recursion Semantics*; RMRS), and NLU modules. Solid arrows represent GRIN links and the dotted lines represent SLLs. The utterance *take the red cross* is represented as word IUs, which are GRIN by the part of speech tags, phrase-structure parse, semantic representation, and the intention. Note that *red* and *cross* are GRIN by the same syntactic IU, which in turn is GRIN by two semantic IUs. Succeeding levels of IUs are shifted slightly to the right, representing a processing delay. The X14 slot in the bolded NLU frame refers to the cross-shaped object in the game board on the right.

from its left buffer, performs some kind of processing on that data, and places the processed result onto its right buffer. The data are packaged as the payload of *incremental units* (IU) which are passed between modules. The IUs themselves are also interconnected via so-called *same level links* (SLL) and *grounded-in links* (GRIN), the former allowing the linking of IUs as a growing sequence, the latter allowing that sequence to convey what IUs directly affect them. See Figure 1 for an example; each layer represents a module in the IU-module network and each node is an IU in the IU network. The focus of this paper is the top layer (module), but how it is produced depends on the layers below it.

2.2 Related Work

The work presented in this paper connects and extends recent work in *grounded semantics* (Roy, 2005; Hsiao et al., 2008; Liu et al., 2012; Chai et al., 2014), which aims to connect language with the world, but typically does not work incrementally; *semantic parsing / statistical natural language understanding* via logical forms (Zettlemoyer and Collins, 2007; Zettlemoyer and Collins, 2009), *dependency-based compositional semantics* (Liang et al., 2011), *neural networks* (Huang and Er, 2010), *Markov Logic Networks* (Meurs et al., 2008; Meza-Ruiz et al., 2008), and *Dynamic Bayesian Networks* (Meurs et al., 2009); see also overviews of NLU in (De Mori et al., 2008; Tur and De Mori, 2011), but typically neither provide situated interpretations nor incremental specifications of the representations; *incremental* NLU (DeVault et al., 2009; DeVault et al., 2011; Aist et al., 2007; Schlangen and Skantze, 2009), which focuses on incrementality, but not on situational grounding; as well as integration of *gaze* into language understanding (Prasov and Chai, 2010).

We move beyond this work in that we present a model that is incremental, uses a form of grounded semantics, can easily incorporate multi-modal information sources, and which inference can be performed quickly, satisfying the demands of real-time dialogue.

3 Task and Model

3.1 Task

The task for our model is as follows: to compute at any moment a distribution over possible intentions which the speaker wanted to convey in the utterance, expressed as semantic *frames*, given the unfolding utterance and information about the state of the world in which the utterance is happening. The *slots* of these frames are to be filled with semantic constants, that is, they are uniquely resolved, if appropriate, to objects in the shared environment. This is illustrated in Figure 1 where the words of the utterance give

rise to the part-of-speech tags, the incrementally growing syntax, semantic representation, and, finally, the intention. Note how x14 in the bolded NLU frame resolves to an object identifier for a real object in the shared scene (red cross in the bottom-left of the game board shown on the right in the figure).

3.2 Model

Kennington et al., (2013) presented a simple, incremental model of NLU, which is an update model (i.e., increments build on previous ones) and which can potentially work in real time and in situated environments. The goal of the model is to recover I, the intention of the speaker behind the utterance, word by word. We observe U, the current word (or in this paper, a semantic meaning representation, see below) and an unobserved mediating variable R which represents visual or abstract properties of the object of the intention. Formally, we are interested in $P(I|U)$, the probability of a certain intention I underlying utterance U. We assume a latent variable R (p*R*operties of entities in the world), and build a generative model (that is, model the joint $P(I, R, U)$). Going from $P(I, R|U)$ and making certain independence assumptions, we arrive at

$$P(I|U) = \frac{P(I)}{P(U)} \sum_{r \in R} P(U|R = r)P(R = r|I) \tag{1}$$

That is, we assume that R is only conditional on I, and U is only conditional on R, and we can move $P(I)$ and $P(U)$ out of the summation, as they do not depend on R. This is an update model in the usual sense that the posterior ($P(I|U)$) at one step becomes the prior ($P(I)$) at the next. $P(R|I)$ provides the link between the intentions and the properties.

Another variant of the model which we will use in this paper is as follows: we rewrite $P(U|R)$ using Bayes' rule, which cancels $P(U)$ and introduces $P(R)$ into the summation, but $P(R)$ can be dropped since (in this work) it can be approximated with a uniform distribution, yielding:

$$P(I|U) = P(I) \sum_{r \in R} P(R = r|U)P(R = r|I) \tag{2}$$

There are, however, three important differences between the realisation of our model and the one presented in Kennington et al., (2013), all of which are a direct result of replacing, as we do here, the n-gram model represented by $P(U|R)$ with output from a parser that produces a *Robust Minimal Recursion Semantics* (RMRS) semantic representation (Copestake, 2007). Such a representation provides our model with a structured way to abstract over the surface forms. We will first give a brief explanation of the RMRS framework, then describe each of the three differences between our model and that of Kennington et al., (2013), namely (1) how the language grounds with the world, (2) how the frame is built, and (3) when to consider evidence for the slots in the frame.

RMRS RMRS is a framework for representing semantics that factors a logical form into *elementary predicates* (EP). For example in Table 1, the first row represents the first word of an utterance, *take*, and the corresponding RMRS representation; the EPs *take* and *addressee* are produced. The EPs in this example have *anchor* variables and in most cases, an EP has an argument *entity*. Relations between EPs can be expressed via *argument relations*, e.g., for *take* in the table, there is an ARG1 relation, denoting *addressee* as the first argument of the predicate *take*. Other relations include ARG2 and BV (relating determiners to the words they modify). A full example of an utterance and corresponding RMRS representation can be found in Table 1, where each row in the word column makes up the words of the example utterance.

In this paper we are interested in processing utterances incrementally. As argued in Peldzsus et al., (2012), RMRS is amenable to incremental processing by allowing for *underspecification* in how relations are represented (RMRS can also underspecify scope, but we don't consider that here). Table 1 has an example of an underspecified relation: when the second word *the* is uttered, the RMRS segment predicts that the entity represented by x14 will be the ARG2 relation of the EP for *take*, but the actual word that

word	RMRS segment
take	$a7 : addressee(x8), a1 : take(e2), ARG1(a1, x8)$
the	$a13 : def(), ARG2(a1, x14), BV(a13, x14)$
red	$a33 : red(e34), ARG1(a33, x14)$
cross	$a19 : cross(x14)$
next to	$a49 : next(e50), ARG1(a49, x14), ARG2(a49, x53)$
the	$a52 : def(), BV(a52, x53)$
blue	$a72 : blue(e73), ARG1(a72, x53)$
piece	$a58 : piece(x53)$

Table 1: Example RMRS representation for the utterance *take the red cross next to the blue piece*. Each row represents an increment of the utterance.

produces the EP that has `x14` as an argument has not yet been uttered. Each row in the table represents what we would want an RMRS parser to produce for our model at each word increment.

A more detailed explanation of RMRS can be found in Copestake (2007). We will now discuss the three key differences of our model with that of previous work.

(1) Grounding Semantics with the Visual World In Kennington et al., (2013), the utterance was represented via n-grams, which was used to ground with the world. Here, we ground RMRS structures with the world. For example, Figure 1 shows which words produced which RMRS increments; our model learns the co-occurances between those increments and properties of objects (real properties such as colors, shapes, and spatial placements, or abstract properties; e.g., `take` is a property of the action *take*).

(2) Building the Frame In this paper, intentions are represented as frames. However, unlike Kennington et al., (2013), we don't assume beforehand that we know the slots of the frame. To determine the slots, we turn again to RMRS and build a slot for each *entity* that is produced (more on this below). This kind of frame, coupled with the RMRS representation, shows not just a meaning representation, but also *interpretation* of the representation in the current model (the real situation / visual domain of discourse), outputted incrementally making our model *fully* incremental in the sense of Heintze et al., (2010). The final, bolded NLU frame in Figure 1 shows the addressee (in this case, the dialogue system) as the recipient of the request, the request itself is a `take` request, where the object to be taken is `obj5`, as indexed by the real world, and that object happens to be red (i.e., `e12` represents the notion of *redness*).

(3) Driven by Sematics Another important difference is *when* to consider the semantic evidence and when to ignore it, in terms of when to apply the model for interpretation of the slots. In Kennington et al., (2013), each slot in the frame was processed at each increment in the entire utterance, regardless of whether n-grams in that segment contributed to the interpretation of that slot. In our approach, again, we turn to RMRS. At each word increment, RMRS produces a corresponding, underspecified semantic meaning represenation which is added to at the next increment. Our model takes the new information and only attempts to process the interpretation for those "active" entities. For example, by the time *red* is uttered in Figure 1, the processing for entities `x8`, `e2`, and `e12` is complete, but the processing for `x14` is under way, and active as long as `x14` is referenced as an entity in the RMRS increment.

With these important extensions, our model of NLU is highly driven by the semantic meaning representation that is being built incrementally for the utterance. We will now show through two experiments how our approach improves upon previous work.

4 Experiments

Similar to Kennington et al., (2013), we use the model represented formally in Equation 2, where $P(R|U)$ is realised using a maximum entropy classifier (ME) that predicts properties from RMRS evidence.[1] We use the German RMRS parser described in Peldszus et al (2012), Peldszus and Schlangen (2012) which is a top-down PCFG parser that builds RMRS structure incrementally with the parse.

We train an individual model for each RMRS entity type (e.g., `e` and `x`), where the features are the entity type, relations, and predicates of an RMRS increment and the class label are the visual properties.

[1] http://opennlp.apache.org/

The RMRS representations are not checked for accuracy (i.e., they do not represent ground truth); we use the top-predicted output of the RMRS parser explained in Peldszus et al (2012).

4.1 Pento Puzzle with Speech

Figure 4: Pento frame example from our model

Data and Task The *Pentomino* domain (Fernández et al., 2007) contains task-oriented conversational data which has been used in several situated dialogue studies (Heintze et al., 2010; Peldszus et al., 2012; Kennington and Schlangen, 2012; Kennington et al., 2013). This corpus was collected in a Wizard-of-Oz study, where the user goal was to instruct the computer to pick up, delete, rotate or mirror puzzle tiles on a rectangular board (as in Figure 2), and place them onto another board. For each utterance, the corpus records the state of the game board before the utterance, the immediately preceding system action, and the intended interpretation of the utterance (as understood by the Wizard) in the form of a semantic frame specifying action-type and arguments, where those arguments are objects occurring in the description of the state of the board. The language of the corpus is German. See Figure 2 for a sample source board, and Figure 3 for an annotated frame.

The task that we want our model to perform is as follows: given information about the state of the world (i.e., game board), previous system action, and the ongoing utterance, incrementally build the frame by providing the interpretation of each RMRS entity, represented as a distribution over all possible interpretations for that entity (i.e., domain of discourse).

Procedure To make our work comparable to previous work, results were obtained by averaging the results of a 10-fold validation on 1489 Pento boards (i.e., utterances+context, as in (Kennington and Schlangen, 2012)). We used a separate set of 168 boards for small-scale, held-out experiments. For incremental processing, we used INPROTK.[2] We calculate accuracies by comparing against a gold frame, with assumptions. We check to see if the slot values (3 slots in total) exist in the frame our model produces. If a gold slot value exists in any slot produced by our model, it is counted as correct (it is difficult to tell which slot from our model's frame maps to which slot in the gold frame, we leave this for future work). A fully correct frame would contain all three values. For example, each of the values for the gold slots in Figure 3 exist in the example frame our model would produce in Figure 4, marking each gold slot as correct, and the entire frame as correct since all three were correct together. To directly compare with previous work, we will use the gold slot names `action`, `object`, and `result` in the Results section. We perform training and evaluation on hand-transcribed data and on automatically transcribed data, using the incremental speech recogniser (Sphinx4) in InproTK. We report results on sentence-level and incremental evaluations.

On the incremental level, we followed previously used metrics for evaluation:
first correct: how deep into the utterance do we make the first correct guess?
first final: how deep into the utterance do we make the correct guess, without subsequent changes?
edit overhead: what is the ratio of unnecessary edits / sentence length, where the only *necessary* edit is the first prediction for an entity?

Results Figure 5 shows the results of our evaluation in graph and table form. As expected, our model dramatically improved the `result` value, which generally is verbally represented towards the end of

Bolded values represent the highest values for that row. Note that the column chart begins at 60%. The chart and table show the same information.

an utterance. This resulted in a dramatic increase in frame accuracy (a somewhat strict metric). Our model fares better than previous work using speech (in parentheses in the figure), but is outperformed by the n-gram approach. These results are encouraging, however we leave improvements on automatically transcribed speech to future work.

Incremental Table 2 shows the incremental results of Kennington et al.,(2013), and Table 3 shows our results. Utterances are binned into short, normal, and long utterance lengths (1-6, 7-8, 9-17 words, respectively; 7-8 word utterances were the most represented). Previous work processed all three slots throughout the ongoing utterance, whereas the model presented here only processed entities (that could give rise to these slots) as dictated by the RMRS. This causes a later overall *first correct*, but an overall earlier *first final*, with a much narrower window between them. This represents an ideal system that waits for processing a slot until it needs to, but comes to a final decision quickly, without changing its mind later. This is further evidenced by the *edit overhead* which is lower here than previous work. This has implications in real-time systems that need to define *operating points*; i.e., a dialogue system would need to wait for specific information before making a decision.

4.2 Pento Puzzle with Speech, Gaze, and Deixis

Data and Task The second experiment uses data also from the Pentomino domain, as described in (Kousidis et al., 2013; Kennington et al., 2013), also a Wizard-of-Oz study consisting of 7 participants, example in Figure 1. The user was to select a puzzle tile (out of a possible 15) on a game board shown on a large monitor, and then describe this piece to the "system" (wizard). Speech, eye gaze (tracked by *Seeingmachines FaceLab*) and pointing gestures (tracked by *Microsoft Kinect*) were recorded. After the participant uttered a confirmation, the wizard began a new episode, generating a new random board and

the process repeated.

The task for the NLU in this experiment was reference resolution. The information available to our model for these data included the utterance (hand-transcribed) the visual context (game board), gaze information, and deixis (pointing) information, where a rule-based classifier predicted from the motion capture data the quadrant of the screen at which the participant was pointing. These data were very noisy (and hence, realistic) despite the constrained conditions of the task; the participants were not required to say things a certain way (as long as it was understood by the wizard), their hand movements potentially covered their faces which interfered with the eye tracker, and each participant had a different way of pointing (e.g., different gesture space, handedness, distance of hand from body when pointing, alignment of hand with face, etc.).

Procedure Removing the utterances which were flagged by the wizard (i.e., when the wizard misunderstood the participant) and the utterances of one of the participants (who had misunderstood the task) left a total of 1051 utterances. We used 951 for development and training the model, and 100 for evaluation. We give results as resolution accuracy. All models were trained on hand-transcribed data, but two evaluations were performed: one with hand-transcribed data, and one with speech automatically transcribed by the Google Web Speech API.[3] Gaze and deixis are incorporated by incrementally computing properties to be provided to our NLU model; i.e., a tile has a property in R of being `gazed_at` if it is gazed at for some interval of time, or tiles in a quadrant of the screen have the property of being `pointed_at`. Figure 6 shows an example utterance, gaze, and gesture activity over time and how they are reflected in the model. Our baseline model is the NLU without using gaze or deixis information; random accuracy is 7%. We will compare our model with that of an NGRAM (up to trigram) model in the evaluations, for each of the conditions (baseline, deixis, gaze, deixis and gaze).

We also include the percentage of the time the gold tile is in the top 2 and top 4 rankings (out of 15); situations in which a dialogue system could at least provide alternatives in a clarification request (if it could detect that it should have low confidence in the best prediction; which we didn't investigate here). For gaze, we also make the naive assumption that over the utterance the participant (who in this case is the speaker) will gaze at his chosen intended tile most of the time.

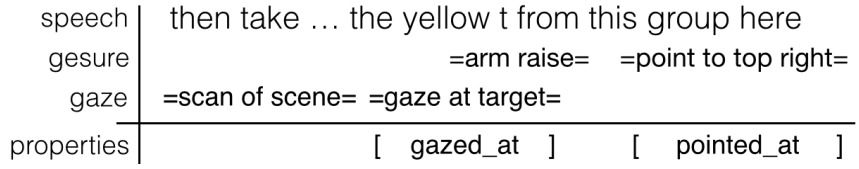

Figure 6: Human activity (top) aligned with how modalities are reflected in the model for Gaze and Point (bottom) over time for example utterance: *take the yellow* t *from this group here*. The intervals of the properties are denoted by square brackets.

Results Table 4 shows the results of our evaluation. Overall, the model that uses RMRS outperforms the model that uses NGRAMS under all conditions using hand-transcribed data. The results for speech tell a different story; speech with NGRAMS is generally better – an effect of the model here relying on parser output. Overall, both model types increase performance when using hand-transcribed or automatically-transcribed speech when incorporating other modalities, particularly pointing. Furthermore, the Top 2 and Top 4 columns show that this model has an overall good distribution, especially in the case of RMRS and pointing, where the target object is in the top four ranks 90% of the time. This would allow a real-time system to ask a specific clarification request to the human, with a high confidence that the object is among the top four ranking objects.

Incremental For further incremental results, Figure 7 shows the rank of each object on an example board using our baseline model for the utterance *nimm das rote untere kreuz* (take the red below cross /

take the red cross below). Once *das* (the) is uttered, RMRS makes an X entity and the model begins to interpret. The initial distribution appears to be quite random as *das* does not have high co-occurence with any particular object property. Once *rote* (red) is uttered, all non-red objects fall to the lowest ranks in the distribution. Once *untere* (under / below) is uttered, all of the red pieces in the bottom two quadrants increase overall in rank. Finally, as *kreuz* (cross) is uttered, the two crosses receive the highest ranks, the bottom one being the highest rank and intended object. Note the rank of the cross in the top left quadrant over time; it began with a fairly high rank, which moved lower once *untere* was uttered, then moved into second rank once *kreuz* was uttered. As the utterance progresses the rank of the intended object decreases, showing that our model predicted the correct piece at the appropriate word.

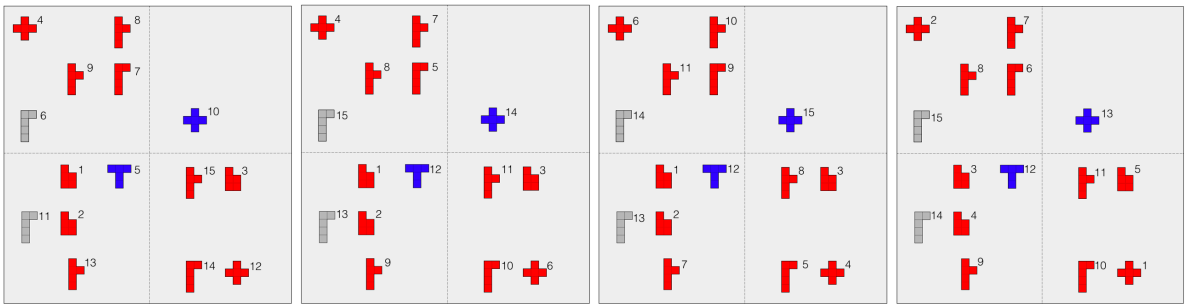

Figure 7: Example of reference resolution for the utterance: *nimm das rote untere kreuz / take the red below cross*; objects are annotated with their rank in the distribution as outputed by the NLU model at each increment. The board size has been adjusted for formatting purposes.

5 Discussion and Conclusions

We have presented a model of NLU that uses a semantic representation to recover the intention of a speaker utterance. Our model is general in that it doesn't fit a template or ontology like other NLU approaches (though we would need to determine how a dialogue manager would make use of such a frame), and grounds the semantic representation with a symbolic representation of the visual world. It works incrementally and can incorporate other modalities incrementally. It improves overall upon previous work that used a similar model, but relied on n-grams. Our model implicitely handles complex utterances that use spatial language. However, we leave important aspects, such as negation in an utterance, to future work (they were not very common in our data).

The experiments in this paper were done off-line, but we have a real-time system currently working. Our model incorporates in real-time the gesture and gaze information as it is picked up by the sensors, as well as the speech of the user. We leave a full evaluation using this interactive setup with human participants for future work.

Abstract

We address the problem of estimating the quality of Automatic Speech Recognition (ASR) output at utterance level, without recourse to manual reference transcriptions and when information about system's confidence is not accessible. Given a source signal and its automatic transcription, we approach this problem as a regression task where the word error rate of the transcribed utterance has to be predicted. To this aim, we explore the contribution of different feature sets and the potential of different algorithms in testing conditions of increasing complexity. Results show that our automatic quality estimates closely approximate the word error rate scores calculated over reference transcripts, outperforming a strong baseline in all the testing conditions.

1 Introduction

In recent years, the increasing usage of large vocabulary continuous speech recognition (LVCSR) systems to transcribe audio recordings from different sources (*e.g.* Youtube videos, TV programs, DVD movies, meetings, etc) has sparked the need of accurate, fast and cost-effective methods to estimate the quality of ASR output. This need contrasts with the fact that, after decades of progress in ASR research, the established evaluation protocol is based on computing word error rate scores (WER)[1] over large test sets of hand-crafted reference transcriptions. Indeed, despite its reliability, reference-based performance assessment has an evident drawback represented by the cost of acquiring manual transcripts. Besides increasing the cost-effectiveness of ASR evaluation routines, bypassing this bottleneck has several other motivations. From an application perspective, for instance, reference-free quality estimation methods could be used to: *i)* decide at run-time whether a given input signal has been properly recognized (*e.g.* if a user spoken utterance needs to be repeated in a dialogue application), *ii)* decide if an automatic transcription is acceptable as is (*e.g.* if manual revision is needed in an automatic subtitling application), or *iii)* select the best transcription among options from multiple ASR systems.

When information about the inner workings of the system used to produce the transcriptions is accessible, current reference-free *confidence estimation* methods can supply ASR applications with reliable indicators about output reliability. This condition, however, does not always hold in the aforementioned scenarios. A clear motivating example is provided by the exponential growth of captioned TED Talks and Youtube videos,[2] for which no information is available about how transcriptions have been produced. In this case, neither reference-based methods, nor standard confidence measures can be applied to obtain useful quality estimates. Nevertheless, in this scenario, supplying reliable indicators of transcription quality has a huge market potential (*e.g.* to reduce the costs of manual revision/translation) which motivates our research.

Focusing on these compelling needs, **this paper investigates the automatic prediction of ASR output quality when: *i)* manual reference transcripts are not available and *ii)* information about the**

[1] The word error rate is the minimum edit distance between an hypothesis and the reference transcription. Edit distance is calculated as the number of edits (word insertions, deletions, substitutions) divided by the number of words in the reference.

[2] Since 2009, Youtube videos in English can be automatically captioned. In 2012, for the 72 hours of video uploaded per minute, such functionality was already available for 10 languages. Currently, more than 200 million Youtube videos have either automatic or human-created captions (source: http://goo.gl/9swYSS).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1813–1823, Dublin, Ireland, August 23-29 2014.

inner workings of the ASR system is not accessible. Casting the problem as a supervised regression task, we experiment in a range of testing conditions on a well-known LVCSR setting (*i.e.* the automatic transcription of TED talks). In this framework, we analyse the performance of various models (*i.e.* their capability to predict utterance-level WER scores) as a function of the different learning algorithms used, the proposed features, and the amount of training data available.

Our features are categorized according to the type of information they aim to capture. Since the nature of the proposed features is a relevant aspect for the applicability of our approach, an important distinction is made between "glass-box" and "black-box" features, which are respectively informed and agnostic about systems' internal decoding strategies. The former can play an important role when all the intermediate processing steps are accessible (*e.g.* in the selection of the best possible transcription hypothesis). In contrast, black-box features have a wider applicability to situations where such information is not available (*e.g.* to estimate the quality of online video subtitles).

Another important aspect relevant to our study is the relation between the accuracy of utterance-level quality predictions and the degree of homogeneity of training and test data. Indeed, as in any supervised learning framework, the similarity between training and test data has a direct impact on (classification and regression) results. In order to fully understand the potential of our approach, we hence measure performance variations under different levels of similarity between the data used to train the regressor and the data used for evaluation. To this aim, our experiments account for a range of possible conditions. These vary from the situation in which training and test are fully homogeneous (*i.e.* same dataset, with training instances produced by the same ASR system) to the more challenging situation where training and test are not homogeneous (*i.e.* different datasets, with training instances produced by different ASR systems). Our results, obtained with two different state-of-the-art algorithms for regression, demonstrate that in all such variable conditions our ASR quality estimation models lead to accurate predictions (*i.e.* close the word error rate scores calculated over reference transcripts).

To the best of our knowledge, this paper represents the first extensive investigation on *reference-free* and *system-agnostic* automatic estimation of ASR output quality. Along this direction, our main contributions can be summarized as follows:

1. We propose a supervised, application-oriented approach to ASR quality estimation that bypasses the need of manual reference transcriptions and is system-independent.

2. We evaluate our method with different learning algorithms and in different conditions, showing that its estimates closely approximate the WER scores calculated over reference transcripts.

3. We perform feature analysis, isolating the contribution of each feature set in all the testing conditions.

4. We analyse the learning curves of our best models, investigating the relation between performance results and the amount of data needed for training.

Overall, these contributions provide useful insights about the feasibility of automatic ASR quality estimation, opening interesting research avenues relevant for system development and for ASR applications.

2 Related Work

As a *reference-free* automatic evaluation method, our work introduces a valid application-oriented alternative to the standard evaluation protocols used within current ASR evaluation campaigns such as IWSLT (Federico et al., 2011; Federico et al., 2012; Cettolo et al., 2013).[3] Besides that, our approach to ASR *quality* estimation (QE) also differs from the well-established *confidence* estimation (CE) techniques proposed in previous ASR literature (Sukkar and Lee, 1996; Evermann and Woodland, 2000; Wessel et al., 2001; Sanchis et al., 2012; Seigel, 2013, *inter alia*). Such difference firstly relies in the fact that, while in CE is the system itself that provides an indicator of the reliability of its output transcriptions, QE aims to provide an external and more objective measure of goodness through WER predictions. A

[3] See http://www.iwslt2013.org/ for details about the last edition of the IWSLT Workshop held in 2013.

second (related) difference is that, in contrast with previous CE methods that heavily rely on information about the internal behaviour of the ASR system, our technique does not necessarily depend on the access to such information. This extends its applicability to scenarios (out of the scope of CE research) where the quality of transcriptions produced by (possibly unknown) ASR systems has to be evaluated/compared solely based on information about the input audio signals and the output transcriptions.

An interesting approach exploiting ASR word accuracy estimates to automatically score the proficiency of non-native English speakers has been proposed by Yoon et al. (2010). To our knowledge this work is the most similar to the one presented here, although it differs in the application domain and several other aspects. First of all, similar to CE methods, it makes some use of glass-box features derived from knowledge about the ASR internal workings (*e.g.* word confidence and acoustic/language model probabilities). Secondly, the domain addressed is constrained to responses to prompted utterances, while in this paper we address a large unconstrained domain, namely the automatic transcription of lectures (TED talks) covering different topics. Finally, (Yoon et al., 2010) is based on a rather simple model whose performance is not carefully analysed from the learning point of view (*e.g.* by comparing the contribution different state-of-the-art algorithms) as we do here.

The problem of automating system evaluation without a gold standard has been addressed also in other NLP areas. For instance, (Louis and Nenkova, 2013) recently addressed the assessment of machine-generated summaries without model summaries. The strongest parallelism with our work, however, can be found in the Machine Translation (MT) evaluation field, where the goal of bypassing the need of manually-created reference translations has motivated a large body of research.[4] Quality estimation for MT and ASR have a number of commonalities. First, they both deal with a "source" (respectively a sentence in a language *L* and an acoustic utterance) and an "hypothesis" whose quality has to be estimated without references (respectively a translation in a language *L1* and an automatic transcription of the audio signal). Second, they can be addressed at various granularities. Indeed, ASR output quality estimation is similar to its MT counterpart where research focused on quality predictions at word level (Ueffing and Ney, 2007; Bach et al., 2011), sentence level (Specia et al., 2009; Mehdad et al., 2012) and document level (Soricut and Echihabi, 2010). Third, both tasks are suitable for supervised machine learning methods, either for classification (Blatz et al., 2003; Quirk, 2004) or for regression (Specia et al., 2010; Specia, 2011). Finally, both tasks motivate efforts in designing features capable to capture the difficulty to process the source, the plausibility of the output hypothesis and (but not necessarily) the confidence of the decoding process (Felice, 2012; Rubino et al., 2013b).

3 Approach

We approach the automatic estimation of ASR output quality as a supervised regression problem. Given a training set of (*signal*, *transcription*, *WER*) instances, the task is to predict the WER of each instance in a test set of unseen (*signal*, *transcription*) pairs.

Features. As shown in Table 1, the features used in our experiments (68 in total) can be categorized in four main groups. The first group (*ASR features*) includes several glass-box features proposed in previous literature on ASR confidence estimation (Litman et al., 2000; Gabsdil and Lemon, 2004; Goldwater et al., 2010; Higgins et al., 2011). These features are suitable only for the ideal situation in which information about systems' internal decoding strategies is available (as in the experiments discussed in §4.1). We use them as a term of comparison to evaluate the usefulness of the other three groups (*signal*, *hybrid* and *textual*), which belong to the black-box type. These features, which are totally uninformed about the decoding process, have wider applicability to the system-independent ASR quality estimation tasks that represent our target scenario (see Sections 4.2 and 4.3). More in detail:

- **ASR features** aim to capture the confidence of the speech recognizer and the reliability of the whole decoding process. In our experiments, as we do not have access to decoders of other systems, they are computed only for the ASR system developed in our labs (Falavigna et al., 2013). These features

[4] For a complete overview of the current approaches to MT quality estimation we refer the reader to the WMT12 and WMT13 shared task reports (Callison-Burch et al., 2012; Bojar et al., 2013).

are extracted both from word graphs (WGs) and *n*-best lists (n=100). In Table 1 "*Total probability*" is the weighted sum of log Language Model (LM) and log Acoustic Model (AM) probabilities. LM probability is computed with a *4*-gram backoff LM, trained over about 5 billion words using the IRSTLM toolkit (Federico et al., 2008) and the modified shift-beta smoothing method. AM probability is computed using a set of tied-state triphone Hidden Markov Models having, as output state density, a mixture of Gaussian probability densities with diagonal covariance matrices. "*Mean probability*" is obtained dividing the total probability by the number of hypothesized ASR output items (words + silences). Confidence scores are computed averaging time posterior word probabilities (Evermann and Woodland, 2000). "*Proportion of low confidence words*" is the fraction of words having confidence values ≤ 0.5. The remaining ASR features are directly extracted from word graphs and *n*-best lists scores.

- **Signal features** aim to capture the difficulty to transcribe a given input looking at the signal as a whole. They are computed from raw vectors extracted through frame analysis (we employ *20ms* analysis window and *10ms* analysis step). For each analysed window, 12 Mel Frequency Cepstral Coefficients (MFCCs) are evaluated plus log energy. Then, for each given segment, minimum, maximum and mean values of raw energy, as well as the mean MFCCs values and total segment duration, are computed to form the signal feature vector.

- **Hybrid features** provide a more fine-grained way to capture the difficulty of transcribing the signal. This is done by considering information about word and silence/noise regions, as well as their respective duration. These features are computed after having performed forced alignment between the input audio signal and the corresponding automatic hypotheses. Forced alignment is carried out with our ASR system (Falavigna et al., 2013), in order to detect audio segments related to words, hesitations and silences in the hypothesis. Pitch features have been computed with the Praat software tool (Boersma and Weenink, 2005).

- **Textual features** aim to capture the plausibility (*i.e.* the fluency) of an output transcription. To this aim, we consider surface information (such as the number of words and the percentage of numbers/content-words/nouns/verbs in the hypothesis) as well as information about LM perplexity and probability of the hypothesis (both at the level of words and parts of speech)[5].

Feature selection is performed throughout all our experiments to maximize results and, at the same time, analyse the contribution of the proposed features. To this aim, we use Randomized Lasso, or stability selection (Meinshausen and Bühlmann, 2010), which re-samples the training data several times and fits a Lasso regression model on each sample. Features that appear in a given number of samples are considered more informative for the task at hand, and hence retained (those marked in bold in Table 1 are the most informative ones based on the experiments described in Sections 4.2 and 4.3).

Learning algorithms. To build our regression models we experimented with two non-parametric learning approaches: Support Vector Machines (SVMs) (Shawe-Taylor and Cristianini, 2004) and Extremely Randomized Trees (XT) (Geurts et al., 2006). **SVMs** are non-parametric deterministic algorithms that have been widely used in several fields, in particular in NLP where they are the state-of-the-art for various tasks. **Extra-Trees** are a tree-based ensemble method for supervised classification and regression that were also successfully used for MT quality estimation (de Souza et al., 2013; de Souza et al., 2014a). In XTs each tree can be parametrized differently. When a tree is built, the node splitting step is done at random by picking the best split among a random subset of the input features. The results of the individual trees are combined by averaging their predictions. Hyper-parameter optimization of the SVM (with Radial basis function kernel – RBF) and XT models was performed using randomized search (Bergstra and Bengio, 2012). We used both learning methods as implemented in the Scikit-learn package (Pedregosa et al., 2011).

[5]The PoS LM has been obtained by processing with the TreeTagger (Schmid, 1995) the same data used for the word LM.

[6]Hesitations, such as *"uhm"*, *"eh"* and *"ah"* are found through matches with a predefined list. Consecutive repeated words in the same utterance are also considered as hesitations.

ASR (16)	Total probability of ASR output ($w \cdot logP_{LM} + logP_{AM}$), mean probability, total acoustic probability, mean acoustic probability, mean confidence score, Std of confidence scores, confidence scores per second, proportion of low-confidence words, WG node density, WG transition density, Mean/Std/Min n-best probability, Mean/Std/Min n-best acoustic probability.

Table 1: Full list of the 68 features used in our experiments, divided into four groups. The most predictive black-box features (resulting from feature selection in the §4.3 experiments) are marked in bold.

4 Experiments

To evaluate our approach we carried out three sets of experiments. In each set our feature groups are analysed: *i)* with the two learning algorithms, *ii)* in combination/isolation, *iii)* with/without feature selection. The three sets differ in terms of the difficulty of the quality estimation task from the learning point of view. To experiment with situations of increasing complexity, we alternate conditions in which all the features (glass-box and black-box) can be used, training and test sets are non-/homogeneous, the quality estimator is trained on transcriptions generated by the same/different ASR systems.

Data. The data used in the experiments consists of the audio recordings delivered for the IWSLT 2013 evaluation campaign (Cettolo et al., 2013). One of the tasks of IWSLT 2013 is the automatic transcription of English TED talks, a global set of conferences whose audio/video recordings are publicly available. The main challenges for ASR in these talks include: the large variability of topics (hence a large, unconstrained vocabulary), the presence of non-native speakers and a rather informal speaking style. Each IWSLT participant submitted one primary ASR output run for each of the talks included in the test set plus some optional contrastive ASR outputs. In addition, participants sent submissions for the ASR tracks delivered for the 2012 evaluation campaign. Our experiments have been carried out on the primary submissions, sent by 8 participants, related to the 2012 (consisting in 11 different talks) and 2013 (28 different talks) test sets. The 2012 test set has a total duration of around *1h45sec*, it contains *1,118* reference sentences and *18,613* running words. On such dataset, participants' primary submissions achieved a mean utterance WER ranging from 10.5% to 18.4% (in this work a WER score is computed for each reference sentence, and mean utterance WER represents the average of sentence WERs). The 2013 test set has a total duration of around *3h55sec*, it contains *2,238* reference sentences and *41,545* running words. On this dataset, primary participants' submissions achieve a mean utterance WER ranging from 15.9% to 30.8%.

In our experiments, we always use *1,118* utterances for training the regressor and *1,120* for testing. To this aim, the IWSLT 2013 data is randomly sampled three times in training and test sets of such dimensions. While for the 2012 test set manual utterance segmentation has been provided by the organizers, for the 2013 data the participants had to employ their own automatic segmentation systems before decoding the audio tracks (thus resulting in a different number of ASR sentence hypotheses for each team). Hence,

to ensure that each participant has the same number of ASR sentence hypotheses, an alignment with the reference manual segmentation has been performed in our experiments.

Evaluation. Our evaluation is carried out in terms of Mean Absolute Error (MAE), a standard metric for regression problems. The MAE is the average of the absolute errors $e_i = |f_i - y_i|$, where f_i is the prediction of the model and y_i is the actual WER for the i^{th} test instance. WER is calculated with the NIST SCLITE Scoring Package.[7] As it is a measure of error, lower MAE scores indicate that our predictions are closer to the real WER calculated for each test instance against the reference transcripts. For each experiment, we report the mean and the standard deviation of the MAE achieved by the best performing QE models on the IWSLT 2013 test sets.

Baseline. Besides measuring performance in terms of global MAE, each model is compared against a common baseline for regression tasks. This baseline, which is particularly relevant in settings featuring different data distributions between training and test sets, is calculated by labelling each test instance with the mean WER score calculated on the training set. Previous works, also in MT quality estimation, demonstrated that its results can be particularly hard to beat (Rubino et al., 2013a).

4.1 Experiment 1

In the first set of experiments we consider the easiest situation from the learning perspective. In this setting we predict the WER of transcriptions produced by our ASR system (denoted by *X*), whose inner workings are known (thus enabling the use of glass-box features). To investigate the relation between prediction accuracy and the degree of homogeneity of training and test data, we experiment both with similar datasets (disjoint training and test sampled from IWSLT13) and different datasets (IWSLT12 for training and samples from IWSLT13 for test). Results are reported in Table 2, where the notation "*LetterYear - LetterYear*" indicates the systems and the datasets used for training and test (respectively our system *X*, and data from IWSLT*12* and/or IWSLT*13*).

Train - Test	ALL (glass-box + BB_COMB)		ASR (glass-box)		BB_COMB (Signal+Hybrid+Textual)		Baseline
X13 - X13	**11.56±0.29**	SVR	12.11±0.29	XT	15.17±0.06	XT	19.84±0.06
X12 - X13	**12.61±0.13**	XT	13.78±0.16	XT	16.78±0.18	XT	19.06±0.12

Train - Test	Signal		Hybrid		Textual		Baseline
X13 - X13	16.42±0.1	XT	17.61±0.12	XT	17.42±0.15	SVR	19.84±0.06
X12 - X13	18.85±0.09†	XT	18.39±0.22	XT	17.58±0.15	XT	19.06±0.12

Table 2: MAE results using the same system on different datasets, with and without glass-box features.

As can be seen from the table, the two models using ALL the features achieve the largest improvements over the strong baseline used for comparison (up to *8.2* MAE points in the *X13 - X13* setting). This is not surprising if we consider the high predictive power of ASR (glass-box) features that, when used in isolation, lead to a considerably lower MAE with respect to the other three groups. However, it's worth observing that also the combination of only the black-box features (BB_COMB) allows the QE predictors to significantly outperform the baseline (up to *4.67* MAE points in *X13 - X13*). Such improvements come from the joint contribution of each of the three groups, which achieve good results also in isolation. Indeed, except in one case where the gain over the baseline is not significant[8] (*X12 - X13* with the Signal features), their MAE reduction ranges between *0.67* (*X12 - X13* Hybrid) and *3.42* MAE points (*X13 - X13* Signal). The good prediction capability of the black-box features is also shown by the fact that, when combined with the glass-box features, they lead to improvements between *0.55* and *1.17* MAE points over the ASR features alone. Considering the privileged condition of the (system-informed) glass-box features, this is a remarkable result that suggests some complementarity between the two groups.

In general, our supervised approach is sensitive to the similarity between training and test. This is evidenced by higher MAE results when non-homogeneous datasets (*i.e. X12 - X13*) are processed. In

[7] http://www1.icsi.berkeley.edu/Speech/docs/sctk-1.2/sclite.htm

[8] Statistical significance is measured by considering the overlap of confidence intervals defined by the standard deviation range around the mean. In our tables, the results marked with the "†" symbol are not significantly better than the baseline.

terms of algorithms, XT generally performs better than SVR, in particular when the QE model is trained and tested on non-homogeneous data. This can be explained by their higher generalization capability due to variance reductions as explained in (Hastie et al., 2009, Chapter 15).

4.2 Experiment 2

In this set of experiments we consider a situation of intermediate difficulty from the learning perspective. Our objective is to evaluate, on homogeneous datasets (sampled from IWSLT13), the output of ASR systems whose inner workings are not known (hence only black-box features can be used). To make our analysis more complete, we also evaluate the performance of models trained on a given ASR system to predict the WER of hypotheses produced by a different one. This situation is closer to application scenarios in which the evaluated ASR system is unknown and different from the one used to train the quality estimator. Two systems with very different performance are considered for this purpose: the best and the worst according to the official IWSLT 2013 ranking (respectively denoted by *A* and *Z*).

Train - Test	BB_COMB		Signal		Hybrid		Textual		Baseline
A13 - A13	**11.18±0.22**	SVR	11.91±0.23	SVR	12.76±0.18	SVR	12.57±0.13	SVR	14.35±0.1
Z13 - A13	**16.01±0.23**	SVR	18.04±0.22	SVR	17.24±0.22	SVR	18.01±0.2	XT	21.58±0.15
Z13 - Z13	**15.52±0.6**	XT	16.94±0.41	XT	17.04±0.56	SVR	17.84±0.4	XT	19.65±0.43
A13 - Z13	**17.36±0.43**	XT	18.7±0.53	XT	18.21±0.45	XT	19.38±0.45	XT	21.03±0.51

Table 3: MAE results using different systems on the same dataset, without glass-box features.

The results reported in Table 3 confirm that: *i)* the combination of black-box features (BB_COMB) always leads to the best QE models, which significantly outperform the baseline, *ii)* the same holds also when each single group is used in isolation, *iii)* with less homogeneous training and test data, XT performs generally better than SVR.

In addition, it's worth noting that when a QE model is trained and tested on data transcribed by the same ASR system the results are significantly better (the MAE is always about *1.0 - 6.0* points lower). Indeed, as also shown by the same behaviour of our baseline, this condition is simpler and more suitable for supervised learning methods. This depends on the fact that each ASR system has its own coherent behaviour, which results in transcriptions with similar characteristics that supervised models are able to learn (*e.g.* recurring errors, similar WER distributions). In contrast, when training and test data are produced by different ASR systems, supervised learning becomes more difficult and the output predictions less reliable. Each feature group is affected by this situation, but it is interesting to note that the Hybrid features are more robust than the other two groups to less homogeneous datasets. This can be explained by the fact that they are extracted after applying forced alignment by means of a third system, which is likely to normalise and reduce the difference between training and test data. Overall, also in this more complex scenario where the glass-box features cannot be used, our results demonstrate a good prediction capability of the QE models, which are still able to beat a strong baseline.

4.3 Experiment 3

In the third set of experiments we consider the hardest case from the learning point of view. In this setting the evaluated ASR systems are unknown and training/test data are non homogeneous (*i.e.* training from IWSLT12, test from samples of IWSLT13). Results are reported in Table 4.

Train - Test	BB_COMB		Signal		Hybrid		Textual		Baseline
A12 - A13	**12.81±0.08**	XT	13.57±0.13†	XT	12.85±0.1	XT	13.25±0.23†	XT	13.65±0.17
Z12 - A13	14.78±0.1	SVR	15.66±0.09†	XT	**13.56±0.09**	SVR	13.63±0.24	SVR	15.51±0.35
Z12 - Z13	**17.16±0.4**	XT	19.34±0.32†	XT	17.68±0.3	XT	19.59±0.11†	XT	19.98±0.29
A12 - Z13	**19.83±0.23**	XT	21.85±0.2	XT	20.68±0.13	XT	22.62±0.08	XT	23.04±0.18

Table 4: MAE results using different systems on different dataset, without glass-box features.

Also in the most challenging scenario our results substantially confirm the previous findings. Indeed, except in one case (*Z12 - A13*), the following observations still hold: *i)* when used in combination, the

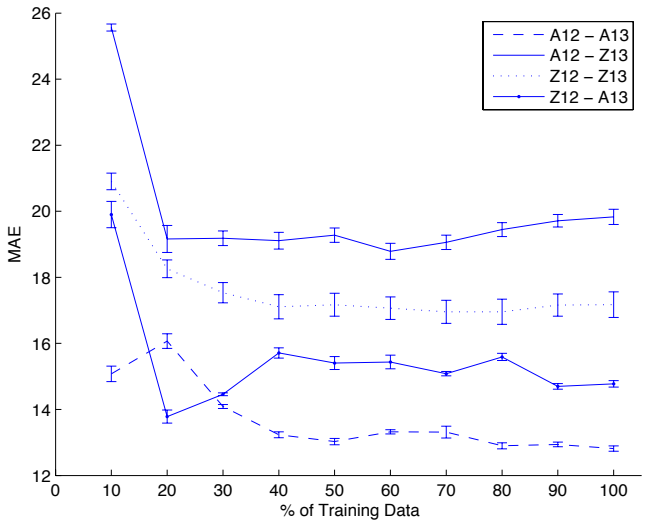

Figure 1: Learning curves for the best systems of "Experiment 3" (using BB_COMB features).

black-box features (BB_COMB) lead to the best QE models, which significantly outperform the baseline, *ii)* this holds also when each single group is used in isolation (although not significantly in 5 out of 12 settings), *iii)* with less homogeneous training and test data, XT performs generally better than SVR.

Unsurprisingly, as also observed in the previous set of experiments, the low homogeneity of training and test data has an impact on the accuracy of the predictions. The effect of training and testing on less homogeneous data produced by different systems is now clearly visible. Except for the more robust Hybrid features, which in the *Z12 - A13* setting produce the best model, the results obtained with the two other groups decreased to the point that their improvement over the baseline is often not significant. Nevertheless, even under the challenging conditions posed by this realistic and application-oriented scenario, reference-free and system-agnostic ASR evaluation remains a feasible task.

5 Feature Analysis and Learning Curves

In order to gain additional insights about the effectiveness of our method, we performed a further analysis of the "Experiment 3" results. In such challenging scenario, the most interesting from the application perspective, we first identified the most predictive features among those in the BB_COMB set. To this aim, we collected the features that are always chosen by the feature selection algorithm proposed in §3. The resulting list contains features from all the three black-box groups (marked in bold in Table 1). This confirms their complementarity in predicting the quality of a transcribed utterance.

In the same setting, we also investigated the relation between the amount of data used to train our models and the accuracy of their predictions. To this aim, we measured performance variations when the same models (*i.e.* those obtained with the BB_COMB set) are trained on different amounts of data. For each training set, nine subsets were created (with 10%, 20%,..., 90% of the data) by sub-sampling sentences from a uniform distribution. The process was iterated 5 times. Each subset was used to build the relative QE regressor, which was then evaluated on our test sets. Figure 1 shows the resulting learning curves (each point is the average result of the 5 runs on each test set; the error bars show $\pm$1std). As can be seen from all the curves, after an initial fluctuation of the MAE, performance results with 40% of the training data are comparable with those obtained using the whole training set. Moreover, it's worth remarking that in three out of four cases the models trained with such amount of data already outperform the baseline (for *Z12 - A13* the MAE is only 0.01 point higher). This suggests that reference-free, system-independent models for ASR quality estimation are able to provide informative predictions even with a limited amount ($\sim$400 manual transcripts) of training instances.

6 Conclusion

We investigated the problem of automatically predicting the word error rate of an automatically-transcribed utterance in a large vocabulary continuous speech recognition setting. In such scenario, we proposed a supervised regression approach that bypasses the need of manual reference transcriptions and does not necessarily depend on information about system's confidence (*first contribution* of the paper). Then, by evaluating models obtained with different state-of-the-art learning algorithms, we showed that our automatic predictions outperform a strong baseline and closely approximate the WER scores calculated over reference transcripts (*second contribution*). Different feature groups have been proposed and their contribution has been analysed in a range of testing conditions of increasing difficulty (*third contribution*). This made possible to isolate informative features that significantly contribute to the performance of our quality estimation models, and to get useful insights about the potential of our approach when different sources of information (glass-box, black box features) are available. Finally, analysing the relation between prediction performance and the size of the training set, we showed that the results obtained with 40% of the data are already comparable to our best MAE (*fourth contribution*).

Our analysis revealed a dependency between the performance of the quality estimation models and the degree of homogeneity between training and test data. This aspect is particularly relevant from the application perspective since in real working conditions the availability of *large amounts* of *representative* training instances is far from being guaranteed. In quality estimation for machine translation (a task featuring strong similarities with ours), these issues have recently motivated studies on domain adaptation and online learning techniques (de Souza et al., 2014b; Turchi et al., 2014). This suggests, as a first direction for future work, the investigation of approaches capable to better exploit the available training data and mitigate the impact of large differences between training and test instances.

Abstract

In this paper, we present a generic anaphora engine for Indian languages, which are mostly resource-poor languages. We have analysed the similarities and variations between pronouns and their agreement with antecedents in Indian languages. The generic algorithm developed uses the morphological richness of Indian languages. The machine learning approach uses the features which can handle major Indian languages. We have tested the system with Indo-Aryan and Dravidian languages namely Bengali, Hindi and Tamil. The results are encouraging.

1 Introduction

Natural language has different types of anaphoric expressions and these expressions bring elegance and make the natural language text interesting to read. Anaphoric expression in a discourse refers to another item in a discourse. The task of resolving anaphors with its referent, antecedent is called as anaphora resolution. Anaphora resolution is required in most of the NLP applications to achieve required performance. The importance of anaphora resolution in various tasks is demonstrated by researchers by integrating anaphora resolution with answer extraction system, automatic summarization system, relation extraction system, document similarity identifier etc.

Most of the anaphora resolution systems are developed for particular languages. The researchers have analyzed anaphors across languages at various levels such as syntactic, semantic, discourse, structured, and unstructured features. But there are very few attempts for language independent approaches. In this paper, we present a generic anaphora resolution engine for Indian languages. We have come up with a language independent engine, which takes shallow parsed text as input. The morphological richness of Indian languages is tapped to come up with a language independent anaphora resolution engine.

Early works in anaphora resolution by Hobbs (1978), Carbonell and Brown (1988), Rich and LuperFoy (1988) etc. were mentioned as knowledge intensive approach, where syntactic, semantic information, world knowledge and case frames were used. Centering theory, a discourse based approach for anaphora resolution was presented by Grosz (1977), Joshi and Kuhn (1979), Joshi and Weinstein (1981), Strube and Hahn (1999). Salience feature based approaches were presented by Lappin and Leass (1994), Kennedy Boguraev (1996) and Sobha et al., (2000). Indicator based resolution methods were presented by Mitkov (1997, 1998). One of the early works using machine learning technique was Dagan Itai's (1990) unsupervised approach based on co-occurrence words. With the use of machine learning techniques researchers work on anaphora resolution and noun phrase anaphora resolution simultaneously. The other machine learning approaches for anaphora resolution were the following. Aone and Bennett (1995), McCarty and Lahnert (1995), Soon et al., (2001), Ng and Cardia (2002) had used decision tree based classifier. Daelman and Van de Bosh (2005), Hendrickx et al., (2008), Recasen (2009) had used TiMBL, a memory based learning approach. Anaphora resolution using CRFs was presented by McCallum and Wellner (2003) for English, Li et al., (2008) for Chinese and Sobha

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1824–1833, Dublin, Ireland, August 23-29 2014.

et al., (2011, 2013) for English and Tamil. Expectation Maximization (EM) was used for anaphora resolution by Charniak and Elsner (2009). Wich et al., (2012) demonstrated a coreference resolution in a large scale using discriminative hierarchical model.

In Indian languages anaphora resolution engines are demonstrated only in few languages such as Hindi, Bengali, Tamil, and Malayalam. Most of the Indian languages do not have parser and other sophisticated pre-processing tools. The earliest work in Indian language, Vasisth was a rule based multilingual anaphora resolution platform by Sobha and Patnaik (2000, 2002), where the authors had exploited the morphological richness of Malayalam and Hindi. Prasad and Strube (2000), Uppalapu et al., (2009) and Dekwale et al., (2013) had presented different approaches using Centering theory for Hindi. Dutta et al (2008) had presented a Hindi anaphora resolution system using Hobbs' algorithm. Murthy et al., (2007) had presented a comparison on Tamil anaphora resolution using multi-linear regression and salience factor based approach. Sobha et al., (2007) presented a salience factor based with limited shallow parsing of text. Akilandeswari et al., (2013) used CRFs for resolution of third person pronoun and Akilandeswari et al., (2012) presented a work on resolution of 'atu', third person neuter pronoun in Tamil. Balaji et al., (2012) presented resolution using two stage bootstrapping approach. The author had used UNL representation. Ram et al., (2013) used Tree CRFs for anaphora resolution for Tamil with features from dependency parsed text.

One of the earliest multilingual anaphora resolution systems was presented by Aone and Mckee (1993), where the authors had used Global discourse world which contained syntactic, semantic, rhetorical and other information. They demonstrated the system for English, Spanish and Japanese. Mitkov (1998) extended the indicators based approach for other languages and presented it for English, Polish and Arabic. As mentioned earlier, Vasisth was the only multilingual attempt for Indian language anaphora. SemEval-2010 Task 1: Coreference resolution in Multiple Language, a tool contest accelerated the research in multilingual anaphora resolution. The contest had six languages, namely, English, German, Italian, Dutch, Spanish and Catalan. There were six participants, among them only two participants presented results for all six languages. The systems presented in the contest were RelaxCor, Corry, SUCRE, BART, TANL-1 and UBIU (Recasens et al., 2010). The multilingual anaphora resolution in Indian languages was re-initiated by Anaphora Resolution in Indian languages, the tool contest conducted as a part of ICON 2011 (Sobha et al., 2011). The contest had three languages, namely, Hindi, Bengali and Tamil. There were four participants and all the four submitted results for Bengali. Tamil and Hindi had two participants. This task boosted the anaphora resolution work in Bengali. Senapati et al., (2013) presented a work on Bengali anaphora resolution by customizing GuiTAR and BART tool was customized for Bengali by Sikdar et al., (2013). In all the above published multilingual systems, there was a language dependent module plugged in. In the present work, we have tried to come up with an approach without using language specific modules. We have developed a generic anaphora engine as the system is designed to work for different languages. We have overcome the agreement problem with the PNG information obtained from in-depth morphological analysis and PNG agreement heuristic rules. These rules are capable of filtering the possible candidate antecedents for an anaphor (pronouns) using the PNG information across languages.

The rest of the paper is organised as follows: In the following section we have described nature of Indian languages and variation in antecedent-anaphor agreement in Indian languages. Section 3, we have explained our approach towards generic engine by overcoming the variation in antecedent-anaphor agreements. In section 4, we have presented our experiment and results. And the last is the conclusion section.

2 Characteristics of Indian Language Anaphora

Indian languages are morphologically rich and verb-final languages. These languages have relatively free word order and clausal structures are more fixed order. Indian languages fall under the following broader families of languages, Indo-Aryan, Dravidian and Tibeto-Burman. Indo-Aryan family includes languages such as Hindi, Bengali, Marathi, Punjabi etc, Dravidian includes languages such as Telugu, Kannada, Malayalam, Tamil, Tibeto-Burman includes languages such as Bodo, Manipuri etc. Dravidian languages are highly agglutinated and have rich productive suffixation than the Indo-Aryan languages. Plural marker and case markers get affixed to the nouns and tense markers and Person, Number, Gender (PNG) markers affix with verbs. In certain Indo-Aryan languages such as Hindi, case

markers occur as postpositions following the nouns. These postpositions are handled in the preprocessing stage to occur in the noun morphological analysis. Indian languages vary largely in the distinction of Number (singular/plural) and Gender in pronouns. Few of the Indian languages and their details of Number and Gender Distinction in those languages are presented in table 1.

Language	**Number Distinction (singular/plural)**	**Gender Distinction**
Hindi	Yes	No
Sanskrit	Yes	Yes
Punjabi	Yes	No
Gujarati	Yes	No
Assamese	Yes	No
Bengali	Yes	No distinction for Masculine and Feminine. But there is animate- inanimate distinction.
Oriya	Yes	No
Telugu	Yes	Masculine and others
Kannada	Yes	Yes
Malayalam	Yes	Yes
Tamil	Yes	Yes

Table 1: Variation of Pronouns with respect to Number and Gender

The similarities and variations between languages in the number-gender characteristics of the pronouns is presented in Table 1. In the number characteristics the languages are similar whereas in the gender characteristics there are variations. The information in the table 1 brings forth the challenges in capturing the anaphor-antecedent PNG agreement for a generic anaphora resolution engine.

With example 1, 2 and 3, we have demonstrated the variation in Gender, Number distinction in pronouns in Tamil (Ta), Bengali (Bn) and Hindi (Hi).

Example 1

```
Ta:a) raamum        giithavum      cakotharan-cakothari.
      Ram(N)+inc    Gita(N)+inc    brother   -sister.
      (Ram and Gita are brothers and sisters.)

   b) avan     elzhaam     vakuppu      padikkiraan.
      He(PN)   seventh(N)  standard(N)  study(V)+present+3sm
      (He studies in seventh standard.)

   c) aval     paththaam vakuppu      padikkiraal.
      she(PN)  tenth(N)  standard(N)  study(V)+present+3sf
      (She studies in tenth standard.)
```

Example 2

```
Bn:a) raam o giita bhai-bon.
   b) se shapton shreni te pore.
   c) se doshom shreni te pore.
```

Example 3

```
Hi:a) raam aur giitaa bhaii-bahan hai.
   b) vaha satavIM kakshaa meM paTataa hai.
   c) vaha aaTaviM kakshaa meM paTatii hai.
```

Example 1 has three Tamil sentences. The second and third sentence has pronouns 'avan' *he* and 'aval' *she*, the third person masculine and the third person feminine pronouns respectively. Masculine pronoun in second sentence refers to the masculine noun 'raam' and the feminine pronoun in the third sentence refers to the feminine noun 'Gita' in the first sentence. Here the masculine and feminine pro-

nouns have a clear distinction. The three Tamil sentences in example 1 are translated to Bengali and Hindi. The Bengali translation is presented in example 2 and Hindi translation is presented in example 3. In example 2, the second and third sentence has 'se', the third person pronoun. In the second sentence, the pronoun 'se' refers to the masculine noun 'raam' and 'se' in the third sentence refers to feminine noun 'giitaa' in the first sentence. Here the third person pronoun does not have masculine/feminine distinction. Similarly in example 3, which has the Hindi translation, 'vaha', the third person pronoun does not have gender distinction. In sentence 2 of example 3, 'vaha' refers to the masculine noun and in sentence 3, 'vaha' refers to the feminine noun.

These variations in Number and Gender distinction in pronouns pose challenges in coming up with a generic anaphoric engine. The pronoun and its agreement with its antecedents vary between the languages and to handle the agreement we require a language dependent mapping.

3 Generic Anaphora Resolution Engine

Most of the Indian languages are resource poor languages. The morphological richness of these languages, help in building various high end NLP applications such as machine translation, anaphora resolution etc., with limited shallow parsed information without using sophisticated parsing tools. In this work we have tried to build a generic anaphora resolution engine using shallow parsed text. Similarities between Indian languages, described in the previous section, are tapped to come up with a generic approach for anaphora resolution in Indian languages. The variation in the antecedent-anaphor agreement mentioned in the section above is handled by an in-depth morphological analysis of the text. We have used CRFs, a linear graphical machine learning algorithm to resolve the antecedents.

3.1 Preprocessing of Data

We perform limited shallow parsing on the training and testing data. Both the data are pre-processed with morphological analyzer, Part-of-Speech (POS) tagger, Chunker, Clause boundary identifier and Named Entity Recognizer. Here morphological analysis, Part-of-Speech tagging, Chunking are obligatory. Clause boundary identification and Named Entity Recognition are optional pre-processing tasks. These two tasks add information, which can be used as constraint features in the machine learning approach. In this work, we perform a detailed morphological analysis for a given word. This is explained in the following section. The preprocessing tools available in Indian Language –Indian Language Machine Translation (IL-ILMT) consortium are used.

3.2 Detailed Morphological Analysis

We perform an in-depth morphological analysis for a given word. In the in-depth morphological analysis we analyse both inflectional and derivational morphology. The in-depth morphological analysis gives the suffix (case markers with the nouns, tense-aspect-model with the verbs) and PNG characteristics of the words. These suffix information is used in the syntactic feature and verb suffix feature for the machine learning technique which are described further in section 3.4. The post-position occurring with the nouns, its syntactic association with the noun is identified in morphological processing stage and information is used as syntactic feature.

The morphological analyser identifies the root word, its lexical category, gender, number, person, case (direct/oblige), case markers if the word is a noun and tense markers (vibhakthi as called in Indian traditional grammar) if the word is a verb and the suffixes. Gender information holds information such as 'm' – masculine, 'f' – feminine, 'n' – neuter, 'mf' – can be a masculine or feminine, 'fn' – feminine or neuter as in Telugu and 'any' – can be any gender. Number information can be singular, plural, dual or any. Person information can be 1st person, 2nd person, 3rd person or any. We have explained it further with following example words and its analysed output in table 2.

S.No	Language	Word	Analysis of the Word
1	Ta	jaanukku 'John(N)+dative'	<fs af='jaan,n,m,sg,3,d,ukku,ukku'>
2	Ta	viittil 'house(N)+locative'	<fs af='viitu,n,any,sg,3,d,il,il'>
3	Ta	avanaal 'he(pn)+INS'	<fs af='avan,pn,m,sg,3,d,aal,aal'>
4	Ta	avalukku 'he(pn)+dative'	<fs af='aval,pn,f,sg,3,d,ukku,ukku'>
5	Hi	adhikaarii 'officer (N)'	<fs af='adhikaarii,n,m,sg,3,d,,'>

6	Hi	siitaa ‘sita (N)’	<fs af='siitaa,n,f,sg,3,d,,'>
7	Hi	uskaa ‘he/she/it (pn)’	<fs af='vaha,pn,any,sg,3,d,kaa,kaa'>
8	Hi	ve ‘they (pn)’	<fs af='vaha,pn,any,pl,3,d,,'>
9	Bn	chele ‘boy (N)’	<fs af=’chele,n,m,sg,3,d,,'>
10	Bn	meyze ‘girl (N)’	<fs af=’meyze,n,m,sg,3,d,,'>
11	Bn	se ‘he/she (PN)’	<fs af='se,pn,mf,sg,3,d,,'>

Table 2: Words and in-depth analysis

In the table 2, we have presented nouns and pronouns from Hindi (Hi), Bengali (Bn) and Tamil (Ta) and their in-depth analysis. The first word 'jaanukku' is a masculine singular noun. So the analysis has 'm,sg,3'. The second word 'viittil' is a neuter singular noun and its analysis has 'n,sg,3'. The third word is third person masculine and the fourth word is a feminine pronoun, so the analysis are ‘m,sg,3’ and ‘f,sg,3’ respectively. The words in the Fifth and sixth example are Hindi nouns with masculine and feminine gender respectively. The seventh example is third person singular and eighth example is third person plural word from Hindi. Hindi pronouns do not have gender distinction. The gender, number, person for the two pronouns are 'any,sg,3' and 'any,pl,3' respectively. 'any' in the gender slot shows the pronoun can refer to a noun phrase with any gender including neuter gender. The ninth and tenth example words are Bengali nouns ‘boy’ and ‘girl’, with masculine and feminine gender respectively. The eleventh word is a Bengali third person masculine and feminine pronoun. The gender, number, person in the morphological analysis has 'mf,sg,3'. This pronoun can refer to both masculine and feminine noun in Bengali.

3.3 Data Format

After pre-processing, the data is presented in a column format. The following are the columns information. First column has sentence id, followed by word id, POS tag, chunk tag, in-depth morphological analysis, clause information and Named Entity information. The training data has an additional column having the antecedent-anaphor agreement information.

3.4 Architecture of the Engine

The engine works independent of language. We have used heuristic rule based algorithm to select the candidate noun phrases for a given pronoun and machine learning techniques based approach to filter the exact antecedent noun phrase. As every supervised machine learning approach, this approach also has training and testing phase. The architecture of our approach for training and testing is given in figure1 and 2 respectively.

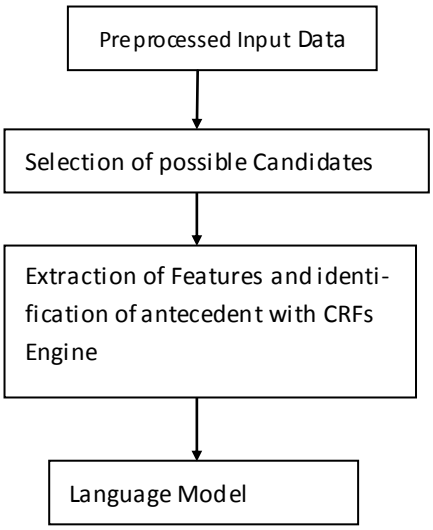

Figure 1: Training phase

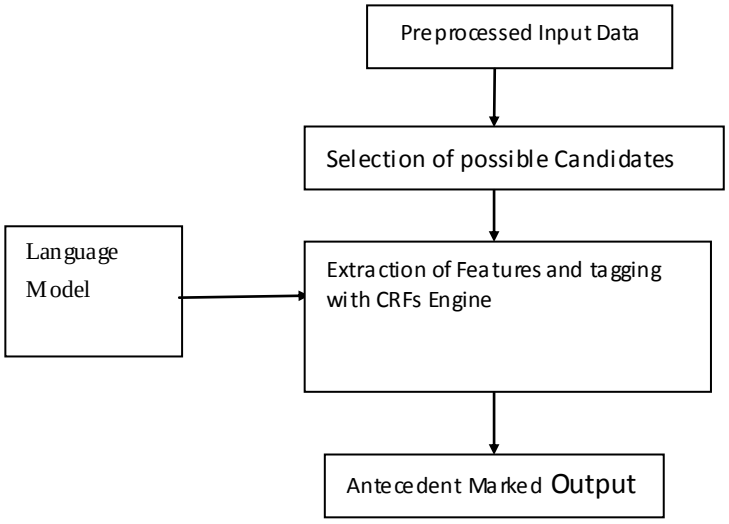

Figure 2: Testing phase

Selection of Candidate Noun Phrases for Antecedent

Both the training and testing phase has selection of the possible candidates. The noun phrases which agree with the pronoun in PNG should be selected as possible candidates for its antecedent. In training phase, the noun phrases which match with PNG of the pronoun and occur in between the anaphor and the antecedent are collected for each pronoun and given for training using the machine learning algorithm. The exact anaphor and antecedent pair forms positive pair and other noun phrases and anaphor form negative pairs for learning. In the testing phase all the noun phrases that match in PNG with the pronouns are collected from the current sentence and four prior sentences. The gender distinction and anaphor-antecedent agreement varies widely among Indian languages. In order to have a language independent engine, these variations have to be dynamically captured and the rules for checking PNG agreement have to be generated. We have used the gender information from the morphological analysis extracted with a set of heuristic rules to capture the variation in PNG agreement. The heuristic rules describe the possible genders that can match with the gender of the pronoun that varies between languages. The heuristic rules are presented below.

1. If the gender of the pronoun is 'm', then the nouns having masculine gender are chosen as candidate antecedents.
2. If the gender of the pronoun is 'f', then the nouns with feminine gender are chosen as candidate antecedents.
3. If the gender of the pronoun is 'n', then the nouns having neuter gender are chosen as candidate antecedents.
4. If the gender of the pronoun is 'mf', then the nouns with gender 'mf', 'm' and 'f' are chosen as candidate antecedents and the nouns with gender 'mf' is given importance.
5. If the gender of the pronoun is 'fn' is the gender of the pronoun, then nouns with 'fn' are chosen as candidate antecedents.
6. If the gender of the pronoun is 'any', then all the nouns are considered for candidate antecedent set and the nouns with gender 'any' is given higher priority.

Once the possible candidates for antecedents for the anaphors are selected, they are given for training/testing using the machine learning technique. Here we have used CRFs, a linear graphical technique to learn and identify the antecedents.

Anaphora Resolver

The core anaphora engine uses CRFs, a machine learning technique. In the training phase the system is provided with annotated data and the features for learning. After the system learns, a model file is generated as output. In the testing phase any unseen text is given for the automatic anaphora resolution. In our approach we have modeled this as a binary classification task. The machine has to classify whether the given candidate antecedent is the real antecedent or not based on the features of the candidate antecedents and the pronoun. The features for learning are extracted from the shallow parsed data. The feature extraction module extracts these features for all possible candidate antecedent and pronoun pairs from the shallow parsed data. The features used for learning are described below. Here we have used the freely available open source CRFs (Kudo, 2005).

Features for Learning

The features required for this task are identified from shallow parsed input sentences. The features for all possible candidate antecedent and pronoun pairs are obtained by preprocessing the input sentences with in-depth morphological analyser, POS tagger, and chunker, clause boundary identifier and Named Entity recognizer, where the last two preprocessing tasks are optional. The features identified can be classified as positional features, syntactic features and constraint features.

a) *Positional Features:* The occurrence of the candidate antecedent is noted. Is it in the same sentence where the pronoun occurs or in the prior sentences? Prior four sentences from the current sentence are considered.

b) *Syntactic Features:*

Syntactic Role: The syntactic role of the candidate noun phrases in the sentence is a key feature. The syntactic role of the noun phrases such as subject, object, indirect object, are obtained from the

case suffix affixed with the noun phrase. We consider Nominative and Dative cases for subject and other cases for object, the position and the other cases for indirect object.

Linguistic Characteristics: POS tag and chunk information of Candidate NP, suffixes affixed with the noun.

c) *Verb Suffixes:* The suffixes which show the gender which gets attached to the verb.

d) *Nature of NP:* Whether the candidate NP (probable antecedent) is Possessive or Existential.

e) *Constraint Features:* The constraint features are obtained from clause boundary and named entities recognized.

The position of the candidate NP with respect to clause boundary such as is candidate NP in current clause or immediate clause or non-immediate clause.

The Named Entity tags associated with the candidate NPs help the learning algorithm to learn constraints that types of NEs that can be its possible antecedents.

f) Combination of the above said features.

The features for learning have been identified based on the characteristics of the pronouns. For example constraint feature (current-clause) and syntactic feature (subject) helps in identifying the antecedent of the reflexives. For relative anaphors the constraint feature (immediate-clause) and syntactic feature (subject) help in identifying the antecedent.

4 Experiment, Results and Discussion

We have tested our approach using the dataset provided in "Anaphora Resolution for Indian Language", a tool contest conducted as a part of ICON 2011. The tool contest had three languages namely Tamil, Hindi and Bengali. The dataset is presented in column format with the following information viz. line index, word index, word, its POS and chunking information, followed by Named Entity information. We have enriched the dataset with in-depth morphological analysis. Table 3 presents the statistics of the ICON 2011 tool contest dataset.

Language	Training Data			Testing Data		
	Bengali	Hindi	Tamil	Bengali	Hindi	Tamil
Total Number of Pronouns	814	835	925	494	507	609
Number of Anaphoric Pronouns	476	557	580	283	344	348
Number of Non-Anaphoric Pronouns	338	278	345	211	163	261

Table 3: Statistics of ICON 2011 Dataset

MUC, B^3, BLANC, CEAF are the common scorers available for coreference resolution, where the coreference chains are being evaluated. Anaphora resolution is generally evaluated with performance measures such as Precision, Recall and F-measure. In this work, we have measured the performance with Precision, Recall and F-Measure and it is presented in table 4.

Example 4

Ta:	**aalluNar**	**rosaiyya**	villavil	kalanthukkoNtaar.	**avar**	athil	uraiyaRRinaal.
	Governor	Rosiah	function+loc	join+past+3SH .	He(gender neutral)	this	gave_lecture

(Governor Rosiah joined the function. He gave the lecture there.)

In above example 4, 'avar' (third honorific singular pronoun) in the second sentence, refers to a masculine noun phrase 'aalluNar rosaiyya' in the previous sentence. The honorific pronoun can also refer to a feminine pronoun. This possibility of referring to both the gender introduces more errors.

In Hindi, most of the pronouns such as "vaha" (he/she/it), "usa" (he/she/it), "unhone" (he/she honorofic) and "khuda" (himself) etc., do not have gender distinction and can be used to refer to antecedents of both feminine and masculine. PNG agreement adds more challenges in anaphora resolution, due to which the system gives more false positives. In our algorithm we were able to reduce the number of false positives and obtained better precision by having positional features and the verb suffixes as learning features. For languages such as Hindi, we observe that there is necessity of having verb

analysis in the text processing component. If we have this information as pre-processed data to the resolution engine, it can reduce ambiguity and improve the anaphora resolution.
As it is seen from the results table we have obtained lesser scores for Bengali. In Bengali third person pronouns such as “ami” (I), “túmi/tui/apni” (you), “se/tini” (he/she), “amra” (we), “tara/tnara” (they), do not have masculine, feminine distinction, but there is animacy distinction. And also the verb has no gender agreement. This adds more challenge to anaphora resolution engine and hence lesser scores than other languages. We identify the animacy feature in the morphological analysis stage for all the languages, but for Bengali language it is not robust and it affects in the anaphora resolution. For such languages the order of NPs and syntactic roles play major role in anaphora resolution. The use of features such as Named Entities helps in improving the resolution of pronouns referring to person and location. The addition of clause boundary information improves resolution by adding structural constraints.

5 Conclusion

We have presented a generic anaphora resolution engine, which can be used for all Indian languages. The three languages, Hindi, Bengali, and Tamil, we have chosen are the most spoken languages belonging to two major language families of India, namely belonging to Indo-Aryan and Dravidian families respectively. Though the Indian languages have similarities, they vary in Person, Number, Gender distinction, which pose a challenge in building language independent engine. The engine is language independent as it uses the information from the in-depth morphological analysis. It is specifically designed in such a way that it is scalable and allows plug-n-play architecture. The core anaphora resolution engine uses CRFs a machine learning technique. This uses feature based learning and we have provided syntactic and positional based features obtained from in-depth morphological analysis. We have obtained encouraging evaluation results. The major contributions of this work are the following:

a) Our attempt is first of its kind in Indian languages to develop a single generic engine, using machine learning.

b) It is a known fact that most of the Indian languages are resource poor, hence we have used very minimal resources, only shallow parsing has been used.

c) The results obtained are comparable to other reported works.

Abstract

Two annotations schemes for presenting the parsed structures are prevalent viz. the constituency structure and the dependency structure. While the constituency trees mark the relations due to positions, the dependency relations mark the semantic dependencies. Free word order languages like Sanskrit pose more problems for constituency parses since the elements within a phrase are dislocated. In this work, we show how the enriched constituency tree with the information of displacement can help construct the unlabelled dependency tree automatically.

1 Introduction

Sanskrit has a rich tradition of linguistic analysis with intense discussions and argumentations on various aspects of language analysis ranging from phonetics (śikṣā), grammar (vyākaraṇa), logic (nyāya), ritual exegesis (karmamīmāṃsā), and literary theory (alaṃkāraśāstra) which is not only useful for analysing Sanskrit but it also has much to offer computational linguistics in these areas. The series of symposia in Sanskrit Computational Linguistics (Huet et al., 2009; Kulkarni and Huet, 2009), the consortium project sponsored by the Technology Development for Indian Languages (TDIL) and the research of individual scholars and the collaborations (Goyal et al., 2012) among them resulted into a) development of several tools ranging from segmenters (Huet, 2009), morphological analysers (Kulkarni and Shukl, 2009), parsers (Goyal et al., 2009; Hellwig, 2009; Kumar, 2012; Kulkarni, 2013) to discourse annotators, b) lexical resources ranging from dictionaries, WordNet (Kulkarni et al., 2010) to Knowledge-Nets (Nair, 2011), and c) annotated corpora [http://sanskrit.uohyd.ernet.in/scl].

Pāṇinian grammar, the oldest dependency grammar, provides a formalism for annotation of the sentences. While the Sanskrit consortium has annotated a few thousand sentences following the dependency grammar, we also came across a very valuable source of annotation of Sanskrit sentences following the constituency structure (Gillon, 1996). The constituency structure was enriched to suite the requirements of Sanskrit. This aroused our curiosity to study the equivalence of the two annotation schemes.

The importance of dependency structure has been well recognised by several computational linguists (Culotta and Sorensen, 2004; Haghighi et al., 2005; Quirk et al., 2005) in the recent past. The dependency format is preferred over the constituency not only from evaluation point of view (Lin, 1998) but also because of its suitability (Marneffe et al., 2006) for a wide range of NLP tasks such as Machine Translation (MT), information extraction, question answering etc.. This has upsurged several works on converting a constituency structure into dependency. The parsers for English now produce the dependency parse as well. Xia and Palmer discuss three different algorithms to convert dependency structures to phrase structures for English (Xia and Palmer, 2001). Magerman gave a set of priority lists, in the form of a head percolation table to find heads of constituents (Magerman, 1994). Yamada and Matsumoto modified these head percolation rules further (Yamada and Matsumoto, 2003). Their method was reimplemented by Nivre, who also defined certain heuristics to infer the arc labels in the dependency tree produced (Nivre, 2006). Johansson and Nugues used a richer set of edge labels and

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1834–1843, Dublin, Ireland, August 23-29 2014.

introduced links to handle long-distance phenomena such as wh-movement, topicalization, expletives and gapping (Johansson and Nugues, 2007). Their conversion procedure made use of this extended structure in Penn Treebank. De et al. described a system for generating typed dependency parsed from the phrase structure parses (De Marneffe et al., 2006). (Palmer et al., 2009; Xia et al., 2009; Bhatt et al., 2009) discuss a multi-layered representation framework for Hindi and Urdu, where the information from syntactic as well as dependency parse is presented together.

In this work, we explore the relationship between enriched constituency structures and dependency structures for Sanskrit language, with main emphasis on the conversion from constituency to dependency structures. This work aims not only at designing an algorithm to convert Treebanks from one type of representation to the other, but also to judge the adequacy of the enriched constituency structure from parsing point of view. This paper has been organized as follows. Section 2 discusses the history and origin of this work. Section 3 describes the background of the constituency and dependency structures, utilized for Sanskrit language. Section 4 discusses the algorithm we used for converting constituency structure into dependency structure. Section 5 describes the results obtained by our approach, with some examples. Section 6 concludes this paper with the directions for future work.

2 Origin of the work

The dataset we are using in this work has its origin in the remarkable treatise on Sanskrit Syntax by Apte (Apte, 1885) which is the most authentic book on Sanskrit Syntax even after 125 years. The work was initiated in 1986 by Brendan Gillon, then a senior fellow at the American Institute of Indian Studies, at Deccan College, put all the prose exercise sentences from Apte's Student Guide onto 5×7 cards, assigning a syntactic parse to each sentence, giving each sentence an English translation and annotating each sentence for miscellaneous syntactic and semantic facts. On the basis of these sentences, Brendan Gillon published the grammar underlying his syntactic parse of these sentences (Gillon, 1996).

In 1991, Brendan Gillon transferred the material from a paper format to an electronic format, making revisions. An example sentence in this dataset is given below:

```
Example{3}
Source{1.1.3 (P) <U 4.5.3>} % Apte{7,3}

Parse
[S [INJ haa ] [ADV katham ]
   [NP1s [NP6 (mahaaraaja<Dasharathasya) ] (dharma<daaraa.h) ]
   [VP 0 [NP1 (priya<sakhii) [NP6 me ] [NP1 Kaushalyaa ] ] ] ]

Gloss{Oh, how is it that the legal wife of King Dasharatha is my dear
friend Kaushalyaa}

Comment{copula: covert: predicational: NP1s VP }
```

Each example is given a serial number, its source - the corresponding reference in Apte's book. Then, its constituency parse is provided in a tree structure. The Sanskrit text is transliterated into Roman using the Velthuis notation[1]. Finally, the gloss (translation) of the prose is provided along with some observations regarding syntax in the field 'comment'. The proper nouns are transliterated following the English convention of capitalisation. The constituency structure is enriched reflecting the morphological information such as the case marker. The underlying constituency structure of the compounds is also shown clearly marking the head of the compound. The requirement that constituency tree be a binary is also done away with, resulting into a more flat structure than the normal hierarchical phrase structure.

In 2004, Gérard Huet re-engineered the document in order to parse it mechanically, and he verified its correct syntactic structure after typographical corrections. He devised an abstract syntax to formalize this constituency structure. In the abstract syntax, the above constituency structure is represented as below:

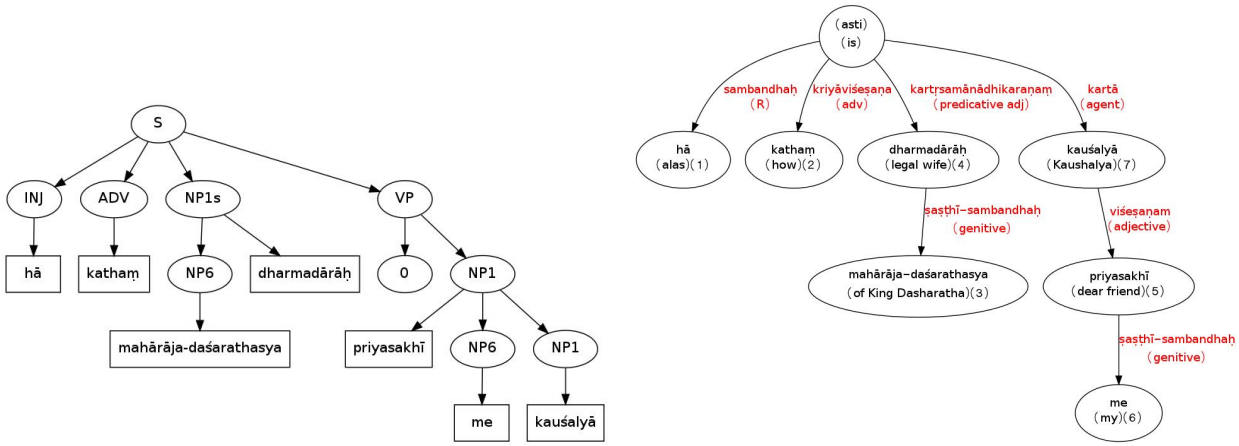
```
list Tag_tree.syntax =
[S
```

[1]Originally developed in 1991 by Frans Velthuis for use with his devnag Devanagari font, designed for the TeX typesetting system.

```
[INJ ("haa", 1); ADV [("katham", 2)];
 NP
  ([Case 1; Role Subject],
  [NP ([Case 6], [N (Compound (Stem <mahaaraaja>, Stem <Dasharathasya>),
   3)]);
   N (Compound (Stem <dharma>, Stem <daaraa.h>), 4)]);
 VP0
  [NP
    ([Case 1],
    [N (Compound (Stem <priya>, Stem <sakhii>), 5);
     NP ([Case 6], [N (Stem <me>, 6)]);
     NP ([Case 1], [N (Stem <Kaushalyaa>, 7)])]);
   NIL 8]]]
```

Each stem is given a unique index. The syntax, while preserving the original structure of the text, gives additional structuring with the word numbers, explicit case markers and stems for the compounds. While these constituent trees preserve much of the tagging related information, they still do not have the gender and number information for the substantives, for instance. This information can enhance the constituency representation further.

The same set of sentences were also parsed manually by Sheetal Pokar, a research scholar at the University of Hyderabad, showing the dependency structure. Sheetal followed the annotation guidelines developed by the Consortium of Institutes working on the Development of Sanskrit Computational Tools[2]. This tagset has a little above 40 tags marking various relations. The dependency tree for the example 3, discussed above, is shown in Figure 1. It is a directed tree with nodes corresponding to the words in the sentence and edges corresponding to the relation between the head and the modifier. Each node has a number indicating the word index. A generic relation *sambandhaḥ* (R) is used if the relation does not fall under any of the given tags. As one may notice, both the constituency as well as the dependency structures posit a NULL verb 'to be' *asti*. Among the Indian schools dealing with verbal cognition, not all schools accept the insertion of missing copula. We follow the grammarian school who accept this insertion.



(a) (b)

Figure 1: Example 3: (a). Constituency Parse and (b). Dependency Parse

While the two structures in Figure 1 mark different kind of information, we notice that the dominance relation in the constituency structure under each phrase corresponds to the the modifier-modified relation in the dependency tree. This was the main motivation to develop the converter to convert a phrase structure into an unlabelled dependency structure.

3 Dependency and Constituency Structures

Verbal understanding of any utterance requires the knowledge of how words in that utterance are related to each other. There are two major representational frameworks for representing this knowledge as a parse tree viz. constituency and dependency parse trees. Constituency trees show how the individual units in a sentence are grouped together leading to semantically richer phrases in the constituency structures. The dependency structure, on the other hand, shows how each word is related to other words in the sentence either directly or indirectly.

The constituency structure derives from the subject-predicate division of Latin and Greek grammars that is based on term logic. Basic clause structure is understood in terms of a binary division of the clause into subject (noun phrase NP) and predicate (verb phrase VP). These ideas originated with Leonard Bloomfield (Bloomfield, 1962) and were further developed by a number of American structuralist linguists, including Harris (Harris, 1955) and Wells (Wells, 1947). Though these grammars were initially conceived as applying only to phrases, it was shown that such rules could be used for analyzing compounds as well as derivational morphology for Sanskrit. Gillon showed that the same extension works for classical Sanskrit as well (Gillon, 1995).

The dependency analysis dates back to Pāṇini who uses the syntactico-semantic relations called *kāraka* relations for the linguistic analysis of a sentence. In modern times, the seminal work of Tesnière (Tesnière, 1959) became the basis for the work on dependency grammar. Meaning-Text Theory (Melĉuk, 1988), Word grammar (Hudson, 1984), Functional Generative Description (Segall et al., 1986) are some of the flavours of the dependency grammar. A dependency parse is generally modelled as a directed tree with nodes representing the words and edges representing the possible relations between them. A typed dependency parse also labels the relations. For every element (word or morph) in a sentence, there is just one node in the syntactic structure.

Xia and Palmer (Xia and Palmer, 2001) discuss three different algorithms to convert dependency structures to phrase structures for English. They also attempt to clarify the differences in representational coverage of the two approaches. In the first stage, they identify the head of each constituent of the sentence, which is further modified to retrieve the semantic head. In the second phase, they label each of the dependency extracted with a grammatical relation using patterns defined over the phrase structure tree. (Palmer et al., 2009; Xia et al., 2009; Bhatt et al., 2009) discuss a multi-layered representation framework for Hindi and Urdu, where the information from syntactic as well as dependency parse is presented together. They first construct a dependency parse and then convert it into the constituency parse tree using conversion rules. A conversion rule is a (DS pattern, PS pattern) pair, where DS and PS correspond to dependency and phrase structure respectively.

The constituency parse we are dealing with being enriched with linguistic information pertaining to the morphology of the simple as well as compound words, it was much simpler to convert this structure into a dependency structure. In the next section, we will discuss our algorithm for converting a constituency structure to a dependency structure.

4 Conversion from Constituency to Dependency Structure in Sanskrit

The notion of 'head' is very important for both the constituency and dependency structures. In the constituency structure, the head determines the main properties of the phrase. Head may have several levels of projection. In the dependency structure, on the other hand, the head is linked to its dependents. The core of the algorithm is to identify the head of each phrase in the constituency tree and establish its relation with the head of its parent node. And also to establish the relation between the head with its dependents. The head for each XP is the node X within that XP. Thus the head for an NP is the noun, head for a VP is the verb, and so on. The head for the S is the head of a VP, in case it is a simple sentence, and head of the VP of the main clause in case it is a complex sentence. In case of complex sentences, we identified the main clause taking clues from the connectives. Each relation is named after the XP of the modifier. Our algorithm for finding the head node is implemented on the abstract syntax discussed in section 2 before. A rough outline of the algorithm is:

1)The head of VP is the ROOT node in the dependency tree.

a) In the case of sentences with sub-ordinate clauses, identify the main clause taking clues from the connectives.
b) Head of a clause is an auxiliary, if present, otherwise the main verb is the head.
c) In the case of sentences with quotative markers, the verb of the main clause is the head.
(The later rule is stronger than the previous.)
2) All the XPs within VP are dependent on the ROOT.
3) If S is the parent of VP, then all the XPs which are children of S are also dependent on this ROOT.

Finding the head for each node was not trivial though, as many of the parses involve dislocated phrases, which were not fully marked. We had to enrich the constituency trees by incorporating the dislocation information, which was provided in comments and was missing from the tree notations. We used '!' and '$' to indicate the dislocation. '!' indicates the position from where a component is dislocated, while '$' indicates the dislocated component. An example of a constituency parse, enriched with dislocation information is given below.

```
Example{2}
Source{1.1.2 (P) <V 3.28; V 3.6.3>} % Apte{7,2}

Parse
[S [ADV sarvatra ] [NP6 audarikasya $1]
   [VP 0 [NP1 abhyavahaaryam [PRT eva ] ] ]
   [NP1s !1 vi.saya.h ] ]

Gloss{In every case, a glutton's object is only food.}

Comment{copula: covert: predicational: VP NP1s
"eva" in predicate NP
left extraposition from NP1s of NP6 within MC, modulo adverbial ADV.}
```

This constituency tree involves one dislocated phrases. This information is marked with '!1'for the place from which it is dislocated and with '$1' for the phrase that has been dislocated. This dislocation information is used by our algorithm to find the right relata for the dislocated words. In case of more than one dislocated phrases, they are numbered sequentially.

5 Results and Discussions

We implemented our algorithm on a dataset of 232 sentences and matched the output of our algorithm with the Gold dataset, the dependency graph constructed manually for the sentences by Sheetal. Figure 2 shows the dependency structure for Example 3, produced by our conversion algorithm.

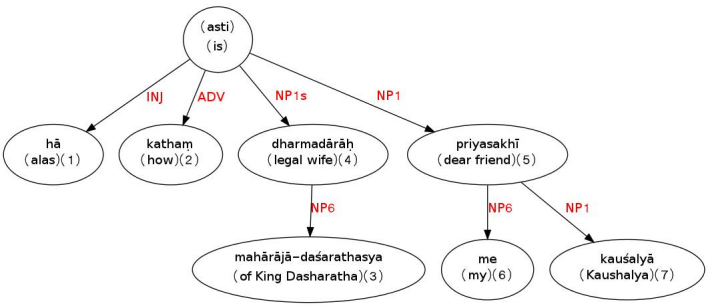

Figure 2: Dependency graph constructed by conversion from constituency structure

The conversion algorithm captures the relations between various constituents and produces a dependency graph. Labels of the dependency graph correspond to the intermediate nodes in the phrase structure. On comparing the graph in Figure 2 with the graph in Figure 1, we find that most of the original connections were captured. However, there was a mismatch in the relation between words *kauśalyā*, *priyasakhī* and *me*. This discrepancy is because of the non-agreement between the annotators as to which one is the head. In case of sentences with apposition, in Sanskrit, the two annotators have difference of opinion as to which among the two is the head. This resulted in the mismatch between the two graphs. The relations in this graph are labelled by the dominating XP.

Pāṇini's grammar provides rules for assigning case markers given the syntactico-semantic relation between the relata. Inverting these rules it should be possible to get the relation labels. These relation labels, however, will not be obtained deterministically. The non-determinism will lead to multiple labelled dependency structures. Hence we could not assign the labels from the tagset, and resorted to the names of the phrases which the word belongs to.

Below we give an example where we found an exact match between the manual dependency graph and the dependency graph, produced by our conversion algorithm, using the constituency parse of the sentence.

```
Example{29}
[S [VP [NP7 tatra ] [CNJ ca ]
       [NP5 [NP6 [AP6 (((nikhila<(dhara.nii<tala))<parya.tana)<khinnasya) ]
                  (nija<balasya) ]
            (vizraama<heto.h) ]
       [NP2 [AP2 katipayaan ] divasaan ]
       ati.s.that ] ]
Gloss{And he remained there for a few days in order to rest his army
exhausted from roaming the entire surface of the earth.}
```

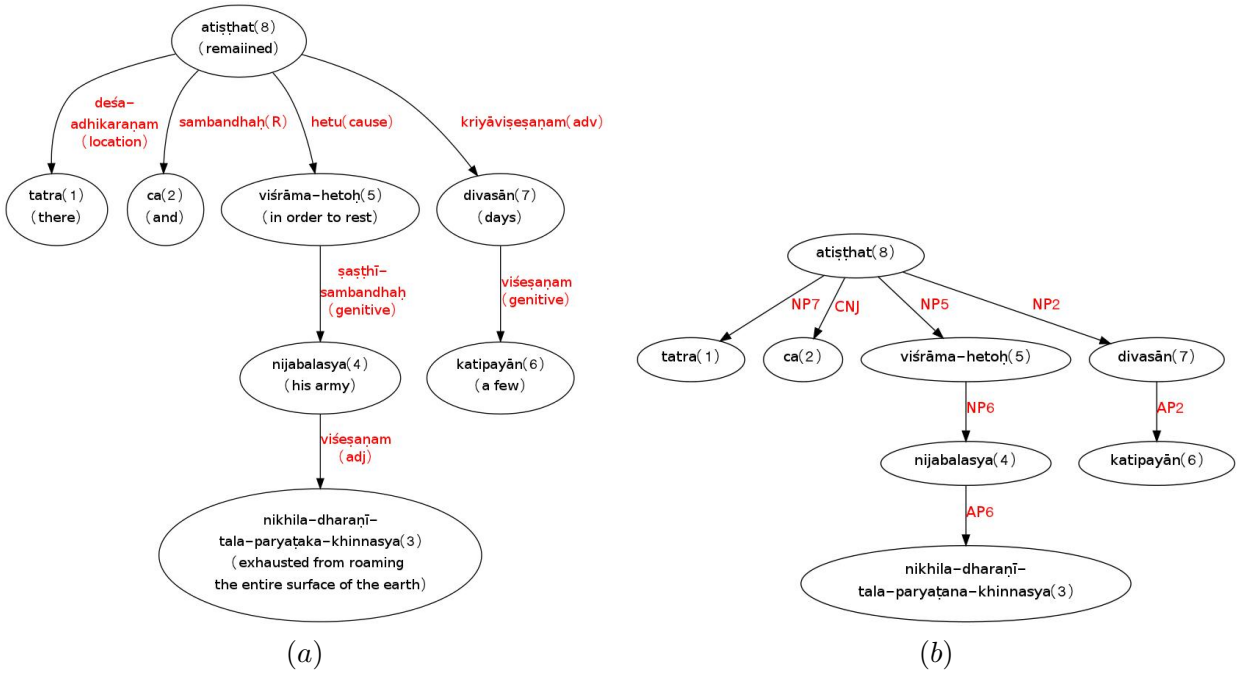

Figure 3: Example 29: (a). Dependency graph constructed manually and (b). Dependency graph constructed by conversion from constituency structure

Out of 232 cases, we found 97 such cases with exact match. For the rest of the cases,
1) In 40 cases, number of words in dependency and phrase-converted graph are different. For example, the words such as *kadācit* 'probably', *yadyapi* 'even if', *tathāpi* 'even then', *athavā* 'or' etc. were treated in one structure as a single word while in the other as two words. These words at morphological level consist of two morphemes which have independent existence. So it was natural to treat these as two words, in the constituency trees. However, at the semantic level, these two words indicate a single meaning which at times is non-compositional. The annotator of dependency graph has treated these as a single word.
2) In 95 cases, one or more relations do not match. These were due to various reasons such as

1. differences in the treatment and identification of adjectives,
2. disagreement in the attachment, and
3. cases of ellipsis, null head, and cases where the treatment of conjunct '*ca*' (and) differs.

These differences are very much important from linguistic analysis point of view. However due to space constraint we illustrate here only two cases where the treatment of the two annotators differ.

```
Example{72}
[S [VOC sakhi [VOC Vaasanti ] ]
   [VP 0 [NP4 du.hkhaaya [PRT eva ] [NP6 su-h.rdaam ] ] ]
   [NP1s [ADV idaaniim ] [NP6 Raamasya ] darshanam ] ]

Gloss{Oh my friend Vaasanti, seeing Raama now leads only to
the unhappiness of his friends.}
```

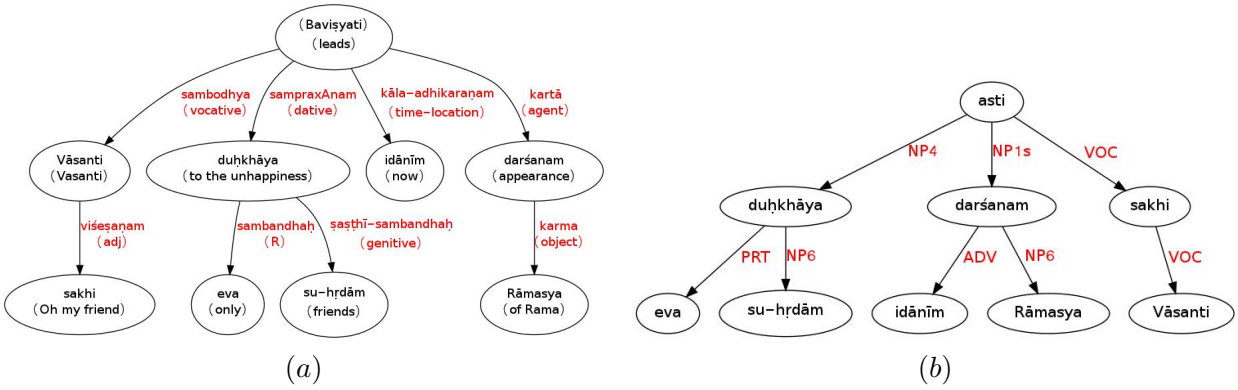

Figure 4: Example 72: (a). Dependency graph constructed manually and (b). Dependency graph constructed by conversion from constituency structure

In this example, there are two places where the annotators disagree.
a) The attachment of the word *idānīm* (now).
b) The decision of head in case of vocative with a modifier.
The null copula (VP 0) in the constituency structure is replaced by the Sanskrit verbal form *asti* uniformly. The annotator of dependency graph has provided a more appropriate verb *bhaviṣyati*. However, we ignore this difference.

Let us look at another example, where the ambiguity in morphological analysis has led to the ambiguity in the readings resulting in the disagreement in the parse.

```
Example{46}
[S [NP1s aarya.h ]
   [VP daapayatu [NP2 [NP6 me ]
                      [NP4 (Vaisha.mpaayana<aanayanaaya) ]
                      (gamana<abhyanuj~naam) ]
                 [NP3 taatena ] ] ]

Gloss{May you, sir, make my father give me permission to go to bring
Vaisha.mpaayana.}
```

In this example, the pronominal form *me* is ambiguous between two readings. It can be either a genitive or a dative of the first person pronoun *asmad* 'I'. The sub-ordinate clause is analysed by Gillon as 'the permission for going to bring Vaiśampāyan by me'. In Sanskrit the first person pronoun in such cases takes genitive case marker. Sheetal on the other hand has analysed it as 'the permission to me for going to bring Vaiśampāyan', where *me* is analysed with dative case. It is clear that 'to bring Vaiśampāyan' is the purpose for going. But since 'permission for going' is a compound in Sanskrit [3], and the 'permission' being the head of this compound, Sheetal avoided linking 'to bring Vaiśampāyana' with 'permission to go' as it results into an '*asamartha samāsa* (incompatible compound formation, where the external modifier connects the modifier component of a compound and not the head). This has resulted into the differences in annotation. Such compounds are not rare. Thus, in order to provide a correct parse, in case of dependency structure, it is necessary to show the internal structure of the compounds as well,

[3]In Sanskrit a compound is always written as a single word without any space in between.

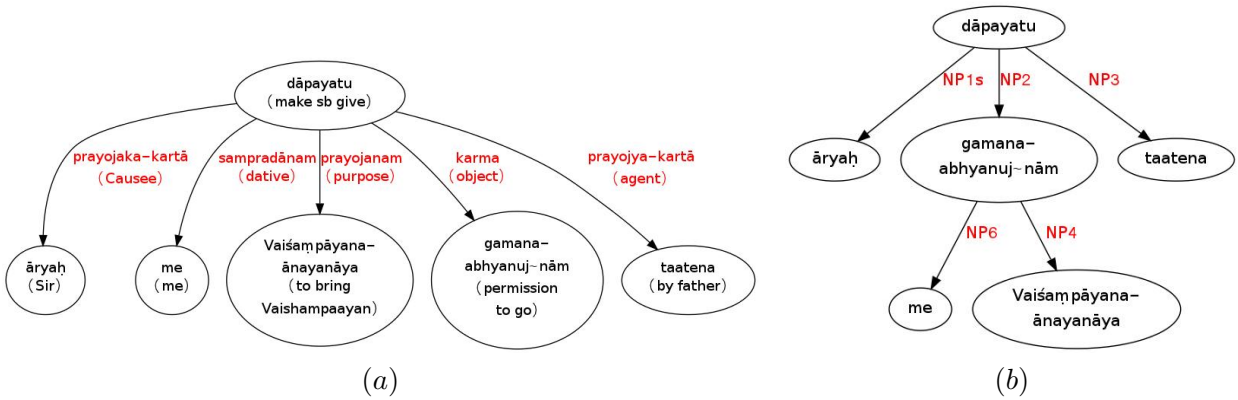

Figure 5: Example 46: (a). Dependency graph constructed manually and (b). Dependency graph constructed by conversion from constituency structure

rather than treating a compound unanalysed. This will allow one to connect the elements to the part of a compound other than the head. Similar treatment is necessary in the phrase structure annotation as well.

We end with example 2 from section 4, where the dislocation information in the constituency tree helps in retrieving the correct dependency structure. In this example, even though the word *audarikasya* has been displaced, the displacement information in the parse tree positions it at the correct place in the dependency tree constructed from the constituency structure.

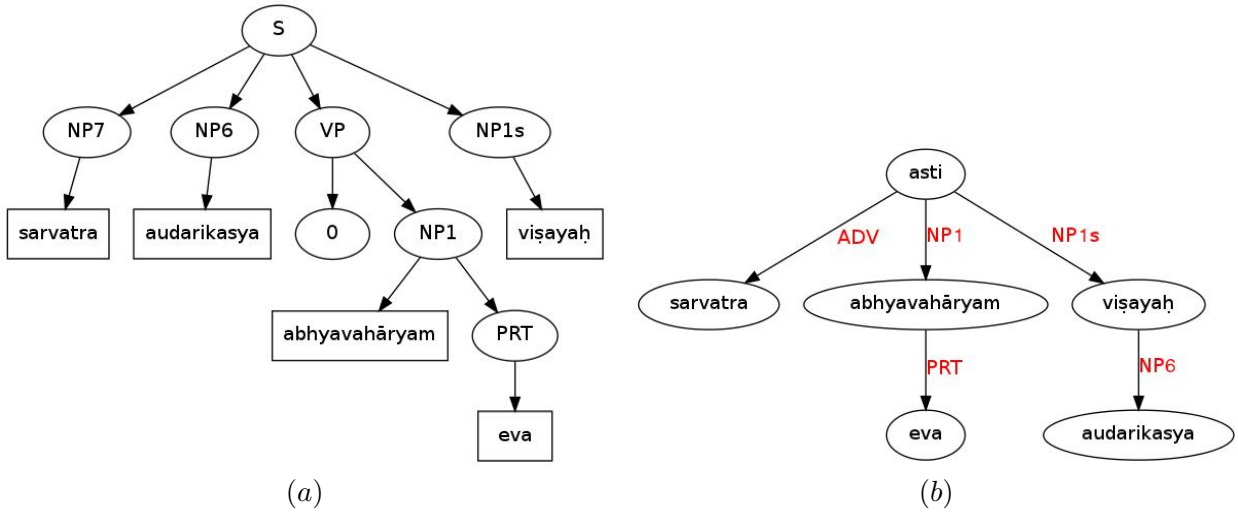

Figure 6: Example 2: (a). Constituency structure and (b). Dependency graph constructed by conversion from constituency structure

6 Conclusions and Future Work

This work focussed mainly on conversion from constituency to dependency structure. The sentences in our dataset are chosen from (Apte, 1885), which is an authentic book for higher learning of Sanskrit, covering a wide range of grammatical constructions. The tool was tested on a dataset of 232 sentences and the initial results were encouraging. Specifically, most of the cases of mismatch were linguistic issues and need further discussion. The phrase labels indicating the case labels is an important extension of the constituency trees to accommodate morphologically rich languages. The enriched constituency structure has an advantage of recording the word order, and at the same time marking the dislocation information. In this work, we have shown that such enriched constituency tree can help construct the unlabelled dependency tree automatically. Further, one may also try inferring the dependency relation names, and use statistical parsing to resolve non-determinism favouring popular usages.

Another interesting aspect would be to try the other way conversion, that is, from dependency to phrase structure. The main challenge for this conversion is to find out the projection table corresponding to each lexical item. This work will also be a first step towards an abstract syntax, which can inherit the properties of both the constituency and dependency structures. If so, this would be an alternative formalism for tagging the Sanskrit corpus.

Acknowledgements

The authors would like to acknowledge the discussions with Gérard Huet, INRIA Paris Rocquencourt, towards enriching the abstract syntax. The work was also supported by Emilie Aussant and Sylvie Archaimbault, laboratoire HTL, Université Paris Diderot.

Uncertainty Detection in Hungarian Texts

Veronika Vincze[1,2]
[1]University of Szeged
Department of Informatics
[2]MTA-SZTE Research Group on Artificial Intelligence
vinczev@inf.u-szeged.hu

Abstract

Uncertainty detection is essential for many NLP applications. For instance, in information retrieval, it is of primary importance to distinguish among factual, negated and uncertain information. Current research on uncertainty detection has mostly focused on the English language, in contrast, here we present the first machine learning algorithm that aims at identifying linguistic markers of uncertainty in Hungarian texts from two domains: Wikipedia and news media. The system is based on sequence labeling and makes use of a rich feature set including orthographic, lexical, morphological, syntactic and semantic features as well. Having access to annotated data from two domains, we also focus on the domain specificities of uncertainty detection by comparing results obtained in indomain and cross-domain settings. Our results show that the domain of the text has significant influence on uncertainty detection.

1 Introduction

Uncertainty detection has become one of the most intensively studied problems of natural language processing (NLP) in these days (Morante and Sporleder, 2012). For several NLP applications, it is essential to distinguish between factual and nonfactual, i.e. negated or uncertain information: for instance, in medical information retrieval, it must be known whether the patient definitely suffers, probably suffers or does not suffer from an illness. This type of information can only be revealed from the texts of the documents if reliable uncertainty detectors are available, which are able to identify linguistic markers of uncertainty, i.e. cues within the text. To the best of our knowledge, uncertainty detectors have been mostly developed for the English language (Morante and Sporleder, 2012; Farkas et al., 2010). Here, we present our machine learning based uncertainty detector developed for Hungarian, a morphologically rich language, and report our results on a manually annotated uncertainty corpus, which contains texts from two domains: first, Hungarian Wikipedia texts and second, pieces of news from a Hungarian news portal.

The main contributions of this paper are the following:

- it presents the first uncertainty corpus for Hungarian;
- it reports the first results on uncertainty detection in Hungarian texts;
- it introduces new features in the machine learning setting like semantic and pragmatic features;
- we show that there are domain specificities in the distribution of uncertainty cues in Hungarian texts;
- we show that domain specificities have a considerable effect on the efficiency of machine learning.

The structure of the paper is the following. First, related work on uncertainty detection is presented. Then our corpus is described in detail, which is followed by the elaboration of machine learning methods and results on uncertainty detection. The paper concludes with a discussion of results and possible ways for future work are also outlined.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1844–1853, Dublin, Ireland, August 23-29 2014.

2 Related Work

In these days, identifying uncertainty cues is one of the popular topics in NLP. This is supported by the CoNLL-2010 Shared Task, which aimed at detecting uncertainty cues in biological papers and Wikipedia articles written in English (Farkas et al., 2010). Moreover, a special issue of the journal Computational Linguistics (Vol. 38, No. 2) was recently dedicated to detecting modality and negation in natural language texts (Morante and Sporleder, 2012). As indicated above, most earlier research on uncertainty detection focused on the English language. As for the domains of the texts, newspapers (Saurí and Pustejovsky, 2009), biological or medical texts (Szarvas et al., 2012; Morante et al., 2009; Farkas et al., 2010; Kim et al., 2008), Wikipedia articles (Ganter and Strube, 2009; Farkas et al., 2010; Szarvas et al., 2012) and most recently social media texts (Wei et al., 2013) have been selected for the experiments.

Systems for uncertainty detection were originally rule-based (Light et al., 2004; Chapman et al., 2007) but recently, they exploit machine learning methods, usually applying a supervised approach (see e.g. Medlock and Briscoe (2007), Morante et al. (2009), Özgür and Radev (2009), Szarvas et al. (2012) and the systems of the CoNLL-2010 Shared Task (Farkas et al., 2010)). In harmony with the latest tendencies, our system here is also based on supervised machine learning techniques, which employs a rich feature set of lexical, morphological, syntactic and semantic features and also exploits contextual features.

Supervised machine learning methods require annotated corpora. There have been several corpora annotated for uncertainty in different domains such as biology (Medlock and Briscoe, 2007; Kim et al., 2008; Settles et al., 2008; Shatkay et al., 2008; Vincze et al., 2008; Nawaz et al., 2010), medicine (Uzuner et al., 2009), news media (Saurí and Pustejovsky, 2009; Wilson, 2008; Rubin et al., 2005; Rubin, 2010), encyclopedia (Farkas et al., 2010), reviews (Konstantinova et al., 2012; Cruz Díaz, 2013) and social media (Wei et al., 2013). For our experiments, however, we make use of the first Hungarian uncertainty corpus created for the purpose of this study.

3 Experiments

In this section, we present our methodology to detect uncertainty cues in Hungarian. We first describe the uncertainty categories applied and report some statistics on the corpus. Then we describe our machine learning approach based on a rich feature set.

3.1 The hUnCertainty Corpus

For the purpose of this study, we manually annotated texts from two domains. First, we randomly selected 1,081 paragraphs from the Hungarian Wikipedia dump. This selection contains 9,722 sentences and 180,000 tokens. Second, we downloaded 300 pieces of criminal news from a Hungarian news portal (`http://www.hvg.hu`), which altogether consist of 5,481 sentences and 94,000 tokens. In total, the hUnCertainty corpus consists of 15,203 sentences and 274,000 tokens.

During annotation, we followed the categorization of uncertainty phenomena as described in Szarvas et al. (2012) and Vincze (2013) with some slight modifications, due to the morphologically rich nature of Hungarian (for instance, modal auxiliaries like *may* correspond to a derivational suffix in Hungarian, which required that in the case of *jöhet* "may come" the whole word was annotated as uncertain, not just the suffix *-het*). Here we just briefly summarize uncertainty categories that were annotated – for a detailed discussion, please refer to Szarvas et al. (2012) and Vincze (2013).

Linguistic uncertainty is traditionally connected to modality and the semantics of the sentence. For instance, the sentence *It may be raining* does not contain enough information to determine whether it is really raining (semantic uncertainty). There are several phenomena that are categorized as semantic uncertainty. A proposition is **epistemically** uncertain if its truth value cannot be determined on the basis of world knowledge. **Conditionals** and **investigations** also belong to this group – the latter is especially frequent in research papers, where authors usually formulate the research question with the help of linguistic devices expressing this type of uncertainty. Non-epistemic types of modality may also be listed here such as **doxastic** uncertainty, which is related to beliefs.

However, there are other uncertainty phenomena that only become uncertain within the context of communication. For instance, the sentence *Many researchers think that COLING will be the best conference of the year* does not reveal how many (and which) researchers think that, hence the source of the proposition about COLING remains uncertain. This is a type of discourse-level uncertainty, more specifically, it is called **weasel** (Ganter and Strube, 2009). On the other hand, **hedges** make the meaning of words fuzzy: they blur the exact meaning of some quality/quantity. Finally, **peacock** cues express unprovable (or unproven) evaluations, qualifications, understatements and exaggerations.

Some examples of uncertainty cues are offered here (in English, for the sake of simplicity):

EPISTEMIC: It **may** be raining.

DYNAMIC: I **have to** go.

DOXASTIC: He **believes** that the Earth is flat.

INVESTIGATION: We **examined** the role of NF-kappa B in protein activation.

CONDITION: **If** it rains, we**'ll** stay in.

WEASEL: **Some** note that the number of deaths during confrontations with police is relatively proportional for a city the size of Cincinnati.

HEDGE: Magdalene Asylums were a **generally** accepted social institution until well into the second half of the 20th century.

PEACOCK: The main source of their inspiration was native Georgia, with its **rich** and **complex** history and culture, its **breathtaking** landscapes and its **courageous** and **hardworking** people.

Table 1 reports some statistics on the frequency of uncertainty cues in Hungarian and it is also visualized in Figure 1. It is revealed that the domain of the texts has a strong effect on the distribution of uncertainty cues: the distribution of semantic uncertainty cues and discourse-level uncertainty cues is balanced in the news subcorpus but in the Wikipedia corpus, about 85% of the cues belong to the discourse-level uncertainty type.

Regarding different classes of uncertainty, we should mention that while weasels constitute the most frequent cue category in Wikipedia texts, they occur less frequently in the news corpus. On the other hand, doxastic cues are frequent in the news corpus but in Wikipedia texts, their number is considerably smaller.

Uncertainty cue	**Wikipedia**		**News**		**Total**	
	#	%	#	%	#	%
Weasel	2150	35.95	258	10.93	2408	28.87
Hedge	2100	35.12	800	33.88	2900	34.77

Table 1: Uncertainty cues.

3.2 Machine Learning Methods

In order to automatically identify uncertainty cues, we developed a machine learning method to be discussed below. In our experiments, we used the above-described corpus and morphologically and syntactically parsed it with the help of the toolkit `magyarlanc` (Zsibrita et al., 2013).

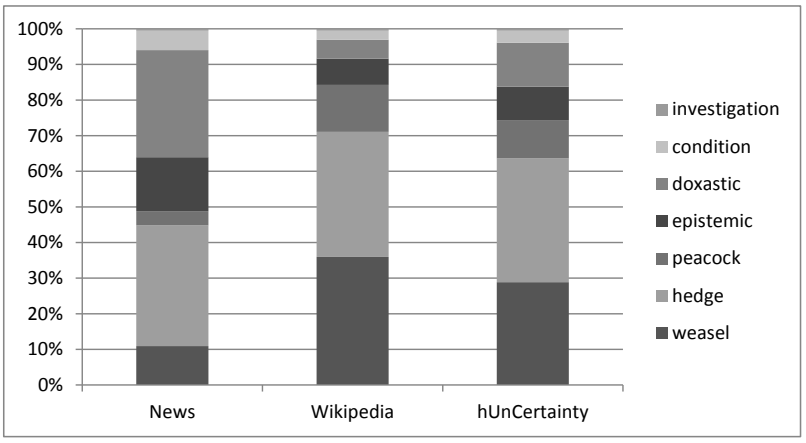

Figure 1: Distribution of cues across domains.

On the basis of results reported in earlier literature, sequence labeling proved to be one of the most successful methods on English uncertainty detection (see e.g. Szarvas et al. (2012)), hence we also applied a method based on conditional random fields (CRF) (Lafferty et al., 2001) in our experiments. We used the MALLET implementation (McCallum, 2002) of CRF with the following rich feature set:

- **Orthographic features:** we investigated whether the word contains punctuation marks, digits, uppercase or lowercase letters, the length of the word, consonant bi- and trigrams...
- **Lexical features:** we automatically collected uncertainty cues from the English corpora annotated on the basis of similar linguistic principles and manually translated these lists into Hungarian. Lists were used as binary features: if the lemma of the given word occurred in one of the lists, the feature was assigned the value *true*, else it was *false*.
- **Morphological features:** for each word, its part of speech and lemma were noted. As mentioned before, modality and mood are morphologically expressed in Hungarian (e.g. in *csinálhatnánk* do-MOD-COND-1PL "we could do", the suffix *-hat* refers to modality and the suffix *-ná* refers to conditional) hence for each verb, it was investigated whether it had a modal suffix, whether it was in the conditional mood and whether its form was first person plural or third person plural as these two latter verbal forms are typical instances of expressing generic phrases or generalizations in Hungarian, which are related to weasels. For each noun, its number (i.e. singular/plural) was marked as feature. For each pronoun, we checked whether it was an indefinite one since indefinite pronouns like *valaki* "someone" or *valamilyen* "some" are often used as weasel cues. For each adjective, we marked whether it was comparative or superlative as they can occur as peacock cues.
- **Syntactic features:** for each word, its dependency label was marked. For each noun, it was checked whether it had a determiner as determinerless nouns may be used as weasels in Hungarian. For each verb, it was checked whether it had a subject[1].
- **Semantic/pragmatic features:** we manually compiled a list of speech act verbs in Hungarian and checked whether the given verb was one of them. Besides, we translated lists of English words with

[1]Hungarian is a pro-drop language, hence the subject is not obligatorily present in the clause. Moreover, applying a third person plural verb without a subject is a common way to express generalization in Hungarian, which is one typical strategy of weasels.

positive and negative content developed for sentiment analysis (Liu, 2012) and checked whether the lemma of the given word occurred in these lists.

As contextual features for each word, we applied as features the POS tags and dependency labels of words within a window of size two. Although earlier research on English uncertainty detection mostly made use of orthographical, morphological and syntactic information (see e.g. Szarvas et al. (2012)), here we included some new feature types in our feature set, namely, pragmatic and semantic features.

Based on this feature set, we carried out our experiments. Since only 3% of the tokens in the corpus function as uncertainty cues, it seemed necessary to filter the training database: half of the cueless sentences were randomly selected and deleted from the training dataset. Moreover, as there were only 44 investigation cues in the data, we omitted this class from training and evaluation as well, due to sparseness problems.

First, we applied ten-fold cross validation on the corpus. Since we had two domains of texts at hand, it enabled us to experiment with the two domains separately as well: ten-fold cross validation was carried out for both domains individually and we also made use of cross-domain settings, where one of the domains was used as the training database but the evaluation was performed on the other domain. For evaluation, we used the metrics precision, recall and F-score. The results of our experiments will be presented in Section 4.

3.3 Baseline Methods

As a baseline, we applied a simple dictionary lookup method. Lists mentioned among the lexical features were utilized here: whenever the lemma of the given word matched one of the words in the list, we tagged it as an uncertainty cue of the type determined by the given list.

4 Results

Table 2 shows the results of the baseline and machine learning experiments on the hUnCertainty corpus, obtained by ten-fold cross validation.

	Dictionary lookup			**Machine learning**			**Difference**		
Type	Precision	Recall	F-score	Precision	Recall	F-score	Precision	Recall	F-score
Weasel	18.12	35.92	24.09	52.48	30.73	38.76	+34.37	-5.19	+14.68
Hedge	55.10	32.42	40.82	61.26	48.94	54.41	+6.17	+16.52	+13.59
Peacock	21.66	30.77	25.42	32.61	11.88	17.41	+10.95	-18.89	-8.01
Epistemic	42.46	30.02	35.18	63.18	34.07	44.27	+20.72	+4.04	+9.09
Doxastic	29.30	46.16	35.85	52.42	46.26	49.15	+23.12	+0.10	+13.30
Condition	31.73	62.90	42.18	51.41	25.80	34.35	+19.68	-37.10	-7.83
Micro P/R/F	29.09	35.74	32.07	55.95	37.46	44.87	+26.86	+1.72	+12.80

Table 2: Results on the hUnCertainty corpus.

The results of the machine learning approach have outperformed those achieved by the baseline dictionary lookup method, except for two classes. This is primarily due to better precision, which has grown for each uncertainty category in the case of sequence labeling. However, recall values are more diverse: for hedges and epistemic cues, it has grown, for doxastic cues it has not changed significantly, but for peacocks and conditional cues we can see a serious decrease. The low recall values might be the reason why the F-score obtained by the dictionary lookup method is higher than the one obtained by machine learning in the case of peacocks and conditionals.

We also experimented separately on the two domains. Table 3 shows those on the news subcorpus, whereas Table 4 shows the results achieved on the Wikipedia subcorpus.

In both domains, we can observe that machine learning methods outperform the baseline dictionary lookup method, except for the peacock and conditional cue classes. However, there are domain differences in the results. First, weasels seem to be much hard to detect in the news subcorpus than in the

	Dictionary lookup			Machine learning			Difference		
Type	Precision	Recall	F-score	Precision	Recall	F-score	Precision	Recall	F-score

Micro P/R/F	32.28	36.40	34.21	59.70	37.5	46.06	+27.42	+1.10	+11.85

Table 4: Results on the Wikipedia subcorpus.

Wikipedia subcorpus (21.55 vs. 43.8 in terms of F-score). Second, peacocks are also harder to detect in the news subcorpus (F-scores of 14.41 vs. 20.22). Third, there is a considerable gap between the recall scores in the case of doxastic cues: in the Wikipedia subcorpus, the dictionary lookup method outperforms CRF (the difference is 36.13 percentage points) but in the news subcorpus, CRF achieves higher recall with 14.23 percentage points.

To further explore domain differences, we carried out some cross validation experiments. First, we trained our CRF model on the Wikipedia domain and then evaluated it on the news domain. Later, the model was trained on the news domain and evaluated on the Wikipedia domain. Tables 5 and 6 present the results, respectively, contrasted to the results achieved in the indomain settings. It is also striking that although the gain in micro F-score is almost the same in the two settings, the biggest difference can be observed for semantic uncertainty classes in the case of the Wikipedia → news setting, while the difference is much bigger for discourse-level uncertainty types in the news → Wikipedia setting.

	Cross validation			Indomain ten fold			Difference

Table 5: Cross-domain results: Wikipedia → news.

As some uncertainty detectors aim at identifying uncertain sentences only, that is, they handle the task at the sentence level and do not pay attention to the detection of individual cues (Medlock and Briscoe, 2007), we also applied a more relaxed evaluation metric. If at least one of the tokens within the sentence was labeled as an uncertainty cue – regardless of its type –, the sentence was considered as uncertain.

	Cross validation			Indomain ten fold			Difference		
Type	Precision	Recall	F-score	Precision	Recall	F-score	Precision	Recall	F-score
Weasel	71.26	6.87	12.53	59.26	34.74	43.8	-12.00	+27.87	+31.27
Hedge	63.48	26.33	37.22	64.59	50.02	56.38	+1.11	+23.69	+19.16

Table 6: Cross-domain results: news → Wikipedia.

Results on the identification of uncertain sentences are summarized in Table 7, in terms of precision, recall and F-score. It is revealed that here there are no sharp differences in performance as far as the indomain settings are concerned since the system can achieve an F-score of about 70 in both domains and on the whole corpus as well. However, in the cross-domain settings lower precision values and F-scores can be observed, while recall values basically remain the same with regard to the indomain settings.

Evaluation setting	Precision	Recall	F-score
hUnCertainty 10 fold	62.20	78.06	69.23
News 10 fold	67.38	78.01	72.30
Wikipedia 10 fold	60.32	80.05	68.80
Wikipedia → news	45.88	74.21	56.70
News → Wikipedia	35.73	84.61	50.24

Table 7: Machine learning results at the sentence level.

5 Discussion

Our results prove that a sequence labeling approach can be efficiently used for the automatic identification of uncertainty cues in Hungarian texts. With our baseline dictionary lookup method, the best results were achieved on the epistemic, conditional and hedge cues while the sequence labeling approach was the most successful on the hedge, epistemic and doxastic cues. All of this indicates that hedge and epistemic cues are the easiest to detect. On the other hand, uncertainty types where there was a small difference between the results achieved by the two approaches (for instance, semantic uncertainty cues in the Wikipedia subcorpus) are mostly expressed by lexical means and these cues are less ambiguous. In this setting, the detection of discourse-level uncertainty categories, however, profits more from machine learning, which is most probably due to the fact that here context (discourse) plays a more important rule hence a sequence labeling algorithm is more appropriate for the task, which takes into account contextual information as well.

In the case of peacocks and conditional cues the sequence labeling approach obtained worse results than dictionary lookup: in each case, precision got higher but recall seriously decreased. This suggests that these classes highly rely on lexical features and our machine learning system needs further improvement, with special regard to specific (lexical) features defined for these uncertainty categories.

As for domain differences, we found that the distribution of uncertainty cues differs in the two subcorpora, weasels being more frequent in Wikipedia whereas doxastic cues are more probable to occur in the news subcorpus. Domain differences concerning weasels and doxastic cues are highlighted in the cross domain experiments as well. When the training dataset contains fewer cues of the given uncertainty type, the performance falls back on the target domain: when trained on the news subcorpus, an F-score of 12.53 can be obtained for weasels in the Wikipedia subcorpus, which is 31.27 points less than the indomain results. Similarly, an F-score of 17.41 can be obtained for doxastic cues in the news domain

when Wikipedia is used as the training set but the indomain setting yields an F-score of 54.32.

All of the above facts may be related to the characteristics of the texts. Weasels are sourceless propositions and in the news media, it is indispensable to know who the source of the news is, thus, pieces are usually reported with their source provided and so, propositions with no explicit source (i.e. weasels) occur rarely in the news subcorpus. On the other hand, doxastic cues are related to beliefs and the news subcorpus consists of criminal news (mostly related to murders). When describing the possible reasons behind each criminal act, phrases that refer to beliefs and mental states are often used and thus this type of uncertainty is likely to be present in such pieces of news but not in Wikipedia articles.

In the cross domain experiments, indomain results outperform those obtained by the cross domain models. The difference in performance is significant (t-test, $p = 0.042$ for the news subcorpus and $p = 0.0103$ for the Wikipedia subcorpus). That is, the choice of the training dataset significantly affects the results, which indicates that there really are domain differences in uncertainty detection. There are only two exceptions that do not correspond to these tendencies: the peacock and conditional cues in the Wikipedia $\rightarrow$ news setting. The reason why a model trained on a different domain can perform better might lie in the size of the subcorpora. The Wikipedia domain contains much more peacock cues than the news domain and although the domains are different, training on a dataset with more cue instances seems to be beneficial for the results.

If we evaluate the models' performance at the sentence level rather than at the cue level, it can be observed that better results can be achieved, especially with regard to recall values. One reason for that may be that a single uncertain sentence may include more than one cues and should one of them be missed, it does not seriously harm performance (in case at least one cue per sentence is correctly detected).

If our results are compared to those achieved on semantic uncertainty cues found in English Wikipedia articles (Szarvas et al., 2012), it can be seen that the task seems to be somewhat easier in English than in Hungarian: that paper reports F-scores from 0.6 to 0.8. One possible reason for this is that there are typological differences between English and Hungarian and so, uncertainty marking is rather lexically determined in English but in Hungarian, morphology also plays an essential role. For instance, the modal suffixes *-hat/-het* correspond to the auxiliaries *may* and *might* and while in English they function as separate lexical items, in Hungarian they are always attached to the verbal stem and never occur on their own. This is reflected in the number of different cues as well: in the English dataset, there are 166 different semantic cues while in Hungarian, there are 319 (and note that the Hungarian corpus is about half of the size of the English one). As such, applying the word form or the lemma as features may result in relatively high F-scores in English, where the word form itself denotes uncertainty, but these features are less effective in Hungarian without any morphological features included. Another language-specific feature is that Hungarian is a pro-drop language, so in some cases, the pronominal subject may be omitted from the sentence. Subjectless sentences are a typical strategy in Hungarian to express sourceless statements (weasels), but the subject can be deleted due to syntactic ellipsis as well, thus distinguishing between subjectless sentences that denote uncertainty and those that do not is a special task in Hungarian uncertainty detection.

The outputs of the machine learning system were further investigated, in order to find the most typical errors our system made. It was revealed that the most problematic issue was the disambiguation of ambiguous cues. For instance, the words *számos* "several" or *sok* "many" may function as hedges or weasels, or *nagy* "big" may be a hedge or a peacock, depending on the context. Such cues were often misclassified by the system. Another common source of errors was that some cues have non-cue meanings as well, like the verb *tart*, which can be a doxastic cue with the meaning "think" but when it means "keep", it is not uncertain at all. The identification of epistemic cues that include negation words was also not straightforward: multiword cues such as *nem zárható ki* "it cannot be excluded" or *nem tudni* "it is not known" were not marked as cues by the system.

6 Conclusions

In this paper, we presented the first results on Hungarian uncertainty detection. For this, we made use of a manually annotated corpus, which contains texts from two domains: Wikipedia articles and pieces of news from a news portal. We contrasted the cue distribution in the two domains and we also experimented with uncertainty detection. For this purpose, we applied a supervised machine learning approach, which was based on sequence labeling and exploited a rich feature set. We reported the first results on uncertainty detection for Hungarian, which also prove that the performance on uncertainty detection is influenced by the domain of the texts. We hope that this study will enhance research on uncertainty detection for languages other than English.

In the future, we would like to improve our methods, especially in order to achieve better recall at the cue level. Furthermore, we would like to investigate domain specificities in more detail and we would also like to carry out some domain adaptation experiments as well.

Rediscovering Annotation Projection for Cross-Lingual Parser Induction

Jörg Tiedemann

Abstract

Previous research on annotation projection for parser induction across languages showed only limited success and often required substantial language-specific post-processing to fix inconsistencies and to lift the performance onto a useful level. Model transfer was introduced as another quite successful alternative and much research has been devoted to this paradigm recently. In this paper, we revisit annotation projection and show that the previously reported results are mainly spoiled by the flaws of evaluation with incompatible annotation schemes. Lexicalized parsers created on projected data are especially harmed by such discrepancies. However, recently developed cross-lingually harmonized annotation schemes remove this obstacle and restore the abilities of syntactic annotation projection. We demonstrate this by applying projection strategies to a number of European languages and a selection of human and machine-translated data. Our results outperform the simple direct transfer approach by a large margin and also pave the road to cross-lingual parsing without gold POS labels.

1 Introduction

Linguistic resources and tools exist only for a minority of the world's languages. However, many NLP applications require robust tools and the development of language-specific resources is expensive and time consuming. Many of the common tools are based on data-driven techniques and they often require strong supervision to achieve reasonable results for real world applications. Fully unsupervised techniques are not a good alternative yet for tasks like data-driven syntactic parsing and, therefore, cross-lingual learning has been proposed as a possible solution to quickly create initial tools for otherwise unsupported languages (Ganchev and Das, 2013).

In syntactic parsing, two main strategies have been explored in cross-lingual learning: annotation projection and model transfer. The first strategy relies on parallel corpora and automatic word alignment that make it possible to map linguistics annotation from a source language to a new target language (Yarowsky et al., 2001; Hwa et al., 2005; Täckström et al., 2013a). The basic idea is that existing tools and models are used to process the source side of a parallel corpus and that projection heuristics guided by alignment can be used to transfer the automatic annotation to the target language text. Using the projected annotation assuming that it is sufficiently correct, models can then be trained for the target language. However, directly projecting syntactic structure results in a rather poor performance when applied to resources that were developed separately for individual languages (Hwa et al., 2005). Extensive additional post-processing in form of transformation rules is required to achieve reasonable scores. Furthermore, incompatible tagsets make it impossible to directly transfer labeled annotation to a new language and previous literature on cross-lingual parsing via annotation projection is, therefore, bound to the evaluation of unlabeled attachment scores (UAS). Less frequent, but also possible, is the scenario where the source side of the corpus contains manual annotation (Agić et al., 2012). This addresses the problem created by projecting noisy annotations, but it presupposes parallel corpora with manual annotation, which are rarely available. Additionally, the problem of incompatible annotation still remains.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1854–1864, Dublin, Ireland, August 23-29 2014.

The second strategy, model transfer instead relies on universal features and the transfer of model parameters from one language to another. The main idea is to reduce the need of language-specific information, e.g. using delexicalized parsers that ignore lexical information. Drawing from a harmonized POS tagset (Petrov et al., 2012), transfer models have been used for a variety of languages. The advantage over annotation projection approaches is that no parallel data is required (at least in the basic settings) and that training can be performed on gold standard annotation. However, it requires a common feature representation across languages (McDonald et al., 2013), which can be a strong bottleneck. There are also several extensions to improve the performance of transfer models. One idea is to use multiple source languages to increase the statistical ground for the learning process (McDonald et al., 2011; Naseem et al., 2012), a strategy that can also be used in the case of annotation projection. Another idea is to enhance models by cross-lingual word clusters (Täckström et al., 2012) and to use target language adaptation techniques with prior knowledge of language properties and their relatedness when using multiple sources in training (Täckström et al., 2013b). Based on the success of these techniques, model transfer has dominated recent research on cross-lingual learning.

In this paper, we return to annotation projection as a powerful tool for porting syntactic parsers to new languages. Building on the availability of cross-lingually harmonized data sets, we show that projection performs well and outperforms direct transfer models by a large margin in contrast to previous findings on projection with incompatible treebanks. In the following, we first revisit the projection algorithms proposed earlier and discuss issues with transferring labels across languages. After that we report experimental results with various settings using human translations and machine-translated data. Finally, we also look at parsing results without gold standard POS labeling, which is ultimately required when porting parsers to new languages that lack appropriate resources.

2 Syntactic Annotation Projection

Hwa et al. (2005) propose a direct projection algorithm for syntactic dependency annotation. The algorithm defines several heuristics to map source side annotations to target languages using word alignments in a parallel corpus. The main difficulties with the projection arise with none-one-to-one links and unaligned tokens. Each of the following alignment types are adressed by the algorithm separately:

one-to-one: Copy relations $R(s_i, s_j)$ between source words s_i and s_j to relations $R(t_x, t_y)$ if s_i is aligned to t_x and s_j is aligned to t_y and nothing else.

unaligned source: Create an empty (dummy) word in the target language sentence that takes all relations (incoming and outgoing arcs) of the unaligned source language word.

one-to-many: Create an empty target word t_z that acts as the parent of all aligned target words $t_x, .., t_y$. Remove the alignments between s_i and $t_x, .., t_y$ and align s_i to the new empty word t_z instead.

many-to-one: Delete all alignments between $s_i, .., s_j$ and t_x except the link between the head of $s_i, .., s_j$ and t_x.

many-to-many: Perform the rule for one-to-many alignments first and then perform the rule for many-to-one alignments.

unaligned target: Remove all unaligned target words.

In contrast to Hwa et al. (2005), we are also interested in labeled attachment and the projection of POS annotation. Therefore, we copy labels through the alignment using the heuristics listed above. Figure 1 illustrates some of the cases discussed. There are some important implications due to the treatment of complex alignment types. The direct projection algorithm frequently creates dummy nodes and relations that have no correspondence in the source language. Here, we need to make some decisions on how to project the annotation from source to target sentences.

First of all, we decided to name all additional tokens created by the algorithm with the same string *DUMMY*. An alternative would be to invent unique names for each newly created token within each sentence but this would blow up the vocabulary and would not add useful information to the data.

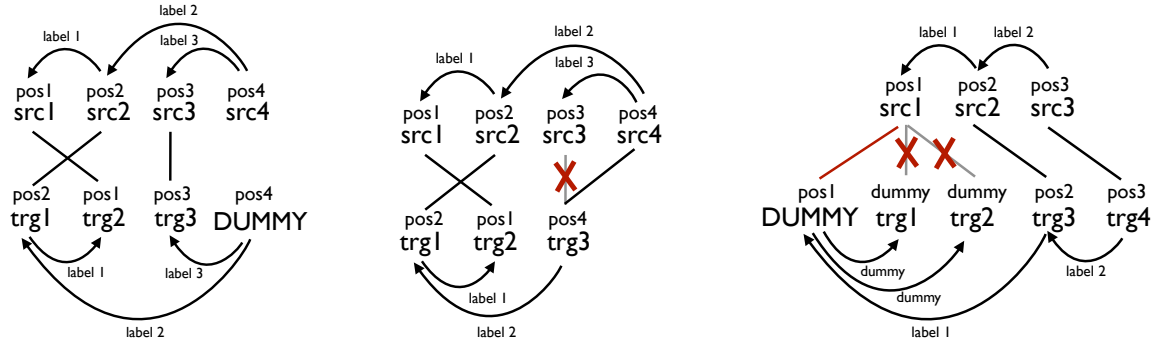

Figure 1: Annotation projection heuristics for special alignment types: Unaligned source words (left image), many-to-one alignments (center), one-to-many alignments (right image).

The second problem is related to the auxiliary relations that are created when treating one-to-many alignments. In these cases, multiple words are attached to newly created dummy nodes. However, no corresponding labels exist in the source language that would allow us to infer appropriate labels for these additional attachments. One possibility would be to use a specific label from the existing set of dependency relations, for example 'mwe'. However, one-to-many alignments do not always refer to proper multi-word expressions but often represent other grammatical or structural differences like the relation between the English preposition *'of'* which is linked together with the determiner *'the'* to the German determiner *'der'* in sentences like *'Resumption OF THE session'* translated to German *'Wiederaufnahme DER Sitzung'*. Therefore, we decided to label these additional dependency with a new unique label *dummy* instead of selecting an existing one.

Yet another problem arises with the projection of POS annotation. Similar to the labeling of dependency relations, we have to decide how to transfer POS tags to the target language in cases of one-to-many alignments. In our implementation, we transfer the source language label only to the newly created dummy node which dominates all target language words linked to the source language word in the projected dependency tree. The daughter nodes, however, obtain the label *dummy* even as their POS annotation. Alternatively, we may project the POS tag to all linked tokens according to the original alignment but our guiding principle is to resolve link ambiguity first using the heuristics in the direct projection algorithm and then to transfer annotation.

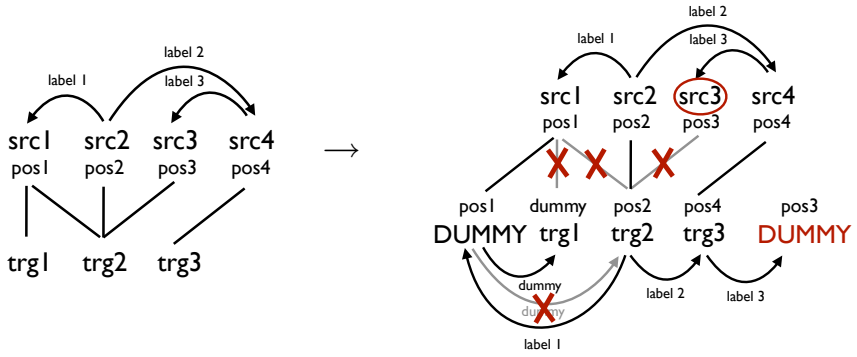

Figure 2: A complex example for annotation projection with many-to-many word alignments.

Finally, we also need to look at the interaction between the various projection heuristics. Figure 2 illustrates a complex case with many-to-many word alignments. Resolving the alignment ambiguity is not entirely straightforward. In our implementation, we start by looking at all one-to-many alignments and resolve them according to the definitions of the projection algorithm. In our example, this creates a *DUMMY* node that dominates target words *trg1* and *trg2* and links between *src1* and (*trg1*,*trg2*) are deleted. We label the new relations with *dummy*. The next step considers many-to-one alignments,

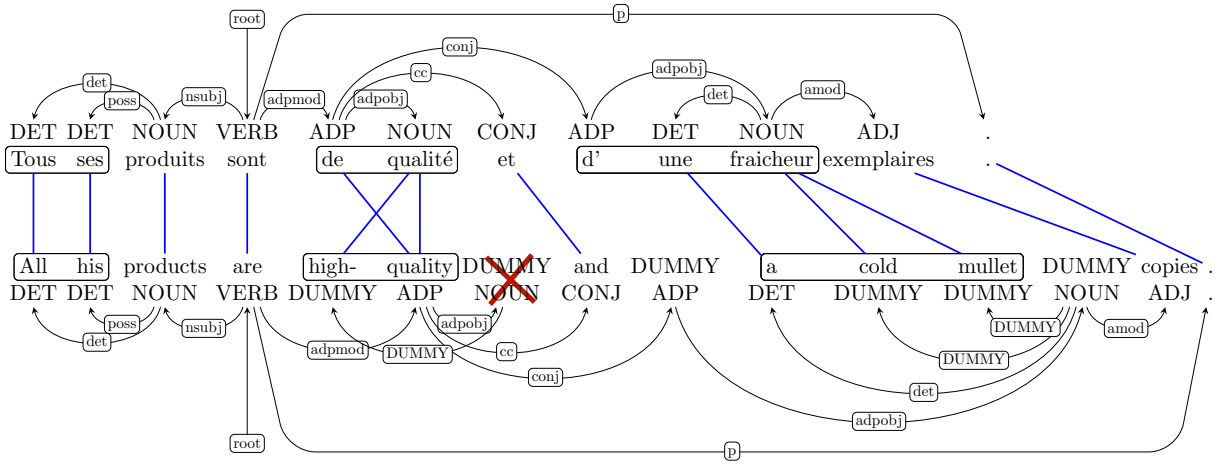

Figure 3: A complete projection example from a translated treebank including transitive relations over a *DUMMY* node that can safely be collapsed (which also removes the non-projectivity of the projected tree). The resulting relation between *quality* and *high-* will be labeled as *adpobj*. Note that projection errors appear due to the ambiguous alignments between *de qualité* and *high- quality*. Boxes indicate phrases that are translated as units by the SMT engine.

which, using the remaining links, is source words (*src2*,*src3*) aligned to *trg2*. According to the algorithm we delete the link between *src3* and *trg2* (because *src2* dominates *src3* in the source language tree) and proceed. This, however, creates an unaligned source language word (*src3*), which we treat in the next step. The unaligned token gives rise to the second *DUMMY* word, which is attached to *trg3* as the result of the alignment between *src4* and *trg3* and the relation between *src4* and *src3*. Finally, we can map all other relations according to the one-to-one alignment rule. This, however, creates a conflict with the already existing *dummy* relation between the first *DUMMY* word and *trg2*. Mapping according to the one-to-one rule turns the relation around and attaches the *DUMMY* word to *trg2* and labels the relation with *label 1*. Now, we could remove the second *DUMMY* node according to the rule about unaligned target language words. However, this rule should not apply to these special nodes as they may play a crucial role to keep elements connected in the final target language tree.

Another difficult case, which is not illustrated here, is when many-to-one alignments need to be resolved but the aligned source language words are siblings in the syntactic tree and no unique head can be identified. In our implementation, we randomly pick a node but more linguistically informed guesses would probably be better. Yet another difficult decision is the placement of the *DUMMY* nodes. We decided to put them next to the head node they attach to. Other heuristics are possible and all placements greatly influence the projectivity of the resulting tree structure. One final adjustment that we apply is the removal of unary productions over *DUMMY* nodes. We collaps all relations that run with single attachments via *DUMMY* nodes to reduce the number of these uninformative tokens. This may also have positive effects on projectivity as we can see in the example in Figure 3.

3 Machine-Translated Treebanks

Another strategy for annotation projection is based on automatic translation. Machine translation models can be used to create synthetic parallel data for projecting annotations from one language to another (Tiedemann et al., 2014). Recent advances in machine translation (MT) are now making this a realistic alternative. The use of direct treebank translation instead of existing parallel corpora has several important advantages. First of all, we skip the use of an error-prone annotation step when producing the source language side of the training data. Starting with a noisy source language annotation, we accumulate two sources of errors in annotation projection. However, with direct translation we can start with the gold standard annotation provided in the original treebank. Furthermore, we avoid problems of domain shifts which is typically the case when applying a parser trained on one domain to texts (a parallel corpus in

our case) coming from another domain. Finally, we can also assume that machine translation produces output which is closer to the original text than most human translations will be in any parallel corpus. Even if this may sound as a disadvantage, for projection this is preferred. Being close to the original source makes it easier to map annotation from one language to another as we expect a lower degree of grammatical and structural divergences that originate in the linguistic freedom human translators can apply. Furthermore, common statistical MT models inherently provide alignments between words and phrases, which removes the requirement to apply yet another error-prone alignment step on the parallel data. In the experiments below we, therefore, explore the translation strategy as yet another way of applying annotation projection.

4 Experiments

In the following, we show our experimental results using annotation projection in several cross-lingual scenarios. However, we start by presenting a delexicalized baseline, which is, to our knowledge, the only previous model that has been presented for labeled dependency parsing across languages using the recently created Universal Treebank. We will use this baseline as reference point even though our projection models are not directly comparable with delexicalized direct transfer models. Note that all results below are computed on the held-out test data sections of the Universal Treebank if not stated otherwise.

4.1 Delexicalized Baselines

McDonald et al. (2013) present the Universal Treebank that comes with a harmonized syntactic annotation scheme across six languages. This data set enables cross-lingual learning of labeled dependency parsing models. McDonald et al. (2013) propose delexicalized models as a simple baseline for model transfer and present encouraging labeled attachment scores (LAS) especially for closely related languages. As a reference, we have created similar baseline models using the same data set but a slightly different setup, which is compatible with the experiments we present later. Table 1 summarizes the scores in terms of LAS for all language pairs in the data set.[1] In our setup, we apply MaltParser (Nivre et al., 2006) and optimize feature models and learning parameters using MaltOptimizer (Ballesteros and Nivre, 2012). For all cross-lingual experiments (columns represent target languages we test on), we always use the same feature model and parameters as we have found for the source language treebank. Contrasting our models with the scores from McDonald et al. (2013), we can see that they are comparable with some differences that are due to the tools and learning parameters they apply which are along the lines of Zhang and Nivre (2011).

4.2 Annotation Projection with Human Translations

Our first batch of projection experiments considers parallel data taken from the well-known Europarl corpus, which is frequently used in research on statistical machine translation (SMT). It contains large quantities of translated proceedings from the European Parliament for all but one language (namely

[1]Note that we include punctuation in our evaluation. Ignoring punctuation leads to slightly higher scores but we do not report those numbers here.

Korean) that are included in the Universal Treebank v1. The entire corpus (version 7) contains over two million sentences in each language and we use increasing amounts of the corpus to investigate the impact on cross-lingual parser induction. The corpus comes with automatic sentence alignments and is quite clean with respect to translation quality and sentence alignment accuracy. It is, therefore, well suited for our initial experiments with annotation projection even though the domain does not necessarily match the one included in the treebank test sets.

Another important prerequisite for annotation projection is word alignment. Following the typical setup, we rely on automatic word alignment produced by models developed for statistical machine translation. Similar to Hwa et al. (2005), we apply GIZA++ (Och and Ney, 2003) to align the corpus for all language pairs in all translation directions using IBM model 4 Viterbi alignments. In contrast to Hwa et al. (2005), we then use symmetrization heuristics to combine forward and backward alignments, which is common practice in the SMT community. In particular, we apply the popular grow-diag-final-and heuristics as implemented in the Moses toolbox (Koehn et al., 2007).

Let us first look at unlabeled attachment scores to compare results that can be achieved with harmonized annotation in contrast to the ones that we can see on the cross-lingually incompatible data from the CoNLL shared task (Buchholz and Marsi, 2006). Table 2 lists the scores that we obtain when applying our implementation of the direct projection algorithm.[2] As expected, the performance on the CoNLL data is rather poor, which confirms the findings of Hwa et al. (2005) even though our scores are significantly above their results without post-correction. The scores on the Universal Treebank data, however, are up to about 20 UAS points higher than the corresponding results on CoNLL data but without any of the extensive post-processing transformations proposed by Hwa et al. (2005).

Moreover, the real power of the harmonized annotation in the Universal Treebank comes from the possibility to obtain attachment labels. The table in Figure 4 shows the labeled attachment scores obtained for training on 40,000 sentences[3] of each language pair. Next to the table in Figure 4 we also show the

Table 3: Cross-lingual parsing results (LAS) using translated treebanks (phrase-based model) and DCA-based annotation projection. The table to the left contrasts the result with two-sample jackknifing experiments where the source side dependencies are created by automatically parsing each half of the treebank using a model trained on the other half of the training data.

learning curves for increasing amounts of training data using the example of data projected from English to other languages. The figure illustrates that the LAS levels out at around 10,000 - 20,000 sentences and this trend is essentially the same for all other languages as well.

4.3 Annotation Projection with Synthetic Machine-Translated Data

The next possibility we would like to explore is the use of synthetic parallel data. Annotating parallel data with a statistical parser may lead to quite a lot of noise especially when the domain does not match the original training data. Starting with noisy source language annotations, the projection algorithm may transfer errors to the target language that can cause problems for the target language parsing model induced from that data. Using machine translation and the original source language treebanks, we avoid this kind of error propagation. Furthermore, we suspect that human translations are more difficult to align on the word level then machine translated data which are inherently based on word alignments and, therefore, tend to be more literal and consistent (Carpuat and Simard, 2012). Using statistical MT as our translation model, we can also obtain such alignment as a given output from the decoding process, which makes it unnecessary to run yet another error-prone process such as automatic word alignment. Furthermore, the treebank data is too small to be used alone with generative statistical alignment models. Concatenating the data with larger parallel data would help but domain mismatches may, again, negatively influence the alignment performance.

In the following, we show the cross-lingual scores obtained by translating all treebanks in the Universal Treebank to all other languages. We leave out Korean here again, because no SMT training data is included in Europarl for that language. The translation models are trained on the entire Europarl corpus using a standard setup for phrase-based SMT and the Moses toolbox for training, tuning and decoding (Koehn et al., 2007). For tuning we use MERT (Och, 2003) and the newstest 2012 data provided by the annual workshop on statistical machine translation.[4] and for language modeling, we use a combination of Europarl and News data provided from the same source. The language model is a standard 5-gram model estimated from the monolingual data using modified Kneser-Ney smoothing without pruning (applying KenLM tools (Heafield et al., 2013)).

Table 3 summarizes the labeled attachment scores obtained with our projection approach on synthetic machine-translated data. The main observation we can make here is that this approach is very robust with respect to the noise introduced by the translation engine. Automatic translation is a difficult task on its own but we still achieve results that are similar to the ones from the projection approach on human translated data. Note that our training data is now much smaller[5] compared to the data sizes used in Section 4.2 and, still, we outperform those models in several cases. This seems to prove that it can be a clear advantage to start with gold annotations in the source language and to have a close alignment between source and target language. An indication for this effect is illustrated by the contrastive jackknifing experiments shown in Table 3. The scores are generally lower with two minor exceptions. Note

[4] http://www.statmt.org/wmt14

[5] Most treebanks includes 2,000-5,000 sentences, except English with about 40,000 sentences.

that this experiment does not cover domain shift problems. Another trend that can be seen in our results is that some languages such as German are more difficult to translate to (which can be confirmed by the SMT literature) leading to lower cross-lingual parsing performance.

4.4 The Impact of Word Alignment

Crucial for the success of annotation projection is the quality of the word alignment used to map information from the source to the target language. Not only alignment errors cause problems but also ambiguous alignments can lead to projection difficulties as we have discussed before. In the previous sections, we relied on symmetrized word alignments that are common in the SMT community, which are based on Viterbi alignments created by the final IBM model 4 in the typical training pipeline. Even though this is a reasonable setup for training phrase-based SMT models (as presented in the previous section), the chosen symmetrization heuristics (grow-diag-final-and) may not be well suited for accurate annotation projection. In particular, it is known that these heuristics focus on recall and tend to add many additional links that may not be useful for our projection task and even lead to some confusion as depicted in the example in Figure 3.

In order to investigate the impact of word alignment, we, therefore, decided to look at other sym-

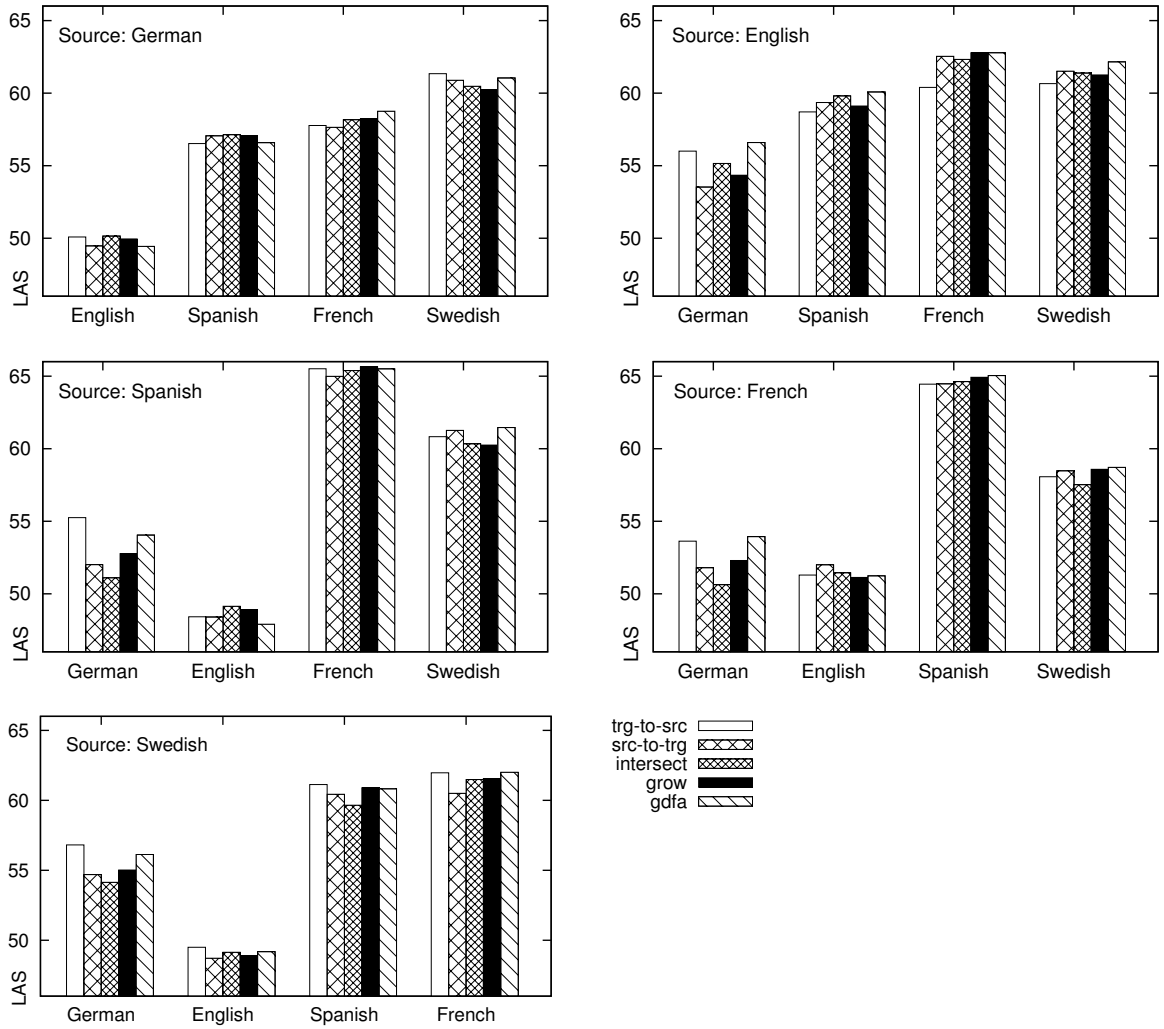

Figure 5: The impact of word alignment symmetrization on projection and parsing accuracy. *src-to-trg* and *trg-to-src* refer to the original directional Viterbi word alignments created by IBM model 4 in both directions; *intersect* refers to the intersection of both IBM 4 alignments; *grow* and *gdfa* (grow-diag-final-and) refer to popular symmetrization heuristics used in the SMT community.

metrization heuristics and their effect on projection and the quality of the parser model trained on the projected data. For this, we return to the setup of projecting annotations on human translations using the Europarl corpus with the same settings as described in Section 4.2 (using 40,000 sentences for the projection). We now compare five different word alignments based on IBM model 4 trained on the entire corpus for each language pair. First of all, we look at the original directional word alignment from source to target language and vice versa. We then include the intersection of these two directional link sets to represent a symmetrization heuristics that produces very sparse but high precision word alignments. Finally, we also consider the *grow* heuristics that adds adjacent alignment points coming from the union of directional alignment links to the sparse intersection of the same. In this way, the resulting word alignment covers most words while keeping precision at a rather high level. All of these alignment types are then contrasted with the *grow-diag-final-and* heuristics that we use in our default setup.

Figure 5 plots the parsing performance across languages based on the projection with the various alignment techniques listed above. A general observation is that the differences are rather small in most cases. Projecting annotation using the direct correspondence assumption seems to be quite robust with respect to alignment noise. In our experiments, no specific tendencies can be identified that would allow to draw immediate conclusions and to give clear recommendations for our task. Somewhat surprisingly we can see that the recall-oriented alignment heuristics (*grow-diag-final-and*) actually perform quite well in many cases, leading either to the best performing model or to one that is very close to the best result. However, in some cases, these models fall behind the ones based on alignment intersections (for instance Spanish-English) or directional word alignments (for example for Spanish-German, French-English, Swedish-German). A striking difference can be seen in the annotations projected to German. There, the target-to-source alignment performs pretty well and outperforms in two cases all other alignment types in the down-stream task. Furthermore, the intersection falls far behind in three of these cases, which indicates that both alignment directions are probably very different from each other leading to a very sparse word alignment when intersecting them. One possible reason for the success of the directional alignment might be that it favors the mapping to a compounding language such as German that frequently requires many-to-one links. However, the same effect cannot be seen for the other compounding language in our test set, Swedish.

4.5 Parsing Without Golden POS Labels

For a truly unsupported language, it does not make sense to assume a high quality POS tagger. Nevertheless, most cross-lingual experiments test their performance on data with human annotated golden POS labels. This is similar to the tradition of monolingual parsing where test accuracy is measured with perfect tokenization and completely correct POS annotation. In practice, this would not be realistic where new data needs to be parsed without proper tagging and unambiguous tokenization.

Direct transfer models are even more dependent on POS labels as those are the only source of information they can work with when making attachment decisions. Annotation projection approaches, on the other hand, are able to transfer POS information as well, which allows to train tagger models on projected data. In this section, we would like to test the feasibility of such an idea to see if we can truly port a parser to a new language without additional assumptions.

The first step is to train tagger models on our projected data sets. For this, we use the translated treebanks and a simple word-by-word translation approach in which we translate single-word-phrases only in our standard SMT model. The word-by-word translation model assures that we do not contaminate the data with DUMMY nodes and labels even though the translation quality lags behind the more powerful phrase-based models with larger translation options. We train standard Markov taggers with suffix backoff using HunPos (Halácsy et al., 2007) on each of the projected training data sets from the Universal Treebank. Table 4 summarizes the performance of all tagger models tested on the test sets in the treebank. The tagger all use the same universal POS tagset with its 12 labels as used in the Universal Treebank (Petrov et al., 2012). As we can see, the performance of those taggers is not great but still rather informative with overall accuracy values around 80%. The drop from source data to projected data is about 10-15 absolute points, which is, however, quite dramatic. Assuming that this is the best we can

achieve for the target language, we now have to look at the parsing performance when relying on such noisy annotation.

Firstly, we look at the delexicalized baselines. The bottom-left part of Table 4 lists the labeled attachment scores when gold POS labels are replaced with automatic tags created by the corresponding projection tagger. The drop is huge and the original scores that were well above 50-70% go down to not more than 30-40% LAS. Clearly, this was to be expected as proper POS labeling is crucial for these models. Let us now look at the annotation projection approach using a translated treebank as our parallel data set. Table 4 on the bottom-right lists the corresponding labeled attachment scores with automatic POS tags. As expected, the performance is considerably lower than with golden POS labels, which are still the most informative features in those models. However, the performance remains in a range of above 40-50% LAS. Clearly, the lexical features help to keep the performance up at a higher level than the delexicalized baselines. We believe, that this difference can be crucial when porting language tools to new languages and that the models can be further optimized to rely less on golden POS tags.

5 Conclusions

In this paper we revisit annotation projection for cross-lingual parser induction. We show that annotation can successfully be transfered to target languages if the annotation is harmonized across languages. Despite previous negative results on diverse treebanks we demonstrate that direct projection works very well for a number of languages and outperforms direct delexicalized transfer models by a large margin. The approach is also quite robust with respect to word alignment. Furthermore, we show that machine translation can be a useful alternative for this strategy and that projected data can also be used to induce basic information such as POS labels in combination with syntactic parser models.

Synchronous Constituent Context Model for Inducing Bilingual Synchronous Structures

Abstract

Traditional Statistical Machine Translation (SMT) systems heuristically extract synchronous structures from word alignments, while synchronous grammar induction provides better solutions that can discard heuristic method and directly obtain statistically sound bilingual synchronous structures. This paper proposes Synchronous Constituent Context Model (SCCM) for synchronous grammar induction. The SCCM is different to all previous synchronous grammar induction systems in that the SCCM does not use the Context Free Grammars to model the bilingual parallel corpus, but models bilingual constituents and contexts directly. The experiments show that valuable synchronous structures can be found by the SCCM, and the end-to-end machine translation experiment shows that the SCCM improves the quality of SMT results.

1 Introduction

Traditional Statistical Machine Translation (SMT) learns translation model from bilingual corpus that is sentence aligned. No large-scale hand aligned structures inside the parallel sentences are usually available to the SMT community, while the aligned structures are essential for training the translation model. Thus, various unsupervised methods had been explored to automatically obtain aligned structures inside the parallel sentences. Currently, the dominant method is a two step pipeline that obtains word alignments by unsupervised learning (Brown et al., 1993) at the first step, then obtains aligned structures at the second step by heuristically extracting all bilingual structures that are consistent with the word alignments.

The second step in this two step pipeline is problematic due to its obtained aligned structures, whose counts are heuristically collected and violate valid translation derivations, while most SMT decoders perform translation via valid translation derivations. This problem leads to researches on synchronous grammar induction that discards the heuristic method and the two separate steps pipeline.

Synchronous grammar induction aims to directly obtain aligned structures by using one statistically sound model. The aligned structures in synchronous grammar induction are hierarchical/syntax level (Cohn and Blunsom, 2009) synchronous structures, which can be modeled by Synchronous Context Free Grammars (SCFGs) (Cohn and Blunsom, 2009; Levenberg et al., 2012; Xiao et al., 2012; Xiao and Xiong, 2013) or a kind of SCFGs variant - Inversion Transduction Grammars (ITGs) (Neubig et al., 2011; Cohn and Haffari, 2013). Both SCFGs and ITGs are studied in recent years by using generative or discriminative modeling.

This paper departs from using the above two traditional CFGs-based grammars, and proposes Synchronous Constituent Context Model (SCCM) which models synchronous constituents and contexts directly so that bilingual translational equivalences can be directly modeled. The proposed SCCM is inspired by researches on monolingual grammar induction, whose experience is valuable to the synchronous grammar induction community due to its standard evaluation on released monolingual treebanks, while no hand annotated bilingual synchronous treebank is available for evaluating synchronous

grammar induction. According to the evaluation results, the state-of-the-art monolingual grammar induction was achieved by Bayesian modeling of the Constituent Context Model (CCM) (Duan et al., 2013; Klein and Manning, 2002), while traditional CFGs based monolingual grammar induction methods perform well below the CCM.

In view of the significant achievements of the CCM in monolingual grammar induction, we propose the SCCM to apply the CCM to the bilingual case. The tremendous possible constituents and contexts incurred in this bilingual case put a challenge for the SCCM to model such kind of sparse variables. We further propose a non-parametric Bayesian Modeling of the SCCM to cope with the sparse variables. Experiments on Chinese-English machine translation show that meaningful synchronous phrases can be detected by our SCCM, and the performance of the end-to-end SMT is significantly improved.

The rest of the paper is structured as follows: we propose the SCCM in Section 2. The non-parametric Bayesian modeling of the SCCM is presented in Section 3, followed by the presentation of posterior inference for the Bayesian SCCM. Then experiments and results are presented. Conclusion are presented in the final section.

2 Synchronous Constituent Context Model (SCCM)

We propose the SCCM to model synchronous structures explicitly. Unlike Synchronous Context Free Grammars (SCFGs) which are defined on latent production rules of parallel corpus, the SCCM deals with both synchronous tree spans ($syn\ spans$) and non-synchronous spans ($non\text{-}syn\ spans$). All spans are represented by two kinds of strings: bilingual constituents and bilingual contexts. The SCCM is a generative model defined over such representations.

2.1 Bilingual Constituents and Contexts

By extending the concept of constituents and contexts introduced in (Klein and Manning, 2002), we define bilingual constituents and contexts as follows. Bilingual constituents are pairs of contiguous surface strings of sentence spans (bilingual subsequences), bilingual contexts are tokens preceding and following the bilingual constituents. In the SCCM, each bi-span in a sentence pair, either a $syn\ span$ or a $non\text{-}syn\ span$, is represented by a bilingual constituent and a bilingual context.

Fig. 1 gives an illustration of the bilingual constituents and contexts. In Fig. 1-(a), a latent synchronous tree over the example sentence pair is illustrated. With the word alignments shown in the sentence pair, the latent tree over the target sentence "$e_1\ e_2\ e_3$" can be inferred. For the ease of presentation, the latent target side tree is neglected in Fig. 1-(a).

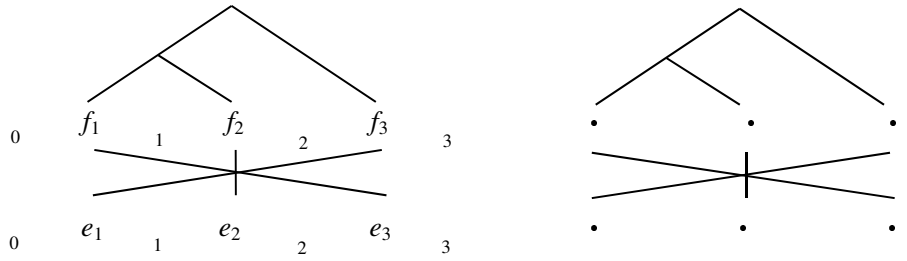
Given the synchronous tree, two sets of bilingual constituents and contexts can be extracted as shown in the two tables of Fig. 1. One is about $syn\ span$s, the other is about $non\text{-}syn\ span$s. $\diamond$ appearing in the contexts denotes a sentence boundary. *nil* appearing in the constituents of the non-tree spans denotes an empty span, which is actually a space between two terminals (or between a terminal and $\diamond$).

2.2 Generative Model

The SCCM computes the joint probability of a sentence pair S and its synchronous tree T as below:

$$\begin{aligned} &P(S,T) = P(S|T)P(T) = P(S|T)P(B)P(T|B) \\ &= P(S|T)P(B) \prod_{\substack{0\le i\le j\le m \\ 0\le p\le q\le n}} P(\alpha_{ij,pq}|B_{ij,pq})P(\beta_{ij,pq}|B_{ij,pq}) \end{aligned} \tag{1}$$

where B denotes a synchronous bracketing skeleton, in which no words are populated. Fig. 1-(b) shows the skeleton of Fig. 1-(a). The skeleton B is considered being filled by the synchronous tree T, and $P(T|B)$ is decomposed into conditional probabilities of bilingual constituents α and contexts β conditioning on $B_{ij,pq}$, a Boolean variable indicating whether the under-consideration bi-span $<i,j><p,q>$ is a $syn\ span$ or not. In particular, $\alpha_{ij,pq}$ denotes the bilingual constituent spanning from i to j on source side sentence, and spanning from p to q on target side sentence. $\beta_{ij,pq}$ denotes the context of $\alpha_{ij,pq}$.



(*a*) (*b*)

syn span	<0,1><2,3>	<1,2> <1,2>	<2,3><0,1>	<0,2><1,3>	<0,3><0,3>
constituent	$(f_1)(e_3)$	$(f_2)(e_2)$	$(f_3)(e_1)$	$(f_1 f_2)(e_2\ e_3)$	$(f_1 f_2 f_3)(e_1\ e_2\ e_3)$
context	$(\diamond\text{-}f_2)(e_2\text{-}\diamond)$	$(f_1\text{-}f_3)(e_1\text{-}\ e_3)$	$(f_2\text{-}\diamond)(\diamond\text{-}\ e_2)$	$(\diamond\text{-}f_3)(e_1\text{-}\diamond)$	$(\diamond\text{-}\diamond)(\diamond\text{-}\diamond)$

constituent	$(f_2 f_3)(e_1)$	$(nil)(e_2)$	…
context	$(f_1\text{-}\diamond)(\diamond\text{-}e_2)$	$(f_1\text{-}f_2)(e_1\text{-}\ e_3)$	…

Figure 1: Illustration of bilingual constituents and contexts over a sentence pair which consists of a source side sentence "$f_1\ f_2\ f_3$" and a target side sentence "$e_1\ e_2\ e_3$". In (a), the bottom numbers around each word are indexes for denoting spans. A synchronous tree is illustrated in (a), based on which two sets of bilingual constituents and contexts are extracted as shown in the two tables below the tree. Take a $syn\ span$ <1,2><1,2> for example, the source side span <1,2> is "f_2" and the target side span <1,2> is "e_2". They constitutes a bilingual constituent "$(f_2)(e_2)$", whose context is "$(f_1\text{-}f_3)(e_1\text{-}e_3)$" that is preceding and following the bilingual constituent. Figure (b) shows the skeleton of figure (a).

$B_{ij,pq}$ is defined as below:

$$B_{ij,pq} = \begin{cases} 1 & if\ bispan < i,j >< p,q > is\ a\ syn\ span \\ 0 & otherwise \end{cases}$$

In the SCCM, skeletons Bs are restricted to be binary branching and are distributed uniformly. Furthermore, since T and S are consistent, $P(S|T)$ is always equal to 1 in Eq. (1). Therefore, we can infer (with the expansion of the continued multiplication operator of Eq. (1)):

$$P(S,T) \propto \prod_{<i,j><p,q>\in T} (P(\alpha_{ij,pq}|B_{ij,pq}=1)P(\beta_{ij,pq}|B_{ij,pq}=1)) \prod_{<i,j><p,q>\notin T} (P(\alpha_{ij,pq}|B_{ij,pq}=0)P(\beta_{ij,pq}|B_{ij,pq}=0)) \quad (2)$$

where $<i,j><p,q> \in T$ indicates that bi-span $<i,j><p,q>$ is a $syn\ span$ contained in T, $<i,j><p,q> \notin T$ indicates otherwise case. Formula (2) is the basis for Bayesian modeling of the SCCM and the posterior inference that are proposed in the following sections.

3 Bayesian Modeling for the SCCM

For the SCCM, the posterior of a synchronous tree T given the observation of a sentence pair S is: $P(T|S) \propto P(S,T)$. As shown in formula (2), it turns out that the posterior $P(T|S)$ depends on the four kinds of distributions:

$$P(\alpha_{ij,pq}|B_{ij,pq}=1) \qquad P(\beta_{ij,pq}|B_{ij,pq}=1)$$
$$P(\alpha_{ij,pq}|B_{ij,pq}=0) \qquad P(\beta_{ij,pq}|B_{ij,pq}=0)$$

We propose to define two kinds of Bayesian priors over the constituents related variables $\alpha_{ij,pq}|B_{ij,pq}$ and the contexts related variables $\beta_{ij,pq}|B_{ij,pq}$ respectively. Since constituents exhibits richer appearances than contexts, the proposed Bayesian prior over $\alpha_{ij,pq}|B_{ij,pq}$ is more complicate than that over $\beta_{ij,pq}|B_{ij,pq}$.

Specifically, one of the non-parametric Bayesian priors, the Pitman-Yor-Process (PYP) prior, is defined on $\alpha_{ij,pq}|B_{ij,pq}$. The PYP prior can produce the power-law distribution (Goldwater et al., 2009) that is commonly observed in natural languages, and can flexibly model distributions on layer structures due to its defined distribution on distribution hierarchy. The PYP prior had been successfully applied on many NLP tasks such as language modeling (YeeWhye, 2006), word segmentation (Johnson et al., 2007b; Goldwater et al., 2011), dependency grammar induction (Cohen et al., 2008; Cohn et al., 2010), grammar refinement (Liang et al., 2007; Finkel et al., 2007) and Tree-Substitution Grammar induction (Cohn et al., 2010). We use the PYP to model the constituents' layered structure by using the PYP's distribution hierarchy. On $\beta_{ij,pq}|B_{ij,pq}$, we use the Dirichlet distribution for its simplicity because contexts appear in much fewer kinds of surface strings than those of constituents.

3.1 The PYP Prior over Bilingual Constituents

Constituents consist of both words and POS tags. Though in much monolingual grammar induction works, only POS tag sequences were used as the observed constituents for their significant hints of phrases (Klein and Manning, 2002; Cohn et al., 2010), our work needs considering raw words as observation data too because word alignments encode the important translation correspondence and contribute to synchronous bi-spans. But it causes severe data sparse problem due to the quite large number of unique constituents consisting of both words and POS tags. Besides, constituents can be extremely long which intensify the data sparse problem. So, solely using the surface strings of constituents is impractical.

In this section, we propose a hierarchical representation of constituents to overcome the data sparse problem and use the PYP prior on this kind of representation. From top to bottom, the hierarchical representation encodes the information of a bilingual constituent from fine-grained level to coarse-grained levels. The probability of a fine-grained level can be backed-off to the probabilities of coarse-grained levels.

The first (top) level of the hierarchical representation is the bilingual constituent itself. The second level is composed of two sequences: one is word sequence, the other is POS tags sequence. The third level mainly decomposes the second level into boundaries and middle words/POSs. Since the target of inducing synchronous structures in this paper is to induce the latent phrasal equivalences of a parallel sentence, boundaries of bilingual constituents play the key role of identifying phrasal equivalences. The third level is the function to make use of boundaries. Fig. 2 gives an illustration of the hierarchical representation.

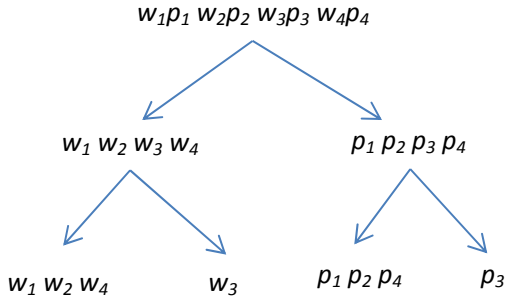

Figure 2: Illustration of the hierarchical representation of a bilingual constituent "w_1p_1 w_2p_2 w_3p_3 w_4p_4". Here w and p denote word and POS respectively, and the suffixes denote positions. Note that both w and p are composite, w denotes a source side word and a target side word, and p denotes the POS case. The second level decomposes the first level into a word sequence and a POS sequence, and the third level decomposes further into boundaries and middle words/POSs. The boundary width in this figure is two for left side boundary and one for right side boundary.

The PYP prior encodes distribution on distribution. Recursively using the PYP prior can create a distribution hierarchy, which is appropriate for modeling the distribution over the hierarchical representations of constituents. Smoothing is fulfilled through backing-off fine-grained level distributions to coarse-grained level distributions.

3.1.1 The PYP Hierarchy

We define the PYP hierarchy over the hierarchical representation of bilingual constituents in a top-down manner. For the topmost (first) level:

$$\begin{aligned} \alpha_{ij,pq}|B_{ij,pq} = b &\sim G_b^{first} \\ G_b^{first} &\sim PYP(d_b^{first}, \theta_b^{first}, P_{word-pos}(.|B_{ij,pq} = b)) \end{aligned}$$

The PYP has three parameters: $(d_b^{first}, \theta_b^{first}, P_{word-pos})$. $P_{word-pos}(.|B_{ij,pq} = b)$ is a $base\ distribution$ over infinite space of bilingual constituents conditioned on span type b, which provides the back-off probability of $P(\alpha_{ij,pq}|B_{ij,pq} = b)$. The remaining parameters d_b^{first} and θ_b^{first} control the strength of the base distribution.

The back-off probability $P_{word-pos}(\alpha_{ij,pq} = x|B_{ij,pq} = b)$ is defined as below:

$$P_{word-pos}(\alpha_{ij,pq} = x|B_{ij,pq} = b)) = P_{word}(Rw(x)|b) \times P_{pos}(Rp(x)|b)$$

where $Rw(x)$ is the function returning a word sequence of a bilingual constituent x, $Rp(x)$ returning the correspondent POS sequence. This is the second level of the hierarchical representation of bilingual constituents as illustrated in Fig. 2. Further, $Rw(x)$ and $Rp(x)$ are decomposed into the third level of the hierarchy. Taking $Rw(x)$ for example:

$$P_{word}(Rw(x)|B_{ij,pq} = b)) = P_{word-bound}(Rwb(x)|b) \times \frac{1}{|W|^{|Rw(x)|-|Rwb(x)|}}$$

where Rwb is a function returning a word sequence's boundary representation, $|W|$ is the vocabulary size, $|Rw(x)| - |Rwb(x)|$ is the number of the words in $Rw(x)$ excluding those in the boundary representation. The above equation models the generation of a word sequence with surface string $Rw(x)$ (given b) by first generating its boundary representation $Rwb(x)$, then generating its middle words from a uniform distribution over the vocabulary. $P_{pos}(Rp(x)|B_{ij,pq} = b))$ is defined similarly.

We put the Dirichlet prior over $P_{word-bound}(Rwb(x)|b)$:

$$\begin{aligned} Rwb(x)|b &\sim Discrete(G_b^{Rwb}) \\ G_b^{Rwb} &\sim Dirichlet(\tau_b) \end{aligned}$$

For $P_{pos-bound}(Rpb(x)|b)$, similar definition to $P_{word-bound}(Rwb(x)|b)$ is applied.

3.2 The Dirichlet Prior over Bilingual Contexts

The Dirichlet prior is defined as below:

$$\begin{aligned} \beta_{ij,pq}|B_{ij,pq} = b &\sim Discrete(G_b^{Dir}) \\ G_b^{Dir} &\sim Dirichlet(\tau_b) \end{aligned}$$

A context $\beta_{ij,pq}$ (given the specific span type b) is drawn $i.i.d$ according to a multinomial parameter G_b^{Dir}, which is drawn from the Dirichlet distribution with a real value parameter τ_b.

4 MCMC Sampling for Inferring the Latent Synchronous Trees

We approximate the distribution over latent synchronous trees by sampling them from the posterior $P(T|S)$, where T is a latent synchronous tree of a sentence pair S. As presented in the beginning of section 3, the posterior depends on $P(\alpha_{ij,pq}|B_{ij,pq} = b)$ and $P(\beta_{ij,pq}|B_{ij,pq} = b)$, on which we put the PYP prior and the Dirichlet prior respectively. Because of integrating out all Gs in all of the priors, interdependency between samples of $\alpha_{ij,pq}|B_{ij,pq} = b$ or $\beta_{ij,pq}|B_{ij,pq} = b$ is introduced, resulting in simultaneously obtaining multiple samples impractical. On the other hand, blocked sampling, which obtains sentence-level samples simultaneously (Blunsom and Cohn, 2010; Cohn et al., 2010; Johnson et al., 2007a) is attractive for the fast mixing speed and the easy application of standard dynamic programming algorithms.

4.1 Metropolis-Hastings (MH) Sampler

We apply a MH sampler similar to (Johnson et al., 2007a) to overcome the difficulty of obtaining multiple samples simultaneously from posterior. The MH sampler is a MCMC technique that draws samples from a true distribution by first drawing samples simultaneously from a proposal distribution, and then correcting the samples to the true distribution by using an accept/reject test. In practical, the proposal distribution is designed to facilitate the use of blocked sampling that applies standard dynamic programming, and the resulting samples are corrected by the accept/reject test to the true distribution.

In our case, the proposal distribution is the Maximum-a-Posteriori (MAP) estimate of $P(\alpha_{i,j}|B_{i,j} = b)$ and $P(\beta_{i,j}|B_{i,j} = b)$, and the blocked sampling of T applies a dynamic programming algorithm that is based on the inside chart derived from a transformation of Eq. (1):

$$P(S,T) = K(S) \prod_{<i,j><p,q>\in T} \phi(ij,pq)$$

$$where\ \phi(ij,pq) = \frac{P(\alpha_{ij,pq}|B_{ij,pq}=1)P(\beta_{ij,pq}|B_{ij,pq}=1)}{P(\alpha_{ij,pq}|B_{ij,pq}=0)P(\beta_{ij,pq}|B_{ij,pq}=0)}$$

$K(S)$ is a constant given S. The inside chart I can be constructed recursively as below:

$$I_{ij,pq} = \begin{cases} \phi(ij,pq) & if\ j-i \leq 1\ and\ q-p \leq 1 \\ \phi(ij,pq) \sum\limits_{\substack{i\leq u\leq j \\ p\leq v\leq q}} (I_{iu,pv}I_{uj,vq} + I_{iu,vq}I_{uj,pv}) & otherwise \end{cases}$$

Based on this inside chart, a synchronous tree can be top-down sampled (Johnson et al., 2007a), then is accepted or rejected by the MH-test to correct to the true distribution.

5 Experiments

The experiments were conducted on both a pilot word alignment task and an end-to-end Chinese-to-English machine translation task to test the quality of the learned synchronous structures by the SCCM. The bi-side monolingual gold bracketings contained in Penn treebanks were not used for evaluating the quality of the learned synchronous structures because of great syntactic divergence between source tree and target tree, which results in that gold monolingual syntactic trees on both sides are asynchronous (large number of tree nodes can not be aligned). The synchronous grammar induction community assumes the existence of synchronous grammar for MT, and do not evaluate synchronous grammar induction on monolingual gold treebanks because of their asynchronous property. The synchronous grammar induction community is not the same with the multilingual grammar induction community, which targets at inducing bi-side monolingual syntactic trees. Due to the same reason, our synchronous bracketing induction method was not evaluated on bi-side monolingual bracketing trees which are asynchronous.

5.1 Sampler Configuration

Our sampler was initialised with trees through a random split process. Firstly, we used GIZA++ model 4 to get source-to-target and target-to-source word alignments, and used grow-diag-final-and (gdfa) heuristic to extract reliable word alignments for each sentence pair. Secondly, we randomly split each sentence pair in a top-down manner, and make sure that each split is consistent with the GIZA++ gdfa word alignments. For example, given a sentence pair of m source words and n target words, we randomly choose a split point at each side and the alignment type (straight alignment or inverted alignment), then recursively build bi-spans further on each new split. Finally, a synchronous binary tree is built at the end of this process [1]. Note that all splits must be consistent with the GIZA++ gdfa word alignments. When a piece of word alignments (such as non-ITG alignment structure) do not permit binary split, we keep this structure unsplitted and continue split only on its sub-structures that are ITG derivable.

Our sampler ran 200 iterations for all data. After each sampling iteration, we resample all the hyperparameters using slice-sampling, with the following priors: $d \sim Beta(1,1)$, $\theta \sim Gamma(10, 0.1)$.

The time complexity of our inference algorithm is $O(n^6)$, which is not practical in applications. We reduce the time complexity by only considering bi-spans that do not violate GIZA++ intersection word alignments (intersection of source-to-target and target-to-source word alignments) (Cohn and Haffari, 2013).

5.2 Word Alignment Task

5.2.1 Experimental Setting

Since there are no annotated synchronous treebanks, we evaluate the SCCM indirectly by evaluating its output word alignments on a gold standard English Chinese parallel tree bank with hand aligned word alignments referred as HIT corpus[2]. The HIT corpus, which was collected from English learning text books in China as well as example sentences in dictionaries, was originally designed for annotating bilingual tree node alignments. The annotation strictly reserves the semantic equivalence of the aligned sub-tree pair. The byproduct of this corpus is the hand aligned word alignments, which was utilized to evaluate word alignment performance[3]. The word segmentation, tokenization and parse-tree in the corpus were manually constructed or checked. The statistics of the HIT corpus are shown in table 1.

Table 1: Corpus statistics of the HIT corpus.

	ch	en
sent	16131	
word	210k	209k
avg. len.	13.06	13.0

5.2.2 Results

We adopt the commonly used metric: the alignment error rate (AER) to evaluate our proposed alignments (a) against hand-annotated alignments, which are marked with sure (s) and possible (p) alignments. The AER is given by (the lower the better):

$$AER(a, s, p) = 1 - \frac{|a \cap s| + |a \cap p|}{|a| + |s|}$$

In the HIT corpus, only sure alignments were annotated, possible alignments were bypassed because of the strict annotation standard of semantic equivalence.

The word alignments evaluation results are reported in Table 2. The baseline was GIZA++ model 4 in both directions with symmetrization by the grow-diag-final-and heuristic (Koehn et al., 2003). A

[1] The initialization with different random split bi-trees results in marginal variance of performances.

[2] HIT corpus is designed and constructed by HIT-MITLAB. http://mitlab.hit.edu.cn/index.php/resources.html

[3] We did not use annotated tree node alignments for synchronous structure evaluation because the coverage of tree nodes that can be aligned is quite low. The reason of low coverage is that Chinese and English exhibit great syntax divergences from monolingual treebank point of view.

released induction system - PIALIGN (Neubig et al., 2011)[4] was also experimented to compare with our proposed induction system - SCCM.

PIALIGN is a model that generalizes adaptor grammars for machine translation (MT), while our model is to generalize CCM for MT. Adaptor grammars has been successfully applied on shallow unsupervised tasks such as morphlogical/word analysis, while CCM has obtained state-of-the-art performance on the more complex unsupervised task - inducing syntactic trees. In view of CCM's successful monolingual application, we generalize it to bilingual case. In depth comparison: our SCCM deals with both consituents and distituents, and contexts of them, while PIALIGN only deals with constituents. Furthermore, SCCM does not model non-terminal rewriting rules, while PIALIGN model those rules which can rewrite a non-terminal into a complete subtree as adaptor grammars does. In addition, PIALIGN adopts a beam search algorithm of (Saers et al., 2009). Through setting small beam size, PIALIGN's time complexity is almost $O(n^3)$. But as critisized by (Cohn and Haffari, 2013), their heuristic beam search algorithm does not meet either of the Markov Chain Monte Carlo (MCMC) criteria of ergodicity or detailed balance. Our method adopts MCMC sampling (Johnson et al., 2007a) which meets the MCMC criteria.

We can see that the two induction systems perform significantly better than GIZA++, and our proposed SCCM performs better than PIALIGN. Manual evaluation for the quality of the phrase pairs generated from word alignments is also reported in Table 2. We considered the top-100 high frequency phrase pairs that are beyond word level and less than six words on both sides, and report the proportion of reasonably well phrase pairs through manual check. We found that more good phrase pairs can be derived from the SCCM's word alignments than from others.

Table 2: Quality of word alignments and their generated phrase pairs.

	AER	good phrase pairs proportion
GIZA++	0.322	0.493
PIALIGN	0.263	0.531
SCCM	0.255	0.534

5.3 Machine Translation Task

5.3.1 Experimental Setting

A released tourism-related domain machine translation data was used in our experiment. It consists of a parallel corpus extracted from the $Basic\,Travel\,Expression\,Corpus$ (BTEC), which had been used in evaluation campaigns of the yearly International Workshop on Spoken Language Translation (IWSLT). Table 3 lists statistics of the corpus used in the experiment.

Table 3: Statistics of the corpus used by IWSLT

	ch	en
sent	23k	
word	190k	213k
avg. len.	8.3	9.2

We used CSTAR03 as development set, used IWSLT04 and IWSLT05 official test set for test. A 4-gram language model with modified Kneser-Ney smoothing was trained on English side of parallel corpus. We use minimum error rate training (Och, 2003) with nbest list size 100 to optimize the feature weights for maximum development BLEU. Experimental results were evaluated by case-insensitive BLEU-4 (Papineni et al., 2001). Closest reference sentence length was used for brevity penalty.

5.3.2 Results

Following (Levenberg et al., 2012; Neubig et al., 2011; Cohn and Haffari, 2013), we evaluate our model by using the SCCM's output word alignments to construct a phrase table. As a baseline, we train a phrase-based model using the moses toolkit [5] based on the word alignments obtained using GIZA++

[4]http://www.phontron.com/pialign/

[5]http://www.statmt.org/moses

model 4 in both directions and symmetrized using the grow-diag-final-and heuristic (Koehn et al., 2003). For comparison with CFG-based induction systems, word alignments generated by the PIALIGN were also used to train a phrase-based model.

In the end-to-end MT evaluation, we used the standard set of features: relative-frequency and lexical translation model probabilities in both directions; distance-based distortion model; language model and word count. The evaluation results are reported in table 4. Word alignments derived by the two induction systems can be more helpful to obtain better translations than GIZA++ derived word alignments. The SCCM, while departing from traditional CFG-based methods, achieves comparable translation performance to the PIALIGN.

Table 4: BLEU on both the development set: CSTAR03, and the two test sets: IWSLT04 and IWSLT05.

	CSTAR03	IWSLT04	IWSLT05
GIZA++	0.4304	0.4190	0.4866
PIALIGN	0.4661	0.4556	0.5248
SCCM	0.4560	0.4469	0.5193

6 Conclusion

A new model for synchronous structure induction is proposed in this paper. Different to all the previous works that are based on Context Free Grammars, our proposed SCCM deals with bilingual constituents and contexts explicitely so that bilingual translational equivalences can be directly modeled. A non-parametric Bayesian modeling of the SCCM is applied to cope with the sparse representations of bilingual constituents and contexts. Both intrinsic evaluation on word alignments and extrinsic evaluation on end-to-end machine translation were conducted. The intrinsic evaluation show that the highest quality word alignments were obtained by our proposed SCCM. Such statistically sound word alignments of the SCCM were used in the extrinsic evaluation on machine translation, showing that significantly better translations were achieved than those obtained by using the word alignments of GIZA++, the widely used word aligner in the two-step pipeline.

Abstract

In this paper we show how the task of syntactic parsing of non-segmented texts, including compound recognition, can be represented as constraints between phrase-structure parsers and CRF sequence labellers. In order to build a joint system we use dual decomposition, a way to combine several elementary systems which has proven successful in various NLP tasks. We evaluate this proposition on the French SPMRL corpus. This method compares favorably with pipeline architectures and improves state-of-the-art results.

1 Introduction

Dual decomposition (DD), which can be used as a method to combine several elementary systems, has already been successfully applied to many NLP tasks, in particular syntactic parsing, see (Rush et al., 2010; Koo et al., 2010) *inter alia*. Intuitively, the principle can be described quite simply: at decoding time, the combined systems seek for a consensus on common subtasks, in general the prediction of some parts of the overall structure, via an iterative process imposing penalties where the systems disagree. If the systems converge to a solution, it is formally guaranteed to be optimal. Besides, this approach is quite flexible and easy to implement. One can add or remove elementary systems without rebuilding the architecture from the ground up. Moreover, the statistical models for the subsystems can often be estimated independently at training time.

In this paper we show how syntactic parsing of unsegmented texts, integrating compound recognition, can be represented by constraints between phrase-structure parsers and sequence labellers, either for compound recognition or part-of-speech (POS) tagging, and solved using DD. We compare this approach experimentally with pipeline architectures: our system demonstrates state-of-the-art performance. While this paper focuses on French, the approach is generic and can be applied to any treebank with compound information, and more generally to tasks combining segmentation and parsing.

This paper is structured as follows. First, we describe the data we use to build our elementary systems. Second, we present related work in compound recognition, in particular for French, and the type of information one is able to incorporate in tag sets. Third, we show how CRF-based sequence labellers with these different tag sets can be combined using DD to obtain an efficient decoding algorithm. Fourth, we extend our method to add phrase-structure parsers in the combination. Finally, we empirically evaluate these systems and compare them with pipeline architectures.

2 Data

We use the phrase-structure treebank released for the SPMRL 2013 shared task (Seddah et al., 2013). This corresponds to a new version of the French Treebank (Abeillé et al., 2003). One of the key differences between French data and other treebanks of the shared task is the annotation of compounds. Compounds are sequences of words with a certain degree of semantic non-compositionality. They form

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1875–1885, Dublin, Ireland, August 23-29 2014.

a single lexical unit to which one can assign a single POS. In the SPRML corpus 15% of the tokens belong to a compound, or 12.7% if we omit numerals: the training, development and test sets respectively comprise 23658, 2120 and 4049 compounds.

In the treebank, compounds are annotated as subtrees whose roots are labelled with the POS of the compounds with a + suffix. Each leaf under a compound is the daughter of its own POS tag, which is in turn the daughter of the root of the compound. For example, the tree in Figure 1 contains a subtree with the compound adverb *pour l'instant* (so far) whose category `ADV+` dominates the preposition `pour`, the determiner *l'*, and the noun *instant*.

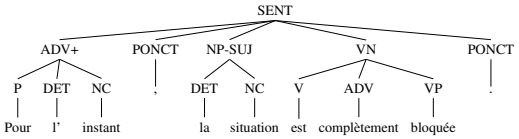

Figure 1: Syntatic annotation in the SPRML FTB: *So far, the situation has been completely blocked.*

The sequence labellers used in the experiments are able to exploit external lexical resources that will help coping with data missing from the training corpus. These resources are dictionaries, consisting of triplets `(flexed form, lemma, POS tag)`, where form and lemma may be compound or simple. Several such dictionaries exist for French. We use:

- DELA (Courtois et al., 1997) contains a million entries, among which 110,000 are compounds;
- Lefff (Sagot, 2010) contains 500,000 entries, among which 25,000 are compounds;
- Prolex (Piton et al., 1999) is a toponym dictionary with approximately 100,000 entries.

The described resources are additional to the SPMRL shared task data (Seddah et al., 2013), but were also used in (Constant et al., 2013a) for the shared task.

3 Compound Recognition

3.1 Related Work

The compound recognition traditionally relies on 2 types of information: lexical and syntactic clues. A strong lexical association between the tokens of a compound can be detected using a compound dictionary or by measuring a degree of *relatedness*, which can be learnt on a corpus. Some recent approaches use sequence labellers. The linear chain CRF model (Lafferty et al., 2001) is widely used, see for example (Vincze et al., 2011; Constant and Tellier, 2012). It has proven to be a very adequate model: it is flexible enough to incorporate information from labelled data and external resources (POS taggers, compound lexicons or named entity recognisers).

The compound recognition may also be directly performed by syntactic parsers learnt from corpora where compounds are marked, such as the one we use in this paper[1] (Arun and Keller, 2005; Green et al., 2011; Green et al., 2013; Constant et al., 2013b), but these results are contradictory. Green et al. (2011) experimentally show that a lexicalised model is better than an unlexicalised one. On the other hand, Constant et al. (2013b) show that, using products of PCFG-LA (Petrov, 2010), unlexicalised models can be more accurate. They obtain performance on a par with a linear chain CRF system without external information. But such information is difficult to incorporate directly in a PCFG-LA model. Constant et al. (2012) resort to a reranker to add arbitrary features in the parse selection process, but their system showed inferior performance compared with a CRF model with access to the same external information.

[1]Such an approach has been used already for joint named entity recognition and parsing based on CRF (Finkel and Manning, 2009).

3.2 Annotation schemes

Compound recognition can be seen as a segmentation task which consists in assigning to each token a label with segmentation information. We use label `B` if the token is the beginning of a word (single or compound), and label `I` if the token is inside a compound, but not in initial position. This lexical segmentation can be enriched with additional information, for example POS tags of compounds or tokens in compounds, and gives a variety of tag sets. This leads us to define 5 simple tag sets for our problem, each with very simple information, that will be combined in the next section. These tag sets are exemplified on a sentence with the compound *vin rouge* (red wine).

1. (basic) recognition with two labels (`B` and `I`)
   Luc/B aime/B le/B vin/B rouge/I (Luc likes red wine)
2. (partial) recognition with compound POS tags: `[BI]-POS` for tokens in compounds; `B` for others
   Luc/B aime/B le/B vin/B-NC+ rouge/I-NC+
3. (partial-internal) recognition with token POS tags in compounds
   Luc/B aime/B le/B vin/B-NC rouge/I-ADJ
4. (complete) recognition with POS tags for all tokens; in compounds use compound POS tags
   Luc/B-NPP aime/B-V le/B-DET vin/B-NC+ rouge/I-NC+
5. (complete-internal) recognition with POS tags for all tokens; in compounds use token POS tags
   Luc/B-NPP aime/B-V le/B-DET vin/B-NC rouge/I-ADJ

4 Dual decomposition for compound recognition using CRFs

4.1 A maximisation problem

4.1.1 CRF

A conditional random field (Lafferty et al., 2001), or CRF, is a tuple $c = (\Sigma, \mathcal{L}_c, w_c, \{f_p^c\}_p)$ which defines the conditional probability of a sequence of labels $y \in \mathcal{L}_c^*$ given a sequence of words of the same length $x \in \Sigma^*$ as a logistic regression of the form:

$$P_c(y|x) = \frac{\exp\left(\sum_{p\in\mathcal{P}(x)} w_c \cdot f_p^c(x, y_p)\right)}{Z(w_c, x)}, \text{ where} \tag{1}$$

- $w_c \in \mathbb{R}^d$ is a d-dimensional weight vector, where d is the number of features of the system,
- Z is the partition function
- $\mathcal{P}(x)$ is a set of *places*, in our case the set of unigram and bigram decompositions of sequences of words. A place p is of the form $[i]_x$ for unigrams and $[i, i+1]_x$ for bigrams. We omit x when context is unambiguous.
- y_p is the restriction of y to the place p, and we will write y_i for $y_{[i]}$ and $y_i y_{i+1}$ for $y_{[i,i+1]}$
- f_p^c is the feature function for the place p that projects (x, y_p) on $\mathbb{R}^d$.

Our goal is to find the best labelling, i.e. the one that maximises the conditional probability given a sequence of tokens. One can observe that this labelling also maximises the numerator of Equation 1, as $Z(w_c, x)$ does not depend on y. We therefore write:

$$\hat{y}^c = \arg\max_y \sigma_c(x, y) = \arg\max_y \sum_{p\in\mathcal{P}(x)} w_c \cdot f_p^c(x, y_p) \tag{2}$$

4.1.2 Viterbi Algorithm for CRFs

Since our combination of CRF systems relies on the Viterbi algorithm, we review it briefly. For a given input sentence $x = x_1 \dots x_n$, we represent the problem of finding the best labelling with a CRF c as a best path algorithm in a directed acyclic graph $\mathcal{G}_c = (\mathcal{V}, \mathcal{E})$ built from a set of nodes $\mathcal{V}$ and a set of edges $\mathcal{E}$. Nodes are pairs (x_i, l) where x_i is an input token and l is an admissible label for x_i.[2] Edges connect nodes of the form (x_i, l) to nodes of the form (x_{i+1}, l') and the weights of these arcs are given by c. In order to find the weight of the best path in this graph, that corresponds to the score of the best labelling, we use Algorithm 1.[3] One can remark that the score of a node decomposes as a score s_1, computed from a vector of unigram features, written $f^c_{[i]}(x, l)$, and a score s_2 computed from a vector of bigram features, written $f^c_{[i-1,i]}(x, l', l)$.[4] The Viterbi algorithm has a time complexity linear in the length of the sentence and quadratic in the number of labels of the CRF.

Algorithm 1 Viterbi Algorithm for CRFs with unigram and bigram features

Viterbi$(\mathcal{G}_c, w_c, \{f^c_p\}_p, \Lambda^{BI}, \Lambda^{IB})$:
for all node v **do**
  $\pi[v] = -\infty$
end for
$\pi[$ (<s>, START) $] = w \cdot f_{p_0}(x,$ START$)$
for all non initial node $v = (x_i, l)$ in topological order **do**
  $s_1 \leftarrow w_c \cdot f^c_{[i]}(x, l)$
  $s_2 \leftarrow -\infty$
  for all incoming edge $v' = (x_{i-1}, l') \rightarrow v$ **do**
    $t \leftarrow \pi[v'] + w_c \cdot f^c_{[i-1,i]}(x, l', l)$
    $t \leftarrow t - b(l')i(l) \cdot \Lambda^{BI}[i] - i(l')b(l) \cdot \Lambda^{IB}[i]$ ▷ only for DD: we ignore this line otherwise
    if $t > s_2$ **then**
      $s_2 = t$
    end if
  end for
  $\pi[v] \leftarrow s_1 + s_2$
end for
return the best scoring path $\pi[$ (</s>, STOP) $]$

4.2 Dual decomposition for CRF combinations

In Section 3.2 we described several annotation schemes that lead to different CRF models. These schemes give the same lexical segmentation information but they use more or less rich part-of-speech tag sets. It is not clear *a priori* if the richness of the tag set has a beneficial effect over segmentation prediction: there is a compromise between linguistic informativeness and data sparseness. Instead of trying to find the best annotation scheme, we propose a consensus-based joint system between several CRF-based sequence labellers for the task of text segmentation relying on dual decomposition (Rush et al., 2010). This system maximises the sum of the scores of combined CRFs, while enforcing global consistency between systems in terms of constraints over the admissible solutions. These constraints are specifically realised as reparametrisations of the elementary CRFs until a consensus is reached. Since we deal with several annotation schemes, we will use predicates to abstract from them:

- $b(l)$ is true if l starts with B;
- $i(l)$ is true if l starts with I;
- $bi(i, y)$ is true if $b(y_{i-1})$ and $i(y_i)$ are true;
- $ib(i, y)$ is true if $i(y_{i-1})$ and $b(y_i)$ are true.

For a labelling y, we define 2 boolean vectors that indicate where the compounds begin and end:

[2] We also include two additional nodes: an initial state (<s>, START) and a final state (</s>, STOP).
[3] Algorithm 1 calculates the score and backpointers must be added to retrieve the corresponding path.
[4] This algorithm takes as input 2 vectors that will be used for DD and will be explained in § 4.2. They can be ignored now.

- $D(y)$, such that $D(y)[i] = 1$ if $bi(i, y)$, and 0 otherwise;
- $F(y)$, such that $F(y)[i] = 1$ if $ib(i, y)$, and 0 otherwise.

As we want to *combine* CRFs, the solution of our system will be a *tuple* of label sequences with the same compound segmentation. For an input sequence x, this new maximisation problem is:

$$(P): \qquad \textit{find} \max_{(y^1,\dots,y^n)} \sum_{c=1}^{n} \sigma_c(y^c) = \sum_{c=1}^{n} \sum_{p\in\mathcal{P}(x)} w_c \cdot f_p^c(x, y_p^c) \tag{3}$$

$$\textit{s.t.}\ \exists u_1, u_2\, \forall c \in [\![1, n]\!],\ D(y^c) = u_1, F(y^c) = u_2 \tag{4}$$

Objective (3) indicates that we seek for a tuple for which the sum of the scores of its elements is maximal. Constraints (4) imply that the compound frontiers – transitions `B` to `I` and `I` to `B` – must be the same for each element of the tuple. There are several ways to tackle this problem. The first one is by swapping the sum signs in (3) and noticing that the problem could then be represented by a joint system relying on dynamic programming – a CRF for which labels would be elements of the product $\mathcal{L} = \mathcal{L}_1 \times \cdots \times \mathcal{L}_n$ – and for which it is straightforward to define a weight vector and feature functions. We can therefore reuse the Viterbi algorithm but the complexity is quadratic in the size of $\mathcal{L}$, which is impractical[5].

In any case, this approach would be inadequate for inclusion of parsers, and we therefore rely on lagrangian relaxation. We modify the objective by introducing Lagrange multipliers, two real vectors Λ_c^{BI} and Λ_c^{IB} indexed by bigram places[6] for each CRF c of the combination. We obtain a new problem with the same solution as the previous one, since constraints (4) are garanteed to be satisfied at optimality:

$$\max_{(y^1,\dots,y^n,u_1,u_2)} \min_{(\Lambda^{BI},\Lambda^{IB})} \sum_{c=1}^{n} \sigma_c(y^c) - \sum_{c=1}^{n} \left[(D(y^c) - u_1) \cdot \Lambda_c^{BI} + (F(y^c) - u_2) \cdot \Lambda_c^{IB}\right] \tag{5}$$

The next step is dualisation, which gives an upper bound of our problem:

$$\min_{(\Lambda^{BI},\Lambda^{IB})} \max_{(y^1,\dots,y^n,u_1,u_2)} \sum_{c=1}^{n} \sigma_c(y^c) - \sum_{c=1}^{n} D(y^c)\cdot\Lambda_c^{BI} + u_1 \sum_{c=1}^{n} \Lambda_c^{BI} - \sum_{c=1}^{n} F(y^c)\cdot\Lambda_c^{IB} + u_2 \sum_{c=1}^{n} \Lambda_c^{IB} \tag{6}$$

We then remark that $\sum_{c=1}^{n} \Lambda_c^{BI}$ and $\sum_{c=1}^{n} \Lambda_c^{IB}$ must be zeros at optimum (if the problem is feasible).[7] It is convenient to convert this remark to hard constraints in order to remove any reference to vectors u_i – and therefore to the coupling contraints – from the objective. We obtain the constrained problem with the same optimal solution :

$$(Du): \qquad \textit{find} \min_{(\Lambda^{BI},\Lambda^{IB})} \sum_{c=1}^{n} \max_{y^c} \left[\sigma_c(y^c) - D(y^c)\cdot\Lambda_c^{BI} - F(y^c)\cdot\Lambda_c^{IB}\right] \tag{7}$$

$$\textit{s.t.}\ \sum_{c=1}^{n} \Lambda_c^{BI} = 0 \text{ and } \sum_{c=1}^{n} \Lambda_c^{IB} = 0 \tag{8}$$

In order to solve (Du) we use the projected subgradient descent method that has already been used in many problems, for example MRF decoding (Komodakis et al., 2007). For the problem at hand, this method gives Algorithm 2. This iterative algorithm consists in reparametrising the elementary CRFs of the system, by modifying the weights associated with the bigram features in places that correspond to compound frontiers, penalising them on CRFs that diverge from the average solution. This is performed

[5] One could object that some combinations are forbidden. It remains that the number of labels still grows exponentially.

[6] Bigram places are identified by their second position.

[7] Otherwise the sum expressions would be unbounded and their maximum is $+\infty$ for an appropriate value of u_i.

by amending the vectors Λ_c^{BI} and Λ_c^{IB} that are updated at each iteration proportionally to the difference between the feature vectors for c and the average values of these vectors. Hence the farther a solution is from the consensus, the more penalised it gets at the next iteration. This algorithm stops when the updates are null for all CRFs: in this case the consensus is reached.

Algorithm 2 Best segmentation with combined CRF system via subgradient descent

Require: n CRF $c = (\Sigma, \mathcal{L}_c, w_c, \{f_p^c\}_p)$, an input sentence x, a maximum number of iterations τ, stepsizes $\{\alpha_t\}_{0 \leq t \leq \tau}$

for all CRF c, bigram end position i, bigram label pair (l, m) **do**
  $\Lambda_c^{BI}[i, l, m]^{(0)} = 0; \quad \Lambda_c^{IB}[i, l, m]^{(0)} = 0$
end for
for $t = 0 \rightarrow \tau$ **do**
  for all CRF c **do**
  $y^{c^{(t)}} = Viterbi(\mathcal{G}_c, w_c, f_c, \Lambda_c^{BI^{(t)}}, \Lambda_c^{IB^{(t)}})$
  end for
  for all CRF c **do**
    $\Delta_c^{BI^{(t)}} \leftarrow \alpha_t \left(D\left(y^{c^{(t)}}\right) - \frac{\sum_{1 \leq d \leq n} D\left(y^{d^{(t)}}\right)}{n} \right); \quad \Delta_c^{IB^{(t)}} \leftarrow \alpha_t \left(F\left(y^{c^{(t)}}\right) - \frac{\sum_{1 \leq d \leq n} F\left(y^{d^{(t)}}\right)}{n} \right)$
    $\Lambda_c^{BI^{(t+1)}} \leftarrow \Lambda_c^{BI^{(t)}} + \Delta_c^{BI^{(t)}}; \quad \Lambda_c^{IB^{(t+1)}} \leftarrow \Lambda_c^{IB^{(t)}} + \Delta_c^{IB^{(t)}}$
  end for
  if $\Delta_c^{BI^{(t)}} = 0$ and $\Delta_c^{IB^{(t)}} = 0$ for all c **then**
    Exit loop
  end if
end for
return $(y^{1^{(t)}}, \cdots, y^{n^{(t)}})$

We set the maximum number of iteration τ to 1000. For the step size, we use a common heuristic: $\alpha_t = \frac{1}{1+k}$ where k is the number of times that (Du) has increased between two successive iterations.

4.3 Experimental results for CRF combinations

We modified the `wapiti` software (Lavergne et al., 2010) with Algorithm 2. Table 1 reports segmentation results on the development set with the different tag sets, the best DD combination, and the best voting system.[8]

Tag Set CRF / combination	Recall	Precision	F-score
partial-internal	79.59	85.49	82.44
partial	78.98	85.57	82.14
basic	79.74	84.65	82.12
complete	79.69	83.10	81.36
complete-internal	79.03	82.66	80.80
`MWE` basic complete partial-internal	80.82	86.07	**83.36**
vote (basic complete partial-internal)	80.49	85.46	82.90

Table 1: Segmentation scores of CRF systems (dev)

System	F-score (all)	F-score (compounds)
complete	94.29	78.32
`MWE`	94.59	**80.00**

Table 2: Segmentation + POS tagging (dev)

We see that the best system is a combination of 3 CRFs (tag sets *basic*, *complete* and *partial-internal*) with DD, that we call `MWE` in the remaining of the paper. The subgradient descent converges on all instances in 2.14 iterations on average. The DD combination is better than the voting system.

We can also evaluate the POS tagging accuracy of the system for systems including the *complete* tag set. We compare the results of the *complete* CRF with the `MWE` combination on Table 2. The second column gives the F-score of the complete task, segmentation and POS tagging. The third column restricts the evaluation to compounds. Again, the `MWE` combination outperforms the single system.

[8] Each system has one vote and in case of a draw, we pick the best system's decision.

In some preliminary experiments, the weights of the CRF systems were based on unigram features mainly – i.e. those described in (Constant et al., 2012). As our CRFs are constrained on transitions from `B` to `I` and `I` to `B`, penalising systems resulted in modifying (low) bigram weights and had only a minor effect on the predictions and consequently the projected gradient algorithm was slow to converge. We therefore added bigram templates for some selected unigram templates, so that our system can converge in a reasonable time. Adding these bigram features resulted in slower elementary CRFs. On average the enriched CRFs were 1.8 times slower that their preliminary counterparts.

5 Dual Decomposition to combine parsers and sequence labellers

We now present an extension of the previous method to incorporate phrase-structure parsers in the combination. Our approach relies on the following requirement for the systems to agree: if the parser predicts a compound between positions i and j, then the CRFs must predict compound frontiers at the same positions. In this definition, like in previous CRF combinations, only the positions are taken into account, not the grammatical categories. From a parse tree a, we define two feature vectors:

- $D(a)$, such that $D(a)[i] = 1$ if a contains a subtree for a compound starting at position $i-1$
- $F(a)$, such that $F(a)[i] = 1$ if a contains a subtree for a compound ending at position $i-1$

In other words, $D(a)[i]$ indicates whether the CRFs should label position $i-1$ with `B` and position i with `I`, while $F(a)[i]$ indicates whether the CRFs should label position $i-1$ with `I` and position i with `B`. See Figure 2 for an example.

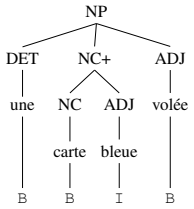

Figure 2: Parser and CRF alignments (A stolen credit card)

5.1 Parsing with probabilistic context-free grammars

We follow the type of reasoning we used in § 4.2. With a PCFG g, we can define the score of a parse for an input sentence x as the logarithm of the probability assigned to this parse by g. Finding the best parse takes a form analogous to the one in Equation 2, and we can write the CKY algorithm as a best path algorithm with penalties on nodes, as we did for the Viterbi algorithm previously. This is closely related to the PCFG combinations of (Le Roux et al., 2013). We introduce penalties through two real vectors Λ^{BI} and Λ^{IB} indexed by compound positions. The modified CKY is presented in Algorithm 3[9] where the parse forest $\mathcal{F}$ is assumed to be already available and we note w the vector of rule log-probabilities.

5.2 System combination

As in § 4.2, our problem amounts to finding a tuple that now consists of a parse tree and several labellings. All systems must agree on compound frontiers. Our objective is:

$$(P') : \quad \textit{find} \max_{(a,y^1,\ldots,y^n)} \sigma_p(a) + \delta \sum_{c=1}^{n} \sigma_c(y^c) \tag{9}$$

$$\textit{s.t.} \ \exists u_1, u_2 \, \forall c \in [\![1,n]\!], \, D(y^c) = u_1, F(y^c) = u_2, D(a) = u_1, F(a) = u_2 \tag{10}$$

[9] Without loss of generality, only binary rules are taken into account.

Algorithm 3 CKY with node penalties for compound start/end positions

CKY$(\mathcal{F}, w, \Lambda^{BI}, \Lambda^{IB})$:
for all node v in the forest $\mathcal{F}$ **do**
    $\pi[v] = -\infty$
end for
for all leaf node x **do**
    $\pi[x] = 0$
end for
for all non-terminal node (A, i, j) in topological order **do**
    for all incoming hyperedge $u = (B, i, k)(C, k+1, j) \rightarrow (A, i, j)$ **do**
        $s \leftarrow \pi[(B, i, k)] + \pi[(C, k+1, j)] + w_{A \rightarrow BC}$ ▷ $w_{A \rightarrow BC}$ is the score for rule $A \rightarrow BC$
        if A is a compound label **then**
            $s \leftarrow s - \Lambda^{BI}[i] - \Lambda^{IB}[j+1]$
        end if
        if $s > \pi[(A, i, j)]$ **then**
            $\pi[(A, i, j)] \leftarrow s$
        end if
    end for
end for
return hyperpath with score $\pi[(\text{ROOT}, 1, n)]$

We use δ to set the relative weights of the CRFs and the PCFG. It will be tuned on the development set. We then reuse the same procedure as before: lagrangian relaxation, dualisation, and projected subgradient descent. Algorithm 4 presents the function we derive from these operations.

Algorithm 4 Find the best segmentation with a PCFG and CRFs

Require: a PCFG parser p, n CRFs, an input sentence x, a bound τ
set Lagrange multipliers (penalty vectors) to zero
for $t = 0 \rightarrow \tau$ **do**
    for all CRF c **do**
        $y^{c^{(t)}} \leftarrow Viterbi(\mathcal{G}_c, w_c, f_c, \Lambda_c^{BI^{(t)}}, \Lambda_c^{IB^{(t)}})$
    end for
    $a^{(t)} \leftarrow CKY(\mathcal{F}, w, \Lambda_p^{BI^{(t)}}, \Lambda_p^{IB^{(t)}})$
    for all CRF c and parser p **do**
        Update penalty vectors proportionally to the difference between corresponding solution and average solution
    end for
    if *update* is null for all c and p **then**
        Exit loop
    end if
end for
return $(a^{(t)}, y^{1^{(t)}}, \cdots, y^{n^{(t)}})$

Algorithm 4 follows the method used in § 4 and simply adds the PCFG parser as another subsystem. This method can then be extended further: for instance, we can add a POS tagger (Rush et al., 2010) or multiple PCFG parsers (Le Roux et al., 2013). Due to lack of space, we omit the presentation of these systems, but we experiment with them in the following section.

6 Experiments

For this series of experiments, we used `wapiti` as in § 4.3 and the `LORG` PCFG-LA parser in the configuration presented in (Le Roux et al., 2013) that we modified by implementing Algorithm 4. This parser already implements a combination of parsers based on DD, a very competitive baseline.

For parse evaluation, we used the EVALB tool, modified by the SPMRL 2013 organisers, in order to compare our results with the shared task participants. We evaluated several configurations: (i) the `LORG` parser alone, a combination of 4 PCFG-LA parsers as in (Le Roux et al., 2013), (ii) a pipeline of `POS`, a CRF-based POS tagger, and `LORG`, (iii) joint `LORG` and `POS`, using DD as in (Rush et al., 2010), (iv) joint `LORG` and `MWE` (our best CRF combination for compound segmentation) using DD, and (v) joint `LORG`, `POS` et `MWE` using DD. We also compare these architectures with 2 additional pipelines, in which we first run `MWE` and then merge compounds as single tokens. The converted sentences are then sent to a version of `LORG` learnt on this type of corpus. After parsing, compounds are *unmerged*,

replaced with the corresponding subtree. In one of these two architectures, we add a POS tagger.

The evaluations for the parsing task of all these configurations are summarised in Table 3. The best system is the DD joint system combining the POS tagger, the parser and the compound recognisers.

System	Recall	Precision	Fscore	EX	Tag
LORG	82.01	82.37	82.19	18.06	97.35
pipeline POS → LORG	82.36	82.59	82.47	19.22	97.73
DD POS + LORG	82.48	82.73	82.61	19.19	97.84
DD MWE + LORG	82.91	83.07	82.99	19.19	97.41
DD POS + MWE + LORG	83.38	83.42	**83.40**	20.73	97.85
pipeline MWE MERGE → LORG → UNMERGE	82.56	82.63	82.59	18.79	97.39
pipeline MWE MERGE/POS → LORG → UNMERGE	82.73	82.64	82.69	20.02	97.57

Table 3: Parse evaluation on *dev* set (recall, precision and F-score, exactness and POS tagging).

Table 4 shows evaluation results of our best system and comparisons with baseline or alternative configurations on the SPMRL 2013 *test* set.

Parsing The DD method performs better than our baseline, and better than the best system in the SPMRL 2013 shared task (Björkelund et al., 2013). This system is a pipeline consisting of a morpho-syntactic tagger with a very rich and informative tag set, a product of PCFG-LAs, and a parse reranker. Although this approach is quite different from ours, we believe our system is more accurate overall because our method is more resilient to an error from one of its components.

Compound recognition and labelling For the task of recognition alone, where only the frontiers are evaluated, the DD combinations of CRFs performs better than the best single CRF which itself performs better than the parser alone, but the complete architecture is again the best system. If we also evaluate compound POS tags, we get similar results. The DD combination is always beneficial.

System	Recall	Precision	Fscore	EX	Tag
LORG	82.79	83.06	82.92	22.00	97.39
(Björkelund et al., 2013)	–	–	82.86	–	–
DD POS + MWE + LORG	83.74	83.85	**83.80**	23.81	97.87
compound recognition LORG	78.03	78.63	78.49	–	–
compound recognition best single CRF (partial-internal)	78.27	82.84	80.49	–	–
compound recognition MWE	79.68	83.50	81.54	–	–
compound recognition DD POS + MWE + LORG	80.76	84.19	**82.44**	–	–
compound recognition + POS tagging LORG	75.43	75.71	75.57	–	–
compound recognition + POS tagging MWE	76.49	80.10	78.28	–	–
compound recognition + POS tagging DD POS + MWE + LORG	77.92	81.23	**79.54**	–	–

Table 4: Evaluation on SPMRL 2013 *test* set: parsing (first 3 lines), and compound recognition.

7 Conclusion

We have presented an original architecture for the joint task of syntactic parsing and compound recognition. We first introduced a combination of recognisers based on linear chain CRFs, and a second system that adds in a phrase-structure parser. Our experimental prototype improves state-of-the-art on the French SPMRL corpus.

In order to derive decoding algorithms for these joint systems, we used dual decomposition. This approach, leading to simple and efficient algorithms, can be extended further to incorporate additional components. As opposed to pipeline approaches, a component prediction can be *corrected* if its solution is too far from the general consensus. As opposed to joint systems relying on pure dynamic programming to build a complex single system, the search space does not grow exponentially, so we can avoid using pruning heuristics such as beam search. The price to pay is an iterative algorithm.

Finally, this work paves the way towards component-based NLP software systems that perform complex processing based on consensus between components, as opposed to previous pipelined approaches.

Abstract

Completely data-driven grammar training is prone to over-fitting. Human-defined word class knowledge is useful to address this issue. However, the manual word class taxonomy may be unreliable and irrational for statistical natural language processing, aside from its insufficient linguistic phenomena coverage and domain adaptivity. In this paper, a formalized representation of function word subcategorization is developed for parsing in an automatic manner. The function word classification representing intrinsic features of syntactic usages is used to supervise the grammar induction, and the structure of the taxonomy is learned simultaneously. The grammar learning process is no longer a unilaterally supervised training by hierarchical knowledge, but an interactive process between the knowledge structure learning and the grammar training. The established taxonomy implies the stochastic significance of the diversified syntactic features. The experiments on both Penn Chinese Treebank and Tsinghua Treebank show that the proposed method improves parsing performance by 1.6% and 7.6% respectively over the baseline.

1 Introduction

Probabilistic context-free grammar (PCFG) is widely used in the fields of speech recognition, machine translation, information retrieval, etc. It takes the empirical rules and probabilities from a Treebank. However, due to the context-free assumption, PCFG does not always perform well (Klein and Manning, 2003). For instance, it assumes adverbs, including temporal adverbs, degree adverbs and negation adverbs, to share the same distribution, whereas the distinction would provide useful indication for disambiguating the syntactic structure of the context.

It arose that the manual word classification in linguistic research was used to enrich PCFG and improve the performance. However, from the point of view of statistical natural language processing, there are some drawbacks for manual classification. Firstly, Linguistic phenomena covered by the manual refinement may be limited by the linguistic observations of human. Secondly, the evidence of manual refinement is often based on a particular corpus or specific sources of knowledge acquisition. As a result, its adaptivity to different domains or genres may be insufficient. As for function words, due to the ambiguity and complexity in syntactic grammar, it is more difficult to develop formalized representation than for content words. There are diversified standards for grammar refinement. Consequently, the word classification or category refinement can be conducted in distinct manners, while each of them is reasonable in some sense. A delicate hierarchical classification inevitably involves in multiple dividing standards. However, the word sets under distinct dividing standards may be overlapping. The problems come up that how to choose the set of the multiple standards to cooperate to build the taxonomy, and how to decide the priority of each standard. Regarding that the manual method is hard to overcome critical issues, manual taxonomy for function words may not be reliable for statistical natural language processing.

This article attempts to address these issues in a data-driven manner. we first manually construct a cursory and flat classification of function words. A hierarchical split-merge approach is employed to

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1886–1896, Dublin, Ireland, August 23-29 2014.

introduce our classification, and the PCFG training procedure is supervised to alleviate the over-fitting issue. The priorities of the subcategorization standards are determined by the measurement of effectiveness for parsing in a greedy manner in the hierarchical classification. And the hierarchical structure of the classification is learned by data-driven approach in the course of grammar induction, so as to fit the practical usages in the Treebank. Accordingly, the grammar learning process is no longer a unilaterally supervised training by hierarchical knowledge, but an interactive process between the knowledge representation induction and the grammar training. That is, the grammar induction is supervised by the knowledge and the structure of the taxonomy is learned simultaneously. These two processes are iterated for several rounds and the hierarchical structure of the function word taxonomy is constructed. In each round, the induced grammar could benefit from the optimized taxonomy during the learning process. The category split in the early rounds take more priorities than in the late ones. Thus, the learned taxonomy implies the stochastic significance of the series of the syntactic features.

Experiments on Penn Chinese Treebank Fifth Edition (CTB5.0) (Xue et al., 2002) and Tsinghua Chinese Treebank (TCT) (Zhou, 2004) are performed. The results show that the induced grammars with refined conjunction categories gain parsing performance improvement by 1.6% on CTB and by 7.6% on TCT. During the training process, a taxonomy of function words is learned, which reflects their practical usages in the corpus.

The rest of this paper is organized as follows. We first review related work on category refinement for parsing. Then we describe our manually defined categories of function words in Section 3. The hierarchical state-split approach for introducing the the categories are presented in Section 4, and our taxonomy learning method is described in Section 5. In Section 7, experimental comparison is conducted among various methods on granularity choosing. And conclusions of this research are drawn in last section.

2 Related Work

A variety of techniques have been proposed to enrich PCFG in either manual (Klein and Manning, 2003; Zhang and Clark, 2011) or automatic (Petrov, 2009; Cohen et al., 2012) manner.

2.1 Automatic Refinement of Function Words for Parsing

One way of grammar refinement is data-driven state-split methods (Matsuzaki et al., 2005; Prescher, 2005). The part-of-speech and syntactic tags in the grammar are automatically split to encode the kinds of linguistic distinctions exhibited in the Treebank. The hierarchical state-split approach (Petrov et al., 2006) started from a bare-bones Treebank derived grammar, and iteratively refined it in a split-merge-smooth cycle with the EM-based parameter re-estimation. It achieved state of the art accuracies for many languages including English, Chinese and German.

One tag is usually heterogeneous, in the sense that its word set can be of multiple different types. Nevertheless, the automatic process tries to split the tags through a greedy data-driven manner, where multiple distinctive information is used simultaneously when dividing tags. Thus the refined tags are not intuitively interpretable. Meanwhile, considering that the EM algorithm usually gets stuck at a sub-optimal configuration, this data-driven method suffers from the risk of over-fitting. As shown in their experiments, there is little to be gained from splitting the closed part-of-speech classes (e.g. DT, CC, IN) or the nonterminal ADJP.

To alleviate the risk of over-fitting, we employ the human-defined knowledge to constrain the splitting process in this research. Based on the state-split model, our approach aims to reach a compromise between manual and automatic refinement approaches.

2.2 Manual Refinement of Function Words for Parsing

The other way to refine the annotation for training a parser is incorporating knowledge base. Semantic knowledge of content words has been proved to be effective in alleviate the data sparsity. Some researches utilized semantic knowledge in WordNet (Miller, 1995; Fellbaum, 1999) for English parsing (Fujita et al., 2010; Agirre et al., 2008), and Xiong et al. (2005; Lin et al. (2009) improved Chinese pars-

ing by incorporating semantic knowledge in HowNet (Dong and Dong, 2003; Dong and Dong, 2006). While WordNet and Hownet contain word classification for content words, Li et al. (2014b; Li et al. (2014a) have focused on exploiting manual classification for conjunction in parsing.

Klein and Manning (2003) examined the annotation in Penn English Treebank, manually split the majority of the part-of-speech (POS) tags. For the function words, they split the tag "IN" into subordinating conjunctions, complementizers and prepositions, and appended B̂E to all forms of "be" and ĤAVE to all forms of "have". Conjunction tags are also marked to indicate whether they were "But", "but" or "&". The experimental results showed that the split tags of function words surprisingly make much contribution to the overall improved parsing accuracy. Levy and Manning (2003) transferred this work to Penn Chinese Treebank. They found that, in some cases, certain adverbs such as "however (然而)" and "especially (尤其是)" preferred IP modification and could help disambiguate IP coordination from VP coordination. To capture this point, they marked those adverbs possessing an IP grandparent. However, these manual refinement methods seems to split the tags in a rough way, which might account for a modest accuracy achieved. Some existing work used heuristic rules to simply split the tags of function words (Klein and Manning, 2003; Levy and Manning, 2003). They demonstrated that many function words stood out to be helpful in predicting the syntactic structure and syntactic label.

3 Manual Tabular Subcategories of Function Words

When subcategorizing function words, in this section, we manually list various grammatical distinctions that are commonly made in traditional and generative grammar in a fairly flat taxonomy. The grammar training procedure learns by using our manual taxonomy as a starting point, and constructs a reasonable and subtle hierarchical strucutre based on the distribution of function words usages in the corpus.

Based on some existing knowledge base (Xia, 2000; Xue et al., 2000; Zhu et al., 1995; Wang and Yu, 2003) and previous research work (Li et al., 2014b), we investigate and summarize the usage of function words, and come up with a hierarchical subcategories. The taxonomy of the function words is represented in a tree structure, where each subcategory of a function word corresponds to a node in the taxonomy, the nonterminals are subcategories and the terminals are words.

For the convenience and consistence, our manual classification just gives a rough and broad taxonomy. It is labor-intensive and error-prone of classifying the function words manually to produce a consistent output. Fine-grained hierarchical structure is not obligatory, but would be harmful if inappropriately classified, as it may mislead the learning process. To avoid this kind of risk, the elaboration is saved, rather than introducing unnecessary bias. The learning process would perform the hierarchical classification according to the distribution in the corpus.

For instance, the distinction within conjunctions is intricate. Conjunctions are the words that are called "connective words" in traditional Chinese grammar books. In Penn Chinese Treebank, they are tagged as coordinating conjunctions (CC), subordinating conjunctions (CS), or adverbs (AD) according to their syntactic distribution. CC conjoins two equivalent constituents (noun phrases, clauses, etc.), each of which has approximately the same function as the whole construction. CS precedes a subordinating clause, whereas conjunctive adverbs often appear in the main clause and pair with a subordinating conjunction (e.g., if (如果)/CS ... then (就)/AD). However, in Chinese, it is often hard to tell the subordinating clause from the main clause in the compound statement. As a result, in the prospective of linguistic computing, the confusion is that, CS and conjunctive adverbs both precedes the subordinating clauses or main clauses, while CC connects two phrases or precedes the main clause. In our scheme, we simply conflates the CC, CS and conjunctive adverbs together. This result in a general "conjunction" category, within which we just enumerate all the possible uses of the conjunctions. As a result, the structure of our human-defined taxonomy is fairly flat, as briefly shown in Figure 1 and Figure 2. Our scheme releases our hands from the confusing situations, by leaving them to our data-driven method described in the following section. Figure 1 and Figure 2 abbreviate the manual classification and their corresponding examples.

Many prepositions in Chinese are evolved from verbs, thus the linguistic characteristics of prepositions are somewhat similar to verbs. Therefore, this paper divides the preposition word set according to

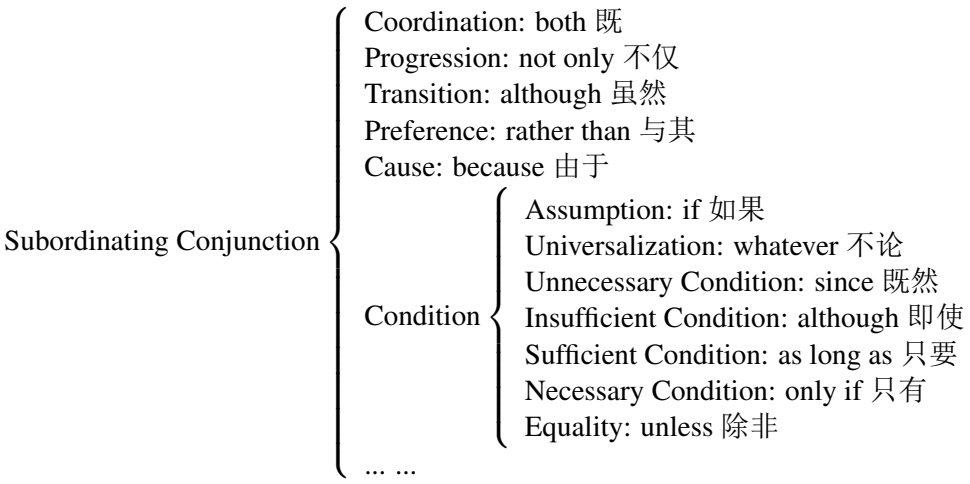

Figure 1: Abbreviated Hierarchical subcategories of subordinating conjunctions with examples.

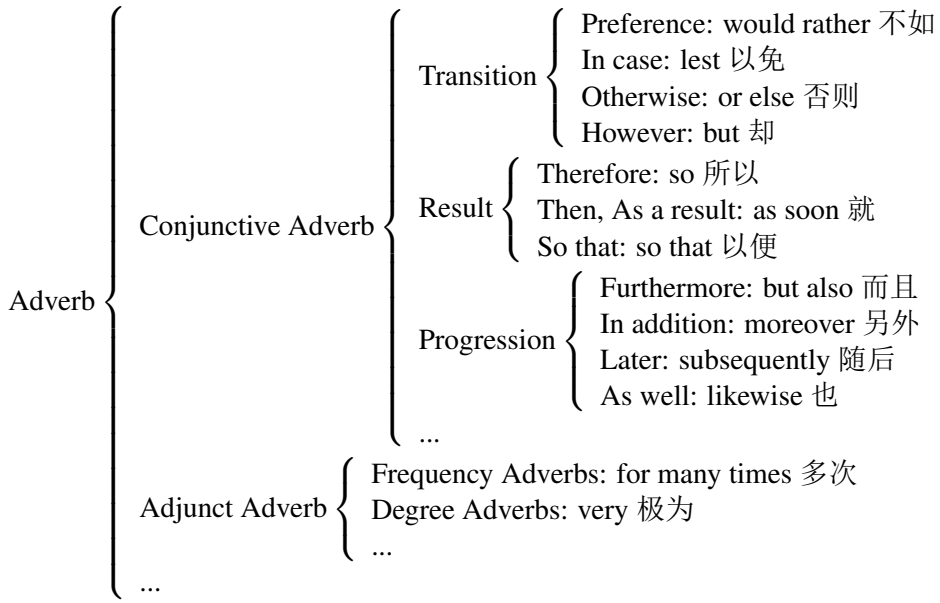

Figure 2: Abbreviated Hierarchical subcategories of adverbs with examples.

the types of their associated arguments: “benefactive”, such as “ 为(for)” and “给(to)”, marks the beneficiary of an action; “locative”, such as “在(in)”, marks adverbials that indicate the place of the event; “direction”, such as “ 向(towards)” and “ 由(from)”, marks adverbials that answer the questions “from where?” and “to where?”; “temporal”, such as “在(on)”, marks temporal or aspectual adverbials that answer the question “when?”, and so on.

4 Refining Grammar with Hierarchical Category Refinement

In this section, we choose the appropriate granularity in a data-driven manner based on the split-merge learning method in Section 2.1. Our approach first initializes the categories with the most general subcategories in the taxonomy and then splits the categories through the hypernym-hyponym relation in the

taxonomy. Data-driven method is used to merge the overly refined subcategories.

The top category in the taxonomy is used as the starting annotations of POS tags. As we cannot predict which layer should be the most adequate one, we try to avoid applying any priori restriction on the refinement granularity, and start with the most general tags.

With the hierarchical knowledge, it turns out to be a critical issue that which granularity should be used to refine the tags for parsing. We intend to take neither too coarse subcategories nor too fine ones in the hierarchical knowledge for parsing. Instead, it would be our advantage to split the tags with the very granularity where needed, rather than splitting them all to one specific granularity in the taxonomy.

For example, "Conjunctive Adverbs" are divided into three subcategories in our taxonomy as shown in Figure 2. The evidence for the refinement may occur in very rare case, and certainly some of the context of the different subcategories are quite the same. Splitting symbols with the same context is not only unnecessary, but potentially harmful, since it unreasonably fragments observations of other symbols' behavior.

In this paper, the hierarchical subcategory knowledge is used to refine grammars by supervising the automatic hierarchical state-split approach. In the split stage in each cycle, the function word subcategory is split along the hierarchy of the knowledge, instead of being randomly split and classified automatically. In this way, we try to alleviate the over-fitting of the greedy data-driven approach, and a new set of knowledge-related tags are generated. In the following step, we retreat some of the split subcategories to their more general layer according to its likelihood loss of merging them. In this way, we try to avoid the excessive refinement in our hierarchical knowledge without sufficient data support.

There are two issues that we have to consider in this process: a) how to deal with the polysemous words, and b) how to deal with the multi-branch situation other than binary branch in the taxonomy. Regarding to the polysemous words, they occur mostly in two situation for function words. Some are the polysemous words which can be taken as conjunctions or auxiliary words, while the others can be taken as preposition or adverbs. Fortunately there is no ambiguity for a word given its POS tag, so we could neglect this situation in the split process when training. We demonstrated the solution for the multiple branches in the Section 5.

5 Learning the Taxonomy of Function Words

There are multiple subcategorization criterions for building function word taxonomy, and it is difficulty for human to rank the ordering in the classification process. This section represents the method of learning the taxonomy of the function words in data-driven manner. Based on the manual tabular classification, the similar word classes are conflated to express the data distribution.

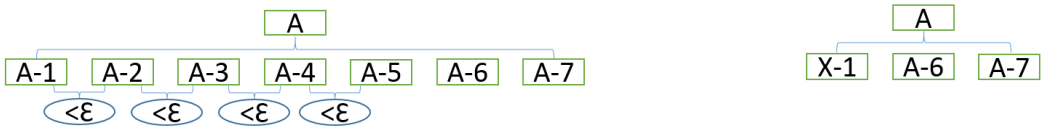
The multiple branches in the taxonomy are intractable for the original split-merge method, because it splits every category into two and merges half of them for efficiency. If we follow this scheme in our training process, it would be difficult to deal with the multi-branch situation in the taxonomy, because how to choose the first two to split among the multiple branches is another challenge. It is an equally difficult problem for us to binarize the taxonomy by hand comparing to directly choosing the granularity.

It would be our advantage to binarize the taxonomy by a data-driven method. For automatic binarization, a straightforward approach is to measure the utility of traversing all the plausible ways of cutting all the branches into two sets individually and use the best one. Then we can deal with the divided two sets in the same manner recursively. However, not only is this impractical, requiring an entire training phase for each possible binarization scheme which is exponentially expensive, but it assumes the contributions of multiple binarizations in different branches are independent. In fact, extra sub-symbols may need to be added to several nonterminals before they can cooperate to pass information along the parse tree.

Therefore, we go in the opposite direction, and propose an extended version of split-merge learning to handle the multiple branches in the taxonomy. That is, we split each state into all the subcategories in the lower layer in the taxonomy even if it has multiple branches, train, and then measure for every two sibling subcategories in the same layer the loss in likelihood incurred when merging them. If this loss is small, the new division of these two subcategories does not carry enough useful information and can be merged back. Contrary to the gain in likelihood for splitting, the loss in likelihood for merging can be

efficiently approximated (Petrov et al., 2006).

More specifically, we assume transitivity in merging multiple subcategories in one layer. Figure 3 gives an illustration. After the split stage, the category A has been split into subcategories A-1, A-2, ... to A-7. Then we compute the loss in likelihood of the training data by merging back each pair of two subcategories through A-1 to A-7. If the loss is lower than a certain threshold [1] set for each round of merge, this pair of newly split subcategories will be merged. We only show the sibling ones for brevity in this example. Assume the losses of merging these pairs (A-1, A-2), (A-2, A-3), (A-3, A-4) and (A-4, A-5) are below the threshold ε. Thus, A-1, A-2, A-3, A-4 and A-5 are merged to X-1 due to the transitivity of the connected points, where X-1 is the automatically generated subcategory which contains the five conflated subcategories as its descendants. At the meantime, A-6 and A-7 still remain. This scheme is an approximation because it merges subcategories that should be merged with the same subcategory. But it will leave the split of this instances to the next round when more evidence on interaction with other more refined subcategories is given.



(a) Refined subcategories before the merge stage

(b) Refined subcategories after the merge stage

Figure 3: Illustration of merging the subcategories for multiple branches in the taxonomy. Where ε is a certain threshold below which this pair of subcategories will be merged, and X is the automatically generated subcategory which contains the conflated subcategories as its descendants.

After merging in each round, the hierarchical knowledge is reshaped to fit the practical usage in the Treebank. The split-merge cycles allow us to progressively increase the complexity of the hierarchical knowledge, and the more useful distinctions are represented as the higher level in the taxonomy, which gives priority to the most useful distinctions in return by supervising the grammar induction. Figure 4 demonstrates the transformation of the hierarchical structure from the tabular classification. Along this road, the training scheme is not a unilateral training, but an interactive process between the knowledge representation learning and the grammar training. Our learning process exerts a mutual effect to both the induced grammar and the optimized structure of the hierarchical knowledge. In this way, the set of dividing standards are chosen iteratively according to their syntactic features. The more effective divisions are conducted in the early stages. In the following stages, the divisions which interact with previous divisions to give the most effective disambiguating information are adopted. The final taxonomy are built based on manual classification in data-driven approach, and the hierarchical structure are optimized and rational in the perspective of actual data distribution. Figure 4 illustrates a concrete instance of the procedure of learning the taxonomy. On one hand, this procedure provides a more rational hierarchical subcategorization structure according to data distribution. On the other hand, the order of the division criterions represents the priorities the grammar induction takes for each criterion. The structure in the higher levels of the taxonomy are determined by the dominant syntactic characteristics. And the division in the later iterations are on the basis of minor distinctive characteristics.

6 Experiments and Results

6.1 Data Set

We present experimental results on both CTB5.0 (All traces and functional tags were stripped.) and TCT.

We ran experiments on CTB5.0 using the standard data allocation: files from CHTB_001.fid to CHTB_270.fid, and files from CHTB_400.fid to CHTB_1151.fid were used as training set. The development set includes files from CHTB_301.fid to CHTB_325.fid, and the test set includes files CHTB_271.fid

[1] In practice, instead of setting a predefined threshold for merging, we merge a specific number of the newly split subcategories.

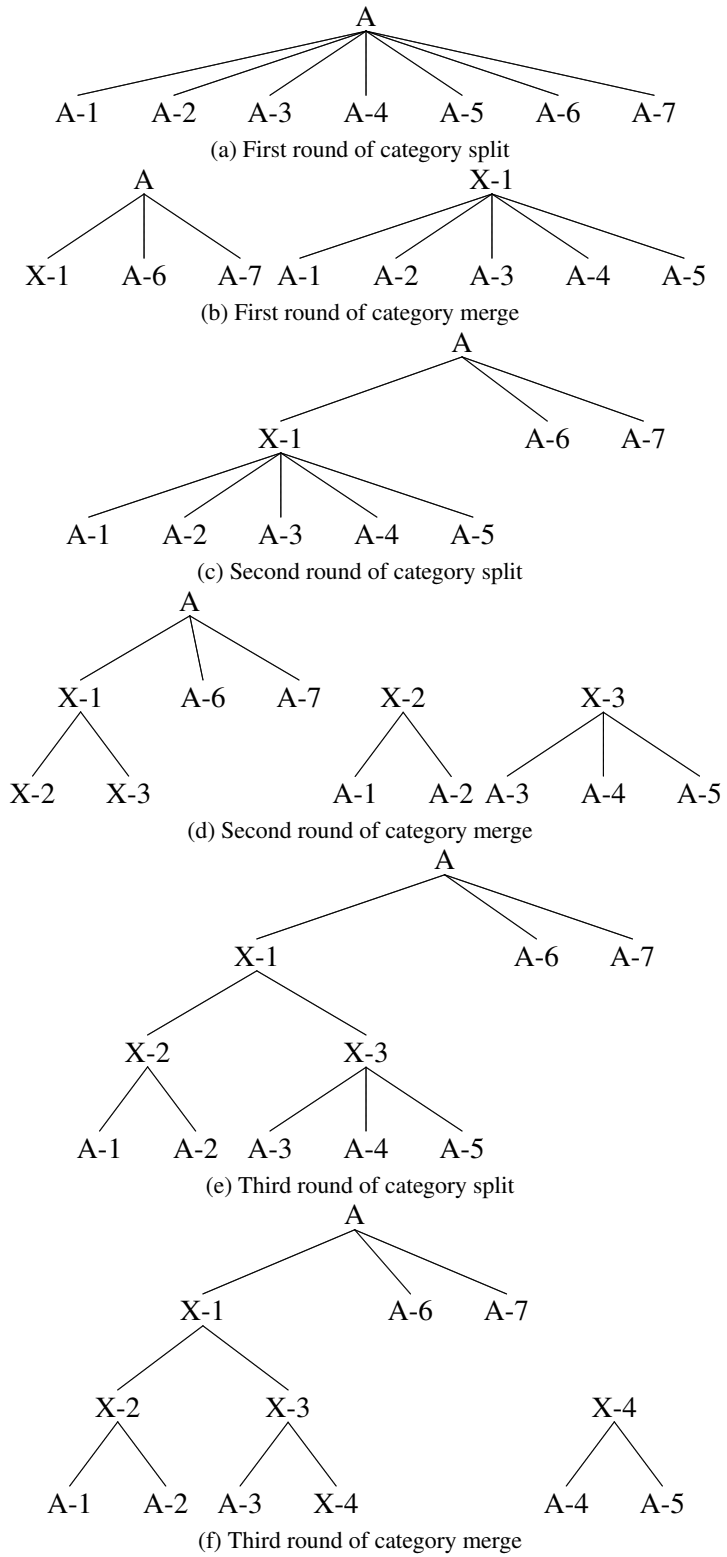


Figure 4: Iteration of grammar induction and taxonomy structure learning

to CHTB_300.fid. Experiments on TCT use the data set as in CIPS-SIGHAN-ParsEval-2012 (Zhou, 2012). We have parsed on the segmented text in the Treebank, namely, no use of gold POS-tags, use of gold segmentations, and full-length sentences. This is the same as for other 5 parsers in Table 1 for comparison. All the experiments were carried out after six cycles of split-merge.

6.2 Final Results

The final results are shown in Table 1. Our final parsing performance is higher than both the manual annotation method (Levy and Manning, 2003) and the data-driven method (Petrov, 2009).

Parser	Precision	Recall	F_1
Levy(2003)	78.40	79.20	78.80
Petrov(2009)	84.82	81.93	83.33
Lin(2009)	86.00	83.10	84.50
Qian(2012)	84.57	**83.68**	84.13
Zhang(2013)	84.42	84.43	84.43
This paper	**86.55**	83.41	**84.95**

Table 1: Our final parsing performance compared with the best previous work on CTB5.0.

On test set TCT, the method achieves the best precision, recall and F-measure in the CIPS-SIGHAN-ParsEval-2012 competition, and table 2 compares our results with the system of Beijing Information Science and Technology University (BISTU) which got the second place in the competition.

Parser	Precision	Recall	F_1
BISTU	70.10	68.08	69.08
This paper	**76.81**	**76.66**	**76.74**

Table 2: Our final parsing performance compared with the best previous works on TCT.

Given the manual labor required for generating the taxonomy (and in languages where there is a taxonomy, determining whether it is suitable), this first study focuses on a language where there is quite a bit of under- and over-specification in the Treebanks' tag sets. So this work is only implemented on Chinese. We regard it as future work to transfer this approach to other languages.

6.3 Analysis

The outline of constructing the taxonomy of function words are as follows. Firstly, the function words are manually subcategorized in a rough and cursory way. When dealing with subcategories hard to resolve their relation of subordination, we simply treat them as siblings in the tree in a rather flat stricture, and leave the elaboration of exquisite clustering to the algorithms. The data-driven approach in Section 4 automatically choose the appropriate granularity of refinement for our grammar. Moreover, the split-merge learning for multiple branches in the hierarchical subcategories in Section 5 exploits the relationship between the sibling nodes in the same layer, making use of the Treebank data to adjust and optimize the hierarchy.

During the split-merge process, the hierarchical subcategories are learned to fit the data, which is a transformation of our manually defined hierarchy. The transformed hierarchy is just the route map of subcategories employed in our model. As abbreviated in Figure 5 and Figure 6, many distinctions between word sets of the subcategories have been exploited by our approach, and the learned taxonomy is interpretable. For instance, It shows that the learned structure of the taxonomy is reasonable.

6.4 Comparison with Previous Work

Although the taxonomy of function words are learned in the grammar training process, the grammar is trained on the Treebank in supervised manner. Thus, this work is not directly relevant with unsupervised grammar induction literature (Headden III et al., 2009; Berant et al., 2007; Mareček and Žabokrtskỳ, 2014).

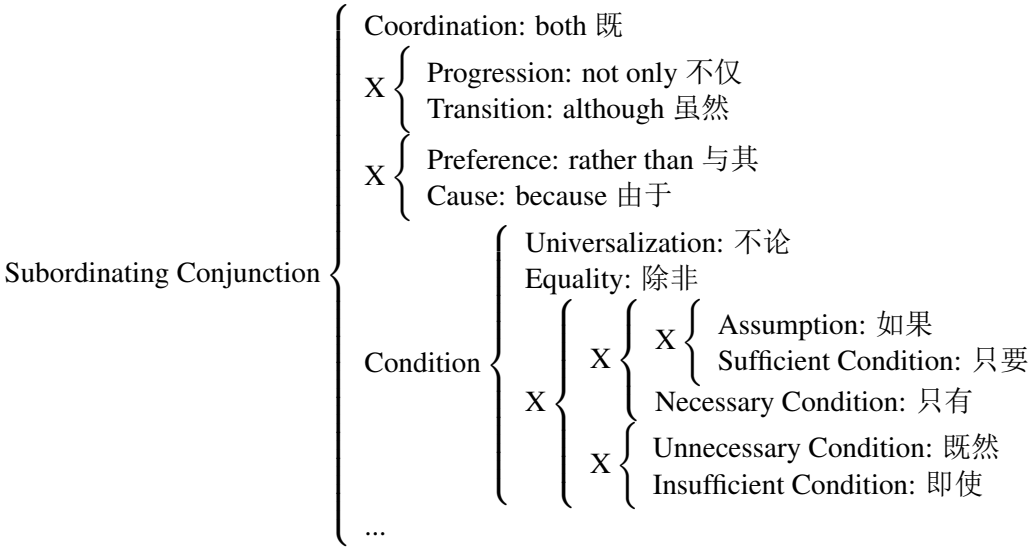

Figure 5: Abbreviated automatically learned hierarchical subcategories of subordinating conjunctions with examples. Where "X" represents the automatically generated subcategory.

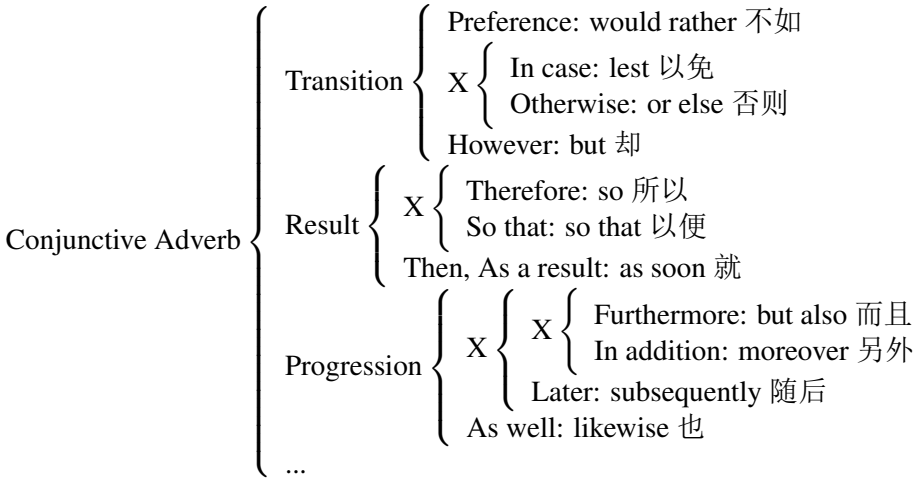

Figure 6: Abbreviated automatically learned hierarchical subcategories of adverbs with examples.

Lin et al. (2009) and Li et al. (2014b) presented ideas of using either hierarchical semantic knowledge from HowNet for content words or grammar knowledge for subordinating conjunctions. They introduced hierarchical subcategory knowledge in a different stage. They split the original Treebank categories in split-merge process according to the data, and then find a method to map the subcategories to the node in the taxonomy, and constrain their further splitting. Comparing to their work, our approach is more delicate, which is splitting the categories according to the knowledge, and learning the knowledge structure according to data during the training course. Lin et al. (2009) incorporated semantic knowledge of content words into the data-driven method. It would be promising if this work stacks with the content word knowledge. However, the work with content word knowledge have to handle the polysemous words in the semantic taxonomy, so they split the categories according to the data, and then find a way to map the subcategories to the node in the taxonomy, and constrain their further splitting. It is our goal to make these two methods compatible with each other.

Incorporating word formation knowledge achieved higher parsing accuracy according to Zhang and

Clark (2011). However, they ran their experiment on gold POS-tags and a different data set split, which is different form the setup of work in Table 1 including this work. They also presented their result on automatically assigned POS-tags and the same data set split as in the work in Table 1 to facilitate the performance comparison. It gave F_1 score of 81.45% for sentences with less than 40 words and 78.3% for all sentences, significantly lower than Petrov and Klein (2007).

Zhang et al. (2013) exhaustively exploited character-level syntactic structures for words, and achieved 84.43% on F_1 measure. They placed more emphasis on the word-formation of content words, which our model highlights the value of the function words. The complementary intuitions make it possible to integrate these approaches together in the future work.

7 Conclusion

This paper presents an approach for inducing finer syntactic categories while learning the taxonomy for function words. It used linguistic insight to guide the state-split process, and the hierarchical structure representing syntactic features of function word usages was established during the grammar training process. Empirical evidence has been provided that automatically subcategorizing function words contributes to high parsing performance. The induced grammar supervised by the taxonomy outperformed pervious approaches, which benefited from both the knowledge and the data-driven method. The proposed approach for learning the structure of the taxonomy could be generalized to construct semantic knowledge base.

Abstract

While lexicalized reordering models have been widely used in phrase-based translation systems, they suffer from three drawbacks: context insensitivity, ambiguity, and sparsity. We propose a neural reordering model that conditions reordering probabilities on the words of both the current and previous phrase pairs. Including the words of previous phrase pairs significantly improves context sensitivity and reduces reordering ambiguity. To alleviate the data sparsity problem, we build one classifier for all phrase pairs, which are represented as continuous space vectors. Experiments on the NIST Chinese-English datasets show that our neural reordering model achieves significant improvements over state-of-the-art lexicalized reordering models.

1 Introduction

Reordering plays a crucial role in phrase-based translation (Koehn et al., 2003; Och and Ney, 2004). While local reordering can be directly memorized in phrases, modeling reordering at a phrase level still remains a major challenge: it can be cast as a travelling salesman problem and proves to be NP-complete (Knight, 1999; Zaslavskiy et al., 2009).

The past decade has witnessed the rapid development of phrase reordering models (e.g., (Och et al., 2004; Tillman, 2004; Zens et al., 2004; Xiong et al., 2006; Al-Onaizan and Papineni, 2006; Koehn et al., 2007; Galley and Manning, 2008; Feng et al., 2010; Green et al., 2010; Bisazza and Federico, 2012; Cherry, 2013), just to name a few). Among them, *lexicalized reordering models* (Tillman, 2004; Koehn et al., 2007; Galley and Manning, 2008) have been widely used in practical phrase-based systems. Unlike the distance-based reordering model (Koehn et al., 2003) that only penalizes phrase displacements in terms of the degree of nonmonotonicity, lexicalized reordering models introduce reordering probabilities conditioned on the words of each phrase pair. They often distinguish between three orientations with respect to the previous phrase pair: *monotone*, *swap*, and *discontinuous*. As lexicalized reordering models capture the phenomenon that some words are far more likely to be displaced than others, they outperform unlexicalized reordering models substantially.

Despite their apparent success in statistical machine translation, lexicalized reordering models suffer from the following three drawbacks:

1. *Context insensitivity*. Lexicalized reordering models determine the orientations only depending on the words of current phrase pairs. In fact, a phrase pair usually has different orientations in different contexts. It is important to include more contexts to improve the expressive power of reordering models.

2. *Ambiguity*. Short phrase pairs, which are observed in the training data more frequently, usually have multiple orientations. We observe that about 92.4% of one-word Chinese-English phrase pairs are ambiguous. This makes it hard to decide which orientation should be properly used in decoding.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1897–1907, Dublin, Ireland, August 23-29 2014.

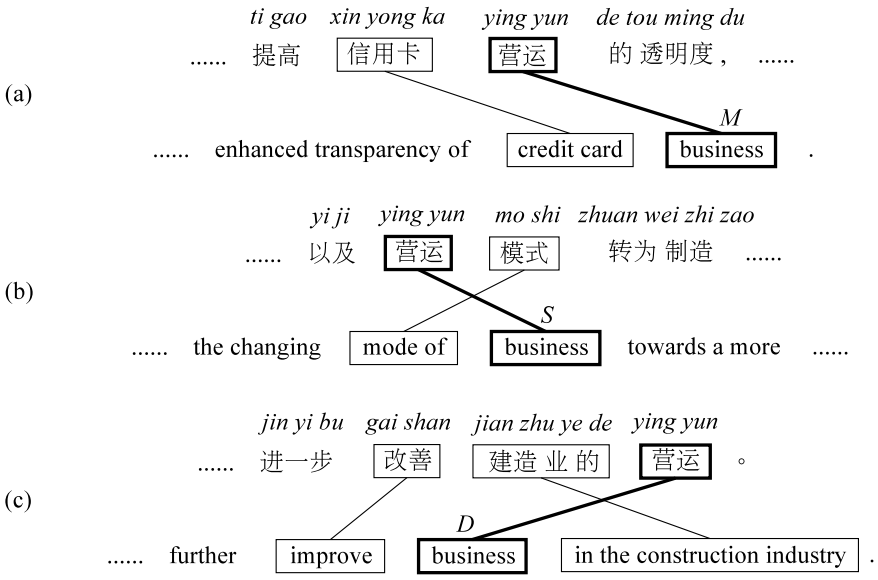

Figure 1: Ambiguity in phrase reordering. The phrase pair ⟨"*yingyun*", "business"⟩ is labeled with different orientations in different contexts: (a) *monotone*, (b) *swap*, and (c) *discontinuous*. Lexicalized reordering models use fixed probability distributions (e.g., 17.50% for M, 1.59% for S, and 80.92% for D) in decoding even though the surrounding contexts keep changing.

3. *Sparsity*. Lexicalized reordering models maintain a reordering probability distribution for each phrase pair. As most long phrase pairs that are capable of memorizing local word selection and reordering only occur once in the training data, maximum likelihood estimation can hardly train the models accurately.

In this work, we propose a neural reordering model for phrase-based translation. The contribution is twofold. Firstly, unlike conventional lexicalized reordering models, the neural reordering model conditions reordering probabilities on the words of both the current and previous phrase pairs. Including the words of previous phrase pairs significantly improves context sensitivity and reduces reordering ambiguity. Secondly, to alleviate the data sparsity problem, we build a neural classifier for all phrase pairs, which are represented as continuous space vectors. Experiments on the NIST Chinese-English datasets show that our neural reordering model achieves significant improvements over state-of-the-art lexicalized models.

2 Lexicalized Reordering Models

The lexicalized reordering models (Tillman, 2004; Koehn et al., 2007; Galley and Manning, 2008) have become the *de facto* standard in modern phrase-based systems. These models are called *lexicalized* because they condition reordering probabilities on the words of each phrase pair. Depending on the relationship between the current and previous phrase pairs, lexicalized reordering models often define *orientations* to classify different reordering patterns.

More formally, we use $\mathbf{f} = \{\tilde{f}_1, \ldots, \tilde{f}_n\}$ to denote a sequence of source phrases, $\mathbf{e} = \{\tilde{e}_1, \ldots, \tilde{e}_n\}$ to denote the phrase sequence on the target side, and $\mathbf{a} = \{a_1, \ldots, a_n\}$ to denote the alignment between source and target phrases. A source phrase $\tilde{f}_{a_i}$ and a target phrase $\tilde{e}_i$ form a phrase pair. Lexicalized reordering models aim to estimate the conditional probability of a sequence of orientations $\mathbf{o} = \{o_1, \ldots, o_n\}$:

$$P(\mathbf{o}|\mathbf{f}, \mathbf{e}, \mathbf{a}) = \prod_{i=1}^{n} P(o_i|\mathbf{f}, \tilde{e}_1, \ldots, \tilde{e}_i, a_1, \ldots, a_i) \quad (1)$$

where each o_i takes values over a set of predefined orientations. For simplicity, current lexicalized

model	source phrase length						
	1	2	3	4	5	6	7
$P(o_i\|\tilde{f}_{a_i}, \tilde{e}_i, a_{i-1}, a_i)$	92.74	54.01	24.09	14.40	10.78	8.47	6.95
$P(o_i\|\tilde{f}_{a_i}, \tilde{e}_i, \tilde{f}_{a_{i-1}}, \tilde{e}_{a_{i-1}}, a_{i-1}, a_i)$	21.72	5.22	2.63	1.48	0.98	0.67	0.54

Table 1: Percentages of phrase pairs that have multiple orientations. Including previous phrase pairs in modeling significantly reduces the reordering ambiguity for the M/S/D orientations. For example, while 92.74% of 1-word Chinese-English phrase pairs have multiple orientations observed in the training data, the ratio dramatically drops to 21.72% if the orientations are conditioned on both the current and previous phrase pairs.

reordering models use orientations conditioned only on a_{i-1} and a_i:

$$P(\mathbf{o}|\mathbf{f}, \mathbf{e}, \mathbf{a}) \approx \prod_{i=1}^{n} P(o_i|\tilde{f}_{a_i}, \tilde{e}_i, a_{i-1}, a_i) \tag{2}$$

The most widely used orientations are *monotone* (M), *swap* (S), and *discontinuous* (D): [1]

$$o_i = \begin{cases} M & \text{if } a_i - a_{i-1} = 1 \\ S & \text{if } a_i - a_{i-1} = -1 \\ D & \text{if } |a_i - a_{i-1}| \neq 1 \end{cases} \tag{3}$$

As lexicalized reordering models maintain a reordering probability distribution for each phrase pair, it is hard to accurately learn reordering probabilities for long phrase pairs that are usually observed only once in the training data. On the contrary, short phrase pairs that occur in the training data for many times tend to be ambiguous. For example, as shown in Figure 1, a Chinese-English phrase pair ⟨"*yingyun*", "business"⟩ is observed to have different orientations in different contexts.

It is unreasonable to use fixed reordering probability distributions in decoding as the surrounding contexts keep changing. Previous study shows that considering more contexts into reordering modeling improves translation performance (Khalilov and Simaan, 2010). Therefore, we need a more powerful mechanism to include more contexts, resolve the reordering ambiguity, and reduce the data sparsity.

3 A Neural Reordering Model

3.1 The Model

Intuitively, conditioning reordering probabilities on the words of both the current and previous phrase pairs will significantly reduce both reordering ambiguity and context insensitivity. The new reordering model is given by

$$P(\mathbf{o}|\mathbf{f}, \mathbf{e}, \mathbf{a}) \approx \prod_{i=1}^{n} P(o_i|\tilde{f}_{a_i}, \tilde{e}_i, \tilde{f}_{a_{i-1}}, \tilde{e}_{i-1}, a_{i-1}, a_i) \tag{4}$$

where $\langle \tilde{f}_{a_{i-1}}, \tilde{e}_{i-1} \rangle$ is the previous phrase pair.

Including the previous phrase pairs improves the context sensitivity. For example, given a phrase pair ⟨"*yingyun*", "business"⟩, its orientation is more likely to be *monotone* if it is preceded by a noun phrase pair such as ⟨"*xinyongka*", "credit card"⟩. On the contrary, the probability of the *discontinuous* orientation is higher if the previous phrase pairs contain verbs such as ⟨"*gaishan*", "improve"⟩. Therefore, the new model is capable of capturing the phenomenon that the orientation of a phrase pair depends on its surrounding contexts.

Another advantage of including previous phrase pairs is the reduction of reordering ambiguity. As shown in Table 1, 92.74% of 1-word Chinese-English phrase pairs have multiple orientations (i.e., M, S,

[1] There are many variants of lexicalized reordering models depending on the model type, orientation, directionality, language, and collapsing. See http://www.statmt.org/moses/?n=FactoredTraining.BuildReorderingModel for more details.

and D) observed in the training data. The ratio decreases with the increase of phrase length. In contrast, the new model is much less ambiguous (e.g., the ratio of ambiguous one-word phrase pairs dramatically drops to 21.72%) as it is conditioned on both the current and previous phrase pairs.

Unfortunately, including more contexts in modeling also increases the data sparsity. We observe that about 90% of reordering examples (i.e., the current and previous phrase pairs) are observed only once in the training data. As a result, it is more difficult to train lexicalized reordering models accurately using maximum likelihood estimation.

To alleviate the data sparsity problem, we use the following two strategies:

1. *Reordering as classification*. Instead of maintaining a reordering probability distribution for each phrase pair, we build a reordering classifier for all phrase pairs (Xiong et al., 2006; Li et al., 2013). This significantly reduces data sparsity by considering all occurrences of extracted phrase pairs as training examples. We find that $500,000$ reordering examples suffice to train a robust classifier (Section 4.5).

2. *Continuous space representation*. Instead of using a symbolic representation of phrases, we use a continuous space representation that treats a phrase as a dense real-valued vector (Socher et al., 2011b; Li et al., 2013). Consider two phrases "in London" and "in Centara Grand". It is usually easy to predict the orientations of "in London" because it might be observed in the training data for many times. This is not the case for "in Centara Grand" as it might occur only once. However, if the two phrases happen to have very similar continuous space representations, "in Centara Grand" is likely to have a similar reordering probability distribution with "in London".

To generate vector space representation for phrases, we follow Socher et al. (2011a) to use recursive autoencoders. Given two words w_1 and w_2, suppose their vector space representations are c_1 and c_2. The vector space representation p of the two-word phrase $\{w_1, w_2\}$ can be computed using a two-layer neural network:

$$p = g^{(1)}(W^{(1)}[c_1; c_2] + b^{(1)}) \tag{5}$$

where $[c_1; c_2] \in \mathbb{R}^{2n}$ is the concatenation of c_1 and c_2, $W^{(1)} \in \mathbb{R}^{n \times 2n}$ is a weight matrix, $b^{(1)}$ is a bias vector, and $g^{(1)}$ is an element-wise activation function.

In order to measure how well p represents c_1 and c_2, they can be reconstructed using another two-layer neural network:

$$[c_1'; c_2'] = g^{(2)}(W^{(2)}p + b^{(2)}) \tag{6}$$

where $c_1' \in \mathbb{R}^n$ and $c_2' \in \mathbb{R}^n$ are reconstructed vectors of c_1 and c_2, $W^{(2)} \in \mathbb{R}^{2n \times n}$ is a weight matrix, $b^{(2)} \in \mathbb{R}^n$ is a bias vector, and $g^{(2)}$ is an element-wise activation function. The reconstruction error can be measured by comparing c_1 and c_2 with c_1' and c_2'. This process runs recursively in a bottom-up style to obtain the vector space representation of a multi-word phrase (Socher et al., 2011a). Socher et al. (2011a) find that minimizing the norms of hidden layers leads to the reduction of reconstruction error in an undesirable way. Therefore, we normalize p such that $||p||_2 = 1$.

Treating phrase reordering as a classification problem, we propose a neural reordering classifier that takes the current and previous phrase pairs as input. The neural network consists of four recursive autoencoders and a softmax layer. The input of the classifier are the previous phrase pair and the current phrase pair. Four recursive autoencoders are used to transform the four phrases (i.e., $\tilde{f}_{a_i}, \tilde{e}_i, \tilde{f}_{a_{i-1}}, \tilde{e}_{i-1}$) into vectors. Then, these vectors are fed to the softmax layer to predict reordering orientations. Note that the recursive autoencoders for the same language share with the same parameters. Our neural network is similar to that of Li et al. (2013). The major difference is that Li et al. (2013) need to compute vector space representation for variable-sized blocks ranging from words to sentences on the fly both in training and decoding. In contrast, we only need to compute vectors for phrases with up to 7 words in the training phase, which makes our approach simpler and more scalable to large data.

Formally, given the previous phrase pair $\langle \tilde{f}_{a_{i-1}}, \tilde{e}_{i-1} \rangle$, the current phrase pair $\langle \tilde{f}_i, \tilde{e}_i \rangle$ and the orientation o_i, the reordering probability is computed as

$$P(o_i | \tilde{f}_{a_i}, \tilde{e}_i, \tilde{f}_{a_{i-1}}, \tilde{e}_{i-1}, a_{i-1}, a_i) = g(W^o c(\tilde{f}_{a_i}, \tilde{e}_i, \tilde{f}_{a_{i-1}}, \tilde{e}_{i-1}) + b^o), \quad (7)$$

where W^o is a weight matrix, b^o is a bias vector, $c(\tilde{f}_{a_i}, \tilde{e}_i, \tilde{f}_{a_{i-1}}, \tilde{e}_{i-1})$ is the concatenation of the vectors of the four phrases. [2]

Following Och (2003), we use a linear model in our decoder with conventional features (e.g., translation probabilities and n-gram language model). The neural reordering model is incorporated into the discriminative framework as an additional feature.

3.2 Training

Training the neural reordering model involves minimizing the following two kinds of errors:

- *Reconstruction error*: It measures how well the computed vector space representations represent the input vectors. It is defined as the average reconstruction error of all the parent nodes in the trees formed during computing the vector space representation for all the phrases in the training data.
- *Classification error*: It measures how well the resulting classifier predicts the reordering orientations. It is defined as the average cross-entropy errors of all the training examples.

In our experiments, the objective function is a linear interpolation of the reconstruction error and the classification error.

Following Socher et al. (2011b), we use L-BFGS (Liu and Nocedal, 1989) to optimize the parameters. At the beginning of each iteration, a binary tree for each phrase is constructed using a greedy algorithm (Socher et al., 2011b). [3] With these trees fixed, the partial derivatives with respect to parameters are computed via the backpropagation through structures algorithm (Goller and Kuchler, 1996).

When optimizing the parameters of the softmax layer, the training procedure keeps the parameters of the recursive autoencoders and word embedding matrices fixed. The corresponding error function is the classification error as described above. We also use L-BFGS to optimize the parameters and the standard error backpropagation algorithm (Rumelhart et al., 1986) to compute the derivatives.

3.3 Decoding

As the vector space representation of a phrase is calculated based on all the words in the phrase, using the neural reordering model complicates the conditions for risk-free hypothesis recombination (Koehn et al., 2003). Therefore, many hypotheses are not likely to be recombined if the neural reordering model is directly integrated in decoding, making the decoder to only explore in a much smaller search space. [4] Therefore, we use Moses to generate search graphs and then use *hypergraph reranking* (Huang and Chiang, 2007; Huang, 2008) to find most probable derivations using the neural reordering model.

4 Experiments

4.1 Data Preparation

We evaluate our reordering model on Chinese-English translation. The training corpus consists of 1.23M sentence pairs with 32.1M Chinese words and 35.4M English words. A 4-gram language model was trained on the Xinhua portion of the English GIGAWORD corpus using KenLM (Heafield, 2011), which contains 398.6M words. We used the NIST 2006 MT Chinese-English dataset as the development set, and NIST 2002-2005, 2008 MT Chinese-English datasets as the test sets. Case-insensitive BLEU is used

[2] In practice, as suggested by Socher et al. (2011b), we feed the four average vectors of the vectors present in each recursive autoencoders to the softmax layer. Taking "resident population" as an example, there are three vectors in the binary tree used by the corresponding recursive autoencoder, denoted as $\hat{x}_1$, $\hat{x}_2$ and $\hat{x}_3$. The average vector is computed as $\bar{x} = \frac{1}{3}\sum_{i=1}^{3} \hat{x}_i$.

[3] As phrases in phrase-based translation are not necessarily syntactic constituents, we do not use parse trees in this work.

[4] Experimental results show that we can only achieve comparable performance with Moses by integrating neural reordering model directly in decoding.

Model	Orientation	MT06	MT02	MT03	MT04	MT05	MT08
distance	N/A	29.56	31.40	31.27	31.34	29.98	23.87
word	M/S/D	30.19	32.03	31.86	*32.09*	30.55	24.20
	left/right	30.17	31.98	31.52	31.98	30.19	24.30
phrase	M/S/D	30.24	32.35	31.85	32.00	*30.78*	24.33
	left/right	29.57	*32.64*	31.53	31.90	30.70	24.28

	left/right	**31.03****	**33.03****	**32.48****	**32.52****	**31.11***	**25.20****

Table 2: Comparison of distance-based, lexicalized, and neural reordering models in terms of case-insensitive BLEU-4 scores. "distance" denotes the distance-based reordering model (Koehn et al., 2003), "word" denotes the word-based lexicalized model (Tillman, 2004), "phrase" denotes the phrase-based lexicalized model (Koehn et al., 2007), "hierarchical" denotes the hierarchical phrase-based reordering model (Galley and Manning, 2008), and "neural" denotes our model. The "left" and "right" orientations only considers whether the current source phrase is on the left of the previous source phrase or not. We use "*" to highlight the result that is significantly better than the best baseline (highlighted in italic) at $p < 0.05$ level and "**" at $p < 0.01$ level. The neural model does not work well for the M/S/D orientations due to the non-separability problem (Section 4.3).

as the evaluation metric. As a trade-off between expressive power and computational cost, we set the dimension of the word embedding vectors to 25. [5] Both $g^{(1)}$ and $g^{(2)}$ are set to $\tanh(\cdot)$. The other hyperparameters are optimized via random search (Bergstra and Bengio, 2012).

4.2 Comparison of Distance-based, Lexicalized, and Neural Reordering Models

We compare three kinds of reordering models with increasing expressive power:

1. *distance-based model*: penalizing phrase displacements proportionally to the amount of nonmonotonicity (Koehn et al., 2003);

2. *lexicalized models*: conditioning the reordering probabilities on the current phrase pairs. The orientations can be determined with respect to words (Tillman, 2004), phrases (Koehn et al., 2007), or hierarchical phrases (Galley and Manning, 2008);

3. *neural model*: conditioning the reordering probabilities on both the current and previous phrase pairs.

For lexicalized and neural models, we further distinguish between two kinds of orientation sets: {*monotone, swap, discontinuous*} and {*left, right*}. The *left*/*right* orientations only consider whether the current source phrase is on the left of the previous source phrase or not. Therefore, *swap* and *discontinuous-left* are merged into *left* while *monotone* and *discontinuous-right* into *right*.

All these reordering models are tested using Moses (Koehn et al., 2007), except that the neural model needs an additional hypergraph reranking procedure (Section 3.3). Implemented using Java, it takes the reranker 0.748 second to rerank a hypergraph on average.

Table 2 shows the case-insensitive BLEU-scores of distance-based, lexicalized, and neural reordering models on the NIST Chinese-English datasets. "distance" denotes the distance-based reordering model (Koehn et al., 2003), "word" denotes the word-based lexicalized model (Tillman, 2004), "phrase" denotes the phrase-based lexicalized model (Koehn et al., 2007), "hierarchical" denotes the hierarchical phrase-based reordering model (Galley and Manning, 2008), and "neural" denotes our model.

[5] We find that the dimensions of vectors do not have a significant impact on translation performance. For efficiency, we set the dimension to 25.

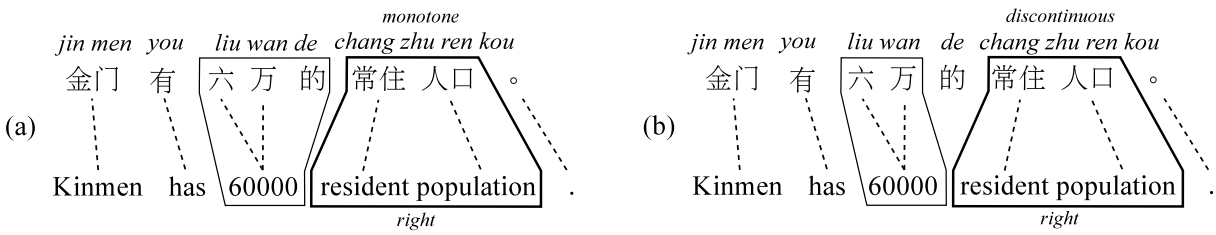

Figure 2: The non-separability problem for the neural reordering model. Given an aligned Chinese-English sentence pair, the unaligned Chinese word "*de*" makes a big difference in determining M/S/D orientations. In (a), "*de*" is included in the previous source phrase and thus the orientation is *monotone*. In (b), however, it is not included in the previous source phrase and the orientation is *discontinuous*. In our neural reordering model, "*liu wan de*" and "*liu wan*" have very similar vector space representations yet different orientations (i.e., M and D). In other words, training examples labeled with M, S, D are prone to be mixed with each other in the vector space. Therefore, it is difficult to find a hyperplane to separate M, S and D examples in the high-dimensional space.

We find that lexicalized reordering models obtain significant improvements over the distance-based model, which indicates that conditioning reordering probabilities on the words of the current phrase pairs does improve the expressive power. Our neural model using *left*/*right* orientations significantly outperforms all variants of lexicalized models. We use "*" to highlight the result that is significantly better than the best baseline (highlighted in italic) at $p < 0.05$ level and "**" at $p < 0.01$ level. This suggests that conditioning reordering probabilities on the words of current and previous phrase pairs is helpful for resolving reordering ambiguities and reducing context insensitivity.

4.3 The Non-Separability Problem

In Table 2, the neural model using the M/S/D orientations fails to outperform lexicalized models significantly. One possible reason is that the neural model suffers from the *non-separability problem* due to the M/S/D orientations.

As shown in Figure 2, given an aligned Chinese-English sentence pair, the unaligned Chinese function word "*de*" makes a big difference in determining M/S/D orientations. In (a), "*de*" is included in the previous source phrase and thus the orientation is *monotone*. In (b), however, "*de*" is not included in the previous source phrase and the orientation is *discontinuous*. In our neural reordering model, "*liu wan de*" and "*liu wan*" have very similar vector space representations yet different orientations (i.e., M and D). In other words, training examples labeled with M, S, D are prone to be mixed with each other in the vector space. Therefore, it is difficult to find a hyperplane to separate M, S and D examples in the high-dimensional space.

Fortunately, we find that using the *left*/*right* orientations can alleviate this problem. As the *left*/*right* orientations only consider whether the current source phrase is on the left of the previous source phrase or not, unaligned source words will not change orientations. For example, both Figure 2(a) and 2(b) are identified as the *right* orientation.

As a result, using *left*/*right* orientations in the neural reordering model not only has a higher classification accuracy (85%) over using the M/S/D orientations (69%), but also achieves higher BLEU scores on all NIST datasets systematically.

4.4 The Effect of Distortion Limit

Figure 3 shows the performance of the lexicalized model and our neural model with various distortion limits. The lexicalized model is the word-based model with M/S/D orientations. The neural model uses *left*/*right* orientations. The neural model consistently outperforms the lexicalized model, especially for large distortion limits. This finding suggests that the neural model is superior to lexicalized models in predicting long-distance reordering.

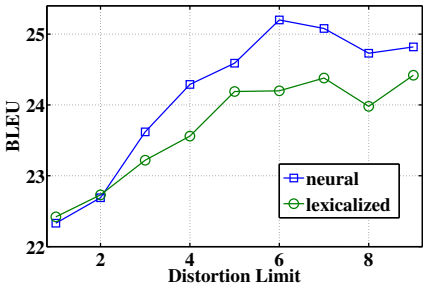

Figure 3: BLEU with various distortion limits.

# examples	Accuracy	BLEU
100,000	83.55	30.92
200,000	84.40	31.03
300,000	84.55	31.01
400,000	84.95	30.93
500,000	85.25	31.27
3,000,000	85.55	31.03

Table 3: Effect of training corpus size.

Vectors	MT06	MT02	MT03	MT04	MT05	MT08
ours	31.03	33.03	32.48	32.52	31.11	25.20
word2vec	30.44	32.28	32.00	32.07	30.24	24.54

Table 4: Comparison of neural reordering models trained based on word vectors produced by our model (ours) and word2vec (Mikolov et al., 2013).

4.5 The Effect of Training Corpus Size

Table 3 shows the classification accuracy and translation performance with various number of randomly sampled reordering examples for training the neural classifier. The classification accuracy and translation performance generally rise as the number of reordering example increases.[6] Surprisingly, both the classification accuracy and translation performance of using 500,000 reordering examples are close to using 3,000,000 reordering examples, suggesting that a relatively small amount of reordering examples are enough for training a robust classifier.

4.6 Learned Vector Space Representations

We randomly sampled 200,000 English phrases and found 999 clusters according to the vector space representations computed by recursive autoencoders using the k-means algorithm (MacQueen, 1967). The distance between two phrases is calculated by the Euclidean distance between their vector space representations.

Figure 4 shows 10 of the 999 clusters. An interesting finding is that phrase pairs that are close in the vector space share with similar reordering patterns rather than semantic similarity. For example, "by june 1" and "within the agencies" have similar distributions on the *left*/*right* orientations but are totally unrelated in terms of meaning. As a result, the vector representations of words trained using unlabeled data hardly helps in training the neural reordering model. Table 4 shows the results when we replace the word vectors of our model with those trained using word2vec (Mikolov et al., 2013). The recursive autoencoders and the classifier are retrained. The performance of the neural reordering model trained in this way drops significantly, which confirms our analysis.

5 Related Work

Reordering as classification is a common way to alleviate the data sparsity problem. Xiong et al. (2006) use a maximum entropy model to predict whether to merge two blocks in a straight or an inverted order in their ITG decoder. Nguyen et al. (2009) build a similar model for hierarchical phrase reordering models (Galley and Manning, 2008). Green et al. (2010) and Yahyaei and Monz (2010) predict finer-grained distance bins instead. Another direction is to learn sparse reordering features and create more flexible distributions (Cherry, 2013). Although these models are effective, feature engineering is a major challenge. In contrast, our neural reordering model is capable of learning features automatically.

[6]The reason why the BLEU scores oscillate slightly on the training set is that classification accuracy is not directly correlated with BLEU scores. Optimizing the neural reordering model directly with respect to BLEU score may further improve the performance. We leave this for future work.

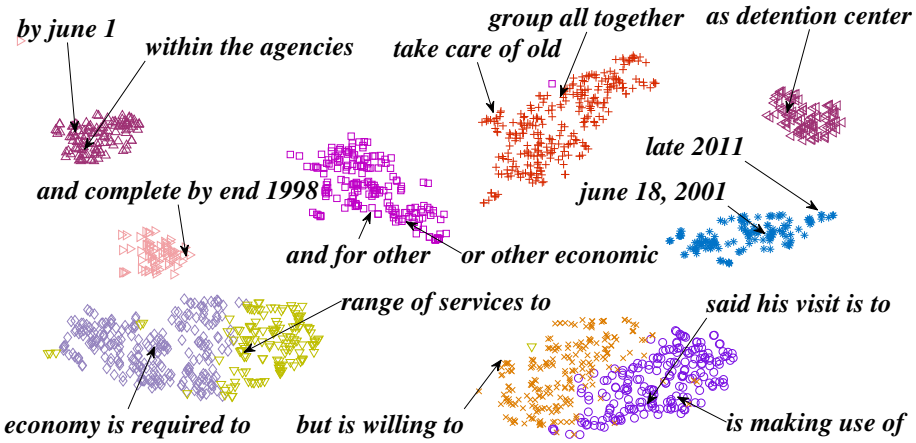

Figure 4: Phrase clusters as calculated by the Euclidean distance in the vector space. English phrases that have similar reordering probability distributions rather than similar semantic similarity fall into one cluster.

Along another line, n-gram-based models (Mariño et al., 2006; Durrani et al., 2011; Durrani et al., 2013) treat translation as Markov chains over minimal translation units (Mariño et al., 2006; Durrani et al., 2013) or operations (Durrani et al., 2011) directly. Although naturally leveraging both the source and target side contexts, these approaches still face the data sparsity problem.

Our work is closely related to Li et al. (2013). The major difference is that Li et al. (2013) need to compute vector space representation for variable-sized blocks ranging from words to sentences on the fly both in training and decoding. In contrast, we only need to compute vectors for phrases with up to 7 words in the training phase, which makes our approach simpler and more scalable to large data.

6 Conclusion

We have shown that surrounding context is effective for resolving reordering ambiguities in phrase-based models. As the data sparseness problem is the major challenge for using context in reordering models, we propose to use a single classifier based on recursive autoencoders to predict reordering orientations. Experimental results show that our neural reordering model outperforms the state-of-the-art lexicalized reordering models significantly and consistently across all the NIST datasets under various settings.

There are a few future directions we plan to explore. First, as the machine translation system and neural classifier are trained separately, the neural network training only has an indirect effect on translation quality. Jointly training the machine translation system and neural classifier is an interesting topic. Second, it is interesting to develop more efficient models to leverage larger contexts to resolve reordering ambiguities. Third, we plan to extend our work to other translation models such as syntax-based and n-gram based models (Mariño et al., 2006; Durrani et al., 2011; Durrani et al., 2013). Finally, as we cast phrase reordering as two-category classification problem (i.e, *left* vs. *right*), it is interesting to intersect structured SVM (Tsochantaridis et al., 2005) with neural networks to develop a large margin training algorithm for our neural reordering model.

Abstract

In this paper, we propose a recurrent neural network-based tuple sequence model (RNNTSM) that can help phrase-based translation model overcome the phrasal independence assumption. Our RNNTSM can potentially capture arbitrary long contextual information during estimating probabilities of tuples in continuous space. It, however, has severe data sparsity problem due to the large tuple vocabulary coupled with the limited bilingual training data. To tackle this problem, we propose two improvements. The first is to factorize bilingual tuples of RNNTSM into source and target sides, we call factorized RNNTSM. The second is to decompose phrasal bilingual tuples to word bilingual tuples for providing fine-grained tuple model. Our extensive experimental results on the IWSLT2012 test sets[1] showed that the proposed approach essentially improved the translation quality over state-of-the-art phrase-based translation systems (baselines) and recurrent neural network language models (RNNLMs). Compared with the baselines, the BLEU scores on English-French and English-German tasks were greatly enhanced by 2.1%-2.6% and 1.8%-2.1%, respectively.

1 Introduction

The phrase-based translation systems (Koehn et al., 2003) rely on language model and lexicalized reordering model to capture lexical dependencies that span phrase boundaries. Their translation models, however, do not explicitly model context dependencies between translation units. To address this limitation, Marino et al. (2006) and Crego and Yvon (2010) proposed n-gram-based translation systems to capture dependencies across phrasal boundaries. The n-gram translation models have been shown to be effective in helping the phrase-based translation models overcome the phrasal independence assumption (Durrani et al., 2013; Zhang et al., 2013). Most of the n-gram translation models (Marino et al., 2006; Durrani et al., 2013; Zhang et al., 2013) employed Markov (n-gram) model over sequence of bilingual tuples also known as minimal translation units (MTUs).

Recently, some pioneer studies (Schwenk et al., 2007; Son et al., 2012) proposed feed-forward neural networks with factorizations to model bilingual tuples in a continuous space. Although the authors reported some gains over the n-gram model in machine translation tasks, these models can only capture a limited amount of context and remain a kind of n-gram model. In language modeling, experimental results in (Mikolov et al., 2011; Arisoy et al., 2012; Sundermeyer et al., 2013) showed that recurrent neural networks (RNNs) outperform feed-forward neural networks in both perplexity and word error rate in speech recognition even though it is harder to train properly.

Therefore, in this paper we take the advantages of RNN and tuple sequence model and propose recurrent neural network-based tuple sequence models (RNNTSMs) to improve phrase-based translation system. Our RNNTSMs are capable of modeling long-span context and have better generalization. Compared with such related studies as (Schwenk et al., 2006; Son et al., 2012), our main contributions can

[1]The IWSLT workshop aims at translating TED speeches (http://www.ted.com), a collection of public lectures covering a variety of topics.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1908–1917, Dublin, Ireland, August 23-29 2014.

be summarized as: (i) our models can be regarded as deep neural network translation models because they can capture arbitrary-length context potentially, which are proven to estimate more accurate probabilities of bilingual tuples; (ii) we extend the conventional RNNTSM to factorized RNNTSMs that can significantly overcome the data sparseness problem caused by the large vocabularies of bilingual tuples by incorporating the factors from the source and the target sides in addition to bilingual tuples; (iii) we investigate heuristic rules to decompose phrasal bilingual tuples to word bilingual tuples for reducing the out-of-tuple-vocabulary rate and providing fine-grained tuple sequence model; (iv) we integrate the proposed models into the state-of-the-art phrase-based translation system (MOSES) as a supplement of the work in (Son et al., 2012) that is a complete n-gram translation system.

2 Related Work

The n-gram translation model (Marino et al., 2006) is a Markov model over phrasal bilingual tuples and can improve the phrase-based translation system (Koehn et al., 2003) by providing contextual dependencies between phrase pairs. To further improve the n-gram translation model, Crego and Yvon (2010) explored factored bilingual n-gram language models. Durrani et al. (2011) proposed a joint sequence model for the translation and reordering probabilities. Zhang et al. (2013) explored multiple decomposition structures as well as dynamic bidirectional decomposition. Since neural networks advance the state of the art in the fields of image processing, acoustic modeling (Seide et al., 2011), language modeling (Bengio et al., 2003), natural language processing (Collobert et al., 2011; Socher et al., 2013), machine transliteration (Deselaers et al., 2009), etc, some prior studies have been done on neural network-based translation models (NNTMs).

One kind of the NNTMs relies on word-to-word alignment information or phrasal bilingual tuples. For example, Schwenk et al. (2007) investigated feed-forward neural networks to model bilingual tuples in continuous space. Son et al. (2012) improved this idea by decomposing tuple units, i.e., distinguishing the source and target sides of the tuple units, to address data sparsity issues. Although the authors reported some gains over the n-gram model in the BLEU scores on some tasks, these models can only capture a limited amount of context and remain a kind of n-gram model. In addition, a feed-forward neural network independent from bilingual tuples was proposed (Schwenk, 2012), which can infer meaningful translation probabilities for phrase pairs not seen in the training data.

Another kind of the NNTMs do not rely on alignment. Auli et al. (2013) and Kalchbrenner and Blunsom (2013) proposed joint language and translation model with recurrent neural networks, in which latent semantic analysis and convolutional sentence model were used to model source-side sentence. Potentially, they can exploit an unbounded history of both source and target words thanks to recurrent connections. However, they only modestly observed gains over the recurrent neural network language model. Previous studies (Wu and Wang, 2007; Yang et al., 2013) showed that the performance of word alignment (alignment error rate) is nearly 80%. That means explicit word alignment may be more reliable as a way to represent the corresponding bilingual sentences compared with an implicit compressed vector representation (Auli et al., 2013).

Our RNNTSM takes the advantages of the above NNTMs, that is, RNN enables our model to capture long-span contextual information, while tuple sequence model uses word alignment without much information loss. Furthermore, factorized RNN and word bilingual tuples are proposed to address data sparsity issue. To the best of our knowledge, few studies have been done on this aspect.

3 Tuple Sequence Model

In tuple sequence model, bilingual tuples are translation units extracted from word-to-word alignment. They are composed of source phrases and their aligned target phrases that are also known as minimal translation units (MTUs) and thus cannot be broken down any further without violating the constrains of the translation rules. This condition results in a unique segmentation of the bilingual sentence pair given its alignment. In our implementation, GIZA++ with `grow-diag-final-and` setting is used to conduct word-to-word alignments in both directions, source-to-target and target-to-source (Och and

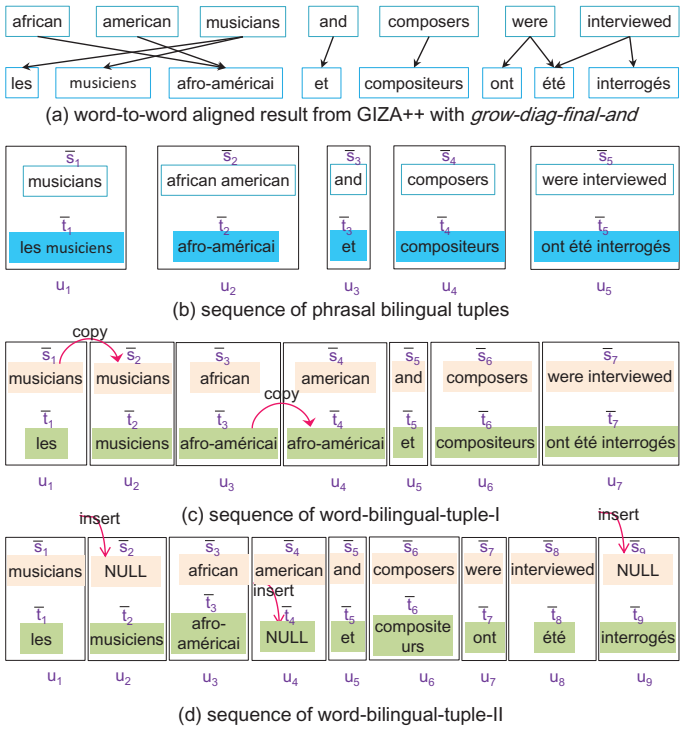

Figure 1: An example of generating basic bilingual tuples from word alignment information.

Ney, 2003). Ncode toolkit[2] is used to generate a unique bilingual segmentation of word-to-word aligned sentence. Figure 1(a)-(b) illustrates the process of generating bilingual tuple. As can be seen in Figure 1, bilingual tuple u_1 is composed of source phrase $\bar{s}_1$ (musicians) and target phrase $\bar{t}_1$ (les musiciens) linked to $\bar{s}_1$. Because this type of bilingual tuples are composed of one or more words from the source side and zero or more words from the target side, we call them phrasal bilingual tuples.

The phrasal bilingual tuple is not able to provide translations for individual words that appear tied to other words unless they occur alone in some other tuple. For example, if target phrase $\bar{t}_k$="les musiciens" is always aligned to source phrase $\bar{s}_k$="musicians" in the training corpus, then no word-to-word translation probability for "musicians:musiciens" will exist. This becomes a serious drawback when a large number of phrasal bilingual tuples are extracted from one-to-many, many-to-one, and many-to-many alignments. To tackle the issue, we propose to decompose phrasal bilingual tuples into word bilingual tuples for providing fine-grained tuple sequence model. Suppose source phrase $\bar{s}_k$, a sequence of source word $s_{k1}, s_{k2}, ..., s_{kI}$, is aligned to target phrase $\bar{t}_k$, a sequence of target word $t_{k1}, t_{k2}, ..., t_{kJ}$, in which I and J refer to the number of words in source phrase and that in target phrase. The following two types of heuristic rules are considered.

(**word-bilingual-tuple-I**): For one-to-many alignments, we copy s_{kI} $J-1$ times to fill the short phrase $\bar{s}_k$. For many-to-one alignments, we copy t_{kJ} $I-1$ times to fill the phrase $\bar{t}_k$. For many-to-many alignment, a maximum phrase length, we set it to 5, is used to avoid vocabulary explosion. That means, if $I > 5$; then $\bar{s}_k$=⟨unk⟩, if $J > 5$; then $\bar{t}_k$=⟨unk⟩.

(**word-bilingual-tuple-II**): For one-to-many, many-to-one, and many-to-many alignments, we insert a special token "NULL" $\mid J - I \mid$ times to fill the short phrase, and map each word in the extended phrase monotonically to generate a word-wise tuple sequence.

The Figure 1(c)-(d) demonstrate the decomposition results. As shown in Figure 1(c), the translation probability of "musicians" being aligned to "musiciens" can be learned in the word bilingual tuples. The word bilingual tuples enable our model use information from source-side of the tuples for computing translation probabilities of some tuples. For example, translating "musicians:musiciens" benefits from its source word "musicians". Table 2 in Section 4 shows the sizes of the tuple vocabularies. We can see

[2] http://ncode.limsi.fr/

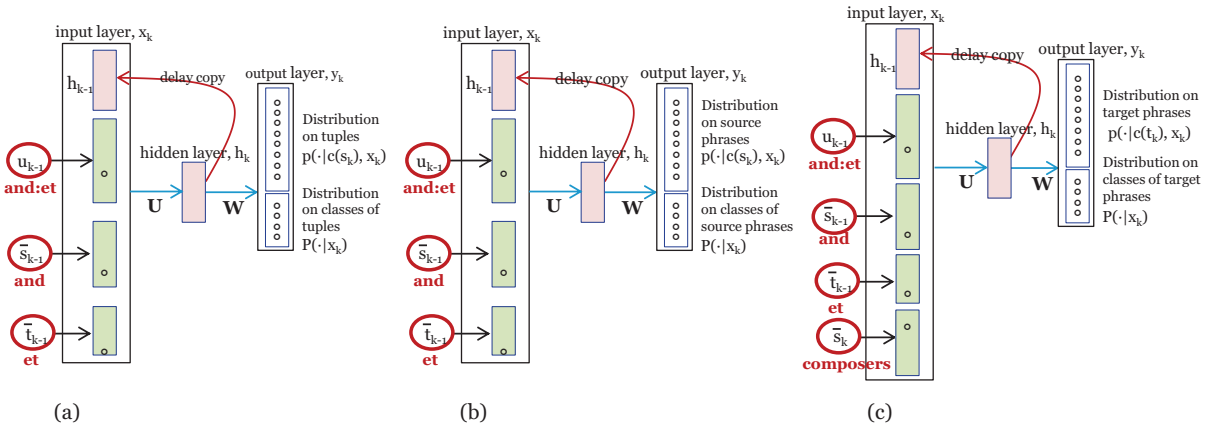

Figure 2: (a): factorized RNNTSM, called fRNNTSM for short, which will go back to the RNNTSM model when $\bar{s}_{k-1}$ and $\bar{t}_{k-1}$ are dropped. (b): fRNNTSM$_{\texttt{source}}$. (c) fRNNTSM$_{\texttt{target}}$.

that the word-bilingual-tuple-I has lower out-of-tuple-vocabulary (OOTV) rate, though it increases the tuple vocabulary. The word-bilingual-tuple-II greatly reduces the tuple vocabulary and the OOTV rate. Note that some words may not be aligned correctly, like "NULL-musiciens". However, generating these tuples can be viewed as a language model process that exploits previous source and target words, and current source word contained in previous tuples like "les-musiciens".

Thus, given a target sentence **t**, a source sentence **s**, and its alignment **a**, the tuple sequence model can be defined over the sequence of bilingual tuples $(u_1, u_2, ..., u_m)$ as follows.

$$p(\mathbf{t}, \mathbf{s}, \mathbf{a}) = \prod_{k=1}^{m} p(u_k|u_{k-1}, u_{k-2}, ..., u_1) = \prod_{k=1}^{m} p(u_k|u_{k-1}, u_{k-2}, ..., u_{k-n+1}) \quad (1)$$

where u_k denotes the k-th bilingual tuple of a given bilingual sentence pair. Each bilingual tuple u_k contains a source phrase $\bar{s}_k$ and its aligned target phrase $\bar{t}_k$[3]. Formally, u_k=$\bar{s}_k$:$\bar{t}_k$. The tuple sequence model does not make any phrasal independence assumption and generates a tuple by looking at a context of previous tuples. The n-gram translation models are Markov models over sequences of tuples, they generate a tuple by looking at previous n-1 tuples.

4 Recurrent Neural Network-based Tuple Sequence Model

In order to use long-span context, this paper presents a recurrent neural network-based tuple sequence model (RNNTSM) to approximate the probability $p(u_i|u_{i-1}, ..., u_1)$. Our RNNTSM can potentially capture arbitrary long context rather than n-1 previous tuples. The input layer encodes bilingual tuples by using 1-of-n coding, and the output layer produces a probability distribution over all bilingual tuples. The hidden layer maintains a representation of the sentence history. This RNNTSM, however, has severe data sparsity problem due to the large tuple vocabulary coupled with the limited bilingual training data.

4.1 Factorized RNNTSM

To solve the problem, we extend the RNNTSM model with factorizing tuples in input layer, as shown in Figure 2(a). Specifically, it consists of an input layer x, a hidden layer h (state layer), and an output layer y. The connection weights among layers are denoted by matrixes **U** and **W**. Unlike the RNNTSM, which predicts probability $p(u_k|u_{k-1}, h_{k-1})$, the factorized RNNTSM predicts probability $p(u_k|u_{k-1}, \bar{s}_{k-1}, \bar{t}_{k-1}, h_{k-1})$ of generating following tuple u_k and is explicitly conditioned on the preceding tuple u_{k-1}, source-side of the tuple $\bar{s}_{k-1}$, and target-side of the tuple $\bar{t}_{k-1}$. It is implicitly conditioned on the entire history by the delay copy of hidden layer h_{k-1}. For those tuples (approximately 20% as shown in Table 2) that are not contained in the training data, i.e., co-occurrence (s_{i-1}, t_{i-1})

[3]Phrases turn to words in the word bilingual tuples. For convenience, we do not distinguish them in our paper.

non-exist while either s_{i-1} or t_{i-1} exists, the factorized RNNTSM backs off to the source- (s_{i-1}) or target-side (t_{i-1}). This process resembles factored n-gram language model (Duh and Kirchhoff, 2004). However, the RNNTSM, computing $p(u_i|u_{i-1}, h_{i-1})$, cannot estimate the probabilities for those tuples. In the special case that $\bar{s}_{k-1}$ and $\bar{t}_{k-1}$ are dropped, the factorized RNNTSM goes back to the RNNTSM. For convenience, u_{k-1}, $\bar{s}_{k-1}$ and $\bar{t}_{k-1}$ are called features. In the input layer, each feature is encoded into a feature vector using the 1-of-n coding. The tuple u_{k-1}, the source phrase $\bar{s}_{k-1}$ and the target phrase $\bar{t}_{k-1}$ are encoded into $|u|$-dimension feature vector v^{u}_{k-1}, $|\bar{s}|$-dimension feature vector $v^{\bar{s}}_{k-1}$ and $|\bar{t}|$-dimension feature vector $v^{\bar{t}}_{k-1}$, respectively. Here, $|u|$, $|\bar{s}|$ and $|\bar{t}|$ stand for the sizes of the tuple, the source phrase, and the target phrase vocabularies. Finally, the input layer x_k is formed by concatenating feature vectors and hidden layer h_{k-1} at the preceding time step, as shown in the following equation.

$$x_k = [v^{u}_{k-1},\ v^{\bar{s}}_{k-1},\ v^{\bar{t}}_{k-1},\ h_{k-1}] \tag{2}$$

The neurons in the hidden and output layers are computed as follows:

$$\begin{aligned} h_k &= f(\mathbf{U} \times x_k), \ \ y_k = g(\mathbf{W} \times h_k) \\ f(z) &= \frac{1}{1+e^{-z}}, \quad g(z) = \frac{e^{z_m}}{\sum_k e^{z_k}} \end{aligned} \tag{3}$$

To speed-up both in the training and testing processes, we map bilingual tuples into classes with frequency binning and divide the output layer into two parts following (Mikolov et al., 2010). The first part estimates the posterior probability distribution over all classes. The second computes the posterior probability distribution over the tuples that belong to class $c(u_k)$, the one that contains predicted tuple u_k. Finally, translation probability $p(u_k|u_{k-1}, \bar{s}_{k-1}, \bar{t}_{k-1}, h_{k-1})$ is calculated by,

$$p(u_k|u_{k-1}, \bar{s}_{k-1}, \bar{t}_{k-1}, h_{k-1}) = p(c(u_k)|x_k) \times p(u_k|c(u_k), x_k) \tag{4}$$

4.2 Factorized RNNTSM on source and target phrases

The above factorized RNNTSM is conditioned on the previous context during computing the probability for tuple u_k. It does not exploit its source side $\bar{s}_k$. For example, tuple "composers:compositeurs" does not benefit from "composers". To address this limitation, we rewrite the probability in Equation 1.

$$\begin{aligned} p(u_k|u_{k-1}, u_{k-2}, ..., u_1) &= p(s_k, t_k|u_{k-1}, u_{k-2}, ..., u_1) \\ &= p(s_k|u_{k-1}, u_{k-2}, ..., u_1) \times p(t_k|s_k, u_{k-1}, u_{k-2}, ..., u_1) \end{aligned} \tag{5}$$

The first sub-model $p(s_k|u_{k-1}, u_{k-2}, ..., u_1)$ computes the probability distribution over source phrases. This model, called fRNNTSM$_{\texttt{source}}$ for short, can be regarded as a reordering model. The second sub-model $p(t_k|s_k, u_{k-1}, u_{k-2}, ..., u_1)$ is a translation model, abbreviated as fRNNTSM$_{\texttt{target}}$, which computes the probability distribution over $\bar{t}_k$ that are translated from $\bar{s}_k$. The two sub-models are computed with the recurrent neural networks shown in Figure 2(b)-(c). Another advantage of using the factorized RNNTSM on source and target phrases separately is that their training become faster because the vocabulary sizes of the source and target phrases are much smaller than that of the tuples.

4.3 Training

Training can be performed by the back-propagation through time (BPTT) algorithm (Boden, 2002) by minimizing an error function defined in the following equations.

$$L = \frac{1}{2} \times \sum_{i=1}^{N} (o_i - p_i)^2 + \gamma \times (\sum_{lk} u^2_{lk} + \sum_{tl} w^2_{tl}) \tag{6}$$

where N is the number of training instances, o_i denotes the desired output; i.e., the probability should be 1.0 for the predicted tuple in the training sentence and 0.0 for all others. γ is the regularization term's weight, which is determined experimentally using a validation set. The training algorithm randomly initializes the matrixes and updates them with Equation 7 over all the training instances in several iterations.

Table 1: BLEU scores of the RNNTSMs, the factorized RNNTSM (fRNNTSM), the fRNNTSM$_{\texttt{source}}$ (sfRNNTSM), the fRNNTSM$_{\texttt{target}}$ with the word-bilingual-tuple-I and their combination. The numbers in the parentheses are the absolute improvements over the Baseline.

In Equation 7, ψ stands for one of the connection weights in the neural networks and η is the learning rate. After each iteration, it uses validation data for stopping and controlling the learning rate. Usually, our RNNs needs 10 to 20 iterations.

$$\psi^{new} = \psi^{previous} - \eta \times \frac{\partial L}{\partial \psi} \tag{7}$$

5 Experiments

We experiment with two language pairs on the IWSLT2012 data sets (Federico et al., 2012), with English as source and French, German as target. The IWSLT data comes from TED speecheds, given by leaders in various fields and covering an open set of topics in technology, entertainment, design, and many others. In the following experiments, the IWSLT dev2010 set is used as the tuning set, the tst2010, tst2011, and tst2012 as the test sets.

Phrase-based translation systems are constructed as baselines using standard settings (GIZA++ alignment, grow-diag-final-and, lexical reordering models, SRILM, and MERT optimizer) in the MOSES toolkit (Koehn et al., 2007). The proposed models are used to re-score n-best lists produced by the baseline systems. The n-best size is set to at most 1000 for each test sentence. During the n-best re-scoring, the weights are re-tuned on the dev2010 data set with MERT optimizer[4]. The proposed RNN-based models are evaluated on a small task and a large task. For the parameters of all the RNN-based models, we set the number of hidden neurons in the hidden layer to 480 and classes in the output layer to 300.

5.1 Small Task

In the small task, the training data only contains the speech-style bi-text, i.e., the human translation of TED speeches. Specially, the corpora for the English-French and English-German pairs contain 139K and 128K parallel sentences. The language model is a standard 4-gram language model with the Kneser-Ney discounting. Both the n-gram LM and the RNNLM are trained on the target side of the bi-text corpus. As the first experiment, we compare the proposed RNNTSMs with the word-bilingual-tuple-I. Table 1 summarizes the results. The main findings from this experiment are: (1) The RNNTSM yields modest improvements of 0.3%-0.4% over the baseline system on most the test sets. (2) The factorized RNNTSMs essentially outperform the baseline and the RNNTSM on all the test sets. Specially, the improvements of the factorized RNNTSM and the combination of the fRNNTSM$_{\texttt{source}}$ and the fRNNTSM$_{\texttt{target}}$ over the baseline for the English-French task range 1.6%-2.2% and 1.7%-2.3%. For the English-German pair, these improvements are between 1.3%-1.4% and 1.1%-1.4%. The results indicate that the factorized RNNTSMs can well address the data sparsity problem of the RNNTSM. (3) The improvements for the English-German pair are comparatively smaller than that for the English-French pair. This is because German is a morphologically rich language (Fraser et al., 2013), its vocabulary is larger and the sparsity

[4]To get statistically reliable comparison (Clark et al., 2011), replication of the MERT optimizer and test set evaluation are performed five times. We finally report the average BLEU scores in the following experiments.

Table 3: BLEU scores of the factorized RNNTSM with various types of bilingual tuples. fRNNTSM$_{\mathrm{p}}$ refers to the fRNNTSM with phrasal bilingual tuples, fRNNTSM$_{\mathrm{I}}$ to the fRNNTSM with the word-bilingual-tuple-I, etc. + means these models are used with the baseline systems. The numbers in the parentheses are the absolute improvements over the +fRNNTSM$_{\mathrm{p}}$.

problem is more serious. (4) There is no significant difference between the factorized RNNTSM and the combination of the fRNNTSM$_{\mathtt{source}}$ and the fRNNTSM$_{\mathtt{target}}$ on most of the test sets except for the tst2011 set of the English-French task. However, the BLEU scores are modestly improved by combining the three factorized RNNTSMs.

The second experiment is to compare the phrasal bilingual tuples and the word bilingual tuples. Table 2 lists the vocabulary sizes of the tuples, source and target phrases. For the word-bilingual-tuple-I, the bilingual tuple vocabulary size increases by 10% in both the English-French and the English-German pairs. Compared with the phrasal bilingual tuples, the bilingual tuple vocabulary size in the word-bilingual-tuple-II slightly changes. In addition, decomposing the tuples is capable to greatly reduce the out-of-tuple-vocabulary rate by approximately 50% in the word-bilingual-tuple-II. Table 3 compares bilingual tuples in terms of BLEU scores. It can be clearly seen that both the word-bilingual-tuple-I and the word-bilingual-tuple-II achieve better performance than the phrasal bilingual tuple on most of the test sets. The BLEU improvements of the word-bilingual-tuple-II over the phrasal tuple range 1.2-1.5 points on the English-German task. The main reason may be lie in: the decomposition can provide word-to-word translation probabilities (such as "musicians:musiciens" in the example of Section 2) for those non-one-to-one alignments. Thus the translation system will have a translation option for an isolated occurrence of such words. Another important observation is that the decomposition performs differently on the English-French and English-German tasks. For example, there exists slight difference between the word-bilingual-tuple-I and the word-bilingual-tuple-II for the English-French task. However, for the English-German task, the word-bilingual-tuple-II significantly outperforms the word-bilingual-tuple-I by 0.4 BLEU scores. Lastly, we achieve modest improvements by combining the two types of word bilingual tuples.

This paper proposes three factorized RNNTSMs and two types of word bilingual tuples. In this experiment, we combine all of them (+Combination contains 6 models) and compare with RNN-based language model (Mikolov et al., 2010). Table 4 summarizes the results. As shown in Table 4 and Table 1, the combination can further enhance the performance on the English-German task. For example, the combination improves the factorized RNNTSM with the word-bilingual-tuple-I from 20.76 to 21.29 on the tst2012 set of the English-German task. Moreover, the combination significantly outperforms the RNNLM. The improvements over the RNNLMs on all test sets range 0.7-1.2 BLEU scores. The

Table 5: BLEU scores of the combination of our proposed models and RNNLM. The numbers in the parentheses are the absolute improvements over the RNNLM.

improvement over the baseline are between 1.9-2.3 BLEU points.

5.2 Large Task

In the large task, the training data includes both speech-style and text-style bi-text corpora. The text-style bi-text corpora are collected from the WMT2012 campaign[5], including CommonCrawl, NewsCommentary, and Europarl. Totally, the numbers of the parallel sentences are 4.35M for the English-French task and 3.85M for the English-German task. The language model is obtained by linear interpolation of several 4-gram models trained on the target side of bi-text corpora and the LDC French Gigaword corpus.

Table 5 reports the results. +Combination means the combination of six models, as described in Table 4. We can observe that: (1) The combination of the proposed RNNTSMs only trained on the speech-style data can essentially enhance the baselines by 1.2-1.8 BLEU points. (2) The improvements over the RNNLMs are significant on the English-German task but these improvements are modest on the English-French task. Note that the factorized RNNTSMs and the RNNLMs in the large task are also only trained the speech-style parallel corpus. In future work, we will train them on a bigger corpus, which can be expected to further increase the performance (Auli et al., 2013; Wu et al., 2012).

6 Conclusion

Most prior neural network-based translation models either employ feed-forward neural networks to explicitly integrate source information via word-to-word alignment, or use recurrent neural networks in which source information is implicitly represented with a compressed vector. In this paper, we present recurrent neural network-based tuple sequence models (RNNTSMs) to compute probabilities of bilingual tuples in continuous space. One of major advantages is their potential to capture long-span history compared with feed-forward neural networks. In addition, our models can well address the data sparsity problem thanks to the fine-grained word bilingual tuples and the factorized recurrent neural networks. As can be concluded from the experimental results on the IWSLT2012 test sets, our factorized RNNTSMs with the proposed bilingual tuples can essentially improve the BLEU scores for the English-French and English-German tasks.

We plan to incorporate re-ordering and syntactic features into RNNTSMs and evaluate them on distant language pairs, such as English-Chinese (Japanese) tasks in the future. Moreover, we will prune large tuple vocabulary and speed up the training on bigger data.

Class-Based Language Modeling for Translating into Morphologically Rich Languages

Arianna Bisazza and **Christof Monz**
Informatics Institute, University of Amsterdam
Science Park 904, 1098 XH Amsterdam, The Netherlands
{a.bisazza,c.monz}@uva.nl

Abstract

Class-based language modeling (LM) is a long-studied and effective approach to overcome data sparsity in the context of n-gram model training. In statistical machine translation (SMT), different forms of class-based LMs have been shown to improve baseline translation quality when used in combination with standard word-level LMs but no published work has systematically compared different kinds of classes, model forms and LM combination methods in a unified SMT setting. This paper aims to fill these gaps by focusing on the challenging problem of translating into Russian, a language with rich inflectional morphology and complex agreement phenomena. We conduct our evaluation in a large-data scenario and report statistically significant BLEU improvements of up to 0.6 points when using a refined variant of the class-based model originally proposed by Brown et al. (1992).

1 Introduction

Class-based n-gram modeling is an effective approach to overcome data sparsity in language model (LM) training. By grouping words with similar distributional behavior into equivalence classes, class-based LMs have less parameters to train and can make predictions based on longer histories. This makes them particularly attractive in situations where n-gram coverage is low due to shortage of training data or to specific properties of the language at hand.

While translation into English has drawn most of the research effort in statistical machine translation (SMT) so far, there is now a growing interest in translating into languages that are more challenging for standard n-gram modeling techniques. Notably, morphologically rich languages are characterized by high type/token ratios (T/T) that reflect in high out-of-vocabulary word rates and frequent backing-off to low order n-gram estimates, even when large amounts of training data are used. These problems have been long studied in the field of speech recognition but much less in SMT, although the target LM is a core component of all state-of-the-art SMT frameworks.

Partly inspired by successful research in the field of speech recognition, various forms of class-based LMs have been shown to improve the quality of SMT when used in combination with standard word-level LMs. These approaches, however, have mostly focused on English (Uszkoreit and Brants, 2008; Dyer et al., 2011; Monz, 2011; Hassan et al., 2007; Birch et al., 2007) with only recent exceptions (Green and DeNero, 2012; Ammar et al., 2013; Wuebker et al., 2013; Durrani et al., 2014). Moreover, there is no published work that systematically evaluates different kinds of classes, model forms and LM combination methods in a unified SMT setting. On the contrary, most of the existing literature on LM combination uses mixtures of multiple *word*-level LMs for domain adaptation purposes.

This paper aims to fill these gaps by applying various class-based LM techniques to the challenging problem of translating *into* a morphologically rich language. In particular we focus on English-Russian, a language pair for which a fair amount of both parallel data and monolingual data has been provided by the Workshop of Machine Translation (Bojar et al., 2013). Russian is characterized by a rich inflectional morphology, with a particularly complex nominal declension (six core cases, three genders and two

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1918–1927, Dublin, Ireland, August 23-29 2014.

number categories). This results in complex agreement phenomena and an extremely rich vocabulary. Indeed, by examining our training data (see Section 4), we find the Russian T/T ratio to be almost two times higher than the English one.

Given this task, we make a number of contributions leading to a better understanding of ways to utilize class-based language models for translating into morphologically rich languages. We conduct a comparative evaluation of different target LMs along the following axes: (1) Classes: data-driven versus shallow morphology-based; (2) Model forms: simple class sequence (stream-based) versus original class-based (Brown et al., 1992); and (3) Combination frameworks: model-level log-linear combination versus word-level linear interpolation. When comparing the different model forms we pay particular attention to the role word emission probabilities play in class-based models, which turns out to be a significant factor for translating into morphologically rich languages. In this context we also evaluate for the first time a specific form of class-based LM called fullibm (Goodman, 2001) within statistical MT.

2 Class-based language models

As introduced by (Brown et al., 1992), the idea of class-based n-gram language modeling is to group words with similar distributional behavior into equivalence classes. The word transition probability is then decomposed into a class transition probability and a word emission probability:

$$P_{\text{class}}(w_i|w_{i-n+1}^{i-1}) = p_0(C(w_i)|C(w_{i-n+1}^{i-1})) \cdot p_1(w_i|C(w_i)) \quad (1)$$

This results in models that are more compact and more robust to data sparsity. Often, in the context of SMT, the word emission probability is dropped and only the class sequence is modeled. In this work, we refer to this model form as *stream-based* n-gram LM:[1]

$$P_{\text{stream}}(w_i|w_{i-n+1}^{i-1}) = p_0(C(w_i)|C(w_{i-n+1}^{i-1})) \quad (2)$$

Stream-based LMs are used, for instance, in factored SMT (Koehn et al., 2007), and in general many of the 'class-based LMs' mentioned in the SMT literature are actually of the latter form (2) (Dyer et al., 2011; Green and DeNero, 2012; Ammar et al., 2013; Chahuneau et al., 2013; Wuebker et al., 2013; Durrani et al., 2014). One exception is the work of Uszkoreit and Brants (2008), who incorporate word emission probabilities in their class-based LM used as an additional feature function in the log-linear combination (cf. Section 3.1). Interestingly, we are not aware of work that compares actual class-based LMs and stream-based LMs with respect to SMT quality.

While class-based LMs are known to be effective at counteracting data sparsity issues due to rich vocabularies, it is worth noting that they adhere to the fundamental constraints of n-gram modeling. Thus, grammatical agreement may be improved by a class-based LM approach only within a limited context window. Previous work that attempted to overcome this limitation includes (i) syntactic LMs for n-best reranking (Hasan et al., 2006; Carter and Monz, 2011) or integrated into decoding with significant engineering challenges (Galley and Manning, 2009; Schwartz et al., 2011) and (ii) unification-based constraints applied to a syntax-based SMT framework (Williams and Koehn, 2011).

We will now describe different kinds of word-to-class mapping functions used by class-based LMs. These can be completely data-driven or based on different sorts of linguistic or orthographic features.

2.1 Data-driven classes

The most popular form of class-based LMs was introduced by (Brown et al., 1992). In this approach, the corpus vocabulary is partitioned into a preset number of clusters by directly maximizing the likelihood of a training corpus. No linguistic or orthographic features are taken into account while training the classes.[2] Later work has focused on decreasing the large computational cost of the exchange algorithm proposed by Brown et al. (1992), either with a distributed algorithm (Uszkoreit and Brants, 2008) or by using a whole-context distributional vector space model (Schütze and Walsh, 2011). In this paper we use the standard SRILM implementation of Brown clustering.

[1] Not to be confused with the incrementally trainable stream-based LMs of Levenberg and Osborne (2009).

[2] Och (1999) extends a similar approach to bilingual clustering with the aim of generalizing the applicability of translation rules in an alignment template SMT framework.

2.2 Linguistic classes

Linguistic knowledge is another way to establish word equivalence classes. Common examples include lemma, part of speech and morphology-based classes, each of which can capture different aspects of the word sequence, such as the relative order of syntactic constituents or grammatical agreement. Hassan et al. (2007) and Birch et al. (2007) went as far as scoring n-grams of Combinatorial Categorial Grammar supertags. When using linguistic classes, one has to deal with the fact that the same word can belong to different classes when used in different contexts. Solutions to this problem include tagging the target word sequence as it is generated (Koehn et al., 2007; Birch et al., 2007; Green and DeNero, 2012), choosing the most probable class sequence for each phrase pair (Monz, 2011) or—even more lightweight—choosing the most probable class for each word (Bisazza and Federico, 2012).

Alternatively, simpler deterministic class mappings can be derived by using shallow linguistic knowledge, such as suffixes or orthographic features. The former can be obtained with a rule-based stemmer (as in this work), or, even more simply, by selecting the ϕ most common word suffixes in a training corpus and then mapping each word to its longest matching suffix (Müller et al., 2012). Orthographic features may include capitalization information or the presence of digits, punctuation or other special characters (Müller et al., 2012).

2.3 Hybrid surface/class models

Müller et al. (2012) obtain the best perplexity reduction when excluding frequent words from the class mapping. That is, each word with more than θ occurrences in the training corpus is assigned to a singleton class with word emission probability equal to 1. The frequency threshold θ is determined with a grid search on a monolingual held-out set. Optimal values for perplexities are shown to vary considerably among languages. In this work we follow this setup closely.

It is worth noting that Bisazza and Federico (2012) have applied a similar idea to the problem of style adaptation: they train a hybrid POS/word n-gram LM on an in-domain corpus and use it as an additional SMT feature function with the goal of counterbalancing the bias towards the style of the large out-of-domain data. The idea of modeling sequences of mixed granularity (word/subword) was earlier introduced to speech recognition by Yazgan and Saraçlar (2004).

The most extensive comparison of distributional, morphological and hybrid classes that we are aware of is the work by Müller et al. (2012), but that does not include any SMT evaluation. Looking at perplexity results over a large number of European language pairs (not including Russian), Müller et al. (2012) conclude that a hybrid suffix/word class-based LM simply built on frequency-based suffixes performs as well as a model trained on much more expensive distributional classes. Motivated by this finding, we evaluate these two kinds of classes in the context of SMT into a morphologically rich language.

2.4 Fullibm language model

As outlined above, the class-based LMs generally used in SMT are in fact stream-based models in the sense that they only estimate the probability of the class sequence (see Equation 2). However, the classic form of class-based LM (Brown et al., 1992) also includes a class-to-word emission probability $p_1(w_i|C(w_i))$ whose utility has not been properly assessed in the context of SMT.

Besides, we observe that a variety of class-based LM variants have been studied in speech recognition but not in SMT. In particular, Goodman (2001) presents a generalization of the standard class-based form where the word emission is also conditioned on the class history rather than on the current class alone. The resulting model is called *fullibm*:

$$P_{\text{fullibm}}(w_i|w_{i-n+1}^{i-1}) = p_0(C(w_i)|C(w_{i-n+1}^{i-1})) \cdot p_1(w_i|C(w_{i-n+1}^{i})) \tag{3}$$

We expect this model to yield more refined, context-sensitive word emission distributions which may result in better target LM probabilities for our SMT system.

3 SMT combining framework

Class-based LMs are rarely used in isolation, but are rather combined with standard word-level models. There exist at least two ways to combine multiple LMs into a log-linear SMT decoder: (i) as separate feature functions in the global log-linear combination or (ii) as components of a linear mixture counting as a single feature function in the global combination.

3.1 Log-linear combination

The standard log-linear approach to SMT allows for the combination of m arbitrary model components (or feature functions), each weighted by a corresponding weight α_m:

$$p(x|h) = \prod_m p_m(x|h)^{\alpha_m} \tag{4}$$

In typical SMT settings, $p_m(x|h)$ are phrase- or word-level translation probabilities, reordering probabilities, and so on. Treating the new LM as an additional feature function has the advantage that its weight can be directly optimized for SMT quality together with all other feature weights, using standard parameter tuning techniques (Och, 2003; Hopkins and May, 2011).

3.2 Linear interpolation

The other widely used combining framework is linear interpolation or mixture model:

$$p(x|h) = \sum_q \lambda_q p_q(x|h) \tag{5}$$

More specifically, word LMs are usually interpolated as a word-level weighted average of the n-gram probabilities:

$$p_{\text{mixLM}}(\mathbf{e}) = \prod_{i=1}^{n} \left(\sum_q \lambda_q p_q(e_i|h_i) \right) \tag{6}$$

The drawback of this approach is that the linear interpolation weights, or *lambdas*, cannot be set with standard SMT tuning techniques. Instead, interpolation weights are typically determined by maximizing the likelihood of a held-out monolingual data set, but this does not always outperform simple uniform weighting in terms of translation quality.[3]

Despite the lambda optimization issue, linear interpolation with uniform or maximum-likelihood weights has been shown to work better for SMT than log-linear combination when combining regular word n-gram LMs (Foster and Kuhn, 2007). However, to the best of our knowledge, the linear interpolation of word- and class-based LMs has never been tested in SMT.

In their intrinsic evaluation, Müller et al. (2012) show that linear mixing with hybrid class/surface models of various kinds consistently decrease the perplexity of a Kneser-Ney smoothed word-level LM, with relative improvements ranging between 3% (English) and 11% (Finnish). All their models are interpolated with class-specific lambda weights, according to the following formula:

$$P_{\text{mix}}(w_i|w_{i-n+1}^{i-1}) \;=\; \lambda_{C(w_{i-1})} \cdot P_{\text{class}}(w_i|w_{i-n+1}^{i-1}) \;+\; (1 - \lambda_{C(w_{i-1})}) \cdot P_{\text{word}}(w_i|w_{i-n+1}^{i-1}) \tag{7}$$

where P_{word} corresponds to the standard n-gram model using the lexical forms. Equation 7 can be seen as a generalization of the simple interpolation $\lambda P_{\text{class}} + (1 - \lambda) P_{\text{word}}$ used by Brown et al. (1992). The class-specific lambdas are estimated by a deleted interpolation algorithm (Bahl et al., 1991). In our experiments, we test both generic and class-specific lambda interpolation for SMT.

[3] Foster and Kuhn (2007) also tried more sophisticated techniques to set interpolation weights but did not obtain significant improvements.

4 Evaluation

We perform a series of experiments to compare the effectiveness for SMT of various class mapping functions, different model forms, and different LM combining frameworks.

The task, organized by the Workshop of Machine Translation (WMT, Bojar et al. (2013)), consists of translating a set of news stories from English to Russian. As shown in Table 1, the available data includes a fairly large parallel training corpus (1.9M sentences) from various sources, a set of Wikipedia parallel headlines shared by CMU,[4] and a larger monolingual corpus for model training (21M sentences). By measuring the type/token ratios of the two sides of a parallel corpus, we can estimate the difference in morphological complexity between two languages: as shown in Table 1, the Russian T/T is almost two times higher than the English one (.0204 vs .0107) in the WMT13 parallel training data. As is usually the case, much more data is available for LM training. Nevertheless we report a rather high out-of-vocabulary word rate on the devsets' reference translations (2.28%).

4.1 Baseline

Our baseline is an in-house phrase-based (Koehn et al., 2003) statistical machine translation system very similar to Moses (Koehn et al., 2007). All system runs use hierarchical lexicalized reordering (Galley and Manning, 2008; Cherry et al., 2012), distinguishing between monotone, swap, and discontinuous reordering, all with respect to left-to-right and right-to-left decoding. Other features include linear distortion, bidirectional lexical weighting (Koehn et al., 2003), word and phrase penalties, and finally a word-level 5-gram target language model trained on all available monolingual data with modified Kneser-Ney smoothing (Chen and Goodman, 1999). The distortion limit is set to 6 and for each source phrase the top 30 translation candidates are considered.

The feature weights for all approaches were tuned by using pairwise ranking optimization (Hopkins and May, 2011) on newstest12. During tuning, 14 PRO parameter estimation runs are performed in parallel on different samples of the n-best list after each decoder iteration. The weights of the individual PRO runs are then averaged and passed on to the next decoding iteration. Performing weight estimation independently for a number of samples corrects for some of the instability that can be caused by individual samples.

4.2 Language models

The additional LMs are trained with Witten-Bell smoothing (Witten and Bell, 1991), which is a common choice for class-based LM training as Kneser-Ney smoothing cannot be used for computing discount factors when the count-of-counts are zero. The main series of experiments employ 5-gram models, but we also evaluate the usefulness of increasing the order to 7-gram (see Table 3).[5]

Data-driven clusters are learned with the standard Brown clustering algorithm, which greedily maximizes the log likelihood of a class bigram model on the training data. Following Ammar et al. (2013), we set the number of data-driven clusters to 600. In preliminary experiments we also tested a 256-cluster setting, but 600 yielded better BLEU scores. For time reasons, we train the clusters on a subset of the

monolingual data including all the parallel data (news commentary) and the large commoncrawl corpus for a total of 1M sentences (22M tokens). We then map all monolingual data to the learned clusters and use that to train all our cluster-based LMs.

For the suffix-based class LMs we closely follow the setup of Müller et al. (2012) with the only difference that we use the Russian Snowball stemmer[6] to segment the vocabulary instead of frequency-based suffixes. The suffix threshold θ (see Section 2.3) is determined by minimizing perplexity on a separate held-out set (5K sentences): θ=5000 is the optimal setting among $\{2000, 5000, 10000, 20000\}$.[7] The same held-out set is used to estimate both the generic and the class-specific lambdas for the linear interpolation experiments.

Table 2 presents an overview of the LMs used in our experiments. We can see on the left side that all class-based LMs have notably higher perplexities compared to the word-level, with the fully suffix-based LM performing worst by far. Nevertheless, all class-based models yield a decrease in perplexity when they are interpolated with the word-level model (right side). The best improvement is achieved by the data-driven classes (225 versus 270, that is -17%), but the result of the hybrid LM is also quite successful (-10%) and much in line with the improvements reported by Müller et al. (2012) on other Slavic languages. Because the fully suffix-based LM yields only a modest reduction, we do not to include it in the SMT evaluation. The right side of Table 2 also shows that using class-specific interpolation weights is not significantly better, and sometimes is even worse than using only one generic λ, at least from the point of view of perplexity. Since weight estimation for linear interpolation is still an open problem for SMT, we decide nevertheless to compare these two interpolation methods in our translation experiments (see Table 4).

4.3 SMT results

Table 3 shows the results for English to Russian translation using log-linear combination with Brown clusters and the hybrid suffix/word classes. Translation quality is measured by case-insensitive BLEU (Papineni et al., 2002) on newstest13 using one reference translation. The relative improvements of the different class-based LM runs are with respect to the baseline which uses a word-based LM only and achieves comparable results to the state-of-the-art. We use approximate randomization (Noreen, 1989) to test for statistically significant differences between runs (Riezler and Maxwell, 2005).

We can see from Table 2(a) that using a stream-based LM as an additional feature, which is log-linearly interpolated with the other decoder features during parameter estimation, leads to small but statistically significant improvements. The results also indicate that using a higher n-gram class model (7-gram) does not yield additional improvements over a 5-gram class model, which is in contrast with the results reported by Wuebker et al. (2013) on a French-German task.

Since the stream-based models ignore word emission probabilities, one would expect further improvements from the theoretically more correct class-based model which include word emission probabilities (see Equation 1). Somewhat surprisingly, this is not the case. On the contrary, both 5- and 7-gram class-based models perform slightly worse than the stream-based models. We suspect that this is due to the limited context used to estimate the emission probabilities in the original Brown class-based models. To verify this we compared this to the fullibm model (Equation 3) which conditions word emission

[6] http://snowball.tartarus.org/algorithms/russian/stemmer.html

[7] Our training corpus is considerably larger than those used by Müller et al. (2012), therefore we search among higher values.

probabilities on the entire n-gram class history of length $n - 1$. The fullibm class-based models yield the biggest statistically significant improvements over the baseline and also compare favorably to the stream-based and original class-based models. Similarly to stream- and class-based models we do not observe a difference in performance between 5- and 7-gram models for fullibm.

Table 2(b) shows the results obtained by the shallow morphology-based classes inspired by Müller et al. (2012). This form of classes is easy to implement in many languages and computationally much cheaper than the Brown clusters. Although less than the data-driven class models, the hybrid suffix/word models also appear to improve translation quality. We can see that fullibm again yields the highest improvements, but we can also observe more consistent trends where longer n-grams help and class-based models are preferable to stream-based models without emission probabilities.

When translating into a morphologically rich language, such as Russian, the role of the target language model is two-fold. On the one hand, it helps choose the correct meaning from the available phrase translation candidates, on the other hand, it helps choose the correct surface realization of the translation candidate that agrees grammatically with the previous target context. For morphologically rich languages the second aspect plays a considerably larger role than for morphologically poor languages. To disentangle these two roles of the language model we also evaluated the different language models with respect to stem-based information only, stripping off any inflectional information using the Snowball stemmer. These results are also reported in Table 3 and in general exhibit the same trend as the surface-based BLEU scores. Again, fullibm performs best, and the original class-based LMs do not lead to any improvements over the baseline. As a general observation, we find that the surface-level gains are most of the time larger than the stem-level ones, which suggests that the additional LMs are mainly improving the choice of word inflections.

All systems compared in Table 3 use a class language model as an additional feature, which is log-linearly interpolated with the other decoder features. Alternatively, the word- and the class-based lan-

Table 4: SMT translation quality on newstest13 when using different LM combining frameworks: additional feature in the log-linear combination or linear interpolation with perplexity-tuned weights (one global lambda or class-specific lambdas).

guage models may be linearly interpolated with weights determined by maximizing the likelihood of a held-out monolingual data set (see Section 3.2). While linear interpolation often outperforms log-linear interpolation for combining language models for domain adaptation (Foster and Kuhn, 2007), this does not seem to be the case for language models for morphologically rich target languages. The results presented in Table 4 consistently show that linear interpolation under-performs log-linear combination under all conditions. Even using class-specific interpolation weights as suggested by Müller et al. (2012) did not lead to any further improvements.

5 Conclusion

We have presented the first systematic comparison of different forms of class-based LMs and different class LM combination methods in the context of SMT into a morphologically rich language.

First of all, our results have shown that careful modeling of class-to-word emission probabilities—often omitted from the models used in SMT—is actually important for improving translation quality. In particular, we have achieved best results when using a refined variant of the original class-based LM, called fullibm, which had never been tested for SMT but only for speech recognition (Goodman, 2001). Secondly, we have found that a rather simple LM based on shallow morphology-based classes can get close, in terms of BLEU, to the performance of more computationally expensive data-driven classes. Although the reported improvements are modest, they are statistically significant and obtained in a competitive large-data scenario against a state-of-the-art baseline.

On the downside, and somewhat in contrast with previous findings in domain adaptation, we have observed that linear interpolation of word- and class-based LMs with perplexity-tuned weights performs worse than the log-linear combination of models with model-level weights globally tuned for translation quality. This result was confirmed also when using class-specific lambdas as suggested by Müller et al. (2012).

Indeed, modeling morphologically rich languages remains a challenging problem for SMT but, with our evaluation, we have contributed to assess how far existing language modeling techniques may go in this direction. Natural extensions of this work include combining multiple LMs based on different, and possibly complementary, kinds of classes such as data-driven and suffix-based, or using supervised morphological analyzers instead of a simple stemmer. In a broader perspective, we believe that future research should question the fundamental constraints of n-gram modeling and develop innovative modeling techniques that conform to the specific requirements of translating into morphologically rich languages.

Acknowledgments

This research was funded in part by the Netherlands Organisation for Scientific Research (NWO) under project numbers 639.022.213 and 612.001.218. We kindly thank Thomas Müller for providing code and support for the weight optimization of linearly interpolated models.

Latent Domain Translation Models in Mix-of-Domains Haystack

Hoang Cuong and **Khalil Sima'an**
Institute for Logic, Language and Computation
University of Amsterdam
Science Park 107, 1098 XG Amsterdam, The Netherlands

Abstract

This paper addresses the problem of selecting adequate training sentence pairs from a mix-of-domains parallel corpus for a translation task represented by a small in-domain parallel corpus. We propose a novel latent domain translation model which includes domain priors, domain-dependent translation models and language models. The goal of learning is to estimate the probability of a sentence pair in mix-domain corpus to be in- or out-domain using in-domain corpus statistics as prior. We derive an EM training algorithm and provide solutions for estimating out-domain models (given only in- and mix-domain data). We report on experiments in data selection (intrinsic) and machine translation (extrinsic) on a large parallel corpus consisting of a *mix of a rather diverse set of domains*. Our results show that our latent domain invitation approach outperforms the existing baselines significantly. We also provide analysis of the merits of our approach relative to existing approaches.

Large parallel corpora are important for training statistical MT systems. Besides size, the *relevance* of a parallel training corpus to the translation task at hand can be decisive for system performance, cf. (Axelrod et al., 2011; Koehn and Haddow, 2012). In this paper we look at data selection where we have access to a large parallel data repository $\mathcal{C}_{mix}$, representing a rather varied mix of domains, and we are given a sample of in-domain parallel data $\mathcal{C}_{in}$, exemplifying a target translation task. Simply concatenating $\mathcal{C}_{in}$ with $\mathcal{C}_{mix}$ does not always deliver best performance, because including irrelevant sentences might be more harmful than beneficial, cf. (Axelrod et al., 2011). To make the best of available data, we must select sentences from $\mathcal{C}_{mix}$ for their relevance to translating sentences from $\mathcal{C}_{in}$.

Axelrod et al. (2011) and follow-up work, e.g., (Haddow and Koehn, 2012; Koehn and Haddow, 2012), select sentence pairs in $\mathcal{C}_{mix}$ using the cross-entropy difference between in- and mix-domain *language models*, both source and target sides, a modification of the Moore and Lewis method (Moore and Lewis, 2010). In the translation context, however, often a source phrase has different senses/translations in different domains, which cannot be distinguished with monolingual language models. The dependence of translation choice on domain suggests that the word alignments themselves can better be conditioned on domain information. However, in the data selection setting, corpus $\mathcal{C}_{mix}$ often does not contain useful domain markers, and $\mathcal{C}_{in}$ contains only a small sample of in-domain sentence pairs.

In this paper we present a *latent domain translation model* which weights every sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle \in C_{mix}$ with a probability $P(D \mid \mathbf{f}, \mathbf{e})$ for being in-domain (D_1) or out-domain (D_0). Our model defines $P(\mathbf{e}, \mathbf{f}) = \sum_{D \in \{D_1, D_0\}} P(D) P(\mathbf{e}, \mathbf{f} \mid D)$, using a latent domain variable $D \in \{D_0, D_1\}$. Using bi-directional translation models, this leads to a domain prior $P(D)$, domain-dependent translation models $P_t(\cdot \mid \cdot, D)$ and language models $P_{lm}(\cdot \mid D)$ as in Equation 1:

$$P(\mathbf{e}, \mathbf{f} \mid D) \;=\; \frac{1}{2} \times \{P_{lm}(\mathbf{e} \mid D) P_t(\mathbf{f} \mid \mathbf{e}, D) \;+\; P_{lm}(\mathbf{f} \mid D) P_t(\mathbf{e} \mid \mathbf{f}, D)\} \tag{1}$$

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1928–1939, Dublin, Ireland, August 23-29 2014.

For efficiency we assume IBM Model I alignments $\mathbf{a}$ and translation tables $t(\cdot)$, e.g., $P_t(\mathbf{e} \mid \mathbf{f}, D) \propto \sum_{\mathbf{a}} \prod_i t(e_i \mid f_{\mathbf{a}_i}, D)$. Language models (LMs) P_{lm} are trained separately, albeit one problem not addressed by earlier work is how to train out-domain LMs given only in- and mix-domain data?

In our model, initially both the translation and LM probabilities estimated from $\mathcal{C}_{in}$ serve as *priors* for weighting sentence pairs in $\mathcal{C}_{mix}$ as being *more* relevant for in-domain translation *than not*. This initial weighting reveals *pseudo out-domain* data in $\mathcal{C}_{mix}$, which we use to train out-domain language models as well as initialize out-domain word alignment tables.[1] With these sharpened translation and language models, training commences using a version of EM (Dempster et al., 1977). Because the *potentially relevant data* in $\mathcal{C}_{mix}$ might be a superset of any in-domain data, the estimates from $\mathcal{C}_{in}$ serve merely as initial model estimates. Metaphorically, iterative EM training resembles `party invitations` on social networks (hence, the *Invitation model*): if initially in/out-domain sentence pairs (the `hosts`) `invite` some sentence pairs from $\mathcal{C}_{mix}$, in the next iteration the new `pseudo` in/out-domain sentences help invite more sentence pairs. In EM, sentence pairs receive weighted, rather than absolute, invitations from in- and out-domain models.

We present extensive experiments on a rather difficult selection task exploiting a large mix-domain corpus of 4.61M sentence pairs. Initially we conduct intrinsic evaluation on the mix-domain corpus where we also hide in-domain data and seek to retrieve it. Subsequently we conduct full MT experiments over the task. The results show that our Invitation model gives far better selections as well as translation performance than the baseline trained on the large data C_{mix}.

1 Invitation models of weighting and selection

By now training data selection from large mix-domain data is an accepted necessity, e.g., (Axelrod et al., 2011; Gascó et al., 2012; Haddow and Koehn, 2012; Banerjee et al., 2012; Irvine et al., 2013). Data selection has a different (but complementary) goal than domain adaptation, which aims at adapting an *existing out-domain system* by focusing on, e.g., translation model (Koehn and Schroeder, 2007; Foster and Kuhn, 2007; Sennrich, 2012), reordering model (Chen et al., 2013) and/or language model adaptation (Eidelman et al., 2012). Our setting is in line with data selection approaches (Moore and Lewis, 2010; Axelrod et al., 2011; Duh et al., 2013), and is somewhat related to phrase pair weighting (Matsoukas et al., 2009; Foster et al., 2010). In this paper we explicitly draw attention to the special case of a mix-domain parallel corpus consisting of a large and rather diverse set of domains.

Our model assigns to every sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle \in \mathcal{C}_{mix}$ a probability as in Equation 2:

$$\begin{aligned} P(D \mid \mathbf{f}, \mathbf{e}) &= \frac{P(\mathbf{f}, \mathbf{e}, D)}{\sum_{D \in \{D_1, D_0\}} P(\mathbf{f}, \mathbf{e}, D)} \\ P(\mathbf{f}, \mathbf{e}, D) &= \frac{1}{2} \times P(D) \times \{P_{lm}(\mathbf{e} \mid D) P_t(\mathbf{f} \mid \mathbf{e}, D) + P_{lm}(\mathbf{f} \mid D) P_t(\mathbf{e} \mid \mathbf{f}, D)\} \end{aligned} \tag{2}$$

Viewed as learning two latent corpora $\mathcal{C}_1$ and $\mathcal{C}_0$, the task is to assign every $\langle \mathbf{f}, \mathbf{e} \rangle \in C_{mix}$ an expected count $P(D_x \mid \mathbf{f}, \mathbf{e})$ that it is in $\mathcal{C}_x \in \{C_0, C_1\}$. Next we discuss the model components each in turn.

The domain-dependent translation models $P_t(\cdot \mid D)$ can be viewed as modeling the probability that $\mathbf{e}$ translates as $\mathbf{f}$ in domain $D \in \{D_0, D_1\}$. Given $\mathbf{f} = f_1, f_2, \ldots, f_m$ and $\mathbf{e} = e_1, e_2, \ldots, e_l$, we assume (hidden) alignments $\mathbf{a} = a_1, a_2, \ldots, a_m$ akin to IBM Model I (Brown et al., 1993):

$$P_t(\mathbf{f}, \mathbf{a} \mid \mathbf{e}, D) = \frac{\epsilon}{(l+1)^m} \prod_{j=1}^{m} t(f_j | e_{a_j}, D) \tag{3}$$

$$P_t(\mathbf{f} \mid \mathbf{e}, D) = \sum_{\mathbf{a}} P_t(\mathbf{f}, \mathbf{a} | \mathbf{e}, D) = \frac{\epsilon}{(l+1)^m} \prod_{j=1}^{m} \sum_{i=0}^{l} t(f_j | e_i, D). \tag{4}$$

[1] Earlier work on data selection exploits the contrast between in-domain and mix-domain instead of (pseudo) out-domain language models. However, the mix-domain language models trained on a mix of rather diverse set of domains could be considered kind of wide-coverage, which makes for a rather weak contrast with the in-domain language models.

where $t(f_j|e_{a_j}, D)$ is the domain-dependent lexical probability of f_j given e_{a_j} with respect to D. One crucial aspect about model inspired by IBM-Model-I is that $P_t(\mathbf{f} \mid \mathbf{e}, D)$ can be estimated efficiently, as in Equation 4. This makes the training particularly efficient as detailed in Section 2

The in-/out-domain source and target language models are not the same as in previous work, e.g., (Axelrod et al., 2011), which employ in-/mix-domain language models. This makes explicit the difficulty in finding data to train out-domain language models, and we present a solution in Section 2.

The domain priors $P(D_1)$ and $P(D_0)$ represent the percentage of the pairs that are in-/ and out domain respectively in $\mathcal{C}_{mix}$ learned by our model. Their estimate during training might be a reasonable selection cut-off threshold. However, we found that it is not entirely clear whether these cut-off criteria might exclude other relevant/irrelevant pairs that are not exactly in-domain. We leave this extension for future work.[2]

Finally, it should be noted that the domain-dependent word alignment model, $t(f|e, D)$ is a generalization of the standard (domain-independent) word alignment model, $t(f|e)$, in which, $t(f|e, D) = \frac{t(f|e)t(D|f,e)}{\sum_f t(f|e)t(D|f,e)}$. Here, $t(D|f, e)$ can be thought of as the *latent word-relevance models*, i.e., the probability that a word pair is relevant for in- (D_1) or out-domain (D_0). Empirical results (beyond the scope of this work) show that training the latent in-domain alignment model, $t(f|e, D_1)$ often gives better translation systems than training the standard (domain-independent) alignment model, $t(f|e)$.

2 Training

With all language models trained separately, our selection model can be viewed to have two sets of domain-dependent parameters $\Theta = \{\Theta_{D_0}, \Theta_{D_1}\}$. The parameters Θ_D consist of the domain-dependent lexical parameters (e.g., $t_{\Theta_D}(f|e, D)$, $t_{\Theta_D}(e|f, D)$) and the domain prior parameter (e.g., $P_{\Theta_D}(D)$). Our training procedure seeks the parameters Θ that maximize the log-likelihood of $\mathcal{C}_{mix}$:

$$\mathcal{L} = \sum_{\mathbf{f},\mathbf{e}} \log P_\Theta(\mathbf{f}, \mathbf{e}) \quad = \quad \sum_{\mathbf{f},\mathbf{e}} \log \sum_D \sum_{\mathbf{a}} P_{\Theta_D}(\mathbf{a}, D, \mathbf{f}, \mathbf{e}) \tag{5}$$

Because of the latent variables $\mathbf{a}$ and D, there is no closed form solution and the model is fit using the EM algorithm (Dempster et al., 1977). EM can be seen to maximize $\mathcal{L}$ via block-coordinate ascent on a lower bound $\mathcal{F}(q, \Theta)$ using an auxiliary distribution over the latent variables $q(\mathbf{a}, D|\mathbf{f}, \mathbf{e})$

$$\mathcal{L} \quad \geq \quad \mathcal{F}(q, \Theta) = \sum_{\mathbf{f},\mathbf{e}} \sum_D \sum_{\mathbf{a}} q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e}) \log \frac{P_{\Theta_D}(\mathbf{a}, D, \mathbf{f}, \mathbf{e})}{q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e})} \tag{6}$$

where the inequality results from log being concave and Jensen's inequality. We rewrite the Free energy $\mathcal{F}(q, \Theta)$ (Neal and Hinton, 1999) as follows:

$$\begin{aligned}
\mathcal{F}(q, \Theta) \quad &= \quad \sum_{\mathbf{f},\mathbf{e}} \sum_D \sum_{\mathbf{a}} q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e}) \log \frac{P_{\Theta_D}(\mathbf{a}, D, \mathbf{f}, \mathbf{e})}{q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e})} \\
&= \sum_{\mathbf{f},\mathbf{e}} \sum_{D,\mathbf{a}} q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e}) \log \frac{P_{\Theta_D}(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e})}{q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e})} \; + \; \sum_{\mathbf{f},\mathbf{e}} \sum_{D,\mathbf{a}} q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e}) \log P_\Theta(\mathbf{f}, \mathbf{e}) \\
&= \sum_{\mathbf{f},\mathbf{e}} \log P_\Theta(\mathbf{f}, \mathbf{e}) - KL[q(\mathbf{a}, D \mid \mathbf{f}, \mathbf{e}) \;||\; P_{\Theta_D}(\mathbf{a}, D|\mathbf{f}, \mathbf{e})]
\end{aligned} \tag{7}$$

where $KL[\cdot||\cdot]$ is the KL-divergence. To find $q^*(\mathbf{a}, D|\mathbf{f}, \mathbf{e})$ that maximizes $\mathcal{F}(q, \Theta)$:

$$\begin{aligned}
q^*(\mathbf{a}, D|\mathbf{f}, \mathbf{e}) \quad &= \quad \operatorname*{argmax}_{q(\mathbf{a},D|\mathbf{f},\mathbf{e})} \mathcal{F}(q, \Theta) = \operatorname*{argmin}_{q(\mathbf{a},D|\mathbf{f},\mathbf{e})} KL[q(\mathbf{a}, D|\mathbf{f}, \mathbf{e})||P_{\Theta_D}(\mathbf{a}, D|\mathbf{f}, \mathbf{e})] \\
&= \quad P_{\Theta_D}(\mathbf{a}, D|\mathbf{f}, \mathbf{e}) = P_{\Theta_D}(D|\mathbf{f}, \mathbf{e}) P_{\Theta_D}(\mathbf{a}|\mathbf{f}, \mathbf{e}, D).
\end{aligned} \tag{8}$$

[2]We especially thank an anonymous reviewer who gave valuable comments related to this point.

Here

$$P_{\Theta_D}(\mathbf{a}|\mathbf{f},\mathbf{e},D) \;=\; \frac{P_{\Theta_D}(\mathbf{f},\mathbf{a}|\mathbf{e},D)}{P_{\Theta_D}(\mathbf{f}|\mathbf{e},D)} \;=\; \frac{\prod_{j=1}^{m} t(f_j|e_{a_j},D)}{\prod_{j=1}^{m}\sum_{i=0}^{l} t(f_j|e_i,D)} \tag{9}$$

The distribution $q^*(\mathbf{a},D|\mathbf{f},\mathbf{e})$ together with $q^*(D|\mathbf{f},\mathbf{e}) = \sum_{\mathbf{a}} q^*(\mathbf{a},D|\mathbf{f},\mathbf{e}) = P_{\Theta_D}(D|\mathbf{f},\mathbf{e})$ can be used to softly fill in the values of $\mathbf{a}$ and D respectively to estimate model parameters.

We now state our derived EM update formulas. We use the notation $P^{(c)}$ and $t^{(c)}$ for current iteration estimates, and $P^{(+)}$ and $t^{(+)}$ for the re-estimates. We denote the expected counts that e aligns to f in the translation $(\mathbf{f}|\mathbf{e})$ with respect to a domain D with $c(f|e;\mathbf{f},\mathbf{e},D)$. Similarly, we denote the expected count of $(\mathbf{f}|\mathbf{e})$ with respect to a domain D by $c(D;\mathbf{f},\mathbf{e})$.

E-step $\forall D \in \{D_0, D_1\}$ do

$$\begin{aligned} c(D;\mathbf{f},\mathbf{e}) &= P^{(c)}(D \mid \mathbf{f},\mathbf{e}) \\ c(f|e;\mathbf{f},\mathbf{e},D) &= P^{(c)}(D \mid \mathbf{f},\mathbf{e}) \frac{t^{(c)}(f \mid e,D)}{\sum_{i=0}^{l} t^{(c)}(f \mid e_i,D)} \sum_{j=1}^{m} \delta(f,f_j) \sum_{i=0}^{l} \delta(e,e_i) \end{aligned}$$

M-step $\forall D \in \{D_0, D_1\}$ do

$$t^{(+)}(f|e,D) = \frac{\sum_{\mathbf{f},\mathbf{e}} c(f|e;\mathbf{f},\mathbf{e},D)}{\sum_{f}\sum_{\mathbf{f},\mathbf{e}} c(f|e;\mathbf{f},\mathbf{e},D)} \qquad P^{(+)}(D) = \frac{\sum_{\mathbf{f},\mathbf{e}} c(D;\mathbf{f},\mathbf{e})}{\sum_{D}\sum_{\mathbf{f},\mathbf{e}} c(D;\mathbf{f},\mathbf{e})}$$

To re-estimate $P(D \mid \mathbf{f},\mathbf{e})$ we substitute the M-step estimates into Equations 3, 4 and 2. We initialize translation tables $t(f|e,D_1)$ and $t(e|f,D_1)$ with non-zero estimates obtained from applying IBM model I to in-domain corpus $\mathcal{C}_{in}$.[3] Before EM training starts we must train the LMs. The in-domain LMs $P_{lm}(\mathbf{e}|D_1)$ and $P_{lm}(\mathbf{f}|D_1)$ are trained on the source and target sides of $\mathcal{C}_{in}$ respectively. For the out-domain LMs $P_{lm}(\mathbf{e}|D_0)$ and $P_{lm}(\mathbf{f}|D_0)$ we need an *out-domain* data set to train them. It would also be reasonable to use the set to train the out-domain tables, $t(\cdot \mid \cdot, D_0)$. This raises an hitherto unattended question regarding how to construct such an out-domain data set.

Inspired by burn-in in sampling, initially we isolate all LMs from our model to train the translation models for a single EM iteration; we initialize the model with a translation table constructed on $\mathcal{C}_{in}$ and uniform otherwise. Using the re-estimates, we score sentence pairs in $\mathcal{C}_{mix}$ with $P(D_1|\mathbf{f},\mathbf{e})$ and select a *burn-in subset* of smallest scoring pairs as *pseudo out-domain data* which can be used to train $P_{lm}(\mathbf{e}|D_0)$ and $P_{lm}(\mathbf{f}|D_0)$. Choosing the optimal size of this subset is difficult, but in practice, we usually choose a subset that has similar size (number of words) to the given in-domain corpus. The rationale behind this choice is to avoid the risk that pseudo out-domain models would dominate the in-domain models during further training. We observe that choosing the same size for a pseudo out-domain corpus is not guaranteed to always give optimal performance, and this point deserves further study.

Finally, once the domain-dependent LMs have been trained, the domain-dependent LM probabilities stay *fixed* during EM. Crucially, it is important to scale the probabilities of the four LMs to make them comparable: we normalize the probability that a LM assigns to a sentence by the total probability this LM assigns to all sentences in $\mathcal{C}_{mix}$.

3 Experimental setting

We carry out experiments in data selection (intrinsic) as well as in machine translation (extrinsic). We build an English-Spanish mix-domain corpus consisting of a large and rather varied set of domains (a

[3]Note that in practice, we usually use only one iteration to train IBM Model I. To simplify the implementation, we ignore factor $\frac{\epsilon}{(l+1)^m}$ in the model (Equation 3), which serves a minor role. It should be also noted that we set a (small) threshold, e.g., $t(\cdot|\cdot,\cdot) = 0.0001$ for all word pairs that do not occur in the in-domain corpus to avoid over-fitting.

haystack) in a way that allows us to directly measure selection quality. Starting out from a general-domain corpus $\mathcal{C}_g$ consisting of $4.51M$ sentence pairs, collected from multiple resources including EuroParl (Koehn, 2005), Common Crawl Corpus, UN Corpus, News Commentary, TAUS Software, TAUS Hardware, and TAUS Pharmacy, and a 177K in-domain (TAUS Legal) sentence pairs.

We create $\mathcal{C}_{mix}$ by selecting an arbitrary 100K pairs of in-domain set and adding them to $\mathcal{C}_g$; the remaining 77K in-domain pairs constitute $\mathcal{C}_{in}$. We think of this as `hiding` in-domain data in $\mathcal{C}_{mix}$ so we can evaluate our ability to retrieve it; in this setting we can evaluate selection directly using pseudo-precision/recall defined as the percentage of selected in-domain pairs to the total selected or to the hidden 100K pairs respectively.

Table 1 summarizes the data and the translation task. It should be noted that a mix-domain corpus, that contains a large and rather varied set of domains, frequently contains subsets with a vocabulary that is close to the in-domain adaptation task; in this case, e.g., Europarl and TAUS Legal share big portions of their source vocabulary, whereas their translations could differ. This makes the selection task far more difficult than assumed by previous approaches as we will show next.

Task	**Corpora**	**English**	**Spanish**
	Mix-Domain Corpus (4.51M sents)	$125,339,057$	$139,655,311$
TAUS Legal	In-Domain Corpus (77K sents)	$1,555,342$	$1,733,370$
	Dev (2K sents)	$27,983$	$30,501$
	Test (2K sents)	$45,736$	$48,999$

Table 1: The data preparation - training, dev and testing corpora (size in words). Note that the dev set contains sentences of 10-25 words, while the test set contains sentences that vary substantially in length, from 5-10 words up to 45-50 words.

Our Invitation model takes 3 EM-iterations to train.[4] We then weigh sentence pairs under our model with $P(D_1 \mid \mathbf{e}, \mathbf{f})$. We test various baseline models, including the bilingual cross-entropy difference model, and the two cross-entropy difference models (on the source language and on the target language).[5] We report *pseudo*-precision/recall at the sentence-level using a range of cut-off criteria for selecting the top scoring instances in the mix-domain corpus.

We use Moses (Koehn et al., 2007) with GIZA++ (Och and Ney, 2003) and k-best batch MIRA (Cherry and Foster, 2012). Final MT systems use the same *non-adapted language models* trained on 2.2M English Europarl sentences plus 248.8K sentences from News Commentary Corpus (WMT 2013).

We report BLEU (Papineni et al., 2002), METEOR 1.4 (Denkowski and Lavie, 2011) and TER (Snover et al., 2006). Statistical significance uses 95% confidence intervals using paired bootstrap re-sampling (Press et al., 1992; Koehn, 2004). The k-best batch MIRA optimizer (Cherry and Foster, 2012) was run at least three times to optimize any SMT system to avoid instability (Clark et al., 2011).[6]

4 Results

Table 2 presents the results showing substantial improvement in selection performance compared to all the baselines. Subsequently we build SMT systems over the selected subsets. We report the translation yielded by these systems over the task in Table 2 as well. It can be easily seen that the baseline approaches that simply train on in- and mix-domain data do not work that well for a difficult selection task from a mix-domain corpus consisting of a large and rather diverse set of domains. The SMT sys-

[4]To train the LM probs, we construct interpolated 4-gram Kneser-Ney language models using BerkeleyLM (Pauls and Klein, 2011). This setting for training language models is used for all experiments in this work.

[5]The script we use to train these models is developed by Luke Orland and available at: `https://github.com/lukeorland/moore\_and\_lewis\_data\_selection`.

[6]Note that metric scores for the systems are averages over multiple runs.

model against our Invitation model for the task. This shows clearly more relevant pairs for our selection model than for the baselines. It should be noted that the baseline models tend to prefer shorter sentences, while our model suffers less from this kind of bias. Table 4 presents the average length (in words) of selected sentences selected by different models over various cut-offs.

Cut-off	Model	In-domain Pairs	pseudo-Precision	pseudo-Recall	BLEU	METEOR	TER
300K	**Without Translation Model**	34156	11.39	34.16	35.8	36.6	47.3
	Without Language Model	51991	17.33	51.99	37.4	37.4	46.6
	Full model	53892	17.96	53.89	37.7	37.5	46.0

Table 5: Experiments exploring the roles of individual components in our model.

Which component type (language or translation models) contributes more to performance? We neutralize each component in turn and build a selection system with the remaining model parameters. Table 5 shows translation models are crucial for performance, while domain-dependent LMs make a small, yet noteworthy contribution. It should also be noted that using the LMs derived separately from in- and out-domain data yields far better performance than the LMs derived from in- and mix-domain data for this task.

System	Phrases	BLEU	METEOR	TER
Large data C_{mix}	236.74M	36.8	37.2	47.1
Subset of 300K	22.47M	37.7	37.5	46.0

Table 6: Translation accuracy comparison.

Finally, we compare a system trained on a selection of the top scored 300K sentences to a baseline large-scale SMT system trained on C_{mix} (4.61M sentences). The baseline trained on C_{mix} works with 236.74M phrase pairs, whereas the Invitation trained system employs a small table of 22.47M phrases. Tabel 6 shows the results. It is interesting that the small MT system trained by Invitation performs significantly better (with p-value $= 0.0001$ for all metrics) than the large-scale system baseline trained on all of C_{mix}.

Subset 300K	*each member state will **monitor** the scientific category of the **evaluation** and the activities of the members of the committees and of experts who has designated, but **refrain** from giving them instructions incompatible with the required functions assumed.*

Table 7: Translation example yielded by systems.

To give a sense of the improvement in translation, we present an example in Table 7. The example is indeed illuminating because it shows the difference in choice between the mix-domain system and

our selection-trained system. The example shows different translation pairs: ⟨supervisará-*monitor*⟩ vs. ⟨supervisará-*oversee*⟩, ⟨evaluación-*evaluation*⟩ vs. ⟨evaluación-*assessment*⟩, and ⟨abstendrá de-*refrain from*⟩ vs. ⟨abstendrá de-*abstain*⟩. Table 8 presents phrase table entries, i.e., $p(e \mid f)$ and $p(f \mid e)$, for the pairs of words in each system.

		supervisará		**evaluación**		**abstendrá de**	
System	**Entry**	**monitor**	**oversee**	**evaluation**	**assessment**	**refrain from**	**abstain**
Large data C_{mix}	$\phi(e\|f)$	0.002	0.020	0.579	0.429	0.002	0.013
	$\phi(f\|e)$	0.119	0.081	0.391	0.403	0.014	0.060
Subset of 300**K**	$\phi(e\|f)$	0.012	0.024	0.487	0.357	0.015	–
	$\phi(f\|e)$	0.203	0.072	0.338	0.417	0.143	–

Table 8: Phrase entry examples. Note that the system trained on the subset of top 300K pairs of sentences does not contain the phrase pair ⟨*refrain from-abstain*⟩.

5 Final Machine Translation experiments: Putting all data together

For final adaptation evaluations we follow (Koehn and Schroeder, 2007; Nakov, 2008) and (Axelrod et al., 2011; Sennrich, 2012), by passing multiple phrase tables directly to the Moses decoder and tuning a system using these different tables together. Table 9 presents the result, showing the consistent improvement of adaptation with Invitation model compared to the baselines (with p-value $= 0.0001$ for all cases) over the mixture data C_{mix}.

Data	**System**	**BLEU**	**METEOR**	**TER**
	In-domain	36.66	37.19	44.76
50K	+ CE Difference (source side)	37.1	36.7	48.1
	+ CE Difference (target side)	37.1	36.6	48.2
	+ Bilingual CE Difference	37.1	36.6	48.2
	+ **Invitation**	38.0	37.2	47.3
100K	+ CE Difference (source side)	37.3	36.8	47.9
	+ CE Difference (target side)	37.2	36.8	48.0
	+ Bilingual CE Difference	37.2	36.8	48.0
	+ **Invitation**	38.4	37.4	46.9
150K	+ CE Difference (source side)	37.1	36.9	48.2
	+ CE Difference (target side)	37.3	36.9	47.9
	+ Bilingual CE Difference	37.0	36.8	48.1
	+ **Invitation**	38.6	37.5	46.6
200K	+ CE Difference (source side)	37.3	36.9	47.7
	+ CE Difference (target side)	37.3	36.9	47.9
	+ Bilingual CE Difference	37.3	36.9	47.8
	+ **Invitation**	38.4	37.6	46.7
250K	+ CE Difference (source side)	37.4	36.9	47.7
	+ CE Difference (target side)	37.3	37.0	47.7
	+ Bilingual CE Difference	37.3	37.0	47.8
	+ **Invitation**	38.6	37.7	46.5
300K	+ CE Difference (source side)	37.3	37.0	47.8
	+ CE Difference (target side)	37.1	37.0	48.0
	+ Bilingual CE Difference	37.3	36.9	47.8
	+**Invitation**	38.9	37.9	46.3

Table 9: Translation results from our domain-adapted SMT systems.

Finally, we also test the adaptation evaluations between the system trained on the small selection of top 300K sentences against the large-scale SMT system trained on C_{mix} when combined with the in-domain trained system. Table 10 presents the results, revealing comparable translation performance, although they are trained on data sets that are significantly different in size.

System	BLEU	METEOR	TER
In-domain + Large data C_{mix}	39.0	38.0	46.3
In-domain + Subset of 300**K**	38.9	37.9	46.3

Table 10: Translation results from our domain-adapted SMT system and the large-scale SMT system. Note that the baseline is slightly better than our domain-adapted SMT system under BLEU and METEOR, however, not statistically significant.

6 Final notes on mix-domain data selection

The specific data selection scenario studied in this paper brings up different aspects that did not receive (sufficient) attention in earlier work on data selection and domain adaptation:

- The mix-domain parallel corpus C_{mix} contains a large variety of domains that overlap and but also differ in lexical choice and translation. This is radically different from the in-/out-domain setting usually assumed in adaptation and constitutes a major challenge for existing selection approaches.
- The way the small in-domain corpus relates to the large mix-domain corpus is also challenging because translation performance often depends on selecting *relevant* sentence pairs, aside from those that are clearly in-domain.
- The lack of out-domain data in a realistic mix-domain scenario, suggests that efforts are needed at finding data that contrasts enough with the in-domain data. In this work we propose an initial training period (burn-in) for isolating pseudo out-domain data. But it might be that relevance-related approaches could also turn out more effective for this.

In our current model we implement the $P(\mathbf{e} \mid D)$ and $P(\mathbf{f} \mid D)$ as language models, inspired by the approaches based on the contrast between the cross-entropies of in- and mix-domain language models (Moore and Lewis, 2010; Axelrod et al., 2011). However, $P(\mathbf{e} \mid D)$ and $P(\mathbf{f} \mid D)$ should work with *relevance models*, i.e., assessing the relevance of sentences to domain D. *Relevance* is a different concept than fluency as embodied by language models, and this aspects demands special attention in future work.[7]

In ongoing large-scale experiments, we now explore the behavior of our Invitation model on a variety of different data settings and compare that to a range of alternative existing approaches. We are also exploring new variations of our Invitation model to find out what the optimal settings might be for different mixes of domains. So far we find that the burn-in and size of pseudo out-domain selection after burn-in can be important in certain situations. We also observe that estimating the suitable size of the selection set is also a topic that demands more attention because the estimate of $P(D_1)$ with the interpretation *percentage of relevant data in* C_{mix} like likely to demand suitable relevance models instead of language models.

We observe that the present Invitation model could be approached from a discriminative perspective, which could be effective for specific data settings. Finally, it is theoretically not clear whether a single approach will be most effective for all practical data scenarios.

7 Conclusions

This work looks at modeling the relevance of sentence pairs from the mix-domain corpus to a task represented by an in-domain sample. In contrast with previous work we cast this as a translation problem with a latent domain variable. Our *Invitation model* based on iterative weighted Invitations using EM, offers a new view on data selection for MT. Our model also offers principled cut-off points for selecting in-domain and other relevant subsets. Experiments on the in-domain task shows our approach outperforms the existing data selection for such a very complex mixture training data.

[7] We thank Amir Kamran for bringing this difference to our attention through ongoing joint experimental work.

The high accuracy in our experiments in this kind of data compared to the baseline suggests that our model might also offer good estimates that can be used for data weighting. In future work we aim to test the Invitation model for instance weighting and explore avenues for using it for selecting and weighting sub-sentential translation pairs (e.g., phrase pairs) that can be used directly for building SMT systems. A further issue is to improve the quality of word alignments induced for mix-domain corpora. We also aim at exploring a discriminative learning approach in conjunction with our model.

Language Family Relationship Preserved in Non-native English

Ryo Nagata

Abstract

Mother tongue interference is the phenomenon where linguistic systems of a mother tongue are transferred to another language. Recently, Nagata and Whittaker (2013) have shown that language family relationship among mother tongues is preserved in English written by Indo-European language speakers because of mother tongue interference. At the same time, their findings further introduce the following two research questions: (1) Does the preservation universally hold in non-native English other than in English of Indo-European language speakers? (2) Is the preservation independent of proficiency in English? In this paper, we address these research questions. We first explore the two research questions empirically by reconstructing language family trees from English texts written by speakers of Asian languages. We then discuss theoretical reasons for the empirical results. We finally introduce another hypothesis called *the existence of a probabilistic module* to explain why the preservation does or does not hold in particular situations.

1 Introduction

Transfer of linguistic systems of a mother tongue to another language, namely *mother tongue interference*, is often observable in the writing of non-native speakers. The reader may be able to determine the mother tongue of the writer of the following sentence from the underlined article error: *The alien wouldn't use my spaceship but the hers*. The answer would probably be French or Spanish; the definite article is allowed to modify possessive pronouns in these languages, and the usage is sometimes negatively transferred to English writing.

Researchers in corpus linguistics including Swan and Smith (2001), Aarts and Granger (1998), and Altenberg and Tapper (1998) have been working on mother tongue interference to reveal overused/underused words, part of speech (POS), or grammatical items. Recently, Nagata and Whittaker (2013) have shown that language family relationship between mother tongues is preserved in English written by Indo-European language speakers; because of the preservation, one can reconstruct a language family tree similar to the canonical Indo-European family tree (Beekes, 2011; Ramat and Ramat, 2006) from their English writings. They have further revealed factors contributing to the preservation of the language family relationship, which they show is useful for related natural language processing (NLP) tasks such as grammatical error detection/correction and native language identification (Wong and Dras, 2009).

At the same time, their findings further introduce the following two research questions: (1) Does the preservation universally hold in non-native English? (2) Is the preservation independent of proficiency in English? The results (Nagata and Whittaker, 2013) for English written by Indo-European language speakers suggest that the answer to question (1) is *yes*. Based on this, we hypothesize that:

Hypothesis I: The preservation of language family relationship universally holds in non-native English.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1940–1949, Dublin, Ireland, August 23-29 2014.

However, one can counter **Hypothesis I**, arguing that the preservation holds only in English written by Indo-European language speakers because Indo-European languages share large part of linguistic properties with English which is a member of the Indo-European languages, which contributes to the preservation. Apparently, this is not the case in languages in other language families. In these languages, other properties than language family relationship may be more dominant. Furthermore, Kachru's Three Circles of English (Kachru, 1992) raises a question. In Kachru's model, world Englishes are classified into the inner, outer, and expanding circles. The inner circle roughly corresponds to the traditional native speakers of English. The outer circle refers to the non-native varieties in the regions where English serves as a useful lingua franca. The expanding circle roughly corresponds to the other non-native speakers of English. Then, it would be difficult to answer question (1) for the outer circle of English (e.g., English in Hong Kong). For example, on one hand, English in Hong Kong is expected to have mother tongue interference from Chinese language. From this point of view, it is expected to have the family relationship with the Sino-Tibetan language family. On the other hand, one can point out that the outer circle of English should be closer to native English than the expanding circle of English (e.g., English in China) is. This implies that English in Hong Kong might have some other relationship with the members in the outer circle. For question (2), the answer is likely *no* considering that theoretically, the higher one's proficiency is, the closer to native English his or her English becomes; it would be difficult to distinguish between native English and English of non-native speakers whose proficiency is very high. With this reason, we hypothesize that:

Hypothesis II: The preservation of language family relationship is dependent on proficiency in English.

In view of this background, we address these research questions in this paper. We first examine the two hypotheses empirically by reconstructing language family trees from English texts written by speakers of Asian languages, including the outer and expanding circles of English. If we can reconstruct language family trees similar to their canonical family trees from these English texts, it will be a good piece of evidence for **Hypothesis I**. Similarly, to examine **Hypothesis II**, we reconstruct a language family tree from the English texts using the information about their proficiency levels. If we cannot reconstruct language family trees similar to the canonical trees, **Hypothesis II** will be accepted. We then explore theoretical reasons for the empirical results. We finally introduce another hypothesis called *the existence of a probabilistic module* to explain why the preservation does or does not hold in particular situations.

The rest of this paper is structured as follows. Sect. 2 introduces the basic approach of this work. Sect. 3 and Sect. 4 examine **Hypothesis I** and **Hypothesis II**, respectively. Sect. 5 describes theoretical reasons for the experimental results.

2 Approach

2.1 Data Set

Through this paper, we use the International Corpus Network of Asian Learners of English (ICNALE) (Ishikawa, 2011) as the target data to examine the two hypotheses. ICNALE consists of English essays of the outer and expanding circles of English in Asia together with those of native speakers of English. Table 1 (a) shows the statistics on ICNALE.

In ICNALE, each essay, except native essays, is annotated with a proficiency level of the writer, ranging from A_2 (lowest) B1_1, B1_2, to B2+ (highest); Table 1 (b) shows the correspondence between these four proficiency levels and TOEIC scores. We use this information to examine **Hypothesis II**.

2.2 Method for Reconstructing Language Family Trees

We employ the method proposed by Nagata and Whittaker (2013) for reconstructing language family trees, which in turn is based on the method proposed by Kita (1999). In this method, each group of the essays in ICNALE is modeled by an n-gram language model. Then, agglomerative hierarchical clustering (Han and Kamber, 2006) is applied to the language models to reconstruct a language family tree. The distance used for clustering is based on a divergence-like distance between two language models that was originally proposed by Juang and Rabiner (1985).

Category	# of essays	# of tokens
Native	400	88,792
Outer Circle		
Hong Kong	200	46,111
Pakistan	400	93,100
Philippines	400	96,586
Singapore	400	96,733
Expanding Circle		
China	800	194,613
Indonesia	400	92,316
Japan	800	176,537
Korea	600	130,626
Thailand	800	176,936
Taiwan	400	89,736

(a) Statistics on ICNALE

Level	A2	B1_1	B1_2	B2+
Score	225-549	550-669	670-784	785+

(b) Correspondence between the Proficiency Levels and TOEIC Score

Table 1: Summary of ICNALE.

To explain the method in more detail, let us define the following symbols used in the method. Let D_i be a set of English texts where i denotes a mother tongue i. Similarly, let M_i be a language model trained using D_i.

To reduce the influences from the topics of the data set, we use an n-gram language model based on a mixture of word and POS tokens. In this language model, content words in n-grams are replaced with their corresponding POS tags. This greatly decreases the influence of the topics of texts. It also decreases the number of parameters in the language model.

To build the language model, the following three preprocessing steps are applied to D_i. First, texts in D_i are split into sentences. Second, each sentence is tokenized, POS-tagged, and mapped entirely to lowercase. For instance, the example sentence in Sect. 1 would give:

> the/DT alien/NN would/MD not/RB use/VB my/PRP$ spaceship/NN but/CC the/DT hers/PRP ./.

Finally, words are replaced with their corresponding POS tags; for the following words, word tokens are used as their corresponding POS tags: coordinating conjunctions, determiners, prepositions, modals, predeterminers, possessives, pronouns, question adverbs. Also, proper nouns are treated as common nouns. At this point, the special POS tags *BOS* and *EOS* are added at the beginning and end of each sentence, respectively. For instance, the above example would result in the following word/POS sequence:

> BOS the NN would RB VB my NN but the hers . EOS.

Note that the content of the original sentence is far from clear while reflecting mother tongue interference, especially in *the hers*.

Now, the language model M_i can be built from D_i. We set $n = 3$ (i.e., trigram language model) and use Kneser-Ney (KN) smoothing (Kneser and Ney, 1995) to estimate its conditional probabilities.

The clustering algorithm used is agglomerative hierarchical clustering with the average linkage method. The distance[1] between two language models is measured as follows. The probability that M_i generates D_i is calculated by $\Pr(D_i|M_i)$. Note that

$$\Pr(D_i|M_i) \approx \Pr(w_{1,i}) \Pr(w_{2,i}|w_{1,i}) \prod_{t=3}^{|D_i|} \Pr(w_{t,i}|w_{t-2,i}, w_{t-1,i}) \quad (1)$$

[1]It is not a distance in a mathematical sense. However, we will use the term *distance* following the convention in the literature.

where $w_{t,i}$ and $|D_i|$ denote the tth token in D_i and the number of tokens in D_i, respectively, since we use the trigram language model. Then, the distance from M_i to M_j is defined by

$$d(M_i \to M_j) \equiv \frac{1}{|D_j|} \log \frac{\Pr(D_j|M_j)}{\Pr(D_j|M_i)}. \quad (2)$$

In other words, the distance is determined based on the ratio of the probabilities that each language model generates the language data. Because $d(M_i \to M_j)$ and $d(M_j \to M_i)$ are not symmetrical, we define the distance between M_i and M_j to be their average:

$$d(M_i, M_j) \equiv \frac{d(M_i \to M_j) + d(M_j \to M_i)}{2}. \quad (3)$$

Equation (3) is used to calculate the distance between two language models for clustering.

To sum up, the procedure of the language family tree construction method is as follows: (i) Preprocess each D_i; (ii) Build M_i from D_i; (iii) Calculate the distances between the language models; (iv) Cluster the language data using the distances; (v) Output the result as a language family tree.

3 Reconstructing Language Family Trees from Asian English

We used the whole ICNALE as the target data. We used a POS-tagger with the Penn Treebank Tagset (Santorini, 1990), which we had specially developed for analyzing non-native English; we trained it on native and non-native corpora we had manually annotated with POS tags, part of which is available to the public as the Konan-JIEM (KJ) learner corpus (Nagata et al., 2011). Then, we generated a cluster tree from the corpus data using the method described in Subsect. 2.2. We used the Kyoto Language Modeling toolkit[2] to build language models from the corpus data. We removed n-grams that appeared less than five times[3] in each subcorpus in the language models.

Fig. 1 shows the resulting cluster tree. The number at each branching node denotes in which step the two clusters were merged.

The cluster tree supports **Hypothesis I** that the preservation of language family relationship universally holds in non-native English. Although the detailed language family relationship is less well-known in these Asian languages than in the Indo-European languages, still the cluster tree shown in Fig. 1 reflects a rational interpretation of their language family relationship. In the cluster tree, Taiwanese and Chinese Englishes are first merged into a cluster. This perfectly agrees with the fact that their mother tongues are primarily Chinese and thus both should belong to the Sino-Tibetan language family. In turn, Japanese and Korean Englishes are merged into a cluster. Their mother tongues are said to be a member of the Altaic language family. Admittedly, it is still controversial whether the two languages belong to the Altaic language family or not. However, the current research often treats them as a member of the Altaic language family (Crystal, 1997). After Japanese and Korean Englishes, Thai and Indonesian Englishes are merged in to a cluster of which mother tongues belong to different language families; the former belong to the Thai language family while the latter mostly belong to the Austronesian language family. Having said that, it has been pointed out that Thai has some language family relationship with the Austronesian language family (Crystal, 1997). All these observations support **Hypothesis I**.

Interestingly, the cluster tree shown in Fig. 1 preserves, together with language family relationship, the three circles of English, namely, the inner (native), outer, and expanding circles of English with an exception of Pakistani English. This can be interpreted as that some other properties are more dominant than language family relationship in the outer circle of English. An implication from this is that we should not treat the outer and expanding circles as a group of non-native speakers of English but separately as different groups in the related NLP tasks such as grammatical error correction. For example, a method performing well on the outer circle of English (e.g., the NUS corpus (Dahlmeier et al., 2013)) does not necessarily perform equally well on the expanding circle of English (e.g., the CLC corpus) and vice versa. Similarly, a model trained on English written by Indo-European language speakers may perform

[2]The Kyoto Language Modeling toolkit: `http://www.phontron.com/kylm/`

[3]We found that the results were not sensitive to the value of frequency cutoff so long as we set it to a small number.

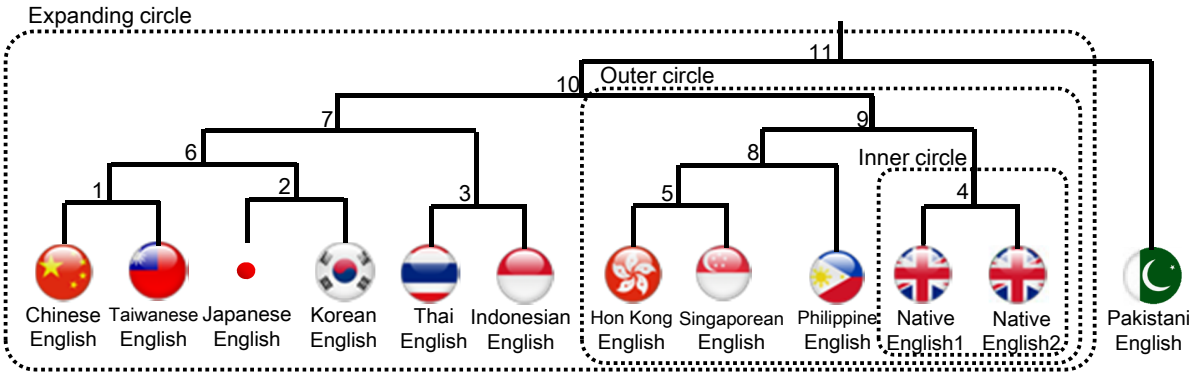

Figure 1: Cluster Tree Reconstructed from Asian Englishes (ICNALE).

better on Chinese English than a model trained on Hon Kong English does. Above all, the subtree for the outer circle of English is a piece of evidence that partly denies **Hypothesis I**.

We further reconstructed a clustering tree from the same data set using 5-gram language models so that the resulting clustering reflects longer-distance syntactic relations. Fig. 2 shows the resulting cluster tree, which reveals that the tree is almost the same as in Fig. 1 with an exception of the Philippine English.

After having observed all these, it would be rational to partly accept **Hypothesis I** and to modify it as follows:

Hypothesis I′: The preservation of language family relationship universally holds in the expanding circle of English.

4 Exploring Correlation between the Preservation and Proficiency

The simplest way to examine **Hypothesis II** would be clustering that uses only either high-proficiency or low-proficiency essays. However, it is not so straightforward because the distribution of each proficiency level varies depending on the English groups. Particularly, some of the 10 non-native Englishes contains no or very few low-proficiency essays[4].

As a simple solution, we first generated a clustering tree from only the high-proficiency essays (B1_2 and B2+) with the same conditions as in Sect. 3. As a more sophisticated solution, we created a new data set from ICNALE so that one of the two Englishes merged into a cluster in Fig. 1 consists of only low-proficiency essays and the other of only high-proficiency essays. For instance, we used only low-proficiency essays (A_2 and B1_1) for Chinese English and only high-proficiency essays (B1_2 and B2+) for Taiwanese English. Then, we generated another cluster tree from the new data set again with the same conditions as in Sect. 3. In addition, as a reference, we generated a cluster tree only using the information about the proficiency levels. In this clustering, we created a vector for each English whose elements and values corresponded to the four proficiency levels and the relative frequencies of the essays falling into the corresponding proficiency level[5]. In this method, we defined the distance for clustering by the Euclidean distance between two vectors.

The idea behind this experiment is as follows. If the preservation is completely independent of proficiency, we will obtain the exact same tree as in Fig.1 both from the only-high-proficiency data set and the high-low proficiency-paired data set. Otherwise, the cluster tree will result in a different form, similar to the one obtained by the vector-based method solely relying on the information about proficiency.

Fig. 1 and Fig. 3 show the cluster trees obtained from the only-high-proficiency data set and the high-low proficiency-paired data set, respectively. In the case of the only-high-proficiency data set, the resulting tree is the exact same as in the one generated from the original data set. Fig. 3 also shows that the cluster tree is very similar to that in Fig. 1. Besides, both tree are far from the cluster tree obtained by the

[4]For instance, Singapore English contains no low-proficiency essays (A2 and B1_1), and Philippine English 26 essays out of 400. See `http://language.sakura.ne.jp/icnale/` for the complete list of the distribution.

[5]We create vectors for the native English essays by setting 1.0 to the element corresponding to B2+ and 0.0 to the others because proficiency levels are not available for the native English essays in ICNALE.

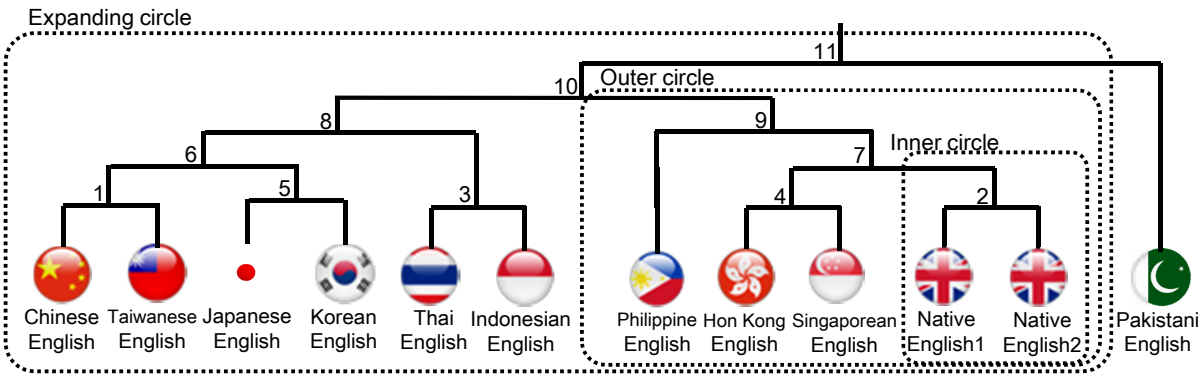

Figure 2: Cluster Tree Reconstructed from Asian Englishes (ICNALE) using 5-gram language models.

vector-based method solely relying on the information about proficiency as shown in Fig. 4. In summary, Fig. 1 to 4 show that the preservation of language family relationship holds in the expanding circle of English regardless of proficiency in English.

These results deny **Hypothesis II** that the preservation of language family relationship is dependent on proficiency in English. Contrary to our expectation, they support[6]:

Hypothesis II′: The preservation of language family relationship is independent of proficiency in English.

5 Discussion

The experiments show that the tree generation method relying on the distributions of word/POS sequences reconstructs from Asian Englishes cluster trees reflecting the family relationship in the Asian languages. These empirical findings, together with those about English written by Indo-European language speakers (Nagata and Whittaker, 2013), support **Hypothesis I′**.

In order to explain theoretically **Hypothesis I′**, we introduce another hypothesis called *the existence of a probabilistic module*, that is, that a probabilistic module that stores the distributional information exists in the human brain. We hypothesize that the probabilistic module consists of sets of probabilities where each set corresponds to a linguistic item which has arbitrariness in its use; the arbitrariness is expressed by means of the probabilities that one of the candidates allowed in the linguistic item is chosen in one's mother tongue. An example of such a linguistic item would be the position of adverb in English where the probabilities in this case represent how likely adverbs appear in certain positions (e.g., the beginning, middle, and end of a sentence). The probabilistic module is equipped with the values of the probabilities which are set according to one's mother tongue. To be precise, in our hypothesis, the probabilities are adapted as follows: (1) proto-languages had developed their values of the probabilities and handed them down to their descendants; (2) over the time, some of the values changed and the others remained unchanged; (3) in turn, the decedent languages handed their values of the probabilities to their descendants with the changes. An example of this would be as follows. The proto-Indo-European language handed down its values of the probabilities to, for example, the Proto-Germanic language and the Proto-Italic language with some changes in the values. Then the Proto-German language handed them down to the Germanic languages such as German and Dutch, again with some changes. So did the Proto-Italic language to the romance languages such as French and Italian. Therefore, the values of the probabilities in German should be more similar to those in Dutch than to those in French or Italian.

With this probabilistic module in the human brain, we can naturally explain the preservation of language family relationship. When non-native speakers use English, the candidates of the arbitrary linguistic items in English are chosen according to the probabilistic module adapted to their mother tongue.

[6]It would be worth while to see if **Hypothesis II** holds in the case of Indo-European Englishes. The difficult part is that there are only a few data annotated with proficiency levels.

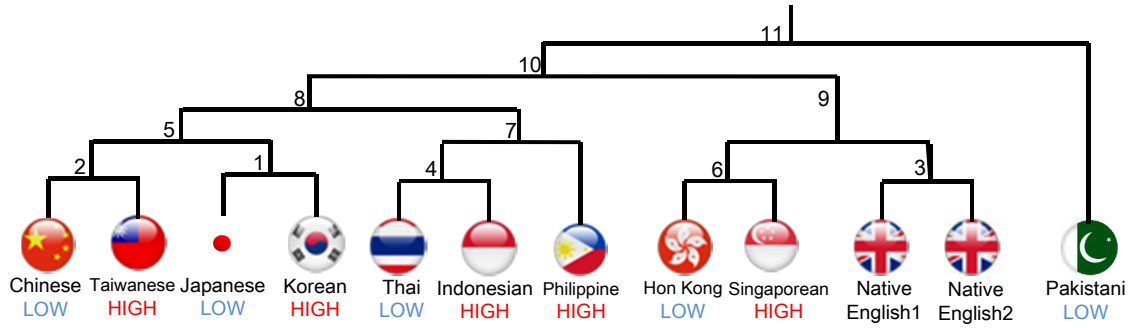

Figure 3: Cluster Tree Reconstructed from the High-low Proficiency-paired ICNALE Data Set (HIGH: high proficiency; LOW: low proficiency).

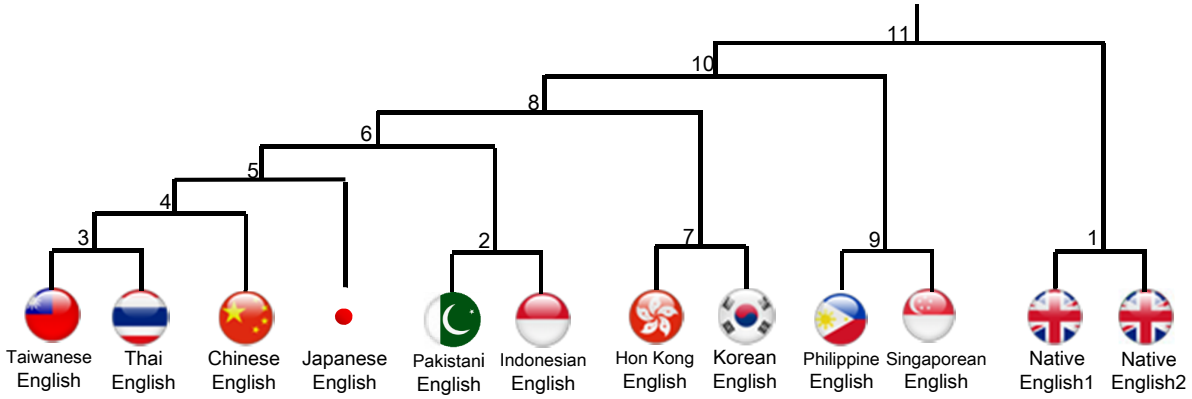

Figure 4: Cluster Tree Generated Based on Only Proficiency Levels.

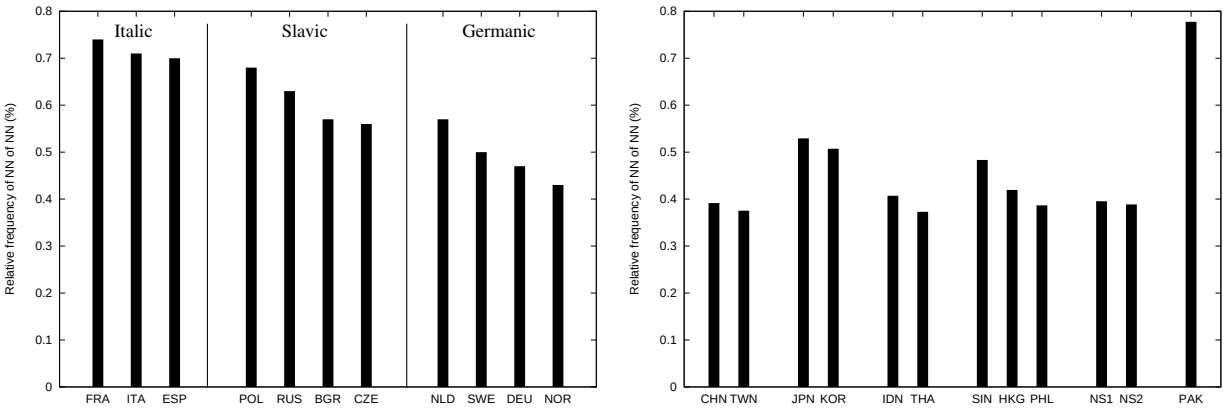
For example, speakers of languages which have a preference for sentence-beginning adverbs would also prefer sentence-beginning adverbs in English writing. Accordingly, the values of the probabilities are implicitly encoded in word/POS sequences such as *BOS RB ,* and *NN RB .*[7] in their English writings, and thus the tree generation method can recognize language family relationship as language family trees via the trigram language model. Provided that the probabilistic module exists in the human brain, this argument can be made about any mother tongues and the target language (not only English) as long as they have arbitrary linguistic items in their language systems, which should be the case in most languages.

This is of course another hypothesis and we need more data and evidence to examine the hypothesis. Nagata and Whittaker (2013) show some evidence that implies the existence of a probabilistic module. They reveal that Englishes written by Indo-European language speakers exhibit certain probabilistic patterns at least in the way of constructing noun phrases (NPs), adverb positions, and article use, reflecting the Italic, Germanic, and Slavic branches of the Indo-European family. Take as an example Fig. 5 (i) which shows frequencies of the trigram *NN of NN* in English written by Indo-European language speakers[8]. Here, note that English language has arbitrariness between the noun-noun compound and the *NN of NN* construction to form an NP (e.g., *education system* vs. *system of education*). Fig. 5 (i) reveals that speakers of the Italic languages (French, Italian, and Spanish) which have a preference for the *NN of NN* construction over the noun-noun compound exhibit relatively high frequencies of the trigram *NN of NN* in English writing. Conversely, speakers of the Germanic languages (Dutch, Swedish, German, and Norwegian) have a preference for the noun-noun compound over the *NN of NN* construction accordingly exhibit lower frequencies of the trigram *NN of NN*. In total, the frequencies roughly classify the 11 Englishes into three groups corresponding to the Italic, Slavic, and Germanic branches of the

[7]These two trigrams roughly correspond to adverbs at the beginning and end of a sentence, respectively.

[8]The ICLE corpus (Granger et al., 2009) was used to calculate the frequencies. The three letters such as FRA in Fig. 5 and Fig. 6 denote the ISO 31661 alpha-3 codes except NS1 (Native Speaker 1) and NS2 (Native Speaker 2).

Indo-European language family.



(i) Indo-European language speakers (ICLE) (ii) Asian language speakers (ICNALE)

Figure 5: Relative Frequency of *NN of NN* in English Texts Written by Non-native Speakers of English.

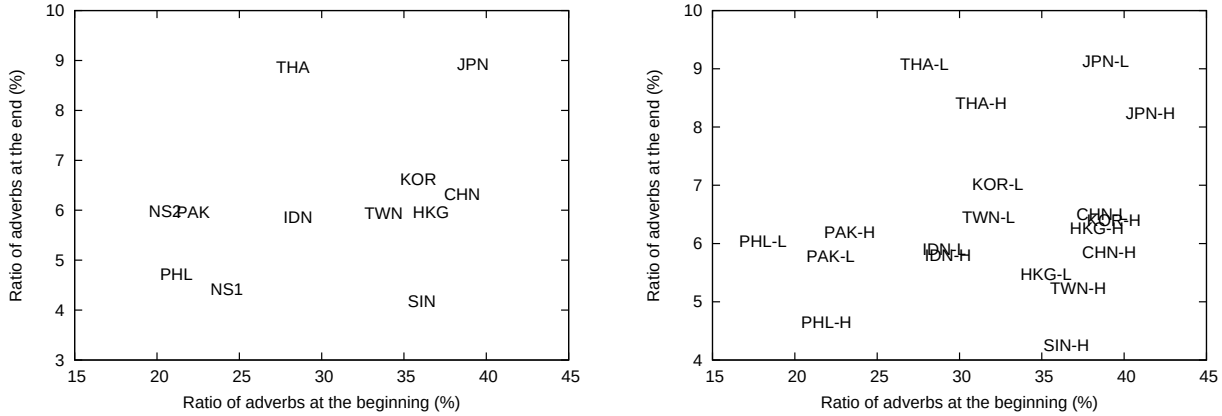
The data of Asian Englishes we used in the experiments exhibit similar tendencies. Fig. 5 (ii) shows frequencies of the trigram *NN of NN* for the Asian Englishes together with the native Englishes (denoted as NS1 and NS2). Fig. 5 (ii) reveals that the pairs of Englishes which share language family relationship each other exhibit similar frequencies of the trigram *NN of NN* as in Fig. 5. Furthermore, Fig. 6 (i) shows a similar tendency in the distribution of adverb positions. The horizontal and vertical axes of Fig. 6 correspond to the ratios of adverbs at the beginning and the end of sentences, respectively, in the Asian and native Englishes. It turns out that the pairs again tend to be located in near positions in the distribution. All of these imply the existence of the probabilistic module.

The probabilistic module also explains why the preservation is independent of proficiency. It is because the values of the probabilities in the probabilistic module will change quite slowly as one improves his or her proficiency. First of all, unlike grammatical errors, explicit feedback such as correction by teachers is not normally given to language learners in the case of the use of the arbitrary linguistic items since any choice among the candidates allowed in a linguistic item is normally correct, as in the adverb positions in English: *Already, I have done it.*, *I have already done it.*, and *I have done it already*, although each of which might have a slightly difference in meaning. Therefore, language learners have little opportunity to adapt the values of the probabilities in their probabilistic module to those in the target language in the first place. Even if feedback is given, it would still be difficult to do so considering that learners scarcely observe the values of the probabilities directly. This is why the values of the probabilities in the probabilistic module tend to be similar within a mother tongue regardless of one's proficiency in English. We can actually see this in Fig. 6 (ii). Fig. 6 (ii) shows the distribution of the ratios of adverbs at the beginning and the end of sentences in the high/low-proficiency essays in ICNALE where X-H and X-L denote high-proficiency and low-proficiency essays of X English, respectively (e.g., THA-H denotes the high-proficiency essays of Thai English). Fig. 6 (ii) reveals that Englishes of the same language speakers tend to remain in near positions regardless of the difference in proficiency.

All these observations would be a good place to start to explore the existence of the probabilistic module. The next step would be to name other arbitrary linguistic items concerning the probabilistic module, one of which for example might be the order of the main and subordinate clauses (e.g., *Because I did it, I did it.* vs *I did it because I did it.*), and then one can reveal their values (probabilities) depending on mother tongues.

6 Conclusions

In this paper, we examined the following two hypotheses: **Hypothesis I**: The preservation of language family relationship universally holds in non-native English; **Hypothesis II**: The preservation of language family relationship is dependent on proficiency in English. The experimental results partly accepted **Hy-**



(i) All levels (ii) High and low levels

Figure 6: Distribution of Adverb Position in Asian Englishes (ICNALE).

pothesis I and revealed that the following hypothesis fitted the data better: **Hypothesis I′**: The preservation of language family relationship universally holds in the expanding circle of English. By contrast, the experimental results denied **Hypothesis II**, supporting the counter hypothesis: **Hypothesis II′**: The preservation of language family relationship is independent of proficiency in English. We then proposed another hypothesis that a probabilistic module exists in the human brain to explain why **Hypothesis I′** and **Hypothesis II′** hold. We further introduced empirical data implying the existence of the probabilistic module.

For future work, we will examine **Hypothesis I′** and **II′** using English texts written by speakers of languages in other families to see if the preservation really universally holds. Also, we will explore the existence of the probabilistic module.

Abstract

There is a growing interest in automatically predicting the gender and age of authors from texts. However, most research so far ignores that language use is related to the social identity of speakers, which may be different from their biological identity. In this paper, we combine insights from sociolinguistics with data collected through an online game, to underline the importance of approaching age and gender as social variables rather than static biological variables. In our game, thousands of players guessed the gender and age of Twitter users based on tweets alone. We show that more than 10% of the Twitter users do not employ language that the crowd associates with their biological sex. It is also shown that older Twitter users are often perceived to be younger. Our findings highlight the limitations of current approaches to gender and age prediction from texts.

1 Introduction

A major thrust of research in sociolinguistics aims to uncover the relationship between social variables such as age and gender, and language use (Holmes and Meyerhoff, 2003; Eckert and McConnell-Ginet, 2013; Eckert, 1997; Wagner, 2012). In line with scholars from a variety of disciplines, including the social sciences and philosophy, sociolinguists consider age and gender as social and fluid variables (Eckert, 2012). Gender and age are shaped depending on the societal context, the culture of the speakers involved in a conversation, the individual experiences and the multitude of social roles: a female teenager might also be a high school student, a piano player, a swimmer, etc. (Eckert, 2008).

Speakers use language as a resource to construct their identity (Bucholtz and Hall, 2005). For example, a person's gender identity is constructed through language by using linguistic features associated with male or female speech. These features gain social meaning in a cultural and societal context. On Twitter, users construct their identity through interacting with other users (Marwick and boyd, 2011). Depending on the context, they may emphasize specific aspects of their identity, which leads to linguistic variation both within and between speakers. We illustrate this with the following three tweets:

Tweet 1: *I'm walking on sunshine <3 #and don't you feel good*
Tweet 2: *lalaloveya <3*
Tweet 3: *@USER loveyou ;D*

In these tweets, we find linguistic markers usually associated with females (e.g. a heart represented as <3). Indeed, 77% of the 181 players guessed that a female wrote these tweets in our online game. However, this is a 16-year old biological male, whose Twitter account reveals that he mostly engages with female friends. Therefore, he may have accommodated his style to them (Danescu-Niculescu-Mizil et al., 2011) and as a result he employs linguistic markers associated with the opposite biological sex.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1950–1961, Dublin, Ireland, August 23-29 2014.

Most of the NLP research focusing on predicting gender and age has approached these variables as *biological* and *static*, rather than *social* and *fluid*. For example, current approaches use supervised machine learning models trained on tweets from males and females. However, the resulting stereotypical models are ineffective for Twitter users who tweet differently from what is to be expected from their biological sex.

As explained above, language use is based on social gender and age identity, and not on biological sex and chronological age. In other words, treating gender and age as fixed biological variables in analyzing language use is too simplistic. By comparing the *biological sex and chronological age* of Twitter users with how they are perceived by the crowd (as an indication of socially constructed identities), we shed light on the *difficulty* of predicting gender and age from language use and draw attention to the *inherent limitations* of current approaches.

As has been demonstrated in several studies, the crowd can be used for experimentation (e.g., Munro et al. (2010)). Our study illustrates the value of the crowd for the study of human behavior, in particular for the experimental study of the social dimension of language use. To collect data, we created an online game (an example of *gamification* (Deterding et al., 2011)) in which thousands of players (the crowd) guessed the biological sex and age of Twitter users based on only the users' tweets. While variance between annotators has traditionally been treated as noise, more recently variation is being treated as a *signal* rather than noise (Aroyo and Welty, 2013). For example, Makatchev and Simmons (2011) analyze how English utterances are perceived differently across language communities.

This paper follows this trend, treating variation as meaningful information. We assume that the crowd's perception (based on the distribution of the players' guesses) is an indication of to what extent Twitter users emphasize their gender and age identity in their tweets. For example, when a large proportion of the players guess the same gender for a particular user, the user is assumed to employ linguistic markers that the crowd associates with gender-specific speech (e.g. iconic hearts used by females).

Our contributions are as follows:

- We demonstrate the use of gamification to study sociolinguistic research problems (Section 3).
- We study the difficulty of predicting an author's gender (Section 4) and age (Section 5) from text alone by analyzing prediction performance by the crowd. We relate our results to sociolinguistic theories and show that approaching gender and age as fixed biological variables is too simplistic.
- Based on our findings, we reflect on current approaches to predicting age and gender from text, and draw attention to the limitations of these approaches (Section 6).

2 Related Work

Gender Within sociolinguistics, studies on gender and language have a long history (Eckert and McConnell-Ginet, 2013). More recently, the NLP community has become increasingly interested in this topic. Most of the work aims at predicting the gender of authors based on their text, thereby focusing more on prediction performance than sociolinguistic insights.

A variety of datasets have been used, including Twitter (Rao et al., 2010; Bamman et al., 2014; Fink et al., 2012; Bergsma and Van Durme, 2013; Burger et al., 2011), blogs (Mukherjee and Liu, 2010; Schler et al., 2005), telephone conversations (Garera and Yarowsky, 2009), YouTube (Filippova, 2012) and chats in social networks (Peersman et al., 2011). Females tend to use more pronouns, emoticons, emotion words, and blog words (*lol, omg, etc.*), while males tend to use more numbers, technology words, and links (Rao et al., 2010; Bamman et al., 2014; Nguyen et al., 2013). These differences have also been exploited to improve sentiment classification (Volkova et al., 2013) and cyberbullying detection (Dadvar et al., 2012).

To the best of our knowledge, the study by Bamman et al. (2014) is the only computational study that approaches gender as a social variable. By clustering Twitter users based on their tweets, they show that multiple gendered styles exist. Unlike their study, we use the crowd and focus on implications for gender and age prediction.

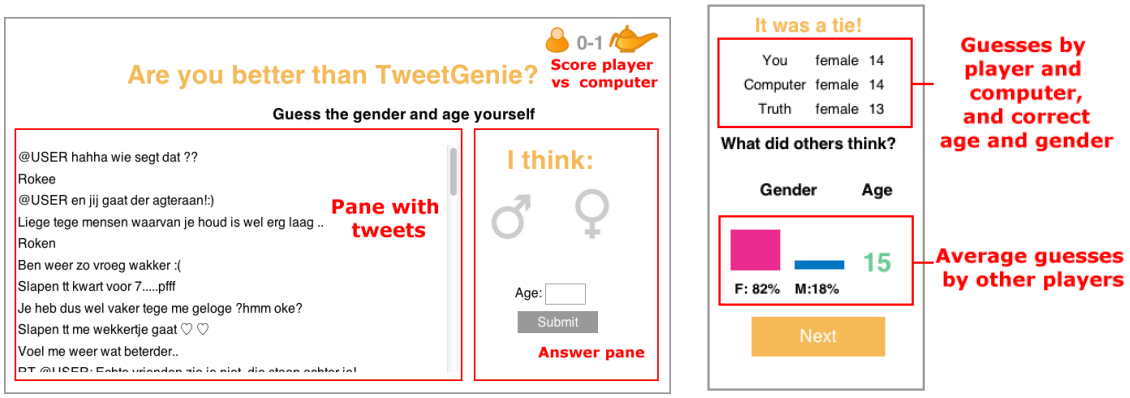

Figure 1: Screenshot of the game. Text is translated into English (originally in Dutch). Left shows the interface when the user needs to make a guess. Right shows the feedback interface.

Age Eckert (1997) makes a distinction between chronological (number of years since birth), biological (physical maturity), and social age (based on life events). Most of the studies on language and age focus on chronological age. However, speakers with the same chronological age can have very different positions in society, resulting in variation in language use. Computational studies on language use and age usually focus on automatic (chronological) age prediction. This has typically been modeled as a classification problem, although this approach often suffers from ad hoc and dataset dependent age boundaries (Rosenthal and McKeown, 2011). In contrast, recent works also explored predicting age as a continuous variable and predicting lifestages (Nguyen et al., 2013; Nguyen et al., 2011) .

Similar to studies on gender prediction, a variety of resources have been used for age prediction, including Twitter (Rao et al., 2010; Nguyen et al., 2013), blogs (Rosenthal and McKeown, 2011; Goswami et al., 2009), chats in social networks (Peersman et al., 2011) and telephone conversations (Garera and Yarowsky, 2009). Younger people use more alphabetical lengthening, more capitalization of words, shorter words and sentences, more self-references, more slang words, and more Internet acronyms (Rosenthal and McKeown, 2011; Nguyen et al., 2013; Rao et al., 2010; Goswami et al., 2009; Pennebaker and Stone, 2003; Barbieri, 2008).

3 Data

To study how people perceive the gender and age identity of Twitter users based on their tweets, we created an online game. Players were asked to guess the gender and age of Twitter users from tweets. The game was part of a website (TweetGenie, www.tweetgenie.nl) that also hosted an automatic system that predicts the gender and age of Twitter users based on their tweets (Nguyen et al., 2014). To attract players, a link to the game was displayed on the page with the results of the automatic prediction, and visitors were challenged to test if they were better than the automatic system (TweetGenie).

3.1 Twitter Data

We sampled Dutch Twitter users in the fall of 2012. We employed external annotators to annotate the biological sex and chronological age (in years) using all information available through tweets, the Twitter profile and external social media profiles such as Facebook and Linkedin. In total over 3000 Twitter users were annotated. For more details regarding the collection of the dataset we refer to Nguyen et al. (2013).

We divided the data into train and test sets. 200 Twitter users were randomly selected from the test set to be included in the online game (statistics are shown in Table 1). Named entities were manually anonymized to conceal the user's identity. Names in tweets were replaced by 'similar' names (e.g. a first name common in a certain region in the Netherlands was replaced with another common name in that region). This was done without knowing the actual gender and age of the Twitter users. Links were replaced with a general [LINK] token and user mentions with @USER.

Gender and age	F, <20	M, <20	F, [20-40)	M, [20-40)	F, ≥40	M, ≥40
Frequency	61	60	24	23	17	15

Table 1: Statistics Twitter users in our game

3.2 Online Game

Game Setup The interface of the game is shown in Figure 1. Players guessed the biological sex (male or female) and age (years) of a Twitter user based on only the tweets. For each user, {20, 25, 30, 35, 40} tweets were randomly selected. For a particular Twitter user, the same tweets were displayed to all players. Twitter users were randomly selected to be displayed to the players.

To include an entertainment element, players received feedback after each guess. They were shown the correct age and gender, the age and gender guessed by the computer, and the average guessed age and gender distribution by the other players. In addition, a score was shown of the player versus the computer.

Collection In May 2013, the game was launched. Media attention resulted in a large number of visitors (Nguyen et al., 2014). We use the data collected from May 13, 2013 to August 21, 2013, resulting in a total of 46,903 manual guesses. Players tweeted positively about the game, such as '*@USER Do you know what is really addictive? "Are you better than Tweetgenie" ...*' and '*@USER Their game is quite fun!*' (tweets translated to English).

We filter sessions that do not seem to contain genuine guesses: when the entered age is 80 years or above, or 8 or below. These thresholds were based on manual inspection, and chosen because it is unlikely that the shown tweets are from users of such ages. For each guess, we registered a session ID and an IP address. A new session started after 2 hours of inactivity. To study player performance more robustly, we excluded multiple sessions of the same player. After three or more guesses had been made in a session, all next sessions from the same IP address were discarded.

Statistics Statistics of the data are shown in Table 2. Figure 2 shows the distribution of the number of guesses per session. The longest sessions consisted of 18 guesses. Some of our analyses require multiple guesses per player. In that case, we only include players having made at least 7 guesses.

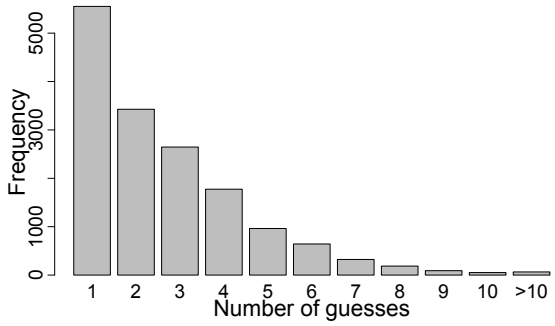

Figure 2: Number of guesses per session

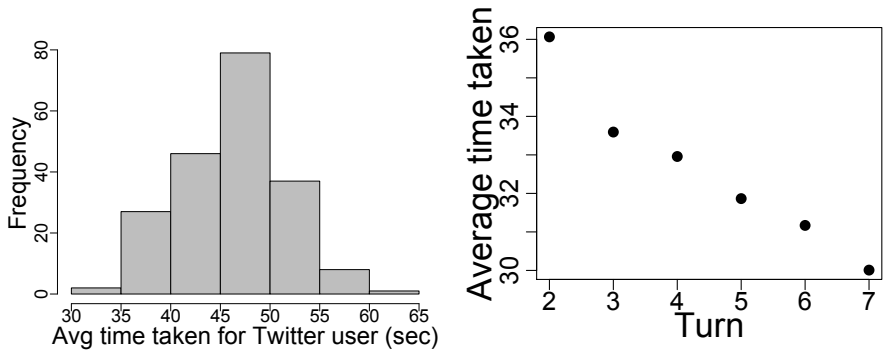
# guesses	41,989
# sessions	15,724
Avg. time (sec) per guess	46
Avg. # guesses / session	2.67

Table 2: Statistics online game (after cleaning)

We calculate the time taken for a guess by taking the time difference between two guesses (therefore, no time for the first guess in each session could be measured). For each Twitter user, we calculate the average time that was taken to guess the gender and age of the user. (Figure 3a). There is a significant correlation (Pearson's r = 0.291, $p < 0.001$) between the average time the players took to evaluate the tweets of a Twitter user and the number of displayed tweets.

There is also a significant correlation between the average time taken for a user and the entropy over gender guesses (Pearson's r = 0.410, $p < 0.001$), and the average time taken for a user and the standard deviation of the age guesses (Pearson's r = 0.408, $p < 0.001$). Thus, on average, players spent more time on Twitter users for whom it was more difficult to estimate gender and age.



(a) Average time taken for Twitter users (b) Average time taken per turn

Figure 3: Time taken in game

We observe that as the game progresses, players tend to take less time to make a guess. This is shown in Figure 3b, which shows the average time taken for a turn (restricted to players with at least 7 guesses). There was no significant correlation between time spent on a guess and the performance of players and we did not find trends of performance increase or decrease as players progressed in the game.

3.3 Automatic Prediction

Besides studying human performance, we also compare the predictions of humans with those of an automatic system. We split the data into train and test sets using the same splits as used by Nguyen et al. (2013). We train a logistic regression model to predict gender (male or female), and a linear regression model to predict the age (in years) of a person.

More specifically, given an input vector $\mathbf{x} \in \mathbb{R}^m$, $x_1, \ldots, x_m$ represent features. In the case of gender classification (e.g. $y \in \{-1, 1\}$), the model estimates a conditional distribution $P(y|\mathbf{x}, \beta) = 1/(1 + exp(-y(\beta_0 + \mathbf{x}^\top \boldsymbol{\beta})))$, where β_0 and $\boldsymbol{\beta}$ are the parameters to estimate. Age is treated as a regression problem, and we find a prediction $\hat{y} \in \mathbb{R}$ for the exact age of a person $y \in \mathbb{R}$ using a linear regression model: $\hat{y} = \beta_0 + \mathbf{x}^\top \boldsymbol{\beta}$. We use Ridge (also called L_2) regularization to prevent overfitting.

We make use of the liblinear (Fan et al., 2008) and scikit-learn (Pedregosa et al., 2011) libraries. We only use unigram features, since they have proven to be very effective for gender (Bamman et al., 2014; Peersman et al., 2011) and age (Nguyen et al., 2013) prediction. Parameters were tuned using cross-validation on the training set.

4 Gender

Most of the computational work on language and gender focuses on gender classification, treating gender as fixed and classifying speakers into females and males. However, this assumes that gender *is* fixed and is something people have, instead of something people *do* (Butler, 1990).

In this section, we first analyze the *task difficulty* by studying crowd performance on inferring gender from tweets. We observe a relatively large group of Twitter users who employ language that the crowd associates with the *opposite* biological sex. This, then, raises questions about the upper bound that a prediction system based on only text can achieve.

Next, we place Twitter users on a *gender continuum* based on the guesses of the players and show that treating gender as a binary variable is too simplistic. While historically gender has been treated as binary, researchers in fields such as sociology (Lorber, 1996) and sociolinguistics (Holmes and Meyerhoff, 2003; Bergvall et al., 1996) find this view too limited. Instead, we assume the simplest extension beyond a binary variable: a one-dimensional gender continuum (or scale) (Bergvall et al., 1996). For example, Bergvall (1999) talks about a '*continuum of humans' gendered practices*'. While these previous studies were based on qualitative analyses, we take a quantitative approach using the crowd.

4.1 Task Difficulty

Majority vote We study crowd performance using a system based on the *majority* of the players' guesses. Majority voting has proven to be a strong baseline to aggregate votes (e.g. in crowdsourcing systems (Snow et al., 2008; Le et al., 2010)). On average, we have 210 guesses per Twitter user, providing substantial evidence per Twitter user. A system based on majority votes achieves an accuracy of 84% (Table 3a shows a confusion matrix). Table 3b shows a confusion matrix of the majority predictions versus the automatic system. We find that the biological sex was predicted incorrectly by both the majority vote system and the automatic system for 21 out of the 200 Twitter users (10.5%, not in Table).

Automatic classification systems on English tweets achieve similar performances as our majority vote system (e.g. Bergsma and Van Durme (2013) report an accuracy of 87%, Bamman et al. (2014) 88%). More significantly, the results suggest that 10.5% (automatic + majority) to 16% (majority) of the Dutch Twitter users do not employ language that the crowd associates with their biological sex. As said, this raises the question of whether we can expect much higher performances by computational systems based on only language use.

		Biological sex	
		Male	Female
Crowd	Male	82	16
	Female	16	86

(a) Crowd (majority)

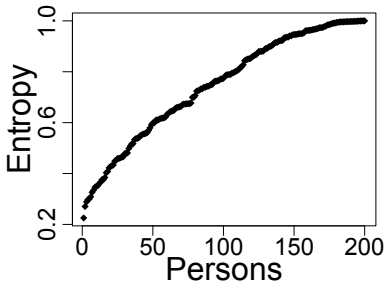
		Crowd	
		Male	Female
Automatic	Male	68	22
	Female	30	80

(b) Automatic vs crowd

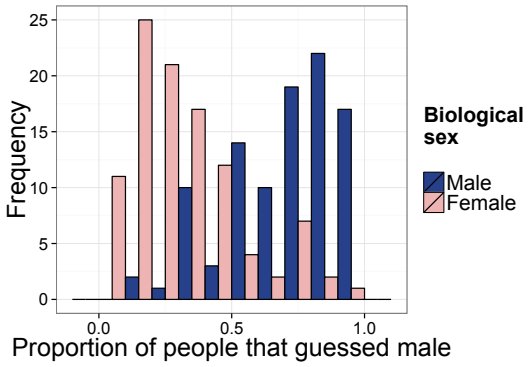
Table 3: Confusion matrices crowd prediction

Individual players versus an automatic system When considering players with 7 or more guesses, the average accuracy for a player is 0.71. Our automatic system achieves an accuracy of 0.69. The small number of tweets per Twitter user in our data (20-40) makes it more difficult to automatically predict gender.

Entropy We characterize the difficulty of inferring a user's gender by calculating the entropy for each Twitter user based on the gender guesses (Figure 4a). We find that the difficulty varies widely across users, and that there are no distinct groups of 'easy' and 'difficult' users. However, we do observe an interaction effect between the entropy of the gender guesses and the ages of the Twitter users. At an aggregate level, we find no significant trend. Analyzing females and males separately, we observe a significant trend with females (Pearson's r = 0.270, $p < 0.01$), suggesting that older female Twitter users tend to emphasize other aspects than their gender in tweets (as perceived by the crowd).



(a) Entropy over gender guesses



(b) A histogram of all Twitter users and the proportion of players who guessed the users were male. For example, there are 25 female users for which 10 - 20% of the players guessed they were male.

Figure 4: Gender prediction

4.2 Binarizing Gender, a Good Approach?

Using data collected through the online game we *quantitatively* put speakers on a gender continuum based on how their tweets are perceived by the crowd. For each Twitter user, we calculate the proportion of players who guessed the users were male and female. A plot is displayed in Figure 4b. We can make the following observations:

First, the guesses by the players are based on their expectations about what kind of behaviour and language is used by males and females. The plot shows that for some users, almost all players guessed the same gender, indicating that these expectations are quite strong and that there are stylistic markers and topics that the crowd strongly associates with males or females.

Second, if treating gender as a binary variable is reasonable, we would expect to see two distinct groups. However, we observe quite an overlap between the biological males and females. There are 1) users who conform to what is expected based on their biological sex, 2) users who deviate from what is expected, 3) users whose tweets do not emphasize a gender identity or whose tweets have large variation using language associated with both genders. We investigated whether this is related to their use of Twitter (professional, personal, or both), but the number of Twitter users in our dataset who used Twitter professionally was small and not sufficient to draw conclusions.

We now illustrate our findings using examples. The first example is a 15-year old biological female for who the crowd guessed most strongly that she is female (96% of n=220). Three tweets from her are shown below. She uses language typically associated with females, talking about spending time with her girlfriends and the use of stylistic markers such as hearts and alphabetical lengthening. Thus, she conforms strongly to what the crowd expects from her biological sex.

Tweet 4: *Gezellig bij Emily en Charlotte.*
Translation: *Having fun with Emily and Charlotte.*

Tweet 5: *Hiiiiii schatjesss!*
Translation: *Hiiiiii cutiesss!*

Tweet 6: ♥ *@USER*

Below are two tweets from a 40 year old biological female who does not employ linguistic markers strongly associated with males or females. Therefore, only 46% of the crowd (n=200) was able to guess that she is female.

Tweet 7: *Ik viel op mijn bek. En het kabinet ook. Geinig toch? #Catshuis*
Translation: *I went flat on my face. And the cabinet as well. Funny right? #Catshuis*

Tweet 8: *Jeemig. Ik kan het bijna niet volgen allemaal.*
Translation: *Jeez. I almost can't follow it all.*

Twitter users vary in how much they emphasize their gender in their tweets. As a result, the difficulty of inferring gender from tweets varies across persons, and treating gender as a binary variable ignores much of the interesting variation within and between persons.

Automatic system We now analyze whether an automatic system is capable of capturing the position of Twitter users on the gender continuum (as perceived by the crowd). We calculate the correlation between the proportion of male guesses (i.e. the position on the gender continuum) and the scores of the logistic regression classifier: $\beta_0 + \mathbf{x}^\top \boldsymbol{\beta}$. While the training data was binary (users were labeled as male or female), a reasonable Spearman correlation of $\rho = 0.584$ ($p < 0.001$) was obtained between the classifier score and the score based on the crowd's perception. We did not observe a significant relation between the score of the classifier (corresponding to the confidence of the gender prediction) and age.

5 Age

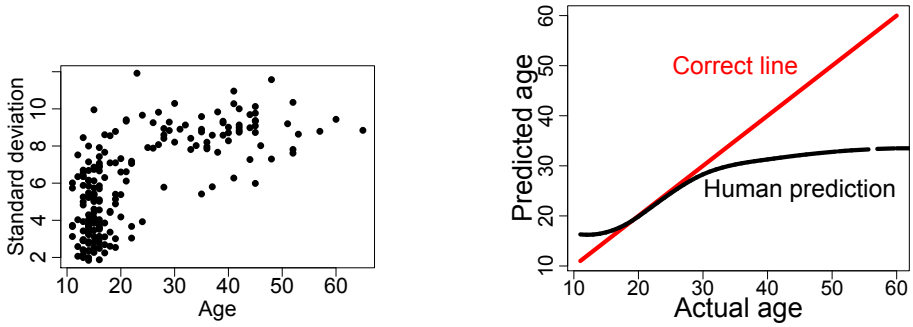
We start with an analysis of task difficulty, by studying crowd performance on inferring age from tweets. Next, we show that it is particularly hard to accurately infer the chronological age of older Twitter users from tweets.

5.1 Task Difficulty

The crowd's average guesses As with a system based on majority vote for gender prediction, we test the performance of a system that predicts the ages of Twitter users based on the average of all guesses. We find that such a system achieves a Mean Absolute Error (MAE) of 4.844 years and a Pearson's correlation of 0.866. Although the correlation is high, the absolute errors are quite large. We find that the crowd has difficulty predicting the ages of older Twitter users. There is a positive correlation (Pearson's $\rho = 0.789$) between the absolute errors and the actual age of Twitter users. There is a negative correlation between the errors (predicted - actual age) and the actual age of Twitter users (Pearson's ρ = -0.872).

We calculate the standard deviation over all the age guesses for a user (Figure 5a) to measure the difficulty of inferring a user's age. There is a positive correlation between age and standard deviation of the guesses ($\rho = 0.691$), which indicates that players have more difficulty in guessing the ages of older Twitter users.

Individual players versus an Automatic System To estimate the performance of individual players, we restrict our attention to players with at least 7 guesses. We find that individual players are, on average, 5.754 years off. A linear regression system achieves a MAE of 6.149 years and a Pearson correlation of 0.812. The small number of tweets in our data (20-40) increases the difficulty of the task for automatic systems.



(a) Standard deviation and actual age

(b) Average age prediction by humans.

Figure 5: Age prediction

5.2 Inferring the Age of Older Twitter Users

Figure 5b shows the average player predictions with the actual age of the Twitter users. The red line is the 'perfect' line, i.e. the line when the predictions would match the exact age. Black represents a fitted LOESS curve (Cleveland et al., 1992) based on the human predictions. We find that the players tend to overpredict the age of younger Twitter users, but even more strikingly, on average they consistently underpredict the age of older Twitter users. The prediction errors already start at the end of the 20s, and the gap between actual and predicted age increases with age.

This could be explained by sociolinguistic studies that have found that people between 30 and 55 years use standard forms the most, because they experience the maximum societal pressure in the workplace to conform (Holmes, 2013). On Twitter, this has been observed as well: Nguyen et al. (2013) found fewer linguistic differences between older age groups than between younger age groups. This makes it difficult for the crowd to accurately estimate the ages of older Twitter users. Younger people and retired people use more non-standard forms (Holmes, 2013). Unfortunately, our dataset does not contain enough retired users to analyze whether this trend is also present on Twitter.

6 Discussion

We now discuss the implications of our findings for research on automatically predicting the gender and age of authors from their texts.

Age and gender as *social* variables Most computational research has treated gender and age as fixed, biological variables. The dominant approach is to use supervised machine learning methods to generalize across a large number of examples (e.g. texts written by females and males). While the learned models so far are effective at predicting age and gender of *most* people, they learn stereotypical behaviour and therefore provide a simplistic view.

First, by using the crowd we have shown that Twitter users emphasize their gender and age in varying degrees and in different ways, so that for example, treating gender as a binary variable is too simplistic (Butler, 1990; Eckert and McConnell-Ginet, 2013). Many users do not employ the stereotypical language associated with their biological sex, making models that take a static view of gender ineffective for such users. More detailed error analyses of the prediction systems will increase understanding of the reasons for incorrect predictions, and shed light on the relation between language use and social variables.

Second, models that assume static variables will not be able to model the interesting variation (Eisenstein, 2013). Models that build on recent developments in sociolinguistics will be more meaningful and will also have the potential to contribute to new sociolinguistic insights. For example, modeling what influences speakers to show more or less of their identity through language, or jointly modeling variation between and within speakers, are in our opinion interesting research directions. The ever increasing amounts of social media data offer opportunities to explore these research directions.

Sampling We have shown that the difficulty of tasks such as gender and age prediction varies across persons. Therefore, creating datasets for such tasks requires maximum attention. For example, when a dataset is biased towards people who show a strong gender identity (e.g. by sampling followers of accounts highly associated with males or females, such as sororities (Rao et al., 2010)), the results obtained on such a set may not be representative of a more random set (as observed when classifying political affiliation (Cohen and Ruths, 2013)).

Task difficulty Our study also raises the question of what level of performance can be obtained for tasks such as predicting gender and age from only language use. Since we often form an impression based on someone's writing, crowd performance is a good indicator of the task difficulty. While the crowd performance does not need to be the upper bound, it does indicate that it is difficult to predict gender and age of a large number of Twitter users.

When taking the majority label, only 84% of the users were correctly classified according to their biological sex. This suggests that about 16% of the Dutch Twitter users do not use language that the *crowd* associates with their biological sex.

We also found that it is hard to accurately estimate the ages of older Twitter users, and we related this to sociolinguistics studies who found less linguistic differences in older age groups due to societal pressure in the workplace.

Limitations A limitation of our work is that we focused on language variation *between* persons, and not on variation *within* persons. However, speakers vary their language depending on the context and their conversation partners (e.g. accommodation effects were found in social media (Danescu-Niculescu-Mizil et al., 2011)). For example, we assigned Twitter users an overall 'score' by placing them on a gender continuum, ignoring the variation we find within users.

Crowdsourcing as a tool to understand NLP tasks Most research on crowdsourcing within the NLP community has focused on how the crowd can be used to obtain fast and large amounts of annotations. This study is an example of how the crowd can be used to obtain a deeper understanding of an NLP task. We expect that other tasks where disagreement between annotators is meaningful (i.e. it is not only due to noise), could potentially benefit from crowdsourcing experiments as well.

7 Conclusion

In this paper, we demonstrated the successful use of the crowd to study the relation between language use and social variables. In particular, we took a closer look at inferring gender and age from language using data collected through an online game. We showed that treating gender and age as fixed variables ignores the variety of ways people construct their identity through language.

Approaching age and gender as *social* variables will allow for richer analyses and more robust systems. It has implications ranging from how datasets are created to how results are interpreted. We expect that our findings also apply to other social variables, such as ethnicity and status. Instead of only focusing on performance improvement, we encourage NLP researchers to also focus on what we can *learn* about the relation between language use and social variables using computational methods.

Exploring Syntactic Features for Native Language Identification: A Variationist Perspective on Feature Encoding and Ensemble Optimization

Abstract

In this paper, we systematically explore lexicalized and non-lexicalized local syntactic features for the task of Native Language Identification (NLI). We investigate different types of feature representations in single- and cross-corpus settings, including two representations inspired by a variationist perspective on the choices made in the linguistic system. To combine the different models, we use a probabilities-based ensemble classifier and propose a technique to optimize and tune it. Combining the best performing syntactic features with four types of n-grams outperforms the best approach of the NLI Shared Task 2013.

1 Introduction and related work

Native Language Identification (NLI) is the task of identifying the native language of a writer by analyzing texts written by this writer in a non-native language. NLI started to attract attention in computational linguistics with the work of Koppel et al. (2005). Since then, the interest has increased steadily, leading to the First NLI Shared Task in 2013, with 29 participating teams (Tetreault et al., 2013).

The task of NLI is usually treated as a text classification problem with the L1s as classes. A wide range of features, reaching from character or word-based n-grams to different types of syntactic models have been employed in NLI. For example, Wong and Dras (2011) utilized character and part-of-speech (POS) n-grams as well as cross-sections of parse trees and Context-Free Grammar (CFG) features, i.e., local trees. Their approach with a binary representation of non-lexicalized rules (except for those rules lexicalized with function words and punctuation) outperformed a setup using only lexical features, such as n-grams, on data from the International Corpus of Learner English (ICLE; Granger et al., 2002). Swanson and Charniak (2012) used binary feature representations of CFG and Tree Substitution Grammar (TSG) rules replacing terminals (except for function words) by a special symbol. TSG outperformed CFG features in their settings. Among several options, Brooke and Hirst (2012) explored using non-lexicalized CFG production rules in a binary feature encoding on three corpora: ICLE, FCE (Yannakoudakis et al., 2011), and Lang-8 (Brooke and Hirst, 2013a). The authors conclude that including CFG features generally boosts the performance of the system. In the context of the First NLI Shared Task, in Bykh et al. (2013) we showed that non-lexicalized frequency-based CFG features contribute relevant information. Other recent work has focused on TSGs (Tetreault et al., 2012; Brooke and Hirst, 2013b; Swanson and Charniak, 2012; Swanson and Charniak, 2013; Swanson, 2013; Malmasi et al., 2013).

Before extending syntactic modeling further, in this paper we want to systematically explore the range of options involving CFG rule features for NLI. We consider non-lexicalized and lexicalized CFG features, and different feature representations, from binary encodings to a normalized frequency encoding inspired by a *variationist sociolinguistic* perspective.

Previous research in this domain often limited the use of lexicalized rules given that the lexicalization may lead to an unintended topic or domain dependence. Yet, NLI research has since established that lexical features, such as word-based n-grams, are among the best performing features both in single-

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1962–1973, Dublin, Ireland, August 23-29 2014.

and in cross-corpus settings (Brooke and Hirst, 2012; Bykh and Meurers, 2012; Jarvis and Crossley, 2012; Brooke and Hirst, 2013b; Bykh et al., 2013; Gebre et al., 2013; Jarvis et al., 2013; Lynum, 2013), making them an essential component of any approach with state-of-the-art performance. At the same time, the question whether an NLI approach and its results capture general characteristics of language and language learning instead of only encoding the characteristics of a specific data set remains an essential concern. In the experiments in this paper, we thus include experiments on both a topic-balanced single-corpus and on a highly heterogeneous cross-corpus data set.

The range of feature types used in NLI research raises a further question, namely how the different sources of information are best combined. The most simple solution is to put all features into a single vector. However, Tetreault et al. (2012) pointed out that the performance can be increased by using a probability-estimate based ensemble (meta-classifier), which was confirmed in Bykh et al. (2013) and Cimino et al. (2013). But which models are worth integrating into such a meta-classifier? Some of the models may be redundant despite performing well individually; on the other hand, some models may improve the ensemble despite performing relatively poorly by itself. We explore this issue by implementing a basic ensemble optimization algorithm performing model selection.

In terms of the structure of the paper, in section 2 we first introduce the corpora used in the single-corpus and cross-corpus settings. Section 3 then presents the first set of experiments, systematically exploring lexicalized and unlexicalized Context-Free Grammar Rules (CFGR) as features. Given the significant complexity of the overall feature space, we then explore model selection for optimizing the ensemble classifier in section 4. In section 5, we combine the CFGR features with n-grams, resulting in the best accuracy reported for the standard TOEFL11 test set. Section 6 sums up the paper and sketches some directions for future research.

2 Data

The research in this paper makes use of two sets of data:

First, there is the TOEFL11 (T11) data set (Blanchard et al., 2013), which was introduced for the NLI Shared Task 2013 and has become a standard frame of reference for NLI research. We use this standard setup for *single-corpus* evaluation, where each L1 is represented by 1100 essays, of which 100 essays are singled out in the standard *test* set. The remaining 1000 essays per L1 (= T11 *train* $\cup$ *dev*) constitute our training data in the single-corpus settings.

Second, we make use of a range of other learner corpora to study how well the results generalize. Concretely, for our *cross-corpus* settings we employ the NT11 corpus of Bykh et al. (2013), which consists of the ICLE (Granger et al., 2009), FCE (Yannakoudakis et al., 2011), BALC (Randall and Groom, 2009), ICNALE (Ishikawa, 2011), and TÜTEL-NLI (Bykh et al., 2013) corpora. In total NT11 includes 5843 texts, with the following division into languages: Arabic (846), Chinese (1048), French (456), German (500), Hindu (400), Italian (467), Japanese (447), Korean (684), Spanish (446), Telugu (200), Turkish (349). In the cross-corpus settings, we train on NT11 and test on the standard T11 *test* set.

3 Systematically exploring Context-Free Grammar Rules (CFGR)

3.1 Features

In this paper, we focus on the CFG production rules (CFGR) as syntactic features for the task of NLI. CFG rules are the most basic and widely used local syntactic units modularizing the overall syntactic analysis of a sentence. We parsed the T11 and NT11 corpora using the Stanford Parser (Klein and Manning, 2002) and extracted all CFG rules from the T11 and NT11 training sets. On this basis we defined the following tree feature types:

1. $CFGR_{ph}$: Only *phrasal* CFG production rules excluding all terminals
   - S $\rightarrow$ NP VP, NP $\rightarrow$ D NN, ...
2. $CFGR_{lex}$: Only *lexicalized* CFG production rules of the type *preterminal* $\rightarrow$ *terminal*
   - JJ $\rightarrow$ *nice*, JJ $\rightarrow$ *quick*, NN $\rightarrow$ *vacation*, ...
3. $CFGR_{ph \cup lex} = CFGR_{ph} \cup CFGR_{lex}$ (i.e., the union of the above two)

A variationist perspective on feature representation We explore four different feature representations: The two standard ones are a frequency-based (*freq*) representation, where the values are the raw counts of the occurrences of the rule in the given parsed document, and a binary (*bin*) representation, which only indicates whether a rule is present or absent in that document.

Complementing these standard feature representations, we explored two options that take as starting point the observation that CFG rules with the same left-hand side category represent different ways to rewrite that category. So in a sense, under a top-down perspective, there is a choice between different ways of realizing a given category.

This is reminiscent of variationist sociolinguistic analysis, where one studies the linguistic choices made by a given speaker and connects the choices with extra-linguistic variables such as the age or gender of a speaker. For example, in William Labov's field-defining study "The Social Stratification of (r) in New York City Department Stores" from his book "Sociolinguistic Patterns" (Labov, 1972), he found that the presence or absence of the consonant [r] in postvocalic position (e.g., *car*, *fourth*) correlates with the ranking of people in status or prestige, i.e., social stratification. Speakers thus make choices in how to realize a given *variable* by producing one of the *variants* (see also Tagliamonte, 2011). Inspired by this perspective, in Meurers et al. (2013) we discussed how a variationist perspective on syntactic alternations can provide interpretable features for NLI classification.

Under a variationist perspective, producing one of the variants of a given variable also means not choosing the other variants of that variable. So it is this grouping of observations that we want to take into account in terms of encoding local trees as features when we interpret the mother category as the variable to be realized and the different CFG rules with that left-hand side as variants of that variable. This results in two feature representations, a simple one (var_s) and a weighted one (var_w).

The var_s and var_w frequency normalizations for each variant v from the set of variants V realizing a particular variable out of the set of variables $\overline{V}$ is defined as follows:

$$var_s(v \in V) = \frac{f(v)}{F(V)}$$

$$var_w(v \in V) = var_s(v) \cdot w(V)$$

Here, $f(v)$ yields the frequency x of a particular variant v, $F(V)$ is the sum over the frequencies of all variants v realizing the variable V, and $w(V)$ is the weight for the variable V:

$$f(v) = x$$

$$F(V) = \sum_{v \in V} f(v)$$

$$w(V \in \overline{V}) = \frac{F(V)}{\sum_{i=1}^{n} F(\overline{V}_i)}$$

The weighting applied in var_w takes into account the frequency proportion of each variable V in the overall variables set $\overline{V}$, assigning higher weights for more frequent variables. Mathematically it reduces to normalizing each variant by the sum of the frequencies over all variants across all variables, i.e., to the relative frequency of each variant v with respect to the set of all variables $\overline{V}$. At the same time, we will see in the next section that the individual variables keep an independent status in terms of the classification setup, where we train a separate classifier for each variable.

3.2 Results

Classifier We use the *L2-regularized Logistic Regression* from the LIBLINEAR package (Fan et al., 2008), which we accessed through WEKA (Hall et al., 2009). To obtain results for all feature representations which are comparable across the different settings we uniformly scale all values employing the -Z option of WEKA. This means that the *freq* feature representation based on the raw frequencies in essence also becomes normalized. This is particularly relevant in the context of the cross-corpus evaluation, where raw frequencies are particularly questionable given highly variable text sizes.

Single- vs. cross-corpus results The results for the *three feature types* using the *four different feature representations* are presented in Table 1. The chance baseline for the given data setup is 9.1%. There are big accuracy differences between the single- and cross-corpus settings despite very similar feature counts. The drop for the cross-corpus settings is roughly around $\frac{1}{2}$ compared to the single-corpus settings. This is in line with previous results on the same data sets using a wide range of features (Bykh et al., 2013), confirming the fact that obtaining high cross-corpus results remains challenging in NLI.

features	single-corpus (sc): T11 training				
	freq	*bin*	var_s	var_w	feat. #
$CFGR_{ph}$	**50.00%**	44.27%	48.45%	49.82%	14,713
$CFGR_{lex}$	75.73%	72.45%	71.00%	**76.91%**	83,402
$CFGR_{ph \cup lex}$	78.18%	73.55%	75.36%	**78.82%**	98,115

features	cross-corpus (cc): NT11 training				
	freq	*bin*	var_s	var_w	feat. #
$CFGR_{ph}$	21.27%	22.91%	26.27%	**27.73%**	15,253
$CFGR_{lex}$	26.73%	32.00%	28.82%	**36.82%**	78,923
$CFGR_{ph \cup lex}$	28.27%	34.27%	32.55%	**38.82%**	94,176

Table 1: Results for the $CFGR$ feature variants obtained on the standard T11 *test* set

Best feature type The $CFGR_{lex}$ feature type clearly outperforms the more abstract $CFGR_{ph}$ feature type, yielding up to 28% difference in accuracy for the single-corpus and up to 9% for the cross-corpus settings. In contrast to previous research assuming that lexicalized trees are too topic-specific, the results show that $CFGR_{lex}$ is a valuable feature type in both the single-corpus and the cross-corpus settings. The $CFGR_{lex}$ features combine syntactic and lexical information, such as the fact that a given token with a particular POS is used, e.g., the token *can* being used as a *noun* in *There is a **can** of beer in the fridge* instead of as the more frequent *modal verb* use in *He **can** dance*. Note that this is different from using word and POS unigrams as features, where the relevant connection is lost. In both the T11 data, which is topic balanced, for single-corpus evaluation and the very heterogeneous NT11 data containing a wide range of topics for cross-corpus evaluation, we obtained consistently better results for $CFGR_{lex}$ than for $CFGR_{ph}$. Some syntactic rules including lexical information thus seem to generalize well across topics. Combining $CFGR_{ph}$ and $CFGR_{lex}$ into $CFGR_{ph \cup lex}$ gives an additional boost in performance.

Best feature representation There are clear differences in Table 1 between the results for the four feature representations. var_w yields the best accuracies in five out of six settings, across different feature types and corpora.

The results show that WEKA-normalized raw frequencies such as *freq* yield the worst results in a cross-corpus setting but perform very well single-corpus, which is in line with the assumption that raw frequency features do not generalize well. In our experiments, the performance of *freq* in a cross-corpus setting is up to 10.55% worse than what is yielded by var_w, despite comparable single-corpus performance. *freq* also consistently performs worse than var_s in the cross-corpus setting, despite outperforming var_s single-corpus.

Using binary features (*bin*) yields better results cross-corpus than *freq*, whereas in the single-corpus setting it is the other way round. The abstraction introduced by the binary feature representation thus shows a positive effect in terms of the capability of the features to generalize to other data sets.

For the abstract $CFGR_{ph}$ features, var_s performs better than *freq* or *bin* in the cross-corpus setting.

The fact that the var_w is performing consistently better than var_s shows that weighting is important. Hence, incorporating the insight from variationist sociolinguistics is not only conceptually interesting as a theoretical perspective, but also provides a quantitative advantage in terms of performance.

CFGR categories as variables As mentioned above, the best performance is achieved by combining $CFGR_{ph}$ and $CFGR_{lex}$ into the $CFGR_{ph \cup lex}$ feature type using the weighted variationist feature representation var_w. Thus, we focused on that feature type and explored it more in depth. We did so by splitting the overall var_w normalized $CFGR_{ph \cup lex}$ feature set by the variable, i.e., the different *mother nodes*. We trained separate models, where each of those models consists of features encoding the different variants, i.e., the different realizations in which a given mother node can be rewritten. Our aim was to investigate the accuracy of the individual variable-based models and their contribution to the overall performance. Figures 1 and 2 depict the single-corpus (sc) and cross-corpus (cc) accuracies yielded by each individual variable-based model, for presentation reasons shown separately for the $CFGR_{ph}$ and the $CFGR_{lex}$ subsets.

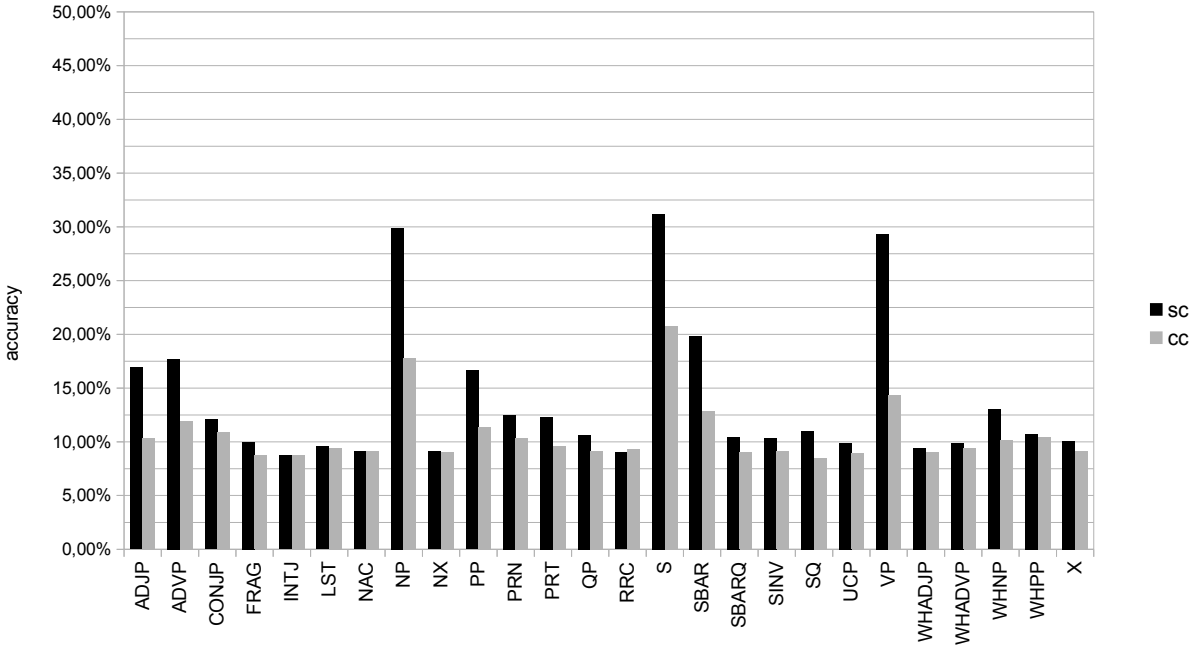

Figure 1: Accuracy for the individual $CFGR_{ph}$ variable based models, var_w normalized

The $CFGR_{ph}$ results in Figure 1 show that a small subset of variables performs relatively well. Most of the models perform poorly, yielding accuracies close to the chance baseline. The best performing variables are essentially the main phrasal categories, such as S, NP, VP, PP, ADJP, ADVP or SBAR.

The results for the $CFGR_{lex}$ in Figure 2 show a similar pattern. There is a subset of variables which perform relatively well, usually models based on the main POS categories, such as the nominal (NN) and verbal (VB) categories as well as adjectives (JJ), prepositions (IN) and adverbs (RB). Some punctuation marks also seem to play a role. The rest of the models yields accuracies around the chance baseline. This might be due to data sparsity given that the main POS categories also are the most frequent. But those main categories also have the highest number of variants through which they can be realized. The good performance of the models for the variables with the highest number of variants thus confirms the assumption that the choice of one of the realization options of a given category is influenced by the L1.

Should we focus only on those high-performing models – or do the other models also contain relevant, independent information which is worth preserving? We address that question in the next section.

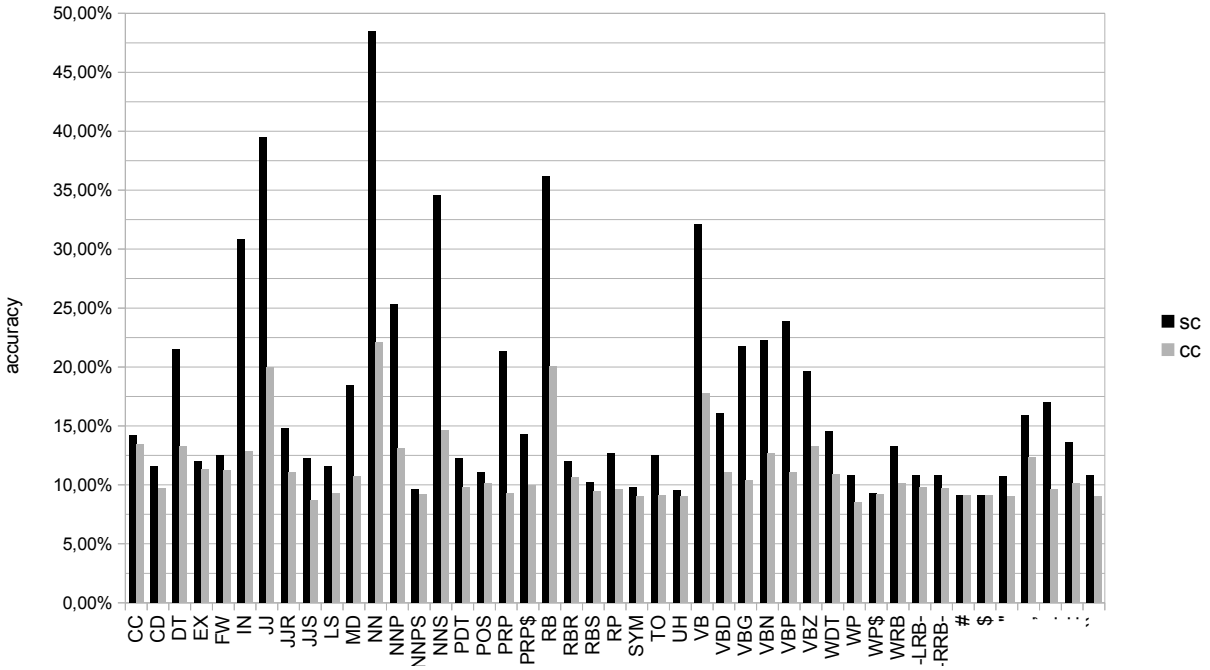

Figure 2: Accuracy for the individual $CFGR_{lex}$ variable based models, var_w normalized

4 Ensemble optimization and tuning

Ensemble generation To combine the individual models, we employ a probability-estimate-based ensemble approach, following Tetreault et al. (2012) and Bykh et al. (2013). This meta-classifier combines the probability distributions provided by the individual classifier for each of the incorporated models as features. To obtain the ensemble training files, we performed 10-fold cross-validation for each model on the corresponding training set and took the probability estimate distributions. For testing, we took the probability estimate distribution yielded by each individual model trained on the corresponding training set and tested on the T11 *test* set. To obtain the probability estimates for the individual models we used LIBLINEAR as described in section 3.2. The ensembles were trained and tested using LIBSVM with an RBF kernel (Chang and Lin, 2011), which outperformed LIBLINEAR for this purpose.

Ensemble optimization (*+opt*) The growing range of features used for NLI raises the question of how to perform model selection. Even when analyzing a single feature type in depth, as we do in section 3.2, we already must determine which of the low-performing models to keep in an ensemble. We approach the question with a simple incremental ensemble optimization algorithm performing model selection.

Algorithm 1 Ensemble Optimization / Ensemble Model Selection

$M_a \leftarrow \{m_1, ..., m_n\}$ ▷ overall ensemble, i.e., all ensemble models
$M_b \leftarrow \emptyset$ ▷ current best performing ensemble
while $M_a \neq \emptyset$ **do** ▷ iterate until M_a is empty
  $m_b \leftarrow \text{MAX}(M_a)$ ▷ get the model with the highest accuracy m_b out of M_a
  $M_t \leftarrow M_b \cup \{m_b\}$ ▷ join the previous best performing ensemble M_b and $\{m_b\}$
  if $\text{ACC}(M_t) > \text{ACC}(M_b)$ **then** ▷ check if the new ensemble is performing better than M_b
    $M_b \leftarrow M_t$ ▷ if the accuracy improves, store the new ensemble in M_b
  end if
  $\text{REMOVE}(m_b, M_a)$ ▷ remove m_b from M_a
end while

In each iteration step the optimization algorithm shown in Algorithm 1 retrieves the current best single model m_b out of the model set M_a (which is initialized with the overall model set for a particular setting), joins it with the previous best performing ensemble M_b (which is initialized to $\emptyset$), compares the accuracy of that new ensemble with the accuracy of the previous best ensemble. It retains the new ensemble as the best ensemble if the accuracy improves, or keeps the previous best ensemble as best ensemble otherwise. In Algorithm 1, we describe only the gist of the optimization, omitting some details to keep it transparent. Some ambiguities have to be resolved. If there are several models in M_a yielding the same accuracy, one has to decide, which of them to pick as the next m_b. We resolve that issue by always picking the model with the least number of features. When several models yield the same accuracy and have the same number of features, we resort to alphabetical order. The optimization is always carried out using 10-fold cross-validation results on the training data (to obtain the accuracy ranking on M_a and to perform each optimization step). The *test* set is not part of the optimization at any point. Only after optimization is the resulting ensemble applied to the *test* set and we report the corresponding accuracies.

Ensemble tuning (*+all*) In order to further tune the ensemble, we explore the following idea: We generate a *single ensemble model* m_{n+1} based on *all* of the features used in a particular setting, i.e., all the features incorporated by the models $m_1 \dots m_n$. Then we include that m_{n+1} model in the M_a ensemble as just another model, and use that new M_a^{+1} ensemble either directly or as basis for the optimization. Since m_{n+1} incorporates all of the features of interest for a particular setting, it is expected to yield more reliable probability estimates than the other individual ensemble models in M_a^{+1}, each covering only a subset of that feature set. Incorporating such an m_{n+1} into the ensemble may stabilize the resulting system, i.e., the machine learning algorithms may learn to rely on m_{n+1} in settings, where the rest of the included models $m_1 \dots m_n$ show a rather poor individual performance and are of limited use. In the tables and explanations below, we refer to the model m_{n+1} as [*all*] and to the M_a^{+1} ensemble as *+all*.

For building the m_{n+1} model included in the M_a^{+1} ensemble there are two options. We can build it on the basis of the probabilities of the models or on the union of the original feature values of those models. In the former case, the final ensemble model essentially is a meta-meta-classifier. For the settings integrating the same type of feature representations (cf. results in Tables 2 and 4), we use the original feature values merged into a single vector to build m_{n+1}. For the settings integrating different feature types (cf. results in Table 6), we use the probability estimates from the models $m_1 \dots m_n$ to build m_{n+1}.

Ensemble results for the CFGR variables The ensemble results for the separate variable-based models for the $CFGR_{ph \cup lex}$ feature type are presented in Table 2. We provide single-corpus (*sc*) and cross-corpus (*cc*) results for different ensemble settings, where *+/- opt* states whether ensemble optimization was performed, and *+/- all* whether tuning was employed. Concretely, *(-opt, -all)* means that the ensemble M_a was used without any optimization or tuning, and correspondingly *(+opt, +all)* means that the optimized and tuned version of M_a (i.e., the optimized version of the ensemble M_a^{+1}) was employed. In the remaining two cases *(+opt, -all)* and *(-opt, +all)* either optimization or tuning was used, respectively. The column *baseline* lists the corresponding results from Table 1, which were obtained by putting all the features in a single vector. The number in parentheses specifies the number of models combined in the ensemble: in the *features* column, it shows the overall number of separate variable-based models, and in the *+opt* columns, it is the number of models selected by the optimization algorithm.

features	data	baseline	ensemble			
			-opt		+opt	
			-all	+all	-all	+all
$CFGR_{ph \cup lex}$ (71)	sc	78.82%	66.00%	79.18%	71.27% (14)	**79.64% (8)**
	cc	38.82%	18.09%	34.18%	32.55% (10)	**39.00% (1)**

Table 2: Results for the $CFGR_{ph \cup lex}$ ensembles with different optimization settings

The results show that generating an ensemble using all of the individual variable-based models without optimization and tuning *(-opt, -all)* leads to a big accuracy drop compared to the baseline. The fact that

the drop in the cross-corpus setting is more than 20% is particularly striking. We assume that this is due to the poor performance of most of the individual models, yielding probabilities of little use overall. The few relatively well-performing models we discussed in section 3.2 apparently are flooded by the noise introduced by the others. Thus, for a set of rather low-performing models without any optimization, it seems preferable to provide the classifier with access to the individual features instead of to the noisy probability estimates. The optimization *(+opt, -all)* leads to a clear improvement over the non-optimized settings. In the single-corpus setting only 14 of the 71 models were kept and in cross-corpus only 10.

Table 3 shows the selected models in the order in which they are selected by the ensemble optimization algorithm. For *(+opt, -all)*, the table basically consists of the best performing variables (i.e., the models containing as features the different ways to rewrite the given mother category) as discussed in section 3.2, suggesting that the algorithm makes meaningful choices.

data	$CFGR_{ph \cup lex}$: selected models	
	+opt, -all	+opt, +all
sc	[NN]+[JJ]+[RB]+[NNS]+[VB]+[NP]+[S]+[VP] +[IN]+[VBP]+[VBG]+[VBN]+[NNP]+[,] (14)	[*all*]+[NN]+[JJ]+[RB]+[PRP]+[VBN]+[NNP]+[WDT] (8)
cc	[NN]+[JJ]+[NNS]+[NP]+[RB]+[VB]+[VP]+[NNP] +[S]+[IN] (10)	[*all*] (1)

Table 3: The $CFGR_{ph \cup lex}$ model sets selected by optimization

The flipside of the coin is that low-performing models generally were not found to have a positive effect and thus were not included. Yet, optimization by itself is not successful overall given that the *(+opt, -all)* accuracy remains below the single feature set baseline.

Applying tuning without optimization *(-opt, +all)* outperforms the optimization result. Thus, including the overall model [*all*] in the ensemble improves the meta-classifier. In the single-corpus setting, the accuracy is slightly higher than the baseline, in cross-corpus it remains below the baseline.

Turning on both optimization and tuning *(+opt, +all)* yields the overall best results of Table 2, 79.64% for single-corpus and 39% for the cross-corpus setting. The corresponding entry in Table 3 shows that tuning significantly reduces the number of selected models. This is not unexpected given that the overall model [*all*] essentially includes all the information. In the cross-corpus setting, [*all*] indeed is the only model selected. Interestingly, in the single-corpus setting, the optimization algorithm identifies some additional models to improve the accuracy, mainly ones that also perform well individually. While this amounts to adding information that in principle is already available to the [*all*] model, the improvement may stem from the abstract nature of the probability estimates used as features of the meta-classifier. When both optimization and tuning are applied, the tuning apparently stabilizes the ensemble leading to higher performance, and the optimization algorithm further improves the result by reducing the noise.

5 Combining CFGR with four types of n-grams

Based on the systematic exploration of the CFGR domain, we turn to combining our new feature type $CFGR_{ph \cup lex}$ with n-gram features as the best performing features for NLI (Tetreault et al., 2013; Jarvis et al., 2013). Adapting the n-gram approach we presented in Bykh and Meurers (2012), we use all recurring n-grams with $1 \leq n \leq 10$ at different levels of representation, including the word-based (W), open-class POS-based (OP) and POS-based (P) n-grams from our previous work as well as lemma-based (L) n-grams (Jarvis et al., 2013). We employ binary feature encoding for all n-gram types.

For POS-tagging we use the OpenNLP[1] toolkit, for lemmatizing we employ the MATE[2] tools (Björkelund et al., 2010). To obtain a fine grained, flexible n-gram setting, we generate an ensemble model for each n-gram type and each n, which results in 40 n-gram models.

[1] `http://opennlp.apache.org`
[2] `https://code.google.com/p/mate-tools`

Table 4 provides the results for the n-gram ensembles built on the basis of the recurring word-, lemma-, POS-, OCPOS-based n-grams with $1 \leq n \leq 10$ in the same format as Table 2 for $CFGR_{ph \cup lex}$.[3] Different from the $CFGR_{ph \cup lex}$ case, the results for the n-gram ensemble model without optimization or tuning *(-opt, -all)* already are 4–5% higher than the single vector baseline.

features	data	baseline	ensemble			
			-opt		+opt	
			-all	+all	-all	+all
N-GRAMS (40)	sc	77.09%	82.27%	82.55%	**83.00% (13)**	82.27% (8)
	cc	31.00%	34.91%	34.55%	**36.45% (6)**	35.45% (6)

Table 4: Results for the n-gram ensembles with different optimization settings

The best results, 83% for single-corpus and 36.45% for the cross-corpus setting, are obtained by applying the optimization. The n-gram ensembles seem to benefit more from optimization than from tuning in general. The feature counts for the n-grams (single-corpus: 4,822,874; cross-corpus: 3,687,375) are far higher than for $CFGR_{ph \cup lex}$ (single-corpus: 98,115; cross-corpus: 94,176), so there may be more noise in the [*all*] model, making it less useful for the tuning step.

Table 5 lists the models selected by the optimization algorithm in order in which they are selected. The n-gram types and the n of the model is indicated, e.g., "[OP-3]" means "OCPOS-based trigrams".

data	N-GRAMS: selected models	
	+opt, -all	+opt, +all
sc	[W-2]+[L-2]+[W-1]+[L-1]+[L-3]+[W-3]+[OP-3] +[OP-1]+[OP-5]+[P-3]+[P-5]+[P-2]+[OP-8] (13)	[*all*]+[W-2]+[L-2]+[W-1]+[L-1]+[L-3]+[OP-4]+[L-4] (8)
cc	[W-2]+[W-1]+[L-1]+[L-3]+[W-3]+[OP-2] (6)	[W-2]+[W-1]+[*all*]+[L-1]+[L-3]+[P-4] (6)

Table 5: The n-gram model sets selected by optimization

For the more surface-based n-gram (word- and lemma-based), the optimizer selected only up to $n = 3$, whereas for the more abstract ones (POS- and OCPOS-based), models up to $n = 8$ were included. Thus, when abstracting from the surface, one can get some useful information out of longer n-grams that apparently is not contained in the short surface-based ones. Different from the $CFGR_{ph \cup lex}$ variables-based ensemble, we here find that relatively low-performing models such as those considering longer n n-grams are kept when optimizing the ensemble.

Having established the performance of the n-gram ensembles, we can turn to combining the $CFGR_{ph \cup lex}$ and n-gram models. The results are presented in Table 6.

features	data	ensemble			
		-opt		+opt	
		-all	+all	-all	+all
(a) $CFGR_{ph \cup lex}$ (71) + N-GRAMS (40)	sc	82.09%	82.91%	82.91% (20)	**83.55% (6)**
	cc	34.09%	36.00%	36.73% (8)	**38.45% (3)**
(b) $CFGR_{ph \cup lex}$ (71) + N-GRAMS [+opt, -all] (ME)	sc	83.09%	83.73%	82.64% (4)	**84.18% (5)**
	cc	37.36%	39.55%	38.00% (3)	**40.27% (3)**
(c) $CFGR_{ph \cup lex}$ [+opt, +all] (ME) + N-GRAMS (40)	sc	83.73%	**84.82%**	84.73% (13)	83.82% (13)
	cc	36.82%	38.91%	42.00% (5)	**43.00%** (4)
(d) $CFGR_{ph \cup lex}$ [+opt, +all] (ME) + N-GRAMS [+opt, -all] (ME)	sc	**83.45%**	**83.45%**	**83.45% (2)**	83.36% (2)
	cc	41.27%	**42.00%**	41.27% (2)	40.55% (2)

Table 6: Optimization results combining n-grams and $CFGR_{ph \cup lex}$

[3]For space reasons, we cannot present the individual results for the separate n-gram models here, but interested readers can consult Bykh and Meurers (2012), where word-, POS- and OCPOS-based n-gram results are discussed in detail. The lemma-based n-grams we are adding here perform very much like the word-based n-grams.

We explore four different ways to combine the two model sets, and the table shows the best results for each of the setups in bold, once for the single-corpus and once for the cross-corpus setting.

For the results of setup (a), we use the ensemble consisting of all individual models separately.

In (b), the $CFGR_{ph \cup lex}$ models are included as in (a), but we replace the n-gram models by a *single meta-ensemble model (ME)* generated using the best n-grams setting *(+opt, -all)*, which consists of 13 models for single-corpus and six models for the cross-corpus setting (see Table 4). ME thus is a *meta-meta-classifier*, generated by applying the ensemble model generation routine to an ensemble.

In (c), we invert the (b) setting: The $CFGR_{ph \cup lex}$ features are replaced by a meta-ensemble generated using the best performing $CFGR_{ph \cup lex}$ setting *(+opt, +all)*, which consists of eight models for the single-corpus, and one model for the cross-corpus setting (see Table 2).

Finally, in (d) we combine the meta-ensemble for $CFGR_{ph \cup lex}$ with the meta-ensemble for the n-grams obtaining an ensemble consisting of two models

The best results of 84.82% in the single-corpus setting and 43% cross-corpus, underlined in the table, are obtained in setup (c). These are the overall best results across all experiments described in this paper. The best result in the single-corpus setting involves tuning only, whereas in the cross-corpus setting it involves tuning and optimization selecting the models [*all*]+[*CFGR +all +opt*]+[W-2]+[W-1].

The single-corpus accuracy of 84.82% is the best result reported so far for the NLI Shared Task 2013 data with the T11 *train* $\cup$ *dev* set for training and the T11 *test* set for testing. The best previous result was 83.6% (Jarvis et al., 2013).

In the cross-corpus setting, the 43% accuracy also outperforms the previous best result on the NT11 data (Bykh et al., 2013) by 4.5%.

In sum, the overall best results in the single-corpus and cross-corpus settings are obtained starting with the whole n-gram model set plus an optimized $CFGR_{ph \cup lex}$ meta-ensemble. This confirms the usefulness of the optimized ensemble setup and underlines that combining a range of linguistic properties, from n-grams at different levels of abstraction to local syntactic trees characteristics, is a particularly fruitful approach for native language identification as a good example of an experimental task putting linguistic modeling to the test with real-life data.

6 Conclusions

In the research presented, we systematically explored *non-lexicalized* and *lexicalized CFG production rules (CFGR)* as features for the task of NLI using both single-corpus and cross-corpus settings. Including lexicalized CFG rule features clearly improved the results in both setting so that it seems worthwhile not to discard them a priori, which was the standard in previous research.

Pursuing a *variationist perspective* to CFGR feature representation resulted in improved performance and it supported an in-depth exploration of the contribution of the different variables and variants as well as of the value of local syntactic features for NLI in general. Training a separate classifier for each variable provides quantitative advantages by facilitating high-performing ensemble setups and supports a qualitative discussion of the categories reflecting the choices made by the learners with a given L1.

Investigating different meta-classifier setups, we explored *ensemble optimization and tuning* techniques that improved the accuracy over putting all features in a single vector or a basic ensemble setup.

Combining the syntactic CFGR with four types of n-grams yielded a *single-corpus* accuracy of *84.82%* on the TOEFL11 *test* set. To the best of our knowledge this is the highest accuracy reported so far on this standard data set of the NLI Shared Task 2013. The combined model also outperformed our best previous cross-corpus result on the NT11 corpus.

In terms of future work, we intend to explore a broader range of linguistic features from a variationist perspective, for example on the morphological level. To investigate the generalizability of the types of features used, we also plan to apply our approach to NLI targeting second langauges other than English.

Abstract

In this work, we discuss the benefits of using automatically parsed corpora to study language variation. The study of language variation is an area of linguistics in which quantitative methods have been particularly successful. We argue that the large datasets that can be obtained using automatic annotation can help drive further research in this direction, providing sufficient data for the increasingly complex models used to describe variation. We demonstrate this by replicating and extending a previous quantitative variation study that used manually and semi-automatically annotated data.

We show that while the study cannot be replicated completely due to limitations of the existing automatic annotation, we can draw at least the same conclusions as the original study. In addition, we demonstrate the flexibility of this method by extending the findings to related linguistic constructions and to another domain of text, using additional data.

1 Introduction

There are many examples of linguistic variation that are not easily explained in terms of rules. One may find two grammatically correct constructions that can be used to express similar meanings, yet speakers still use both of them. A well-known example in English is the dative alternation, where a transitive verb such as *give* can be phrased as a double object construction (1) or as a prepositional dative (2):

(1) He gave his friend the ticket.

(2) He gave the ticket to his friend.

Studies of such phenomena tend to find that there are multiple variables that may influence whether a speaker chooses one or the other construction. This has prompted various multivariate studies by quantitative linguists to analyze instances of such variation in language corpora, starting with Gries (2001), or Bresnan et al. (2007) for a study on the dative alternation. The multivariate statistical models that these studies employ can quantify the contribution of each variable to the variation in probabilistic terms, rather than examining them in isolation.

We show the benefits of using automatically annotated corpora for the study of language variation by replicating a previous, manual multivariate study on Dutch verbal cluster variation (De Sutter, 2009), and extending it to fit more types of clusters. We also show that the same variables are explanatory in at least two different text domains, Wikipedia text and European Parliament proceedings. The larger scale of our investigation allows us to generalize the claims of the previous study to Dutch two-verb cluster variation in general. This topic makes for a good methodological case study for the use of automatically annotated corpora, as verbal clusters are a widely studied phenomena in Dutch syntactic literature (Evers, 1975; Den Besten and Edmondson, 1983; Haegeman and van Riemsdijk, 1986; Zwart, 1996; Wurmbrand, 2004), and the optionality in verbal cluster order has received particular attention in some recent dissertations (De Sutter, 2005; Coussé, 2008; Arfs, 2007). In addition, a methodologically sound quantitative study, which did not make use of automatically annotated data, already exists to compare to (De Sutter, 2009).

This particular case of variation allows for a lot of optionality. The verbal clusters found at the ends of Dutch clauses allow for almost free order variation when there are two verbs. For example, in two-verb clusters the auxiliary verb can be positioned before or after the main verb:

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1974–1984, Dublin, Ireland, August 23-29 2014.

(3) Ik denk dat ik het **begrepen heb**
I think that I it understood have
'I think that I have understood it.'

(4) Ik denk dat ik het **heb begrepen**
I think that I it have understood

As in the dative alternation example, the variation in these two-verb clusters seems to be influenced by multiple variables, beyond the constraints of grammatical rules. Therefore, we consider the multivariate model by De Sutter (2009) to be the most accurate model of Dutch verbal clusters developed so far. Unfortunately, it is also too limited and does not cover all of the constructions that are generally considered to be two-verb clusters. The author claims to have done this for reasons of methodological rigor. However, in a multivariate model the contribution of each variable can be studied independently. If an additional verbal cluster construction is added and it is marked with a variable as being a different construction, it should not make much of a difference for the other variables, assuming that the same set of variables is involved for all verbal cluster constructions. We have included these additional cluster types to create a model with a larger scope, and show that the effects of de Sutter's smaller model are still present. We also compare to a smaller model of our own, created from the large corpus but without the additional cluster types, to verify that our results aren't just an effect of including the additional constructions.

Another reason for excluding the other types of verbal clusters might have been the annotation effort involved in finding corpus examples of them. We avoid this issue by using an automatically annotated corpus, and can extract large samples of various types of constructions simply by defining what counts as a cluster in the syntactic annotation.

In section 2 we briefly discuss Dutch verbal clusters and the variation found in them. We then discuss previous work on modeling of Dutch verbal clusters, including the model by De Sutter (2009) in section 3. Section 4 describes the automatically annotated corpus that we used. In section 5 we discuss the model we created from this data and compare it to that of De Sutter (2009). We also compare models created from two different text types. Section 6 discusses the implications of these results.

2 Verbal cluster variation

In this section, we will briefly summarize how verbal clusters are formed, and discuss the extent of the variation they exhibit. To refer to the two verbal cluster orders, we will follow terminology introduced by Stroop (1970), where construction (3) is called the 2-1 order and construction (4) is 1-2. This is because the finite auxiliary is considered to be the verb that is highest in the syntactic tree, while the main verb is the lowest. This fact lets us number the verbs.

In generative literature, the formation of these clusters is described as a verb movement process known as verb raising, where the main verb is moved upwards in the syntactic tree from its phrase to be joined with the auxiliary verb. This explains the common observation that verbal clusters cannot be interrupted (Evers, 1975), though there are some instances of cluster interruptions, particularly in Flemish Dutch (Evers, 2003). A broad overview of verb raising across Germanic languages is provided in Wurmbrand (2006).

There are various types of two-verb clusters that exhibit order variation:

Auxiliary cluster Examples (3) and (4) show two-verb clusters with auxiliary heads. Following De Sutter (2009) we consider this to be any cluster that is headed by the auxiliaries *hebben* "to have", *zijn* "to be" and *worden* "to be".

Modal cluster A modal verb (*willen* "want", *kunnen* "can") may also be used as a cluster head. Modal clusters are generally treated as a different construction in the literature, as different grammatical rules may apply to it, particularly in other Germanic languages. In Dutch we can observe that the 2-1 order is far more common in this construction, and some authors even say there is no optionality here (i.e. Zuckerman (2001)). We observe that in the Wikipedia part of the Lassy Large corpus, modal clusters occur in the 1-2 order only 0.5% of the time. However, they are considered to be grammatical.

Clusters with other verbs There are verbs such as *staan* 'to stand' and *helpen* 'to help' that can also be raised to form a verbal cluster in certain contexts. This list includes causal verbs, aspectual verbs, and some harder to classify ones, and seems too diverse to be grouped together. For brevity and due to their relative rarity (together

they form about 5.5% of the clusters) we did not include these constructions in our study, though it would certainly be possible to explore them in a large corpus study and perhaps contribute to their classification.

Te-infinitival clusters In the cluster types we discussed so far the auxiliary verb was finite, but there are infinitival clusters as well, where both the auxiliary and the main verb are infinite, and the main verb is marked by the infinitival marker *te*. These clusters are uncommon (2.2% of our dataset) and have not been the focus of any study on variation, though since these clusters form a clear group, we have included them. They occur with both auxiliary and modal heads.

Main clause cluster Verbal clusters can occur in main clauses as well, though in a different form. Stroop (2009) states that three-verb clusters in main clauses are comparable to two-verb clusters in subordinate clauses. In that study, he discusses various cluster types in a corpus of spoken Dutch and observes the distributions between 1-2 and 2-1 orders. While there are three verbs in these main clause clusters, only the last two verbs have free order variation, due to the V2-effect present in Germanic languages:

(5) De fuut **kan** in alle wateren van enig formaat **aangetroffen worden** .
The grebe can in all waters of some size found be .
'The grebe can be found in all bodies of water of substantial size.'

(6) Wegwerpbatterijen **kunnen** niet **worden opgeladen** .
Disposable batteries can not be charged .
'Disposable batteries cannot be charged.'

The finite verb must always be in verb-second position.

Stroop furthermore observes, when looking at larger clusters, that variations of three-verb subordinate clause clusters are distributed similarly to variations of four-verb main clause clusters (that have three verbs with varying order). This observation holds for both Dutch and Flemish data, even though the frequencies of orders are different between the languages. Factors that influence order variation seem to be able to affect main clause and subordinate clause clusters in the same way, as Stroop demonstrated for the regional factor. We are therefore convinced that main clause clusters should be included in studies on verbal cluster variation.

The rules and mechanisms discussed in generative literature allow for a lot of optionality, as discussed above, and thus mainly outline the constructions in which order variation can occur. These accounts generally left open the question of the variation found in the surface order. It appears that syntacticians did not concern themselves with explaining it and considered it to be an effect of a non-syntactic process. This is evident in the analysis adopted by Haegeman and van Riemsdijk (1986).

The issue of explaining the factors that influence the choice between two variants was later picked up by other researchers who were interested in non-syntactic effects as well. Coussé et al. (2008) provide a summary of recent work on verbal cluster variation, in particular, three dissertations on the topic (De Sutter, 2005; Coussé, 2008; Arfs, 2007). A diverse set of variables that may influence the use of 1-2 and 2-1 cluster orders has been found, and they group them into four categories: contextual factors (region and mode of communication), rhythmic factors (adherence to the standard stress pattern of Dutch), semantic factors, and discourse factors (mainly the syntactic priming effect).

From this, Coussé et al. (2008) conclude that the choice of verbal cluster order is influenced by a complex set of interacting factors. Therefore, any model representing this phenomenon would need to take many factors into account. The multivariate modeling technique used by De Sutter (2005) seems to fit this criterion.

We will now discuss some related studies where multivariate modeling has been applied to the study of language variation, as well as a proposal to involve automatically annotated data in linguistic studies, and then discuss De Sutter's multivariate study on verbal cluster order that we are replicating.

3 Multivariate modeling of language variation

In corpus linguistics, linguistic phenomena examined over larger sets of data have often been found to be too complex to model in terms of a single independent variable. In this case, rather than running one statistical test for each variable, it is considered best practice to test for all variables in a single test. The statistical power of such a test will be greater than that of running several tests and applying corrections, which increases the chances of erroneously rejecting the null hypothesis with each test. Starting with Gries (2001), this methodology has

been applied to the study of language variation. A well-known example is the dative alternation study of Bresnan et al. (2007). In these studies, multivariate statistical models are used to quantify the effect size of each variable, indicating their relative importance. Being corpus studies, these quantitative studies generally also emphasize evidence from larger samples of language and operationalize their variables in a precise way.

Gries (2001) discusses the case of English transitive phrasal verbs (*to pick up the book* / *to pick the book up*), and explains 84% of the variation based on a multivariate model containing many variables from previous work. He also critiques previous work on language variation. Firstly, studies often relied on introspective analysis and made-up examples, which can be too subjective, not representative, and in the case of acceptability judgements, not necessarily output of the human language system. Secondly, when only a single variable is examined at a time, many other possible variables may influence the result, even when seemingly minimal pairs are used. Lastly, the provided models cannot be used to predict variation in natural discourse situations. Variables are not weighed, and if two variables have conflicting preferences, the possibility of a prediction is already ruled out.

Despite the methodological precision, the data of the study consisted of only 403 sentences in total, about 200 for each construction. Furthermore, they were chosen manually, introducing some subjectivity into the study. When the statistical tendencies of around 30 variables are studied, 403 sentences do not provide a lot of detail. We believe that these quantitative studies can be further improved by using data from automatically annotated corpora.

3.1 Using automatically annotated data

Corpora that have been annotated by an automatic parser rather than manually, will contain far more data, allowing for larger sample sizes of particular constructions to be found. These samples can be extracted automatically as well. To do so, an exact definition of what constitutes the construction must be formulated at the level of syntax — for example, two verbs that are adjacent and in the same subordinate clause, with one being the head of the other. All of the sentences that match this definition can then be extracted from the corpus. This process avoids subjectivity beyond the definition of the construction. However, it limits the variables that can be used in the study to the ones that are, or can be, automatically annotated in a corpus. It also comes at the cost of accuracy, though in most cases, it is expected that the larger sample size makes up for any random parsing errors. Systematic errors (for example, constructions that the parser consistently fails to annotate) may skew the results however, so care should be taken that the parser is able to annotate the constructions of interest at all.

Some automatically annotated corpora have become available in recent years, though they have not yet been widely used for linguistic study. Nevertheless, I will discuss a few studies that have applied automatically annotated corpora for the purposes of language variation research. The use of automatically parsed corpora as a linguistic resource has been discussed by van Noord and Bouma (2009). They argue that parsing technology has advanced enough to be incorporated into other language technology that can build upon its results. This allowed for the creation of very large corpora of parsed sentences that are sufficiently large to compensate for any parsing error 'noise'. Several applications of such very large corpora can be found in the article.

For the Dutch language, the potential uses of the 500 million word automatically annotated LASSY Large corpus have been discussed (van Noord, 2009). This paper also mentions that some natural language processing tasks, such as learning selection restrictions of specific verbs, cannot be performed successfully using smaller corpora because the sample size would be too small. This issue is likely to apply to any linguistic phenomenon at the level of open-class lexical items (i.e. nouns, verbs or combinations thereof), most of which are rare. For the case of verbal clusters, this shows that using such a large corpus would be required to study the effect of specific main verbs on the order variation.

Automatically annotated data has already been used to study language variation for the famous case of the dative alternation, discussed in the introduction (examples (1), (2)). Lehmann and Schneider (2012) used a 580 million word dependency-parsed corpus of English to study the influence of specific lexical types on this alternation. These types consist of 'triplets' of words: a ditransitive verb, a direct object head and an indirect object head. These three slots of the triplet are all filled with open-class words, therefore requiring vast amounts of data to study: "We indeed find that 580 million words are barely enough data to yield results for full lemma triplets". Unfortunately, the study is a monovariate study where lexical type was the only variable investigated. This does not exclude the possibility of other underlying factors, which the lexemes may happen to correlate with, influencing the variation.

The only other similar variational study we are aware of is on the optionality of the Dutch *om*-complementizer, a variation similar to the optionality of English *that* for relative clauses. In Dutch, *om* as a head of a *to*-infinitival clause is optional in many, though not all cases:

(7) Anna probeerde (om) een bom onschadelijk te maken
Anna tried (CMP) a bom harmless to make
'Anna tried to defuse a bomb.'

Bouma (2013) provides further examples, and creates a model of this variation using data from part of the LASSY Large corpus. This model is multivariate, and includes both lexical effects and other variables, such as clause length. It is implemented as a mixed-effects logistic regression model, in which the verbal governor (i.e. the verb *proberen* in example (7)) is a random effect, and the other non-lexical variables are fixed effects. The other variables are all related to processing complexity, as it is theorized that *om*-insertion reduces processing load by reducing ambiguity. He finds that the best model includes both semantic and complexity features and report a concordance score of 0.809, indicating that the model has modest predictive qualities.

While there are not many examples of such studies, using automatically annotated sources of data appears to be fruitful for studying complex phenomena where many factors may play a role, and a large sample size is desirable. We consider Dutch verbal cluster variation to be such a phenomenon.

3.2 Verbal cluster variation

Going back to the topic of variation in Dutch verbal clusters, we believe that the most methodologically sound study can be found in the dissertation of De Sutter (2005), summarized in De Sutter (2009). In this study, various variables from previous work on verbal clusters were modeled using a multivariate model. Like in Gries (2001), and unlike in Bouma (2013), the starting point was not to create the most optimal model, but to determine the effect of each variable from previous linguistic work. Verbal clusters were extracted semi-automatically from a part of the De Standaard CONDIV corpus, which contains texts from a Flemish newspaper spanning a time period of a few months. By choosing this part of the corpus, the author controlled for regional, register and diachronic variation.

As well as limiting the source data, De Sutter also limited cluster types. Only clusters in complement clauses, introduced by the complementizer *dat* 'that' (no main clause clusters or other subordinates), containing a participle main verb (no infinitival clusters), and only clusters with the non-modal auxiliaries *hebben* "to have", *zijn* "to be" and *worden* "to be" have been included. Only two-verb clusters were considered. These criteria resulted in 2.390 two-verb clusters, 1.601 (66.99%) of which were in the 2-1 order. The data were then annotated for 10 variables, which were mostly extracted from the data manually, and the operationalization of the variables was carefully considered in order to be as objective as possible. The statistical model is then used to reveal the contribution of each variable towards either an 2-1 or 1-2 order choice.

We have tested the same variables, which were identified in previous literature, on our data set as far as they could be operationalized. We will summarize the data and methodology that we used in our study in the next section, and compare it to that of De Sutter (2009). The results will be discussed in section 5.

4 Method and data

We create a multivariate logistic regression model for explaining verbal cluster variation much like that of De Sutter (2009), but based on automatically annotated data. In some cases where we had to choose between creating an optimal model and creating a comparable model, we chose comparability. For example, it is generally best practice to use the most frequent value of a categorical variable as the reference value to compare the effects of the other values to. However, to maintain comparability of the effect sizes of both models we chose to use the same reference values as De Sutter. To demonstrate some benefits of automatically annotated data, we did aim to include more types of two-verb verbal clusters that exhibit optionality, including the major constructions left out by De Sutter. As mentioned, the only constructions exhibiting optionality that we did not include, are the cluster with 'other' verbs instead of auxiliary or modal verbs.

We used the Lassy Large corpus as our source of automatically annotated Dutch language data (van Noord et al., 2013). It contains texts from various written sources annotated with full syntactic dependency trees. The sentences have been parsed automatically by the Alpino parser for Dutch (van Noord et al., 2006). This parser is currently the state of the art, and an evaluation over different types of text shows an average concept accuracy (in terms of correct named dependencies) of 86.52% (van Noord, 2009). For our main comparison, we used the Wikipedia part of this corpus, which consists of the entirety of the Dutch version of the freely editable online encyclopedia Wikipedia on the 4th of August, 2011 (about 145 million words). From this data, 411.623 two-verb verbal clusters were extracted (71.65% of which were in the 1-2 order). We chose to use this part of the corpus as we believe

it to be a good representation of 'average' standard Dutch. While Wikipedia texts have been written and edited by many speakers from different parts of the Dutch-speaking world, and probably by second language learners of Dutch as well, non-standard language is likely to be edited out by other editors. The accuracy of the Alpino parser on this text type was 88.38% in van Noord (2009), better than average but not as good as newspaper texts.

We do recognize that languages can not really be averaged, and a model based on such data will not be able to account for regional diversity or individual differences. Significant regional differences have been observed in the usage of verbal clusters (i.e. the data of Barbiers et al. (2006)), so it would be interesting, and possible, to study this using an automatically annotated corpus where authorship metadata is available. 'Region' could then be added as a variable to the model to explain some of the variation. In this study we won't address this, however, we address the issue of language diversity by comparing the results from the Wikipedia part of the corpus to a model created from the Europarl part of the corpus (containing European parliament texts) in section 5.1.

The verbal clusters were extracted from the corpus using XPath 2.0 queries via the DACT command line tools. These queries precisely define what constitutes a verbal cluster, and every word group matching one of these definitions was extracted. Contextual information necessary to determine the value of the independent variables of each cluster was extracted in a similar way.

In defining and operationalizing the variables discussed by De Sutter (2009), we were limited to the information available in the annotation of the Lassy Large corpus, at least without doing any manual annotation. Some variables had to be operationalized in a different way, or could not be extracted at all. We now briefly summarize our operationalizations in comparison to those of De Sutter. For a more detailed description and motivation for each of the variables, we refer to De Sutter (2009).

The variables we operationalized are listed in the results table (1). To operationalize the TYPE OF THE AUXILIARY VERB, De Sutter divided the auxiliary verbs up into five grammatical classes: *zijn* "to be" as a copulative verb, *zijn* as a passive auxiliary, *zijn* or *hebben* "to have" as temporal auxiliaries, *worden* "to be", and unclassifiable. He developed an algorithm to identify them, which is a complex three-stage pipeline. It is described in De Sutter (2005, p. 205-230), involving 5 syntactic, 5 morphological and 2 semantic criteria. We did not try to re-create it because we would prefer to work with readily available corpus resources as much as possible for methodological demonstration purposes. The algorithm is also not perfect, hence the 'unclassifiable' class. Instead, we categorized the auxiliary verbs at the lexical level. We did group the modal verbs together (which De Sutter did not include in his study), as they appeared to behave very similarly in preliminary checks.

MORPHOLOGICAL STRUCTURE OF THE MAIN VERB encodes whether the main verb is separable or not. Separable particle verbs such as 'wash up' are written as a single word in Dutch, unless the particle is separated from the verb, which may happen even if it interrupts a verbal cluster. LENGTH OF THE MIDDLE FIELD is simply the number of words in the clause before the verbal cluster. Next, there are two variables relating to the word before the verbal cluster. INFORMATION VALUE is operationalized as the openness of this word's class, for which there are three classes: **high**ly informational (nouns, verbs, numerals), **intermediate**ly informational (adjectives and adverbs) and **low** informational (pronouns, conjunctions and prepositions). INHERENCE refers to multi-word units (MWUs), which is a complex concept with no clear definition, but generally describes some sort of collocation of words. The corpus includes annotation on MWUs, and we make use of this annotation to decide whether the preverbal word is part of one.

EXTRAPOSED CONSTITUENTS are constituents that come after the verbal cluster, for which there are three ways to attach to the rest of the sentence: none (no constituent), attached to the main verb of the cluster, or attached somewhere higher up in the tree than the cluster (preverbally). We had to operationalize this variable differently. De Sutter made a distinction between adjuncts and complements, grouping adjuncts with 'none', but we could not extract this distinction from the corpus, hence the difference. The FREQUENCY OF THE MAIN VERB was estimated by counting the number of occurrences of the verb's root in the entire Lassy Large corpus. Lastly, we added two variables to distinguish the new cluster types discussed in section 2 that De Sutter didn't include: FINITENESS OF THE HEAD to mark infinitival clusters, and CONTEXT CLAUSE TYPE for subordinate versus main clause clusters.

There were also two variables that we could not include. Firstly, the DISTANCE BETWEEN ACCENTS, which relates to the hypothesis that order variation may occur to match the stress pattern of Dutch (Schutter, 1996). Our corpus does not contain stress or accent information, and we are not aware of a method for automatic annotation. This variable turned out to have almost no effect in De Sutter's model. Secondly, we left out SYNTACTIC PERSISTENCE, which refers to a priming effect of a previous construction on the next. We decided not to include this variable, as we are mainly using a corpus based on Wikipedia. We cannot make sure that the writer wrote or even read the previous verbal cluster in the text. This variable did have an effect in De Sutter's model (OR=3.28).

5 Results

Table 1 shows the comparison to the model of De Sutter (2009). The table lists all of the explanatory variables used in our logistic regression model, along with their effect size in our model and in the model of De Sutter. Based on these variables, the model can predict the dependent variable of verbal cluster word order, which is expressed as a binary variable representing either 1-2 or 2-1 word order.

For each explanatory variable in the table, one of the possible values was taken as the reference value, or baseline. The baselines were selected to be the same as those of De Sutter, in order to have comparable models. In the cases where variables had to be operationalized differently (where there are gaps in the table), the baselines are of course also different, though we tried to pick the most similar values as the reference. The effect size of each variable for both studies is given as an odds ratio. An odds ratio further from 1 indicates a stronger effect. Odds ratios > 1 indicate an association with the 1-2 word order, odds ratios < 1 indicate 2-1 order. An exception is the MAIN VERB FREQUENCY variable — it is a continuous variable, where an odds ratio cannot be interpreted in the same way. Instead, we show the β estimate of effect size (representing an effect on the dependent variable, cluster order, in terms of standard deviations), and its average standard error.

We did not perform statistical tests to assess whether the effect sizes of the two models differ significantly. Some differences are to be expected, considering the different data sources (Flemish newspapers versus Wikipedia) or other uncontrolled variables. We would mainly like to see whether the same categories show substantial effects relative to their reference values, and whether the effects are in the same direction (either the 1-2 or 2-1 order) in both models. In cases where variables were operationalized in different ways between the two studies, this is indicated by leaving the missing operationalizations blank. The reference value for each variable and study is listed as **1.00**, as the reference value can obviously not have an effect compared to itself, and 1 is the neutral value.

As a first observation for the results in table 1, we can see that the directions and size of the effects are generally similar, except where the variables had to be operationalized differently. For the variables that were operationalized the same — MORPHOLOGICAL STRUCTURE OF THE PARTICIPLE, LENGTH OF MIDDLE FIELD, INHERENCE and MAIN VERB FREQUENCY we observe similar relative effects as De Sutter (2009), and in the same directions. The INFORMATION VALUE of the preverbal constituent shows an effect in the same direction, but far smaller, and not in the same order — Intermediate is more strongly associated with the 1-2 order than High. Perhaps the larger sample size caused this. We have checked that it is not due to the additional cluster types — a model with only subordinate, finite, nonmodal clusters shows an even smaller information value effect size.

We do see differences in the two variables that had to be operationalized differently in our study. For the variable GRAMMATICAL RELATION OF EXTRAPOSITION TO HEAD we interestingly find a very strong effect, though the directions of the effects are reversed compared to de Sutter. This is a complex syntactical property, so we cannot guarantee that it was implemented in exactly the same way besides the noted difference. Either way, we can still conclude that this variable has a strong effect on verbal cluster order. The most striking difference is in the variable TYPE OF AUXILIARY. This is due to the available annotation — as discussed in the last section, a complex additional procedure would be needed to identify the grammatical classes of De Sutter. We still find somewhat of a lexical effect with our operationalization. The auxiliary verbs have a lot of grammatical ambiguity, so it is smaller than the grammatical effect found by De Sutter. We do note a strong tendency of clusters with modal verbs to occur in the 1-2 order. This confirms previous observations that modal clusters have a strong preference for the 1-2 order (Wurmbrand, 2006).

De Sutter does not provide a value of overall model fit that can be compared across models, however, we can look at the concordance index (c-index). This value is an indication of the predictive power of a model. A c-index of 0.5 corresponds with chance level, and 1 indicates perfect prediction. Like de Sutter, we report the c-index after 100 bootstrap repetitions to compensate for overfitting. He reports c = 0.803, and our model has a concordance index of 0.8635. However, it should be noted that these two c-indexes cannot be directly compared between different models, since the variables are somewhat different. These values do indicate that the models are good enough for prediction tasks. They are also similar to the c-score Bouma (2013) reported. We can furthermore look at the intercept of our model, which is 0.6035, and represents the odds of predicting an 1-2 outcome in the case where all the variables have their default value, an indication of the difficulty of the task. Clearly the model predicts better than that. However, it should be noted that this is not a typical predictive task. There is no 100% gold standard as in a parsing task for example, and both orders are grammatically correct. It might very well be that a large amount of the variation is random, depends on extralinguistic factors, or factors not captured by the annotation scheme. The focus here is mainly on finding out how much can be explained by the linguistic variables under discussion, and the effect sizes reported in table 1 are the main measure of that.

Variable	**Categories**	Odds ratio **De Sutter (2009)**	Odds ratio **This study**
TYPE OF AUXILIARY	Copular *zijn*	**1.00**	
	Auxiliary of time	18.30 ***	
	Passive *zijn*	7.82 ***	
	zijn		**1.00**
	worden	11.73 ***	1.19 ***
	hebben		2.19 ***
	Modal verb		132.42 ***
MORPHOLOGICAL STRUCTURE OF THE MAIN VERB	Non-separable	**1.00**	**1.00**
	Separable	3.87 ***	4.92 ***
LENGTH OF MIDDLE FIELD	0-2 words	**1.00**	**1.00**
	3-5 words	2.03 ***	2.42 ***
	6-8 words	2.29 ***	3.23 ***
	9-11 words	2.29 ***	3.34 ***
	12-14 words	2.57 **	3.33 ***
	>14 words	1.98	3.15 ***
INFORMATION VALUE	Low	**1.00**	**1.00**
	Intermediate	1.41	1.21 ***
	High	1.94 ***	1.11 ***

	Complement of main verb	0.47 ***	
	Complement of preverbal head	1.21	
	No extraposition		**1.00**
	Comp/adj of main verb		51.44
	Comp/adj of preverbal head		0.44
MAIN VERB FREQUENCY		$\beta = 2.44^{E-06}$ ASE=7.74^{E-07}**	$\beta = 3.73^{E-08}$ ASE=1.05^{E-08}***
FINITENESS OF THE HEAD	Finite head		**1.00**
	Infinite head		0.03
CONTEXT CLAUSE TYPE	Subordinate clause		**1.00**
	Main clause		0.34

Table 1: Comparison of the size of the effect of the variables on verbal cluster variation for the two studies

One could make the objection that our model is not comparable to that of de Sutter, because it contains different constructions (main clause, infinitival and modal clusters). We controlled for these construction types with variables, but just to verify that this works, we also created a model that excludes all of these additional construction types. The observed effects were very similar to the full model. For reasons of space we cannot provide the entire table, but some of the effects are: *worden* = 2.34 (was 2.19 in the main model) *hebben* = 1.21 (was 1.19), SEPARABLE = 5.01 (was 4.92). We do note a lower c-score here of 0.7649, it appears more difficult to predict verbal cluster order when the clusters are all of the same type. This is somewhat lower than De Sutter's c = 0.803, likely due to the variables we could not include. More interestingly, we were also able to create models for specific construction types, i.e. main clause verbal clusters only, which has not been done before. For reasons of space we cannot list or elaborate on the results here, but we find that the same variables also affect main clause cluster variation. There are some differences in effect direction, mainly for the auxiliary verbs, which makes sense as it is a different construction.

5.1 Europarl corpus

In section 4 we discussed our choice for the Wikipedia part of the Lassy Large corpus. However, this corpus consists of other kinds of sources as well, and now that we have a highly automated way of building the model, it is relatively easy to test it on a different part of the corpus to see whether the same variables hold in a different domain of text. The Dutch Europarl part of the corpus consists of the translated proceedings of the European

Parliament. These texts have been written in a rather formal register by translators of the European Union. This part consists of 37 million words, from which 467.521 verbal clusters were extracted. Interestingly, that's 55.898 more clusters than were extracted from the larger (145 million words) Wikipedia corpus, indicating far more complex syntax in the Europarl corpus.

We find that 86.78% of the clusters is in the 1-2 order, a far higher percentage than is generally reported and higher than the Wikipedia corpus (71.65%). Higher proportions of 1-2 orders are generally associated with more formal registers and with editing guidelines — prescriptivists in the past have considered it to be the Dutch order, while the 2-1 order was nonstandard or German (Coussé et al., 2008). Again, we will not produce the entire table of effect sizes here — it suffices to say that all of the effect directions are the same, and the sizes are also very similar, even for variables that vary between constructions such as TYPE OF AUXILIARY. We may conclude from this that the previously discussed findings are not domain-specific. It is also a demonstration of the flexibility of using automatically annotated data.

6 Discussion

Using an automatically annotated corpus, we have shown that verbal cluster order variation is influenced by the various language-internal variables identified by De Sutter (2009) for all two-verb cluster types with order variation. While the (relative) importance of these variables for non-modal, finite clusters with a complementizer-marked subordinate clause was already established, this study shows that they apply to other types of two-verb clusters as well, even when testing on a larger and more varied dataset. We furthermore showed that these findings can be extended into another domain of text, and are not domain-specific.

Our main contribution is to show that using automatically annotated corpora is an excellent source for obtaining more data for language variation studies. Although some variables (stressed syllables) could not be measured due to a lack of automatically annotated data, advances in other language technology, such as word sense disambiguation, is likely to open up more possibilities for additional kinds of annotation to be applied to huge corpora automatically. It would also be possible to obtain more annotation by combining information from other sources. For example, to estimate syllable stress, one could consider scraping this information from phonetic transcriptions in dictionaries and adding that information to the corpus. Using these huge, automatically annotated resources seems like a natural extension of the recent trend of using large multivariate models, and allows the creation of explanatory models for uncommon linguistic constructions. We have also demonstrated the flexibility of the automatic approach — a model can easily be tested on a different dataset, provided that the right annotation is available.

De Sutter (2009) draws several conclusions, which could also be drawn from our study. Firstly, that the variation appears to be affected by 8 variables simultaneously (7 in our case), and can be predicted well enough by the model. Secondly, there are various methodological conclusions: "We have shown that syntactic variation research needs a rigorous quantitative, corpus-based approach ...". We can only add to this conclusion by stating that this rigorous definition of variables aids in automatic extraction of samples, which lets us retrieve all relevant constructions from large automatically annotated corpora, to the extent that the annotation allows. This, in turn, opens up options for more detailed analysis as outlined in this paper.

6.1 Linguistic interpretation

Even though we have found patterns in the variation and associations with variables that were hypothesized to be related to the phenomenon, this in itself is not an explanation of verbal cluster variation in terms of linguistic theory. We will briefly address this by referring to the hypothesis of De Sutter (2005), who states that the choice between 1-2 and 2-1 order may be related to processing difficulty. He assumes the 2-1 order to be easier to process because he considers the 1-2 order to be a prestige option, implying that the 2-1 order is the default. However, this explanation can go both ways. Recent evidence from child language acquisition supports a default 1-2 order (Meyer and Weerman, 2014). They theorize that children learn about verb raising (which forms clusters) when they acquire the 1-2 order. The most common view is that both 1-2 and 2-1 clusters come from verb raising (Evers, 1975), in which the main verb is moved up the syntactic tree to join the head. Before verb raising, the head verb is in final position, following the base Object-Verb order of Dutch. Raising the verb to form a 2-1 cluster is therefore a vacuous movement, the surface order will be the same as the underlying structure (the head comes last), and provides no evidence of any sort of special verb raising mechanism to child learners of the language. On the other hand, raising the verb to the right to create a 1-2 order violates the base word order of Dutch, and is therefore more straightforward to notice and learn. 2-1 orders can simply be interpreted as Object-Verb orders, until the learner figures out the mechanism of verb raising from the 1-2 order evidence (Meyer and Weerman, 2014). In this theory, 1-2 orders would be the earliest form of verb raising, and therefore more entrenched and easier to process.

Either way, in linguistic contexts that are more difficult to process, speakers are expected to be more likely to use the more entrenched order that is easier to process, whichever it may be. The model may be inconclusive on this matter. De Sutter argues for the 2-1 order by looking at the MAIN VERB FREQUENCY variable, stating that higher-frequency items are easier to access, and the model shows that higher-frequency words are more associated with the 2-1 order. Here, a **less** difficult context is associated with the 2-1 order. However, we can make the opposite argument for the variable LENGTH OF MIDDLE FIELD. It seems plausible that longer clauses are **more** difficult to process, and longer clauses are also associated with the 2-1 order. To invoke the processing hypothesis here, one would have to assume that the 1-2 order is the default and easier to process. Given these two opposites predicted by Meyer and Weerman (2014) and De Sutter (2005), it would be interesting to look for additional variables that are related to processing difficulty and can be extracted from the corpus automatically, such as syntactic complexity. These can then be added to the model to test which order occurs in contexts with higher processing load.

6.2 Future work

We consider several other directions for future work. The model can be extended to other domains that have been discussed in the literature, such as spoken language data from the Corpus of Spoken Dutch which uses a similar annotation scheme. As discussed earlier, regional variation is an interesting topic that could also be modeled using large amounts of data, for example by using the SoNaR corpus which includes metadata on the authors of many of its texts and adding a region variable to the model. We have yet to investigate clusters with more than two verbs, to which the automatic approach is uniquely suited. Larger verbal clusters are less frequent, and thus the best place to find rare constructions is in the largest available corpus. Now that large samples of data are easily available, a method such as collostructional analysis may be used to explore the association between particular main verbs and the 1-2/2-1 order, providing more detail on possible semantic factors.

In this study, we have aimed to follow the methodology of De Sutter (2009) closely, but this also had several downsides. It would also be possible to aim for creating the best possible model over the dataset, though differences that might arise from this (for example, different reference levels) would then make comparisons more difficult. This would allow testing of some potential methodological improvements. Multilevel modeling may be used as in Bouma (2013) to model the effects of individual lexical items. A form of Principal Component Analysis could be applied to generalize over the variables and try to reduce their number. Choosing verbal cluster order could also be viewed as a two-class classification problem, for which many other modeling methods exist.

Acknowledgements

We thank Gosse Bouma and the anonymous reviewers for their useful comments, and Gertjan van Noord and Daniël de Kok for helping to provide efficient access to the corpus data.

Empirical analysis of exploiting review helpfulness for extractive summarization of online reviews

Abstract

We propose a novel unsupervised extractive approach for summarizing online reviews by exploiting review helpfulness ratings. In addition to using the helpfulness ratings for review-level filtering, we suggest using them as the supervision of a topic model for sentence-level content scoring. The proposed method is metadata-driven, requiring no human annotation, and generalizable to different kinds of online reviews. Our experiment based on a widely used multi-document summarization framework shows that our helpfulness-guided review summarizers significantly outperform a traditional content-based summarizer in both human evaluation and automated evaluation.

1 Introduction

Multi-document summarization has great potential in online reviews, as manually reading comments provided by other users is time consuming if not impossible. While extractive techniques are generally preferred over abstractive ones (as abstraction can introduce disfluency), existing extractive summarizers are either supervised or based on heuristics of certain desired characteristics of the summarization result (e.g., maximize n-gram coverage (Nenkova and Vanderwende, 2005), etc.). However, when it comes to online reviews, there are problems with both approaches: the first one requires manual annotation and is thus less generalizable; the second one might not capture the salient information in reviews from different *domains* (*camera* reviews vs. *movie* reviews), because the heuristics are designed for traditional genres (e.g., news articles) while the utility of reviews might vary with the review domain.

We propose to exploit review metadata, that is *review helpfulness ratings*[1], to facilitate review summarization. Because this is user-provided feedback on review helpfulness which naturally reflects users' interest in online review exploration, our approach captures domain-dependent salient information adaptively. Furthermore, as this metadata is widely available online (e.g., Amazon.com, IMDB.com)[2], our approach is unsupervised in the sense that no manual annotation is needed for summarization purposes. Therefore, we hypothesize that summarizers guided by review helpfulness will outperform systems based on textual features/heuristics designed for traditional genres. To build such helpfulness-guided summarizers, we introduce review helpfulness during content selection in two ways: 1) using the review-level helpfulness ratings directly to filter out unhelpful reviews, 2) using sentence-level helpfulness features derived from review-level helpfulness ratings for sentence scoring. As we observe in our pilot study that supervised LDA (sLDA) (Blei and McAuliffe, 2010) trained with review helpfulness ratings has potential in differentiating review helpfulness at the sentence level, we develop features based on the inferred hidden topics from sLDA to capture the helpfulness of a review sentence for summarization purposes. We implement our helpfulness-guided review summarizers based on an widely used open-source multi-document extractive summarization framework (MEAD (Radev et al., 2004)). Both human and

[1]This is the percentage of readers who found the review to be helpful (Kim et al., 2006).

[2]If it is not available, the review helpfulness can be assessed fully automatically (Kim et al., 2006; Liu et al., 2008).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 1985–1995, Dublin, Ireland, August 23-29 2014.

automated evaluations show that our helpfulness-guided summarizers outperform a strong baseline that MEAD provides across multiple review domains. Further analysis on the human summaries shows that some effective heuristics proposed for traditional genres might not work well for online reviews, which indirectly supports our use of review metadata as supervision. The presented work also extrinsically demonstrates that the helpfulness-related topics learned from the review-level supervision can capture review helpfulness at the sentence-level.

2 Related Work

In multi-document extractive summarization, various unsupervised approaches have been proposed to avoid manual annotation. A key task in extractive summarization is to identify important text units. Prior successful extractive summarizers score a sentence based on n-grams within the sentence: by the word frequency (Nenkova and Vanderwende, 2005), bigram coverage (Gillick and Favre, 2009), topic signatures (Lin and Hovy, 2000) or latent topic distribution of the sentence (Haghighi and Vanderwende, 2009), which all aim to capture the "core" content of the text input. Other approaches regard the n-gram distribution difference (e.g., Kullback-Lieber (KL) divergence) between the input documents and the summary (Lin et al., 2006), or based on a graph-representation of the document content (Erkan and Radev, 2004; Leskovec13 et al., 2005), with an implicit goal to maximize the output representativeness. In comparison, while our approach follows the same extractive summarization paradigm, it is metadata driven, identifying important text units through the guidance of user-provided review helpfulness assessment.

When it comes to online reviews, the desired characteristics of a review summary are different from traditional text genres (e.g., news articles), and could vary from one review domain to another. Thus different review summarizers have been proposed to focus on different desired properties of review summaries, primarily based on opinion mining and sentiment analysis (Carenini et al., 2006; Lerman et al., 2009; Lerman and McDonald, 2009; Kim and Zhai, 2009). Here the desired property varies from the coverage of product aspects (Carenini et al., 2006; Lerman et al., 2009) to the degree of agreement on aspect-specific sentiment (Lerman et al., 2009; Lerman and McDonald, 2009; Kim and Zhai, 2009). While there is a large overlap between text summarization and review opinion mining, most work focuses on sentiment-oriented aspect extraction and the output is usually a set of topics words plus their representative text units (Hu and Liu, 2004; Zhuang et al., 2006). However, such a topic-based summarization framework is beyond the focus of our work, as we aim to adapt traditional extractive techniques to the review domain by introducing review helpfulness ratings as guidance.

In this paper, we utilize review helpfulness via using sLDA. The idea of using sLDA in text summarization is not new. However, the model is previously applied at the sentence level (Li and Li, 2012), which requires human annotation on the sentence importance. In comparison, our use of sLDA is at the document (review) level, using existing metadata of the document (review helpfulness ratings) as the supervision, and thus requiring no annotation at all. With respect to the use of review helpfulness ratings, early work of review summarization (Liu et al., 2007) only consider it as a filtering criteria during input preprocessing. Other researchers use it as the gold-standard for automated review helpfulness prediction, a predictor of product sales (Ghose and Ipeirotis, 2011), a measurement of reviewers' authority in social network analysis (Lu et al., 2010), etc.

3 Helpfulness features for sentence scoring

While the most straightforward way to utilize review helpfulness for content selection is through filtering (Liu et al., 2007) (further discussed in Section 4.3), we also propose to take into account review helpfulness during sentence scoring by learning helpfulness-related review topics in advance. Because sLDA learns the utility of the topics for predicting review-level helpfulness ratings (decomposing review helpfulness ratings by topics), we develop novel features (*rHelpSum* and *sHelpSum*) based on the inferred topics of the words in a sentence to capture its helpfulness in various perspectives. We later use them for sentence scoring in a helpfulness-guided summarizer (Section 4.3).

Compared with LDA (Blei et al., 2003), sLDA (Blei and McAuliffe, 2010) introduces a response

variable $y_i \in Y$ to each document D_i during topic discovery. The model not only learns the topic assignment $z_{1:N}$ for words $w_{1:N}$ in D_i, it also learns a function from the posterior distribution of z in D to Y. When Y is the review-level helpfulness gold-standard, the model leans a set of topics predictive of review helpfulness, as well as the utility of z in predicting review helpfulness y_i, denoted as η. (Both z and η are K-dimensional.)

At each inference step, sLDA assigns a topic ID to each word in every review. $z_l = k$ means that the topic ID for word at position l in sentence s is k. Given the topic assignments $z_{1:L}$ to words $w_{1:L}$ in a review sentence s, we estimate the contribution of s to the helpfulness of the review it belongs to (Formula 1), as well as the average topic importance in s (Formula 2). While $rHelpSum$ is sensitive to the review length, $sHelpSum$ is sensitive to the sentence length.

$$rHelpSum(s) = \frac{1}{N} \sum_{l=1}^{l=L} \sum_{k} \eta_k p(z_l = k) \tag{1}$$

$$sHelpSum(s) = \frac{1}{L} \sum_{l=1}^{l=L} \sum_{k} \eta_k p(z_l = k) \tag{2}$$

As the topic assignment in each inference iteration might not be the same, Riedl and Biemann (Riedl and Biemann, 2012) proposed the *mode* method in their application of LDA for text segmentation – use the most frequently assigned topic for each word in all iterations as the final topic assignment – to address the instability issue. Inspired by their idea, we also use the *mode* method to infer the topic assignment in our task, but only apply the *mode* method to the last 10 iterations, because the topic distribution might not be well learned at the beginning.

4 Experimental setup

To investigate the utility of exploiting user-provided review helpfulness ratings for content selection in extractive summarization, we develop two helpfulness-guided summarizers based on the MEAD framework (HelpfulFilter and HelpfulSum). We compare our systems' performance against a strong unsupervised extractive summarizer that MEAD supports as our baseline (MEAD+LexRank). To focus on sentence scoring only, we use the same MEAD word-based MMR (Maximal Marginal Relevance) reranker (Carbonell and Goldstein, 1998) for all summarizers, and set the length of the output to be 200 words.

4.1 Data

Our data consists of two kinds of online reviews: 4050 Amazon camera reviews provided by Jindal and Liu (2008) and 280 IMDB movie reviews that we collected by ourselves. Both corpora were used in our prior work of automatically predicting review helpfulness, in which every review has at least three helpfulness votes. On average, the helpfulness of camera reviews is .80 and that of movie reviews is .74.

Summarization test sets. Because the proposed approach method is purely unsupervised, and we do not optimize our summarization parameters during learning, we evaluate our approach based on a subset of review items directly: we randomly sample 18 reviews for each review item (a camera or movie) and randomly select 3 items for each review domain. In total there are 6 summarization test sets (3 items $\times$ 2 domains), where each contains 18 reviews to be summarized (i.e. "summarizing 18 camera reviews for Nikon D3200"). In the summarization test sets, the average number of sentences per review is 9 for camera reviews, and 18 for movie reviews; the average number of words per sentence in the camera reviews and movie reviews are 25 and 27, respectively.

4.2 sLDA training

We implement sLDA based on the topic modeling framework of Mallet (McCallum, 2002) using 20 topics ($K = 20$) and the best hyper-parameters (topic distribution priors α and word distribution priors

β) that we learned in our pilot study on LDA. [3]

Since our summarization approach is unsupervised, we learn the topic assignment for each review word using the corresponding sLDA model trained on all reviews of that domain (4050 reviews for camera and 280 reviews for movie).[4]

4.3 Three summarizers

Baseline (MEAD+LexRank): The default feature set of MEAD includes *Position*, *Length*, and *Centroid*. Here *Length* is a word-count threshold, which gives score 0 to sentences shorter than the threshold. As we observe that short review sentences sometimes can be very informative as well (e.g., "This camera is so amazing!", "The best film I have ever seen!"), we adjust $Length$ to 5 from its default value 9. MEAD also provides scripts to compute *LexRank* (Erkan and Radev, 2004), which is a more advanced feature using graph-based algorithm for computing relative importance of textual units. We supplement the default feature set with *LexRank* to get the best summarizer from MEAD, yielding the sentence scoring function $F_{baseline}(s)$, in which s is a given sentence and all features are assigned equal weights (same as in the other two summarizers).

$$F_{baseline}(s) = \begin{cases} Position + Centroid + LexRank & \text{if } Length \geq 5 \\ 0 & \text{if } Length < 5 \end{cases} \quad (3)$$

HelpfulFilter: This summarizer is a direct extension of the baseline, which considers review-level helpfulness ratings ($hRating$) as an additional filtering criteria in its sentence scoring function $F_{HelpfulFilter}$. (In our study, we omit the automated prediction (Kim et al., 2006; Liu et al., 2008) and filter reviews by their helpfulness gold-standard directly.) We set the cutting threshold to be the average helpfulness rating of all the reviews that we used to train the topic model for the corresponding domain ($hRatingAve(domain)$).

$$F_{HelpfulFilter}(s) = \begin{cases} F_{baseline}(s) & \text{if } hRating(s) \geq hRatingAve(domain) \\ 0 & \text{if } hRating(s) < hRatingAve(domain) \end{cases} \quad (4)$$

HelpfulSum: To isolate the contribution of review helpfulness, the second summarizer only uses helpfulness related features in its sentence scoring function $F_{HelpfulSum}$. The features are ***rHelpSum*** – the contribution of a sentence to the overall helpfulness of its corresponding review, ***sHelpSum*** – the average topic weight in a sentence for predicting the overall helpfulness of the review (Formula 1 and 2), plus $hRating$ for filtering. Note that there is no overlap between features used in the baseline and HelpfulSum, as we wonder if the helpfulness information alone is good enough for discovering salient review sentences.

$$F_{HelpfulSum}(s) = \begin{cases} rHelpSum(s) + sHelpSum(s) & \text{if } hRating(s) \geq hRatingAve(domain) \\ 0 & \text{if } hRating(s) < hRatingAve(domain) \end{cases} \quad (5)$$

5 Evaluation

For evaluation, we will first present our human evaluation user study and then present the automated evaluation result based on human summaries collected from the user study.

[3] In our pilot study, we experimented with various hyper-parameter settings, and trained the model with 100 sampling iterations in both the **E**stimation and the **M**aximization steps. As we found the best results are more likely to be achieved when $\alpha = 0.5$, $\beta = 0.1$, we use this setting to train the sLDA model in our summarization experiment.

[4] In practice, this means that we need to (re)train the topic model after given the summarization test set.

5.1 Human evaluation

The goal of our human evaluation is to compare the effectiveness of 1) using a traditional content selection method (MEAD+LexRank), 2) using the traditional method enhanced by review-level helpfulness filtering (HelpfulFilter), and 3) using sentence helpfulness features estimated by sLDA plus review-level helpfulness filtering (HelpfulSum) for building an extractive multi-document summarization system for online reviews. Therefore, we use a within-subject design in our user study for each review domain, considering the *summarizer* as the main effect on human evaluation results.

The user study is carried out in the form of online surveys (one survey per domain) hosted by Quadrics. In total, 36 valid users participated in our online-surveys.[5] We randomly assigned 18 of them to the camera reviews, and the rest 18 to the movie reviews.

5.1.1 Experimental procedures

Each online survey contains three summarization sets. The human evaluation on each one is taken in three steps:

Step 1: We first require users to perform **manual summarization**, by selecting 10 sentences from the input reviews (displayed in random order for each visit). This ensures that users are familiar with the input text so that they can have fair judgement on machine-generated results. To help users select the sentences, we provide an introductory scenario at the beginning of the survey to illustrate the potential application in accordance with the domain (e.g., Figure 1).

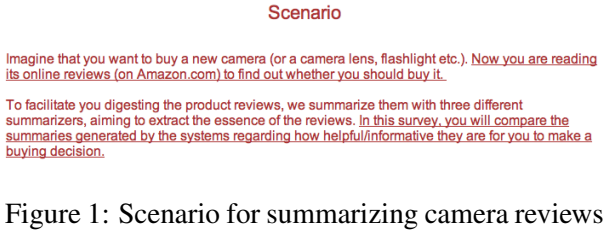

Figure 1: Scenario for summarizing camera reviews

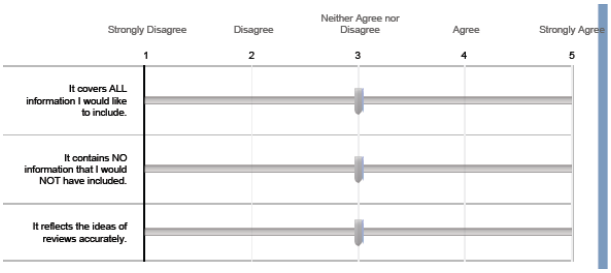

Figure 2: Content evaluation

Step 2: We then ask users to perform **pairwise comparison** on summaries generated by the three systems. The three pairs are generated in random order; and the left-or-right display position (in Figure 3) of the two summaries in each pair is also randomly selected. Here we use the same 5-level preference ratings used in (Lerman et al., 2009), and translate them into integers from -2 to 2 in our result analysis.
Step 3: Finally, we ask users to evaluate the three summaries in isolation regarding the summary quality in three content-related aspects: *recall*, *precision* and *accuracy* (top, middle and bottom in Figure 2, respectively), which were used in (Carenini et al., 2006). In this **content evaluation**, the three summaries are randomly visited and the users rate the proposed statements (one for each aspect) on a 5-point scale.

5.1.2 Results

Pairwise comparison. We use a mixed linear model to analyze user preference over the three summary pairs separately, in which "summarizer" is a between-subject factor, "review item" is the repeated factor, and "user" is a random effect. Results are summarized in Table 1. (Positive preference ratings on "A over B" means A is preferred over B; negative ratings means B is preferred over A.) As we can see, **HelpfulSum** is the best: it is consistently preferred over the other two summarizers across domains and the preference is significant throughout conditions except when compared with HelpfulFilter on movie reviews. **HelpfulFilter** is significantly preferred over the baseline (MEAD+LexRank) for movie reviews, while it does not outperform the baseline on camera reviews. A further look at the compression rate (cRate) of the three systems (Table 2) shows that on average HelpfulFilter generates shortest summaries

[5] All participants are older than eighteen, recruited via university mailing lists, on-campus flyers as well as social networks online. While we also considered educational peer reviews as a third domain, about half of the participants dropped out in the middle of the survey. Thus we only consider the two e-commerce domains in this paper.

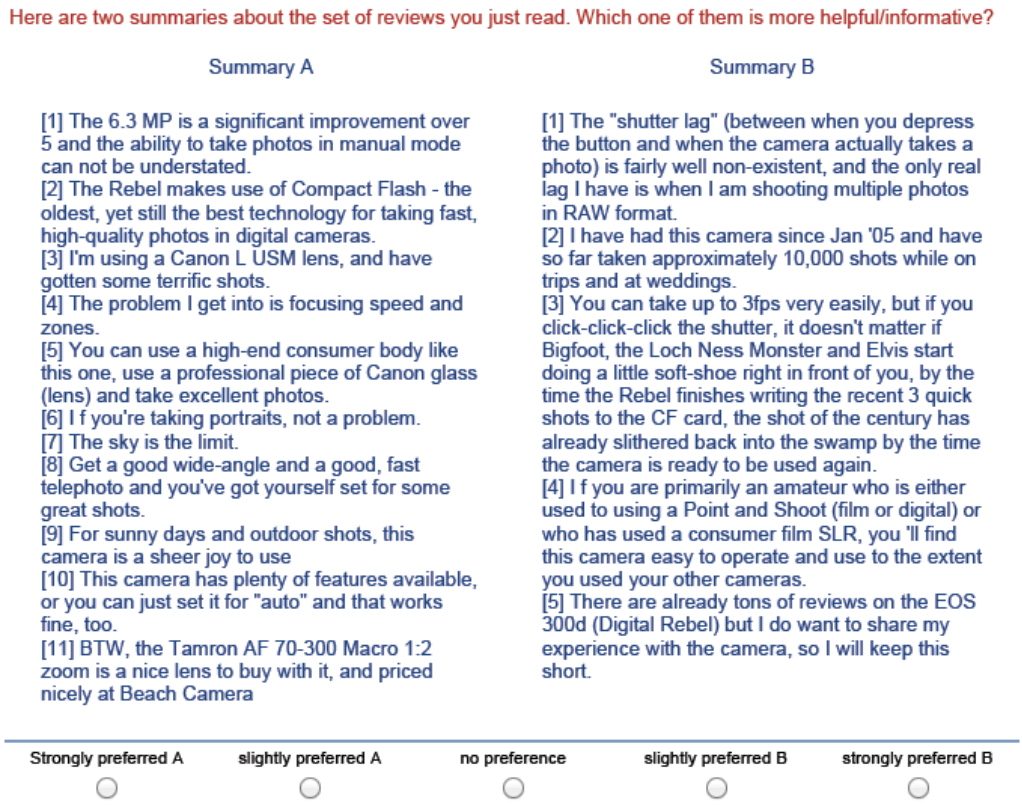

Figure 3: Example of pairwise comparison for summarizing camera reviews (left:HelpfulSum, right: the baseline).

among the three summarizers on camera reviews[6], which makes it naturally harder for **HelpfulFilter** to beat the other two (Napoles et al., 2011).

Pair	Domain	Est. Mean	Sig.
HelpfulFilter	Camera	-.602	.001
over MEAD+LexRank	Movie	.621	.000
HelpfulSum	Camera	.424	.011
over MEAD+LexRank	Movie	.601	.000
HelpfulSum	Camera	1.18	.000
over HelpfulFilter	Movie	.160	.310

Table 1: Mixed-model analysis of user preference ratings in pairwise comparison across domains. Confidence interval = 95%. The preference rating is ranged from -2 to 2.

Summarizer	Camera	Movie
MEAD+LexRank	6.07%	2.64%
HelpfulFilter	3.25%	2.39%
HelpfulSum	5.94%	2.69%
Human (Ave.)	6.11%	2.94%

Table 2: Compression rate of the three systems across domains.

Content evaluation. We summarize the average quality ratings (Figure 2) received by each summarizer across review items and users for each review domain in Table 3. We carry out paired T-tests for every pair of summarizers on each quality metric. While no significant difference is found among the three summarizers on any quality metric for movie reviews, there are differences for camera reviews. In terms of both accuracy and recall, HelpfulSum is significantly better than HelpfulFilter (p=.008 for accuracy, p=.034 for recall) and the baseline is significantly better than HelpfulFilter (p=.005 for accuracy, p=.005 for recall), but there is no difference between HelpfulSum and the baseline. For precision, no significant

[6]While we limit the summarization output to be 200 words in MEAD, as the content selection is at the sentence level, the summaries can have different number of words in practice. Considering that word-based MMR controls the redundancy in the selected summary sentences ($\lambda = 0.5$ as suggested), there might be enough content to select using $F_{HelpfulFilter}$.

difference is observed in either domain.

Summarizer	Camera			Movie		
Metric	Precision	Recall	Accuracy	Precision	Recall	Accuracy
MEAD+LexRank	2.63	**3.24**	3.57	2.50	2.59	2.93
HelpfulFilter	**2.78**	2.74	3.11	2.44	2.61	2.96
HelpfulSum	2.41	3.19	**3.69**	**2.52**	**2.67**	**3.02**

Table 3: Human ratings for content evaluation. The best result on each metric is bolded for every review domain (the higher the better).

With respect to pairwise evaluation, content evaluation yields consistent results on camera reviews between HelpfulFilter vs. the baseline and HelpfulSum vs. HelpfulFilter. However, only pairwise comparison (preference ratings) shows significant difference between HelpfulSum vs. the baseline and the difference in the summarizers' performance on movie reviews. This confirms that pairwise comparison is more suitable than content evaluation for human evaluation (Lerman et al., 2009).

5.2 Automated evaluation based on ROUGE metrics

Although human evaluation is generally preferred over automated metrics for summarization evaluation, we report our automated evaluation results based on ROUGE scores (Lin, 2004) using references collected from the user study. For each summarization test set, we have 3 machine generated summaries and 18 human summaries. We compute the ROUGE scores in a leave-1-out fashion: for each machine generated summary, we compare it against 17 out of the 18 human summaries and report the score average across the 17 runs; for each human summary, we compute the score using the other 17 as references, and report the average human summarization performance.

Evaluation results are summarized in Table 4 and Table 5, in which we report the F-measure for R-1 (unigram), R-2 (bigram) and R-SU4 (skip-bigram with maximum gap length of 4)[7], following the convention in the summarization community. Here we observe slightly different results with respect to human evaluation: for camera reviews, no significant result is observed, while HelpfulSum achieves the best R-1 score and HelpfulFilter works best regarding R-2 and R-SU4. In both cases the baseline is never the best. For movie reviews, HelpfulSum significantly outperforms the other summarizers on all ROUGE measurements, and the improvement is over 100% on R-2 and R-SU4, almost the same as human does. This is consistent with the result of pairwise comparison in that HelpfulSum works better than both HelpfulFilter and the baseline on movie reviews.

Summarizer	R-1	R-2	R-SU4
MEAD+LexRank	.333	.117	.110
HelpfulFilter	.346	**.121**	**.111**
HelpfulSum	**.350**	.110	.101
Human	.360	.138	.126

Table 4: ROUGE evaluation on camera reviews

Summarizer	R-1	R-2	R-SU4
MEAD+LexRank	.281	.044	.047
HelpfulFilter	.273	.040	.041
HelpfulSum	**.325**	**.095**	**.090**
Human	.339	.093	.093

Table 5: ROUGE evaluation on movie reviews

6 Human summary analysis

To get a comprehensive understanding of the challenges in extractive review summarization, we analyze the agreement in human summaries collected in our user study at different levels of granularity, regarding heuristics that are widely used in existing extractive summarizers.

Average word/sentence counts. Figure 4 illustrates the trend of average number of words and sentences shared by different number of users across review items for each domain. As it shows, no sentence is

[7]Because ROUGE requires all summaries to have equal length (word counts), we only consider the first 100 words in every summary.

agreed by over 10 users, which suggests that it is hard to make humans agree on the informativeness of review sentences.

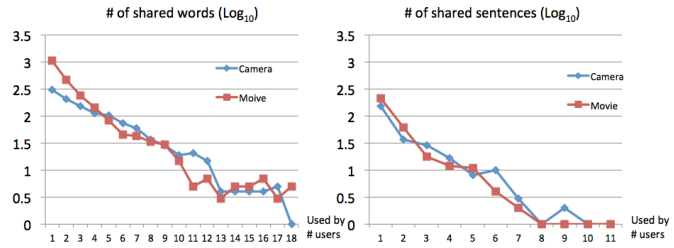

Figure 4: Average number of words (w) and sentences (s) in agreed human summaries

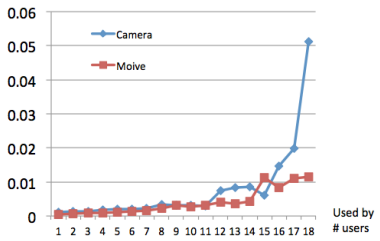

Figure 5: Average probability of words used in human summaries

Word frequency. We then compute the average probability of word (in the input) used by different number of human summarizers to see if the word frequency pattern found in news articles (words that human summarizers agreed to use in their summaries are of high frequency in the input text (Nenkova and Vanderwende, 2005)) holds for online reviews. Figure 5 confirms this. However, the average word probability is below 0.01 in those shared by 14 out of 18 summaries[8] ; the flatness of the curve seems to suggest that word frequency alone is not enough for capturing the salient information in input reviews.

KL-divergence. Another widely used heuristic in multi-document summarization is minimizing the distance of unigram distribution between the summary and the input text (Lin et al., 2006). We wonder if this applies to online review summarization. For each testing set, we group review sentences by the number of users who selected them in their summaries, and compute the KL-divergence (KLD) between each sentence group and the input. The average KL-divergence of each group across review items are visualized in Figure 6, showing that this intuition is incorrect for our review domains. Actually, the pattern is quite the opposite, especially when the number of users who share the sentences is less than 8. Thus traditional methods that aim to minimize KL-divergence might not work well for online reviews.

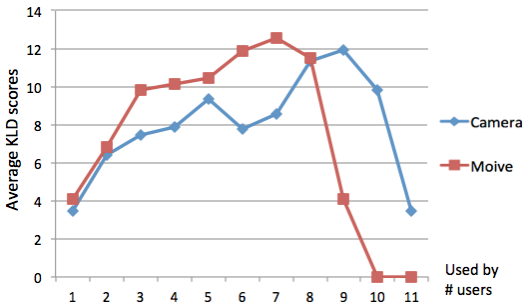

Figure 6: Average KL-Divergence between input and sentences used in human summaries

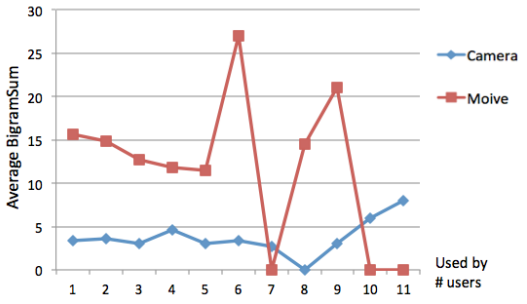

Figure 7: Average BigramSum of sentences used in human summaries

Bigram coverage. Recent studies proposed a simple but effective criteria for extractive summarization based on bigram coverage (Nenkova and Vanderwende, 2005; Gillick and Favre, 2009). The coverage of a given bigram in a summary is defined as the number of input documents the bigram appears in, and presumably good summaries should have larger sum of bigram coverage (BigramSum). However, as shown in Figure 7, this criteria might not work well in our case either. For instance, the BigramSum of the sentences that are shared by 3 human judges is smaller than those shared by 1 or 2 judges.

[8]The average probability of words used by all 4 human summarizers are 0.01 across the 30 DUC03 sets (Nenkova and Vanderwende, 2005).

7 Conclusion and future work

We propose a novel unsupervised extractive approach for summarizing online reviews by exploiting review helpfulness ratings for content selection. We demonstrate that the helpfulness metadata can not only be directly used for review-level filtering, but also be used as the supervision of sLDA for sentence scoring. This approach leverages the existing metadata of online reviews, requiring no annotation and generalizable to multiple review domains. Our experiment based on the MEAD framework shows that HelpfulFilter is preferred over the baseline (MEAD+LexRank) on camera reviews in human evaluation. HelpfulSum, which utilizes review helpfulness at both the review and sentence level, significantly outperforms the baseline in both human and automated evaluation. Our analysis on the collected human summaries reveals the limitation of traditional summarization heuristics (proposed for news articles) for being used in review domains.

In this study, we consider the ground truth of review helpfulness as the percentage of helpful votes over all votes, where the helpfulness votes could be biased in various ways (Danescu-Niculescu-Mizil et al., 2009). In the future, we would like to explore more sophisticated models of review helpfulness to eliminate such biases, or even automatic review helpfulness predictions based on just review text. We also would like to build a fully automated summarizer by replacing the review helpfulness gold-standard with automated predictions as the filtering criteria. Given the collected human summaries, we will experiment with different feature combinations for sentence scoring and we will compare our helpfulness features with other content features as well. Finally, we want to further analyze the impact of the number of human judges on our automated evaluation results based on ROUGE scores.

Abstract

We describe two systems for text simplification using typed dependency structures, one that performs lexical and syntactic simplification, and another that performs sentence compression optimised to satisfy global text constraints such as lexical density, the ratio of difficult words, and text length. We report a substantial evaluation that demonstrates the superiority of our systems, individually and in combination, over the state of the art, and also report a comprehension based evaluation of contemporary automatic text simplification systems with target non-native readers.

1 Introduction

Text simplification has often been defined as the process of reducing the grammatical and lexical complexity of a text, while still retaining the original information content and meaning. However, text can also be simplified in other ways; for instance, by removing peripheral information to reduce text length, through sentence compression or summarisation. A key goal of automatic text simplification is to make information more accessible to the large numbers of people with reduced literacy, motivated by a large body of evidence that manual text simplification is an effective intervention (Anderson and Freebody, 1981; L'Allier, 1980; Beck et al., 1991; Anderson and Davison, 1988; Linderholm et al., 2000; Kamalski et al., 2008). However automatic text simplification systems have rarely been evaluated in a manner that sheds light on whether they can facilitate target users.

To date, evaluations of automatic text simplification have been (a) performed on a small scale, as few as 20–25 sentences in some cases (Wubben et al., 2012; Siddharthan and Mandya, 2014; Narayan and Gardent, 2014), (b) performed on sentences in isolation, thus not measuring incoherence caused at the inter-sentential level that can make text more difficult (Siddharthan (2003a) being the exception), and (c) performed using either automatic metrics (Zhu et al., 2010; Coster and Kauchak, 2011; Woodsend and Lapata, 2011; Wubben et al., 2012; Paetzold and Specia, 2013) or using ratings by fluent readers for fluency, simplicity and meaning preservation (Siddharthan, 2006; Woodsend and Lapata, 2011; Wubben et al., 2012; Paetzold and Specia, 2013; Siddharthan and Mandya, 2014; Narayan and Gardent, 2014; Mandya and Siddharthan, 2014). As such, none of these evaluations can help us answer the basic question: How good is automatic text simplification; i.e., would it facilitate poor readers?

Our goals in this paper are twofold. First, we want to evaluate text simplification systems more systematically than has been attempted before, using both human judgements on a larger scale, and directly testing comprehension on longer passages for target reader populations. Second, we want to compare two different approaches to text simplification. In this paper, we present a text simplification system that can perform lexical and syntactic simplification (§3), as well as a novel sentence compression system designed specifically for the text simplification task (§4), in that it favours compressions with fewer difficult words and with more function words such as connectives that are known to improve readability. We evaluate both, as well as a hybrid system that performs both text simplification and compression (§5, 6).

2 Related Work

Text simplification systems differ primarily in the level of linguistic knowledge they encode. Phrase Based Machine Translation (PBMT) systems (Specia, 2010; Wubben et al., 2012; Coster and Kauchak, 2011) use the least knowledge, and as such are ill equipped to handle simplifications that require morphological changes, syntactic reordering, sentence splitting or insertions. While syntax based MT approaches use syntactic knowledge, existing systems do not offer a treatment of morphology (Zhu et al., 2010; Woodsend and Lapata, 2011; Paetzold and Specia, 2013). This means that while some syntactic reordering operations can be performed well, others requiring morphological changes cannot. Consider converting passive to active voice (e.g., from "trains are liked by John" to "John likes trains"). Besides deleting auxiliaries and reordering the arguments of the verb, there is also a requirement to modify the verb to make it agree in number with the new subject "John", and take the tense of the auxiliary "are".

Hand crafted systems such as Siddharthan (2010) and Siddharthan (2011) use transformation rules that encode morphological changes as well as deletions, re-orderings, substitutions and sentence splitting, and can handle voice change correctly. However, hand crafted systems are limited in scope to syntactic simplification as there are too many lexico-syntactic and lexical simplifications to enumerate manually.

Some contemporary work in text simplification has evolved from research in sentence compression, a related research area that aims to shorten sentences for the purpose of summarising the main content. Sentence compression has historically been addressed in a generative framework, where transformation rules are learnt from parsed corpora of sentences aligned with manually compressed versions, using ideas adapted from statistical machine translation. The compression rules learnt are typically syntactic tree-to-tree transformations (Knight and Marcu, 2000; Galley and McKeown, 2007; Riezler et al., 2003; Cohn and Lapata, 2009; Nomoto, 2008) of some variety. Indeed, Woodsend and Lapata (2011) develop this line of research. Their model is based on quasi-synchronous tree substitution grammar (QTSG) (Smith and Eisner, 2006) and integer linear programming. Quasi-synchronous grammars aim to relax the isomorphism constraints of synchronous grammars, in this case by generating a loose alignment between parse trees. Woodsend and Lapata (2011) use QTSG to generate all possible rewrite operations for a source tree, and then integer linear programming to select the most appropriate simplification. Their system performs lexical and syntactic simplification as well as compression.

Recently, there have been attempts to combine approaches. Narayan and Gardent (2014) use an approach based on semantics to perform syntactic simplification, and PBMT for lexical simplifications. We have also created a hybrid system, but one using linguistically sound hand written rules for syntactic simplification and automatically acquired rules for lexicalised constructs (Siddharthan and Mandya, 2014; Mandya and Siddharthan, 2014). In this paper we combine this work (summarised in §3) with a new method for sentence compression (described in §4).

3 Text Simplification with Synchronous Dependency Grammars

We use the RegenT text simplification (Siddharthan, 2011), augmented with automatically acquired rules, as described in detail elsewhere (Mandya and Siddharthan, 2014; Siddharthan and Mandya, 2014). In this section, we will restrict ourselves to summarising the key features of the system.

Our text simplification system follows the architecture proposed in Ding and Palmer (2005) for Synchronous Dependency Insertion Grammars, reproduced in Fig. 1. It uses the same dataset[1] as Woodsend and Lapata (2011) for learning lexicalised rules. The rules are acquired in the format required by the RegenT text simplification system (Siddharthan, 2011), which is used to implement the simplification. This

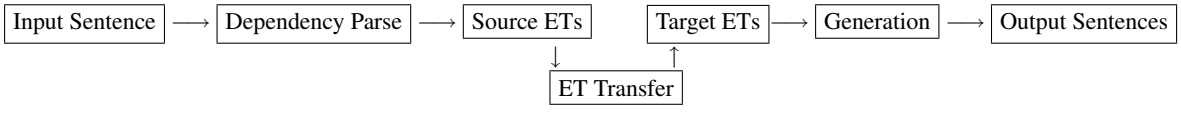

Figure 1: System Architecture

RULE 1: MOST_INTENSIVE2STRONGEST

1. DELETE
   (a) advmod(?X0[intensive], ?X1[most])
   (b) advmod(?X2[storm], ?X0[intensive])
2. INSERT
   (a) advmod(?X2, ?X3[strongest])

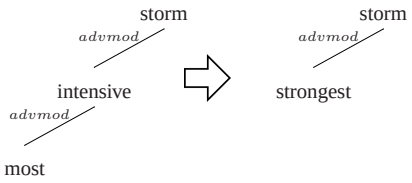

Figure 2: Simplification as a Transfer rule and a transduction of Elementary Trees (ETs)

requires dependency parses from the Stanford Parser, and generates output sentences from dependency parses using the generation-light approach described in (Siddharthan, 2011).

In short, we extract a synchronous grammar from dependency parses of aligned English and simple English sentences, starting from the differences in the parses. For example, consider two aligned sentences from the aligned corpus described in Woodsend and Lapata (2011):

1. (a) It was the second most intensive storm on the planet in 1989.
   (b) It was the second strongest storm on the planet in 1989.

An automatic comparison of the dependency parses for the two sentences reveals that there are two typed dependencies that occur only in the parse of the first sentence, and one that occurs only in the parse of the second. Thus, to convert the first sentence into the second, two dependencies need to be deleted and one inserted. From this example, the rule shown in Fig. 2 is extracted. The rule contains variables (?Xn), which can be forced to match certain words in square brackets.

Such deletion and insertion operations are central to text simplification, but a few other operations are also needed to handle morphology and to avoid broken dependency links in the Target ETs. These are enumerated in (Siddharthan, 2011). By collecting such rules, a meta-grammar is produced that can translate dependency parses in one language (English) into the other (simplified English). The rule above will translate "most intensive" to "strongest", in the immediate lexical context of "storm". The ET Transfer component can be presented either as transformation rules or as a transduction of ETs, as shown in Fig. 2. In Mandya and Siddharthan (2014), we describe how such automatically acquired rules can be generalised to apply in new contexts; for instance, by expanding lexical context to include related words derived from WordNet, or by removing the lexical context for lexical simplifications that are not context dependent.

Learning paraphrase with typed dependency representations has certain advantages to PBMT; for example, consider the rule that simplifies "described as" to "called":

RULE: DESCRIBED_AS2CALLED

1. DELETE:
   (a) prep_as(?X0[described], ?X1)
2. INSERT:
   (a) dobj(?X2[called], ?X1)

This single rule can simplify "*Coulter was described as a polemicist*" to "*Coulter was called a polemicist*" as well as cases where the words are not adjacent, such as "*Coulter has described herself as a polemicist*" to "*Coulter has called herself a polemicist*".

Our text simplification system, as evaluated in this paper, combines a set of 278 hand crafted grammar for syntactic simplification (from the original RegenT system) and 5172 automatically acquired rules, based on the principles described above.

4 Sentence Compression with Reluctant Trimmer

This section describes the mechanics of the reluctant trimmer (RT), or how it works to create a simplified form of sentence. We will explain later where the word 'reluctant' comes from. Broadly, RT comes in two parts: generation and selection. For a given sentence it takes as input, it generates a number of

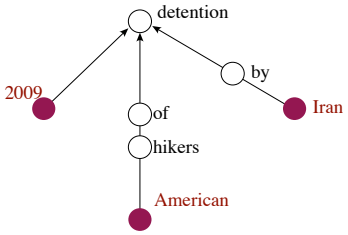

Figure 3: Dependency structure for *"2009 detention of American hikers by Iran"*

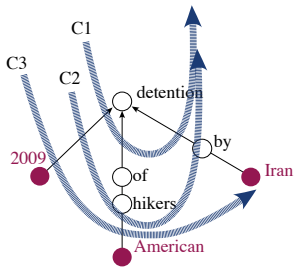

Figure 4: Cropping dependency tree

truncations of the sentence, each of which has some elements removed in a way that largely complies with English syntax. It does this by first parsing the sentence into a a dependency representation, and creating what we call terminating dependency paths out of the representation. After placing them in a lattice format, we run a K-best search over the lattice to generate K best truncations of the sentence. We repeat the process for each sentence found in the text, which will produce a collection of sets of truncation candidates. We then run integer linear programming over the collection, selecting one sentence for each set in a way that satisfies global constraints such as lexical density, the ratio of hard words, and text length. In particular, we regard RT not as an operation that works sentence by sentence, but one that works with text as a whole. We argue that how the sentence is to be compressed is not only dictated by the sentence itself, but also by the text in which it appears.

We start off with an example shown in Figure 3, where we have a phrase "*2009 detention of American hikers by Iran*." Our goal here is to develop a systematic method that will prune the dependency tree so as to generate shorter versions of the sentence largely in compliance with the English grammar. Figure 4 provides an intuitive picture of how this could be done: by cropping the tree along the arrows. We implement the idea by borrowing the notion of *Terminating Dependency Path* (TDP) (Nomoto, 2008), which gives us a way to translate a dependency tree into a trellis of nodes, which in turn allows us to find truncations through dynamic programming.

Figure 5 shows a TDP lattice derived from the dependency tree given in Figure 3. TDPs are depicted as solid blue lines in the figure. It is easy to see that each TDP corresponds to a path in the dependency tree that runs from a leaf to the root. The conversion from dependency tree to TDP lattice is thus straightforward. We perform A* search over the TDP lattice to find the best compression. Assume that we have a path or a sequence of nodes, $\langle n[1], n[2] \ldots, n[j], \ldots, n[z-1], n[z] \rangle$, that takes you from the starting node, $n[1]$, to the goal, $n[z]$, on the TDP lattice. Define the cost C of node $n[x]$ by: $C(x) = g(x) + h(x)$ where $g(x)$ is the cost incurred for the travel from the starting node to $n[x]$ and $h(x)$ the future estimate for the cost of travelling from $n[x]$ to the goal. Let $g(x) = -\sum_{j \in V(1,x)} \text{backward}(j)$ and $h(x) = -\sum_{j \in W(x,z-1)} \text{forward}(j)$, with:

$$\text{backward}(x) = \text{tfidf}(n[x]) + pr(\text{seq}(n[x-1], n[x]) | M), \quad (1)$$

$$\text{forward}(x) = \text{backward}(x+1) \quad (2)$$

$V(1,x)$ is a sequence of nodes that appeared on the path we took to reach $n[x]$ from the starting node, $W(x, z-1)$ a sequence of nodes that gives the shortest possible path (i.e. the path that incurs least cost) from $n[x]$ to the goal. tfidf(n) represents a tfidf score for a word associated with the node n, with tfidf$(n[1]) = 0$ and tfidf$(n[g]) = 0$, and is normalised so that it falls between 1 and 0.[2] seq(n, m) refers to an uninterrupted sequence of words you find on the path that extends from n to m via the root, ignoring duplicates. Figure 6 gives an intuitive sense of how this works. seq (2009, hiker), for instance, can be found by following the blue line in the figure, which results in "*2009 detention of hikers.*" 'M' refers to a language model.[3] $pr(\text{seq}(n, m)|M)$ is the probability of sequence 'seq(n,m)' under language

[2]Document frequencies (df) we used for present purposes are based on those given in the British National Corpus (`www.kilgarriff.co.uk/bnc-readme.html`), which keeps record of the number of files a particular word occurred.

[3]The language model is built here by running SRLM (`www.speech.sri.com/projects/srilm`) on the English

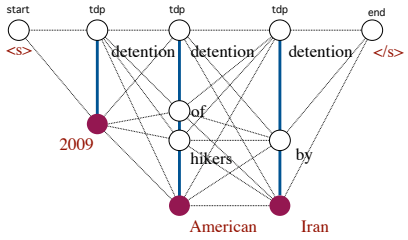

Figure 5: TDP lattice. '$\langle s \rangle$' is a label for the starting node, '$\langle /s \rangle$' that for the goal.

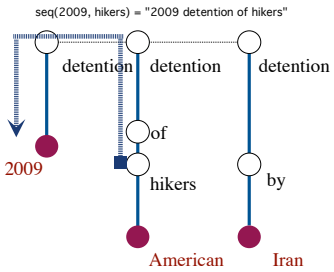

Figure 6: seq(2009,hiker)

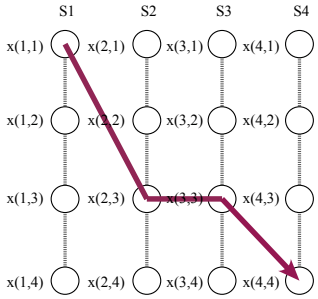

Figure 7: Decoding with ILP

model M.[4] Traversing over the TDP lattice while picking nodes with least costs will produce the best compression, to which we apply Yen (1971)'s algorithm to find K-best alternatives (where K is set to 10 in the experiments reported below).

We now turn to the second part of the story, which is about choosing from each pool of K-best candidates, to create a simplified version of the text. (Recall that we keep a pool of K-best compressions for each of the sentences in a text, and create a simplification by choosing a compression from each pool.) In this paper, we build on a particular simplification approach based on integer linear programming (ILP), by (Dras, 1999), which he dubbed 'reluctant paraphrasing.' In a nutshell, Dras claims that we should make as little change to the text as possible, arguing that any change may run the risk of muddling the meaning of the original text: hence the name 'reluctant paraphrasing.' The following linear program (LP) represents our adaptation of Dras's method. Formula 3 represents the objective function, with 4 through 7 expressing constraints:

$$\min \quad z = \sum c_{i,j} x_{i,j} \qquad (3)$$

subject to:

$$\forall i \sum_j x_{ij} = 1, \quad x_{ij} \in \{0,1\}, \forall ij \qquad (4)$$

$$\frac{W + \sum w_{ij} \cdot x_{ij}}{S} \leq k_1 \qquad (5)$$

$$\frac{H + \sum h_{ij} \cdot x_{ij}}{W + \sum w_{ij} \cdot x_{ij}} \leq k_2 \qquad (6)$$

$$\frac{F + \sum f_{ij} \cdot x_{ij}}{W + \sum w_{ij} \cdot x_{ij}} \geq k_3 \qquad (7)$$

$x_{i,j}$ denotes a candidate for which we are to make a decision on whether to include it in the simplification of a given text d. In particular we mean $x_{i,j}$ to represent the j-th best compression for the i-th sentence in d. Constraint 4 dictates that we have exactly one compression candidate for each sentence in d. w_{ij} indicates the number of changes or deletions we performed on the original sentence to create x_{ij}: -1 if x_{ij} has one less term than the original sentence it is a compression of; 0 if there is no change. W is the number of terms in d, S the number of sentences in d. Constraint 5 states that proportion of the number of terms to that of sentences should be less than or equal to k_1; in other words, changes made to the text should not exceed k_1. H in constraint 6 denotes the total number of 'hard' or difficult words in the original text; h_{ij} the number of changes made to hard words in x_{ij}, namely how many less or more words there remain that are deemed 'hard,' compared to the sentence it comes from.[5]: $h_{ij} = -3$, for example, means that we have three less hard words in x_{ij} than in the original sentence.

Constraint 6 is included here to keep the proportion of hard words in text from growing beyond a

portion of TDT5 corpus and TDT Pilot Study Corpus (both available at Linguistic Data Consortium), the total number of sentences combined reaching 293,971.

[4]We note here that we did not compensate the probability for the length of a word sequence, as we were unable to find an empirical evidence that suggested we should do otherwise.

[5]'Hard words' are defined here as those that fall off of the New General Service List (www.newgeneralservicelist.org) which currently contains 2,881most frequently used words.

particular threshold k_2. The values of k_1, k_2 and k_3 were determined based on the Breaking News English (BNE) corpus (described later), which provides for each story, simplified versions at two levels of difficulty, one being called 'easy' and the other 'hard.' If we take the 'easy' as a gold standard simplification for the 'hard,' we will be able to get estimates of k_1 through k_3. None of the data we used for this purpose, however, is part of the BNE reading test discussed below.

F in constraint 7 represents the total number of function words (those that are not of JJ, MD, NN, RB, or VB in the Penn scheme) while f_{ij} indicates that of changes to function words (the way it works is analogous to h_{ij}). The motivation for the constraint is to prevent function words from being eliminated excessively, which Dras argues, reduces the readability of text. The objective function includes parameters $c_{i,j}$ which serve to indicate the cost of transforming the sentence. In this paper, we define c_{ij} as Levenshtein edit distance between compression and original sentence. In ordinary language, the linear program may read like "Keep changes to a minimum. Accept compressions that look much like the original sentences from which they arise, with less of hard words and content terms and more of function words." Further, we made use of an array of hand-coded constraints in addition to a language model, to ensure that a compression we generate remains as grammatical as possible. Included were those that prohibit the generation of a compression that involves a dangling preposition or breaks apart multi-word prepositions (MWPs) such as *according to*, *compared to*, *in front of*, etc. (the complete list of MWPs we used for this purpose can be found in de Marneffe and Manning (2008)). Added to these were some "don't drop" rules that demanded we keep intact subjects and verbs as well.

Figure 7 illustrates how compression variables $x_{i,j}$ are organised (each of which is depicted as "$x(i, j)$" in the figure). Each vertical line represents a pool of K-best compressions generated for a particular sentence s_i. LP seeks to find a candidate from each pool so that the resulting set of compressions best meets the objective function and conditions it dictates.[6]

5 Evaluation of Fluency, Simplicity and Meaning Preservation

We performed a manual evaluation of how fluent and simple the text produced by our simplification system is, and the extent to which it preserves meaning. We evaluate 3 systems:

TS: The Text Simplification system based on synchronous dependency grammars (§3).

RT: The Reluctant Trimmer for sentence compression (§4).

HYB: A hybrid text simplification system that applies RT to the output of TS.

We used as a baseline Woodsend and Lapata (2011)'s QTSG system that learns a quasi-synchronous tree substitution grammar from the same EW-SEW dataset used by TS. QTSG is the best performing system in the literature with a similar scope to ours in terms of the syntactic, lexical and compression operations performed [7]. QTSG relies entirely on an automatically acquired grammar of 1431 rules, for lexical and syntactic simplification as well as sentence compression. Our TS system has an automatically extracted grammar with 5172 lexicalised rules to augment the existing 278 manually written syntactic rules in RegenT. The RT system is not trained on simplified text. We also compare against the manual simplification (SEW), and the original EW sentences.

Data: We use an evaluation set consisting of 100 sentences from English Wikipedia (EW) aligned with Simple English Wikipedia (SEW) sentences, following recent work (Woodsend and Lapata, 2011; Wubben et al., 2012; Zhu et al., 2010; Mandya and Siddharthan, 2014; Siddharthan and Mandya, 2014). These 100 sentences have been excluded from our training data for rule acquisition, as is standard. Following Wubben et al. (2012), we used all the sentences from the evaluation set for which each of the four systems had performed at least one simplification (as selecting sentences where no simplification is performed by one system is likely to boost its fluency and meaning preservation ratings). This gave us a test set of 50 sentences from the original 100.

[6] As an LP solver, we used lp_solve 5.5.2.0, a mixed integer programming solver, available under public license at SourceForge (`lpsolve.sourceforge.net/5.5`).

[7] The PBMT system of Wubben et al. (2012) reports better results than QTSG, but is not directly comparable because it does not perform syntactic simplifications such as sentence splitting.

	FLUENCY						SIMPLICITY						MEANING					
	EW	SEW	QTSG	TS	RT	HYB	EW	SEW	QTSG	TS	RT	HYB	EW	SEW	QTSG	TS	RT	HYB
Mean	3.97	4.09	2.20	3.53	3.19	3.01	3.40	3.54	2.41	3.79	3.15	2.83	-	4.14	2.52	3.44	3.43	3.28
SD	0.92	0.90	1.35	1.12	1.22	1.22	1.08	1.15	1.28	1.18	1.21	1.23	-	0.89	1.31	1.08	1.15	1.14
Median	4	4	2	4	3	3	3	4	2	4	3	3	-	4	2	4	4	3

Table 1: Results of human evaluation of different versions of simplified text

Method: We recruited participants on Amazon Mechanical Turk, filtered to live in the US and have an approval rating of 80%, and paid $3 for a HIT (Human Intelligence Task). Each HIT contained 10 sentences from Wikipedia (EW), each alongside 5 simplified versions: QTSG, TS, RT, HYB and SEW in a randomised manner. For each of these 10 sets, participants were asked to rate each simplified version for fluency, simplicity and the extent to which it preserved the meaning of the original EW sentence. Participants were also asked to rate the fluency and simplicity of the original EW sentence. We used a Likert scale of 1–5, where 1 is totally unusable output, and 5 is output that is perfectly usable.

Results: The results are shown in Table 1. As seen, our HYB system, and the individual components TS and RT all outperform QTSG with all three metrics. In particular, TS is comparable to the SEW version when one looks at the median scores. Interestingly, TS performs better than SEW with respect to simplicity, suggesting that the system is indeed capable of a wide range of simplification operations. The ANOVA tests carried out to measure significant differences between versions is presented below. Table 3 (Row 1) shows the average number of words in the original and each simplified version.

Fluency: A one-way ANOVA was conducted with *fluency* as the dependent variable and text *version* as the fixed effect. We report a significant effect of version (EW, SEW, QTSG, HYB, TS, RT) on the fluency score (F=173.1, p<10^{-16}). A Tukey's pairwise comparison test (Tukey's HSD, overall $\alpha = 0.05$) indicated significant differences between all pairs, except SEW-EW at $p < 0.05$.

Simplicity: A one-way ANOVA was conducted with *simplicity* as the dependent variable and text *version* as the fixed effect. We report a significant effect of version on the simplicity score (F=29.9, p<10^{-16}). A Tukey's pairwise comparison test (Tukey's HSD, overall $\alpha = 0.05$) indicated significant differences between all pairs except: EW-SEW, RT-EW, and SEW-TS at $p < 0.05$.

Meaning: A one-way ANOVA was conducted with *meaning preservation* as the dependent variable and text *version* as the fixed effect. We report a significant effect of version on the meaning preservation score (F=130.12, p=2x10^{-16}). A Tukey's pairwise comparison test (Tukey's HSD, overall $\alpha = 0.05$) indicated significant differences between all pairs except: RT-TS, RT-HYB and HYB-TS at $p < 0.05$.

Error Analysis: We manually examined sentences that had average ratings below 2. The main cause of error for TS was misparsing, particularly errorful relative clause attachment and the parsing of comma separated lists as apposition. TS fails badly in such cases, and it is possible that methods such as those described in Siddharthan (2003b) are still relevant for correcting parser output. RT suffers mainly when it removes punctuation, which make reading difficult, or names that contain meaning (e.g., "*Seven volumes in length , it was composed by Buddhist priest Jien of the Tendai sect c. 1220.*" got compressed to "*Seven volumes in length it was composed by Jien of the sect c. 1220.*"). The hybrid system can create inconsistencies when TS has split a sentence and RT removes names from only one part ("*Moles can be found in most parts of North America, Asia, and Europe, although there are no moles in Ireland.*" got simplified to "*Moles can be found in parts of America, and Asia and Europe. But, there are no moles.*").

6 Evaluation of Reading Comprehension

We also investigate, for the first time, the effect of contemporary text simplification systems on reading comprehension for non-native speakers with a range of English skills.

Method: The test was conducted on Amazon Mechanical Turk with participants chosen from India and paid $0.75 each. There is no method to selectively recruit low reading skill participants on Turk, so these setting were selected to recruit non-native speakers (India) and minimise participants with postgraduate

degrees (low pay). The test comprised of two components - (a) pre-test for English vocabulary skills; and (b) a reading comprehension test to measure the effect of text simplification.

Pre-test: Reading skills are multifaceted and typically assessed through test batteries that test a range of skills. As such there is no comprehensive assessment possible using a single short online test. As we are recruiting non-native speakers, we chose to use the vocabulary size test (Nation and Beglar, 2007), designed to estimate both first language and second language learners' written receptive vocabulary size in English. The test ranks words based on their corpus frequency, and creates 14 levels, each with 1000 words, so that level 10 for example would contain the 9001^{th} to 10000^{th} most frequent words in English. We designed our vocabulary test by using 28 items, 2 at each level[8]. Each word is tested by showing a short sentence containing it and asking the participant to select the meaning of the word from four options. An estimate of vocabulary size can be got by multiplying the score on this test by 500, so the maximum vocabulary size estimate is 28*500=14,000. Nation and Beglar (2007) spell out three important milestones in terms of word family vocabulary size:

> 5000: Minimum for Non-native speakers of non-European backgrounds to cope at English speaking Universities
>
> 8000: Critical goal for language learners to deal with a range of unsimplified language (98% coverage for newspapers)
>
> 9000: Level of non-native English speaking PhD students (98% coverage for English novels)

In addition, we asked participants to self-report their English language skills by selecting from following options: (a) native; (b) fluent (non-native); (c) good (non-native); and (d) basic (non-native).

Main test: The reading comprehension tests were conducted using 5 news summaries chosen from the Breaking News English[9] (BNE) website, with the permission of its creator and maintainer. The BNE website is a resource that provides high quality news summaries at various levels of simplification for second language learners, and has recently been nominated by the British Council for the 2014 ELTons award for Innovation in Learner Resources. We selected five news stories which had manually constructed summaries at reading levels 6 (hard) and 4 (easy). The website provides a range of exercises following each summary at level 6. We chose to use the multiple choice test to assess reading comprehension. For each of these summaries, we created automatically simplified texts by running our systems on the level 6 text. This resulted in a total of five versions for each news summary - L6 (original); L4 (manual simplification); TS (automatic simplification of L6); RT (compression of L6); and HYB (RT applied to output of TS applied to L6).

We used a balanced design where each participant would (after taking the vocabulary pre-test described above) see each of the 5 news stories in exactly one of the 5 versions in a Latin square design. For each comprehension test, the news summary was shown for a maximum of 150 seconds, after which it was removed and 5 multiple choice comprehension questions presented, which was available for another 150 seconds (2.5 minutes). Participants could finish before the 150 seconds by clicking a "finished" button. Table 3 shows the average length of text in each version.

Results: The first row in Table 2 shows the accuracy (proportion of comprehension questions answered correctly) on the main comprehension test for participants divided into four categories based on their estimated vocabulary from the pre-test. We do not find any significant differences, but it appears that the main benefits of automatic text simplification are for moderate readers (vocabulary between 5K and 8K).

We found a very poor correlation between participants' self reported English language skills and their performance on the vocabulary test ($\rho = -0.01$; $p = 0.55$). The poor correlation was due to certain participants over-estimating their skills. Out of 50 participants, 3 rated themselves as native. However, they could get only about 28% of the answers correct, showing the fact that the participants had over-estimated themselves.

This caused us to doubt the reliability of our version of the vocabulary test[10]. We therefore also attempted to categorise participants based on their overall accuracy over all 25 questions in the com-

[8]The original test uses 10 words from each level, but we required a shorter version.

[9]`www.breakingnewsenglish.com`

[10]The published results are for a 140 question test taking 40 minutes, which we have had to reduce to 28 questions for practical reasons.

Table 3: Effect of simplification of sentence and document lengths

prehension test. While the thresholds of 5000, 8000 and 9000 for vocabulary size are derived from the literature, we had to set these threshold for comprehension scores. To do this in an objective (though still arbitrary) manner, we selected thresholds numerically similar to the vocabulary size thresholds: Excellent ($acc \geq 0.9$), Good($0.9 > acc >= 0.8$), Moderate ($0.8 > acc \geq 0.5$) and Poor ($acc < 0.5$).

The second row in Table 2 shows the accuracy of participants when categorised by average accuracy on the comprehension questions. Note that this categorisation is posthoc (though we have used thresholds derived from the vocabulary test to be objective), and the results pertaining to this categorisation should be regarded as preliminary. This new categorisation based on observed reading ability, rather than predicted language skills, throws up more definitive results. We fitted a Generalised Linear Mixed Model (GLMM), with "correct" answer as the (binary) dependent variable, text "version" (L4, L6, TS, RT, HYB) and "comprehension" (Excellent, Good, Moderate, Poor) as the fixed effects and participant and question as the random effects. We found a strong main effect of comprehension (comprehension=moderate, $z = -3.178$, $p = 0.001$; comprehension=poor, $z = -4.858$, $p < 0.0001$) and a weak effect of version (version=L4, $z = -1.797$, $p = 0.073$); i.e., these three conditions predict a reduced accuracy on the test. We also found a weak interaction between comprehension and version (comprehension=moderate:version=TS, $z = 1.78$, $p = 0.075$); i.e., that TS increases correct answers for readers with moderate reading skills ($p = 0.075$).

Note that L4, RT and HYB all omit information through compression (Table 3 shows text lengths). This explains the drop in comprehension for these versions, as some information needed to answer a question might have been omitted from the summary. Note also that RT and the HYB systems are competitive with the manual simplification L4 for moderate and good readers. Table 4 provides sample texts to illustrate differences.

L6	The United Nations has warned that the Central African Republic (CAR) needs urgent help. The UN Deputy Secretary-General Jan Eliasson said it was 'descending into complete chaos before our eyes'. The landlocked nation has been slowly moving towards a state of total anarchy since rebels seized power in March.
L4	The U.N. has asked for urgent help for the Central African Republic. The UN's Jan Eliasson said it was 'descending into complete chaos'. There is almost a state of anarchy after rebels took power in March.
TS	The United Nations has warned that the Central African Republic , CAR , needs urgent help. The UN Deputy Secretary-General Jan Eliasson said: It was ' descending into complete chaos before our eyes '. The landlocked nation has been slowly moving towards a state of total anarchy. This happened since rebels seized power in March.
RT	The Nations has warned that the Republic needs help. The Deputy Secretary-General Jan Eliasson said it was descending into complete chaos before our eyes. The nation has been slowly moving towards a state of anarchy since rebels seized power in March.

7 Conclusions

We have described and evaluated two different text simplification systems, one that performs lexical and syntactic simplification, and another that performs sentence compression, optimised for the text simplification task. Both systems and their combination outperform a leading contemporary system. The evaluation of reading comprehension with non-native speakers provides preliminary results that automatic text simplification can facilitate comprehension for moderate readers, but not for good ones. A larger evaluation with moderate readers in necessary to confirm this. Finally we plan to make the TS and RT systems available to the public under the Creative Commons license.[11]

Abstract

The relationship between how people describe objects and when they choose to point is complex and likely to be influenced by factors related to both perceptual and discourse context. In this paper, we explore these interactions using machine-learning on a dialogue corpus, to identify multimodal referential strategies that can be used in automatic multimodal generation. We show that the decision to use a pointing gesture depends on features of the accompanying description (especially whether it contains spatial information), and on visual properties, especially distance or separation of a referent from its previous referent.

1 Introduction

The automatic generation of multimodal referring actions is a relatively under-studied phenomenon in Natural Language Generation (NLG). While there has been extensive research on Referring Expression Generation (REG) focusing on the choice of content in expressions such as (1) below (Dale, 1989; Dale and Reiter, 1995; Krahmer and van Deemter, 2012), their multimodal counterpart – exemplified in (2) – raises questions that go beyond these choices.

(1) the group of five large red circles

(2) there's a group of five large red ones [+pointing gesture with arm extended]

One important question concerns the appropriateness of a pointing gesture under different conditions. The relevant conditions here include both the physical or perceptual common ground shared by interlocutors (for example, what other objects are in the vicinity of the target referent, and therefore potentially confusable with it), the discursive common ground (for example, whether this object has been referred to before) and the content of the interlocutor's speech act, that is, what she chooses to say in addition to pointing. For example in (2), the speaker, who is engaged in a dialogue in which she needs to guide her interlocutor through a route on an abstract map (see Section 3 below), has chosen to use the cardinality of the referent (it is a group made up of five circles), its size, and its colour. Her choice of properties may be sufficient to distinguish it from all its distractors in the current context. However, unlike (1), (2) is a *composite utterance* consisting of two communicative modalities, each of which contributes to the communicative intention (Enfield, 2009).

This paper addresses the question of when a pointing gesture is appropriate as part of a composite, multimodal referring action. This is an important component of many multimodal generation systems, including those that communicate through embodied agents. We address this question in a data-driven manner, using a corpus of dialogues in which references have been annotated at both the level of speech and gesture. Our aim is to learn strategies for combinations of pointing and describing, as a function of perceptual and discursive features. We first summarise some relevant psycholinguistic and computational work (Section 2), before describing our corpus data (Section 3) and reporting on the machine-learning experiments conducted (Section 4). Section 5 concludes with some remarks on future work.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2007–2017, Dublin, Ireland, August 23-29 2014.

2 Pointing and reference

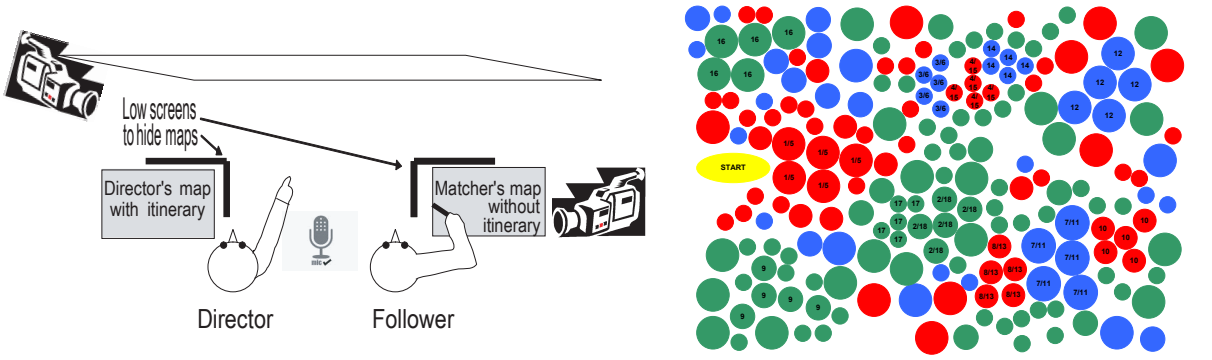
The idea that gesture and speech are planned separately, incorporated in early work on multimodal generation (André and Rist, 1996) is contradicted by more recent psycholinguistic research, in which gesture and language are increasingly viewed as tightly coupled (Kita and Özyürek, 2003; McNeill, 1985; McNeill and Duncan, 2000), contributing jointly to the composite utterances (Enfield, 2009). This view has also influenced recent work in multimodal NLG. For example, Kopp et al. (2008) use 'multimodal concepts', combining propositional and gestural or perceptual information.

In the case of referring expressions, pointing has been treated as a property, on a par with an object's colour or size. Thus, van der Sluis and Krahmer (2007) propose an algorithm in a graph-based framework (Krahmer et al., 2003) which selects pointing gestures of varying degrees of precision based on their cost when compared to other linguistically realisable features. Similarly, Kranstedt and Wachsmuth (2005) propose an extension of Dale and Reiter's (1995) Incremental Algorithm, which initially considers the possibility of producing an unambiguous pointing gesture. If this fails, a pointing gesture that is less precise may be generated, together with descriptive features of an object.

Both of these approaches assume that the choice of modality in a referring action ultimately hinges on a trade-off between what can be said and what is easiest to produce, a view that has some empirical support (Beun and Cremers, 1998; Bangerter, 2004; Piwek, 2007). On the other hand de Ruiter et al. (2012) found that likelihood of pointing was unaffected by the difficulty of using descriptive features. From a computational perspective, our earlier work (Gatt and Paggio, 2013) also found evidence, based on a machine-learning study on dialogue data, for the co-occurrence of pointing with descriptive (especially spatial) features, suggesting that pointing gestures may be planned in tandem (and not in competition) with these features.

The present paper uses the same corpus data as Gatt and Paggio (2013); however, that paper focused on the relationship between descriptive features (in the spoken part of the utterance) and pointing. In contrast, here we take a much broader view, also addressing the impact of the physical/perceptual features of the objects under discussion, and aspects of the discourse history.

3 Data used in this study



(a) Experiment setup

(b) Group circles map (numbers indicate the order in which landmarks are visited along the itinerary)

Figure 1: MREDI dialogue setup (reproduced from Gatt and Paggio (2013)).

We use the MREDI (Multimodal REference in DIalogue) corpus (van der Sluis et al., 2008; Gatt and Paggio, 2013), a collection of MapTask-like dialogues (Anderson et al., 1991). Dialogues in MREDI were conducted by dyads consisting of a Director and a Follower. The Director's task was to guide the Follower along a route through a visually shared 'map', located approximately one metre away, directly in front of them, blown up to roughly A0 size. The Director also had a private map on which the route was indicated, while the Follower's private map was used to mark the route as it unfolded in the course of the conversation. Figure 1a displays the basic setup.

There were no restrictions on what interlocutors could say. Participants in the study were told in advance that they could use both speech and gestures, but were not explicitly instructed to point. The maps consisted of collections of shapes of different colours and sizes and were very densely populated (see Figure 1b). Four maps were used in the study: in two of these, landmarks consisted of individual circles or squares, while in the other two they consisted of groups or clusters of five circles or squares (Figure 1b is a group circle map). In the group maps, all elements of a group of five were of the same colour and size.

On each map, there were 18 'landmarks'; these were the milestones along the itinerary and were marked on the Director's private map, but not visible on the large map that constituted the common ground. For example, the landmarks (groups of 5 circles) in Figure 1b are numbered from 1 to 18. Each dyad did all four maps; the order was randomised for each pair of participants. Participants switched roles between one map and another. In addition to the difference between group and individual landmarks, the maps were designed to manipulate a number of independent variables:

1. **Distinguishing Properties (DistProps):** Landmarks on the itinerary differed from their distractors – the objects in their immediate vicinity (the *focus area*) – in colour, or in size, or in both colour and size. The focus area was defined as the set of objects immediately surrounding a target. This means that different landmarks required different combinations of properties to ensure that they could be unambiguously identified by a description. For example, in Figure 1b, the group marked 17 consists of a landmark where size is the distinguishing feature, since all five circles in the group are small, and the objects in their immediate vicinity are either large or medium-sized. There were equal numbers of landmarks on each map that could be distinguished by colour only, size only, or both.

2. **Prior reference (Discourse):** Some of the landmarks were visited twice in the itinerary; these are indicated using two numbers in Figure 1b. Thus, landmark 8 in this map was also visited later as landmark 13. There were 6 landmarks on each map that were revisited in this way. This is the primary manipulation related to discourse history.

3. **Shift of domain focus (Distance):** Landmarks were located either near to or far away from the previous target. For example, in Figure 1b, landmark 17 and landmark 18 are adjacent ('near' condition), but landmark 17 is far from the preceding landmark 16.

In what follows, we use data from 8 dyads. Similar to Gatt and Paggio (2013), we only consider utterances by Directors. These were transcribed and split up according to the landmark to which they corresponded. In case a landmark was described over multiple turns in the dialogue, each turn was annotated as a separate utterance. Our dataset consists of a total of 2255 such utterances, of which 370 (16.4%) contain a pointing gesture. This is a relatively low proportion of such gestures, compared to some previous studies, such as Beun and Cremers (1998), who found that 48% of referential acts in their task-oriented dialogue corpus included a pointing gesture. However, Beun and Cremers focussed exclusively on first-mention referring expressions. Furthermore, the low proportion of pointing gestures in MREDI may be due to the fact that under our definition, the identification of a landmark may be spread over several turns, with possible interruptions by the Follower. Each such turn constitutes a separate utterance. This raises the likelihood that certain features of the composite utterance, including pointing, will only occur on some of the turns.

3.1 Features

Utterances in MREDI were annotated with the features displayed in Table 1. These codify aspects of the descriptive content of a referential act, as well as the presence or absence of a pointing gesture.

The features originally encoded in the MREDI corpus had frequency values; Gatt and Paggio (2013) used these frequencies in their study. However, for our experiments, we collapsed the features related to descriptive content – hereafter referred to as *descriptive* features – into boolean features. This significantly reduces the feature set and makes the rules acquired in our machine-learning experiments easier

	Feature	Name	Definition	Example
Visual	S	Size	mention of the target size	*the group of small circles*
	Sh	Shape	mention of the target shape	*the circles at the bottom*
	C	Colour	mention of the target colour	*The blue square near the red square*
Deictic/anaphoric	ID	Identity	Statement of identity between the current and a previous or later target	*the red square, the same one we saw at number 5*
	D	Deixis	Use of a deictic reference	*those squares*
Locative	RP	Relative position	Position of the target landmark relative to another object on the map	*the blue square just below the red square*
	AP	Absolute position	Target position based on absolute frame of reference	*The blue circle down at the bottom*
	FP	Path references	References to non-targets on the path leading to the target.	*go east to the first tiny square, past the blue one*
	DIR	Directions	Direction-giving.	*take a right, go across and straight down*
Action	GZ	Gaze	Gaze at the shared map (boolean).	
	Point	Pointing	Use of a pointing gesture (boolean).[1]	

Table 1: Features annotated in the dialogues. All features have frequency values, except for the Action features, which are boolean.

to interpret. Further, it enables us to test our hypothesis that the presence or absence of a *type* of feature (descriptive, physical or discursive) impacts the decision to point. The boolean descriptive features are as follows:

1. **Deixis**: this has the value `true` if the utterance contains a demonstrative pronoun (such as *that*), or a reference to the landmark that identifies it with the previous landmark. Thus, this feature is `true` if $ID > 0$ or $D > 0$ in Table 1;

2. **Locative**: this has the value `true` if the utterance contains any of the spatial properties in Table 1. Thus, the feature is `true` if $AP > 0$ or $RP > 0$ or $FP > 0$ or $DIR > 0$.;

3. **Visual**: this has the value `true` if the utterance contains at least one mention of the landmark's visual properties. This, the feature is `true` if $C > 0$ or $Sh > 0$ or $S > 0$.

In addition to these features, our experiments also made use of the *physical* features (**Distance** and **DistProps**) manipulated as part of the MREDI data collection study (see above), as well as the feature **Discourse**, which encodes prior reference.

Finally, we added a new feature to the dataset, **MapConfl**, which indicates the type of map on which utterances were produced, namely, individual or group circles or squares. This feature was included because the larger size of group landmarks, compared to individuals, may have influenced the decision to point, since groups are more visually salient.

The feature *Gaze* is present whenever a pointing gesture is made; hence, it is not used in the machine learning experiments reported below.

4 Experiments

In our earlier study on the MREDI corpus (Gatt and Paggio, 2013), investigating the relationship between pointing and descriptive features, we found that the latter could indeed be used as predictors of pointing gestures with an accuracy of 0.833 (F-score). The study also concluded that among the descriptive features it was locative properties that were most useful in guiding the decision of whether or not to point, compared to features describing visual characteristics of the objects.

However, in much of the work reviewed in Section 2, especially work arguing in favour of a trade-off in cost between pointing and describing, the occurrence of pointing is made to depend on the physical properties of referents. Therefore, in the present study we want to test whether the occurrence of pointing

gestures can be predicted more accurately as a function of (i) the descriptive features that speakers use to refer to landmarks; (ii) the physical/perceptual context in which they are found and (iii) whether or not they have been referred to earlier in the discourse. Furthermore, we want to investigate which combinations of physical and descriptive features provide the best results.

Two sets of experiments were conducted on different versions of the MREDI dataset. The first dataset (referred to as the complete dataset) is the same one used in the Gatt and Paggio (2013) study. It includes all of the 2255 Director's utterances from the eight dyads in the corpus, including those that did not contain any references at all, linguistic or gestural. Such utterances might, for example, be confirmations or feedback produced in the course of the dialogue.

We also report results on a second dataset (referred to as the referential dataset), consisting of all utterances that contain a reference, either using descriptive features, pointing, or both. This dataset consisted of 1542 utterances. Note that the number of utterances with a pointing gesture is still 370 in the pruned dataset.

The task in the experiments was to classify the binary feature *Point*. As mentioned earlier, 370 of these utterances contain a pointing gesture. In other words, there are 370 occurrences of *Point=1*.

All the experiments were run using the Weka tool (Witten and Frank, 2005), which gives access to many different algorithms, using 10-fold cross-validation throughout. In the experiments with the complete dataset, the ZeroR and OneR classifiers were first run on the data to establish a baseline. ZeroR always chooses the most frequent value of the class that is being predicted; in the present case, it consistently classifies all utterances as *Point = 0*, since the majority of utterances do not containg pointing gestures. OneR identifies a single feature, on the basis of which all classifications are made. On the MREDI data, OneR always assigned *Point = 0* to all utterances, based on a single rule using the *MapConfl* feature (i.e. the type of map or domain in which the dialogue was being carried out). Note that both baseline classifiers were trained using all features.

Various combinations of descriptive and physical features were then tested using different classifiers in Weka, including NaiveBayes, Support Vector Machines, Maximum Entropy (Logistic in Weka) and the J48 Decision Tree classifier. The present paper will report results for the last two of these, for the following reasons. First, these were the ones which performed best. In addition, the decision trees built by J48 provide an analysis tool to understand how the various features interact, given their transparency; on the other hand, MaxEnt sometimes outperforms J48 and provides a 'ceiling', in addition to the baselines described above.

The strategy used in testing feature combinations was essentially ablative. We tested first using all features, and then compared the performance of the classifiers when they use only descriptive features (Visual, Locative and Deixis), or only Discourse together with the physical features (DistProps and Distance). Omitting descriptive features and using only physical features with Discourse invariably performed near or below baseline (see below). Thus, we experimented with combinations of descriptive features and each physical feature, as well as Discourse, individually.

4.1 Results on the complete dataset

The results for the complete dataset are shown in Table 2 in terms of Precision, Recall and F-measure for each of the classifiers. The top rows display the results using all features, while the baseline results are in the bottom rows. The remaining results for different combinations of features are in descending order of F-score.

Interestingly, using all features – i.e. MapConfl, DistProps, Discourse, Distance, Visual, Locative and Deictic – with or without MapConfl, results in worse overall performance than using a combination of descriptive features (Locative, Deictic and Visual) with Distance. This combination is closely matched for accuracy by the combination involving descriptive features, Distance and DistProps. However, dropping Distance (using only descriptive features and DistProps) results in worse performance.

The addition of Distance and/or DistProps clearly improves the predictive accuracy of a classifier that uses descriptive features. However, the worst combination is found when the descriptive features are excluded. This is in line with the results reported by Gatt and Paggio (2013), who found that features of

Classifier	P	R	F	Features
J48	0.827	0.847	0.832	All
Logistic	0.831	0.854	0.828	All
J48	0.833	0.851	0.838	All - MapConfl
Logistic	0.832	0.851	0.837	All - MapConfl
Logistic	0.839	0.853	0.844	Descriptive + Distance
J48	0.839	0.853	0.844	Descriptive minus Deictic + Distance
Logistic	0.839	0.853	0.844	Descriptive minus Deictic + Distance
J48	0.836	0.851	0.84	Descriptive+DistProps + Distance

Table 2: Predicting pointing gestures with different feature combinations in the complete MREDI dataset.

the descriptions produced by speakers were good predictors of pointing.

Adding only DistProps to the descriptive features improved the accuracy of the Logistic classifier somewhat, though it had a greater impact on J48. However, Distance seems to have the greatest impact of the two physical features. Discourse does not appear to play an important role: incorporating this feature does not result in much improvement over using only descriptive features; indeed, in the case of J48, it decreases accuracy.

We also tested one of the best combinations involving descriptive features and Distance but excluding the Deictic feature from the set of descriptive features. This was done because pointing in referential acts is frequently viewed on a par with deictic expressions, insofar as they are both indexical (Bangerter, 2004). This raises the question whether, out of all the descriptive features, Deixis could be considered a somewhat redundant predictor. The results suggest that removing Deixis from the descriptive features does not alter the accuracy of the classifier. We return to the role of Deixis in the discussion in Section 4.3.

4.2 Results on the referential dataset

Exactly the same combinations of features were tested, using 10-fold cross-validation, in separate experiments on the referential dataset. This was done in order to compare the results on a dataset which contains less 'noise', that is, fewer utterances which were non-referential. Such utterances may compromise the predictive validity of certain features, as they inflate the number of utterances in which *Point=0*.

Table 3 contains the results obtained on the reduced dataset. The accuracy is in general lower due to the fact that predicting the absence of pointing is easier in the complete dataset, where many utterances contain no reference at all, descriptive or gestural.

Contrary to the findings on the complete dataset, using the complete set of features as predictors of pointing gives slightly better results than using either descriptive or physical features alone, at least in

Classifier	P	R	F	Features

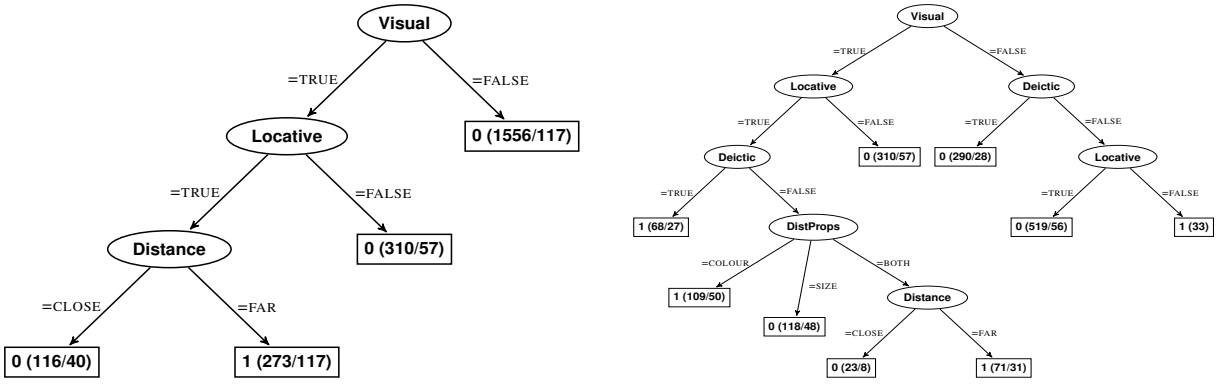
Table 3: Predicting pointing gestures with different feature combinations in the referential MREDI dataset.

the case of the decision tree classifier. This combination also exceeds the combination of descriptives, DistProps and Distance, though only marginally. However, this does remain the next best combination for J48, consistent with the results on the complete dataset. However, this combination performs quite badly in the case of the Logistic classifier.

The fact that using all features performs better this time is probably due to the fact that there are fewer non-referential utterances in this dataset. Once again, the role of Discourse seems marginal.

4.3 Analysis and discussion

Figure 2 shows the decision trees built by J48 for the two datasets when descriptive features are used together with *DistProps* and *Distance*.



(a) Complete MREDI dataset

(b) Referential MREDI dataset

Figure 2: J48 Decision trees from the complete and referential datasets

Our main findings can be summarised as follows. First, descriptive features play an important role in

the prediction of pointing; this replicates previous observations (Gatt and Paggio, 2013). Second, and more importantly, the prediction accuracy improves when physical features, representing aspects of the visual/perceptual context, are taken into account. This is especially true of Distance, suggesting that a sizeable shift of perceptual focus, from one landmark to another further away, motivates a pointing gesture, as shown in both trees in Figure 2. Once again, it is worth comparing this to the results of Beun and Cremers (1998), who find that shifts of perceptual focus play a role in increasing the amount of (descrpitive) information speakers include in a referring expression. However, they find no impact of focus shifts on pointing gestures; our results, by contrast, suggest that such shifts do play a role.

There are a number of striking features in the trees in the figure. First, the descriptive feature Locative plays a crucial role. All cases of pointing involve the presence of a Locative, with one exception: on the referential dataset (Figure 2b), in case no Visual, Deictic or Locative features are used, the tree predicts a pointing gesture. However, this case covers a very small number of instances (33), with 0% error rate. All of these turn out to be utterances where there is no descriptive reference at all and speakers rely exclusively on pointing. Example (3) below is typical of these.

(3) D: And a slightly bigger green to the right of that
M: M-hm
D: In the center of those like pack
M: Yeah
D: is number 9. [+pointing]

Clearly, these are cases in which the pointing gesture occurs as part of an extended sequence of utterances which jointly identify a landmark. Descriptive features have already been uttered; the pointing comes at the very end. In summary, the one case where Locatives don't feature in predicting a pointing gesture turns out to be a rather special case.

A second striking aspect of the trees is that while Deixis plays a predictive role in the tree based on the referential dataset, it doesn't in the case of the complete dataset. This is interesting in view of the relationship that has often been noted between referential pointing gestures and deictic expressions (Bangerter, 2004). Note, however, that there is no inconsistency between the two trees: the single path through the tree in Figure 2a that results in pointing is subsumed by the path in Figure 2b which specifies in addition that Deixis should be `false`, and DistProps should have the value `colour`. This still leaves open the question why Deixis plays no role in the full dataset, despite being included as part of the descriptive features that resulted in this tree. Indeed, we have already shown that, among the descriptive features, Deixis doesn't contribute much predictive power on the full dataset (see Section 4.1).

One possibility is that Deixis is generally under-represented in the corpus. However, there are proportionately fewer utterances in the full dataset containing Deixis (20%), compared to the referential dataset (30%). Furthermore, it may be partially dependent on the Locative features. There may be a priori reasons to assume this as a working hypothesis: Deixis anchors parts of the speech signal to physical properties of the common ground, potentially making it redundant with respect to location (which has already specified the relevant physical/spatial features of the common ground).

	Complete Dataset		**Referential Dataset**	
Locative	*Deictic*		*Deictic*	
	`false`	`true`	`false`	`true`
`false`	74	26	42	58
`true`	88	12	88	12
overall	80	20	70	30

Table 4: Deictic features (D and ID) relative to Locatives. All figures are percentages.

Table 4 displays the distribution of Deictic expressions with respect to Locatives, that is, the proportion of utterances containing a Deictic expression as a function of whether the utterances also contain a Locative expression. The tables shows proportions both for the full and the referential dataset.

Note that when Deictics are used, it is mostly in the absence of a Locative expression. A chi-square test of independence suggests that the frequency of use of Locative and Deictic expressions are not independent (complete dataset: $\chi^2_1 = 63.044, p < .001$; referential: $\chi^2 = 358.21, p < .001$). However, there is a higher proportion of Deictic expressions in the referential dataset (30% overall); this may account for the use of this feature in the decision tree for this dataset (it is more informative). Crucially, the trend in the use of deictic expressions is reversed in the two datasets: when Locative is `false` on the referential dataset, most utterances involve a deictic expression; the reverse is true on the complete dataset.

There is one path through the tree in Figure 2b which seems to contradict the hypothesis that deictic expressions are used in the absence of locatives. There are 68 cases where pointing is used when both Deictic and Locative are `true`. One possibility is that this is caused by our having defined the Deictic feature as `true` whenever there is an actual deictic expression (variable D in Table 1; e.g. *those squares*) or an identity expression (variable ID; e.g. *the same one we saw*). To investigate this further, Table 5 shows a breakdown of the frequencies of the presence or absence of a locative expression, as a function of whether a true deictic (D) or an identity expression (ID) is used in an utterance. Once again, proportions are displayed for both datasets.

True Deictic	**Complete dataset** *Locative*		**Referential dataset** *Locative*	
	`false`	`true`	`false`	`true`
`false`	54	46	26	74
`true`	78	22	76	24

(a) True deictic expressions (D)

Identity	**Complete dataset** *Locative*		**Referential dataset** *Locative*	
	`false`	`true`	`false`	`true`
`false`	56	44	31	69
`true`	68	32	67	33

(b) Identity expressions (ID)

Table 5: Identity (ID) and actual Deictic (D) expressions relative to Locatives. All figures are percentages.

There are two observations that stem from these proportions: First, in line with our earlier observations, there is a greater proportion of true deictic (D) expressions in utterances that contain no locative expression. For example, 78% of utterances in the complete dataset that have no locatives contain a deictic; the corresponding figure in the referential dataset is 76%. The same pattern holds for identity (ID) expressions. Second, out of the utterances that do not contain a locative, the proportion containing a true deictic (D) is greater than the proportion containing an identity expression (ID). This may explain the apparent exception – represented by the path in Figure 2b – to our generalisation that locatives and deictics are redundant with respect to each other, and locatives tend to be avoided if deictics are used. The explanation may lie in the conflation, in the boolean Deictic feature used in our experiments, of true deictics and identity expressions. The path in the decision tree where both Locative and Deictic are `true` may be accounting for utterances in which an identity expression is used, rather than a true deictic.

5 Conclusions and future work

This paper addressed the question of when pointing gestures should be generated, as a function of the features a speaker uses to identify a referent, as well as the features of the context in which an utterance is being produced. The best predictors of pointing are descriptive features, especially locatives, and features of the perceptual context, especially distance from the last referent. The latter is a marker of a shift of perceptual focus, akin to the focus shifts identified by Beun and Cremers (1998). Our study also sheds light on the relationship between pointing and the use of deictic expressions, suggesting that, while the two are often used together, deictics tend to be used more in the absence of locative features.

We also note some limitations of our methodology. Inspection of the results in Tables 2 and 3 shows that the best performing classifiers, though they exceed baselines, do not do so by a wide margin. We believe that one of the main reasons for this is the relative scarcity of pointing gestures in our dataset (as discussed in Section 3), which may have resulted in a sizeable subset of utterances where pointing was relatively straightforward to predict (e.g. based on one feature, as in the `OneR` baseline classifier). This is a limitation we intend to investigate in future work, through a more diverse dataset where pointing

features more strongly. In addition, it is worth noting that the ablative testing reported here does suggest that certain features play a greater role in determining when speakers choose to point.

Our work addresses an important question in Natural Language Generation systems that seek to generate multimodal referring acts, namely, how pointing and describing should be combined and when. In future work, we intend to extend this research in two ways: first, by extending our focus to incorporate the interactive features of a dialogue and their impact on referential success; and second, by focusing on other domains with a view to testing the generalisability of the results.

Generating Acrostics via Paraphrasing and Heuristic Search

Benno Stein **Matthias Hagen** **Christof Bräutigam**

<first name>.<last name>@uni-weimar.de

Abstract

We consider the problem of automatically paraphrasing a text in order to find an equivalent text that contains a given acrostic. A text contains an acrostic, if the first letters of a range of consecutive lines form a word or phrase. Our approach turns this paraphrasing task into an optimization problem: we use various existing and also new paraphrasing techniques as operators applicable to intermediate versions of a text (e.g., replacing synonyms), and we search for an operator sequence with minimum text quality loss. The experiments show that many acrostics based on common English words can be generated in less than a minute. However, we see our main contribution in the presented technology paradigm: a novel and promising combination of methods from Natural Language Processing and Artificial Intelligence. The approach naturally generalizes to related paraphrasing tasks such as shortening or simplifying a given text.

1 Introduction

Given some text, paraphrasing means to rewrite it in order to improve readability or to achieve other desirable properties while preserving the original meaning (Androutsopoulos and Malakasiotis, 2010). The paper in hand focuses on a specific paraphrasing problem: rewriting a given text such that it encodes a given acrostic. A text contains an acrostic if the first letters of a range of consecutive lines form a word or phrase read from top to bottom. A prominent and very explicit example of former Governor Schwarzenegger is shown in Figure 1 (see the third and fourth paragraphs). Schwarzenegger himself characterized the appearance of that acrostic a "wild coincidence".[1] However, such a coincidence is highly unlikely: Using the simplistic assumption that first letters of words are independent of each other if more than ten words are in between (line length in the Schwarzenegger letter) and calculating with the relative frequencies of first letters in the British National Corpus (Aston and Burnard, 1998), the probability for the acrostic in Figure 1 can be estimated at $1.15 \cdot 10^{-12}$. Typically, a given text will not contain a given acrostic but has to be reformulated using different wording or formatting to achieve the desired effect. Thus we consider the purposeful generation of acrostics a challenging benchmark problem for paraphrasing technology, which is subject to soft and hard constraints of common language usage.

The paper shows how heuristic search techniques are applied to solve the problem. Different paraphrasing techniques are modeled as operators applicable to paraphrased versions of a text. By pruning the so-formed search space and by employing a huge corpus of text n-grams for the possible operators, we are able to generate acrostics in given texts. Our algorithmic solution is a novel combination of techniques from Natural Language Processing and Artificial Intelligence. We consider such combinations as a very promising research direction (Stein and Curatolo, 2006; Sturtevant et al., 2012), and we point out that the problem of acrostic generation serves as a serious demonstration object: the presented model along with the heuristic search approach generalizes easily to other paraphrasing tasks such as text shortening, improving readability, or e-journalism.

2 Related Work and Problem Definition

Rewriting a given text in order to "encode" an acrostic is a paraphrasing problem, which in turn is studied in the domain of computational linguistics and natural language processing. We review relevant literature

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2018–2029, Dublin, Ireland, August 23-29 2014.

To the Members of the Californian State Assembly:

I am returning Assembly Bill 1178 without my signature.

For some time now I have lamented the fact that major issues are overlooked while many unnecessary bills come to me for consideration. Water reform, prison reform, and health care are major issues my Administration has brought to the table, but the Legislature just kicks the can down the alley.

Yet another legislative year has come and gone without the major reforms Californians overwhelmingly deserve. In light of this, and after careful consideration, I believe it is unnecessary to sign this measure at this time.

Sincerely,
Arnold Schwarzenegger

Figure 1: Excerpt from a letter of former Governor Arnold Schwarzenegger to the Californian State Assembly in October 2009. The third and fourth paragraphs contain the acrostic "F∗∗∗ You".

of the topic and highlight techniques that will be employed in our work.

An important branch of the paraphrasing literature focuses on analyses with fixed corpora. Such corpora typically are *parallel* in the sense that they contain different formulations of the same facts (Barzilay and McKeown, 2001; Barzilay and Lee, 2003; Callison-Burch, 2008). These "facts" can be news articles on the same event (Clough et al., 2002; Dolan and Brockett, 2005), different translations of a source text to a target language (Pang et al., 2003), or cross-lingual parallel corpora (Bannard and Callison-Burch, 2005). As most of the early parallel corpora were constructed manually (especially the judgments of whether a pair of sentences forms a paraphrase), there are two shortcomings. First, the obtained paraphrases are usually specific to the domain covered in the corpus (e.g., showbiz news) and often do not generalize well. Second and probably more severe is the fact that manually building parallel corpora is very expensive, such that the available ones are rather small: the METER corpus contains only 1717 texts on legal issues and showbiz (Clough et al., 2002), the MSRP corpus contains only 5801 sentence pairs (Dolan and Brockett, 2005). Recently, new methods employ machine learning techniques to automatically build larger paraphrase collections from parallel corpora (Ganitkevitch et al., 2011; Ganitkevitch et al., 2013; Metzler et al., 2011; Metzler and Hovy, 2011). We include the paraphrase database (Ganitkevitch et al., 2013)—a database of extracted patterns from such large scale corpora—as one source of potential paraphrases in our algorithm.

Compared to the large body of literature that "extracts" paraphrases from (parallel) corpora, there is relatively little work on automatically paraphrasing a given text. Some of the early generation methods are based on rules that encode situations wherein a reformulation is possible (Barzilay and Lee, 2003). A problem with rules is that often the rather complicated patterns extracted from text corpora are hardly applicable to a given to-be-paraphrased text: manually created corpora are simply too small and machine generated paraphrasing rules often do not match in a given text. Other early methods use machine translation (Quirk et al., 2004). However, the need for large and expensive parallel manual translation corpora cannot be circumvented by using multiple resources (Zhao et al., 2008).

Another branch of paraphrasing methods is based on large thesaurus resources such as WordNet (Fellbaum, 1998). The idea is to insert synonyms into a text when the context fits (Bolshakov and Gelbukh, 2004; Kauchak and Barzilay, 2006). The most recent approaches are statistics-based (Chevelu et al., 2009; Chevelu et al., 2010; Zhao et al., 2009; Burrows et al., 2013).

Compared to the existing research, we have a more difficult use case here. Existing paraphrase generation focuses on sentence paraphrasing, while we have to consider a complete text that has to be rewritten/reformatted in order to contain a given acrostic. We will employ the above shown state-of-the-art paraphrasing procedures as "operators" in our approach. This new problem setting of applying different operators to a complete text forms a search problem with a huge search space. In order to deal with this search space, we apply powerful search heuristics from Artificial Intelligence. The combination of heuristic search with established text level paraphrasing techniques represents a new approach to tackle problems in computational linguistics. The acrostic generation problem is defined as follows:

ACROSTIC GENERATION

Given: (1) A text T and an acrostic x.
(2) A lower bound $l_{\min}$ and an upper bound $l_{\max}$ on the desired line length.

Task: Find a paraphrased version T^* of T in monospaced font that encodes x in some of its lines when possible. Each line of T^* has to meet the length constraints.

3 Modeling Paraphrasing as Search Problem

This section shows how to model paraphrasing in general and ACROSTIC GENERATION in particular as a search problem (Pearl, 1984). The search space is a universe $\mathcal{T}$ of candidate texts for which we can devise, at least theoretically, a systematic search strategy: if $\mathcal{T}$ is finite, each element $n \in \mathcal{T}$ is analyzed exactly once. The elements in $\mathcal{T}$ represent states (nodes), and there is a limited and a-priori known set of possibilities (edges, paraphrasing operators) to get from a node n to an adjacent or successor node n_i. A paraphrasing operator ϕ provides a number of parameters that control its application. Each state $n \in \mathcal{T}$ is considered an acrostic (sub)problem; the dedicated state $s \in \mathcal{T}$ represents the original problem while $\Gamma \subset \mathcal{T}$ is the set of solution nodes that have no problem associated with. The following subsections will outline important properties of the search space and introduce a suited cost measure to control the exploration of $\mathcal{T}$.

3.1 Search Space Structure

Solving an instance of ACROSTIC GENERATION under a so-called state-space representation means to find a *path* from s, which represents the original text T, to some goal state $\gamma \in \Gamma$. The problem of finding an acrostic consists of tightly connected subproblems (finding subsequences of the acrostic) that cannot be solved independently of each other. Most puzzles such as Rubik's cube are of this nature: changing a decision somewhere on the solution path will affect all subsequent decisions. By contrast, a so-called problem-reduction representation will exploit the fact that subproblems can be solved independently of each other. Many tasks of logical reasoning and theorem proving give rise to such a structure: given a set of axioms, the lemmas required for a proof can be derived independently, which in turn means that the sought solution (a plan or proof) is ideally represented by a *tree*.

Searching $\mathcal{T}$ under a state-space representation means to unfold a tree whose inner nodes link to successor nodes that encode alternative decisions; hence these inner nodes are also called OR-nodes. Each path from s that can be extended towards a goal state γ forms a *solution candidate*. Similarly, searching $\mathcal{T}$ under a problem-reduction representation also means to unfold a tree—however, the tree's inner nodes must be distinguished as AND-nodes and OR-nodes, whereas the successors of an AND-node encode subproblems all of which have to be solved. A solution candidate then is a tree comprised of (1) the root s, (2) OR-nodes with a single successor, and (3) AND-nodes with as many successors as subproblems all of which are characterized by the fact of being extensible towards goal states in Γ. Figure 2 contrasts both search space structures.

Under either representation, OR-graphs as well as AND-OR-graphs, the application of a sequence of

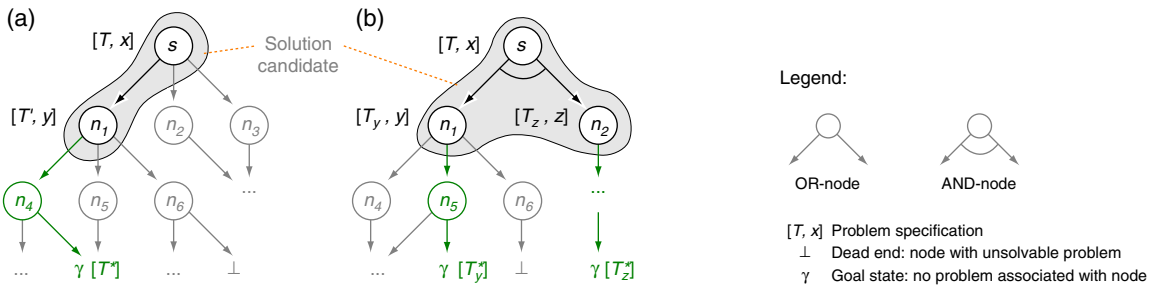

Figure 2: (a) State-space representation (OR-graph) versus (b) Problem-reduction representation (AND-OR-graph). OR-nodes encode alternative decisions, while AND-nodes decompose a problem into subproblems all of which are to be solved.

operators will easily lead to situations where states are revisited—precisely: are generated again. Search algorithms maintain so-called OPEN- and CLOSED-lists to manage the exploration status of generated nodes. However, because of the intricate state encoding, which must inform about the effect of all applied operators from s to an arbitrary node, the exponentially growing number of nodes during search, and the necessity of efficiently querying these lists, sophisticated data structures such as externalized hash tables and key value stores are employed. Typically, these data structures are tailored to the problem domain (here: to paraphrasing), and they model heuristic access strategies to operationalize a probabilistically controlled trade-off between false positive and true negative answers to state queries.

We have outlined the different search space structures since ACROSTIC GENERATION may show an OR-graph puzzle nature at first sight: paraphrasing at some position will affect all following text. Interestingly, there is a limited possibility to introduce "barriers" in the text, which allows for an AND-OR-graph modeling and hence for an isolated subproblem treatment. Examples include paraphrasing operators that do not affect line breaks, or acrostics consisting of several words and thus spanning several paragraphs.

Since in general the underlying linguistic considerations for the construction and maintenance of such barriers are highly intricate and complex, we capture this structural constraint probabilistically as shown in Equation (1). The equation models the problem difficulty or *effort for acrostic generation*, E, and introduces $P_{y \circ z}(|x|)$, which quantifies the probability for the event that an acrostic x can be treated independently as two partial acrostics y and z, where $x = yz$.

$$E(x) = \begin{cases} e(x) & \text{If } |x| = 1. \\ P_{y \circ z}(|x|) \cdot \Big(E(y) + E(z)\Big) + (1 - P_{y \circ z}(|x|)) \cdot E(y) \cdot E(z) & \text{If } |x| > 1. \end{cases} \tag{1}$$

Remarks. The effort for generating a single-letter acrostic of length 1 is $e(x)$, with $e(x) \geq 1$. Based on $e(x)$, we recursively model the *true effort* $E(x)$ for generating an acrostic $x = yz$ as follows: as additive effort if the generation of the acrostics y and z can be done independently, and as multiplicative effort otherwise. Observe how $P_{y \circ z}$ controls the search space structure: if $P_{y \circ z} = 0$ for all partitionings of x into y and z, one obtains a pure state-space representation for ACROSTIC GENERATION. Similarly, the other extreme with $P_{y \circ z} = 1$ results in a series of $|x|$ letter generation problems that can be solved independently of each other.

As an estimate $\hat{e}(x)$ for $e(x)$ we suggest the multiplicative inverse of the occurrence probabilities of the first letters in the English language, as computed from the British National Corpus (BNC). The BNC is a 100 million word collection of written and spoken language from a wide range of sources, designed to represent a wide cross-section of current British English (Aston and Burnard, 1998). The BNC probabilities vary between 0.115719 for the letter "s" and 0.00005 for the letter "z". As an estimate for $P_{y \circ z}$ we suggest the $N(5, 0.5)$ distribution to model the paragraph lengths in T or, equivalently, the number of characters of the (English) words in x. These choices give rise to $\hat{E}(x)$, the *estimated effort* for generating an acrostic x. $\hat{E}(x)$ is used to assess the (residual) problem complexity and, under a maximum likelihood approach, models the expected search effort. There is a close relation between the effort estimate $\hat{E}$ and the quality estimate $\hat{Q}$ introduced below, which will be exploited later on, in Equation (3).

3.2 Cost Measure Structure

Cost measures—equivalently: merit measures—form the heart of systematic search strategies and determine whether an acceptable solution of a complex problem can be heuristically constructed within reasonable time. Here, we refer to general best-first search strategies as well as variants that relax strict admissibility. As a working example consider the following text T about Alan Turing taken from the English Wikipedia, where the task is to generate the acrostic $x = \texttt{Turing}$ with $l_{\min} = 55$ and $l_{\max} = 60$.

```
Alan Mathison Turing was a British mathematician, logician,
cryptanalyst and computer scientist. He was highly influential in
the development of computer science, giving a formalization of the
concepts of algorithm and computation with the Turing machine,
which can be considered a model of a general purpose computer.
```

A possible solution T^* (a paragraph's last line may be shorter than $l_{\min}$):

```
The British mathematician Alan Mathison Turing was also an
unrivaled logician, cryptanalyst and computer scientist. He
revolutionized the development of computer science, giv-
ing a formalization of the concepts of algorithm and defi-
nite computation with the Turing machine, which can be re-
garded a model of a general purpose computer.
```

T^* is of a high quality though it introduces an exaggerating tone, this way violating Wikipedia's neutrality standard. Also note that the applied paraphrasing operators vary in their quality, which is rooted in both the kind and the context of the operators. Table 1 (left) shows a selection of the operators, some of which are applied in a combined fashion. Section 4 introduces the operators in greater detail.

To further formalize the quantification of a cost measure C or a merit measure Q, we stipulate on the following properties:

1. The quality of the original text T cannot be improved. Each paraphrasing operator ϕ introduces unavoidable deficiencies in T.
2. The overall quality of a solution T^* depends on the quality of all applied paraphrasing operators.
3. Following readability theory and relevant research, the severity of text deficiencies—here introduced by a paraphrasing operator ϕ—has a disproportionate impact on the text quality (Meyer, 2003).
4. To render different problems and solutions comparable, the achieved quality of a solution T^* has to be normalized.

Equation (2) below shows the basic structure of Q, the proposed, unnormalized merit measure. Its optimization yields Q^*. $Q^*(n)$ assigns to a node $n \in \mathcal{T}$ the maximum paraphrasing quality of a text T^* that contains the partial acrostic associated with n. Likewise, $Q^*(s)$ characterizes the quality of the optimum solution for solving ACROSTIC GENERATION.

$$\frac{1}{Q^*(n)} = \begin{cases} 0 & \text{If } n \in \Gamma. \\ \min\limits_i \left\{ \dfrac{1}{q(n,n_i)} + \dfrac{1}{Q^*(n_i)} \right\} & \text{Otherwise.} \end{cases} \tag{2}$$

Remarks. The state (node) n_i denotes a direct successor of the state (node) n in the search space $\mathcal{T}$. Associated with n_i is a text resulting from the application of a paraphrasing operator ϕ to the text associated with n, whereas $q(n, n_i)$ quantifies the *local quality* achieved with ϕ. The measure in Equation (2) is both of an additive form and formulated as a minimization problem. As shown in the following, it can be reformulated for a best-first algorithm scheme, ensuring admissibility under a delayed termination condition. Also note that the merit measure operationalizes the above Property 3 via the harmonic mean computation. Accordingly, we obtain a normalized *overall quality* $\bar{Q}^*$ given an acrostic x as $\bar{Q}^* = |x| \cdot Q^*$.

To turn Equation (2) into actionable knowledge, the quality $q(n, n_i)$ of a paraphrasing operator ϕ when moving from n to a successor n_i needs to be quantified. We employ for q the domain $[0; 1]$, where 0 and 1 encode the worst and best achievable quality respectively. By construction the normalized quality $\bar{Q}^*$ will then lie in the interval $[0; 1]$ as well, thus greatly simplifying the interpretation of the measure.

Table 1 (right) shows values for the local quality of the operators in the Alan Turing example, which are derived from linguistic quality considerations and the experimental analysis detailed in Section 5. The comment column argues the linguistic meaningfulness. If we agree on $q = 1.0$ for the first two lines of the generated acrostic $x =$ `Turing` and recursively apply the merit measure defined in Equation (2), we obtain $Q = 0.127$ as unnormalized and $\bar{Q} = |x| \cdot Q = 0.76$ as normalized overall quality.

To make Equation (2) applicable as cost estimation heuristic $f(n)$ in a best-first algorithm scheme, Equation (3) below unravels its recursive structure in the usual way as $f(n) = g(n) + h(n)$. The semantics is as follows: under an optimistic estimate $h(n)$ (= underestimating costs or overestimating merits) the

Table 1: Left: Paraphrasing operators in the Alan Turing example. Right: Values for the local quality of the respective operators, which entail the normalized overall quality $\bar{Q} = 0.76$ for the example.

Line	Operator ϕ	Text → paraphrased text	$q(n, n_i)$	Comment
3	synonym	highly influential → revolutionized	0.9	stylistically well, exaggerating tone
4	hyphenation	giving → giv-ing	0.6	unexpected hyphen for a short word
5	tautology	computation → defi-nite computation	0.6	tautology arguable, hyphen unusual
6	synonym	considered → re-garded	0.7	synonym suited, hyphen acceptable

total cost (the overall quality) for solving ACROSTIC GENERATION via a path *along node* n is always larger (smaller) than $f(n)$. In particular, $g(n)$ accumulates the true cost (the achieved quality) for the partial acrostic via a concrete path $s = n_0, n_1, \ldots, n_k = n$, while $h(n)$ gives an underestimation of the cost (overestimation of the quality) for the remaining part of the acrostic. Observe that the additive form of Equation (2) guarantees the parent discarding property (Pearl, 1984), which states that no decision on a path from n to a goal state γ can change the value for $g(n)$.

A tricky part is the construction of $h(n)$, which, on the one hand, may ensure admissibility, while, on the other hand, should be as close as possible to the real cost. Here, the measure $E(x)$ for the problem difficulty from Equation (1) comes into play, which models the problem decomposability and which informs us about the largest remaining subproblem (= the depth of the deepest remaining OR-graph) when solving x. Without loss of generality, admissibility is ensured if (a) the probability $P_{y \circ z}$ used in $\hat{E}(x)$ is biased towards decomposability, and if (b) we assume that the remaining acrostic x can be solved by always applying the cheapest (maximum quality-preserving) operator $q_{\max}$.

$$\underbrace{\frac{1}{\hat{Q}(n)}}_{f(n)} = \underbrace{\sum_{i=1}^{k} \frac{1}{q(n_{i-1}, n_i)}}_{g(n)} + \underbrace{\log_K \left(\hat{E}(\tau(n)) \right) \cdot \frac{1}{q_{\max}}}_{h(n)}, \quad \text{where } n_0 = s,\ n_k = n \tag{3}$$

Remarks. $\tau(n)$ denotes the remaining acrostic x that is associated with node $n \in \mathcal{T}$. The logarithm base K serves for normalization purposes with regard to the BNC letter frequencies $\hat{e}(x), |x| = 1$, which are used within $\hat{E}(x)$ in Equation (1). We define K as the multiplicative inverse of the occurrence probability of the least frequent letter in the remaining acrostic $x = \tau(n)$, which gives rise to the inequality $\log_K(\hat{E}(x)) \leq |x|$. This choice entails two properties: (1) it underestimates the remaining acrostic length and hence ensures the admissibility characteristic of $h(n)$, and, (2) it yields an increasing accuracy of $h(n)$ when approaching a goal state in Γ. Finally, we can substitute 1.0 as an upper bound for $q_{\max}$, again preserving the admissibility of $h(n)$.

Admissibility, i.e., the guarantee of optimality during best-first search, may not be the ultimate goal: if $h(n)$ underestimates costs (overestimates merits) too rigorously, best-first search degenerates to a kind of breadth-first search—precisely: to uniform-cost search. Especially if computing power is a scarce resource, we may be better off with a depth-preferring strategy. Observe that the logarithm base K in Equation (3) provides us a means to smoothly vary between the two extremes, namely by choosing K from $[K_{\min}; K_{\max}]$, where $K_{\min}$ ($K_{\max}$) specifies the multiplicative inverse of the occurrence probability of the most (least) frequent letter in the remaining acrostic $x = \tau(n)$.

4 Paraphrasing Operators

Most of the following operators used in our heuristic search process employ state-of-the-art linguistic tools or are based on standard knowledge from Wikipedia. Table 2 shows information about the role of individual operators in our experiments from Section 5; the table illustrates also the effort for preparing (offline) and applying (online) the operators.

4.1 Context-Independent Operators

Line break Since we are dealing with text that should spread over several lines, breaking between lines is one of the most basic operators. Similarly, it is the most efficient operator, and Column 4 of Table 2 illustrates the performance of the others in relation to this operator. Line breaks are possible at the end of sentences (i.e., a paragraph break), while a line break in between words is only possible if it falls in the $[l_{\min}; l_{\max}]$-window given by the line length constraints.

Hyphenation Related to line breaks are hyphenations. We re-implemented and employ the standard TEX hyphenation algorithm (Knuth, 1986). Analogous to line breaks, hyphenation is applicable if the line after hyphenating (and line breaking) has a length in the $[l_{\min}; l_{\max}]$-window.

Function word synonym Specific groups of so-called synsemantic words can often be replaced by each other without changing a text's meaning. We have identified 40 such groups from a list of Sequence Publishing[2] and the Paraphrase Database (Ganitkevitch et al., 2013). Examples are {can, may}, {so, thus, therefore, consequently, as a result}, and {however, nevertheless, yet}.

Contraction and expansion Some local text changes can be achieved by contracting or expanding formulations like "he'll" or "won't". We have identified 240 such pairs from Wikipedia.[3] Other possibilities are to spell out / contract standard abbreviations and acronyms. We have mined a list of several thousand such acronyms from the Web.[4] Finally, also small numbers can be spelled out or be written as numerals (e.g., "five" instead of "5"). It is interesting to note that this operator was hardly ever used on successful paths in our experiments.

Spelling In principle, we want to generate text that is correctly spelled. In certain situations, however, it can nevertheless be beneficial to introduce some slight mistakes in order to change word lengths or to generate letters not present in the correctly spelled text. We employ a list of 3 000 common misspellings mined from Wikipedia[5] (e.g., "accidently" instead of "accidentally"). We also include several standard typos related to computer keyboards (e.g., an "m" is often typed as an "n" and vice versa) as well as phonetic misspellings (e.g., "f" and "ph" often sound similar). Since the quality score of wrong spellings tends to be low, this operator has to be treated with care. Especially at the beginning of words, typos are less common than within words such that we allow typos only within words.

Wrong hyphenation Similar to wrong spellings is the purposeful choice of a wrong hyphenation. As with wrong spellings the quality score is typically low. We thus employ this operator very carefully, avoiding for instance syllables on a new line with just two letters. Analogous to correct hyphenation, the line length has to be in the $[l_{\min}; l_{\max}]$-window to apply wrong hyphenation. Despite its questionable quality, this operator is used pretty often in the experiments since it has a very high probability of "generating" a desired letter.

4.2 Context-Dependent Operators

Synonym For identifying synonyms, WordNet's synsets (Fellbaum, 1998) is used. Since only a small subset of the synset members of a to-be-replaced word w is reasonable in the context around w in T, we check in the Google n-gram corpus (Brants and Franz, 2006) whether the synonym in fact fits in the same context. In this regard the public and highly efficient Netspeak API (Stein et al., 2010; Riehmann et al., 2012) is employed. For example, given "hello world", the most frequent phrase with a synonym for world is "hello earth". The Google n-grams are up to five words long, such that at most four context words can be checked before or after w. Previous studies showed that more context yields higher quality synonyms (Metzler and Hovy, 2011; Pasca and Dienes, 2005), so that we use at least two words before or after w. Higher quality scores are achieved if the context is matched before as well as after w.

Table 2: Statistics for the applicability, usage, and effort of single operators. "Application probability" reports whether an operator is applicable at all at some node, "Usage" reports the application probability on a solution path, "Effort" reports the (online) application effort as multiple of the fastest operator (the Line break operator), and "Offline time" reports the preprocessing time in ms per word before the actual search is started. All numbers are profiled within the experiment setup described in Section 5.

Paraphrasing operator	**Application probability** (in %)	**Usage probability** (in %)	**Effort** (multiple of Line break)	**Offline time** (in ms per word)
Line break	16.14	21.13	1.00	0.00
Hyphenation	5.48	9.38	1.22	1.38
Function word synonym	1.43	2.57	1.33	0.01
Contraction and expansion	0.29	0.00	1.93	0.02
Spelling	6.98	1.57	1.18	0.11
Wrong hyphenation	9.53	37.63	1.07	1.38
Synonyms	16.69	2.47	1.66	23.24
Word insertion or deletion	43.46	25.24	2.46	42.75
Average	**12.50**	**12.50**	**1.49**	**14.35**

Word insertion or deletion Similar to the synonym replacement, the insertion or deletion of short phrases is handled. For all positions of the given text, the Google n-grams are checked with Netspeak (see above) for a word w that sufficiently often appears within the context of the text. Similarly, for each word w in the text, it is checked whether there are sufficiently many n-grams without the word but the same surrounding context. In both cases, w is a candidate to be inserted or deleted. Given "hello world", the most frequently used intermediate word is "cruel", yielding the phrase "hello cruel world." Again, as with synonyms, context size and quality are positively correlated. We thus use at least two words as context and favor variants that match more context.

4.3 Further Operator Ideas

In pilot experiments, also the three operator ideas discussed below were analyzed. The ideas show promising results for specific cases, but they easily lead to unexpected text flows due the introduction of odd sentences or names. The operators require future work to better fit them in the given text's context, and they are not employed within the experiments in Section 5.

Tautology It is often possible to introduce entirely new phrases or sentences in a text, which may confirm a previous sentence or which introduce a (nearly) arbitrary but true statement. We tested a small list, including among others "As a matter of fact this is true." or "I didn't know that until now." However, due to improper context such tautologies may mess up a text significantly.

Sentence beginning The beginning of a sentence can often be modified without changing its meaning. Possibilities include the addition of function words like "in general" or "actually", but also the addition of a prefix like "⟨someone⟩ said that …" or "⟨time⟩ ⟨someone⟩ said that …" where ⟨someone⟩ is to be replaced by a person's name or {I, he, she} depending on the full context of the text (e.g., author's name or gender of name mentioned before). The ⟨time⟩ expression may expand to "yesterday" or "last week", etc. Especially with the usage of names, a whole bunch of letters can be generated. However, context is more subtle for this operator compared to the usage of Google n-grams.

Full PPDB The paraphrase database (Ganitkevitch et al., 2013) comes in different sizes and quality levels. Many synonymity relations for nouns are already covered by WordNet, and function word replacements are already an operator on their own. Still, the rich variety of the full data set can form a semantically strong operator. However, in our pilot experiments, the full PPDB patterns often decreased text quality unacceptably, such that we refrained to use PPDB as a single operator in our experiments.

5 Experimental Evaluation

Goal of the evaluation is to show that our approach is able to efficiently generate acrostics in different situations. In this regard, we analyze the general success of acrostic generation, the influence of different operators, and effects on the text quality.

5.1 Experiment Setup

To model different "use cases" in which acrostics have to be inserted, we use texts of different genres: newspaper articles, emails, and Wikipedia articles. We sample 50 newspaper articles from the Reuters Corpus Volume 1 (Lewis et al., 2004), 50 emails from the Enron corpus (Klimt and Yang, 2004), and 50 articles from the English Wikipedia. Each text contains at least 150 words excluding tables and lists.

As target acrostics for all of the above text types, the 25 most common adjectives, nouns, prepositions, verbs, and 50 other common English words are chosen (in total 150 words).[6] This scenario reflects the inclusion of arbitrary words. Other target acrostics are formed by the 100 most common male and female first names from the US (in total 200 words).[7] This models the standard poetry usage of acrostics where often a writer's name is encoded. For all input texts, we also model self-referentiality by using a text's first phrases as the target acrostics (in total 150 phrases for which at least the first word has to be generated). In these cases, the first letter of the acrostic is also the first letter of the text—a fact that enables the controlled evaluation of the importance of the producibility of the first letter.

The evaluation system is a standard quad-core PC running Ubuntu 12.04 with 16 GB of RAM. A relevant subset of all operator application possibilities is preprocessed and stored in-memory (e.g., the synonym n-gram frequencies for every word), whereas the preprocessing time (about one minute in total per run) is not counted for the search process. We then conduct an A* search using the preprocessed operator tables and an admissible instance of Equation (3). To safe runtime, we slightly transform the problem setting and require the acrostic to start at the beginning of the given text. Pilot experiments show that a good choice for line lengths is $l_{\min} = 50$ and $l_{\max} = 70$. Note that this is only slightly more flexible than a standard line length between 55 and 65 characters (i.e., about 10-12 words) but eases acrostic generation. The experiments also reveal that a successful run (the acrostic can be generated) usually takes less than 30 seconds for the search part. An unsuccessful run (the acrostic cannot be generated) takes five to ten minutes until its termination caused by the memory constraints for the open list.

5.2 Experiment Discussion

Given our hardware and time restrictions, about 20% of the runs are successful altogether. The producibility of the first letter is critical for the overall success: we observe an almost 90% success rate for the self-referential acrostics compared to the about 20% for all others. Statistics for the successful runs are given in Table 3. As can be seen, our system is able to generate about 90 000 nodes with 550 goal checks per second. This yields reasonable answer times on the test acrostics: the average number of goal checks needed when the acrostic can be generated is below 10 000 (about 20 seconds of runtime). Only very few successful runs took more than 40 seconds; the self-referential acrostics that often are two or three words long form the main exception. Not that surprisingly, shorter acrostics are on average generated faster than longer ones. Interestingly, besides self-referential acrostics, male first names seem to be the most difficult acrostics when taking the required runtime into account. Note in this regard that many of the (longer) female names start with a more common first letter, which can be generated faster.

Since our approach is the first attempt at the problem of acrostic generation, we cannot compare to other systems from the literature. Instead, we compare to a baseline system that can only use line breaking and hyphenation as its operators. This also helps to further examine the effect of the producibility of the first letter. Whenever the acrostic's first letter is not the first letter of the text, the baseline fails right from the start: recall that for our experiments we require the acrostic to start at the text's beginning. For less than 1% of our test cases, the baseline can generate the acrostic. Most of these few cases are self-referential first words. Even if the first letter is already present, usually the second or third one are not producible by

[6] `en.wikipedia.org/wiki/Common_English_words`, last accessed: June 12, 2014.

[7] `www.ssa.gov/OACT/babynames/decades/century.html`, last accessed: June 12, 2014.

Table 3: Experimental results for complete acrostic generations. For each of the acrostic types (Column 1), several thousand runs were conducted for which we report averaged values of the acrostic lengths in letters (Column 2). The columns 3-10 relate to successful generations and report averaged values for the runtime in seconds, size of the explored search tree, generated nodes and goal checks per second, used main memory, and the quality change according to the introduced measures.

Acrostic type	**Length** (in letters)	**Runtime** (total in s)	**Nodes** (total)	**Nodes** (per s)	**Goal checks** (per s)	**Memory** (in MByte)	**Quality-related measures**		
							Δ WFC	**Δ ARI**	**Δ SMOG**
Common English words									
Adjective	4.36	3.25	286 960	88 269	578	270	-0.99	-1.61	-0.91
Noun	4.47	3.40	285 016	83 837	576	277	-0.39	-0.96	-0.50
Preposition	3.44	3.16	280 593	88 853	556	243	-1.59	-2.28	-1.29
Verb	3.59	2.76	251 161	90 898	595	236	-0.95	-1.60	-0.92
Other	3.29	2.41	218 974	90 755	601	206	-1.10	-2.05	-1.11
Common US first names									
Male	6.00	9.32	851 665	91 368	554	649	-0.74	-1.87	-0.93
Female	6.07	7.82	740 418	94 693	546	575	-0.60	-1.77	-0.93
Self-referential									
First words	10.33	36.09	3 164 873	87 690	518	1 985	-0.31	-0.09	0.20
Average	**5.19**	**8.53**	**759 957**	**89 545**	**565**	**372**	**-0.83**	**-1.53**	**-0.80**

the simple operators. Using all operators, our approach is able to produce a self-referential acrostic of more than seven characters in 80% of the cases. On average, acrostics of ten characters are possible for the self-referential cases. This further highlights the importance of the first letter: whenever it is producible, the success ratio is much higher.

To compare the importance of the different operators, we count for the successful generations in the experiments of Table 3, how often operators are used and how long the search paths are. Table 2 contains information on the applicability of the different operators. About 21% of the operator applications are line breaks, another 9% are hyphenations. Interestingly, about 38% of the operator applications are wrong hyphenations despite the low quality of this operator. Even though our heuristic tries to avoid wrong hyphenations, there are a lot of situations where all other operators fail. Although not reflected by standard quality metrics (see next subsection), a wrong hyphenation usually is eye-catching for human readers, which gives rise to a desirable further quality improvement that should be aimed for in future work. The other operator usages are mostly word insertions and deletions (about 25%), synonym replacements (3%), and function words (3%). The context-independent operators of contractions and spelling correspond to only about 1% of all operator applications.

5.3 Quality-Related Analysis

Table 3 also contains information about the text quality before and after generating the acrostic. To algorithmically measure text quality-related effects, we employ a word frequency class analysis and a readability analysis.

The frequency class WFC(w) of a word w relates to its customariness in written language and has successfully been employed for text genre analysis (Stein and Meyer zu Eißen, 2008). Let $\varphi(w)$ denote the frequency of a word in a given corpus; then the Wortschatz[8] defines WFC(w) as $\lfloor \log_2(\varphi(w^*)/\varphi(w)) \rfloor$, where w^* denotes the most frequently used word in the respective corpus. Here we use as reference the Google n-gram corpus (Brants and Franz, 2006) whose most frequent word is "the", which corresponds to the word frequency class 0; the most uncommonly used words within this corpus have a word frequency class of 26. The readability of the text before and after acrostic generation is quantified according to the standard ARI (Smith and Senter, 1967) and SMOG (McLaughlin, 1969) measures, implemented in the Phantom Readability Library.[9] Both measures have been designed to estimate the U.S. grade

[8] `wortschatz.uni-leipzig.de`, last accessed: June 12, 2014.

[9] `http://niels.drni.de/s9y/pages/phantom.html`, last accessed: June 12, 2014

level equivalent to the education required for understanding a given text. Hence, larger readability scores indicate more difficult texts. The Automated Readability Index ARI (Smith and Senter, 1967) is designed for being easily automatable and uses only the number of characters (excluding whitespace and punctuation), words, and sentences in the text (delimited by a period, an exclamation mark, a question mark, a colon, a semicolon, or an ellipsis). The Simple Measure of Gobbledygook SMOG (McLaughlin, 1969) includes the number of words with more than three syllables, so-called polysyllables.

$$\mathrm{ARI} = 4.71 \cdot \frac{\text{Characters}}{\text{Words}} + 0.5 \cdot \frac{\text{Words}}{\text{Sentences}} - 21.43 \qquad \mathrm{SMOG} = 1.0430 \cdot \sqrt{30 \cdot \frac{\text{Polysyllables}}{\text{Sentences}}} + 3.1291$$

Of course, the above three measures cannot capture text quality as human judges would perceive it. Still, they have their merits and can indicate interesting trends: On average, the texts after acrostic generation use more common words (cf. the negative Δ WFC) and are easier to read (cf. the negative Δ ARI and Δ SMOG) for almost all acrostic types. Thus, one may argue that the quality is not harmed too much; still some issues like wrong hyphenation are ignored by the metrics (cf. the above discussion of individual operators). A deeper analysis of operator quality and improved quality of paraphrased texts (e.g., further operators or avoiding wrong hyphenations) constitute very promising directions for future work.

6 Conclusion and Outlook

We have presented the first algorithmic approach to acrostic generation. The experiments show that the heuristic search approach is able to generate about 20% of the target acrostics in reasonable time, whereas the producibility of the first letter plays a key role. Our solution successfully combines paraphrasing techniques from Natural Language Processing with a heuristic search strategy from Artificial Intelligence. This way, our problem modeling opens a novel and very promising research direction, and the application of our framework to other paraphrasing problems is the most interesting line of future work. As for the acrostic use case, the resulting text's quality gives the most obvious possibility for improvements. We plan to further analyze better quality measures for the individual operators and to develop more sophisticated operators like changing a text's tense or even anaphora exploitation (Schmolz et al., 2012).

Invited Speaker Abstract

Early computational linguists supplied much of theoretical basis that the ALPAC report said was needed for research on the practical problem of machine translation. The result of their efforts turned out to be more fundamental in that it provided a general theoretical basis for the study of language use as a process, giving rise eventually to constraint-based grammatical formalisms for syntax, finite-state approaches to morphology and phonology, and a host of models how speakers might assemble sentences, and hearers take them apart. Recently, an entirely new enterprise, based on machine learning and big data, has sprung on the scene and challenged the ALPAC committee's finding that linguistic processing must have a firm basis in linguistic theory. In this talk, I will show that the long-term development of linguistic processing requires linguistic theory, sophisticated statistical manipulation of big data, and a third component which is not linguistic at all.

Abstract

Translation retrieval aims to find the most likely translation among a set of target-language strings for a given source-language string. Previous studies consider the single-best translation as a query for information retrieval, which may result in translation error propagation. To alleviate this problem, we propose to use the *query lattice*, which is a compact representation of exponentially many queries containing translation alternatives. We verified the effectiveness of query lattice through experiments, where our method explores a much larger search space (from 1 query to 1.24×10^{62} queries), runs much faster (from 0.75 to 0.13 second per sentence), and retrieves more accurately (from 83.76% to 93.16% in precision) than the standard method based on the query single-best. In addition, we show that query lattice significantly outperforms the method of (Munteanu and Marcu, 2005) on the task of parallel sentence mining from comparable corpora.

1 Introduction

Translation retrieval aims to search for the most probable translation candidate from a set of target-language strings for a given source-language string. Early translation retrieval methods were widely used in example-based and memory-based translation systems (Sato and Nagao, 1990; Nirenburg et al., 1993; Baldwin and Tanaka, 2000; Baldwin, 2001). Often, the document set is a list of translation records that are pairs of source-language and target-language strings. Given an input source string, the retrieval system returns a translation record of maximum similarity to the input on the source side. Although these methods prove to be effective in example-based and memory-based translation systems, they heavily rely on parallel corpora that are limited both in size and domain.

More recently, Liu et al. (2012) have proposed a new translation retrieval architecture that depends only on monolingual corpora. Given an input source string, their system retrieves translation candidates from a set of target-language sentences. This can be done by combining machine translation (MT) and information retrieval (IR): machine translation is used to transform the input source string to a coarse translation, which serves as a query to retrieve the most probable translation in the monolingual corpus. Therefore, it is possible for translation retrieval to have access to a huge volume of monolingual corpora that are readily available on the Web.

However, the MT + IR pipeline suffers from the *translation error propagation problem*. Liu et al. (2012) use 1-best translations, which are inevitably erroneous due to the ambiguity and structural divergence of natural languages, as queries to the IR module. As a result, translation mistakes will be

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2031–2041, Dublin, Ireland, August 23-29 2014.

propagated to the retrieval process. This situation aggravates when high-accuracy MT systems are not available for resource-scarce languages.

In this work, we propose to use *query lattice* in translation retrieval to alleviate the translation error propagation problem. A query lattice is a compact representation of exponentially many queries. We design a retrieval algorithm that takes the query lattice as input to search for the most probable translation candidate from a set of target-language sentences. As compared with Liu et al. (2012), our approach explores a much larger search space (from 1 query to 1.24×10^{62} queries), runs much faster (from 0.75 second per sentence to 0.13), and retrieves more accurately (from 83.76% to 93.16%). We also evaluate our approach on extracting parallel sentences from comparable corpora. Experiments show that our translation retrieval system significantly outperforms a state-of-the-art parallel corpus mining system.

2 Related Work

Our work is inspired by three research topics: retrieving translation candidates from parallel corpus, using lattice to compactly represent exponentially many alternatives, and using lattice as query in information retrieval.

1. *Translation Retrieval using Parallel Corpus*. The idea of retrieving translation candidates from existing texts originated in example-based and memory-based translation (Sato and Nagao, 1990; Nirenburg et al., 1993; Baldwin and Tanaka, 2000; Baldwin, 2001). As these early efforts use a parallel corpus (e.g., translation records that are pairs of source-language and target-language strings), they focus on calculating the similarity between two source-language strings. In contrast, we evaluate the translational equivalence of a given source string and a target string in a large monolingual corpus.

2. *Lattice in Machine Translation*. Lattices have been widely used in machine translation: considering Chinese word segmentation alternatives (Xu et al., 2005), speech recognition candidates (Matsoukas et al., 2007), SCFG (Dyer et al., 2008) and so on in the decoding process, minimum bayes risk decoding (Tromble et al., 2008), minimum error rate training (Macherey et al., 2008), system combination (Feng et al., 2009), just to name a few. In this work, we are interested in how to use a lattice that encodes exponentially many translation candidates as a single query to retrieve similar target sentences via an information retrieval system.

3. *Query Lattice in Information Retrieval*. The use of lattices in information retrieval dates back to Moore (1958). Most current lattice-based IR systems often treat lattices as conceptional hierarchies or thesauri in formal concept analysis (Priss, 2000; Cheung and Vogel, 2005). In spoken document retrieval, however, lattices are used as a compact representation of multiple speech recognition transcripts to estimate the expected counts of words in each document (Saraclar and Sproat, 2004; Zhou et al., 2006; Chia et al., 2010). Our work is significantly different from previous work that uses the bag-of-words model because translation retrieval must take structure and dependencies in text into account to ensure translational equivalence.

3 Query Lattice for Translation Retrieval

3.1 Translation Retrieval

Let $\mathbf{f}$ be a source-language string, $\mathbf{E}$ be a set of target-language strings, the problem is how to find the most probable translation $\hat{\mathbf{e}}$ from $\mathbf{E}$. Note that $\mathbf{E}$ is a monolingual corpus rather than a parallel corpus. Therefore, string matching on the source side (Sato and Nagao, 1990; Nirenburg et al., 1993; Baldwin and Tanaka, 2000; Baldwin, 2001) does not apply here.

We use $P(\mathbf{e}|\mathbf{f})$ to denote the probability that a target-language sentence $\mathbf{e}$ is the translation of a source-language sentence $\mathbf{f}$. As suggested by Liu et al. (2012), it can be decomposed into two sub-models by

introducing a coarse translation $\mathbf{q}$ as a hidden variable:

$$P(\mathbf{e}|\mathbf{f}) = \sum_{\mathbf{q}\in\mathbf{Q}(\mathbf{f})} P(\mathbf{q},\mathbf{e}|\mathbf{f}) \quad (1)$$

$$= \sum_{\mathbf{q}\in\mathbf{Q}(\mathbf{f})} P(\mathbf{q}|\mathbf{f}) \times P(\mathbf{e}|\mathbf{q},\mathbf{f}) \quad (2)$$

where $P(\mathbf{q}|\mathbf{f})$ is a **translation** sub-model, $P(\mathbf{e}|\mathbf{q},\mathbf{f})$ is a **retrieval** sub-model, and $\mathbf{Q}(\mathbf{f})$ is the set of all possible translations of the sentence $\mathbf{f}$. Note that $\mathbf{q}$ actually serves as a **query** to the retrieval sub-model.

To take advantage of various translation and retrieval information sources, we use a log-linear model (Och and Ney, 2002) to define the conditional probability of a query $\mathbf{q}$ and a target sentence $\mathbf{e}$ conditioned on a source sentence $\mathbf{f}$ parameterized by a real-valued vector $\boldsymbol{\theta}$:

$$P(\mathbf{q},\mathbf{e}|\mathbf{f};\boldsymbol{\theta}) = \frac{\exp(\boldsymbol{\theta}\cdot\mathbf{h}(\mathbf{q},\mathbf{e},\mathbf{f}))}{\sum_{\mathbf{q}'\in\mathbf{Q}(\mathbf{f})}\sum_{\mathbf{e}'\in\mathbf{E}}\exp(\boldsymbol{\theta}\cdot\mathbf{h}(\mathbf{q}',\mathbf{e}',\mathbf{f}))} \quad (3)$$

where $\mathbf{h}(\cdot)$ is a vector of feature functions and $\boldsymbol{\theta}$ is the corresponding feature weight vector.

Accordingly, the decision rule for the latent variable model is given by

$$\hat{\mathbf{e}} = \arg\max_{\mathbf{e}\in\mathbf{E}} \left\{ \sum_{\mathbf{q}\in\mathbf{Q}(\mathbf{f})} \exp(\boldsymbol{\theta}\cdot\mathbf{h}(\mathbf{q},\mathbf{e},\mathbf{f})) \right\} \quad (4)$$

As there are exponentially many queries, it is efficient to approximate the summation over all possible queries by using maximization instead:

$$\hat{\mathbf{e}} \approx \arg\max_{\mathbf{e}\in\mathbf{E}} \left\{ \max_{\mathbf{q}\in\mathbf{Q}(\mathbf{f})} \left\{ \boldsymbol{\theta}\cdot\mathbf{h}(\mathbf{q},\mathbf{e},\mathbf{f}) \right\} \right\} \quad (5)$$

Unfortunately, the search space is still prohibitively large since we need to enumerate all possible queries. Liu et al. (2012) split Eq. (5) into two steps. In the first step, a translation module runs to produce the 1-best translation $\hat{\mathbf{q}}$ of the input string $\mathbf{f}$ as a query:

$$\hat{\mathbf{q}} \approx \arg\max_{\mathbf{q}\in\mathbf{Q}(\mathbf{f})} \left\{ \boldsymbol{\theta}_t\cdot\mathbf{h}_t(\mathbf{q},\mathbf{e},\mathbf{f}) \right\} \quad (6)$$

where $\mathbf{h}_t(\cdot)$ is a vector of translation features and $\boldsymbol{\theta}_t$ is the corresponding feature weight vector. In the second step, a monolingual retrieval module takes the 1-best translation $\hat{\mathbf{q}}$ as a query to search for the target string $\hat{\mathbf{e}}$ with the highest score:

$$\hat{\mathbf{e}} \approx \arg\max_{\mathbf{e}\in\mathbf{E}} \left\{ \boldsymbol{\theta}_r\cdot\mathbf{h}_r(\hat{\mathbf{q}},\mathbf{e},\mathbf{f}) \right\} \quad (7)$$

where $\mathbf{h}_r(\cdot)$ is a vector of retrieval features and $\boldsymbol{\theta}_r$ is the corresponding feature weight vector.

Due to the ambiguity of translation, however, state-of-the-art MT systems are still far from producing high-quality translations, especially for distantly-related languages. As a result, the 1-best translations are usually erroneous and potentially introduce retrieval mistakes.

A natural solution is to use n-best lists as queries:

$$\hat{\mathbf{e}} \approx \arg\max_{\mathbf{e}\in\mathbf{E}} \left\{ \max_{\mathbf{q}\in\mathbf{N}(\mathbf{f})} \left\{ \boldsymbol{\theta}\cdot\mathbf{h}(\mathbf{q},\mathbf{e},\mathbf{f}) \right\} \right\} \quad (8)$$

where $\mathbf{N}(\mathbf{f}) \subset \mathbf{T}(\mathbf{f})$ is the n-best translations of the input source sentence $\mathbf{f}$.

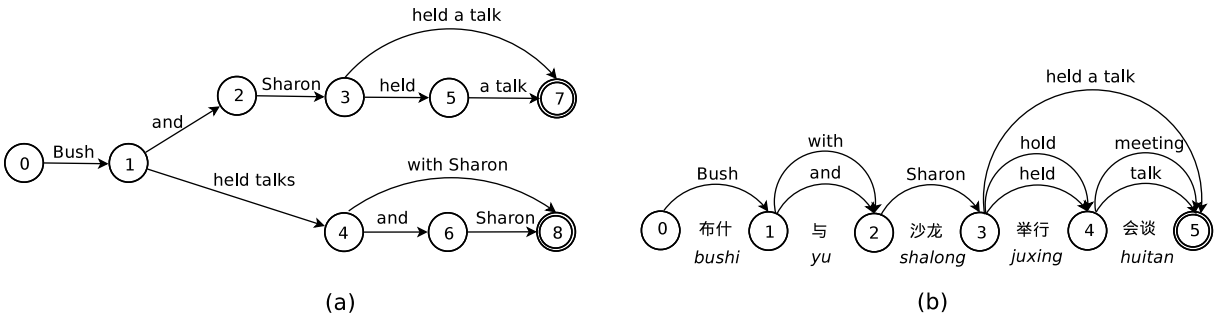

Figure 1: Two kinds of query lattices: (a) search graph that is generated *after* phrase-based decoding and (b) translation option graph that is generated *before* decoding. Translation option graph is more compact and encodes more translation candidates.

Although using n-best lists apparently improves the retrieval accuracy over using 1-best lists, there are two disadvantages. First, the decision rule in Eq. (8) requires to enumerate all the n translations and retrieve for n times. In other words, the time complexity increases linearly. Second, an n-best list only accounts for a tiny fraction of the exponential search space of translation. To make things worse, there are usually very few variations in n-best translations because of spurious ambiguity - a situation where multiple derivations give similar or even identical translations.

Therefore, we need to find a more elegant way to enable the retrieval module to explore exponentially many queries without sacrificing efficiency.

3.2 Query Lattice

We propose to use **query lattice** to compactly represent exponentially many queries. For example, given a source sentence "*bushi yu shalong juxing huitan*", we can use the **search graph** produced by a phrase-based translation system (Koehn et al., 2007) as a lattice to encode exponentially many derivations.

Figure 1(a) shows a search graph for the example source sentence. Each edge is labeled with an English phrase as well as the corresponding translation feature value vector. Node 0 denotes the starting node. Node 7 and node 8 are two ending nodes. Each path from the starting node to an ending node denotes a query. Paths that reach the same node in the lattice correspond to recombined hypotheses that have equivalent feature histories (e.g., coverage, last generated target words, the end of last covered source phrase, etc) in phrase-based decoding.

However, there are two problems with using search graph as query lattice. First, it is computationally expensive to run a phrase-based system to generate search graphs. The time complexity for phrase-based decoding with beam search is $O(n^2b)$ (Koehn et al., 2007), where n is the length of source string and b is the beam width. Moreover, the memory requirement is usually very high due to language models. As a result, translation is often two orders of magnitude slower than retrieval. Second, a search graph has too many "duplicate" edges due to different reordering, which increase the time complexity of retrieval (see Section 3.3). For example, in Figure 1(a), the English phrase "Sharon" occurs two times due to different reordering.

Alternatively, we propose to use **translation option graph** as query lattice. In a phrase-based translation system, translation options that are phrase pairs matching a substring in the input source string are collected *before* decoding. These translation options form a query lattice with monotonic reordering. Figure 1(b) shows an example translation option graph, in which nodes are sorted according to the positions of source words. Each edge is labeled with an English phrase as well as the corresponding translation feature value vector.

We believe that translation option graph has three advantages over search graph:

1. *Improved efficiency in translation*. Translation option graph requires no decoding.

2. *Improved efficiency in retrieval*. Translation option graph has no duplicate edges.

Algorithm 1 Retrieval with lattice as query.

procedure LATTICERETRIEVE($\mathbf{L}(\mathbf{f}), \mathbf{E}, k$)
  $Q \leftarrow$ GETWORDS($\mathbf{L}(\mathbf{f})$) ▷ Get distinct words in the lattice to form a coarse query
  $\mathbf{E}_k \leftarrow$ RETRIEVE($\mathbf{E}, Q, k$) ▷ Retrieve top-k target sentences using the coarse query
  for all $\mathbf{e} \in \mathbf{E}_k$ **do**
    FINDPATH($\mathbf{L}(\mathbf{f}), \mathbf{e}$) ▷ Find a path with the highest score
  end for
  SORT($\mathbf{E}_k$) ▷ Sort retrieved sentences according the scores
  return $\mathbf{E}_k$
end procedure

Algorithm 2 Find a path with the highest score.

procedure FINDPATH($\mathbf{L}(\mathbf{f}), \mathbf{e}$)
  for $v \in \mathbf{L}(\mathbf{f})$ in topological order **do**
    $path(v) \leftarrow \emptyset$ ▷ Initialize the Viterbi path at node v
    $score(v) \leftarrow 0$ ▷ Initialize the Viterbi score at node v
    for $u \in IN(v)$ **do** ▷ Enumerate all antecedents
      $p \leftarrow path(u) \cup \{e_{u \rightarrow v}\}$ ▷ Generate a new path
      $s \leftarrow score(u) +$ COMPUTESCORE($e_{u \rightarrow v}$) ▷ Compute the path score
      if $s > score(v)$ **then**
        $path(v) \leftarrow p$ ▷ Update the Viterbi path
        $score(v) \leftarrow s$ ▷ Update the Viterbi score
      end if
    end for
  end for
end procedure

3. *Enlarged search space*. Translation option graph represents the entire search space of monotonic decoding while search graph prunes many translation candidates.

In Figure 1, the search graph has 9 nodes, 10 edges, 4 paths, and 3 distinct translations. In contrast, the translation option graph has 6 nodes, 9 edges, 10 paths, and 10 distinct translations. Therefore, translation option graph is more compact and encodes more translation candidates.

Although translation option graph ignores language model and lexcialized reordering models, which prove to be critical information sources in machine translation, we find that it achieves comparable or even better retrieval accuracy than search graph (Section 4). This confirms the finding of Liu et al. (2012) that language model and lexicalized reordering models only have modest effects on translation retrieval.

3.3 Retrieval with Query Lattice

Given a target corpus $\mathbf{E}$ and a query lattice $\mathbf{L}(\mathbf{f}) \subset \mathbf{Q}(\mathbf{f})$, our goal is to find the target sentence $\hat{\mathbf{e}}$ with the highest score $\boldsymbol{\theta} \cdot \mathbf{h}(\mathbf{q}, \mathbf{e}, \mathbf{f})$:

$$\hat{\mathbf{e}} \approx \arg\max_{\mathbf{e} \in \mathbf{E}} \left\{ \max_{\mathbf{q} \in \mathbf{L}(\mathbf{f})} \left\{ \boldsymbol{\theta} \cdot \mathbf{h}(\mathbf{q}, \mathbf{e}, \mathbf{f}) \right\} \right\} \quad (9)$$

Due to the exponentially large search space, we use a coarse-to-fine algorithm to search for the target sentence with the highest score, as shown in Algorithm 1. We use an example to illustrate the basic idea. Given an input source sentence "*bushi yu shalong juxing le huitan*", our system first generates a query lattice like Figure 1(a). It is non-trivial to directly feed the query lattice to a retrieval system. Instead, we would like to first collect all distinct words in the lattice: {"*Bush*", "*and*" , "*Sharon*", "*held*", "*a*", "*talk*", "*talks*", "*with*"}. This set serves as a coarse single query and the retrieval system returns a list of target sentences that contain these words:

			Chinese	English
Training			1.21M	1.21M
Dev	in-domain	query	5K	
		document		2.23M
	out-of-domain	query	5K	
		document		2.23M
Test	in-domain	query	5K	
		document		2.23M
	out-of-domain	query	5K	
		document		2.23M

Table 1: The datasets for the retrieval evaluation. The training set is used to train the phrase-based translation model and language model for Moses (Koehn et al., 2007). The development set is used to optimize feature weights using the minimum-error-rate algorithm (Och, 2003). A development set consists of a query set and a document set. The test set is used to evaluate the retrieval accuracy. To examine the effect of domains on retrieval performance, we used two development and test sets: in-domain and out-domain.

President Bush gave a talk at a meeting
Bush held a meeting with Sharon
Sharon and Bush attended a meeting held at London

Note that as a retrieval system usually ignores the structural dependencies in text, the retrieved sentences (scored by retrieval features) are relevant but not necessarily translations of the input. Therefore, we can match each retrieved sentence against the query lattice to find a path with the highest score using additional translation features. For example, the Viterbi path for "*Bush held a meeting with Sharon*" in Figure 1(a) is "*Bush held talks with Sharon*". The translation features of matched arcs in the path are collected to compute the overall score according to Eq. (9). Finally, the algorithm returns a sorted list:

Bush held a meeting with Sharon
President Bush gave a talk at a meeting
Sharon and Bush attended a meeting held at London

More formally, the input of Algorithm 1 are a query lattice $\mathbf{L}(\mathbf{f})$, a target corpus $\mathbf{E}$, and a parameter k (line 1). The function GETWORDS simply collects all the distinct words appearing in the lattice (line 2), which are used for constructing a coarse boolean query Q. Then, the function RETRIEVE runs to retrieve the top-k target sentences $\mathbf{E}_k$ in the target corpus $\mathbf{E}$ only using standard IR features according to the query Q (line 3). These first two steps eliminate most unlikely candidates and return a coarse set of target sentence candidates efficiently. [1] Then, a procedure FINDPATH$(\mathbf{L}(\mathbf{f}), \mathbf{e})$ runs to search for the translation with the highest score for each candidate (lines 4-6). Finally, the algorithm returns the sorted list of target sentences (lines 7-9).

Algorithm 2 shows the procedure FINDPATH$(\mathbf{L}(\mathbf{f}), \mathbf{e})$, which searches for the path with higher score using a Viterbi-style algorithm. The function COMPUTESCORE scores an edge according to the Eq. (9) which linearly combines the translation and retrieval features.

Generally, the lattice-based retrieval algorithm has a time complexity of $O(k|E|)$, where $|E|$ is the number of edges in the lattice.

4 Experiments

In this section, we try to answer two questions:

1. Does using query lattices improve translation retrieval accuracy over using n-best lists?

2. How does translation retrieval benefit other end-to-end NLP tasks such as machine translation?

[1] In our experiments, we set the parameter k to 500 as a larger value of k does not give significant improvements but introduce more noises.

Accordingly, we evaluated our system in two tasks: translation retrieval (Section 4.1) and parallel corpus mining (Section 4.2).

4.1 Evaluation on Translation Retrieval

4.1.1 Experimental Setup

In this section, we evaluate the accuracy of translation retrieval: given a query set (i.e., source sentences), our system returns a sorted list of target sentences. The evaluation metrics include precision@n and recall.

The datasets for the retrieval evaluation are summarized in Table 1. The **training set**, which is used to train the phrase-based translation model and language model for the-state-of-the-art phrase-based system Moses (Koehn et al., 2007), contains 1.21M Chinese-English sentences with 32.0M Chinese words and 35.2M English words. We used the SRILM toolkit (Stolcke, 2002) to train a 4-gram language model on the English side of the training corpus. The **development set**, which is used to optimize feature weights using the minimum-error-rate algorithm (Och, 2003), consists of **query set** and a **document set**. We sampled 5K parallel sentences randomly, in which 5K Chinese sentences are used as queries and half of their parallelled English sentences(2.5K) mixed with other English sentences(2.3M) as the retrieval document set. As a result, we can compute precision and recall in a noisy setting. The **test set** is used to compute retrieval evaluation metrics. To examine the effect of domains on retrieval performance, we used two data sets: **in-domain** and **out-domain**. The in-domain development and test sets are close to the training set while the out-domain data sets are not.

We compare three variants of translation retrieval: 1-best list, n-best list, and lattice. For query lattice, we further distinguish between search graph and translation option graph. They are generated by Moses with the default setting.

We use both translation and retrieval features in the experiments. The translation features include phrase translation probabilities, phrase penalty, distance-based and lexicalized reordering models, language models, and word penalty. Besides the conventional IR features such as term frequency and inverse document frequency, we use five additional featured derived from BLEU (Papineni et al., 2002): the n-gram matching precisions between query and retrieved target sentence ($n = 1, 2, 3, 4$) and brevity penalty. These features impose structural constraints on retrieval and ensure translation closeness of retrieved target sentences. The minimum-error-rate algorithm supports a variety of loss functions. The loss function we used in our experiment is $1-$P@n. Note that using translation option graph as query lattice does not include language models and distance-based lexicalized reordering models as features.

4.1.2 Evaluation Results

Table 2 shows the results on the in-domain test set. The "# candidates" column gives the number of translation candidates explored by the retrieval module for each source sentence on average. The lattices, either generated by search graph or by translation options, contain exponentially many candidates. We find that using lattices dramatically improves the precisions over using 1-best and n-best lists. All the improvements over 1-best and n-best lists are significant statistically. The 1-best, n-best, and the search graph lattice share with the same translation time: 5,640 seconds for translating 5,000 queries. Note that the translation time is zero for the translation option graph because it does not need phrase-based decoding. For retrieval, the time cost for the n-best list method generally increases linearly. As the search graph lattice contains many edges, the retrieval time increases by an order of magnitude as compared with 100-best list. An interesting finding is that using translation options as a lattice contains more candidates and consumes much less time for retrieval than using search graph as a lattice. One possible reason is that a search graph generated by Moses usually contains many redundant edges. For example, Figure 1 is actually a search graph and many phrases occurs multiple times in the lattice (e.g., "and" and "Sharon"). In contrast, a lattice built by translation options hardly has any redundant edges but still represents exponentially many possible translations. We can also see that the lattice constructed by search graph considering language model can benefit the precision much, especially when n is little. But this advantage decreases with n increasing and the time consumed by translation options as lattice is much less than the search graph as lattice. Besides, the margin between them is not too large so we can

method	# candidates	P@n					time	
		n=1	n=5	n=10	n=20	n=100	translation	retrieval
1-best	1	87.40	91.40	92.24	92.88	93.64	5,640	82
10-best	10	89.84	93.20	93.96	94.36	95.56	5,640	757
100-best	100	90.76	94.32	95.00	95.76	96.76	5,640	7,421
lattice (graph)	1.20×10^{54}	93.60	96.08	96.28	96.52	96.80	5,640	89,795
lattice (options)	4.14×10^{62}	93.28	95.84	95.96	96.16	96.84	0	307

Table 2: Results on the in-domain test set. We use the minimum-error-rate training algorithm (Och, 2003) to optimize the feature with the respect to $1-$P@n.

method	# candidates	P@n					time	
		n=1	n=5	n=10	n=20	n=100	translation	retrieval
1-best	1	67.32	76.60	79.40	81.80	83.76	3,660	92
10-best	10	72.68	80.96	83.36	85.84	88.76	3,660	863
100-best	100	78.60	85.76	87.76	89.64	92.16	3,660	8,418
lattice (graph)	1.51×10^{61}	84.32	89.40	90.68	91.56	92.44	3,660	67,205
lattice (options)	1.24×10^{65}	81.92	88.00	89.80	91.24	93.16	0	645

Table 3: Results on the out-of-domain test set.

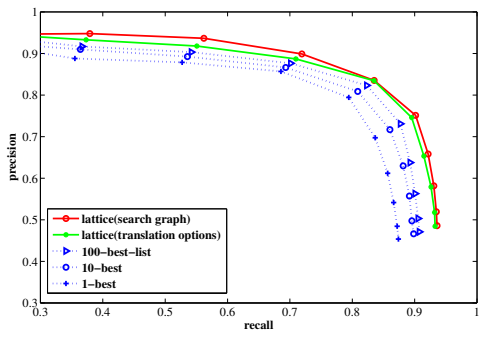

Figure 2: In-domain Precision-Recall curves.

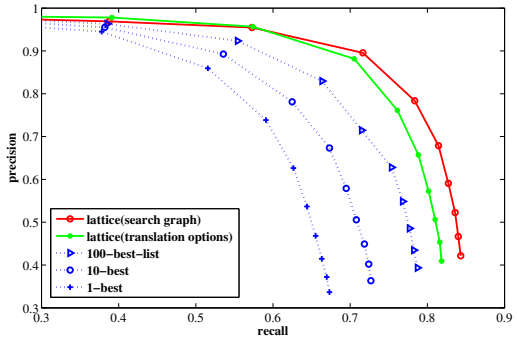

Figure 3: Out-domain Precision-Recall curves.

abandon some little precision for obtain the large time reducing. Therefore, using translation options as lattices seems to be both effective and efficient.

Table 3 shows the results on the out-of-domain test set. While the precisions for all methods drop, the margins between lattice-based retrieval and n-best list retrieval increase, suggesting that lattice-based methods are more robust when dealing with noisy datasets.

Figures 2 and 3 show the Precision-Recall curves on the in-domain and out-of-domain test sets. As the query set is derived from parallel sentences, recall can be computed in our experiments. The curves show that using lattices clearly outperforms using 1-best and n-best lists. The margins are larger on the out-of-domain test set.

4.2 Evaluation on Parallel Corpus Mining

In this section, we evaluate translation retrieval on the parallel corpus mining task: extracting a parallel corpus from a comparable corpus.

4.2.1 Experimental Setup

The comparable corpus for extracting parallel sentences contains news articles published by Xinhua News Agency from 1995 to 2010. Table 4 shows the detailed statistics. There are 1.2M Chinese and 1.7M English articles.

We re-implemented the method as described in (Munteanu and Marcu, 2005) as the baseline system.

language	articles	sentences	words	vocabulary
Chinese	1.2M	18.5M	441.2M	2.1M
English	1.7M	17.8M	440.2M	3.4M

Table 4: The Xinhua News Comparable Corpus from 1995 to 2010

Munteanu and Marcu (2005)			*this work*		
English words	Chinese words	BLEU	English words	Chinese Words	BLEU
5.00M	4.12M	22.84	5.00M	3.98M	25.44
10.00M	8.20M	25.10	10.00M	8.17M	26.62
15.00M	12.26M	25.41	15.00M	12.49M	26.49
20.00M	16.30M	25.56	20.00M	16.90M	26.87

Table 5: Comparison of BLEU scores using parallel corpora extracted by the baseline and our system. Given a comparable corpus (see Table 4), both systems extract parallel corpora that are used for training phrase-base models (Koehn et al., 2007). The baseline system is a re-implementation of the method described in (Munteanu and Marcu, 2005). Our system uses translation option graph as query lattice. Our system significantly outperforms the baseline for various sizes.

It assigned a score to each sentence pair using a classifier. Our system used translation option graph as query lattices due to its simplicity and effectiveness. For each source sentence in the comparable corpus, our system retrieved the top target sentence together with a score.

To evaluate the quality of extracted parallel corpus, we trained phrase-based models on it and ran Moses on NIST datasets. The development set is the NIST 2005 test set and the test set is the NIST 2006 test set. The final evaluation metric is case-insensitive BLEU-4.

4.2.2 Evaluation Results

Table 5 shows the comparison of BLEU scores using parallel corpora extracted by the baseline and our system. We find that our system significantly outperforms the baseline for various parallel corpus sizes. This finding suggests that using lattice to compactly represent exponentially many alternatives does help to alleviate the translation error propagation problem and identify parallel sentences of high translational equivalence.

5 Conclusion

In this work, we propose to use query lattice to address the translation error propagation problem in translation retrieval. Two kinds of query lattices are used in our experiments: search graph and translation option graph. We show that translation option graph is more compact and represents a much larger search space. Our experiments on Chinese-English datasets show that using query lattices significantly outperforms using n-best lists in the retrieval task. Moreover, we show that translation retrieval is capable of extracting high-quality parallel corpora from a comparable corpus. In the future, we plan to apply our approach to retrieving translation candidates directly from the Web, which can be seen as a huge monolingual corpus.

Abstract

Most of the widely-used automatic evaluation metrics consider only the local fragments of the references and translations, and they ignore the evaluation on the syntax level. Current syntax-based evaluation metrics try to introduce syntax information but suffer from the poor parsing results of the noisy machine translations. To alleviate this problem, we propose a novel dependency-based evaluation metric which only employs the dependency information of the references. We use two kinds of reference dependency structures: headword chain to capture the long distance dependency information, and fixed and floating structures to capture the local continuous ngram. Experiment results show that our metric achieves higher correlations with human judgments than BLEU, TER and HWCM on WMT 2012 and WMT 2013. By introducing extra linguistic resources and tuning parameters, the new metric gets the state-of-the-art performance which is better than METEOR and SEMPOS on system level, and is comparable with METEOR on sentence level on WMT 2012 and WMT 2013.

1 Introduction

Automatic machine translation (MT) evaluation plays an important role in the evolution of MT. It not only evaluates the performance of MT systems, but also makes the development of MT systems rapider (Och, 2003). According to the type of the employed information, the automatic MT evaluation metrics can be classified into three categories: lexicon-based metrics, syntax-based metrics and semantic-based metrics.

The lexicon-based metrics, such as BLEU (Papineni et al., 2002), TER (Snover et al., 2006), METEOR (Lavie and Agarwal, 2007) and AMBER (Chen and Kuhn, 2011; Chen et al., 2012), are good at capturing the lexicon or phrase level information, e.g. fixed phrases or idioms. But they cannot adequately reflect the syntax similarity. Current efforts in syntax-based metrics, such as the headword chain based metric (HWCM) (Liu and Gildea, 2005), the LFG dependency tree based metric (Owczarzak et al., 2007) and syntactic/semantic-role overlap (Giménez and Màrquez, 2007) , suffer from the parsing of the potentially noisy machine translations, so the improvement of their performance is restricted due to the serious parsing errors. Semantic-based metrics, such as MEANT (Lo et al., 2012; Lo and Wu, 2013), have the similar problem that the accuracy of semantic role labeling (SRL) can also drop due to the errors in translations. To avoid the parsing of potentially noisy translations, the CCG based metric (Mehay and Brew, 2007) only uses the parsing result of reference and employs 2-gram dependents, but it did not achieve the state-of-the-art performance.

In this paper, we propose a novel dependency tree based MT evaluation metric. The new metric only employs the reference dependency tree, leaving the translation unparsed to avoid the error propagation. We use two kinds of reference dependency structures in our metric. One is the headword chain (Liu and Gildea, 2005) which can capture long distance dependency information. The other is fixed and floating structure (Shen et al., 2010) which can capture local continuous ngram. When calculating the matching score between the headword chain and the translation, we use a distance-based similarity. Experiment

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2042–2051, Dublin, Ireland, August 23-29 2014.

results show that our metric achieves higher correlations with human judgments than BLEU, TER and HWCM on WMT 2012 and WMT 2013. After introducing extra resources and tuning parameters on WMT 2010, the new metric is better than METEOR and SEMPOS on system level and comparable with METEOR on sentence level on WMT 2012 and WMT2013.

The remainder of this paper is organized as follows. Section 2 describes our new reference dependency based MT evaluation metric. In Section 3, we introduce some extra resources to this new metric. Section 4 presents the parameter tuning for the new metric. Section 5 gives the experiment results. Conclusions and future work are discussed in Section 6.

2 RED: A Reference Dependency Based MT Evaluation Metric

The new metric is a REference Dependency based automatic evaluation metric, so we name it RED. We present the new metric detailedly in this section. The description of dependency ngrams is given in Section 2.1. The method to score the dependency ngram is presented in Section 2.2. At last, the method of calculating the final score is introduced in Section 2.3.

2.1 Two Kinds of Dependency Ngrams

To capture both the long distance dependency information and the local continuous ngrams, we use both the headword chain and the fixed-floating structures in our new metric, which correspond to the two kinds of dependency ngram (dep-ngram), headword chain ngram and fixed-floating ngram.

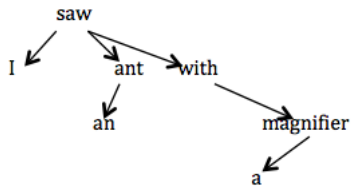

Figure 1: An example of dependency tree.

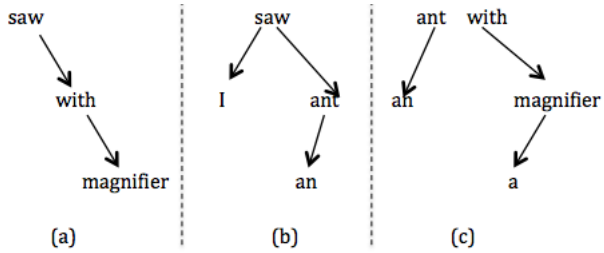

Figure 2: Different kinds of structures extracted from the dependency tree in Figure 1. (a): Headword chain. (b): Fixed structure. (c): Floating structure.

2.1.1 Headword chain

Headword chain is a sequence of words which corresponds to a path in the dependency tree (Liu and Gildea, 2005). For example, Figure 2(a) is a 3-word headword chain extracted from the dependency tree in Figure 1. Headword chain can represent the long distance dependency information, but cannot capture most of the continuous ngrams. In our metric, headword chain corresponds to the headword chain ngram in which the positions of the words are considered. So the form of headword chain ngram is expressed as $(w1_{pos1}, w2_{pos2}, ..., wn_{posn})$, where n is the length of the headword chain ngram. For example, the headword chain in Figure 2(a) is expressed as $(saw_2, with_5, magnifier_7)$.

2.1.2 Fixed and floating structures

Fixed and floating structures are defined in Shen et al. (2010). Fixed structures consist of a sub-root with children, each of which must be a complete constituent. They are called fixed dependency structures because the head is known or fixed. For example, Figure 2(b) shows a fixed structure. Floating structures consist of a number of consecutive sibling nodes of a common head, but the head itself is unspecified. Each of the siblings must be a complete constituent. Figure 2(c) shows a floating structure. Fixed-floating structures correspond to fixed-floating ngrams in our metric. Fixed-floating ngrams don't need the position information, and can be simply expressed as $(w1, w2, ..., wn)$, where n is the length of the

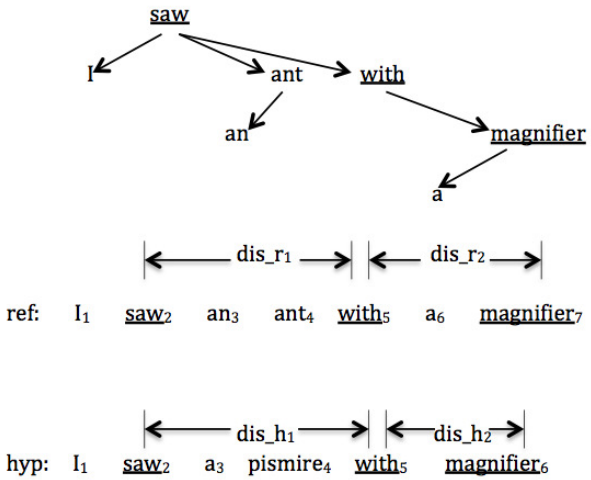

Figure 3: An example of calculating matching score for a headword chain ngram $(saw_2, with_5, magnifier_7)$. dis_r_1 and dis_r_2 are the distances between the corresponding two words in the reference. dis_h_1 and dis_h_2 are the distances between the corresponding two words in the hypothesis.

fixed-floating ngram. For example, the fixed structure in Figure 2(b) and the floating structre in Figure 2(c) can be expressed as (I, saw, an, ant) and $(an, ant, with, a, magnifier)$ respectively.

2.2 Scoring Dep-ngrams

Headword chain ngrams may not be continuous, while fixed-floating ngrams must be continuous. So the scoring methods of the two kinds of dep-ngrams are different, and we introduce the two scoring methods in Section 2.2.1 and Section 2.2.2 respectively.

2.2.1 Scoring headword chain ngram

For a headword chain ngram $(w1_{pos1}, w2_{pos2}, ..., wn_{posn})$, if we can find all these n words in the string of the translation with the same order as they appear in the reference sentence, we consider it a match and the matching score is a distance-based similarity which is calculated by the relative distance, otherwise it is not a match and the score is 0. The matching score is a decimal value between 0 and 1, which is more suitable than just use integer 0 and 1. For example, if the distance between two words in reference is 1, but the distance in two different hypotheses are 2 and 5 respectively. It's more reasonable to score them 0.5 and 0.2 rather than 1 and 0.

The relative distance dis_r_i between every two adjacent words in this kind of dep-ngram is calculated by Formula (1), where pos_{wi} is the position of word wi in the sentence. In Formula (1), we have $1 \leq i \leq n-1$ and n is the length of the dep-ngram. Then a vector $(dis\_r_1, dis\_r_2, ..., dis\_r_{n-1})$ is obtained. In the same way, we obtain vector $(dis\_h_1, dis\_h_2, ..., dis\_h_{n-1})$ for the translation side.

$$dis\_r_i = |pos_{w(i+1)} - pos_{wi}| \tag{1}$$

The matching score $p_{(d,hyp)}$ for a headword chain ngram (*d*) and the translation (*hyp*) is calculated according to Formula (2), where $n > 1$. When the length of the dep-ngram equals 1, the matching score equals 1 if the translation has the same word, otherwise, the matching score equals 0.

$$p_{(d,hyp)} = \begin{cases} exp(-\frac{\sum_{i=1}^{n-1} |dis\_r_i - dis\_h_i|}{n-1}) & if\ match \\ 0 & if\ unmatch \end{cases} \tag{2}$$

An example illustrating the calculation of the matching score $p_{(d,hyp)}$ is shown in Figure 3. There is a 3-word headword chain ngram $(saw_2, with_5, magnifier_7)$ in the dependency tree of the reference.

For this dep-3gram, the words are represented with underline in the reference dependency tree and the reference sentence in Figure 3. We can also find all the same three underlined words in the translation with the same order as they appear in the reference. Therefore, there is a match for this dep-3gram. To compute the matching score between this dep-3gram and the translation, we have:

- Calculate the distance

$$dis\_r_1 = |pos_{with} - pos_{saw}| = |5-2| = 3 \qquad dis\_r_2 = |pos_{magnifier} - pos_{with}| = |7-5| = 2$$
$$dis\_h_1 = |pos_{with} - pos_{saw}| = |5-2| = 3 \qquad dis\_h_2 = |pos_{magnifier} - pos_{with}| = |6-5| = 1$$

- Get the matching score as Formula (3) according to Formula (2). d denotes $(saw_2, with_5, magnifier_7)$ and hyp denotes the translation in the example.

$$p_{(d,hyp)} = exp(-\frac{|dis\_r_1 - dis\_h_1| + |dis\_r_2 - dis\_h_2|}{3-1}) = exp(-\frac{|3-3| + |2-1|}{3-1}) = exp(-0.5) \tag{3}$$

We also tried other methods to calculate the matching score, such as the cosine distance and the absolute distance, but the relative distance performed best. For a headword chain ngram with more than one matches in the translation, we choose the one with the highest matching score.

2.2.2 Scoring fixed-floating ngram

The words in the fixed-floating ngram are continuous, so we restrict the matched string in the translation also to being continuous. That means, for a fixed-floating ngram $(w1, w2, ..., wn)$, if we can find all these n words continuous in the translation with the same order as they appear in the reference, we think the dep-ngram can match with the translation. The matching score can be obtained by Formula (4), where d stands for a fixed-floating ngram and hyp stands for the translation.

$$p_{(d,hyp)} = \begin{cases} 1 & if\ match \\ 0 & if\ unmatch \end{cases} \tag{4}$$

2.3 Scoring RED

In the new metric, we use Fscore to obtain the final score. Fscore is calculated by Formula (5), where α is a value between 0 and 1.

$$Fscore = \frac{precision \cdot recall}{\alpha \cdot precision + (1-\alpha) \cdot recall} \tag{5}$$

The dep-ngrams of the reference and the string of the translation are used to calculate the precision and recall. In order to calculate precision, the number of the dep-ngrams in the translation should be given, but there is no dependency tree for the translation in our method. We know that the number of dep-ngrams has an approximate linear relationship with the length of the sentence, so we use the length of the translation to replace the number of the dep-ngrams in the translation dependency tree. Recall can be calculated directly since we know the number of the dep-ngrams in the reference. The precision and recall are computed as follows.

$$precision = \frac{\sum_{d \in D_n} p_{(d,hyp)}}{len_h}, \quad recall = \frac{\sum_{d \in D_n} p_{(d,hyp)}}{count_{n(ref)}}$$

D_n is the set of dep-ngrams with the length of n. len_h is the length of the translation. $count_{n(ref)}$ is the number of the dep-ngrams with the length of n in the reference.

The final score of RED is achieved using Formula (6), in which a weighted sum of the dep-ngrams' Fscore is calculated. w_{ngram} ($0 \leq w_{ngram} \leq 1$) is the weight of dep-ngram with the length of *n*. Fscore$_n$ is the Fscore for the dep-ngrams with the length of *n*.

$$RED = \sum_{n=1}^{N}(w_{ngram} \times Fscore_n) \tag{6}$$

3 Introducing Extra Resources

Many automatic evaluation metrics can only find the exact match between the reference and the translation, and the information provided by the limited number of references is not sufficient. Some evaluation metrics, such as TERp (Snover et al., 2009) and METOER, introduce extra resources to expand the reference information. We also introduce some extra resources to RED, such as stem, synonym and paraphrase. The words within a sentence can be classified into content words and function words. The effects of the two kinds of words are different and they shouldn't have the same matching score, so we introduce a parameter to distinguish them. The methods of applying these resources are introduced as follows.

- Stem and Synonym

  Stem(Porter, 2001) and synonym (WordNet[1]) are introduced to RED in the following three steps. First, we obtain the alignment with Meteor Aligner (Denkowski and Lavie, 2011) in which not only exact match but also stem and synonym are considered. We use stem and synonym together with exact match as three match modules. Second, the alignment is used to match for a dep-ngram. We think the dep-ngram can match with the translation if the following conditions are satisfied. 1) Each of the words in the dep-ngram has a matched word in the translation according to the alignment; 2) The words in dep-ngram and the matched words in translation appear in the same order; 3) The matched words in translation must be continuous if the dep-ngram is a fixed-floating ngram. At last, the match module score of a dep-ngram is calculated according to Formula (7). Different match modules have different effects, so we give them different weights.

  $$s_{mod} = \frac{\sum_{i=1}^{n} w_{m_i}}{n}, \ \ 0 \leq w_{m_i} \leq 1 \tag{7}$$

  m_i is the match module (exact, stem or synonym) of the ith word in a dep-ngram. w_{m_i} is the match module weight of the ith word in a dep-ngram. n is the number of words in a dep-ngram.

- Paraphrase

  When introducing paraphrase, we don't consider the dependency tree of the reference, because paraphrases may not be contained in the headword chain and fixed-floating structures. First, the alignment is obtained with METEOR Aligner, only considering paraphrase. Second, the matched paraphrases are extracted from the alignment and defined as paraphrase-ngram. The score of a paraphrase is $1 \times w_{par}$, where w_{par} is the weight of paraphrase-ngram.

- Function word

  We introduce a parameter w_{fun} ($0 \leq w_{fun} \leq 1$) to distinguish function words and content words. w_{fun} is the weight of function words. The function word score of a dep-ngram or paraphrase-ngram is computed according to Formula (8).

  $$s_{fun} = \frac{C_{fun} \times w_{fun} + C_{con} \times (1 - w_{fun})}{C_{fun} + C_{con}} \tag{8}$$

  C_{fun} is the number of function words in the dep-ngram or paraphrase-ngram. C_{con} is the number of content words in the dep-ngram or paraphrase-ngram.

[1] http://wordnet.princeton.edu/

We use RED-plus (REDp) to represent RED with extra resources, and the final score are calculated as Formula (9), in which $Fscore_p$ is obtained using $precison_p$ and $recall_p$ as Formula (10).

$$REDp = \sum_{n=1}^{N} (w_{ngram} \times Fscore_{p_n}) \tag{9}$$

$$Fscore_p = \frac{precision_p \cdot recall_p}{\alpha \cdot precision_p + (1-\alpha) \cdot recall_p} \tag{10}$$

$precision_p$ and $recall_P$ in Formula (10) are calculated as follows.

$$precision_p = \frac{score_{par_n} + score_{dep_n}}{len_h}\ , \quad recall_p = \frac{score_{par_n} + score_{dep_n}}{count_n(ref) + count_n(par)}$$

len_h is the length of the translation. $count_{n(ref)}$ is the number of the dep-ngrams with the length of n in the reference. $count_n(par)$ is the number of paraphrases with length of n in reference. $score_{par_n}$ is the match score of paraphrase-ngrams with the length of *n*. $score_{dep_n}$ is the match score of dep-ngrams with the length of *n*. $score_{par_n}$ and $score_{dep_n}$ are calculated as follows.

$$score_{par_n} = \sum_{par \in P_n} (1 \times w_{par} \times s_{fum})\ , \qquad score_{dep_n} = \sum_{d \in D_n} (p_{(d,hyp)} \times s_{mod} \times s_{fun})$$

P_n is the set of paraphrase-ngrams with the length of *n*. D_n is the set of dep-ngrams with the length of *n*.

4 Parameter Tuning

There are several parameters in REDp, and different parameter values can make the performance of REDp different. For example,w_{ngram} represents the weight of dep-ngram with the length of *n*. The effect of ngrams with different lengths are different, and they shouldn't have the same weight. So we can tune the parameters to find their best values.

We try a preliminary optimization method to tune parameters in REDp. A heuristic search is employed and the parameters are classified into two subsets. The parameter optimization is a grid search over the two subsets of parameters. When searching Subset 1, the parameters in Subset 2 are fixed, and then Subset 1 and Subset 2 are exchanged to finish this iteration. Several iterations are executed to finish the parameter tuning process. This heuristic search may not find the global optimum but it can save a lot of time compared with exhaustive search. The optimization goal is to maximize the sum of Spearman's ρ rank correlation coefficient on system level and Kendall's τ correlation coefficient on sentence level. ρ is calculated using the following equation.

$$\rho = 1 - \frac{6 \sum d_i^2}{n(n^2-1)}$$

where d_i is the difference between the human rank and metric's rank for system i. n is the number of systems. τ is calculated as follows.

$$\tau = \frac{\text{number of concordant pairs} - \text{number of discordant pairs}}{\text{number of concordant pairs} + \text{number of discordant pairs}}$$

The data of into-English tasks in WMT 2010 are used to tune parameters. The tuned parameters are listed in Table 1.

5 Experiments

5.1 Data

The test sets in experiments are WMT 2012 and WMT 2013. The language pairs are German-to-English (de-en), Czech-to-English (cz-en), French-to-English (fr-en), Spanish-to-English (es-en) and Russian-to-English (ru-en). The number of translation systems for each language pair are showed in Table 2. For each language pair, there are 3003 sentences in WMT 2012 and 3000 sentences in WMT 2013.

Parameter	α	w_{fun}	w_{exact}	w_{stem}	w_{syn}	w_{par}	w_{1gram}	w_{2gram}	w_{3gram}
tuned values	0.9	0.2	0.9	0.6	0.6	0.6	0.6	0.5	0.1

Table 1: Parameter values after tuning on WMT 2010. α is from Formula (10). w_{fun} is the weight of function word. w_{exact}, w_{stem} and w_{syn} are the weights of the three match modules 'exact stem synonym' respectively. w_{par} is the weight of paraphrase-ngram. w_{1gram}, w_{2gram} and w_{3gram} are the weights of dep-ngram with the length of 1, 2 and 3 respectively.

Language pairs	cz-en	de-en	es-en	fr-en	ru-en
WMT2012	6	16	12	15	-
WMT2013	12	23	17	19	23

Table 2: The number of translation systems for each language pair on WMT 2012 and WMT 2013.

We parsed the reference into constituent tree by Berkeley parser[2] and then converted the constituent tree into dependency tree by Penn2Malt[3]. Presumably, the performance of the new metric will be better if the dependency trees are labeled by human. Reference dependency trees are labeled only once and can be used forever so it will not increase costs.

5.2 Baselines

In the experiments, we compare the performance of our metric with the widely-used lexicon-based metrics such as BLEU[4], TER[5] and METEOR[6], dependency-based metric HWCM and semantic-based metric SEMPOS (Macháček and Bojar, 2011) which has the best performance on system level according to the published results of WMT 2012.

The results of BLEU are obtained using 4-gram with smoothing option. The version of TER is 0.7.25. The results of METEOR are obtained by Version 1.4 with task option '*rank*'. We re-implement HWCM which employs an epsilon value of 10^{-3} to replace zero for smoothing purpose. The correlations of SEMPOS are obtained from the published results of WMT 2012 and WMT 2013.

5.3 Experiment Results

The experiments on both system level and sentence level are carried out. On system level, the correlations are calculated using Spearman's rank correlation coefficient ρ (Pirie, 1988). Kendall's rank correlation coefficient τ (Kendall, 1938) is employed to evaluate the sentence level correlation. Our method performs best when the maximum length of dep-ngram is set to 3, so we only present the results with the maximum length of 3. RED represents the new metric with exact match and the parameter values are set as follows. $\alpha = 0.5$. $w_{1gram} = w_{2gram} = w_{3gram} = 1/3$. REDp represents the new metric with extra resources and tuned parameter values which are listed in Table (1).

5.3.1 System level correlations

The system level correlations are shown in Table 3. RED is better than BLEU, TER and HWCM on average on both WMT 2012 and WMT 2013, which reflects that using syntactic information and only parsing the reference side are helpful. REDp gets the best result on all of the language pairs except cz-en on WMT 2012. The significant improvement from RED to REDp illustrates the effect of extra resources and the parameter tuning. Stem, synonym and paraphrase can enrich the reference and provide extra knowledge for automatic evaluation metric. There are several parameters in REDp, and different parameter values can make the performance of REDp different. So the performance can be optimized through parameter tuning. SEMPOS got the best correlation according to the published results of WMT

5.3.2 Sentence level correlations

The sentence level correlations on WMT 2012 and WMT 2013 are shown in Table 4. RED is better than BLEU and HWCM on all the language pairs, which reflects the effectiveness of syntactic information and only parsing the reference. By introducing extra resources and parameter tuning, REDp achieves significant improvement over RED. Stem, synonym and paraphrase can enrich the reference and provide extra knowledge for automatic evaluation metric. There are several parameters in REDp, and different parameter values can make the performance of REDp different. A better performance can be exploited through parameter tuning. From the results of REDp and METEOR, we can see that REDp gets the comparable results with METEOR on sentence level on both WMT 2012 and WMT 2013.

6 Conclusion and Future Work

In this paper, we propose a reference dependency based automatic MT evaluation metric RED. The new metric only uses the dependency trees of the reference, which avoids the parsing of the potentially noisy translations. Both long distance dependency information and the local continuous ngrams are captured by the new metric. The experiment results indicate that RED achieves better correlations than BLEU, TER and HWCM on both system level and sentence level. REDp, the improved version of RED through adding extra resources and preliminary parameter tuning, gets state-of-the-art results which are better than METEOR and SEMPOS on system level. On sentence level, REDp gets the comparable performance with METEOR.

In the future, we will use the dependency forest instead of the dependency tree to reduce the effect of parsing errors. We will also apply RED and REDp to the tuning process of SMT to improve the translation quality.

Abstract

We investigate the usefulness of syntactic knowledge in estimating the quality of English-French translations. We find that dependency and constituency tree kernels perform well but the error rate can be further reduced when these are combined with hand-crafted syntactic features. Both types of syntactic features provide information which is complementary to tried-and-tested non-syntactic features. We then compare source and target syntax and find that the use of parse trees of machine translated sentences does not affect the performance of quality estimation nor does the intrinsic accuracy of the parser itself. However, the relatively flat structure of the French Treebank does appear to have an adverse effect, and this is significantly improved by simple transformations of the French trees. Finally, we provide further evidence of the usefulness of these transformations by applying them in a separate task – parser accuracy prediction.

1 Introduction

Quality Estimation (QE) for Machine Translation (MT) involves judging the correctness of the output of an MT system given an input and no reference translation (Blatz et al., 2003; Ueffing et al., 2003; Specia et al., 2009). An accurate QE-for-MT system would mean that reliable decisions could be made regarding whether to publish a machine translation as is or to re-direct it to a translator, either for post-editing or to be translated from scratch. The scores produced by a QE system can also be used to choose between translations, in a system combination framework or in n-best list reranking. The work presented here takes place in the context of a wider study, the aim of which is to develop an English-French QE system so that technical support material that is produced on a daily basis by a company's English-speaking customers can be translated automatically into French and made available with confidence to the company's French-speaking customer base.

It is reasonable to assume that syntactic features are useful in QE for MT as a way of capturing the syntactic complexity of the source sentence, the grammaticality of the target translation and the syntactic symmetry between the source sentence and its translation. This assumption has been borne out by previous research which has demonstrated the usefulness of syntactic features for English-Spanish QE (Hardmeier et al., 2012; Rubino et al., 2012). We focus more closely on understanding the role of syntax by comparing the use of hand-crafted features and tree kernels (Collins and Duffy, 2002; Moschitti, 2006), and by teasing apart the contribution of target and source syntax.

We find that both tree kernels and manually engineered features produce statistically significantly better results than a strong set of non-syntactic features provided as a baseline by the organisers of the 2012 WMT shared task on QE for MT (Callison-Burch et al., 2012), and that both types of syntactic features can be combined fruitfully with this baseline. Furthermore, we show that it is worthwhile to combine tree kernels with hand-crafted features. Our tree kernel features are the complete set of tree fragments of both the constituency and dependency trees of the source and target sentences. Our hand-crafted feature set consists of an initial set of 489 constituency and dependency features which are then reduced to a set of 144 with no significant loss in performance.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2052–2063, Dublin, Ireland, August 23-29 2014.

We then show that source (English) constituency trees significantly outperform target (French) translation constituency trees in this task. We hypothesise that this is happening because a) the French parser has a lower accuracy compared to the English, or b) the target trees sentences are harder to parse, representing, as they do, potentially ill-formed machine translations which may result in noisier parse trees which are harder to learn from. If the first hypothesis were true, we would expect to see a drop in the accuracy of our QE system when we use lower-accuracy parses. We do not observe this. If the second hypothesis were true, we would expect to observe that the target trees were also less useful than the source trees in the opposite translation direction (French-English). Instead, we find that the target (English) constituency trees significantly outperform the source (French) constituency trees, suggesting that the difference between source and target that we observe in the original English-French experiment is related neither to intrinsic parser accuracy nor to translation direction but rather to the languages/treebanks.

We explore the extent to which the difference between French and English constituency trees is due to the relatively flatter structure of the French treebank. We use simple transformation heuristics to introduce more nodes into the French trees and significantly improve the performance. We also apply these heuristics in a second task, parser accuracy prediction. This task is similar to QE for MT except we are predicting the quality of a parse tree in the absence of a reference parse tree. We also find here that the modified trees also outperform the original trees, suggesting that one must proceed with caution when using French Treebank tree fragments in a machine-learning task.

The paper's novel contributions are as follows:

1. Evidence that syntactic information is useful in English-French QE for MT and further evidence that it is useful in QE for MT in general
2. A comparison of two methods of representing syntactic information in QE
3. A more comprehensive set of syntactic features than has been previously been used in QE for MT
4. A comparison of the role of source and target syntax in English-French QE for MT
5. A set of heuristics that can be applied to French Treebank trees resulting in performance improvements in the tasks of both QE for MT and parser accuracy prediction

The rest of this paper is organised as follows: we discuss related work in using syntax in QE in Section 2, we describe the data in Section 3, and we then go on to describe the QE framework and the systems built in Section 4. We follow this with an investigation of the role of source and target syntax in Section 5 before presenting our heuristics to modify the French constituency trees in Section 6.

2 Related Work

Features extracted from parser output have been used before in training QE for MT systems. Quirk (2004) uses a single syntax-based feature which indicates whether a full parse for the source sentence could be found. Hardmeier et al. (2012) employ tree kernels to predict the 1-to-5 post-editing cost of a machine-translated sentence. They use tree kernels derived from syntactic constituency and dependency trees of the source side (English) and only dependency trees of the translation side (Spanish). The tree kernels are used both alone and combined with non-syntactic features. The combined setting ranked second in the 2012 shared task on QE for MT (Callison-Burch et al., 2012). Rubino et al. (2012) explore a variety of syntactic features extracted from the output of both a hand-crafted broad-coverage grammar/parser and a statistical constituency parser on the WMT 2012 data set. They find that the syntactic features make an important contribution to the overall system. In a framework for combining QE and automatic metrics to evaluate MT output, Specia and Giménez (2010) use part-of-speech (POS) tag language model probabilities of the MT output 3-grams as features for QE and features built upon syntactic chunks, dependencies and constituent structure to build automatic MT evaluation metrics. Avramidis (2012) builds a series of models for estimating post-editing effort using syntactic features such as parse probabilities and syntactic label frequency. In a similar vein, Gamon et al. (2005) use POS tag trigrams, CFG rules and features derived from a semantic analysis of the MT output to classify it as fluent or disfluent.

In this work, we compare the use of tree kernels and hand-crafted features extracted from the constituency and dependency trees of the source and target sides of a translation pair, as well as comparing the role of source and target syntax. In addition, we conduct a more in-depth analysis of these approaches and compare the utility of syntactic information extracted from the source side and target sides of the translation.

3 Data

While there is evidence to suggest that predicting human evaluation scores is superior to predicting automatic metrics in QE for ME (Quirk, 2004), it has also been shown that human judgements are not necessarily consistent (Snover et al., 2006). A more practical consideration is that human evaluation exists for just a few language pairs and domains. To the best of our knowledge, the only available English-to-French data set which contains human judgements of translation quality are as follows:

- CESTA (Hamon et al., 2007), which is selected from the Official Journal of the European Commission and also from the health domain. In addition to the domain (and style) difference to newswire (the domain on which our parsers are trained), a major stumbling block which prevents us from using this data set is its small size: only 1135 segments have been evaluated manually.
- WMT 2007 (Callison-Burch et al., 2007), which contains only 302 distinct source segments (each with approx. 5 translations) only half of which is in the news domain.
- FAUST[1], which is out-of-domain and difficult to apply to our setting as the evaluations and post-edits are user feedbacks, often in the form of phrases/fragments.

Thus, we instead attempt to predict automatic metric scores as there is a sufficient amount of parallel text for our language pair and domain. We use `BLEU`[2](Papineni et al., 2002), `TER`[3](Snover et al., 2006) and `METEOR`[4] (Denkowski and Lavie, 2011), which are the most-widely used MT evaluation metrics. All metrics are applied at the segment level.[5]

We randomly select 4500 parallel segments from the News development data sets released for the WMT13 translation task (Bojar et al., 2013). In order to be independent of any one translation system, we translate the data set with the following three systems and randomly choose 1500 distinct segments from each:

- ACCEPT[6]: a phrase-based Moses system trained on training sets of WMT12 releases of Europarl and News Commentary plus data from Translators Without Borders (TWB)
- SYSTRAN: a proprietary rule-based system
- Bing[7]: an online translation system

The data set is randomly split into 3000 training, 500 development and 1000 test segments. We use the development set for tuning model parameters and building hand-crafted feature sets, and the test set for testing model performance and analyses purposes.

4 Syntax-based QE

One way to employ syntactic information in a machine-learning task is to manually compile a set of features that can be extracted automatically from a parse tree. An example of one such feature is the label of the root of the tree. Another method is to directly use these trees in a *tree kernel* (Collins and Duffy, 2002; Moschitti, 2006). This approach allows exponentially-sized feature spaces (e.g. all subtrees

[1] `http://www.faust-fp7.eu/faust/Main/DataReleases`

[2] Version 13a of MTEval script was used at the segment level.

[3] TER COMpute 0.7.25: `http://www.cs.umd.edu/~snover/tercom/`

[4] METEOR 1.4: `http://www.cs.cmu.edu/~alavie/METEOR/`

[5] We present `1-TER` to be more easily comparable to `BLEU` and `METEOR`. There is no upper bound for `TER` scores unlike the other two metrics. Scores higher than 1 occur when the number of errors is higher than the segment length. To avoid this, scores higher than 1 are cut-off to 1 before being converted to `1-TER`.

of a tree) to be efficiently modelled using dynamic programming and has shown to be effective in many natural language processing tasks including parsing and named entity recognition (Collins and Duffy, 2002), semantic role labelling (Moschitti, 2006), sentiment analysis (Wiegand and Klakow, 2010) and QE for MT (Hardmeier et al., 2012). Although there can be overlap between the information captured by the two approaches, each can capture information that the other one cannot. In addition, while tree kernels involve minimal feature engineering, hand-crafted features offer more flexibility. Moschitti (2006) shows that combining the two is beneficial. We use both hand-crafted features and tree kernels, applied separately and combined together.

For parsing the English and French data into their constituency structures, a PCFG-LA parser[8] is used. We train the English parser on the training section of the Wall Street Journal (WSJ) section of the *Penn Treebank* (PTB) (Marcus et al., 1993). The French parser is trained on the training section of the *French Treebank* (FTB) (Abeillé et al., 2003). We obtain dependency parses by converting the English constituency parses using the `Stanford` converter (de Marneffe and Manning, 2008) and the French parses using `Const2Dep` (Candito et al., 2010). We evaluate the performance of the QE models using Root Mean Square Error (`RMSE`) and Pearson correlation coefficient (`r`). To compute the statistical significance of the performance differences between QE models, we use paired bootstrap resampling following Koehn (2004). We randomly resample (with replacement) a set of N instances from the predictions of each of the two given systems, where N is the size of the test set. We repeat this sampling N times and count the number of times each of the two settings is better in terms of each measure (RMSE and `Pearson r`). If a setting is better more than 95% of the time, we consider it statistically significant at $p < 0.05$.

In the following sections, we first describe our baseline systems and then the quality estimation systems build using tree kernels, hand-crafted features and a combination of both.

4.1 Baseline QE Systems

In order to verify the usefulness of syntax-based QE, we build two baselines. The first baseline (`BM`) uses the mean of the segment-level evaluation scores in the training set for all instances. In the second baseline (`BW`), the 17 baseline features of the WMT12 QE Shared Task are used. `BW` is considered a strong baseline as the system that used only these features was ranked higher than many of the participating systems. We use support vector regression implemented in the `SVMLight` toolkit[9] to build `BW`. The Radial Basis Function (RBF) kernel is used. The results for both baselines are presented in the first two rows of Table 1. Since `BW` is a stronger baseline than `BM`, we will compare all syntax-based systems to `BW` only.

4.2 Syntax-based QE with Tree Kernels

Tree kernels are kernel functions that compute the similarity between two instances of data represented as trees based on the number of common fragments between them. Therefore, the need for explicitly encoding an instance in terms of manually-designed and extracted features is eliminated, while benefitting from a very high-dimensional feature space. Moschitti (2006) introduces an efficient implementation of tree kernels within a support vector machine framework. Instead of extracting all possible tree fragments, the algorithm compares only tree fragments rooted in two similar nodes. This algorithm is made available through `SVMLight-TK` software[10], which is used in this work.

In order to extract tree kernels from dependency trees, the labels on the arcs must be removed. Following Tu et al. (2012), the nodes in the resulting tree representation are word forms and dependency relations, omitting POS tag information. An example is shown in Figure 1. A word is a child of its dependency relation to its head. The dependency relation in turn is the child of the head word. This continues until the root of the tree.

Based on preliminary experiments on our development set, we use *subset* tree kernels, where the tree fragments are subtrees rooted at any node in the tree so that no production rule expanding a node in the

[8] `https://github.com/CNGLdlab/LORG-Release`. The Lorg parser is very similar to the Berkeley parser (Petrov et al., 2006), the main difference being its unknown word handling mechanism (Attia et al., 2010).

subtree is split. Unlike *subtree* kernels, *subset* tree kernels allow tree fragments with non-terminals as leaves. We tune the C parameter for Pearson r on the development set, with all other parameters left as default.

We build a system with all four parse trees for every training instance, which includes the constituency and dependency trees of the source and target side of the translation. The third row of Table 1 shows the performance of this system which is named TK. The results achieved using this system represent a statistically significant improvement over the BW baseline results. In order to examine their complementarity, we combine these tree kernels and the baseline features (BW+TK) in the fourth row of Table 1. This combined system performs better than the two individual systems.

While BLEU prediction is the most accurate (lowest RMSE), METEOR prediction appears to be the easiest to learn (highest Pearson r). TER prediction seems to be more difficult than BLEU and METEOR prediction, especially in terms of prediction error. This is probably related to the distribution of each of these metric scores in our data set. The standard deviations (σ) of BLEU, TER and METEOR scores are 0.1620, 0.1943 and 0.1652 respectively. The substantially higher σ of TER scores makes them harder to predict accurately leading to higher prediction error.

4.3 Syntax-based QE with Hand-crafted Features

We design a set of constituency and dependency *feature types*, some of which have previously been used by the works described in Section 2 and some introduced here. Each feature type contains at least two features, one extracted from the source and the other from the translation. Numerical feature types can be further instantiated by extracting the ratio and differences between the source and target side feature values. Some feature types are parametric meaning that they can be varied by changing the value of a parameter. For example, the non-terminal label is a parameter for the non-terminal-label-count

	Constituency
∗1	Label of the root node of the constituency tree
2	Height of the constituency tree which is the number of edges from root node to the farthest terminal (leaf) node
∗3	Number of nodes in the constituency tree
4	Log probability of the constituency parse assigned by the parser
∗5	Parseval F_1 score of the tree with respect to a tree produced by the Stanford parser (Klein and Manning, 2003)
∗6	Right hand side of the CFG production rule expanding the root node
7	All non-lexical and lexical CFG production rules expanding the tree nodes
∗8	Average arity of the non-lexical CFG production rules expanding the constituency tree nodes
9	Counts of each non-terminal label in the tree
∗10	POS unigrams, 3-grams and 5-grams
11	POS n-gram scores against language models trained on the POS tags of the respective treebanks using the SRILM toolkit (`http://www.speech.sri.com/projects/srilm/`) with Witten-Bell smoothing
∗12	Counts of each 12 universal POS tags (Petrov et al., 2012)
∗13	Location of the first verb in the sentence in terms of the token distance from the beginning
∗14	Average number of POS n-grams in each n-gram frequency quartile of the POS corpora of the respective treebanks
	Dependency
∗1	POS tag of the top node (dependent of the dummy root node) of the dependency tree
∗2	Number of dependents of the top node
∗3	Sequence of all dependency relations which modify the top node
∗4	Sequence of the POS tags of the dependents of the top node
∗5	Average number of dependents per node
∗6	Height of the tree computed in the same way for the constituency tree
∗7	3- and 5-gram sequences of dependency relations of the tokens to their head
∗8	Number of most frequent dependency relations in our `News` training set
∗9	Dependency relation n-gram scores against language models trained on the respective treebanks for each language
∗10	Average number of dependency relation n-grams in each n-gram frequency quartile of the respective treebanks
∗11	Pairs of tokens and their dependency relations to their head

Table 2: Constituency and dependency feature types

feature type. Therefore, it instantiates as several features, one for each non-terminal-label.

As in `BW`, we use support vector machines (SVM) to build the QE systems using these hand-crafted features. We keep only those features which fire for more than a threshold which is set empirically on the development set. Table 2 lists our syntax-based feature types and their descriptions. Those that have, to the best of our knowledge, not been used in QE for MT before are marked with an asterisk.

The total number of feature-value pairs in the full feature set is 489. Since this feature set is large and contains many sparse features, we attempt to reduce it through ablation experiments in which we directly compare the effect of leaving out features that we suspect may be redundant. For example, we investigate whether either the ratio or difference of the source and target numerical features or both of them are redundant by building three systems, one without ratio features, one without difference features and one with neither. This process is also carried out for log probability and perplexity features, original and universal POS-tag-based features, n-gram and language model score features, lexical and non-lexical CFG rules, and n-gram orders (i.e. 3-gram vs. 5-gram features). This process proved useful: we found, for example, that either 3- or 5-grams worked better than both together and features based on universal POS tags better than those based on original POS tags.

The final reduced feature set contains 144 features-value pairs. We build one QE system with all 489 features `HC-all` and one with the reduced set of 144 features `HC` . Table 3 compares the performance on the development and test set. The system with the reduced feature set performs consistently better than the `HC-all` system on the development set, mostly with statistically significant differences. However, on the test set, the performance degrades albeit not statistically significantly. Considering a more than 70% reduction in feature set size, this relatively small degradation is tolerable. We use the reduced feature set as our hand-crafted feature set for the rest of the work.

Compared to `TK` in Table 1 (third and fourth versus fifth and sixth rows), the performances are lower for all MT metrics, though not statistically significantly. It is worth noting that we observed an opposite

behaviour on the development set, where hand-crafted features largely outperform tree kernels. This suggests that the tree kernels are more generalisable. We also combine these features with the WMT 17 baseline features (BW+HC). This combination also improves over both syntax-based and baseline systems, confirming again the usefulness of syntactic information in addition to surface features.

We combine tree kernels and hand-crafted features to build a full syntax-based QE system (SyQE), which improves over both TK and HC (Table 1) . The improvements for TER and METEOR prediction are slight but statistically significant for BLEU prediction. This system is also combined with BW in BW+SyQE (the last row of Table 1), resulting in statistically significant gains for all metrics.

5 Source and Target Syntax in Syntax-based QE

We now turn our attention to the parts played by source and target syntax in QE for MT. To save space, we present only the BLEU scores for the tree kernel systems. Table 4 shows the results achieved by systems built using either the source or target side of the translations.

At a glance, it can be seen that the source side constituency tree kernels outperform the target side ones, while the opposite is the case for dependency tree kernels. The differences for constituency trees are however substantially bigger. When both constituency and dependency trees are combined, the source side trees perform better (TK-CD-S vs. TK-CD-T).

The following three hypotheses could explain this difference between TK-C-S and TK-C-T:

1. **The Role of Parser Accuracy:** The fact that French parsing models do not reach the high Parseval F1s achieved by English parsing models could explain the difference in usefulness between the French and English consistuency trees. On the standard parsing test sets, the English parsing model achieves an F1 of 89.6 and the French an F_1 of 83.4.
2. **Parsing Machine Translation Output:** The difference between the source and target could be happening because the target side is machine translation output and (presumably) represents a lower

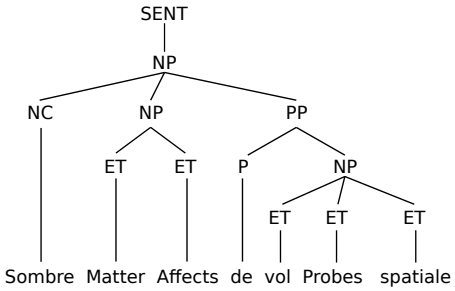

Figure 2: Parse tree of the machine translation of *Dark Matter Affects Flight of Space Probes* to French

quality set of sentences than the source (see Figure 2 for an example of a parse tree for a poor translation).

3. **Differences in Annotation Strategies:** The difference between the source and target could be due to the idiosyncrasies of the underlying treebanks which is not carried over via the conversion tools to the dependency structure.

Hypotheses 1 and 2 relate the usefulness of parse trees in QE to the intrinsic quality of the parse trees. French constituency trees are less accurate than English ones, either because the French parsing model is not as accurate as the English one (Hypothesis 1) or because the possibly ungrammatical nature of the French parsing input adversely affects the quality of the parse tree (Hypothesis 2). Although this low quality would be expected to affect the dependency trees in the same way since they are directly derived from the consistency trees, this is not the case and it appears that the problematic aspects of the French parses are abstracted away from the dependency trees.

To test the first hypothesis, we investigate the role of parser accuracy in QE. For both languages, we substitute the standard parsing models used in all our prior experiments with "lower-accuracy" models trained using only a fraction of the training data (following Quirk and Corston-Oliver (2006)). The English parsing model achieves an F_1 of 72.5 and the French an F_1 of 66.5, representing drops of approximately 17 points from the original models. The RMSE and Pearson r of the new QE model are 0.1583 and 0.2350 compared to 0.1581 and 0.2437 of the one trained with original trees (see also the third row of Table 1). These results show that the use of these lower-accuracy models has only a minimal and statistically insignificant effect on QE performance, suggesting that intrinsic parser accuracy is not the reason why the target constituency trees are less useful than the source constituency trees.[11]

To investigate the second hypothesis, we switch the translation direction to French-to-English. Therefore, we now parse the well-formed French input sentences and the machine-translated English segments. If the second hypothesis were true, the target side parse trees in this direction would still underperform the source side ones. The results are shown in Table 5. All the systems using target trees outperform those using source trees. The difference between source and target in the models that use constituency trees is especially substantial and statistically significant. Thus, it is apparent that the suspected lower quality of constituency parse trees of MT output is not the reason for the lower QE performance.

We now seek the answer in our third hypothesis, i.e. in the difference between the annotation schemes of the PTB and the FTB. One major difference, noted by, for example, Schluter and van Genabith (2007), is that the FTB has a relatively flatter structure. It lacks a verb phrase (`VP`) node and phrases modifying the verb are the sibling of the verb nucleus. We investigate this further in the next section.

6 Modifying French Parse Trees

In order to test whether the annotation strategy is a reason for the lower performance of French constituency tree kernels, we apply a set of three heuristics which introduce more structure to the French parse trees (1&2) or simply make them more PTB-like (3):

- *Heuristic 1* automatically adds a `VP` node above the verb node (`VN`) and at most 3 of its immediate adjacent nodes if they are noun or prepositional phrases (`NP` or `PP`).

[11] See (Kaljahi et al., 2013) for a more detailed exploration of the role of parser accuracy in QE for MT.

Table 6: QE with tree kernels using original and modified French trees ($_m$)

- *Heuristic 2* stratifies some of the production rules in the tree by grouping together every two equal adjacent POS tags under a new node with a tag made of the POS tag suffixed with _St.
- *Heuristic 3* moves coordinated nodes (the immediate left sibling of the COORD node) under COORD.

Figure 3 shows examples of the application of each of these methods. We apply these heuristics to the parsed MT output in the English-French translation direction and rebuild the tree kernel system with translation side constituency trees (TK-C-T) and the full tree kernel system (TK-CD-ST) with the modified trees. The results are presented in Table 6. Despite the possibility of introducing linguistic errors, these heuristics yield a statistically significant improvement in QE performance. Unsurprisingly, the changes are bigger for the system with only translation side constituency trees as in the full system there are three other tree types involved. These results suggest that the structure of the French constituency trees is a factor in the lower performance of its tree kernels in QE.[12]

The gain achieved by applying these heuristics is related to the fact that there are more similar fragments extracted from the modified structure which are useful for the tree kernel system. For example, in the original top left tree in Figure 3, there is no chance that a fragment consisting only of VN and NP – a very common structure and thus useful in calculating tree similarity – will be extracted by the *subset* tree kernel. The reason is that this kernel type does not allow the production rule to be split (in this case the rule expanding the S node). However, after applying Heuristic 1, the fragment equivalent to VP -> VN NP production rule can be easily extracted. Among the three heuristics, the first one contributes the largest part of the improvement; the other two have a very slight effect according to the results of their individual application, though they contribute to the overall performance when all three are combined.

The success of using modified French trees in improving tree kernel performance may of course depend on the data set and even the task in hand, and may not be generalisable. We next explore this question by applying the modification to a different task *and* a different data set.

6.1 Parser Accuracy Prediction

The task we choose is parser accuracy prediction, the aim of which is to predict the accuracy of a parse tree without a reference (QE for parsing). The task was previously explored for English by Ravi et al.

[12] We also see a slightly smaller improvement for the hand-crafted features using the modified French trees. The combination of tree kernels and hand-crafted features with the modified trees leads to a statistically significant improvement over the combination with the original trees.

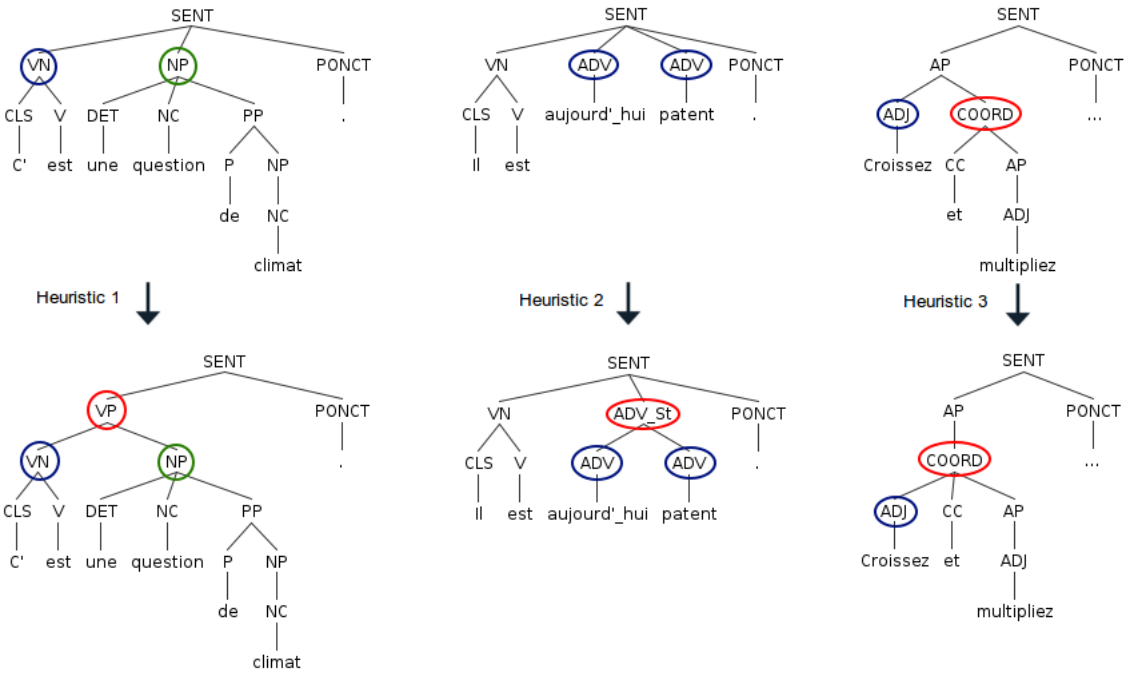

Figure 3: Application of tree modification heuristics on example French translation parse trees

	RMSE	r
PAP	0.1239	0.4035
PAP_m	0.1233	**0.4197**

Table 7: Parser Accuracy Prediction (PAP) performance with tree kernels using original and modified French trees ($_m$)

(2008). We build a tree kernel model to predict the accuracy of French parses. To train the system, we parse the training section of FTB with our French parser and score them using F_1. We use the FTB development set to tune the SVM C parameter and test the model on the FTB test set. Two parser accuracy prediction models are then built using this setting, one with the original parse trees and the second with the modified parse trees produced using the three heuristics listed above. The results are presented in Table 7.

Both RMSE and Pearson r improve with the modified trees, where the r improvement is statistically significant. Although the improvement we observe is not as large as the one we observed for the QE for MT task, the results add weight to our claim that the structure of the FTB trees should be optimised for use in tree kernel learning.

7 Conclusion

We analysed the utility of syntactic information in QE of English-French MT and found it useful both individually and combined with standard QE features. We found that tree kernels are a convenient and effective way of encoding syntactic knowledge but that our hand-crafted feature set also brings additional, useful information. As a result of comparing the role of source and target syntax, we also found that the constituent structure in the FTB could be amended to be more useful in QE for MT and parser accuracy prediction. Now that we have explored the role of syntax in this project, our next step is try to further improve our QE system by adding semantic information. However, there are many other ways in which the research in this paper could be further extended. Our focus is on the language pair English-French and the QE task but it would certainly be interesting to perform a similar analysis on the role of syntax in QE for other language pairs, or to investigate the impact of French tree modification on other tasks.

Acknowledgments

This research has been supported by the Irish Research Council Enterprise Partnership Scheme (EPSPG/2011/102 and EPSPD/2011/135) and the computing infrastructure of the Centre for Next Generation Localisation at Dublin City University. Abstract

In this paper we explicitly consider source language syntactic information in both rule extraction and decoding for hierarchical phrase-based translation. We obtain tree-to-string rules by the GHKM method and use them to complement Hiero-style rules. All these rules are then employed to decode new sentences with source language parse trees. We experiment with our approach in a state-of-the-art Chinese-English system and demonstrate +1.2 and +0.8 BLEU improvements on the NIST newswire and web evaluation data of MT08 and MT12.

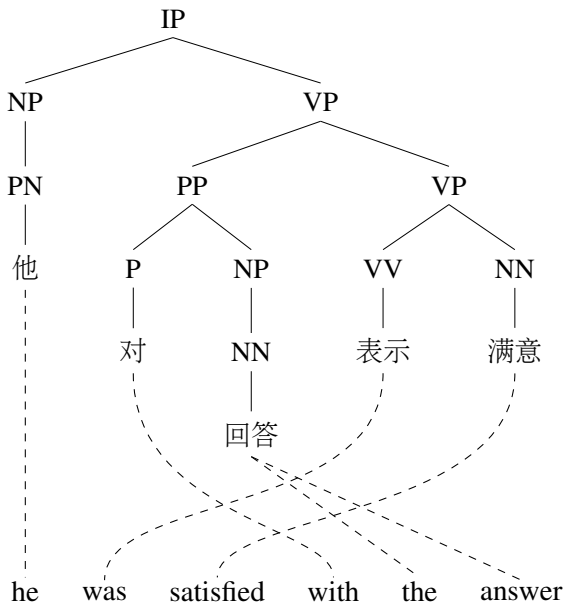
1 Introduction

Synchronous context free grammars (SCFGs) are widely used in statistical machine translation (SMT), with hierarchical phrase-based translation (Chiang, 2005) as the dominant approach. Hiero grammars are easily extracted from word-aligned parallel corpora and can capture complex nested translation relationships. Hiero grammars are formally syntactic, but rules are not constrained by source or target language syntax. This lack of constraint can lead to intractable decoding and bad performance due to the over-generation of derivations in translation. To avoid these problems, the extraction and application of SCFG rules is typically constrained by a source language span limit; (non-glue) rules are lexicalised; and rules are limited to two non-terminals which are not allowed to be adjacent in the source language. These constraints can yield good performing translation systems, although at a sacrifice in the ability to model long-distance movement and complex reordering of multiple constituents.

By contrast, the GHKM approach to translation (Galley et al., 2006) relies on a syntactic parse on either the source or target language side to guide SCFG extraction and translation. The parse tree provides linguistically-motivated constraints both in grammar extraction and in translation. This allows for looser span constraints; rules need not be lexicalised; and rules can have more than two non-terminals to model complex reordering multiple constituents. There are also modelling benefits as more meaningful features can be used to encourage derivations with "well-formed" syntactic tree structures. However, GHKM can have robustness problems in that translation relies on the quality of the parse tree and the diversity of rule types can lead to sparsity and limited coverage.

In this paper we describe a simple but effective approach to introducing source language syntax into hierarchical phrase-based translation to get the benefits of both approaches. Unlike previous work, we do not resort to soft/hard syntactic constraints (Marton and Resnik, 2008; Li et al., 2013) or Hiero-style rule extraction algorithms for incorporating syntactic annotation into SCFGs (Zollmann and Venugopal, 2006; Zhao and Al-Onaizan, 2008; Chiang, 2010). We instead use GHKM syntactic rules to augment the baseline Hiero grammar and decoder. Our approach uses GHKM rules if possible and Hiero rules if not. We report performance on a state-of-the-art Chinese-English system. In a large-scale NIST evaluation task, we find significant improvements of over 1.2 and 0.8 BLEU relative to a strong Hiero baseline on the newswire and web evaluation data of MT08 and MT12. We also investigate variations in the GHKM formalism and find, for example, that our approach works well with binarized trees.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2064–2074, Dublin, Ireland, August 23-29 2014.



Hiero-style SCFG Rules

h_1	X → ⟨他, he⟩
h_2	X → ⟨对, with⟩
h_3	X → ⟨回答, the answer⟩
h_4	X → ⟨表示 满意, was satisfied⟩
h_5	X → ⟨X_1 表示 满意, was satisfied X_1⟩
h_6	X → ⟨X_1 表示 X_2, was X_2 X_1⟩
h_7	X → ⟨X_1 对 X_2 表示 满意, X_1 was satisfied with X_2⟩

Tree-to-String Rules

r_1	NP(PN(他)) → he
r_2	P(对) → with
r_3	NP(NN(回答)) → the answer
r_4	VP(VV(表示) NN(满意)) → was satisfied
r_5	PP(x_1:P x_2:NP) → x_1 x_2
r_6	VP(x_1:PP x_2:VP) → x_2 x_1
r_7	IP(x_1:NP x_2:VP) → x_1 x_2
r_8	VP(PP(P(对) x_1:NP) x_2:VP) → x_2 with x_1

Figure 1: Hiero-syle and tree-to-string rules extracted from a pair of word-aligned Chinese-English sentences with a source language (Chinese) parse tree.

2 Background

2.1 Hierarchical Phrase-based Translation

In the hierarchical phrase-based approach, translation is modelled using SCFGs. In general, probabilistic SCFGs can be learned from word-aligned parallel data using heuristic methods (Chiang, 2007). We can first extract initial phrase pairs and then obtain hierarchical phrase rules (i.e., rules with non-terminals on the right hand side). Once the SCFG is obtained, new sentences can be decoded by finding the most likely derivation of SCFG rules. See Figure 1 for example rules extracted from a sentence pair with word alignments. A sequence of such rules covering the words of the source sentence is a SCFG derivation, e.g., rules h_7, h_1 and h_3 generate a derivation for the sentence pair.

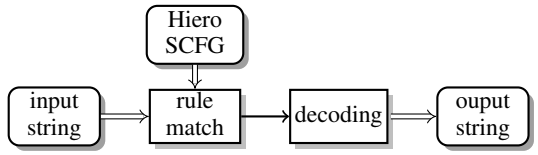
The Hiero SCFG allows vast numbers of derivations which can make unconstrained decoding intractable. In practice, several constraints are applied to control the model size and reduce ambiguity. Typically these are: (a) a rule span limit to be applied in decoding and sometimes also in rule extraction, set to 10; (b) a limit on the rank of the grammar (number of non-terminals that can appear on a rule), set to 2; and (c) a prohibition of consecutive non-terminals on the source language side of a rule (except the glue rules).

2.2 Tree-to-String Translation

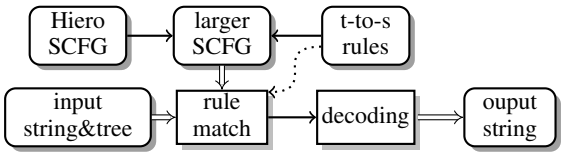
Instead of modelling the problem based on surface strings, tree-to-string systems model the translation equivalency relations from source language syntactic trees to target language strings using derivations of tree-to-string rules (Liu et al., 2006; Mi et al., 2008; Huang and Mi, 2010; Feng et al., 2012). A tree-to-string rule is a tuple $\langle s_r, t_r, \sim \rangle$, where s_r is a source language tree-fragment with terminals and non-terminals at leaves; t_r is a string of target-language terminals and non-terminals; and $\sim$ is a 1-to-1 alignment between the non-terminals of s_r and t_r, for example, VP(VV(提高) x_1:NN) → increases x_1 is a tree-to-string rule, where the non-terminals labeled with the same index x_1 indicate the alignment.

To obtain tree-to-string rules, a popular way is to perform the GHKM rule extraction (Galley et al., 2006) on the bilingual sentences with both word alignment and source (or target) language phrase-structure tree annotations. In GHKM extraction, we first compute the set of the minimally-sized translation rules that can explain the mappings between source language tree and target-language string while respecting the alignment and reordering between the two languages. More complex rules are then learned by composing two or more minimal rules. See Figure 1 for rules extracted using GHKM.

One of the advantages of the above model is that non-terminals in tree-to-string rules are linguistically



(a) decoding with Hiero rules only



(b) decoding with Hiero and tree-to-string rules

Figure 2: Overview of the Hiero baseline (a) and our approach (b). ⇒ means input or output of the decoder. t-to-s is a short for tree-to-string.

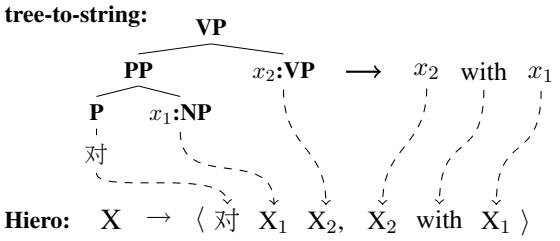


Figure 3: Converting the tree-to-string rule r_8 from Figure 1 to a Hiero-style rule.

motivated and can span word sequences with arbitrary length. Also, one can use rules with consecutive (or more than two) source language non-terminals when the source language parse tree is available. For example, r_8 in Figure 1 has a good Chinese syntactic structure indicating the reordered translations of NP and VP. However, such a rule would not normally be included in a Hiero grammar, as it would require consecutive source language non-terminals (see Figure 3).

3 The Proposed Approach

Both the tree-to-string model and the hierarchical phrase-based model have their own strengths and weaknesses. For example, tree-to-string systems are good at modelling long distance reordering, while hierarchical phrase-based systems are relatively more powerful in handling ill-formed sentences[1] and free translations (Zhao and Al-Onaizan, 2008; Vilar et al., 2010). Here we present a method to enhance hierarchical phrase-based systems with tree-to-string rules and benefit from both models. The idea is simple: we obtain both the tree-to-string grammar and the Hiero-style SCFG from the training data, and then use tree-to-string rules as additional rules in decoding with the SCFG.

Figure 2 shows an overview of our approach and the usual hierarchical phrase-based approach. Our approach requires source language parse trees to be input in both rule extraction and decoding. In rule extraction, we acquire tree-to-string rules using the GHKM method and Hiero-style rules using the Hiero-style rule extraction method to form a larger SCFG. Then, we make use of both the input string and parse tree to decode with the SCFG rules. We now describe our approach.

3.1 Transforming Tree-to-String Rules into SCFG Rules

As described in Section 2, tree-to-string rules have a different form from that of SCFG rules. We will use tree-to-string rules in our hierarchical phrase-based systems by converting each tree-to-string rule into an SCFG rule. The purpose of doing this is to make tree-to-string rules directly accessible to the Hiero-style decoder which performs decoding with SCFG rules.

The rule mapping is straightforward: given a tree-to-string rule $\langle s_r, t_r, \sim \rangle$, we take the frontier nodes of s_r as the source language part of the right hand side of the resulting SCFG rule, and keep t_r and $\sim$ unchanged. Then we replace the non-terminal label with that used in the hierarchical phrase-based system (e.g., X). See Figure 3 for rule mapping of rule r_8 of Figure 1.

In this way, every tree-to-string rule is associated with exactly one SCFG rule. Therefore we can obtain a larger SCFG by combining the rules from the original Hiero-style SCFG and the transformed tree-to-string rules. As explained next, to prevent computational problems we will apply these new rules

[1]For example, the parser fails for 4% of the sentences in our training corpus, and 3% and 6% of the newswire and web development/test sentences, indicating that the data is sometimes ill-formed.

only on the spans that are consistent with the input parse trees. The main goal is to use the tree and the adapted tree-to-string rules to provide the decoder with new linguistically-sensible translation hypotheses that may be prevented by the usual Hiero constraints, and to do so without incurring a computational explosion.

We categorize SCFG rules into two categories based on their availability in Hiero and GHKM extraction. If an SCFG rule is obtained from Hiero extraction, it is a *type 1* rule; If not (i.e., this rule is only available in GHKM extraction), it is a *type 2* rule. E.g., the SCFG rule in Figure 3 is a type 2 rule because it is not available in the original Hiero-style SCFG but can be generated from the tree-to-string rule.

Next we describe how each of these rule types are applied in decoding. We also describe which features are used and how they are computed for each rule type.

3.2 Decoding

Both types of SCFG rules can be employed by usual Hiero decoders with a slight modification. Here we follow the description of Hiero decoding by Iglesias et al. (2011). The source sentence is parsed under the Hiero grammar using the CYK algorithm. Each cell in the CYK grid has associated with it a list of rules that apply to its span; these rules are used to construct a recursive transition network (RTN) which represents all translations of the source sentence under the grammar. The RTN is expanded to a weighted finite state automaton for composition with n-gram language models (de Gispert et al., 2010). Translations are produced via shortest path computation.

This procedure accommodates type 1 rules directly. For tree-to-string rules associated with type 2, we attempt to match rules to the source syntactic tree. If a match is found: the source span of the matching tree fragment is noted and the CYK cell for that span is selected; the tree-to-string rule is converted to a Hiero-style rule; and that rule is added to the list of rules in the selected CYK cell. Once this process is finished, RTN construction, expansion, and language model composition proceeds as usual. Similar modifications could be made to incorporate these rules into cube pruning (Chiang, 2007), cube growing (Huang and Chiang, 2007), and PDT intersection and expansion (Iglesias et al., 2011). We now elaborate on the rule matching strategy.

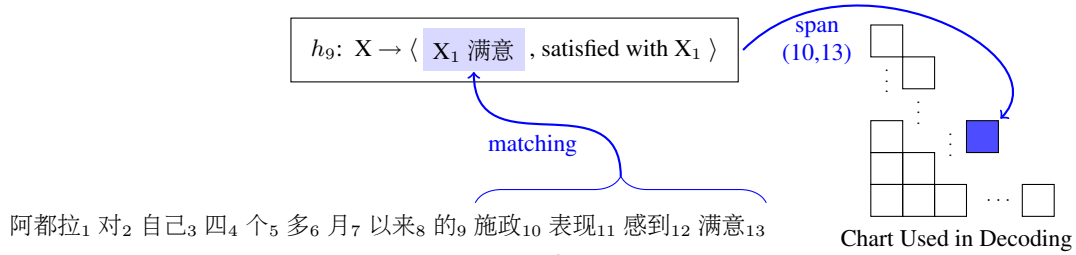
Type 1 Rules The source sentence is parsed as is usual in Hiero-style translation, with the exception that we impose no span limit on rule applications for source spans corresponding to constituents in the Chinese syntactic tree. Rule matching, the procedure that determines if a rule applies to a source span, is based on string matching (see Figure 4(a)). For example, the type 1 rule h_9 in Figure 4(c) can be applied to spans (1,13) and (2,13) since both of them agree with tree constituents (see Figure 4(b)). But h_9 is not applied to span (3,13) because that span is longer than 10 words and agrees with no syntactic tree constituent.

Type 2 Rules If the source side of a tree-to-string rule matches an input tree fragment: 1) that rule is converted to a Hiero-style SCFG rule (Section 3.1); and 2) the Hiero-style rule is added to the rules linked with the CYK grid cell associated with the span of the source syntactic tree fragment. Here, rules are applied via tree matching. For example, rule h_{11} in Figure 4(b) matches the tree fragment spanning positions (2,13).

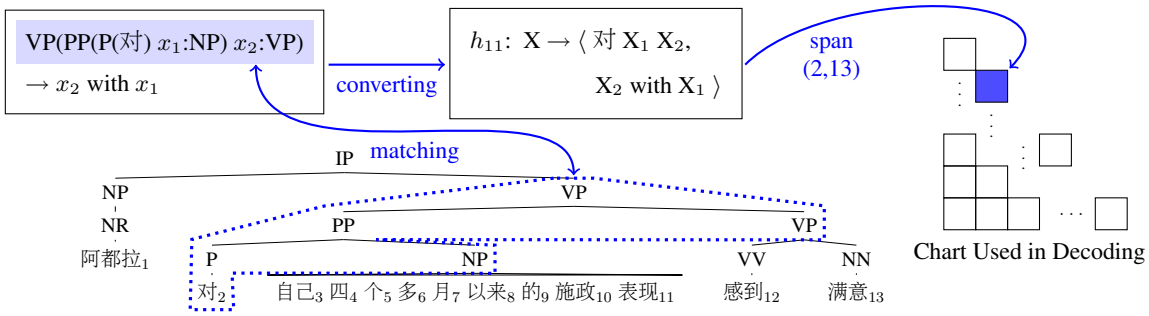
It is worth noting that some type 1 rules may be found via both Hiero-style and tree-to-string grammar extraction. In this case we monitor whether a rule can be applied as a tree-to-string rule using tree-matching so that features (Section 3.3) and weights can be set appropriately. As an example, rule h_{10} in Figure 4 is available in both extraction methods. For span (2,11), this rule can be matched via both string matching and tree matching. We then note that we can apply h_{10} as a tree-to-string rule for span (2, 11) and activate the corresponding features defined in Section 3.3. For other spans (e.g., spans (2,3)-(2,10)), no tree fragments can be matched and the baseline features are used for h_{10}.

3.3 Features

The baseline feature set used in this work consists of 12 features (Pino et al., 2013), including a 4-gram language model, a strong 5-gram language model, bidirectional translation probabilities, bidirectional lexical weights, a word count, a phrase count, a glue rule count, a frequency-1 rule count, a frequency-2



(a) matching a type 1 rule (h_9) with the input string



(b) matching a type 2 rule (h_{11}) with the input parse tree

ID	Type	Hiero-style Rule	Tree-to-string Rule	Applicable Spans
h_8	type 1	X → ⟨ 感到 满意, is satisfied ⟩	N/A	(12,13)
h_9	type 1	X → ⟨ X$_1$ 满意, satisfied with X$_1$ ⟩	N/A	(i,13), $i = 1, 2$ or $4 \leq i \leq 12$
h_{10}	type 1	X → ⟨ 对 X$_1$, with X$_1$ ⟩	PP(P(对) x_1NP) → with NPx_1	(2,j), $3 \leq j \leq 11$ or $j = 13$
h_{11}	type 2	X → ⟨ 对 X$_1$ X$_2$, X$_2$ with X$_1$ ⟩	VP(PP(P(对) x_1:NP) x_2:VP) → x_2 with x_1	(2,13)

(c) example rules used in decoding

Figure 4: Decoding with both Hiero-style and tree-to-string grammars (span limit = 10). A span (i,j) means spanning from position i to position j.

rule count, and a larger-than-frequency-2 rule count [2]. In addition, we introduce several features for applying tree-to-string rules.

- **Rule type indicators**. We consider four indicator features, indicating tree-to-string rules, lexicalized tree-to-string rules, rules with consecutive non-terminals, and non-lexicalized rules. Note that the tree-to-string rule indicator feature is in principle a generalization of the soft syntactic features (Marton and Resnik, 2008), in that a bonus (or penalty) is applied when a rule application is consistent with a source tree constituent. The difference lies in that the tree-to-string rule indicator feature does not distinguish between different syntactic labels, whereas soft syntactic features do.

- **Features in syntactic MT**. In general tree-to-string rules have their own features which are different from those used in Hiero-style systems. For example, the features in syntactic MT systems can be defined as the generation probabilities conditioned on the root symbol of the tree-fragment. Here we choose five popular features used in syntactic MT systems, including the bi-directional phrase-based conditional translation probabilities (Marcu et al., 2006) and three syntax-based conditional probabilities (Mi and Huang, 2008). All these probabilities can be computed by relative-frequency estimates. For example, the phrase-based features are the probabilities of translating between the frontier nodes of s_r and t_r. The syntax-based features are the probabilities of generating r conditioned on its root,

[2]We experimented with soft syntactic features (Marton and Resnik, 2008) but found no improvement over our baseline system.

source and target language sides, respectively. More formally, we use the following estimates for these probabilities:

$$\begin{aligned}
\mathrm{P}_{phr}(t_r \mid s_r) &= \frac{\sum_{r'':\varphi(s_{r''})=\varphi(s_r)\wedge t_{r''}=t_r} c(r'')}{\sum_{r':\varphi(s_{r'})=\varphi(s_r)} c(r')} \\
\mathrm{P}_{phr}(s_r \mid t_r) &= \frac{\sum_{r'':\varphi(s_{r''})=\varphi(s_r)\wedge t_{r''}=t_r} c(r'')}{\sum_{r':t_{r'}=t_r} c(r')} \\
\mathrm{P}(r \mid root(r)) &= \frac{c(r)}{\sum_{r':root(r')=root(r)} c(r')} \\
\mathrm{P}(r \mid s_r) &= \frac{c(r)}{\sum_{r':s_{r'}=s_r} c(r')} \\
\mathrm{P}(r \mid t_r) &= \frac{c(r)}{\sum_{r':t_{r'}=t_r} c(r')}
\end{aligned}$$

where $c(r)$ is the count of r, and $root(\cdot)$ and $\varphi(\cdot)$ are functions that return the source root symbol for a tree-to-string rule and the sequence of leaf nodes for a tree-fragment respectively.

4 Evaluation

4.1 Experimental Setup

We report results in the NIST MT12 Chinese-English task, where our baseline system was among the top academic systems. The parallel training corpus consists of 9.2 million sentence pairs which are provided within the NIST Chinese-English MT12 track. Word alignments are obtained using MTTK (Deng and Byrne, 2008) in both Chinese-to-English and English-to-Chinese directions, and then unioning the links. The data from newswire and web genres was used for tuning and test. The development sets contain 1,755 sentences and 2160 sentences for the two genres respectively. The test sets (newswire: 1,779 sentences, web: 1768 sentences) contain all newswire and web evaluation data of MT08 (mt08), MT12 (mt12), and MT08 progress test (mt08.p). All Chinese sentences in the training, development and test sets were parsed using the Berkeley parser (Petrov and Klein, 2007). A Kneser-Ney 4-gram language model was trained on the AFP and Xinhua portions of the English Gigaword in addition to the English side of the parallel corpus. A stronger 5-gram language model was trained on all English data of NIST MT12 and the Google counts corpus using the "stupid" backoff method (Brants et al., 2007).

For decoding we use HiFST, which is implemented with weighted finite state transducers (de Gispert et al., 2010). A two-pass decoding strategy is adopted; first, only the 4-gram language model and the translation model are activated; and then, the 5-gram language model is applied for second-pass rescoring of the translation lattices generated by the first-pass decoding stage. We extracted SCFG rules from the parallel corpus using the standard heuristics (Chiang, 2007) and filtering strategies (Iglesias et al., 2009). The span limit was set to 10 in extracting basic phrases and decoding. All features weights were optimized using lattice-based minimum error rate training (Macherey et al., 2008).

For tree-to-string extraction, we used a reimplementation of the GHKM method (Xiao et al., 2012) and extracted rules from a 600K-sentence portion of the parallel data. To prune the tree-to-string rule set, we restricted the extraction to rules with at most 5 frontier non-terminals and 5 terminals. Also, we discarded lexicalized rules with a Chinese-to-English translation probability of < 0.02 and non-lexicalized rules with a Chinese-to-English translation probability of < 0.10.

4.2 Results

We report MT performance in Table 1 by case-insensitive BLEU (Papineni et al., 2002). The experiments are organized as follows:

- Baseline and Span Limits (exp01 and exp02)
  First we study the effect of removing the span limit for tree constituents, that is, SCFG rules can be

Entry	System	Newswire					Web				
		tune (1755)	mt08 (691)	mt12 (400)	mt08.p (688)	all test (1779)	tune (2160)	mt08 (666)	mt12 (420)	mt08.p (682)	all test (1768)
exp01	baseline	35.84	35.85	35.47	35.50	35.63	29.98	25.15	23.07	27.19	25.33

exp10	exp04 + forest binariz.	37.03	37.27	37.09	36.62	36.98*	31.20	25.99	23.59	28.09	26.15*

Table 1: Case-insensitive BLEU[%] scores of various systems. += means incrementally adding methods/features to the previous system. * means that a system is significantly different than the exp01 baseline at $p < 0.01$.

applied to any spans when they respect the tree constituents of the input tree. It can be regarded as the simplest way of using source syntax in Hiero-style systems. Seen from Table 1, removing the span limit shows modest BLEU improvements. It agrees with the previous result that loosening the constraints on spans is helpful to systems based on the hard syntactic constraints (Li et al., 2013).

- GHKM+Hiero (exp03 and exp04)
  The results of our proposed approach (w/o new features) are reported in exp03 and exp04. We see that incorporating tree-to-string rules yields +0.6 and +0.5 improvements on the collected newswire and web test sets (exp03 vs exp01). The new features (Section 3.3) give a further improvement (exp04 vs exp03). This result confirms that the system can learn a preference for certain types of rules using the new features.

- Impact of Search Space (exp05)
  We also study the impact of search space on system performance. To do this, we force the improved system (exp04) to respect source tree constituents and to discard any hypotheses which violate the tree constituent constraints. Seen from exp05, this system has a lower BLEU score than both the Hiero baseline (exp01) and GHKM+Hiero system (exp04), strongly suggesting that restricting MT systems to a smaller space of hypotheses is harmful.

- GHKM+Hiero, Spans > 10 Only (exp06)
  Another interesting question is whether tree-to-string rules and features are more helpful to larger spans. We restricted our approach to spans > 10 only and conducted another experiment. As is shown in exp06, applying tree-to-string rules and features for large spans is beneficial (exp06 vs. exp01). But it underperforms the system with the full use of tree-to-string rules (exp06 vs. exp04). This interesting observation implies that applying tree-to-string rules on smaller spans introduces good hypotheses that can be selected with our additional features.

- Impact of Failed Parses (exp07)
  As noted in Section 3, the parser fails to parse some of the sentences in our experiments. In this case our approach generates the baseline result using the Hiero model (i.e., type 1 rules only). To investigate the effect of failed parse trees on system performance, we also report the BLEU score including null translations for which the parser fails. As shown in exp07, there are significantly lower BLEU scores when null translations are included. It indicates that our approach is more robust than standard tree-to-string systems which would generate an empty translation if the source language parser fails.

- Results on Binarization (exp08-10)
  Tree binarization is a widely used method to improve syntactic MT systems (Wang et al., 2010). exp08-10 show the results of our improved system with left-heavy, right-heavy and forest-based bina-

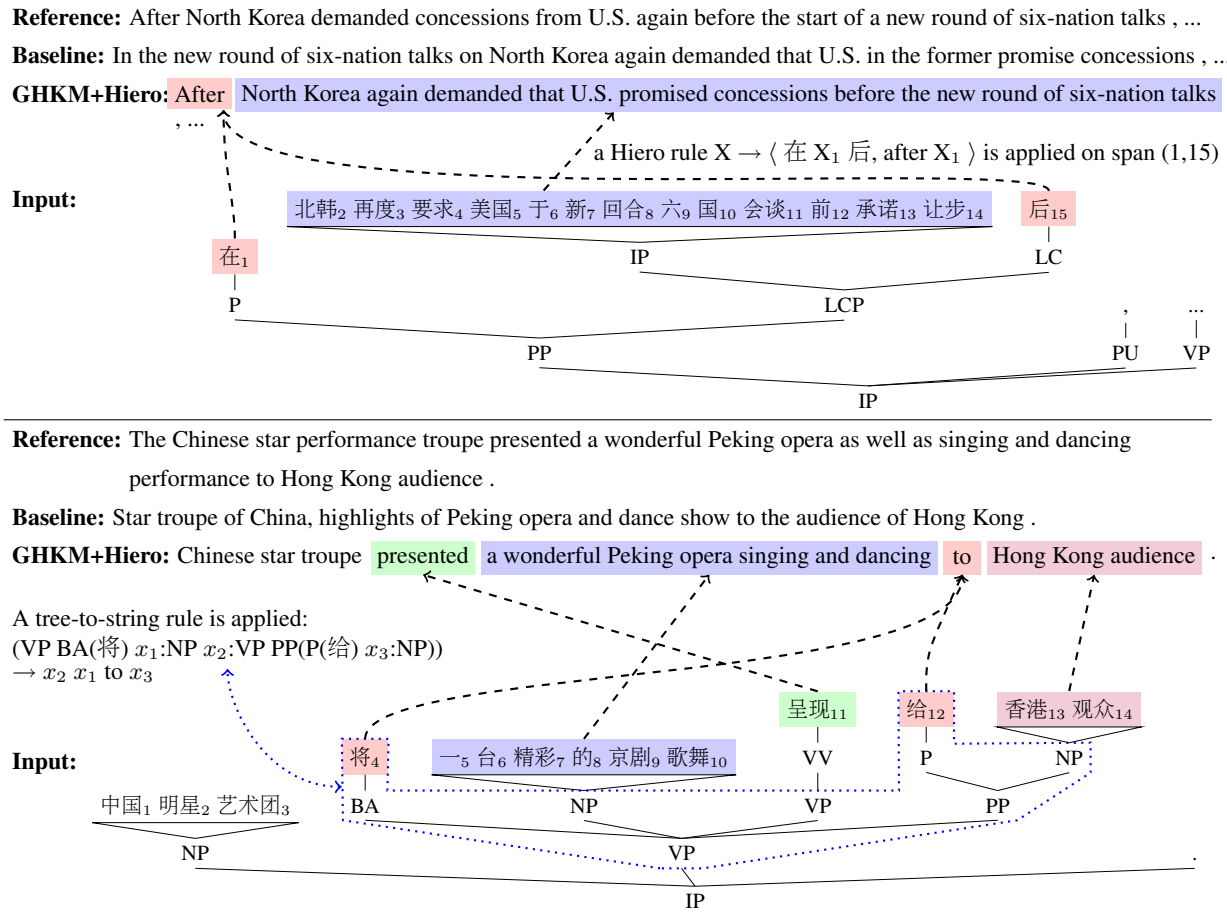

Figure 5: Comparison of translations generated by the baseline and improved systems.

rization[3]. We see that left-heavy binarization is very helpful and exp08 achieves overall improvements of 1.2 and 0.8 BLEU points on the newsire and web data. In contrast, right-heavy binarization does not yield promising performance. This agrees with the previous report (Wang et al., 2010) that MT systems prefer to use certain ways of binarization in most cases. exp10 shows that the additional trees introduced in our forest-based scheme are not sufficient to make a big impact on BLEU scores. Possibly larger gains can be obtained if taking a forest of parse trees from the source parser, but this is outside the scope of this paper.

4.3 Analysis

We then analyse rule usage in the 1-best derivations for our improved system on the tuning set. We find that type 2 rules represent 13.97% of the rules used in the 1-best derivations. Also, 44.45% of the applied rules are available from the tree-to-string model (i.e., rules that use the features described in Section 3.3). These numbers indicate that the tree-to-string rules are beneficial and our decoder likes to use them.

Finally, we discuss two real translation examples from our tuning set. See Figure 5 for translations generated by different systems. In the first example, the Chinese input sentence contains 在 ... 后 which is usually translated into *after* ... (i.e., a Hiero rule X → ⟨ 在 X_1 后, after X_1 ⟩). However, because the " 在 ... 后" pattern spans 15 words and that is beyond the span limit, our baseline is unable to apply this desired rule and chooses a wrong translation *in* for the Chinese word 在. When the source parse tree

[3]We found that the CTB-style parse trees usually have a very flat top-level IP (i.e., single clause) tree structure. As the IP structure in Chinese is very complicated, the system might prefer a flexible binarization scheme. Thus we considered both left and right-heavy binarization to form a binarization forest for IPs in Chinese parse trees, and binarized other tree constituents in a left-heavy fashion.

is available, our approach removes the span limit for spans that agree with the tree constituents. In this case, the MT system successfully applies the rule on span (1, 15) and generates a much better translation.

In the second example, the translation of the input sentence requires complex reordering of adjacent constituents. The baseline system cannot handle this case and generates a monotonic translation using the glue rules. This results in a wrong order for the translation of Chinese verb 呈现 (*show*). By contrast, the improved system chooses a tree-to-string rule with three non-terminals (some of which are adjacent in the source language) and perfectly performs a syntactic movement of the required tree constituents.

5 Related Work

Recently linguistically-motivated models have been intensively investigated in MT. In particular, source tree-based models (Liu et al., 2006; Huang et al., 2006; Eisner, 2003; Zhang et al., 2008; Liu et al., 2009a; Xie et al., 2011) have received growing interest due to their good abilities in modelling source language syntax for better lexicon selection and reordering. Alternatively, the hierarchical phrase-based approach (Chiang, 2005) considers the underlying hierarchical structures of sentences but does not require linguistically syntactic trees on either language side.

There are several lines of work for augmenting hierarchical phrase-based systems with the use of source language phrase-structure trees. Liu et al. (2009b) describe novel approaches to translation under multiple translation grammars. Their approach is very much motivated by system combination, and they develop procedures for joint decoding and optimisation within a single system that give the benefit of combining hypotheses from multiple systems. They demonstrate their approach by combining full tree-to-string and Hiero systems. Our approach is much simpler and emphasises changes to the grammar rather than the decoder or its parameter optimisation (MERT). Our aim is to augment the search space of Hiero with linguistically-motivated hypotheses, and not to develop a new decoder that is capable of translation under multiple grammars. Moreover, we consider Hiero as the backbone model and only introduce tree-to-string rules where they can contribute; we show that extracting tree-to-string rules from just 10% of the data suffices to get good gains. This results in a small number of tree-to-string rules and does not slow down the decoder.

Another related line of work is to introduce syntactic constraints or annotations to hierarchical phrase-based systems. Marton and Resnik (2008) and Li et al. (2013) proposed several soft or hard constraints to model syntactic compatibility of Hiero derivations and input source language parse trees. We note that, despite significant development effort, we were not able to improve our baseline through the use of these soft syntactic constraints; it was this experience that led us to develop the hybrid approach described in this paper.

Several research groups used syntactic labels as non-terminal symbols in their SCFG rules and develop new features (Zollmann and Venugopal, 2006; Zhao and Al-Onaizan, 2008; Chiang, 2010; Hoang and Koehn, 2010). However, all these methods still resort to rule extraction procedures similar to that of the standard phrase/hierarchical rule extraction method. In contrast, we use the GHKM method which is a mature technique to extract rules from tree-string pairs but does not impose those Hiero-style constraints on rule extraction. More importantly, we consider the hierarchical syntactic tree structure to make use of well-formed rules in decoding, while such information is not used in standard SCFG-based systems. We also keep to the simpler non-terminals of Hiero, and do not 'decorate' any non-terminals with syntactic or other information.

6 Conclusion

We have presented an approach to improving Hiero-style systems by augmenting the SCFG with tree-to-string rules and syntax-based features. The input parse trees are used to introduce new linguistically-sensible hypotheses into the translation search space while maintaining the Hiero robustness qualities and avoiding computational explosion. We obtain significant improvements over a strong Hiero baseline in Chinese-to-English. Further improvements are achieved when applying tree binarization.

Abstract

With recent advances in the areas of knowledge engineering and information extraction, the task of linking textual mentions of named entities to corresponding ones in a knowledge base has received much attention. The rich, structured information in state-of-the-art knowledge bases can be leveraged to facilitate this task. Although recent approaches achieve satisfactory accuracy results, they typically suffer from at least one of the following issues: (1) the linking quality is highly sensitive to the amount of textual information; typically, long textual fragments are needed to capture the context of a mention, (2) the disambiguation uncertainty is not explicitly addressed and often only implicitly represented by the ranking of entities to which a mention could be linked, (3) complex, joint reasoning negatively affects the efficiency.

We propose an entity linking technique that addresses the above issues by (1) operating on a textual range of relevant terms, (2) aggregating decisions from an ensemble of simple classifiers, each of which operates on a randomly sampled subset from the above range, (3) following local reasoning by exploiting previous decisions whenever possible. In extensive experiments on hand-labeled and benchmark datasets, our approach outperformed state-of-the-art entity linking techniques, both in terms of quality and efficiency.

1 Introduction

Named-entity linking (NEL) is the task of establishing a mapping from textual mentions of named entities to canonical representations of those entities in a knowledge base. Often, textual mentions are ambiguous; that is, a mention could refer to multiple named entities, but only one of them is correct in the given textual context. Resolving these ambiguities is often referred to as *named entity disambiguation* (NED), which is a highly challenging aspect of an NEL process. More specifically, a robust NEL algorithm has to robustly resolve ambiguities and thus build on robust NED methods. The NED problem, however, is often ill-posed, as only the right context and background knowledge can help disambiguate entities. In many cases, the contextual information is implicit in nature and may be latently spread across various passages or documents, and background knowledge may not be sufficient, which makes the disambiguation task challenging even for human readers. As an example, consider the sentence: "*London spent $80,000 ($2,040,000 in current value) to build a 15,000-square-foot stone mansion ('Wolf House') on the property.*" A human reader knows that in general money is spent by people, but sometimes also city councils can spend money, and hence, in the above sentence "London" may refer to a person or to the city of London. However, when considering the contextual information, especially the key phrase "Wolf House", and the fact that this was the name of the mansion of the writer Jack London, the disambiguation of "London" becomes obvious.

The NED problem is abundant, and the above subtleties place it right at the heart of many artificial intelligence applications, such as semantic search, machine translation, business intelligence, topic detection, text summarization, machine vision, and many more. In the context of information systems, the problem has been addressed in many different flavors and settings, e.g., in the structured setting of

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2075–2086, Dublin, Ireland, August 23-29 2014.

record-linkage and *duplicate detection*, where the goal is find database records that refer to the same named entity (Bhattacharya and Getoor, 2007; Naumann and Herschel, 2010), in the semi-structured setting of cleaning XML data (Weis and Naumann, 2005) or annotating Web tables (Limaye et al., 2010), in the context of enriching Wikipedia information boxes (Wu and Weld, 2008), for the alignment of knowledge bases (Aumueller et al., 2005; Lacoste-Julien et al., 2013), and most prominently, in the setting of Natural Language Processing (Bagga and Baldwin, 1998; Mann and Yarowsky, 2003; Fleischman and Hovy, 2004; Bunescu and Pasca, 2006; Cucerzan, 2007), which is also the setting of this work.

In the latter setting, the proliferation of clean knowledge bases with rich semantic relations between Web entities, e.g., DBpedia (Auer et al., 2007), Freebase (Bollacker et al., 2008), or YAGO (Suchanek et al., 2007), has given rise to novel, reliable NEL techniques (see Section 2) that exploit the semantic relatedness between entities for the linking process (Shen et al., 2012; Hoffart et al., 2011b; Hoffart et al., 2012).

Our disambiguation model builds on a majority-voting strategy that employs a bagging of multiple ranking classifiers, thus the name BEL: Bagging for Entity Linking. Each ranking classifier operates on a randomly sampled subset of terms surrounding the mention in focus. These terms are sampled from a so-called textual *range of relevant terms*, i.e., terms that are most promising for determining the context of the mention. Finally, based on the sampled terms, each ranking classifier proposes a ranked list of candidate entities and the mention is linked to the entity that is proposed as top-ranked candidate by the majority of the classifiers.

In summary, the main contributions of this work are:

1. A novel ensemble-based disambiguation approach that exploits the terms that surround a textual mention to best capture its context; a parsimonious linking model that combines the above method with a prior probability (similar to the one presented in (Fader et al., 2009), (Hoffart et al., 2011b), or (Lin et al., 2012)) of a candidate named entity being referred to by a given mention yields a highly efficient linking process.

2. An analysis of the disambiguation impact of the components used in BEL on the final linking decision.

3. A detailed quality and efficiency comparison with the state-of-the-art methods of Cucerzan (2007), Hoffart et al. (2011b), and Hoffart et al. (2012) on multiple real-world and synthetic datasets; apart from being more efficient, BEL also achieves a linking quality that is comparable to or even better than that of the above methods.

The remainder of the paper is organized as follows: The next section discusses related work. Section 3 is devoted to our NEL approach. The experimental evaluation is presented in Section 4, before we conclude in Section 5.

2 Background and Related Work

There is a vast array of literature on the topic of resolving ambiguous mentions of named entities. We focus on relevant disambiguation strategies for the NEL problem and leave aside natural language processing (NLP) techniques on named entity recognition and part-of-speech tagging; although, admittedly, for the recognition of entity mentions, such techniques are indispensable. In this work, we assume such NLP techniques are given and use the Stanford NER Tagger (Finkel et al., 2005) to reliably recognize textual mentions of named entities. Another field that we bypass is that of *record linkage* or *duplicate detection*, where the focus is on comparing sets of database records and identifying mappings between records referring to the same entity. Obviously, record linkage methods operate on structured data, such as database entries with a predefined set of attributes (commonly with a known value range), which is different from our NLP setting.

In traditional methods, each mention and each named entity is represented by a vector of terms occurring in its textual context. Vector-based similarity measures are applied to capture the affinity between a mention and a named entity. The feature values can go beyond simple unigram terms and consist

of compound terms, such as bigrams, key phrases, encyclopedic facts, or categorical descriptions. For example, Pedersen et al. (2005) employed salient bigrams to represent the context of a mention; Mann and Yarowsky (2003) included biographic facts into the vector representation of a named entity, whereas Cucerzan (2007) extended the term-based feature set of a Wikipedia entity by information from other articles linking to it, but instead of using the whole article text, only some key phrases and immediate Wikipedia categories were included. Bunescu and Pasca (2006), after deriving an entity dictionary from Wikipedia, for a given mention, rank entities by a kernel-based similarity between the textual context of the mention and the Wikipedia text and categories of the candidate entity. The mention is linked to the most similar entity.

The disambiguation problem has also been formulated as a probabilistic reasoning problem. For example, Fleischman and Hovy (2004) trained a maximum entropy model to infer the probability that two mentions represent the same entity and used a modified agglomerative clustering algorithm to cluster mentions using the probabilistic similarity measure. Similarly, Sil et al. (2012) used a log-linear model to represent the probability of a named entity being referred to by a mention. For both above methods, the selection of features and efficient strategies for learning their weights are crucial, as ideally all feature weights should be learned in a joint fashion, which can be computationally expensive and is often impeded by the "curse of dimensionality".

Note that many of the above techniques model the implicit relatedness between terms (and term compounds), where the general idea is that two terms are related if many Web pages contain both of them. Measures building on this idea were refined and extended in (Milne and Witten, 2008) and (Huang et al., 2012), especially for the relatedness between Wikipedia articles. Such implicit relatedness can lead to a large candidate space; to effectively prune this space, entity prominence priors have been integrated in various recent disambiguation models, e.g., (Fader et al., 2009; Hoffart et al., 2011b; Lin et al., 2012).

Other techniques model explicit, relationship-based similarities between entities; for example, Du et al. (2013) employed similarity measures that captured the average pair-wise proximity between candidate entities in the knowledge graph, as well as their average pair-wise conceptual similarity by means of the lowest-common-ancestor classes. (Hoffart et al., 2011b; Hoffart et al., 2012) exploited the hypernymy- and key-phrase-based relatedness, between the k candidate entities in the knowledge base, to jointly link k mentions occurring in the same paragraph. A prior probability of a candidate entity being referred to by a mention was combined with the above relatedness measures in an objective maximization function. The intuition behind the hypernymy-based relatedness was that in order for k mentions (that occur in the same textual context) to be linked correctly to $l \leq k$ named entities in the knowledge base, the l entities should jointly exhibit a high "semantic" relatedness, which in (Hoffart et al., 2011b) is referred to as *coherence*. Despite this principled modeling of the NEL problem in (Hoffart et al., 2011b; Hoffart et al., 2012) and the impressive quality results reported in those works, efficiency seems to be the main bottleneck of such collective inference models. We argue that a Web-scale NEL process should avoid complex reasoning strategies wherever possible. Concerns along these lines have been also expressed in (Lin et al., 2012), where the authors highlight the need for the application of NEL techniques at Web scale.

The approach presented in this paper, BEL, avoids complex, coherence-based joint reasoning. It also avoids the processing of long textual passages, where multiple mentions have to occur. Instead, we show that a careful light-weight, independent reasoning on the linking of mentions can lead to a linking quality that is comparable to and sometimes even better than the one achieved by the above methods.

3 The BEL Algorithm

In this work, the focus is not on the recognition of named entity mentions in a text but rather on their disambiguation once the mentions are known. Throughout this work we assume that a reliable named entity recognition tool is available. BEL relies on the Stanford NER Tagger (Finkel et al., 2005) to recognize textual mentions of named entities. Once the mentions have been recognized, BEL retrieves promising candidate entities from the knowledge base and employs a careful, majority-voting algorithm to take the best possible linking decision based on the textual context of the mentions. The method is

described in the following subsections.

3.1 High-Level Overview of the BEL Algorithm

Algorithm 1 gives a high-level overview of the BEL approach. The only assumption we make is that the textual corpus from which the knowledge base has been derived is freely available. For example, the textual corpus of knowledge bases such as YAGO or DBpedia is Wikipedia, which is an open source of information about the entities in the two knowledge bases.

Exemplarily, in Algorithm 1, we use the YAGO knowledge base to highlight the main idea of the algorithm. YAGO is a clean knowledge base with structured information about a large proportion of the entities contained in Wikipedia, thus being a popular representative of many state-of-the-art knowledge bases derived from Wikipedia.

Once the set of mentions has been derived from a given document (line 1), for each mention, a list of promising candidates is derived from Wikipedia. The candidates are ranked by a so-called "prominence" score, representing the probability of a Wikipedia article (i.e., the entity represented by the article) being referred to by the mention (lines 2, 3). In case the list of candidates is empty, the corresponding mention is linked to a designated entity, E_{NULL}, meaning that the mention cannot refer to a YAGO entity (lines 4, 5). The same holds for the case that the top-ranked candidate occurs in Wikipedia but not in YAGO (lines 7 - 9). Otherwise, the joint majority decision of multiple bagged ranking classifiers is computed (lines 11 - 13). Only if there is a majority consensus about a candidate (i.e., the candidate is ranked as top candidate by the majority of the classifiers), the mention is linked to that candidate; otherwise, the mention is linked to E_{NULL} (lines 14 - 18).

Algorithm 1 Bagging for Entity Linking Algorithm

Input: document file $\mathbf{D} = (t_1, t_2, \ldots)$, HashMap $\mathbf{V}$ that maps the ID of a ranking classifier to the top-ranked candidate entity by that classifier.
Output: linkage between mentions $\mathbf{M} = \{m_1, m_2, \ldots\}$ in $\mathbf{D}$ and corresponding entities $\mathbf{E} = \{e_1, e_2, \ldots\}$ in YAGO.

1: $\mathbf{M} :=$ *recognizeMentions*($\mathbf{D}$)
2: **for** each mention $m_i \in \mathbf{M}$ **do**
3: $\quad \mathbf{L}_{m_i} :=$ *getTopKCandidates*(k,m_i) /*according to the "prominence" score $S_{PR}(e, m_i)$*/
4: $\quad$ **if** $\mathbf{L}_{m_i}$ is empty **then**
5: $\quad\quad$ link m_i to E_{NULL} /*i.e.,mention cannot be linked*/
6: $\quad$ **else**
7: $\quad\quad$ $e' := arg\,max_{e \in L_{m_i}} S_{PR}(e, m_i)$
8: $\quad\quad$ **if** e' is not in YAGO **then**
9: $\quad\quad\quad$ link m_i to non-YAGO entity E_{NULL}
10: $\quad\quad$ **else**
11: $\quad\quad\quad$ **for** each ranking classifier S_n **do**
12: $\quad\quad\quad\quad$ $\mathbf{V}$.put($n, arg\,max_e(SimScore(e, S_n, m))$)
13: $\quad\quad\quad$ **end for**
14: $\quad\quad\quad$ **if** an e^* occurs more than $\frac{|\mathbf{V}|}{2}$ in $\mathbf{V}.values()$ **then**
15: $\quad\quad\quad\quad$ link m_i to e^*
16: $\quad\quad\quad$ **else**
17: $\quad\quad\quad\quad$ link m_i to non-YAGO entity E_{NULL}
18: $\quad\quad\quad$ **end if**
19: $\quad\quad$ **end if**
20: $\quad$ **end if**
21: **end for**

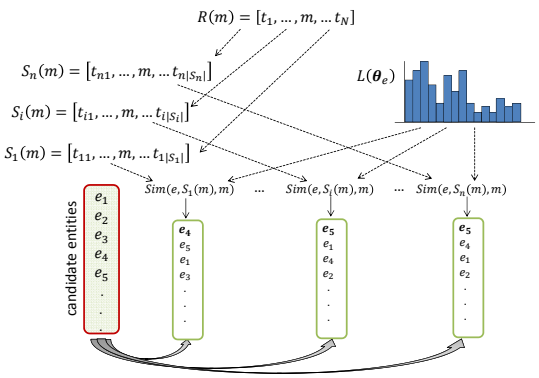

Figure 1: Strategy for generating ranking classifiers, each of which operates on a randomly sampled subset $S_i(m)$ from a set $R(m)$ of relevant terms surrounding m and assigns contextual similarity scores to the candidate entities based on that subset.

In addition, for efficiency reasons, BEL exploits previous disambiguation decisions whenever possible. If a mention occurs multiple times in a document and was already reliably linked b times to the same named entity in YAGO, the previous linking decisions (for that mention) are reused without rerunning the disambiguation process (i.e., in the experimental evaluation of BEL, the default value of b is 2). This heuristics may lead to incorrect linkings, but in empirical evaluations on real-world datasets the algorithm has shown a robust quality behavior, while being highly efficient (see Section 4).

The runtime of the algorithm is dominated by the computation of the contextual similarity scores of each ranking classifier. More specifically, since the parameters needed by each classifier are precomputed, each classifier needs only $O(N \log N)$ steps to propose a context-based ranking of the N candidates derived by the "prominence" score. Since the classifiers operate independently from each other,

the algorithm allows parallel computation of the contextual similarity scores. However, in this work we have implemented a sequential version, which for K different ranking classifiers has a complexity of $O(KN \log N)$.

3.2 Bagging of Ranking Classifiers for Majority Voting

The main idea behind BEL is to leverage different contextual representations of a mention. Each such representation is used by one ranking classifier to rank the candidate entities by their similarity to that representation. As shown in lines 14 and 15 of Algorithm 1, the mention is linked to the candidate that is ranked as top entity by the majority of the classifiers. This idea gives rise to several questions: (1) How to derive the different contextual representations of a mention? (2) How to compute the similarity between a contextual representation and a candidate entity? (3) How to prune the candidate space in such a way that only the most promising entities are considered by each of the ranking classifiers?

Obviously, the latter question is focused on efficiency; to address it, we exploit a precomputed index, constructed by exploiting the intra-Wikipedia links and the Wikipedia Redirect Pages. For every mention m, the index contains entities that might refer to it along with a probabilistic "prominence" score $P(e|m)$ by which a candidate entity e might refer to the mention. To compute this "prominence" score, we collect all terms that occur in a Wikipedia article or redirect-page and are hyperlinked to another Wikipedia article. From this collection we derive relative frequencies by which a Wikipedia entity (i.e., specific article) was hyperlinked from a given term. For example, Jordan is hyperlinked to the article about the country of Jordan 60% of the time, 20% of the time it is hyperlinked to the basketball player Michael Jordan, etc. These relative frequencies are estimations of the probability of an entity given a mention $P(e|m)$. Empirically (see also Figure 2a in the evaluation section) we have found out that when ranked by this score, the top-40 candidate entities already yield a overwhelming coverage rate of ≈92.4% for the correct entity. For top-100 this coverage rate increases only marginally (by only ≈0.5%). Thus considering only the top-40 entities in the candidate lists (which in general might contain hundreds or even thousands of entities), is not only an efficient but also an effective pruning strategy.

The second question involves the semantics of the similarity score. Suppose that $S_i(m)$ stands for the i'th contextual representation of the mention m. Our model is probabilistic in nature and holistic in the sense that the above "prominence" score $P(e|m)$ just falls off the model by following principled mathematical derivations. We start by reasoning about the probability of a candidate entity e given the mention m and its context $S_i(m)$:

$$P(e|S_i(m), m) = \frac{P(S_i(m)|m, e)P(m|e)P(e)}{P(S_i(m)|m)P(m)} \tag{1}$$

$$= \frac{P(e|m)P(S_i(m)|m, e)}{P(S_i(m)|m)} \tag{2}$$

$$\propto P(e|m)P(S_i(m)|m, e) \tag{3}$$

$$\propto logP(e|m) + logP(S_i(m)|m, e) \tag{4}$$

The last two steps in the above derivation mean that ranking the candidate entities by the similarity score $P(e|m)P(S_i(m)|m, e)$ or by $logP(e|m) + logP(S_i(m)|m, e)$ yields the same ranking as $P(e|S_i(m), m)$. Note that in general $S_i(m)$ depends on the entity e and not on the mention m. Hence, we can estimate $P(S_i(m)|m, e)$ as $P(S_i(m)|e)$. So the final similarity score is given by:

$$Sim(e, S_i(m), m) := logP(e|m) + logP(S_i(m)|e) \tag{5}$$

We estimate $P(S_i(m)|e)$ as the probability of $S_i(m)$ being generated by a language model (Zhai and Lafferty, 2004) on the terms describing e in Wikipedia. Those terms are collected from the Wikipedia article of e after removing stop words. Such a language model is described by means of frequency parameters $\boldsymbol{\theta}_e$. We construct it by indexing the terms and their frequencies in the corresponding Wikipedia articles. Figure 1 depicts the general idea behind our approach. For different contextual representations $S_1(m), ..., S_n(m)$ of a mention m, the ranking classifier responsible for $S_i(m)$ computes $Sim(e, S_i(m), m)$ for each candidate entity e and ranks the candidates by this score. Finally m is linked to the candidate that is ranked as the top entity by the majority of the ranking classifiers. This majority

voting strategy reduces the uncertainty of the linking process and leads to higher precision than a single ranking classifier, while still maintaining a high recall.

The final question concerns the computation of the contextual representations $S_i(m)$ of a mention m. We derive such representations by randomly sampling terms that occur in the local vicinity of a mention in the text. More specifically, to generate a contextual representation $S_i(m)$ from a range of N relevant terms around a mention m, we uniformly sample N times with replacement. We run the same procedure for all n representations. This sampling technique is known as bootstrapping (Breiman, 1996) and has been shown to have several advantages over other sampling procedures, such as increasing the contextual diversity and mitigating strong dependencies between features. Indeed, in the experiments, the bagging of the ranking classifiers lead to a significant improvement of $\approx$2.5% in terms of precision compared to the simple case where no bagging is used (see Section 4).

3.3 Recognizing Non-YAGO Entities

For an improved accuracy of the linking process, it is also crucial to reliably recognize true negatives, i.e., mentions that refer to entities that are not present in the underlying knowledge base. In case of the YAGO knowledge base, we first check whether the most prominent Wikipedia entity for a given mention is presented in YAGO; if this is not the case, the mention is classified as a non-YAGO entity. Note that many entities from Wikipedia are not present in YAGO, either due to recently added articles, or to articles that represent concepts[1]. Furthermore, a flexible threshold is used to recognize a non-YAGO entity. It is calculated as the maximum similarity score among the Wikpedia entities in the candidate list that are not present in the knowledge base, or as a default "prominence" score, when there is no such entity. If none of the candidates has a higher score than the threshold, the corresponding classifier proposes E_{NULL} as the best candidate. Also, in the simple case that the retrieved list of candidates is empty, the mention is classified as a non-YAGO entity. Although, these strategies are relatively straight-forward, they lead to a notable improvement in the recognition of true negatives. Further investigation of more elaborate strategies for the reliable detection of true negatives is part of our future work agenda.

3.4 Efficiency Aspects

For a better overview of the key efficiency aspects that are leveraged by BEL, we give here a succinct summary:

- Early pruning of the candidate space while maintaining a high coverage of promising candidates
- Local and independent reasoning strategy based on sliding windows and bootstrapping aggregation for the disambiguation process
- Highly efficient, in-memory processing of randomly sampled subsets
- Previous disambiguation decisions are exploited whenever possible; e.g., for people, locations, or company names that reoccur in a similar form in a document, the disambiguation process is run only once.

As it will be shown in the next section, the above considerations lead to a highly efficient linking process that often outperforms the evaluated state-of-the-art techniques, both in terms of quality and efficiency.

4 Experimental Evaluation

4.1 Datasets

Three datasets were used to evaluate the BEL approach. As a knowledge base for evaluation, we used YAGO2 (Hoffart et al., 2011a).

[1] In YAGO, the concepts have been derived from WordNet.

Table 1: Datasets overall information

	CoNLL-YAGO	CUCERZAN	KORE
articles	76	336	50
mentions (total)	1431	5343	148
mentions (non-YAGO)	279	936	7
word count (avg.)	173	384	12

CoNLL-YAGO: This dataset contains 76 randomly picked Reuters news articles of CoNLL 2003 data (Tjong Kim Sang and De Meulder, 2003). We have manually labeled the mentions, which are recognized by the Stanford NER Tagger (Finkel et al., 2005), to the corresponding entities in YAGO2.
CUCERZAN: This dataset consists of 350 Wikipedia articles that were randomly selected by S. Cucerzan to evaluate his approach (Cucerzan, 2007). The annotated entities in this corpus are named entities derived from the hyperlinks of mentions in these 350 Wikipedia articles. Since some of the articles are not available anymore in the Wikipedia archive, we have recovered 336 out of the 350 articles of the original corpus.
KORE: This small dataset was produced in the realm of AIDA (Hoffart et al., 2012). It is a synthetic corpus consisting of 50 very short articles, where each article contains one or more hand-crafted sentences about different ambiguous mentions of named entities. This dataset is quite difficult, as the named entities in this corpus are ambiguous with sparse context.

4.2 Evaluated Approaches

We compared BEL to three other prominent approaches (Hoffart et al., 2011b; Hoffart et al., 2012; Cucerzan, 2007), which, as reported in the corresponding papers, outperform many state-of-the-art algorithms in terms of disambiguation and linking quality. Experience-wise, we can confirm that the very recent AIDA approaches (Hoffart et al., 2011b; Hoffart et al., 2012) have indeed raised the bar for many entity linking methods. In our experiments, these algorithms showed a highly reliable behavior, even with respect to difficult disambiguation tasks.

The AIDA approach comes in different versions: In its original version (Hoffart et al., 2011b), it exploits a graph-based connectivity between candidate entities of multiple mentions (i.e., graph coherence, e.g., derived from the *type, subclassOf* edges of the knowledge graph or from the incoming links in Wikipedia articles) to determine the most promising linking of the mentions. We refer to this version of AIDA as AIDA-GRAPH. In another version that has been optimized for datasets such as KORE (Hoffart et al., 2012), AIDA's coherence model has been extended to recognize key-phrases for named entities, which are then used to determine a similarity score based on key-phrase overlap between candidate entities. We refer to this version as AIDA-KORE.

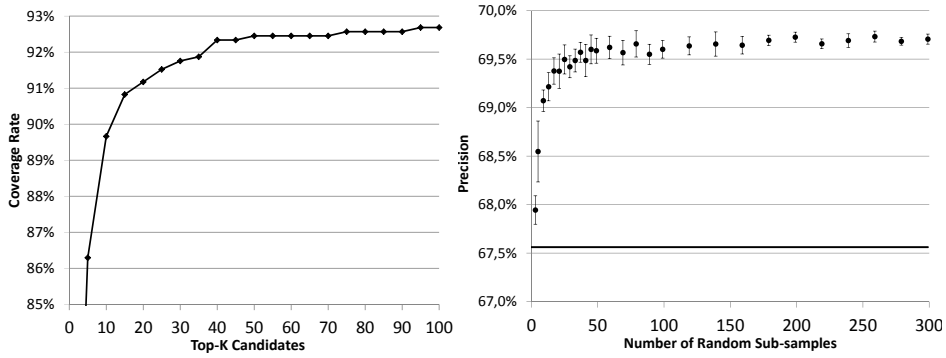
Cucerzan (2007) finds a linking of mentions to Wikipedia entities, such that the sum of vector-based similarities between the candidate entities and the document (containing the mentions) as well as the similarities between pairs of candidate entities is maximized. We refer to this method as LED (Large-scale Entity Disambiguation). The original work has been conducted at Microsoft and the code is proprietary. Hence, we had to re-implement the algorithm according to the descriptions in the paper. To make sure that algorithm was correctly implemented, we evaluated it on the original dataset, and achieved results comparable to those presented in the original paper. Note that, since many entities from Wikipedia are not present in YAGO, the task of linking mentions of the CUCERZAN dataset to YAGO is different from the original task addressed in (Cucerzan, 2007), where mentions were linked to Wikipedia articles.

4.3 Parameter Analysis for BEL

For BEL, the parameters are optimized to deal with common natural-language articles on the Web (e.g., articles from encyclopedic pages or news sites). The same parameter settings are used on all three datasets described above to show the performance of BEL on different types of corpora. To achieve such a common setting of the parameters, we trained BEL on articles sampled from the above datasets, each of which exhibits specific textual characteristics.

4.3.1 Pruning Candidate Lists

In BEL, each mention is assigned a list of candidates. In general, such a list could contain hundreds or even thousands of entities. However, the mention should be linked to at most one entity in the list.



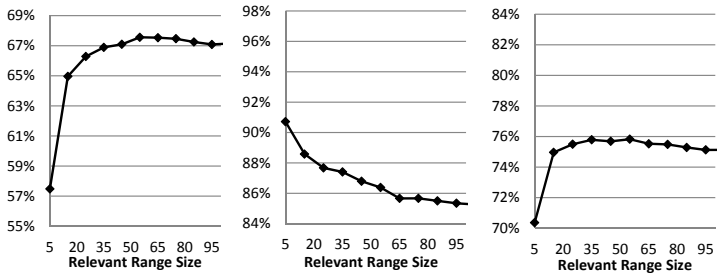
(a) (b)

Figure 2: Parameter analysis experiments (in %): (a) Correct Entity Coverage Rate. (b) Performance of bagging strategy in precision in comparison to the performance of a single classifier.

We randomly picked 1000 mentions from the three datasets to analyze the impact of the candidate list size. The coverage rate (i.e., the relative frequency by which the correct entity is contained in the list) in relation to the list size is shown in Figure 2a. The lists are sorted by decreasing "prominence" scores (see Section 3). In this experiment, 139 mentions have no corresponding entity in YAGO, while 61 correct entities are missing, which means that the maximum coverage rate that a candidate selection strategy can achieve is $800/861 \approx 92.92\%$. As the curve shows, most of the correct entities are indeed located within the top positions of the candidate lists. Therefore, we prune the ranked lists by selecting the top-40 candidates for further processing.

4.3.2 Range of Relevant Terms

As mentioned earlier, the bagging of classifiers is aimed at capturing the contextual information of a mention by randomly sampling terms surrounding it, a process that is repeated several times, once for every ranking classifier. As a sampling procedure we employ bootstrapping (Breiman, 1996), which captures the diversity of contextual information derived from the original range, while mitigating dependencies between terms. We analyze the quality of this bagging strategy mainly based on two criteria: (1) the size of the range of relevant terms, and (2) the bagging size (i.e., number of randomly sampled subsets).



(a) Precision (b) Recall (c) F1-measure

Figure 3: Performance of the language model by increasing the size of the range of relevant terms.

The impact of the range size on the linking quality is intricate, in the sense that a larger range contains more noise, while a smaller one has sparser context. In BEL, the range of relevant terms is empirically calibrated, by evaluating the performance of BEL on different range sizes after removing stop words and non-English terms. To avoid any bias from the "prominence" score and to focus only on the context, we set the $logP(e|m)$-component of the scoring function to 0. Figure 3 shows the average performance

based on 10-fold cross validation on all evaluation datasets. The F1-measure achieves maximum when the range of relevant terms contains 55 terms, which is also in agreement with the optimal setting found by Gooi and Allan (2004). Thus, we define the size of the range to be 55. When a document contains less terms, BEL takes the whole text into account.

The bagging strategy of BEL encourages the contextual diversity, while it reduces the linking uncertainty by employing majority voting. Here, to show the impact of our bagging strategy, we randomly pick 80% articles from our datasets for different bagging sizes. Since the bagging strategy is mainly affected by contextual information, we turn off the component responsible for the "prominence" score and run BEL 10 times for each bagging size on these articles. In Figure 2b, the black horizontal line with precision 67.56% is the baseline derived from the single language model classifier. The black dots denote the average precisions and the error bars show the corresponding standard deviation. As the figure shows, by increasing the bagging size the precision increases, while the standard deviation decreases. Considering the precision, efficiency, and stability of the algorithm, we use 199 subsets as the default setting (an odd number of voters is more likely to avoid ties when there are two top-ranked candidates by the voters). Note that, the linking process is stricter and thus leads to a decreased recall. However, the experimental result shows that the impact of the bagging strategy on the increase of precision is consistently higher than its impact on the decrease of the F1-measure; the precision increases from 67.56% to 69.73%, while the F1-measure decreases from 75.82% to 75.32%. Moreover, in our opinion, it is better to suggest that a mention is not in the knowledge base than link it to a wrong entity.

BEL has been evaluated with respect to its linking quality and efficiency. The employed evaluation measures and the results are presented in the following subsections.

4.3.3 Evaluation Measures

For the quality evaluation, we have measured precision, recall, and the F1-measure of each of the above approaches on the mentioned datasets.

A *true positive (tp)* is a mention that has been correctly linked to a YAGO entity. An incorrect linking is defined to be a *false positive (fp)*. Furthermore, a *true negative (tn)* refers to a mention that is correctly identified as an entity that does not occur in YAGO (i.e., non-YAGO entity). The remaining cases are defined as *false negatives (fn)*. Precision is then defined as $P = tp/(tp + fp)$ and recall as $R = tp/(tp + fn)$. The F1-measure is obtained from the harmonic mean of precision and recall as $F = 2PR/(P+R)$.

For the efficiency evaluation, we have measured the runtime (in seconds) of each approach on each dataset.

4.3.4 Evaluation of Linking Quality

The results of the quality evaluation are shown in Table 2, along with the corresponding confidence intervals, which are calculated by repeating 30 times a random sampling of subsets containing 60% of the documents from each dataset. For each dataset, the results computed on all documents are within the intervals that correspond to a confidence level of 99% according to the Student's t-distribution to show that although some of the datasets are of moderate size, the 99% confidence interval of the scores computed on the sampled subsets is relatively small.

As it can be seen, BEL significantly outperforms all the other approaches on the CoNLL-YAGO dataset, especially on precision. Also, for the CUCERZAN dataset, the quality of BEL is comparable to that of AIDA-GRAPH and AIDA-KORE, and it significantly outperforms LED. Moreover, in terms of precision, BEL performs also on this latter dataset significantly better than the other approaches (i.e., from a statistical point of view). Together with BEL's impressive efficiency (see Section 4.3.5), the precision-related quality is a crucial scalability aspect, since when processing a high throughput of documents it is highly important that the produced linkings be rather correct.

For the KORE dataset, AIDA-KORE outperforms other approaches. However, it should be noted that KORE is a very challenging dataset and that the AIDA-KORE approach has been specifically tailored to such datasets. Also note that although the AIDA-KORE algorithm shows a high linking quality in the experiments, it is the least efficient approach, since it performs complex joint reasoning over groups of candidate entities and mentions. In our experiments, we had to wait more than 15 hours for the

evaluation results of this approach for KORE dataset, since the mentions contained in this corpus are highly ambiguous.

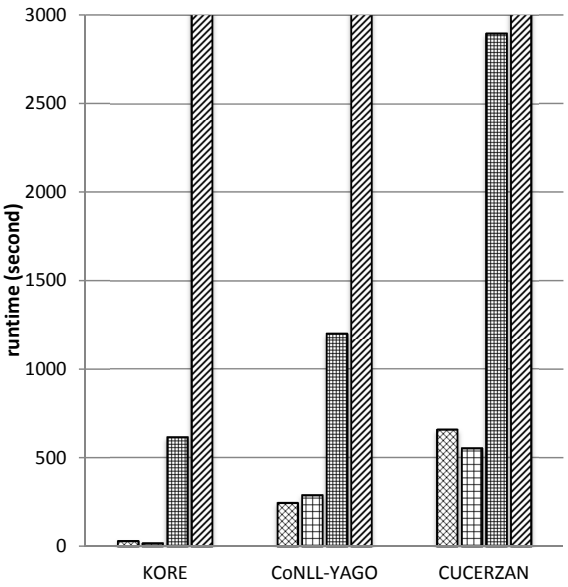
In comparison to a greedy linking strategy, where a mention is simply linked to the most prominent entity according to the "prominence" score, which is our baseline BEL-PROM, BEL performs much better on all three datasets. This fact highlights the importance of the contextual similarity component in the model.

Table 2: Evaluation results (in %).

	Method	Precision	Recall	F1
CoNLL-YAGO	LED	62.35 (-1.92,+0.25)	96.13 (-0.43,+0.27)	75.63 (-1.50,+0.18)
	AIDA-GRAPH	78.67 (-0.80,+1.23)	96.29 (-0.20,+0.64)	86.59 (-0.41,+0.82)
	AIDA-KORE	77.11 (-0.86,+0.80)	96.21 (-0.64,+0.25)	85.61 (-0.67,+0.47)
	BEL-PROM	68.37 (-0.89,+1.30)	97.40 (-0.25,+0.32)	80.30 (-0.61,+0.97)
	BEL	**81.40** (-1.33,+0.78)	95.72 (-0.38,+0.25)	**87.98** (-0.85,+0.46)
CUCERZAN	LED	63.47 (-0.40,+1.01)	96.94 (-0.11,+0.24)	76.72 (-0.28,+0.75)
	AIDA-GRAPH	81.30 (-0.57,+0.16)	94.64 (-0.28,+0.17)	87.47 (-0.40,+0.11)
	AIDA-KORE	81.35 (-0.83,+0.03)	97.31 (-0.25,+0.10)	**88.61** (-0.57,+0.03)
	BEL-PROM	73.92 (-0.53,+0.29)	98.83 (-0.11,+0.06)	84.58 (-0.37,+0.20)
	BEL	**82.37** (-0.31,+0.25)	93.46 (-0.71,+0.27)	87.56 (-0.35,+0.12)
KORE	LED	40.14 (-3.30,+0.88)	100.00 (-0.00,+0.00)	57.28 (-3.52,+0.79)
	AIDA-GRAPH	62.33 (-1.83,+0.93)	100.00 (-0.00,+0.00)	76.79 (-1.43,+0.68)
	AIDA-KORE	**66.67** (-2.29,+1.91)	94.95 (-0.87,+1.82)	**78.33** (-1.60,+1.48)
	BEL-PROM	31.29 (-1.83,+1.47)	100.00 (-0.00,+0.00)	47.67 (-2.23,+1.61)
	BEL	54.55 (-2.40,+2.53)	76.61 (-0.76,+2.20)	63.72 (-1.72,+2.08)

Table 3: Efficiency comparison

Method	KORE	CoNLL-YAGO	CUCERZAN
BEL	30.02s	244.34s	657.44s
LED	17.70s	288.52s	552.26s
AIDA-GRAPH	615.35s	1,202.66s	2,897.43s
AIDA-KORE	>15h	>11h	>25h



4.3.5 Efficiency Evaluation

The lean algorithmic design of BEL enables a highly efficient linking process. For the efficiency comparison, we used a Pentium 3.1GH machine with 8GB of main memory. The indexes for the language models of YAGO2 entities, as well as the indexed YAGO2 knowledge base (that was used by all approaches for the linking) were maintained in a PostgreSQL 9.1 database.

For each dataset, Table 3 shows the runtime of each approach. Obviously, the joint reasoning strategy of AIDA-GRAPH comes at high efficiency costs; on all datasets it has been outperformed by the other approaches. While LED is slightly more efficient than BEL on the KORE and CUCERZAN datasets, as shown in Table 2, it often pays a high cost in terms of quality, and BEL also outperforms it in terms of efficiency on the CoNLL-YAGO dataset. Note that the runtime of LED and BEL are both practically viable from a user's perspective. The AIDA-KORE approach, on the other hand, lacks practical viability, since it needs several hours to process even moderately sized datasets (e.g., approx. 11 hours for the CoNLL-YAGO dataset). For the CUCERZAN dataset, which is the largest one, although the F1-measure of AIDA-KORE is approximately 1% higher than BEL, one needs to wait more than 25 hours to get the result. Instead, BEL can finish the linking process in around 11 minutes.

4.3.6 Discussion

Both, the "prominence" score and the contextual score derived from the proposed bagging strategy have advantages and limitations; they are orthogonal in nature, and their individual strengths are manifested in different ways in the final decision of the algorithm. The value of the "prominence" score has a high impact on the final decision, when BEL is run on articles about famous people, organizations, locations, products, events etc. Typical examples of articles that contain such entities are news reports,

scholarly articles containing encyclopedic knowledge, and product descriptions. In contrast, the bagged language models have a high impact on the final decision in cases where the occurring mentions are highly ambiguous but contain valid key information surrounding the mention. Examples for such articles can be found in all three datasets we have used.

Although in many cases, linking the mention to the most prominent candidate entity leads to the correct decision (e.g., "Australia" refers most probably to the country), this strategy is not reliable for many ambiguously used mentions. For example, in one article of CoNLL-YAGO dataset, the named entity "Australia National Cricket Team" in YAGO, was also often referred to by "Australia". Nevertheless, BEL was able to establish a linking to the correct named entity.

The datasets we have annotated and a preliminary online-demo of the algorithm are available online[2].

5 Conclusion

The focus of this work has been on lean and light-weight classification algorithms, which as an ensemble provide a reliable and efficient linking strategy. The comparison of our approach, BEL, with state-of-the-art techniques on manually-labeled, benchmark datasets shows that BEL indeed fulfills the above criteria. Especially on longer, real-world texts, BEL shows an unprecedented quality and efficiency behavior. Further research is needed to understand how such an approach can be optimized for short texts containing highly ambiguous mentions of named entities. We are convinced that BEL provides a robust basis for further research in this area.

Exploratory Relation Extraction in Large Text Corpora

Alan Akbik **Thilo Michael** **Christoph Boden**

Einsteinufer 17, 10587 Berlin, Germany
{firstname.lastname}@tu-berlin.de

Abstract

In this paper, we propose and demonstrate *Exploratory Relation Extraction* (ERE), a novel approach to identifying and extracting relations from large text corpora based on user-driven and data-guided incremental exploration. We draw upon ideas from the information seeking paradigm of Exploratory Search (ES) to enable an exploration process in which users begin with a vaguely defined information need and progressively sharpen their definition of extraction tasks as they identify relations of interest in the underlying data. This process extends the application of Relation Extraction to use cases characterized by imprecise information needs and uncertainty regarding the information content of available data.

We present an interactive workflow that allows users to build extractors based on entity types and human-readable extraction patterns derived from subtrees in dependency trees. In order to evaluate the viability of our approach on large text corpora, we conduct experiments on a dataset of over 160 million sentences with mentions of over 6 million FREEBASE entities extracted from the CLUEWEB09 corpus. Our experiments indicate that even non-expert users can intuitively use our approach to identify relations and create high precision extractors with minimal effort.

1 Introduction

1.1 Motivation and Problem Statement

Relation Extraction (RE) is the task of creating extractors that automatically find instances of semantic relations in unstructured data such as natural language text (Riloff, 1996). An example extraction task might be to find instances of the EDUCATEDAT relation, which relates persons to their educational institution and may include the entity pair <*Sigmund Freud, University of Vienna*> as relation instance. Motivated by an explosion of readily available sources of text data such as the Web, RE offers intriguing possibilities for querying and analyzing data as well as extracting and organizing the contained information (Sarawagi, 2008). As scalable computing architectures capable of processing ever larger amounts of data are being developed (Dean and Ghemawat, 2004) and dependency parsers are becoming more accurate and more robust (Petrov and McDonald, 2012), so rises the potential of developing means to directly access the structured information contained in natural language text.

In spite of such positive trends however, currently established methods of creating relation extractors suffer from a number of limitations. The first is one of *cost*; the process of creating extractors requires either labeled data to be produced at sufficient quality and quantity in order to train a supervised machine learning algorithm (Culotta and Sorensen, 2004; Mintz et al., 2009), or the manual creation of a complex set of extraction rules (Strötgen and Gertz, 2010; Reiss et al., 2008). In either case, the process is tedious and time-consuming and requires trained specialists with an extensive background in NLP, rule-writing or machine learning (Chiticariu et al., 2013). Worse, this process needs to be repeated for every relation and domain of interest. Due to this cost, great care must be taken when deciding which relation types to look for in a given text corpus.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2087–2096, Dublin, Ireland, August 23-29 2014.

This leads to the second limitation, namely the necessary *a priori specification* of relations. Current methods generally require a careful upfront definition of the RE tasks in order to start producing labeled training data or extraction rule-sets. Practical scenarios, however, are often characterized by imprecise and rapidly changing information needs and uncertainty regarding the type of information contained in large, given text corpora (Chiticariu et al., 2013). This severely limits the practicability of currently established RE methods.

1.2 Exploratory Search for Relations

To address these limitations, we propose a process of *exploration* for relations of interest in available data. We propose to substantially reduce entry barriers into RE so that extraction tasks no longer need to be exactly pre-specified and expensively prepared by generating labeled training data in advance. Instead, we propose a manual, rule-based approach in which extraction rules are kept very simple so that users can formulate natural language-like patterns as exploratory queries for relations against a text corpus.

We draw inspiration from the information seeking paradigm of *Exploratory Search (ES)* (Marchionini, 2006; White and Roth, 2009), where users start with a vaguely defined information need and - with a mix of look-up, browsing, analysis and exploration - progressively discover information available to address it and simultaneously concretize their information need. One of the challenges associated with the often desired capability of ES is the design of interactive interfaces to support users as they navigate through complex environments. Similarly, our challenge is to create an intuitive workflow that allows non-experts in NLP to engage in relation exploration.

We propose to simplify the search for information by using natural language-like queries that match subtrees in large corpora of dependency parsed data while hiding the complexity from the users. Explorative queries return matching relation instances and source sentences, as well as suggestions for further queries computed from the available data. By following a process of experimental querying and accepting or rejecting pattern suggestions, users identify relations of interest and group patterns into extractors. Our goal is to make use of such data-guidance to facilitate exploration while giving as much explicit control to a user as possible.

1.3 Contributions

In this paper, we propose and demonstrate *Exploratory Relation Extraction (ERE)*, a user-driven and data-guided incremental exploration approach to Relation Extraction. We give details on our relation extraction pattern language and introduce a guided, interactive workflow aimed at allowing users to explore parsed text corpora for relations at minimal effort. We conduct two experiments on a large corpus of over 160 million sentences from the CLUEWEB09 to determine in how far non-experts can use ERE to discover and extract relations. We discuss the results of the user study, as well as strengths and weaknesses of our proposed approach.

2 Exploratory Relation Extraction

In this section, we present our approach for Exploratory Relation Extraction. We provide details on how we define extraction patterns and how we preemptively extract all subtrees in dependency trees from a given text corpus (Section 2.1). We then outline a data-guided incremental workflow to explore the indexed data for relations (Section 2.2) and illustrate this with an exemplary execution (Section 2.3).

2.1 Human-Readable Relation Extraction Patterns

Like much previous work in RE (Culotta and Sorensen, 2004; Schutz and Buitelaar, 2005; Uszkoreit, 2011), we define extraction patterns using features from dependency-parsed sentences. As recent work has shown (Del Corro and Gemulla, 2013; Akbik et al., 2013b), patterns in dependency trees are well-suited to manual rule based RE, as they enable more succinct and thus more human-readable rule sets. Following this work, we define RE patterns as subtrees in dependency trees.

In our work, we follow the idea of Preemptive Information Extraction (Shinyama and Sekine, 2006) in which all possible relations for a given text corpus are preemptively generated in advance. Applied

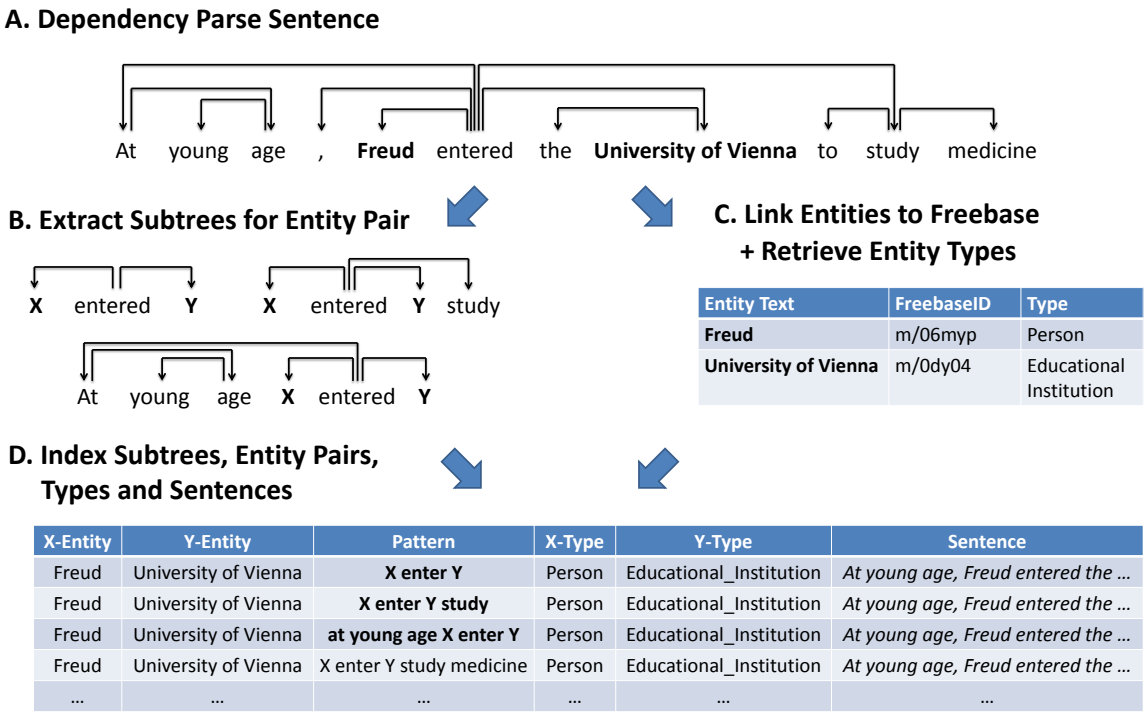

Figure 1: Illustration of the subtree generation process. We parse each sentence in a given document collection using a dependency parser and annotate all entities (**A**). Then, we generate all possible subtrees in the dependency tree that span pairs of annotated entities, three of which are illustrated in **(B)**, and link entities to their FREEBASE IDs to determine their entity types (**C**). We then generate a lexical, lemmatized representation of these subtrees which we store along with the entity pair, their entity types and sentence they are observed with **(D)**.

to our problem this means that we generate all possible dependency subtrees, arguing that depending on the user's information need, any such pattern may be valuable. Since we are interested in binary relations only, we generate only those subtrees that span two named entities in a sentence. In addition, we also determine the fine-grained entity types for named entities in order to allow users to optionally restrict patterns to match only entities of certain types. Previous work has shown the benefit of including fine-grained type restrictions into patterns (Akbik et al., 2013a).

We illustrate this process with an example sentence in Figure 1, for which we determine all subtrees that span the indicated entity pair. In the subtrees, we replace the entity tokens with the placeholders "*X*" and "*Y*", where the former is the placeholder for the X-entity and the latter the placeholder for the Y-entity. For better human-readability, we lexicalize the patterns by lemmatizing the words and discarding information on typed dependencies. We also link the entities in the sentence to entries in the FREEBASE knowledge base (Bollacker et al., 2008), allowing us to retrieve their fine grained entity types.

We then index the information on lexicalized patterns, the entities they span and their types, as well as the sentences in which the patterns were found (Figure 1D). This allows users to query for any combinations of patterns and entity type restrictions and retrieve matching entity pairs and sentences from the index. For instance, a user may query for all entity pairs that match the "*at young age X enter Y*" pattern, and optionally restrict the Y-entity to be only of type ORGANIZATION, or more specific types such as CHURCH or UNIVERSITY. We argue that because patterns are lexicalized variants of dependency subtrees and entity type restrictions can have human readable names, such queries are intuitive to users even without an NLP background. The use and preemptive indexing of human-readable patterns decreases the entry barriers into the ERE process, as this enables users to exploratively query parsed text corpora.

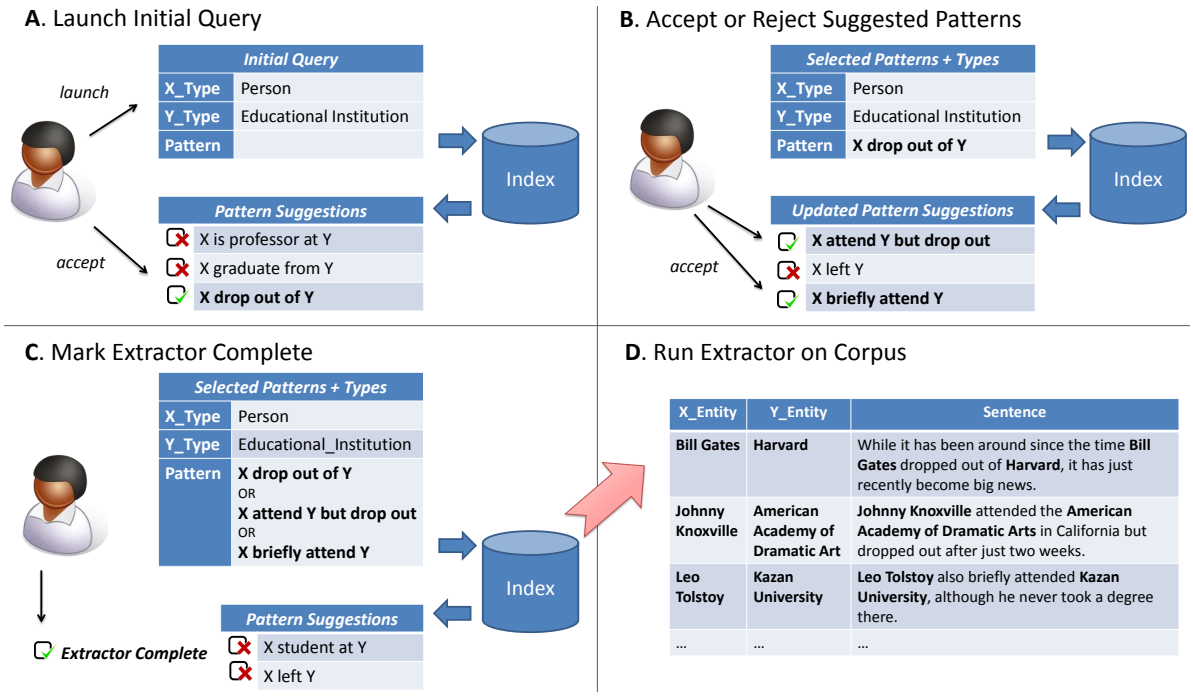

Figure 2: Illustration of the exploratory relation extraction process. The user begins with specifying entity types of interest and receives a set of pattern suggestions (**A**). Intrigued by the pattern "X drop out from Y", the user affirms this pattern. This prompts updated pattern suggestions which the user affirms or rejects (**B**). When no more interesting patters are offered, the user marks the extractor as complete (**C**) and runs it on a corpus, retrieving relation instances and matching sentences (**D**).

2.2 Guidance From Available Data

A second key component is to provide guidance in the exploration process by computing suggestions for patterns from user input and enabling an interactive workflow that allows users to work with available data. Such guidance is needed for two reasons: First, though much effort is invested in human-readable extraction patterns, users may need support in formulating patterns and choosing entity type restrictions. This is especially the case when users are non-experts in the domain of interest and they strive to identify a range of appropriate patterns. Second, users may be uncertain of the information content of a given text corpus. By providing guidance through automatic pattern suggestions that reflect available information, we help users find patterns for their information need.

Users formulate an *entry point* to launch the exploration process, either by providing entity types, patterns or both. We guide the formulation of this initial query through autocomplete options. If the user enters only types for the entities, the system offers the most common patterns that are observed between entities of these types. The user can also search for patterns that contain a certain keyword.

In either case, the system suggests patterns that meet the user-defined entry point. Patterns are ordered by their absolute count in the corpus so that more common patterns are displayed at the top of the list. In addition, verb-based patterns are favored using a scoring metric that assigns extra points to patterns that include verbs. To assist a user in understanding a pattern, we optionally display example sentences and entity pairs in which it matches.

The user then starts a process of selecting (and de-selecting) entity type restrictions and pattern, thus refining the extractor while being guided by constantly updated pattern suggestions. The user continues this process until satisfied with the created extractor at which point it can be saved and the discovered relation instances downloaded. The user can now repeat the workflow to create more extractors.

2.3 Exploration Workflow Example

Suppose we have a user who is given a large text corpus and is asked to link persons to their respective educational institutions, but is unsure of what type of relevant information may be found in the corpus. Knowing only that relations should hold between entities of type PERSON and entities of type EDUCATIONAL_INSTITUTION, the user starts an exploration process by providing only these entity type restrictions. This is illustrated in Figure 2A).

A query is run against the index that identifies common patterns that hold between entities of such types, including "*X be professor at Y*", "*X study at Y*" and "*X drop out from Y*". Recall that each pattern is a human-readable version of a subtree in a dependency tree with two placeholders for entities, namely "X" and "Y". These placeholders may match named entities of any type, or can be restricted to matching only entities of certain types such as persons, organizations or locations. By clicking on a pattern, the user retrieves entity pairs and sentences in which a pattern matches; For example, the user is informed that the pattern "*X study at Y*" finds the relation instance <*Bill Gates, Harvard University*> in the sentence "***Bill Gates** briefly studied at **Harvard University***.".

Intrigued by the pattern "*X drop out from Y*", the user affirms this pattern and rejects all other suggestions. This causes a new query to be run against the parsed data, this time consisting of the entity restrictions as well as the pattern. As the query is now more concrete, the pattern suggestions are updated to reflect this new information. The user is presented with similar patterns such as "*Y dropout X*" and "*X attend Y but drop out*". This is illustrated in Figure 2B).

The user repeats this, selecting or de-selecting patterns (Figure 2B). At each interaction, suggestions are updated to reflect the current selection. When the user is satisfied with the identified relation, the selected set of patterns and restrictions is saved as an extractor (Figure 2C) and executed against the entire text corpus (Figure 2D). This returns lists of matching relation instances and sentences. The user has thus started with an imprecise information need and identified a relation of interest in a given text corpus, namely a relation for persons that attended an educational institution but did not graduate.

3 Experiments

In order to examine in how far our approach indeed contributes to overcoming the limitations of RE outlined in Section 1.1, namely the significant cost and the necessary a-priory specification of relations, we conduct a user study with 10 subjects that have little or no NLP background. We ask the users to apply the workflow for two separate tasks: An *extraction task* in which users are given four clearly defined semantic relations and an *exploration task* in which users are asked to identify relations for more vaguely defined information needs. We only provide the users with a brief introduction into the workflow. For the extraction task, we measure the time spent per extractor and estimate the quality of the created extractors in terms of precision and recall. For the exploration as well as for the extraction task we also qualitatively inspect discovered relations and evaluate user feedback.

3.1 Datasets

ClueWeb09. As source of text data, we use the English language portion of the well-known CLUEWEB09[1] reference corpus, consisting of roughly 5 billion crawled Web pages. We use boilerplating to remove HTML markup and sentence splitting to determine English language sentences.

FACC1. We use the recently released FACC1 (Gabrilovich et al., 2013) resource, a high quality named entity linking effort that was executed on the CLUEWEB09 corpus, linking over 6 billion entity mentions to their corresponding FREEBASE entries. Using this data, we identify over 160 million sentences in CLUEWEB09 that contain at least two entities we can link to FREEBASE. We parse all such sentences using the ClearNLP toolkit (Choi and McCallum, 2013).

Gold Standard Relation Annotations. As gold standard, we use the FREEBASE relation annotations as well as annotations from the "*Relation Extraction Corpus*"[2] a large, human-judged dataset of five relations about public figures on Wikipedia that was released by Google. Four of these relations involve

Table 1: Evaluation results for the 4 well-defined relations in the extraction task. We note differences from user to user, especially with regards to the number of found instances (**#INST**), the number of selected patterns (**#PAT**) and the time spent per relation. Extractors generally find large amounts of relation instances at high precision (**P**), while recall values (**R**) are lower. Users are ordered by the total number of patterns they selected. User 1 selected the most patterns overall and found the most instances for the BORNIN, DIEDIN and EDUCATEDAT relations (highlighted bold). User 10 both spent the most time overall while selecting the fewest patterns. User 7 spent the least amount of time overall.

FREEBASE entities, namely BORNIN, DIEDIN, EDUCATEDAT and GRADUATEDWITHDEGREE. We use these relations in the extraction task.

3.2 Extraction Task

We evaluated the user-created extractors against the gold standard annotations. However, even with relatively large sources of annotations, only roughly 5% of entity pairs in our 160 million sentences have a known FREEBASE relation. We therefore compute precision and recall only for labeled entity pairs, and separately list the absolute number of extracted relation instances.

Large amounts of relation instances at high precision. As Table 1 indicates, many users were able to create extractors that find very large amounts of instances (over 100.000 instances in some cases) at high precision in an average time of 9 to 12 minutes, while recall values tend to be lower. This tendency to favor precision at the cost of recall has been observed in previous works on rule-based RE (Wang et al., 2012). Nevertheless, we analyzed precision and recall in greater detail by manually evaluating a sample of 200 false positives and 200 false negatives by hand to discover the reasons for precision and recall

loss.

Mismatch between gold standard and results. As Table 2 shows, false positives are most commonly due to inconsistencies between extraction results and the gold standard annotations concerning the level of granularity of a relation instance. For example, we found BORNIN and DIEDIN relation instances that indicated a person's place of birth or death at lower or higher granularity than FREEBASE records. An example of this is given in Table 2 for Abraham Lincoln's place of death; we find the more granular <Lincoln, Hildene>, while the gold standard expects <Lincoln, Vermont>. While different from the gold standard, such instances are not false, which suggests that actual precision may be higher than the measured values indicate.

Missed patterns and entity types. The most common causes of recall loss are patterns that users failed to select. In Table 2, we distinguish between "common" patterns that were found by at least one user and "long tail" patterns that were found by none. While we did not expect a user-driven approach to identify long tail patterns, we were surprised that some users failed to find more common patterns. Similarly, the second most common cause of precision loss are entity type restrictions that users failed to correctly select, again to our surprise. We proceeded to interview the users to determine reasons for this.

3.3 Exploration Task

We also asked users to explore the corpus for a vaguely defined information need, namely for relations that pertain to "celebrities", as well as one arbitrary relation. Users spent widely varying amounts of time (between 5 and 50 minutes) on this task due to differences in motivation, as some users had interpreted the search for "interesting" relations as a challenge. For each relation, users provided a short description.

Some relations not in Freebase. While the most common types of relations found for entities of type CELEBRITY regarded different types of romantic involvements with other celebrities such as marriages and divorces, some relations were identified that are not found in FREEBASE. This included a relation that connects a celebrity to the sports team they support or the car they drive (see Table 3). This indicates a potential for using ERE to identify new relations for addition to existing knowledge bases.

Closed-class words can be relevant. Interestingly, one user also worked with patterns that involved closed-class word classes, such as "if" and "whether". Table 3 shown an example of a relation that indicates speculative birthplaces using such words.

3.4 User Feedback and Discussion

Approach more suited to exploration than extraction. When interviewing the users, we found that they generally favored the exploration over the extraction tasks as here the search could be directed to more fine-granular and specialized relations. One of the main problems encountered was the "halting problem", i.e. the question of when to stop adding patterns to an extractor. For some relations, such as BORNIN, users already found thousands of relation instances after selecting the first pattern, which caused two problems; First, they were unsure of the quality of the selected pattern(s), as they were unable to manually check thousands of relation instances for their validity. Second, they were unsure if more patterns were even needed if the first few already found such amounts of relation instances. These problems were not encountered in the exploration tasks, as here users could decide the information need for themselves and select patterns accordingly.

Difficulties concerning entity types. Another main difficulty related to the precise meaning of FREEBASE entity types; For instance, there are several location types, such as LOCATION.LOCATION, LOCATION.DATED_LOCATION and LOCATION.STATISTICAL_REGION, which users found to be confusing, a problem that was compounded by occasional entity linking errors. Many users expressed the desire to specify custom entity types as restrictions in order to have a similar level of control here as over the choice of patterns.

Low entry barriers but allow additional complexity. Overall, we found that users were generally able to start exploring the corpus using our workflow immediately after the brief introduction. Users stated the natural language-like representation of patterns to be intuitively readable, although for some it required a trial and error process to understand how patterns matched entities in sentences. Similarly, some users wished to understand in greater detail how entity types are determined and whether this could

FALSE POSITIVES		
CLASS	COUNT	EXAMPLE SENTENCE
FB Mismatch	95	**Lincoln** died at **Hildene** , his Vermont home, on July 26, 1926.
Type Error	82	[..] the scene where **Boromir** is killed in The **Fellowship of the Ring**.
FB Incomplete	14	Later that year, on December 27, **Dorr** died in **Providence**, in his native Rhode Island.
Other	9	Brieven van liederen **Rascal Flatts** die in het schijfcd album omvatten **Feels Like Today**.

FALSE NEGATIVES		
CLASS	COUNT	EXAMPLE SENTENCE
Common	87	**Klein** holds a **Bachelor of Arts**.
Long Tail	79	**Roger Blandford** is a native of England and took his **BA**, MA and [..].
Other	34	[..], 1974; **MS**, 1976; PhD, University of Pierre and **Marie Curie**, 1982.

Table 2: Analysis of 200 false positives and 200 false negatives to determine error classes for precision and recall loss. Each error class is listed with an example sentence. Main reasons for false positives included a mismatch in granularity between extraction results and annotations, wrongly specified types by the users or cases in which instances were found that were not in FREEBASE. Main reasons for false negatives were mostly patterns that users failed so select, either common patterns, or more rare patterns from the long tail.

NAME	DESCRIPTION	EXAMPLE PATTERNS	EXAMPLE INSTANCES
CELEBRITYDIVORCE	Divorce between two celebrities	"X and Y divorce", "X divorce Y",	<Nicole Kidman, Tom Cruise> <Federline, Spears>
CELEBRITYDRIVESCAR	Finds the cars that celebrities drive	"X drives Y", "X 's car Y",	<Arnold Schwarzenegger, H1> <Leonardo DiCaprio, Toyota Prius>
CONTESTEDBITHPLACE	Relates persons to their speculative birthplace	"if X born in Y", "whether X born in Y",	<Barack Obama, Kenya> <Barack Obama, Nigeria>

Table 3: Examples for relations discovered in the exploration task. CELEBRITYDIVORCE represents a commonly discovered relation, while CELEBRITYDRIVESCAR represents a relation that is presently not part of Freebase. CONTESTEDBITHPLACE is an example of a relation that utilizes closed-world words in patterns.

be influenced. This indicates the need for adding options in future work that give more experienced users more technical information (and control) on dependency trees and FREEBASE types.

4 Previous Work

While no directly comparable approach to Exploratory Relation Extraction is known to us, we take inspiration from a number of previous works.

Exploratory Search (Marchionini, 2006; White and Roth, 2009) is an information seeking paradigm in the field of Information Retrieval, where - like in our proposed approach - users begin an exploration process with an imprecise information need and progressively discover available information to address and sharpen it. Unlike our approach, users search for documents and must consume the unstructured information themselves. We instead apply this paradigm to RE and strive to find structured, relational information in text corpora of unknown content as well as generate Realtion Extractors in the process.

Preemptive Information Extraction (Shinyama and Sekine, 2006), as well as much work in Open Information Extraction (Yates et al., 2007) that builds on this idea, is the preemptive (or open) extraction of all possible relations in a text corpus. We draw inspiration from this idea in our preemptive subtree generation approach; however, while we extract all possible subtrees for each relation regardless of whether they point to a relation or not, Preemptive and OpenIE approaches aim to produce facts and therefore much more narrowly extract predicates using rule-sets (Del Corro and Gemulla, 2013), classifiers (Schmitz et al., 2012) or both (Etzioni et al., 2011).

Manual Rule-Based RE. We also build our work on the field of manual, rule-based RE, which has been observed to be predominantly preferred industry solution due to interpretability of extraction rules and

easy adaption to changing domains (Chiticariu et al., 2013; Chiticariu et al., 2010). The lack of tools to assist rule developers in exploring and choosing between different automatically generated rules has been stated to be one of the major challenges associated with rule-based RE systems. Recent research has moved towards more guided (Li et al., 2012) and more interactive (Akbik et al., 2013b) workflows for the creation of rule-based extractors. Our proposed approach follows this direction, but is the first approach to combine both with automatic suggestions and enable exploratory search for relations.

Precomputing Resources of Relational Patterns. Our work also bears some resemblance to previous work that have grouped similar extraction patterns into clusters (Li et al., 2011) or arranged them in a taxonomy (Nakashole et al., 2012), with the goal of facilitating relation extraction efforts. Contrary to these works, we do not precompute a static resource but rather continuously re-compute pattern suggestions on the basis of user interactions and the text corpus that the user is working with. In addition, our suggestions are based on both user-selected patterns as well as entity type restrictions.

5 Conclusion and Future Work

In this paper, we proposed Exploratory Relation Extraction as a method of exploring text corpora of uncertain content for relations of interest given an imprecise information need. We have presented and evaluated a user-driven and data-guided incremental exploration workflow that enables non-expert users to identify relations and create high precision extractors with minimal effort. Our results indicate that applying ideas from Exploratory Search to RE is beneficial and can extend the application of RE to use cases characterized by more imprecise information needs and uncertainty regarding the information content of available data. In order to facilitate the discussion of our approach with the research community, we release our work publicly through a Web demonstrator[3].

Future work will investigate extending the approach to relations that hold between an arbitrary number of entities as well as the detection of custom entity types. We aim to allow users to store and combine extractors - for example relation extractors that use custom entity type detectors - to address more complex information needs and distribute the exploration and extraction processes along larger groups of users. This way we seek to enable collaborative RE approaches for creating large knowledge bases from text.

Abstract

In this work we present an annotation framework to capture causality between events, inspired by TimeML, and a language resource covering both temporal and causal relations. This data set is then used to build an automatic extraction system for causal signals and causal links between given event pairs. The evaluation and analysis of the system's performance provides an insight into explicit causality in text and the connection between temporal and causal relations.

1 Introduction

Causality is a concept that has been widely investigated from a philosophical, psychological and logical point of view, but how to model its recognition and representation in NLP-centered applications is still an open issue. However, information on causality could be beneficial to a number of natural language processing tasks such as question answering, text summarization, decision support, etc. The lack of information extraction systems focused on causality may depend also on the lack of unified annotation guidelines and standard benchmarks, which usually foster the comparison of different systems performances. Specific phenomena related to causality, such as causal arguments (Bonial et al., 2010), causal discourse relations (The PDTB Research Group, 2008) or causal relations between nominals (Girju et al., 2007), have been investigated, but no unified framework has been proposed to capture causal relations between events, as opposed to the existing TimeML standard for temporal relations (Pustejovsky et al., 2010).

The work presented in this paper copes with this issue by *i)* proposing an annotation framework to model causal relations between events and *ii)* detailing the development and the evaluation of a supervised system based on such framework.

We take advantage of the formalization work carried out for the TimeML standard, in which events, temporal relations and temporal signals have been carefully defined and annotated. We propose to model causal relations in a similar way to temporal relations, inheriting from TimeML the notion of event, relation and signal, even though our approach to causality is well rooted in the *force dynamic* model by Talmy (1985).

Besides, we focus our preliminary annotation on TimeBank (Pustejovsky et al., 2006), a corpus widely used by the research community working on temporal processing. This should possibly enable the adaptation of existing temporal processing systems to the analysis of causal information, given that we rely on well-known standards and data. On the other hand, this makes it easier for us to straightforwardly investigate the relation between temporal and causal information, given that a causing event should always take place *before* a resulting event.

2 Related Work

Research on the extraction of event relations has concerned both the analysis of the temporal ordering of events and the recognition of causality relations. However, the two research lines have progressed quite independently from each other. Recent works on temporal relations mostly revolve around the last

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2097–2106, Dublin, Ireland, August 23-29 2014.

TempEval-3[1] shared task on temporal and event processing. The task organizers released some data sets annotated with events, time expressions and temporal relations in TimeML format (Pustejovsky et al., 2003), mainly used for training and evaluation purposes. The results of TempEval-3 reported by UzZaman et al. (2013) show that, even though the performance of systems for extracting TimeML events and time expressions is quite good (>80% F-score), the overall performance of end-to-end event extraction pipelines is negatively affected by the poor performance of modules for temporal relation extraction. In fact, the state-of-the-art performance on the temporal relation extraction task yields only around 36% F-score (Bethard, 2013).

The problem of detecting causality between events is as challenging as recognizing their temporal order, but less analyzed from an NLP perspective. Besides, it has mostly focused on specific types of event pairs and causal expressions in text, and has failed to provide a global account of causal phenomena that can be captured with NLP techniques. SemEval-2007 Task 4 "Classification of Semantic Relations between Nominals" (Girju et al., 2007) gives access to a corpus containing nominal causal relations among others, as causality is one of the considered semantic relations in the task. Bethard et al. (2008) collected 1,000 conjoined event pairs connected by *and* from the Wall Street Journal corpus. The event pairs were annotated manually with both temporal (BEFORE, AFTER, NO-REL) and causal relations (CAUSE, NO-REL). They use 697 event pairs to train a classification model for causal relations, and use the rest for evaluating the system, which results in 37.4% F-score. Rink et al. (2010) perform textual graph classification using the same corpus, and make use of manually annotated temporal relation types as a feature to build a classification model for causal relations between events. This results in 57.9% F-score, 15% improvement in performance compared with the system without the additional feature of temporal relations.

The interaction between temporal and causal information, and the contribution of temporal information to the identification of causal links, are also one of the issues investigated in this paper. However, we aim at providing a more comprehensive account of how causal relations can be explicitly expressed in a text, and we do not limit our analysis to specific connectives.

Do et al. (2011) developed an evaluation corpus by collecting 20 news articles from CNN, allowing the detection of causality between *verb-verb*, *verb-noun*, and *noun-noun* triggered event pairs. Causality between event pairs is measured by taking into account Point-wise Mutual Information (PMI) between the cause and the effect. They also incorporate discourse information, specifically the connective types extracted from the Penn Discourse TreeBank (PDTB), and achieve a performance of 46.9% F-score. Unfortunately, the data set is not freely available, hence, comparing our work with theirs is not possible.

The most recent work of Riaz and Girju (2013) focuses on the identification of causal relations between verbal events. They rely on the unambiguous discourse markers *because* and *but* to automatically collect training instances of cause and non-cause event pairs, respectively. The result is a knowledge base of causal associations of verbs, which contains three classes of verb pairs: *strongly causal*, *ambiguous* and *strongly non-causal*.

The lack of a standard benchmark to evaluate systems for the extraction of causal relations between events makes it difficult to compare the performance of different systems, and to identify the state-of-the-art approach to this particular task. For this reason, we annotated TimeBank, a freely available corpus, with the aim of making it available to the research community for further evaluations.

3 Data annotation

In order to develop a classifier for the detection of causal relations between events, we first define annotation guidelines for explicit causality and then manually annotate a data set for training and testing.

3.1 Annotation scheme

Since one of the goals of this work is to investigate the interaction between temporal and causal information, we define an annotation scheme strongly inspired by the TimeML standard for events, time expressions and temporal relations. First, we inherit from TimeML the definition of events, which includes all types

[1] http://www.cs.york.ac.uk/semeval-2013/task1/

of actions (punctual and durative) and states. Hence, we do not limit our annotation only to specific PoS such as verbal or nominal events.

Similar to the <TLINK> tag in TimeML for temporal relations, we introduce the <CLINK> tag to mark a causal relation between two events. Both TLINKs and CLINKs mark directional relations, i.e. they involve a source and a target event. However, while a list of relation types is part of the attributes for TLINKs (e.g. BEFORE, AFTER, INCLUDES, etc.), for CLINKs only one relation type is foreseen, going from a *source* (the cause, indicated with $_{S}$ in the examples) to a *target* (the effect, indicated with $_{T}$).

We also introduce the notion of causal signals through the <C-SIGNAL> tag. <SIGNAL>s have been introduced in TimeML to annotate temporal prepositions and other temporal connectives and subordinators. If a SIGNAL marks the presence of a temporal relation in a text, its ID is added to the attributes of such TLINK. In a similar way, C-SIGNALs are used to mark-up textual elements signalling the presence of causal relations, which include all causal uses of *prepositions* (e.g. because of, as a result of, due to), *conjunctions* (e.g. because, since, so that), *adverbial connectors* (e.g. so, therefore, thus) and *clause-integrated expressions* (e.g. the reason why, the result is, that is why). Also for CLINKs it is possible to assign a *c-signalID* attribute, in case a C-SIGNAL marks the causal relation between two events in text.

Concerning the notion of causality, it is particularly challenging to provide guidelines that clearly define how to identify it in text, since causality exists as a psychological tool for understanding the world independently of language and it is not necessarily grounded in text (van de Koot and Neeleman, 2012). There have been several attempts in the psychology field to model causality, including the counterfactual model (Lewis, 1973), the probabilistic contrast model (Cheng and Novick, 1991; Cheng and Novick, 1992) and the dynamics model (Wolff and Song, 2003; Wolff et al., 2005; Wolff, 2007), which is based on Talmy's force dynamic account of causality (Talmy, 1985; Talmy, 1988). We choose to lean our guidelines on the latter model, since it accounts also for different ways in which causal concepts are lexicalized.

Specifically, Wolff (2007) claims that causation covers three main types of causal concepts, i.e. CAUSE, ENABLE and PREVENT. These causal concepts are lexicalized through three types of verbs listed in Wolff and Song (2003): *i)* CAUSE-type verbs, e.g. *cause, prompt, force*; *ii)* ENABLE-type verbs, e.g. *allow, enable, help*; and *iii)* PREVENT-type verbs, e.g. *block, prevent, restrain*. These categories of causation and the corresponding verbs are taken into account in our guidelines (Tonelli et al., 2014).

We assign a CLINK if, given two annotated events, there is an explicit causal construction linking them. Such construction can be expressed in one of the following ways:

1. Expressions containing **affect verbs** (*affect, influence, determine, change, etc.*), e.g. *Ogun ACN crisis* $_{S}$ ***influences*** *the launch* $_{T}$ *of the All Progressive Congress*.
2. Expressions containing **link verbs** (*link, lead, depend on, etc.*), e.g. *An earthquake* $_{T}$ *in North America was* ***linked*** *to a tsunami* $_{S}$ *in Japan*.
3. **Basic constructions involving causative verbs** of CAUSE, ENABLE and PREVENT type, e.g. *The purchase* $_{S}$ ***caused*** *the creation* $_{T}$ *of the current building*.
4. **Periphrastic constructions involving causative verbs** of CAUSE, ENABLE and PREVENT type, e.g. *The blast* $_{S}$ ***caused*** *the boat to heel* $_{T}$ *violently*. With "periphrastic" we mean constructions where a causative verb (*caused*) takes an embedded clause or predicate as a complement expressing a particular result (*heel*).
5. Expressions containing **CSIGNALs**, e.g. *Its shipments declined* $_{T}$ ***as a result of*** *a reduction* $_{S}$ *in inventories by service centers*.

We annotate both intra- and inter-sentential causal relations between events, provided that one of the above constructions is present. We do not annotate causal relations that are implicit and must be inferred by annotators, because they may be highly ambiguous and would probably affect inter-annotator agreement.

3.2 Corpus statistics

Based on the guidelines above, we manually annotated causality in the TimeBank corpus taken from TempEval-3, containing 183 documents with 6,811 annotated events in total.[2] We chose this corpus because gold events were already present, between which we could add causal links. Besides, one of our research goals is the analysis of the interaction between temporal and causal information, and TimeBank already presents full manual annotation of temporal information according to TimeML standard.

However, during annotation, we noticed that some events involved in causal relations were not annotated, probably because the corpus was originally built focusing on events involved in temporal relations. Therefore, we annotated also 137 new events, which led to around 56% increase in the number of annotated CLINKs.

The total number of annotated CSIGNALs is 171 and there are 318 CLINKs, much less than the number of TLINKs found in the corpus, which is 5,118. Besides, not all documents contain causality relations between events. From the total number of documents in TimeBank, only 109 (around 60%) of them contain explicit causal links and only 87 (around 47%) of them contain CSIGNALs. We also found that there is no temporal signal (marked by <SIGNAL> tag) annotated in TimeBank, which is unfortunate since it could help in disambiguating causal signals from temporal signals.

Annotation was performed using the CAT tool (Bartalesi Lenzi et al., 2012), a web-based application with a plugin to import annotated data in TimeML and add information on top of it. The agreement reached by two annotators on a subset of 5 documents is 0.844 Dice's coefficient on C-SIGNALs (micro-average over markables) and of 0.73 on CLINKs. The built corpus is then used as training and test data in the experiments for the classification of CSIGNALs and CLINKs, as described in Section 4. This preliminary analysis on the corpus, however, shows that explicit causal relations between events are less frequently found in texts than temporal ones. This may lead to data sparseness problems.

4 Experiments

Using the 183 documents from TimeBank manually enriched with causal information for training and testing, we implement two different classifiers: the first one is a CSIGNAL labeler, that takes in input information on events and temporal expressions as annotated in the original TimeBank, and classifies whether a token is part of a causal signal or not (Section 4.1). The second one is a CLINK classifier, which given an event pair detects whether they are connected by an explicit causal link (Section 4.2). Both experiments are carried out based on five-fold cross-validation. The overall approach is largely inspired by our existing framework for the classification of temporal relations (Mirza and Tonelli, 2014).

4.1 Automatic Extraction of CSIGNALs

The task of recognizing CSIGNALs can be seen as a text chunking task, i.e. using a classifier to determine whether a token is part of a causal signal or not. Since the extent of causal signals can be expressed by multi-word expressions, we employ the IOB tagging convention to annotate the data, where each token can either be classified into B-CSIGNAL, I-CSIGNAL or O (for other). We build our classification model using the Support Vector Machine (SVM) implementation provided by YamCha[3], a generic, customizable, and open source text chunker. In order to provide the classifier a feature vector to learn from, we perform the two following steps:

1. Run the *TextPro* tool (Pianta et al., 2008) to get information on base NP chunking and whether a token is part of named entity or not.
2. Run *Stanford CoreNLP* tool[4] to get information on lemma, part-of-speech (PoS) tags and dependency relations between tokens.

In the end, the feature vector includes *token*, *lemma*, *PoS tag*, *NP chunking*, *dependency path*, and *several binary features*, indicating whether a token is: *i)* an event or part of a temporal expression,

[2]The annotated data set is available at `http://hlt.fbk.eu/technologies/causal-timebank`

[3]`http://chasen.org/~taku/software/yamcha/`

[4]`http://nlp.stanford.edu/software/corenlp.shtml`

according to gold TimeML annotation; *ii)* part of a named entity or not; and *iii)* part of a specific discourse connective type.

Dependency information is encoded as the dependency path between the current token and its *governor*. For example, in *"He fell because the chair was broken"*, there is a dependency relation *mark (broken, because)*, where *mark* indicates the presence of a finite clause subordinate to another clause (de Marneffe and Manning, 2008). Thus, we encode the dependency feature for the token *because* as *mark (broken)*. If the governor is an event, e.g. *broken* is annotated as an event, the dependency feature is represented as *mark (*EVENT*)* instead.

The mentioned binary features are introduced to exclude the corresponding token as a candidate token for a causal signal. In other words, if a token is part of a named entity or an event, it is very unlikely that it will be part of a causal signal. The same holds for all connective types that do not express causal relations, e.g. temporal or concessive ones. In order to obtain this information, we include in the feature vector the information about discourse connectives acquired using the *addDiscourse* tool (Pitler and Nenkova, 2009), which identifies connectives and assigns them to one of four semantic classes in the framework of the Penn Discourse Treebank (The PDTB Research Group, 2008): TEMPORAL, EXPANSION, CONTINGENCY and COMPARISON. Note that causality is part of the CONTINGENCY class.

System	Precision	Recall	F-score
Rule-based (baseline)	54.33%	40.35%	46.31%
Supervised chunking	91.03%	41.76%	57.26%

Table 1: Evaluation of CSIGNAL extraction system

Table 1 shows the performance of our classification model in a five-fold cross-validation setting, which yields a good precision but a poorer recall, summing up into 57.26% F-score. We also compare our supervised model with a baseline rule-based system, which labels as CSIGNALs all causal connectors listed in our annotation guidelines and those appearing in specific syntactic constructions. For instance, *from* and *by* are always labeled as CSIGNAL when they are governed by a passive verb annotated as event and govern another event, as in the sentence *"The building was* damaged $_{\text{T}}$ ***by*** *the* earthquake $_{\text{S}}$*."* Note that this is quite a strong baseline, since the rule-based algorithm embeds some of the intuitions on syntactic dependencies expressed also as features in the supervised approach.

4.2 Automatic Extraction of CLINKs

Similar to causal signal extraction, we approach the problem of detecting causal links between events as a supervised classification task. Given an ordered pair or events (e_1,e_2), the classifier has to decide whether there is a causal relation between them or not. However, since we also consider the directionality of the causal link, an event pair (e_1,e_2) is classified into 3 classes: CLINK (where e_1 is the source and e_2 is the target), CLINK-R (with the reverse order or source and target) or NO-REL. Again, we use YamCha to build the classifier. This time, a feature vector is built for each pair of events and not for each token as in the previous classification task.

As candidate event pairs, we take into account every possible combination of events in a sentence in a forward manner. For example, if we have e_1, e_2 and e_3 in a sentence (in this order), the candidate event pairs are (e_1,e_2), (e_1,e_3) and (e_2,e_3). We also include as candidate event pairs the combination of each event in a sentence with events in the following one. This is necessary to account for inter-sentential causality, under the simplifying assumption that causality may occur only between events in two consecutive sentences.

We implement a number of features, some of which are computed independently based on either e_1 or e_2, e.g. lemma, PoS, while some others are pairwise features, which are computed based on both elements, e.g. dependency path, signals in between, etc. The implemented features are as follows:

String and grammatical features. The tokens and lemmas of e_1 and e_2, along with their PoS and a binary feature indicating whether e_1 and e_2 have the same PoS tags.

Textual context. The sentence distance and event distance of e_1 and e_2. Sentence distance measures

how far e_1 and e_2 are from each other in terms of sentences, i.e. 0 if they are in the same sentence. The event distance corresponds to the number of events occurring between e_1 and e_2 (i.e. if they are adjacent, the distance is 0).

Event attributes. Event attributes as specified in TimeML annotation, which consist of *class*, *tense*, *aspect* and *polarity*. Events being a noun, adjective and preposition do not have tense and aspect attributes in TimeML. Therefore, we retrieve this information by extracting the tense and aspect of the verbs that govern them, based on their dependency relation. We also include four binary features representing whether e_1 and e_2 have the same event attributes or not. These features, especially the *tense* and *aspect* one, are very relevant for detecting causality. For instance, if e_1 is in the future tense and e_2 in the past tense, there cannot be a causal relation connecting e_1 (as source) and e_2 (as target or result).

Dependency information. We include as features *i)* the dependency path that exists between e_1 and e_2, *ii)* the type of causative verb connecting them (if any) and *iii)* binary features indicating whether e_1/e_2 is the *root* of the sentence. This information is based on the collapsed representation of dependency relations provided by the parsing module of Stanford CoreNLP. Consider the sentence *"Profit from coal fell* $_{\text{T}}$ *to $41 million from $58 million, partly* ***because of*** *a miners' strike* $_{\text{S}}$*."* Based on the collapsed typed dependencies, we would obtain a direct relation between *fell* and *strike*, which is *prep_because_of (fell, strike)*. This information combined with the classification of *because of* as a causal signal would straightforwardly identify the relation connecting the two events as causal.

Causal signals. We take into account the annotated CSIGNALs connecting two candidate events. We look for causal signals occurring between e_1 and e_2, or before e_1. We also include the position of the signals (*between* or *before*) as feature, since it is crucial to determine the direction of the causality of a given ordered event pair. This is particularly evident if you consider the position of causal signals in the following examples: *i)* "The building collapsed $_{\text{T}}$ **because of** the earthquake $_{\text{S}}$" vs. *ii)* "**Because of** the earthquake $_{\text{S}}$ the building collapsed $_{\text{T}}$." This feature is also very relevant in connection with the *Textual context*, since two events being in two different sentences are linked by an explicit causal relation only in specific cases, for instance if there is a CSIGNAL in between, typically at the beginning of the second sentence. Note that in case of several CSIGNALs occurring between e_1 and e_2, we take the closest CSIGNAL to e_2, as in the sentence "The building was damaged $_{\text{S}}$ **by** the earthquake , **thus**, people moved $_{\text{T}}$ away". The dependency path between the causal signal and e_1/e_2 is also important to determine the correct involved events in the causal relations. For instance, in the sentence "They decided $_{\text{T}}$ to move **because of** the earthquake $_{\text{S}}$", the involved event is *decided* instead of *move*.

Temporal relations (TLINKs). Rink et al. (2010) showed that including temporal relation information in detecting causal links results in improving classification performance. Nevertheless, they only analyze this phenomenon when causality is expressed by the conjunction *and*. We decided to include this information in the feature set by specifying the temporal relation type connecting e_1 and e_2, if any, to see whether TLINKs help in improving causality detection also in a more comprehensive setting.

We evaluate our approach in a five-fold cross-validation setting, and we compare the performance of our classifier with a baseline rule-based system. This relies on an algorithm that, given a term t belonging to *affect*, *link*, *causative* verbs (basic and periphrastic constructions) or *causal signals* (as listed in the annotation guidelines), looks for specific dependency constructions where t is connected to two events. If such dependencies are found, a CLINK is automatically set between the two events identifying the source and the target of the relation. Further details on the baseline system and its evaluation can be found in Mirza et al. (2014).

In our experimental setting, we evaluate two versions of the CLINK classifier: the first includes as features the *gold annotated* CSIGNALs in the classification model, while the second takes in input the CSIGNALs *automatically annotated* by the classifier described in Section 4.1. We also evaluate the contribution of *dependency*, *CSIGNAL* and *TLINK* features by excluding each of them from the classification model.

Evaluation results are reported in Table 2. We observe that the baseline is always outperformed by the other classifiers. CSIGNAL is the most important feature, with a particularly high impact on recall. The

intuition behind this result is that, if a CSIGNAL is present, it is a strong indicator of a causal relation being present in the surrounding context. This is similar to what Derczynski and Gaizauskas (2012) report for temporal information, showing that temporal signals provide useful information in TLINK classification. Dependency information contributes to the performance of the classifier, but is less relevant than TLINK information. A more detailed analysis of the relation between temporal and causal information is reported in the following section. The significantly decreasing recall of the classifier using the automatic extracted CSIGNALs as features is most probably caused by the low recall of the CSIGNAL extraction system.

System	Precision	Recall	F-score
Rule-based (baseline)	36.79%	12.26%	18.40%
Supervised classification (with gold CSIGNALs)	74.67%	35.22%	47.86%
- without dependency feature	65.77%	30.82%	41.97%
- without CSIGNAL feature	57.53%	13.21%	21.48%
- without TLINK feature	61.59%	29.25%	39.66%
Supervised classification (with automatic CSIGNALs)	67.29%	22.64%	33.88%

Table 2: Performance of CLINK extraction system

5 Discussion

We further analyse the output of the automatic extraction systems, in order to understand some phenomena triggering the results.

5.1 Recognizing CSIGNALs

When we manually inspect the output of the CSIGNAL extraction system, we find that the false positives are actually the causal signals that annotators missed in the corpus, and not ambiguous connectives. The system surprisingly yields better precision than human annotation, finding new correct signals.

The recall, however, suffers most probably from data sparseness. It is possible that during the cross-validation experiments some splits do not have enough data to learn from, recalling that only around 47% of the documents contain annotated CSIGNALs. Furthermore, 20% of the false negative cases are due to classifier's mistakes in detecting the causal signal *by*, which is highly ambiguous. Our assumption with the rule-based system that "*by* is likely to be a causal signal when it is used to modify a passive verb" is too restrictive, since *by* can convey a causal meaning even if the target event is not in the passive voice, as in the example *"The embargo is meant to cripple* $_{\text{T}}$ *Iraq* ***by*** *cutting* $_{\text{S}}$ *off its exports of oil and imports of food and military supplies."*

Another ambiguous causal signal that the classifier fails to detect is the conjunction *and*. We believe that more training data, and perhaps more lexical information on the tokens connected by the conjunction *and*, are needed for the classifier to be able to disambiguate them.

5.2 Detecting CLINKs

We found that most of the mistakes done by the classifier, as well as by the rule-based system, are caused by the dependency parser output that tends to establish a dependency relation between a causative verb or causal signal and the closest verb. For example, in the sentence *"StatesWest Airlines withdrew* $_{\text{T}}$ *its offer to acquire Mesa Airlines* ***because*** *the Farmington carrier did not respond* $_{\text{S}}$ *to its offer"*, the dependency parser identify *because* as the mark of *acquire* instead of *withdrew*.

Moreover, also for this task data sparseness is definitely an issue. One possible solution would be to annotate more data, for instance the AQUAINT data set used for TempEval-3 competition (UzZaman et al., 2013). Another possibility would be to automatically generate additional data from the Penn Discourse TreeBank corpus, where causality is one of the discourse relations annotated between argument pairs. However, a further processing step would be needed to identify inside the argument spans the events between which a relation holds, which may introduce some errors.

Regarding the directionality of causal relations, the classifier is generally quite precise. 112 out of 150 CLINKs detected by the classifier actually match a causal relation present in the gold annotated data. Only 8 of them have been classified with the wrong direction. We believe that using the TLINK types as features contributes to this good performance in disambiguating causality direction (CLINK vs. CLINK-R).

5.3 Interaction between temporal and causal information

We provide in Table 3 some statistics on the overlaps between causal links and temporal relation types from the gold data. The *Others* class in the table includes SIMULTANEOUS, IS_INCLUDED, BEGUN_BY and DURING_INV relations. These counts were obtained by overlapping the temporal information in TimeBank with the causal information manually added for our experiments. In total, only 32% of the gold causal links have the underlying temporal relations. Note that the annotators could not see the temporal links already present in the data, therefore they were not biased by TLINKs when assessing causal links.

	BEFORE	AFTER	IBEFORE	IAFTER	Others	Total
CLINK	15	5	0	0	4	24
CLINK-R	1	67	0	3	8	79

Table 3: Statistics of CLINKs overlapping with TLINKs

The data confirm our intuition that temporal information is a strong constraint when detecting causal relations, with the BEFORE class having the most overlaps with CLINK and AFTER with CLINK-R. This is in line with the outcome of our feature analysis reported in Table 2, suggesting that feeding temporal information into a causal relation classifier yields an improvement in performance. However, the converse would be less effective, since the occurrences of explicit causal relations are by far less frequent than temporal ones. Besides, we found that the few cases where CLINKs overlap with AFTER relation are not due to annotation mistakes, as in the example *"But some analysts questioned* $_{\text{T}}$ *how much of an impact the retirement package will have,* ***because*** *few jobs will end* $_{\text{S}}$ *up being eliminated."*

Finally, the performance achieved by our system in causal relation extraction (with gold C-SIGNALs) is 47.86% F-score, which is better than the performance of the state-of-the-art temporal relation extraction system with 36.26% (Bethard, 2013). This probably depends on the fact that extracting CLINKs is a simpler task compared with TLINK extraction: in the first case 3 classes are considered, while temporal relation types are classified into 14 classes.

6 Conclusions

In this paper, we presented a framework for annotating causal signals and causal relations between events. Besides, we implemented and evaluated two supervised systems, one classifying C-SIGNALs and the other CLINKs.

With the first task, we showed that while recognizing unambiguous causal signals is very trivial, ambiguous signals such as *by* and *and* are very difficult to identify because they occur in diverse syntactic constructions. We definitely need more data to learn from, and perhaps use more lexical information on the words connected by such causal signals as features. The knowledge base of causal associations between verbs developed by Riaz and Girju (2013) may be a useful resource to provide such information, and we will explore this possibility in the future.

We found that the low recall achieved by the CLINK classifier is probably affected by wrong dependencies identified by the Stanford parser. In the future, we would like to test also the C&C tool (Curran et al., 2007) to extract dependency relations, since it has a better coverage of long-range dependencies. We have also shown that causal signals are very important in detecting explicit causal links holding between two events. Finally, we showed that temporal relation types help in disambiguating the direction of causality, i.e. to determine the source and target event. However, the converse may not hold, since the causal links in the data set are very sparse, and only 2% of the total TLINKs overlap with CLINKs.

Abstract

Distantly supervised relation extraction, which can automatically generate training data by aligning facts in the existing knowledge bases to text, has gained much attention. Previous work used conjunction features with coarse entity types consisting of only four types to train their models. Entity types are important indicators for a specific relation, for example, if the types of two entities are "PERSON" and "FILM" respectively, then there is more likely a "DirectorOf" relation between the two entities. However, the coarse entity types are not sufficient to capture the constraints of a relation between entities. In this paper, we propose a novel method to explore fine-grained entity type constraints, and we study a series of methods to integrate the constraints with the relation extracting model. Experimental results show that our methods achieve better precision/recall curves in sentential extraction with smoother curves in aggregated extraction which mean more stable models.

1 Introduction

Relation Extraction is the task of extracting semantic relations between a pair of entities from sentences containing them. It can potentially benefit many applications, such as knowledge base construction, question answering (Ravichandran and Hovy, 2002), textual entailment (Szpektor et al., 2005), etc. Traditional supervised approaches for relation extraction (Zhou et al., 2005)(Zhou et al., 2007) need to manually label training data, which is expensive and limits the ability to scale up. Due to the shortcoming of supervised approaches mentioned above, recently, a more promising approach named distantly supervised relation extraction (or distant supervision for relation extraction) (Mintz et al., 2009) has become popular. Instead of manual labeling, it automatically generates training data by aligning facts in existing knowledge bases to text.

However, the paradigm of distant supervision also causes new problems of noisy training data both in positive training instances and negative training instances. To overcome the false positive problem caused by the distant supervision assumption, researches in (Riedel et al., 2010)(Hoffmann et al., 2011)(Surdeanu et al., 2012) proposed multi-instance models to model noisy positive training data, where they assumed that at least one sentence in those containing an entity pair is truly positive. Takamatsu et al. (Takamatsu et al., 2012) claimed that the at-least-one assumption in multi-instance models would fail when there was only one sentence containing both entities. They proposed a method to learn and filter noisy pattern features from training instances to overcome the false positive problem. Researchers (Xu et al., 2013)(Zhang et al., 2013)(Ritter and Etzioni, 2013) tried to address the problem of false negative training data caused by the incomplete knowledge base. Xu el al. (Xu et al., 2013) used the pseudo-relevance feedback method trying to find out the false negative instances and add them into positive training instances. Zhang et al. (Zhang et al., 2013) employed some rules to select negative training instances carefully, hoping not to include the false negative instances. And Ritter et al. (Ritter and Etzioni, 2013) used hidden variables to model the missing data in databases based on a graphical model. The training data generation process for all the above work is under the framework of (Mintz et al., 2009),

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2107–2116, Dublin, Ireland, August 23-29 2014.

one important step of which is to recognize entity mentions from text and assign them entity types which are used to compose features for training the model. The entity types they used are very coarse only consisting of four categories (PERSON, ORGANIZATION, LOCATION, NONE). We argue that the coarse entity types are not sufficient to indicate relations.

A specific relation constrains the entity types of its two entities. For instance, the *SingerOf* relation limits the entity type of its first entity as PERSON or more fine-grained ARTIST, and the entity type of its second entity as ART or more fine-grained MUSIC. Therefore, when extracting a relation instance, the entity types of its two entities are important indicators for a specific relation. Previous work used conjunction features (Details in Section 3.3) by combining the coarse entity types of entity mentions with its contextual lexical and syntactic features. However, the conjunction features may fail to distinguish the relations. For example, the following two sentences contain two relation instances, one is *DirectorOf(Ang Lee, Life of Pi)*, and the other is *AuthorOf(George R.R. Martin, A Song of Ice and Fire)*.

1. **Ang Lee**'s **Life of Pi** surprised many by scoring a leading four Oscars on Sunday night...
2. Westeros is the premiere fansite for **George R.R. Martin**'s **A Song of Ice and Fire**.

Only using the above conjunction features, we cannot tell the difference between the two entity pairs, and are probable to incorrectly classify them as the same relation. By contrast, if we can assign each entity with fine-grained entity types, for example, *Ang Lee* as the entity type ARTIST and *George R.R. Martin* as AUTHOR, we may succeed in classifying the two entity pairs correctly.

To achieve the goal mentioned above, there are mainly three challenges: (1) how to define the fine-grained type set; (2) how to assign the types to entity mentions; (3) how to integrate the fine-grained entity type constraints with the relation extracting model. To address these challenges, in this paper, we propose a novel approach to explore the fine-grained entity type constraints for distantly supervised relation extraction. First, we use the types defined in (Ling and Weld, 2012) stemmed from Freebase[1] as the fine-grained entity type set (introduced in Section 3.1). Second, we leverage Web knowledge to train a fine-grained entity type classifier and predict entity types for each entity mention. Third, we study several methods to integrate the type constraints with an existing system *MULTIR*, a multi-instance multi-label model in (Hoffmann et al., 2011), to train the extractor.

In summary, the contribution of this paper can be concluded as follows.

(a) We explore the effect of fine-grained entity type constraints on distantly supervised relation extraction. A novel method is proposed to leverage Web knowledge to automatically train a fine-grained entity type classifier, which is used to predict the fine-grained types of each entity mention.

(b) We study a series of methods for integrating the fine-grained entity type constraints with the extracting model and compare their performance with different parameter settings.

(c) We conduct experiments to demonstrate the effects of the newly exploited fine-grained entity type constraints. It shows that our method achieves a much better precision/recall curves over the baseline system in sentential extraction, and improves the performance with a smoother precision/recall curve in aggregated extraction, which means a more stable model.

2 Distant Supervision for Relation Extraction

We define a relation instance (or a fact), which means a binary relation, as $r(e_1, e_2)$. r is the relation, and e_1 and e_2 mean the two entities in the relation instance, for example, $BornIn(Yao\ Ming, Shanghai)$. Distant supervision supplies a method to automatically generate training data. In this part, we will introduce the general steps in distant supervision for relation extraction. First, we define the notations we use. Σ denotes sentences comprising the corpus, E denotes entity mentions in the corpus which are consecutive words with the same named entity tags assigned by an NER system, Δ denotes the facts (or relation instances) in the existing knowledge base. R denotes the relations in Δ.

Figure 1: Fine-grained entity type set.

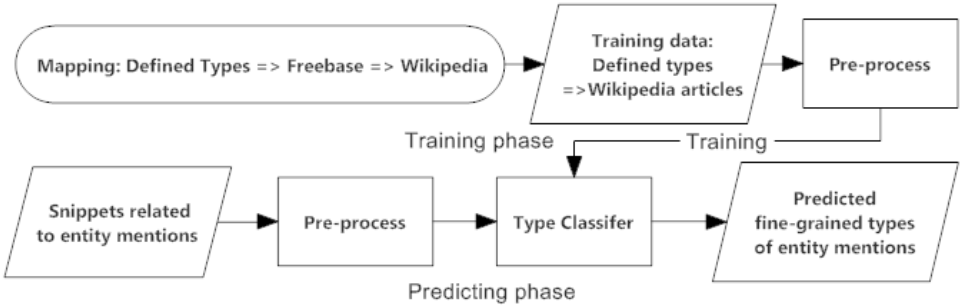

Figure 2: Framework of fine-grained entity type classifier.

To generate training data, we align pairs of entity mentions in the same sentence with Δ. The aligned entity mentions E_{train} and their sentences Σ_{train} along with R_{train} are used as training data. Features are extracted from them to train the relation extracting model.

To predict the unknown data for extracting new relation instances, we input pairs of entity mentions $E_{predict}$ and the sentences containing them $\Sigma_{preidct}$ into the trained extracting model for extracting new relation instances.

3 Fine-grained Entity Type Constraints

Entity mentions in sentences are considered consecutive words with the same entity types (Section 2). The entity types are part of the lexical and syntactic features(Mintz et al., 2009), and the feature setting is followed by other related work. Their entity types are assigned by an NER system and consist of four categories (PERSON, ORGANIZATION, LOCATION, NONE). The types of entity mentions in a relation are important indicators for the very type of relation. However, the coarse (only four types) entity types may not capture sufficient constraints to distinguish a relation. In this section, we explore fine-grained entity type constraints and study different methods to integrate them with the extracting model.

This section first introduces the fine-grained entity type set(Section 3.1), and then describes our method which leverages Web knowledge to train the fine grained entity type classifier and assign entity mentions with the fine-grained entity types (Section 3.2). At last, we illustrate methods to integrate fine-grained entity type constraints with the relation extracting model.

Entity pair	[Hank Ratner], [Cablevision]					
Sentence	Cablevision's $600 million offer came in the form of a letter to Peter S.Kalikow, chairman of the M.T.A., from the Garden's vice chairman, Hank Ratner.					
Conjunction	Reverse	Left	NE1	Middle	NE2	Right
Feature examples	False		PER		ORG	
	False	Hank[NMOD]	PER	[NMOD]chairman ... offer[SBJ]	ORG	
	True	B_-1	ORG	POS $ ... NN NN,	PER	.B_1

Table 1: Examples of conjunction features.

3.1 Fine-grained Entity Types

Figure 1 is the type set we use. It was introduced in (Ling and Weld, 2012) and was derived from Freebase types. The bold types in each small box of Figure 1 are upper-class types for others in that small box. For example, $/actor$ is a lower-class type of $/person$ which is denoted as $/person/actor$. And $/person$ and $/person/actor$ coexist in the type set.

3.2 Fine-grained Entity Type Classifier

In this section, we describe our method that leverages Web knowledge to train a fine-grained entity type classifier and predict entity types of each entity mention. Its architecture is shown in Figure 2.

3.2.1 Training

The training data are obtained from Wikipedia. Because the defined fine-grained types are tailored based on Freebase types, we can find the mappings between the two type sets, for example, $/person/doctor$ maps to two Freebase types $/medicine/physician$ and $/medicine/surgeon$. And Freebase WEX[2] supplies a mapping between Freebase types to Wikipedia articles. As a result, we can map Wikipedia articles to defined fine-grained types.

Based on the mappings, we obtain Wikipedia articles for each type as training data and negative training examples are sampled from articles not contained in the mappings. We preprocess the articles by: stop words filtering, stemming, and term frequency filtering and use a maxent model to train the classifier.

3.2.2 Predicting

To predict types of each entity mention, we first use search engines to expand entity mentions. Specifically, each entity mention is used as a query sent to the search engine[3]. Titles and descriptions of top k returned snippets are selected (We keep the top 20 in the experiments). The obtained text are preprocessed with the same method as training examples. Then we use the trained fine-grained entity type classifier to predict the types of each entity mention.

After predicting, we obtain a ranked list of types for each entity mention, which are ranked by the predicting scores.

3.3 Integrating Fine-grained Entity Type Constraints into the Extracting Model

This section introduces our methods to integrate the fine-grained entity type constraints with the extracting model. First of all, we briefly review the features used in previous models which derived from (Mintz et al., 2009) and (Riedel et al., 2010). Their features mainly comprise two types: lexical features (POS tags, words and entity types) and syntactic features (dependency parsing tags, words and entity types). Each feature is a conjunction with several parts: entity types of two entity mentions, the left context window of the first entity mention, the right context window of the second entity mention and the part between them (the window contains none or one or two words). Table 1 shows an example of the conjunction features.

[2]http://wiki.freebase.com/wiki/WEX

[3]We use Bing search API. http://datamarket.azure.com/dataset/bing/search

To integrate the exploited fine-grained entity type constraints with the extracting model, we proposed three methods (substitution, augment and selection) to make the type constraints take effects.

3.3.1 Substitution Method

In this method, we substitute coarse entity types of the features with the entity mentions' fine-grained types, and use the new features to train the model. Instead of substituting directly, an entity mention is first represented by its fine-grained types and the upper-class of the fine-grained type, for example, $/person/politician$ derives two types $/person$ and $/person/politician$ itself. The reason is that the extracting model can benefit from the related types like the upper-class types. And then we use the obtained entity types to substitute the old coarse entity types as new features greedily, which means that all the possible combinations of types between the entity pair are considered. For example, "$Barack\ Obama$" has the fine-grained type $/person/politician$ and his birth place "$Hawaii$" has the type $/location/island$, then there are 4 combinations between the two entities, they are ($/person$, $/location$), ($/person$, $/location/island$), ($/person/politician$, $/location$) and ($/person/politician$, $/location$).

3.3.2 Augment Method

In this method, we generate new features by substituting the coarse entity types with predicted fine-grained types, and expand the old features with new features. Different from the substitution method, we do not add the upper-class types, for that we think the coarse types in old features have the same effect. In this method, we use the fine-grained constraints as a complementary.

3.3.3 Selection Method

The selection method is similar to the augment method. The difference is that we do not expand all old features with new features. We select some of them to expand. The reason is that some of the conjunction features are of high-precision themselves, it can clearly indicate the relations with its left, middle and right parts, even without the entity types (informative ones). If we expand these features, it may cause more noisy features. So we expect to only expand the ones that lack of the indicating abilities (non-informative ones). In this paper, we employ a simple method to distinguish between the informative ones and non-informative ones by the length of the features, which means that the longer is more informative than the shorter. In our experiments, the length threshold is set as 20.

In the predicting phase (Section 3.2), we obtain a ranked type list for each entity mention. The top list types are considered in our methods. Experiments in Section 4.3 are conducted on top k $\{k \in 1, 2, 3\}$ type/types in the obtained ranked list. And they are combined with a greedy method similar to that in the substitution method explained above.

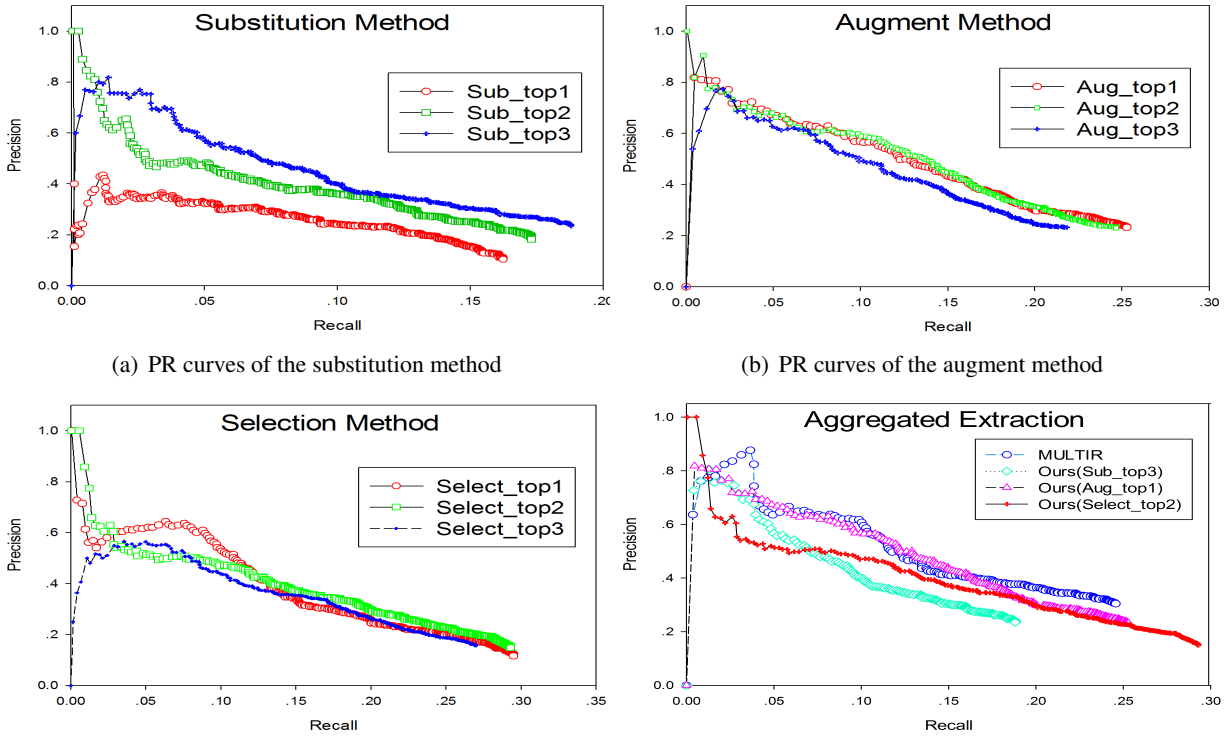
4 Experiments

4.1 Settings

We use the same data sets as (Riedel et al., 2010) and (Hoffmann et al., 2011), where NYTimes sentences in the years 2005-2006 are used as training corpus Σ_{train} for distant supervision and sentences in 2007 are used as testing corpus $\Sigma_{predict}$. The data was first tagged with an NER system (Finkel et al., 2005) and consecutive words with the same tag are extracted as entity mentions. And then, entity mentions E_{train} in training corpus are aligned to facts Δ in Freebase as training examples to train the models.

We integrate our fine-grained entity type constraint with MULTIR, an existing multi-instance multi-label extracting model in (Hoffmann et al., 2011). Following their setttings, we conduct experiments on aggregated extraction and sentential extraction to show the effect of fine-grained entity type constraints.

- **Aggregated extraction**: Aggregated extraction is corpus-level extraction. When given an entity pair, it predicts its relation types based on the whole corpus. After extraction, the precision and recall are computed by comparing the results with facts in Freebase. The evaluation underestimates the accuracy because there may be correct facts in the extracted results but not existing in Freebase, these facts are labeled as incorrect by mistake here. Because aggregated extraction is an automatic evaluation, it is used to tune parameters like held-out evaluation in (Mintz et al., 2009).



(a) PR curves of the substitution method

(b) PR curves of the augment method

(c) PR curves of the selection method

(d) Comparison with other methods

Figure 3: Precision-recall (PR) curves of the aggregated extraction.

- **Sentential extraction**: Sentential extraction predicts an entity pair only based on a specified sentence containing the pair of entities. We use manually labeled data in (Hoffmann et al., 2011) as benchmark. The data consist of 1,000 sentences and are sampled from the results their system outputs and sentences aligned with facts in Freebase. As they stated in their paper, these results provide a good approximation to the true precision but can overestimate the actual recall.

4.2 Experimental Results

In aggregated extraction, we first evaluate the three type-constraint integration methods (substitution, augment and selection) with the top k $\{k \in 1, 2, 3\}$ type/types (Section 3.3). And then, we compare the best parameter setting methods with previous work. In sentential extraction, we compare methods tuned in aggregated extraction with $MULTIR$.

4.2.1 Aggregated Extraction

Figure 3 shows the precision-recall (PR) curves of the aggregated extraction. In it, Sub_topk $\{k \in 1, 2, 3\}$ means using the substitution method (Section 3.3) with top k fine-grained entities types returned by the type classifier in Section 3.2. Correspondingly, Aug_topk is for the augment method and $Select\_topk$ is for the selection method.

Figure 3(a) shows that Sub_top3 outperforms the other two settings of k in the substitution method, it seems that more fine-grained types produce better curves. In Figure 3(b), Aug_top1 and Aug_top2 achieve similar performances. However, when adding one more type with $k = 3$, we obtain a lower curve, which contradicts the trend showed in the curves of the substitution method (Figure 3(a)). Figure 3(c) shows the PR curves of three selection methods, $Select\_top1$ has a better performance at the beginning. Then $Select\_top2$ exceeds it a bit consistently.

In Figure 3(d), we demonstrate the comparison of best tuned methods above with previous work. They are Sub_top3, Aug_top1 and $Select\_top2$. From Figure 3(d), it shows that, among the three of our methods, Aug_top1 achieves better precisions along the PR curves, and $Select\_top2$ reaches the best

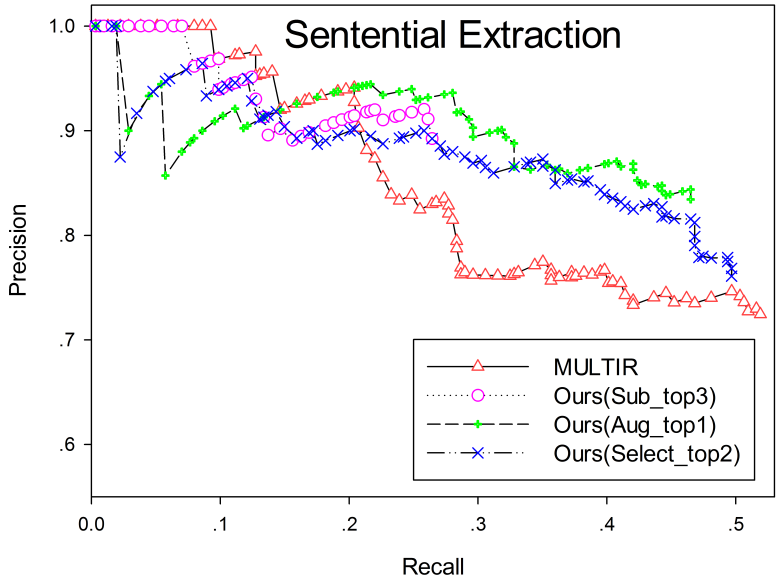


Figure 4: Comparison with MULTIR

recall at the highest recall point. Comparing to other methods, the PR curve of Aug_top1 reaches a higher recall with 29.3% at the highest recall point than *MULTIR* (24.5%). $Select\_top2$ achieves 29.3% at the highest recall point, best among all methods. And by integrating the fine-grained entity type constraints, they improve the PR curve of *MULTIR* with a more smoother curve without most of the depressions seen in *MULTIR*. As stated in (Hoffmann et al., 2011), the smoother curve indicated a more stable model.

4.2.2 Sentential Extraction

Figure 4 shows the precision-recall (PR) curves of the sentential extraction. In the evaluation, we compare the three best integration methods tuned in aggregated extraction with original *MULTIR*. Among our three method, Aug_top1 outperforms in precision and achieves a better curve in general among the three methods, however, $Select\_top2$ gains a better recall at the end. Sub_top3 has the worst recall. In general, our methods have much better precisions than *MULTIR*. Aug_top1 and $Select\_top2$ achieve better curves than *MULTIR*. Since the evaluation of sentential extraction is a good approximation of precision, it implies that the proposed methods are effective.

4.2.3 Analysis

On one hand, among the three proposed integration methods, generally, the augment method and selection method get better performance. The reason is that substitution method uses predicted fine-grained entity types to replace the old coarse features in the conjunction features completely, and the conjunction features are sensitive to entity types for different entity types indicate different conjunction features, as a result, if we can not promise a good accuracy in the type classification which is hard to achieve in classifying hundreds of fine-grained types, the performance will be badly influenced. Different from the substitution method, augment method and selection method keep the old features with coarse features, they use the features with fine-grained entity type constraints as extra information to help the extraction and achieve better results.

On the other hand, comparing to other methods, by integration the exploited fine-grained entity type constraints, our methods achieve improvements in both aggregated and sentential extraction. It proves that the fine-grained entity type constraints we exploit are effective, and our proposed integration methods succeed in integrating the constraints into the extracting model. Our augment method outperforms *MULTIR* in precision along the PR curves in sentential extraction and improve it performance with a more smoother PR curve in aggregated extraction, which indicates a more stable model. Moreover, the method gets a better recall. And our selection method consistently outperforms *MULTIR* in sentential

	k=1	k=2	k=3
Recall@k	0.596	0.740	0.806

Table 2: Evaluation of the fine-grained type classifier.

extraction. In aggregated extraction, it also achieves a smoother curve and an impressive promotion at the highest recall point. Since the evaluation of aggregated extraction only considers the facts existing in Freebase which may incorrectly label the right extracting results and underestimate the true precision, and based on its better performance of precision in sentential extraction, we consider it is a more promising method. This paper only employs very naive method to select the non-informative features by its length (Section 3.3.3), a more effective selecting method may lead further improvements.

4.3 Performance of Entity Type Classifier

We evaluate the performance of the fine-grained entity type classifier (Section 3.2). In section 3.2, we sample the training examples from a collection of Wikipeida articles mapped with the fine-grained types. To generate test entity mentions, we first remove the sampled training articles from the collection, and then sample the articles from it, where the titles of sampled articles are used as the test entity mentions (we sample 12,000 test entity mentions) and their mapped fine-grained types are used as benchmark. After that, the predicting method in Section 3.2.2 is used to expand mentions and predict the types of each test entity mention. After predicting, we obtain a ranked list of types for each test entity mention.

To evaluate, we define a notation of *Hit@k*, which equals 1 if the true type of an entity mention is hit in the top k predicted types, otherwise equals 0. And then we evaluate it by the $Recall@k$ defined bellow.

$$Recall@k = \frac{\Sigma_{i=1}^{12000} Hit@k_i}{12000} \quad (1)$$

In equation (1), i means the ith test entity mention. Table 2 shows the results for the top 3 predicted types.

5 Related Work

Distant supervision (also known as weak supervision or self supervision) is used to a broad class of methods in information extraction which aims to automatically generate labeled data by aligning with data in knowledge bases. It is introduced by Craven and Kumlien (Craven et al., 1999) who used the Yeast Protein Database to generate labeled data and trained a naive-Bayes extractor. Bellare and McCallum (Bellare and McCallum, 2007) used BibTex records as the source of distant supervision. The KYLIN system in (Wu and Weld, 2007) used article titles and infoboxes of Wikipedia to label sentences and trained a CRF extractor aiming to generate infoboxes automatically. The Open IE systems TEXTRUNNER (Yates et al., 2007) and WOE (Wu and Weld, 2010) trained their extractors with the automatic labeled data from Penn Treebank and Wikipedia infoboxes respectively.

Mintz (Mintz et al., 2009) first introduced their work that performed distant supervision for relation extraction. It used Freebase as the knowledge base to align sentences in Wikipedia as training data and trained a logistic regression classifier to extract relations between entities.Distant supervision supplied a method to generate training data automatically, however it also bring the problem of noisy labeling. After their work, a variety of methods focused to solve this problem. Riedel (Riedel et al., 2010) proposed a multi-instance model to model the false positive noise in training data with the assumption that at least one of the labeled sentences truly expressed their relation. After their work, Hoffmann (Hoffmann et al., 2011) and Surdeanu (Surdeanu et al., 2012) tried to not only model the noisy training data, but also overcame the problem of multi-label where two entities may exist more than one relation, they proposed graphic models as kinds of multi-instance multi-label learning methods and made improvements over previous work. The at-least-one assumption would fail when encountering entity pairs with only one aligned sentence. Takamatsu (Takamatsu et al., 2012) employed an alternative approach without the mentioned assumptions. Their work predicted negative patterns using a generative model and remove labeled data containing negative patterns to reducing noise in labeled data.

Besides the problem of false positive training examples caused by distant supervision. There were a bunch of researches trying to solve the problem of false negative training examples caused by incomplete knowledge bases. Zhang (Zhang et al., 2013) made heuristic rules to filter the false negative training examples. And Xu (Xu et al., 2013) tried to overcom this problem by pseudo-relevance feedback. Min (Min et al., 2013) improved MIML in (Surdeanu et al., 2012) by adding a new layer in their 3-layer graphic model to model the incomplete knowledge base. Ritter (Ritter and Etzioni, 2013) employed similar intuition with (Xu et al., 2013) that they thought rear entities missing in the database would be often mentioned in the text. They proposed a latent-variable approach to model it and showed its improvement over aggregate and sentential extraction.

6 Conclusion

In this paper, we propose a novel approach to explore the fine-grained entity type constraints for distantly supervised relation extraction. We leverage Web knowledge to automatically train a fine-grained entity type classifier and predict entity types of each entity mention. And we study a series of methods to integrate the type constraints with a relation extraction model. At last, thorough experiments are conducted. The experimental results imply our methods are effective with better precision/recall curves in sentential extraction and smoother precision/recall curves in aggregated extraction, which indicate more stable models.

In the future we hope to explore more details of integration methods that integrates fine-grained entity type constraints with relation extraction models, especially the selection integration method. We consider that a more effective method to distinguish between the informative and non-informative features will lead more improvements.

Using Collections of Human Language Intuitions to Measure Corpus Representativeness

Reinhard Rapp

Abstract

In corpus linguistics there have been numerous attempts to compile balanced corpora, resulting in text collections such as the Brown Corpus or the British National Corpus. These corpora are meant to reflect the average language use a native speaker typically encounters. But is it possible to measure in how far these efforts were successful? Assuming that humans' language intuitions are based on our brain's capability to statistically analyze perceived language and to memorize these statistics, we suggest a method for measuring corpus representativeness which compares corpus statistics to three types of human language intuitions as collected from test persons: Word familiarity, word association, and word relatedness. We compute a representativeness score for a corpus by extracting word frequency, word co-occurrence, and contextual statistics from it and by comparing these statistics to the human data. The higher the similarity, the more representative the corpus should be for the language environments of the test persons. Our findings confirm the expectation that corpus size and corpus balancing matter.

1 Introduction

Balanced corpora, i.e. corpora consisting of a carefully sampled mix of texts, have often been considered important for providing a standard of average language use. Well known examples of such corpora include the *Brown Corpus* (Francis & Kuçera, 1989) and the *British National Corpus* (Burnard & Aston, 1998). But to obtain a balance many decisions concerning the corpus design have to be made. Biber (1993) mentions, among other things, that it has to be decided for what target population a corpus is meant to be representative, that estimates concerning the quantities of various text types are required, and that decisions with regard to the number of individual text samples and their sizes have to be made.

However, there is no easy and well established way to verify the success of these measures. Current suggestions include, for example, to consider a corpus as representative if it is not dominated by sublanguage (Temnikova et al., 2014), or to more or less give up on the concept of representativeness and to concentrate on considering the suitability of a corpus for particular tasks. Saldanha (2009) comes to the conclusion that "The problem with making representativeness the defining characteristic of a corpus is that it is very difficult to evaluate."

Our goal here is to make an attempt to measure corpus representativeness in a standardized way, thereby avoiding to observe test persons' average language input as this would not be very practical. Our starting point is that a representative corpus should reflect as well as possible average language use as encountered by native speakers. We also assume that human language acquisition is essentially corpus-based (Rapp, 2011). This implies the following: The human brain analyzes particular statistical properties of perceived language and memorizes them. During language production these properties

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2117–2128, Dublin, Ireland, August 23-29 2014.

are reproduced. It has been shown that in certain test situations it is possible to isolate intuitions related to some specific statistics. These include the following three which we will utilize for measuring corpus representativeness: Word frequency, word co-occurrence, and common context of words. In terms of human language intuitions, these three statistical properties relate to word familiarities, word associations, and word relatedness.

What we suggest is to extract data relating to these three types of statistical properties from a corpus and to compare it to the respective experimental data as obtained from test persons. The higher the average agreement, the more representative the corpus should be for the language environment of the test persons.[1]

Related work has been conducted by Brisbaert & New (2009), which is mentioned in section 2.1, and in our own previous studies (Rapp, 2014a and Rapp, 2014c), of which the current work is an extension. A nice summary of how to measure corpus representativeness through psycholinguistic measures is provided in a presentation by Francom & Ussishkin (2011). Gries (2010), though in a slightly different context, emphasizes the need of external validation: "For corpus linguists, that means that our measures must be validated against corpus-external evidence because, strictly speaking, as long as we corpus linguists do not show that our dispersions and adjusted frequencies correspond to something outside of our corpora, we have failed to provide the most elementary aspect of a new measure – its validation."

The remainder of this paper is structured as follows: We first describe the experimental data used, i.e. the familiarity norms, the association norms, and the synonym data (describing word relatedness). Next we present the algorithms used to extract the corresponding statistics from the corpora. By comparing the human and the corpus-derived data, we introduce three quantitative measures of corpus representativeness, which we subsequently combine. The paper concludes with a discussion and an outlook on future work.

2 Human language intuitions

2.1 Word familiarities

Psychologists have collected word familiarity ratings from test persons. For this purpose, the subjects were asked to come up with subjective familiarities for given words. Usually a scale between 1 and 7 was used, whereby 1 means unfamiliar and 7 means very familiar. The outcome of such experiments are the so-called familiarity norms, i.e. large tables listing the subjects' familiarity ratings. In the current work we used the familiarity data for 4920 words from an online version[2] of the *MRC Psycholinguistic Database* (Coltheart, 1981).

In previous studies (e.g. Rapp, 2005) it has been shown that there is a strong correlation between the human familiarity judgments and the log occurrence frequencies of the words in corpora. For illustration, Table 1 shows the top five most familiar words in the MRC database together with their frequencies in the Brown corpus and compares them to some of the least familiar words. As can be seen, the familiar words have consistently much higher corpus frequencies. To explain this finding, Rapp (2005) hypothesized that human familiarity ratings are based on the word frequencies as observed by the test persons in the language they perceive in everyday life.

However, if we assume that the familiarity norms reflect word frequencies in perceived language, then it should be possible to use them as a standard for measuring the frequency aspect of corpus representativeness. A corpus whose word frequencies are highly correlated to the familiarity norms is more likely to be a good surrogate for everyday language, although word frequency of course reflects only one of many properties of a corpus. Nevertheless, for a corpus to be representative, it is a necessary (though not sufficient) condition that its word frequencies are similar to those in everyday language.

[1] Let us mention that there is some analogy to automatic MT evaluation, namely when computing the BLEU score: There a machine translation is compared to a human translation (which is based on human intuitions) by identifying matches between n-grams of various lengths. Then a combined score is computed from the results obtained for each n-gram length.

[2] http://websites.psychology.uwa.edu.au/school/MRCDatabase/uwa_mrc.htm

We should mention that instead of using word familiarity data it is also possible to use reaction times as obtained in the word recognition task.[3] Brisbaert & New (2009) did so and related the reaction times to the corpus frequencies of the words for the purpose of measuring corpus representativeness. In essence, although they tested on other corpora, their findings seem to be similar to what we report here based on word familiarities.

FAMILIAR WORDS			UNFAMILIAR WORDS		
WORD	FAMILIARITY	BROWN FREQUENCY	WORD	FAMILIARITY	BROWN FREQUENCY
BREAKFAST	6.6	53	LOQUACITY	1.4	1
AFTERNOON	6.5	106	MIEN	1.4	1
CLOTHES	6.5	89	YUCCA	1.4	1
BEDROOM	6.5	52	BURGHER	1.3	1
DAD	6.5	15	PAEAN	1.3	2

Table 1: Words with high and low familiarity ratings in the MRC Psycholinguistic Database together with their frequency counts in the Brown Corpus (words with a corpus frequency of zero are not included).

2.2 Word associations

The second type of human intuitions to be considered are word associations as obtained from test persons. Such data has been collected from native speakers in large scale experiments, as exemplified in the *Edinburgh Associative Thesaurus* (*EAT*; Kiss et al., 1973) which is the largest classical collection of its kind. The EAT comprises the associative responses as requested from around 100 British students for each of 8400 stimulus words and is available online.[4]

To collect the data, the subjects were given questionnaires with lists of stimulus words, and were asked to write down for each stimulus word the spontaneous association which first came to mind. This leads to collections of associations, the so-called association norms, as exemplified in Table 2.

ABOVE	CONSTELLATİON	FEMİNİNE
below (59)	stars (39)	masculine (26)
high (4)	star (33)	girl (14)
over (4)	sky (5)	woman (8)
sky (4)	andromeda (2)	female (6)
all (3)	aquarius (2)	sex (3)
up (3)	plough (2)	beauty (2)
me (2)	aircraft (1)	bird (2)
under (2)	cancer (1)	girls (2)

Table 2: Top eight associations to three stimulus words as taken from the EAT. The numbers of subjects responding with the respective word are given in brackets.

2.3 Word relatedness

The third type of human intuitions which we consider concerns word relatedness. Landauer & Dumais (1997) introduced a dataset for testing semantic relatedness, namely the synonym portion of the *Test of English as a Foreign Language* (TOEFL). The TOEFL is an often obligatory test for non-native speakers of English who intend to study at a university with English as the teaching language. The data used by Landauer & Dumais had been acquired from the *Educational Testing Service* and comprises 80 test items. As summarized in Rapp (2009), each item consists of a problem word embedded

[3] In the so-called word recognition task test persons are presented strings of characters and their task is to decide whether or not a string matches an English word. It turns out that the average reaction time is inversely related to the familiarity of a word (i.e. the less familiar a word, the longer the reaction time).

[4] http://www.eat.rl.ac.uk/

in a sentence and four alternative words, from which the test taker is asked to choose the one with the most similar meaning to the problem word. For example, given the test sentence *"Both boats and trains are used for transporting the materials*" and the four alternative words *planes*, *ships*, *canoes*, and *railroads*, the subject would be expected to choose the word *ships*, which is supposed to be the one most similar to *boats*.

However, Landauer & Dumais (1997) did not use the test sentences. Instead, only the lists of problem words together with their alternatives were used. A system capable of computing word relatedness should be able to determine for each problem word the alternative word which comes closest in meaning.

Although the TOEFL dataset has been widely used (see e.g. the overview on related work on the ACL Wiki[5]), there are two disadvantages with it: A minor one is that it is not freely available on the web. A more severe one is that it is rather small: This means that statistical variation is strong (which will be illustrated in section 5.3), and that overfitting can easily happen. That is, a system trained on this data may not well perform on other data.

For this reason we decided to come up with a new dataset which avoids these problems. It is based on the index of Fernald's (1896) synonym and antonym dictionary as provided in the Project Gutenberg version.[6] This index lists in alphabetical order English words together with their synonyms. As in the dictionary there is no indication as to the quality of a synonym, in order to avoid arbitrary selections, from this list we removed all words for which several synonyms were listed in the index. In a semi-automatic way, we also removed a number of other items, e.g. those containing multiword units or numbers. As a result, we obtained a list of 4050 words together with their synonyms.

To obtain a dataset analogous to the TOEFL synonym set, we required three alternative words for each item. We could have used random words e.g. taken from the vocabulary of the British National Corpus (BNC). However, as the BNC is from a much later time period, this might have introduced a systematic bias. So we thought we should better use the words from the synonym dictionary itself. Note that the synonyms corresponding to the 4050 words represent a much smaller vocabulary as many of the synonyms are synonyms for several words. For this reason, we used the headwords themselves and applied the following procedure to generate the alternative words from them:

1) We sorted our list of items according to the synonyms in alphabetical order.
2) As the first column of alternative words, we used the given words but shifted them by 1000 positions, i.e. positions 1 to 3050 were matched with 1001 to 4050, and positions 3051 to 4050 where matched with 1 to 1000.
3) Analogous for the second column of alternative words, but here we shifted by 2000 positions.
4) Same for the third column of alternative words, but here we shifted by 3000 positions.

Word	Synonym	Alternative Words		
abandoned	addicted	rescind	bliss	receipts
abdicate	abandon	conflict	indubitable	archaic
aberration	insanity	rational	meliorate	assured
abetter	accessory	carnal	amicable	urbane
abettor	accessory	imbruted	brotherly	policy
abhorrence	abomination	kindliness	supposition	resignation
abiding	permanent	remain	life	stanch
ability	power	chimerical	frontier	diet
abject	pitiful	despotic	blanch	fray
abjure	abandon	contest	overt	disused

Table 3: Ten entries from the synonym dataset derived from Fernald (1896).

[5] http://aclweb.org/aclwiki/index.php?title=TOEFL_Synonym_Questions_(State_of_the_art)
[6] http://www.gutenberg.org/files/28900/28900-h/28900-h.htm

To give an impression of the dataset, its alphabetically first ten entries are shown in Table 3. Let us now quickly discuss some properties of the new dataset: The pros are that it is about 50 times larger than the TOEFL dataset and that it can be freely distributed. The cons are that it is based on somewhat outdated language (the dictionary was published in 1896) and that the alternative words were not carefully selected but generated in a somewhat arbitrary fashion. Also, it is not known how test persons would perform on this dataset, whereas for the TOEFL dataset human performance is known at least for some test takers, i.e. non-native speakers of English. A commonality between both datasets is that the synonyms were produced by experts, i.e. reflect the experts' language intuitions.

3 Corpora

As in previous work (Rapp, 2014a) our corpus representativeness measure is to be applied to a number of well known corpora. These are:

1) Brown Corpus (balanced corpus of 1 million words; Francis & Kuçera, 1989)
2) British National Corpus (BNC; balanced corpus of 100 million words; Burnard & Aston, 1998)
3) English Wikipedia (300 million words of encyclopaedic texts)[7]
4) ukWaC (British English web corpus of 2 billion words)[8]
5) English Gigaword Corpus 4th edition (4 billion words of newswire text)[9]

Both the MRC familiarity norms and the EAT do not distinguish between uppercase and lowercase characters. For this reason, we also did not make such a distinction and, in a pre-processing step, converted all corpora as well as the human data to lowercase only.

For the results presented later we had to measure the size of our corpora and also of partial corpora. We do this by counting the number of running words. Hereby, to avoid language specific sophistications, we count as a word any string which is delimited by either white space (blanks, tabulator, new line) or by transitions between alpha and non-alpha characters.[10]

4 Procedure

4.1 Corpus statistics concerning word familiarities (statistics of order zero)

In the case of word familiarities the statistics extracted from the corpora are the log frequencies of the words. The MRC database contains familiarities for 4920 words. As just two of them are multiword units, we considered this an inconsistency and removed them, so that 4918 words remained.

Word	Word frequency in the BNC	Word familiarity in the MRC database
a	2247100	632
abandon	1316	510
abandonment	500	359
abasement	20	226
abatement	137	294
abbess	57	187
abdication	124	284
abdomen	303	426
abduction	230	413
aberration	149	208

Table 4: BNC frequencies and MRC familiarities for the (alphabetically) first ten words covered in the familiarity norms of the MRC database.

[7] We use the English part of the Wikipedia XML Corpus (Denoyer & Gallinary, 2006). Although this is considerably smaller than current versions, it has the advantage that it is an offline copy so that our results can be replicated.
[8] http://wacky.sslmit.unibo.it/doku.php?id=corpora
[9] http://catalog.ldc.upenn.edu/LDC2009T13
[10] Alternatively, it would also be possible to simply count the number of characters for measuring corpus size (though this seems less customary). But word segmentation is required later on anyway (for computing the representativenesss scores).

The two types of data, namely the word familiarities from the MRC database and the word frequencies as extracted from one of the corpora, were merged as exemplified in Table 4 for the case of the BNC. Note that although the test subjects' familiarity judgements were originally on a scale between 1 (not familiar) and 7 (highly familiar), to avoid decimal numbers when averaging results, all ratings were multiplied by 100. Computing corpus representativeness now simply involves taking the logarithm of the frequencies in column 2, and then computing Pearson's correlation coefficient between the resulting vector and column 3. However, as especially for small corpora many of the word frequencies can be zero, and as the logarithm of zero is not defined, we applied the usual heuristic of adding one to each frequency count before taking the logarithm.

4.2 Corpus statistics concerning word associations (1st order statistics)

As described in Rapp (2014c), we assume that there is a relationship between word associations as collected from human subjects and word co-occurrences as observed in a corpus, and our hypothesis is that the strength of this relationship can be used as a measure of corpus representativeness. A corpus leading to simulated associations akin to the ones collected from humans is likely to be a good surrogate for everyday language, although – similarly to what we said about word frequencies – word co-occurrence counts constitute only one of many properties of a corpus.

For extracting word associations from corpora, in the literature many algorithms were described (e.g. Wettler & Rapp, 1989; Church & Hanks, 1990; Wettler et al., 2005). In analogy, we used the following procedure: For all words with a BNC corpus frequency of 50 or higher we computed the co-occurrence vectors. That is, each vector contains the number of co-occurrences of the stimulus word with all other co-occurring words. It counts as a co-occurrence if two words appear together within a distance of at most ten words, i.e. a text window of ±10 words around the stimulus word is considered. Hereby the exact distance within the window is not taken into account.

In a further step an association measure was applied to the co-occurrence vectors, namely Ted Dunning's (1993) log-likelihood ratio. The resulting vectors we call association vectors. Given these vectors, the strongest association to a given stimulus word can be determined by simply looking for the highest value within the respective association vector. The corresponding word is considered to be the associative response predicted by the system. For the same stimulus words used in Table 2, Table 5 shows some sample associations as computed using the British National Corpus.

ABOVE	CONSTELLATİON	FEMİNİNE
below (59)	stars (39)	masculine (26)
level	star (33)	women (2)
average (1)	southern	gender
high (4)	triangle	woman (8)
feet	bright	female (6)
water	planet (1)	men
head	rather	male (1)
see	south	more
ground	find	hair
left	map	soft

Table 5: Top ten corpus-derived associations for three stimulus words. The numbers of subjects from the EAT responding with the respective word (if larger than zero) are given in brackets.

Concerning evaluation, in principle the idea is to find matches between the human and the corpus-based associations. One possibility is to simply count the number of cases where the primary associative response matches the strongest corpus-based association. However, when it comes to very small corpus sizes of e.g. just 1000 words (see Section 5), the problem of data sparseness becomes so severe that a more tolerant evaluation method leads to more robust results less susceptible to statistical variation. This is why for measuring accuracy we count the number of cases where the respective primary associative response is listed within the top ten corpus-based associations, rather than insisting on a

match with the strongest association. This simple modification leads to improvements in reliability when measuring very low accuracies.

4.3 Corpus statistics concerning word relatedness (2nd order statistics)

Our algorithm for computing word relatedness consists of the following three steps:

1) Counting word co-occurrences.
2) Applying an association measure to the raw co-occurrence counts.
3) Computing vector similarities.

Steps 1 and 2 are in principle analogous to the previous subsection. Only, as mentioned in Rapp (2009), for computing vector similarities it turns out that it is better to consider a smaller window size (such as ±1 or ±2 around the given word). Also, we used a simpler association measure, namely $log(n_{ij}+1)$, whereby n_{ij} is the number of co-occurrences between words i and j, as it slightly outperformed the log-likelihood ratio in this particular setting.

For step 3 (computing vector similarities) we use the standard cosine measure. Table 6 shows some results as obtained using the British National Corpus. For a quantitative evaluation we utilized the TOEFL synonym data as follows: We compared our system's results to the answers as provided in the TOEFL dataset. Remember that in the TOEFL synonym test the subjects had to choose the word most similar to a given stimulus word from a list of four alternatives. Accordingly, in the simulation, we assumed that the system made the right decision if the correct answer was ranked best among the four alternatives. In a further run, we applied exactly the same procedure to the test set derived from Fernald's synonym dictionary.

burden	responsibility (0.62), expense (0.61), expenditure (0.59), problem (0.59), cost (0.59)
arrogant	rude (0.62), naive (0.61), stupid (0.61), impatient (0.61), haughty (0.61)
desperation	panic (0.60), despair (0.60), exasperation (0.59), stillness (0.58), impatience (0.58)
memorandum	appendix (0.59), document (0.59), submission (0.57), constitution (0.57), disclosure (0.57)
trivial	unimportant (0.63), ridiculous (0.60), trifling (0.60), straightforward (0.60), bizarre (0.60)

Table 6: Semantic similarities extracted from the BNC for five English words using only vocabulary from the synonym test set based on Fernald (1896).

5 Results

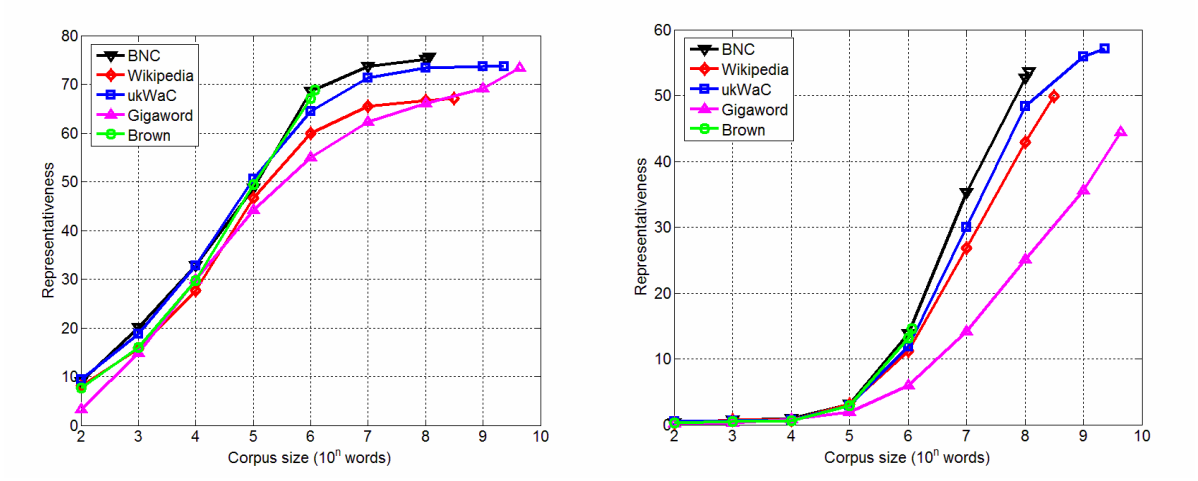
5.1 Results based on word familiarities

These results are given in Figure 1a. There we find in graphical form for each of the five corpora the computed Pearson's correlation coefficients between the words' familiarities and their log corpus frequencies. For easier comparison with the other results (which are percentages) we multiply these correlations by 100 and take the product as the familiarity-based *representativeness of a corpus*. The range of values can thus be between 0 and 100, whereby 0 denotes a complete lack of representativeness, and 100 denotes perfect representativeness. The representativeness scores are also computed for partial corpora, whereby all parts have in common that they start with the beginning of the respective corpus.

We can see in Fig. 1a that, as expected, the representativeness is almost zero if only the first 100 words of a corpus are taken into account, and gradually increases to at least 67 for the full corpora. The horizontal axis has a logarithmic scale, but still the curves flatten with increasing corpus size, especially above 1 million words.

5.2 Results based on word associations

These results are given in Fig. 1b. For each of the five corpora (and their parts) the percentages of primary associative responses are given which ranked among the top ten in the corpus-based associations. These percentages we take as the association-based representativeness of the respective corpus. The range of values is between 0 and 100.



(a) Familiarity

(b) Association

(c) Relatedness

(d) Average

Fig. 1: Results for the three approaches and their average.

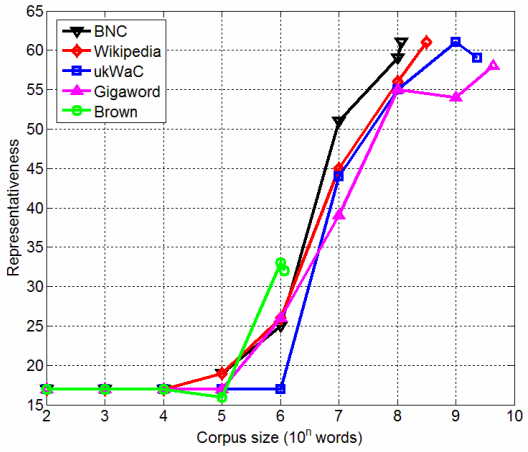


Fig. 2: Results for the TOEFL synonym data.

5.3 Results based on word relatedness

The respective results for the TOEFL synonym data (based on a window size of ±1 words) are given in Fig. 2. There we find for each of the five corpora the percentage of TOEFL questions which were answered correctly. These percentages we take as the relatedness-based representativeness of the respective corpus. Note that the level for very small corpora is higher here as in the TOEFL data with a limited number of candidate words there is a better chance to randomly hit the correct word. As can be seen, the curves are somewhat erratic which is an indication that the test set of 80 items is too small.

For this reason, we did not further use these results but replaced them with those from the synonym test set derived from Fernald (1896). The respective results are shown in Figure 1c.[11] As can be seen, the much higher number of test items leads to smoother curves, but nevertheless the tendencies from the TOEFL data are roughly confirmed.

5.4 Results based on the overall average

The average of the curves in Fig. 1a to 1c is shown in Fig. 1d. The motivation is that this way all three types of statistics are taken into account in a straightforward way. The underlying reasoning is analogous to the BLEU score (Papineni et al., 2002) used in machine translation evaluation: There n-gram matches between a machine translation and a reference translation are counted separately for n-grams of various lengths, and then the individual scores are combined.

6 Discussion

If we compare the curves in Figures 1a, 1b, and 1c it is apparent that the shapes are rather different. This can be explained by the order of the respective statistics: The familiarity-based approach uses statistics of order zero (word frequencies), the association-based approach first order statistics (word co-occurrences), and the relatedness-based approach second order statistics (common context). Although for all three methods a flattening of the curves can be expected for large corpora for the reason that there is an upper limit of corpus representativeness (100) leading to saturation, apparently for the first and second order statistics larger corpora would be required to make this happen.

Concerning very small partial corpora, for the familiarity based approach the curves quickly rise, whereas for the association-based and the relatedness-based approaches the increases in accuracy are small at the beginning. This is also to be expected because in a partial corpus of e.g. 1000 words there is still a chance to find a particular word, but there is almost no chance to find a particular co-occurrence or a common context.

So these discrepancies between the approaches are not a major surprise. Of more interest is a comparison of the results between the different corpora, i.e. their relative performance for each of the methods.

Following Rapp (2014a), concerning the representativeness of our five corpora and their parts, we had tried to come up with some hypotheses before we started to compute the results. These were our predictions:

1) Representativeness should increase with corpus size.
2) The Brown corpus and the BNC should be more representative than unbalanced corpora of the same size.
3) The Brown corpus (1 million words) should be more representative than the first million words of the British National Corpus as the latter is balanced only over its full size (100 million words), but not over its first million words.
4) For same sizes, we would expect ukWaC to be more representative than Wikipedia as we think that corpus heterogeneity is a plus for representativeness. ukWaC is obviously more heterogeneous as, for example, it is multi genre multi topic whereas Wikipedia is single genre multi topic.
5) The Gigaword Corpus should be the least representative for identical sizes. Although, like Wikipedia, it is also single genre multi topic, the distribution of topics is not as wide because in newsticker texts there are strong foci e.g. on politics and sports.

[11] As the Synonym-Dataset involves many very rare words, to reduce data sparseness we used a larger window size of ±2 words to compute these results.

If we compare these hypotheses to the actual results shown in Figures 1a, 1b, and 1c, the findings are as follows:

Hypothesis 1, namely that the representativeness of all corpora steadily increases with corpus size, is clearly confirmed by all three approaches.

Hypothesis 2, saying that the balanced corpora, namely the Brown corpus and the BNC, should be more representative for their sizes than non-balanced corpora, is also confirmed by all approaches. At 1 million words, these two are the top performers. At 100 million words, the BNC performs best. Note, however, that the smaller the corpus sizes, the less predictable the results as the sampling errors increase.

Hypothesis 3 (Brown better than BNC for 1 million words) could sometimes be confirmed but not consistently. Instead, for all approaches the results of these two corpora are fairly close. This indicates that the BNC also seems to have a fairly good balance over the first million words. Concerning the association-based approach, the BNC also has the advantage that its British English should reflect the EAT associations (collected in Edinburgh) better than the American English of the Brown corpus.

Hypothesis 4, namely that ukWaC is better than Wikipedia, is confirmed for the familiarity- and the association-based approach, but not for the relatedness-based approach. Our explanation for the discrepancy is that the relatedness-data contains a larger proportion of outdated and rare words, and that for rare words the coverage of a corpus becomes more important. In this respect, Wikipedia with its wide coverage of topics is likely to have an advantage over the ukWaC corpus.

Hypothesis 5, saying that the Gigaword corpus should be the least representative, is confirmed for almost all corpus sizes.

Overall, several of our hypotheses were consistently confirmed by all approaches. This finding provides some evidence that the computed scores are actually related to what might sensibly be considered as the representativeness of a corpus.

Concerning the average representativeness score (Fig. 1d), we can conclude that overall it seems to make sense to balance a corpus, and that corpus heterogeneity is a plus.

7 Summary and outlook

In this work we defined the term *corpus representativeness* as the ability of a corpus to represent the average language use a native speaker encounters in everyday life. As we cannot easily observe test persons over years, our suggestion was to utilize human intuitions on word familiarities, on word associations, and on word relatedness.

Previous work has provided evidence that human word familiarities are based on word frequencies in perceived language (Rapp, 2005), that human word associations are based on the co-occurrences of words (Wettler et al., 2005), and that human relatedness judgments are based on common context (cf. Harris' (1954) distributional hypothesis). Although all of this may still be controversial, in the current work we took these findings for granted but turned round the perspective. We said that a corpus is representative for the language environment of a group of persons if the word familiarities, the word associations, and the predictions of word relatedness derived from it resemble these persons' intuitions.

For full and partial versions of five well known English corpora we computed the word familiarities, word associations, and word relatedness scores for test sets of several thousand words. We then, for each corpus, compared the extracted information to the human data, and computed similarity scores which we took as measures of corpus representativeness. We also computed a combined score by averaging the results from all three measures.

A shortcoming of our approach is the following: Our measures are limited in so far as they only consider three particular aspects of corpus representativeness, namely word familiarity word association, and word relatedness. They do not explicitly consider higher level features e.g. concerning syntax, semantics, pragmatics, or style.[12] We nevertheless hope that what we described can serve as a starting point for further discussion.

Concerning future work, a possible strait of research would be to modify the relatedness-based approach in a way that the WordSimilarity-353 Test Collection[13] could be used. This test set provides

[12] In section 5.4, when combining our three approaches, we already mentioned an analogy to the BLEU score. A related commonality is that the BLEU score also has these shortcomings.

[13] http://www.cs.technion.ac.il/~gabr/resources/data/wordsim353/

direct similarity estimates between words, so a correlation to corpus-derived estimates could be computed in analogy to what we did for the familiarity-based approach.

We would also like to extend the approach to other corpus statistics which seem relevant for human language processing. For example, we might look at associations when given several stimulus words (see Rapp, 2014b), or we could try to predict a word from its WordNet synset. The latter would have the advantage that WordNets are available for many languages, so the corpus representativeness scores could be measured for a number of languages where other human data is scarce.

Related to this would be the use of the Princeton evocation data[14] which provides human similarity estimates between WordNet synsets. The aim would be to replicate these similarities using multiword associations.

Abstract

We propose an algorithm for coreference resolution based on analogy with shift-reduce parsing. By reconceptualising the task in this way, we unite ranking- and cluster-based approaches to coreference resolution, which have until now been largely orthogonal. Additionally, our framework naturally lends itself to rich discourse modelling, which we use to define a series of psycholinguistically motivated features. We achieve CoNLL scores of 63.33 and 62.91 on the CoNLL-2012 DEV and TEST splits of the OntoNotes 5 corpus, beating the publicly available state of the art systems. These results are also competitive with the best reported research systems despite our system having low memory requirements and a simpler model.

1 Introduction

Coreference resolution is the task of partitioning mentions in a document, usually noun phrases, into clusters which correspond to their real world referents. It is typically approached as a classification task between mentions; given a set of mentions, systems predict the likelihood of their being coreferential with one another and translate these scores into a clustering in a decoding phase.

The task has received considerable research attention due to its importance for downstream inference in tasks such as named entity linking and relation extraction. While simple, local models of coreference have established a reasonable baseline, encoding global consistency requirements remains a challenge since their complete representation is computationally intractable. Two promising but orthogonal directions addressing the need for global consistency measures are ranking-based decoding (Ng and Cardie, 2002; Denis et al., 2007; Fernandes et al., 2012; Durrett and Klein, 2013; Chang et al., 2013) and cluster-based modelling (Rahman and Ng, 2009; Raghunathan et al., 2010; Lee et al., 2011; Klenner and Tuggener, 2011). However, among current systems, decoding strategies are increasingly complex and cluster-based models do not fully leverage psycholinguistic cues such as reading order.

The primary contribution of our work is a reconceptualisation of the coreference task by analogy with the shift-reduce parsing algorithm. This reconceptualisation allows us to capitilise on both ranking- and cluster-based approaches and our system, LIMERIC, outperforms systems using either approach in isolation. We go beyond the shift-reduce algorithm by interpreting our stack of partially formed clusters as a reader's mental status while reading. This allows us to introduce a series of rich discourse features which capture antecedent competition and cognitive accessiblity via a cluster's position in the stack.

Our system is simple and efficient, using maximum-margin averaged perceptron classification and optional beam-search decoding during inference. Despite requiring only a limited amount of memory, our system achieves the competitive CoNLL scores of 63.33 and 62.91 on the CoNLL-2012 DEV and TEST splits of the OntoNotes 5 corpus (Pradhan et al., 2012). We argue that this is due to its more faithful representation of cognitive processing and that extending psycholinguistic insights in modelling is a very promising research direction for even further improvement.

2 Related work

Early computational approaches to coreference resolution were built around what is now referred to as mention-pair models. Such models use two stage resolution; the first stage calculates pairwise scores reflecting the likelihood that a mention and its candidate antecedents are coreferential while the second phase decodes these scores into coreference clusters. The simplest way to decode is locationally greedy (Soon et al., 2001), in that the closest candidate with a compatibility score over some threshold is deemed a mention's antecedent. Anaphoricity determination (determining whether a mention constitutes a good first mention of an entity) is mediated by the threshold since a mention without a sufficiently good candidate antecedent starts a new cluster. While these local models achieve a reasonable baseline (Soon et al. (2001) achieves MUC F-scores of 62.6 and 60.4 on MUC 6 and 7), they can make global consistency errors which limit their usefulness downstream. For instance, in the following excerpt from `bn/voa/00/voa_0068` of OntoNotes 5, it is possible that a system uses local evidence such as synonymy to misclassify the ship as the antecedent of a huge Norwegian transport vessel and similarly The battered US Navy destroyer Cole as the antecendent of the ship; unfortunately, these local decisions imply a clustering in which Cole is referred to as a Norwegian transport vessel.

> **The battered US Navy destroyer Cole** has begun **its** journey home from Yemen ... Flanked by other US warships and guarded by aircraft, **the ship** was towed out of Aden Harbor to rendezvous with **a huge Norwegian transport vessel**

While exhaustive comparison would remedy the situation, complete inference has exponential time complexity and so is unrealistic for practical systems. Furthermore, since humans are able to resolve reference on the fly, it seems reasonable that psycholinguistic heuristics would similarly help the task while remaining efficient.

Active research aims to approximately encode global consistency measures, via ranking-based decoding and cluster-level modelling. Ranking-based decoding strategies (Ng and Cardie, 2002; Denis et al., 2007) improve locationally greedy decoding by defining a search window and deeming the best, rather than the closest, candidate within the window to be a mention's antecedent. The publicly available Reconcile system[1] (Stoyanov et al., 2010a; Stoyanov et al., 2010b) uses a simple encoding of this strategy while more recent approaches (Fernandes et al., 2012; Durrett and Klein, 2013; Chang et al., 2013) incorporate the concept within highly sophisticated models. While these systems achieve state of the art performance, they do so at the expense of model complexity.

In cluster-level modelling approaches (Rahman and Ng, 2009; Raghunathan et al., 2010; Lee et al., 2011; Klenner and Tuggener, 2011), instead of basing scoring on the compatibility of pairs of mentions, mentions are compared against incrementally grown partial clusters. This, for instance, may allow a huge Norwegian transport vessel to be compared against a cluster containing both the ship and The battered US Navy destroyer Cole, allowing nationality discord to weigh against the clustering. In this way, global consistency information becomes more important as a mention needs to be compatible with multiple mentions in a cluster, rather than its closest or best antecedent. However, there have been problems with these implementations including their being heavily focussed on surface level features and failing to fully utilise psycholinguistic cues such as reading order. A notable exception is Recasens et al. (2013), which provides a computational model of low salience discourse entities and demonstrates its efficacy in filtering system mentions in the Stanford sieve system (Raghunathan et al., 2010; Lee et al., 2011).

Consistent with Klenner and Tuggener (2011) and others, we argue that psycholinguistic insight is the key to unite cluster- and ranking-based models. This is because theories such as Centering Theory (Grosz et al., 1995) and Accessibility Theory (Ariel, 2001) describe how the human mind keeps track of discourse referents as entities rather than distinct mentions, and resolves anaphora via ranked cognitive accessibility. By reformulating the coreference resolution by analogy with the shift-reduce parsing algorithm, we gain access to the stack of active discourse entities which we rank in order of salience. In this way, the stack in our model becomes an approximation of a reader's mental state when reading a document, allowing us to directly model cognitive models of discourse.

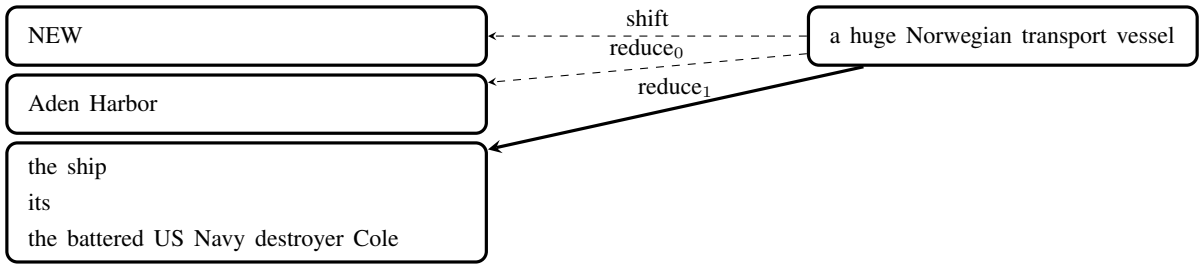

Figure 1: shift-reduce comparisons, `bn/voa/00/voa_0068`

3 Psycholinguistically informed coreference resolution

The shift-reduce algorithm (Aho and Johnson, 1974) is widely used in parsing due to its efficiency, the simplicity of its data structures, and its limited memory usage. For syntactic parsing, a queue is initialised with a series of tokens which is processed in a single reading order pass. Tokens either *shift* onto a stack as a leaf fragment or *reduce* with an existing fragment to former a larger phrasal unit. For the reduce operation, the classifier needs to determine into which fragment the token should merge.

By drawing an analogy between tokens and phrases in syntactic parsing with mentions and clusters in coreference resolution, we derive an algorithm for the latter. In particular, we can initialise a queue of mentions and maintain a stack of clusters which incrementally grow as we read a document. Our classifier is similarly tasked with determining whether a mention should shift onto the stack as the first mention of a new discourse entity or should reduce with an already active one (see Figure 1 for the example of resolving the enqueued mention a huge Norwegian transport vessel). For reduce operations, we additionally need to determine into which entity cluster the mentions should merge. In this way, the shift-reduce algorithm expresses a joint decision of anaphoricity and coreferentiality.

We draw from shift-reduce parsing its simplicity and small memory requirement since we believe these give rise to a more faithful representation of cognitive processing. There are, however, some technical points to consider. Instead of the reduce operation applying to a small window at the top of the stack (top two in the case of binarised grammars), we want to search potentially the whole stack, as described the general formulation of the algorithm. While a full search gives our process worst case $O(n^2)$ time complexity, this is only occurs in the case of an incoherent document which mentions each of its discourse entities exactly once. In the average case, exhaustive stack search still represents a time saving compared to full mention-pair models which compare each mention against all potential antecedent *mentions*. Also, we don't aim to form a single full tree covering all the mentions but rather a collection of clusters. While it is possible to define a document graph of coreference relations (as demonstrated in Fernandes et al. (2012)), it is not necessary to do so.

The algorithms we employ for training and inference our system are represented in Figure 2.

Initialisation

We initialise the stack to be empty and the queue to be the complete set of mentions extracted from the parse structure and named entities in a document. Following the literature, our mention extraction module is designed to be high recall since missed mentions are guaranteed to hurt performance, while it is possible to learn that spurious mentions should not be reported (e.g. Durrett and Klein (2013)). Thus, we train and test on predicted mentions despite the availability of gold mentions for training (to keep system input as similar as possible between training and testing environments) and at test time (since this is not realistic). In this way, we learn a model that is robust to noise in mention extraction.

Learning

On each training pass through a document, we read the enqueued mentions exactly once, in reading order without look ahead. As each mention comes to head the queue, we generate a training instance in which the classifier decides whether it is more likely that the mention *shift* onto the stack as the first mention of a new discourse entity or *reduce* with the cluster of an already active one. In particular, the reduce score

```
initialise queue;
initialise stack;
while queue do
    active = queue.pop();
    prediction = classify(active, stack);
    gold = correct_classification(active, stack);
    if prediction != gold then
        update(prediction, gold);
    end
    cluster = apply_pred(active, stack, gold);
    promote(cluster, stack);
end
```

```
initialise queue;
initialise stacks;
while queue do
    active = queue.pop();
    forall stacks do
        prediction = classify(active, stack);
        cluster = apply_pred(active, stack, prediction);
        promote(cluster, stack);
    end
    prune_stacks(stacks);
end
```

Figure 2: learning (left) and inference (right) algorithms

is the highest of all potential merges. Features are generated on the fly to reduce memory requirements, and because the state of the system is determined by each move made. The margin of classification is widened by augmenting by one the scores corresponding to non-gold decisions.

We then determine whether any difference exists between the classifier's decision and the gold answer key by looking for one of five errors, three taken from Durrett and Klein (2013) (falsely anaphoric, falsely new, wrong link made) and two inspired by the categories used in Kummerfeld and Klein (2013) (extra mention and extra entity). If an error is detected, we perform perceptron updates of the feature weights, increasing those corresponding to the gold decision and decreasing those corresponding to the incorrect prediction. We find that varying the feature value update according to the error made has a performance benefit, particularly when 'falsely new' is given a faster learning rate. This may due to sparsity: across a corpus, the number of first mentions of an entity is smaller than both that of subsequent mentions, and singleton mentions. We note that it should be possible to learn a model using uniform updates by increasing the number of training iterations, though this increases the chance of overfitting. Also, tuning these parameters may affect different balances in error types for different applications.

As noted in Rahman and Ng (2009), since the mention-cluster indicator functions do not apply to the case where a new entity is formed (shift operations), reduce comparisons activate many more features than shift ones do. During development, we noticed that this marked difference in feature set size was negatively impacting performance as reduce operations were unfairly favoured. To grow the shift feature weights faster, we introduced a scaling parameter on the update of these feature weights; we found the ratio of the feature space sizes to work well.

As the final stage, the system applies the decided move. There are two valid 'decided' moves, namely the correct decision, read from the gold standard, or the (potentially incorrect) predicted decision. In this work, we train by following the path of correct decisions, though we plan future research implementing the latter. We hope this will improve the robustness of our system given analogous findings in shift-reduce parsing (Zhang and Nivre, 2012). Novel to our approach, the cluster resulting from application of the decided move is promoted to the top of the stack since recency increases cognitive accessibility. This is a crucial implementation detail given the cognitive interpretation we give to the stack of clusters.

Inference

A benefit of our formulation of the coreference task is that inference is little different to training, without feature weight tuning. In both, documents are processed via a queue of mentions, though a single stack is replaced by possibly multiple in a beam regularly pruned to a fixed width. This has possible cognitive underpinnings since humans need to be able to back track if an interpretation proves incorrect. Analogously, it allows our system to reduce the impact of potentially harmful local decisions. Interestingly, we find in Section 6 that this has little appreciable impact on performance, though this is consistent with Zhang and Nivre (2012), which finds that beam search in inference can hurt the performance of a shift-reduce syntactic parser trained on gold decisions.

4 Rich discourse features

We base our feature space on the pool of features described in the literature (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008; Stoyanov et al., 2010a; Stoyanov et al., 2010b; Raghunathan et al., 2010; Lee et al., 2011). We introduce *Discourse likelihood* as a novel extension of work in Recasens et al. (2013), designed to mediate system conservativeness in the decision between whether a cluster remains a singleton or grows into a larger cluster. Conjunct discord is introduced as a finer grained extension of traditional number agreement features.

If existing features apply to single mentions or single clusters, they apply in this same way in our system. To map the mention-pair features in the literature into functions which take a mention-cluster pair, we use a range of strategies including the existence of a compatible mention for the active among the cluster pool (Raghunathan et al., 2010), binned proportion of clustered mentions compatible with the active mention (Rahman and Ng, 2009), or the maximum compatibility score between the clustered mentions and the active one (based on Ponzetto and Strube (2006)).
The examples here correspond to the reduce$_1$ move in Figure 1.

Lexical data driven lexicalised features from Durrett and Klein (2013); for the active mention the ship, we would generate the features like **`head_word:ship first_pos:DT last_shape:LOWER`**

String match existence and proportion of clustered mentions with various string matches with the active mention, e.g. **`head_match:none acronym:none`**

Attribute agreement agreement in animacy, gender, number, and NER values pooled across the cluster, and active, e.g.**`number_agree:true`**

Attribute discord where mentions are conjunctions, disagreement between the number of sibling NP children; disagreement between the citation form of any pronouns in cluster and active

Syntax existence of i-within-i (restriction on anaphora due to government and binding requirements on a sentence's parse tree) or subject-object relation between active and any clustered mention e.g.**`iwithini:none`**

Semantics binned value of maximum Lin et al. (2012) similarity score between active and clustered mention heads, e.g. **`lin:high`** since ship and vessel are highly related; disagreement between coarse grained semantic classes of nominals determined from WordNet (Fellbaum, 1998)

Length length of mention in number of tokens **`mlength:3`**; length of cluster in number of mentions

Distance distance between active and closest clustered mention, measured in number of sentences and number of intervening mentions

Discourse patterns whether any subsequent mention is an indefinite nominal

Discourse likelihood an integer value representing the likelihood that cluster has proposed length (singleton or not) given the internal morphosyntactics of the clustered mentions; likelihood of stack given likelihood of contained clusters

4.1 Stack features

Since position in stack in our model represents relative cognitive accessibility, we introduce Depth features as the cognitive analogues of Distance features, designed to more faithfully represent accessibility.

Stack depth depth from top of the stack, binned as top cluster in stack, within five clusters from the top, within ten clusters from the top, outside this[2]; raw depth, depth normalised in turn by ignoring singletons and ignoring clusters not containing a proper name mention **`raw_depth:high`**, **`ne_depth:top`** were all used, with the last two designed to capture the impact of salience

[2]these values were empirically optimised, though we note that they reflect known constraints on human short-term memory

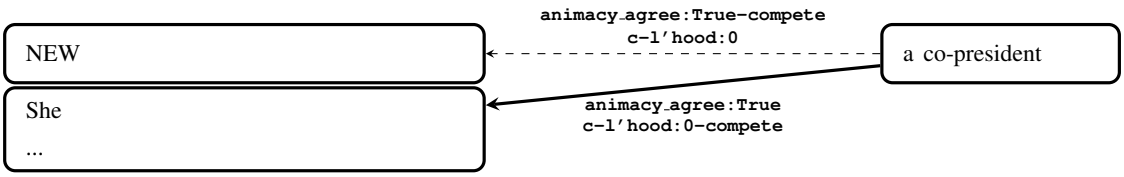

Figure 3: stack features, bn/mnb/00/mnb_0023

Stack competition In an aim to model the competition between clusters in the stack, we introduce stack competition features. In addition to evaluating our mention-cluster features between the active mention and its proposed antecedent, we also evaluate them between it and the other clusters comprising the stack. If a stacked cluster evaluates positively with any of these, we generate a labelled version of the indicated feature. By having these features compete with those of the proposed antecedent, we hope to better learn a more global ranking of candidates than straightforward search window strategies do. Figure 3 shows how stack features can be used to distinguish between the attractiveness of merging an indefinite nominal into a cluster (attractive due to matching linguistic attributes) as compared to starting a new discourse entity (attractive due to discourse likelihood of indefinite nominal in a new cluster).

4.2 Discourse transition prefixing

After Durrett and Klein (2013), we use discourse transition strings formed from the types of the mention and its closest candidate antecedent as feature prefixes, e.g. **m:nominal+a:nominal**. While this inflates the potential size of the feature space[3], the features generated are more meaningful since we would expect many indicator functions to behave differently for pronouns than for subsequent proper names, for example, reintroducing entities. Also, since we use perceptron learning, feature weights are only tuned if the feature is useful in making a decision during training.

5 Results

We evaluate LIMERIC on the OntoNotes 5 corpus (Pradhan et al., 2012) with the included parse and NER annotations. Our experimental setup matches the specifications of the CoNLL-2012 shared task: we use the standard corpus splits, official scorer, and report performance on the CoNLL metric which averages the MUC F-score (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998) and CEAFE (Luo, 2005).

We compare our performance against that of three state of the art systems which reflect the diversity of current approaches. Stanford[4] (Lee et al., 2011) has rule-based decoding with cluster-based modelling. Berkeley[5] (Durrett and Klein, 2013) uses mention-pair features in a factor graph model. Since reported performance for this system is on CoNLL-2011, we compare against the publicly available system using the SURFACE model, which doesn't use features induced from English Gigaword (Graff et al., 2007). Chang et al. (2013)'s L^3M systems comprise both mention-pair and cluster-based variants; we focus on the former here since these perform better on OntoNotes 5. L^3M represents a maximum-margin approach to ranking models, where CL^3M adds some cluster modelling via a constraint term.

5.1 Performance

Table 1 presents our performance on DEV and TEST. Our core LIMERIC system includes all features described in Section 4 including our novel discourse features Discourse patterns, Discourse likelihood, and Stack depth. In development, we experiment with system configurations by deactivating semantic features (-*s*) and activating stack competition features (+*c*) in turn. Despite a good CEAFE score, we opt not to include stack competition features in our final system.

Given the simplicity of our learning and decoding, our system compares favourably with existing systems. In all configurations, we beat both publicly available systems and the mention-pair variant L^3M: by uniting aspects of ranking- and cluster-based approaches, we achieve benefits beyond either in

[3] since distinct feature strings correspond to completely distinct features

[5] http://nlp.cs.berkeley.edu/berkeleycoref.shtml

System	MUC	B^3	CEAFE	CoNLL
Stanford	64.30	70.46	46.35	60.37
Berkeley	66.10	68.56	50.09	61.58
L^3M	67.88	71.88	47.16	62.30
CL^3M	69.20	**72.89**	48.67	**63.59**
LIMERIC	**71.02**	68.66	50.31	63.33
LIMERIC +*c*	70.67	68.33	**50.55**	63.18
LIMERIC -*s*	70.53	68.21	50.34	63.03

System	MUC	B^3	CEAFE	CoNLL
Stanford	63.83	68.52	45.36	59.23
Berkeley	69.09	65.89	48.26	61.08
L^3M	68.31	70.81	46.73	61.95
CL^3M	69.64	**71.93**	48.32	**63.30**
LIMERIC	**71.52**	67.47	**49.75**	62.91

Table 1: CoNLL-2012 DEV (left) and TEST (right)

isolation. Also, we consistently outperform CL^3M on two of the three performance metrics; our method for uniting existing approaches is more direct and psycholinguistically faithful than that in CL^3M and our competitive system results are promising for future work.

Our system's MUC and CEAFE scores are the highest across all systems on both datasets. Our high CEAFE score in particular suggests that our system produces an accurate *number* of clusters. We explore this further in Figure 4 using the tool described in Kummerfeld and Klein (2013)[6]. Between Berkeley and LIMERIC, the notable difference is that we make considerably fewer Divided Entity and Missed Entity errors for a small increase in Conflated Entity errors. By introducing features which model when a new discourse entity should form and how the relative accessibility of already active ones impacts coreference decisions, we more accurately predict the bounds of entity clusters. This modelling is independent of surface features: 85% and 96% of Berkeley's Divided Entity errors occur where there is no head match and string match between mentions, respectively, compared to our values of 87% and 96%.

We note also that, given Kummerfeld and Klein's finding that MUC recall is highly sensitive to Divided Entity errors and B^3 precision to Conflated Entity errors, we can understand our performance on these metrics, particularly if our errors occur in larger clusters.

Between LIMERIC and LIMERIC+*c*, the notable difference is that LIMERIC+*c* makes fewer Missed Mention errors, but at a high cost to Extra Entity errors. A principled solution for future work might be to enrich our model of what makes a discourse transition unfavourable, in contrast to the predominate tradition of modelling what makes a discourse transition favourable.

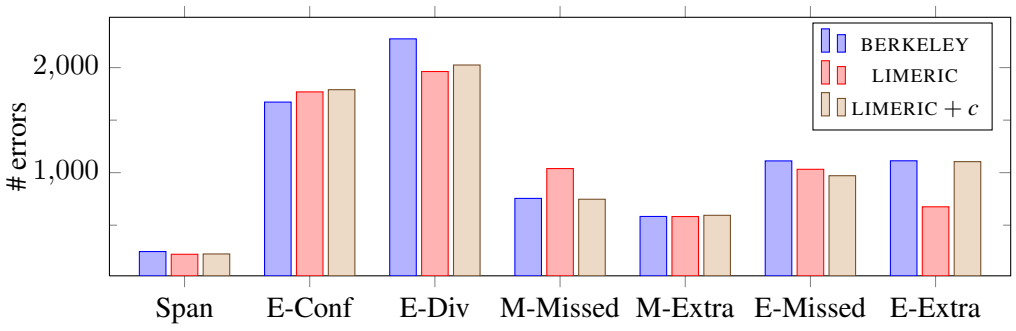

Figure 4: error counts in fine grained categories of Kummerfeld and Klein (2013)

6 System analysis

Features

Since we use simple, linear learning, it is possible to analyse feature weights to introspect system performance. In particular, we would like to understand why our stack competition features, which are well principled, did not give a substantial performance gain. We do this by analysing the number of non-zero

[6] https://code.google.com/p/berkeley-coreference-analyser/

Features	% non-zero	avg. mag.
Surface	17.4	0.23
POS	61.9	4.55
Shape	57.3	3.77
Str match	93.7	20.60
Length	48.7	2.37
Distance	92.5	19.74

Features	% non-zero	avg. mag.
Attr agree	88.3	24.88
Attr discord	74.6	20.00
WN similarity	94.5	21.67
Competition	**87.9**	**15.28**
Likelihood	**61.4**	**7.47**
Depth	**93.9**	**11.73**

Table 2: proportion of features within a set with non-zero weight in LIMERIC+*c* model (left) and average magnitude of this weight across the set (right); novel features are indicated in bold

features in our feature sets as an indication of how often they were useful in distinguishing predictions, and average feature weight magnitude as an indication of how trusted they were in inference.

Given the performance decrease of LIMERIC+*c* against our base system, it is surprising that it is the competition features which appear to be the best performing of our novel feature space. We are cautious that their very high feature weight could represent overfitting and future work could use regularisation, as well as explore any discourse level differences between TRAIN and the TEST datasets.

Depth in stack performs well, particularly given that it captures similar information to Distance and feature weight needs to be shared between the two feature sets. The least useful feature set is Surface, probably due to our large feature space size and its sparseness. Since this comprises the greatest number of features, we anticipate its deactivation will improve efficiency for a minimal impact on performance.

Stack

Our reported performance is based on a search of the full stack, but this gives rise to a large time cost which is not practical given the role of coreference resolution to inform downstream inference. While recency is important cue for coreference, it is not clear what bounds we can place on candidate generation while maintaining good performance. Figure 5 plots the depth from the top of the stack of the correct reduce operation in DEV.

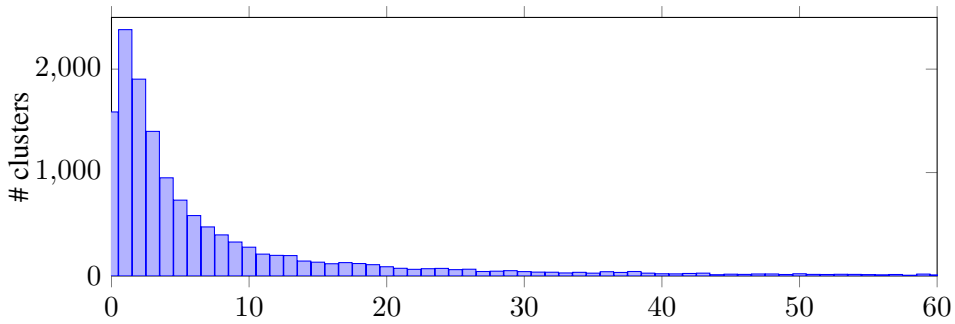

Figure 5: distribution of correct merge targets in the stack, DEV

We note a very long tail to this distribution and cut it off at depth 60, which cumulatively represents 97% of the data. The vast majority of correct merge targets are near the top of the stack, with 78% up to depth 10 and 88% up to depth 20. Setting maximum search depth to 60 yields a model which scores 61.31 on DEV. While this outperforms Stanford and is competitive with Berkeley, the magnitude of loss is surprising given the distribution in Figure 5. Error analysis shows an increased number of Conflated Entity and Extra Mention errors, which were shown in Kummerfeld and Klein (2013) to have a substantial precision cost. We note that this is consistent with our system having good accuracy in predicting whether or not a new entity cluster should form, but being restricted to choose an incorrect merge target when the correct one is outside its search window.

Configuration	MUC	B^3	CEAFE	CoNLL
LIMERIC+*c*	**70.67**	**68.33**	50.55	**63.18**
classifier scoring	70.36	68.12	50.65	63.04
# beams=1	70.52	68.21	**50.66**	63.13
no beam threshold	69.60	67.42	50.12	62.38

Table 3: impact of various parameters for beam search, DEV

Beam search

Beam search affects both time and space complexity since each classification step proposes new stacks which need to be compared for pruning. Our final system uses a maximum beam size of 10 with a conservative threshold of 5 for new stack formation. We find little difference between using classification score or stack discourse likelihood as our pruning metric. The results in Table 3 indicate that beam search isn't essential for state of the art performance in our system, our rich feature set is adequate alone. If we limit the beam to a single stack, we still have competitive performance with CL^3M. Indeed, if we do not set a strict threshold on the score at which a new stack is formed, we are forced to maintain the maximum 10 stacks and this actually hurts performance. These findings are consistent with those in Zhang and Nivre (2012), which demonstrates that performance gains are only seen from beam search at run time when their shift-reduce parser was trained similarly, maintaining a beam of potentially incorrect predictions and learning to recover as well as possible from unfavourable states.

7 Conclusion

The primary contribution of our work is a reconceptualisation of coreference by analogy with the shift-reduce parsing algorithm. We present LIMERIC, a simple, low memory coreference resolution system which achieves the competitive CoNLL scores of 63.33 and 62.91 on the CoNLL-2012 DEV and TEST splits of OntoNotes 5. Our framework unites ranking- and cluster-based approximations to global consistency encoding, and we outperform systems using either in isolation. By interpreting the stack of incrementally growing entity clusters in our system as a reader's mental status while reading, we naturally extend the shift-reduce algorithm to express a series of rich discourse features which perform well in feature analysis. Our results demonstrate the promise of psycholinguistic insights for coreference resolution and future directions include further extension of our discourse, as well as semantic, model. We plan future work in enriching our training process with beam search, and incorporating more insights from Centering and Accessibility Theories.

Left-corner Transitions on Dependency Parsing

Hiroshi Noji and **Yusuke Miyao**

Abstract

We propose a transition system for dependency parsing with a left-corner parsing strategy. Unlike parsers with conventional transition systems, such as arc-standard or arc-eager, a parser with our system correctly predicts the processing difficulties people have, such as of center-embedding. We characterize our transition system by comparing its oracle behaviors with those of other transition systems on treebanks of 18 typologically diverse languages. A crosslinguistical analysis confirms the universality of the claim that a parser with our system requires less memory for parsing naturally occurring sentences.

1 Introduction

It is sometimes argued that transition-based dependency parsing is appealing not only from an engineering perspective due to its efficiency, but also from a scientific perspective: These parsers process a sentence incrementally similar to a human parser, which have motivated several studies concerning their cognitive plausibility (Nivre, 2004; Boston and Hale, 2007; Boston et al., 2008). A cognitively plausible dependency parser is attractive for many reasons, one of the most important being that dependency treebanks are available in *many languages*, so it is suitable for crosslinguistical studies of human language processing (Keller, 2010). However, current transition systems based on shift-reduce actions fully or partially employ a bottom-up strategy[1], which is problematic from a psycholinguistical point of view: Bottom-up or top-down strategies are known to fail in predicting the difficulty for certain sentences, such as center-embedding, which people have troubles in comprehending (Abney and Johnson, 1991).

We propose a transition system for dependency parsing with a left-corner strategy. For constituency parsing, unlike other strategies, the arc-eager left-corner strategy is known to correctly predict processing difficulties people have (Abney and Johnson, 1991). To the best of our knowledge, however, the idea of left-corner strategy has not been introduced in the dependency parsing literature. We define the memory cost for a transition system as the number of unconnected subtrees on a stack. Under this condition, the proposed system incurs non-constant memory cost only when encountering center-embedded structures.

After developing the transition system, we characterize it by looking into the following question: Is it true that naturally occurring sentences can be parsed on this system with a lower memory overhead? This should be true under the assumptions that 1) people avoid generating a sentence that causes difficulty for them, and 2) center-embedding is a kind of such structure. Specifically, we focus on analyzing the oracle transitions of the system, i.e., parser actions to recover the gold dependency tree for a sentence. In English, it is known that left-corner transformed treebank sentences can be parsed with less memory (Schuler et al., 2010), but our focus in this paper is on the language universality of the claim in a crosslingual setting. Two different but relevant motivations exist for this analysis. The first is to answer the following scientific question: Is the claim that people tend to avoid generating center-embedded sentences language universal? This is unclear since the observation that a center-embedded sentence is

[1]The top-down parser of Hayashi et al. (2012) is an exception, but its processing is not incremental.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2140–2150, Dublin, Ireland, August 23-29 2014.

difficult to comprehend is from psycholinguistic studies mainly on English. The second motivation is to verify whether a parser with the developed system can be viable for crosslinguistical study of human language processing. There is evidence that a human parser cannot store elements of a small constant number, such as three or four (Cowan, 2001). If our system confirms to such a severe constraint, we may claim its cognitive plausibility across languages. We will pursue these questions using the multilingual dependency treebanks from the CoNLL-X and 2007 shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007).

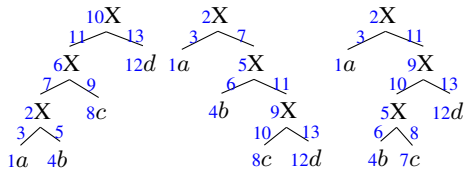
In short, our contributions of this paper can be sketched as follows:

1. We formulate a transition system for dependency parsing with a left-corner strategy.
2. We characterize our transition system with its memory cost by simulating oracle transitions along with other transition systems on the CoNLL multilingual treebanks. This is the first empirical study of required memory for left-corner parsing in a *crosslinguistical* setting.

2 Memory cost of Parsing Algorithms

In this work, we focus on the memory cost for dependency parsing transition systems. While there have been many studies concerning the memory cost for an algorithm in constituency parsing (Abney and Johnson, 1991; Resnik, 1992), the same kind of study is rare in dependency parsing. This section discusses the memory cost for the current dependency parsing transition systems. Before that, we first review the known results in constituency parsing regarding memory cost.

2.1 Center-Embedding and the Left-Corner Strategy



The structures on the right side are called left-branching, right-branching, and center-embedding, respectively. People have difficulty when parsing center-embedded structures, while no difficulty with right-branching or left-branching structures. An example of a center-embedded sentence is *the rat [the cat [the dog chased] bit] ate the cheese*, which is difficult, but if we rewrite it as *the cheese was eaten [by the rat [that bit the cat [that chased the dog]]]*, which is a kind of right-branching structure, the parse becomes easier.

Abney and Johnson (1991) showed that top-down or bottom-up strategies[2] fail to predict this result. For example, for the right-branching structure, a bottom-up strategy requires $O(n)$ memory, since it must first construct a subtree of c and d, but the center-embedded structure requires less memory. The arc-eager left-corner strategy correctly predicts the difficulty of a center-embedded structure, which is characterized by the following order of recognitions of nodes and arcs:

1. A node is enumerated when the subtree of its first child has been enumerated.
2. An arc is enumerated when two nodes it connects have been enumerated.

The numbers on the trees above indicate the order of recognition for this strategy. We can see that it requires a constant memory for both right-branching and left-branching structures. For example, for the right-branching structure, it reaches 7 after reading b, which means that a and b are connected by a subtree. On the other hand, for the center-embedded structure, it reaches 6 after reading b, but a and b cannot be connected at this point, requiring extra memory.

2.2 Transition-based Dependency Parsing

Next, we summarize the issues with current transition systems for dependency parsing with regards to their memory cost. A transition-based dependency parser processes a sentence on a transition system, which is defined as a set of configurations and a set of transitions between configurations (Nivre, 2008). Each configuration has a stack preserving constructed subtrees on which we define the memory cost as a function for each system.

[2]We should distinguish between two types of characterizations of parsing: *strategy* and *algorithm*. A parsing strategy is an abstract notion that defines "a way of enumerating the nodes and arcs of parse trees" (Abney and Johnson, 1991), while a parsing algorithm defines the implementation of that strategy, typically with push-down automata (Johnson-Laird, 1983; Resnik, 1992). A parsing strategy is useful for characterizing the properties of each parser, and we concentrate on the *strategy* for exposition of constituency parsing. For dependency parsing, we mainly discuss the algorithm, i.e., the transition system.

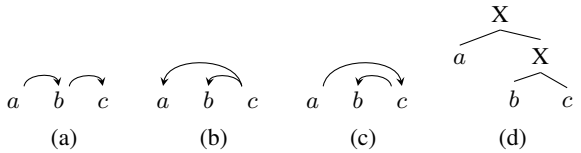


Figure 1: (a)–(c): Right-branching dependency trees for three words; (d): the corresponding CNF.

	Arc-standard	Arc-eager	Left-corner
left-branching	$O(1)$	$O(1)$	$O(1)$
right-branching	$O(n)$	$O(1 \sim n)$	$O(1)$
center-embedding	$O(n)$	$O(1 \sim n)$	$O(n)$

Table 1: Order of the memory cost for each structure for each transition system. $O(1 \sim n)$ means that it processes some structures with a constant cost but some with a non-constant cost.

Arc-Standard We define the memory cost as the number of elements on the stack since all stack elements are disjoint. In this setting, we can see that the arc-standard system has a problem for a right-branching structure, such as $a \curvearrowright b \curvearrowright c \curvearrowright \cdots$, in which the system first pushes all words on the stack before connecting each pair of words, requiring $O(n)$ memory. Nivre (2004) discussed the problem with this system in greater detail, observing that its stack size grows when processing structures that become right-branching when converted to the Chomsky normal form (CNF) of a context-free grammar (CFG). Figure 1 lists those dependency structures for three words, for which the system must construct a subtree of b and c before connecting a to either, requiring extra memory. This is because the system builds a tree bottom-up: each token collects all dependents before being attached to its head. In fact, the arc-standard system is essentially equivalent to the push-down automaton of a CFG in the CNF with a bottom-up strategy (Nivre, 2004), so it has the same property as the bottom-up parser for a CFG.

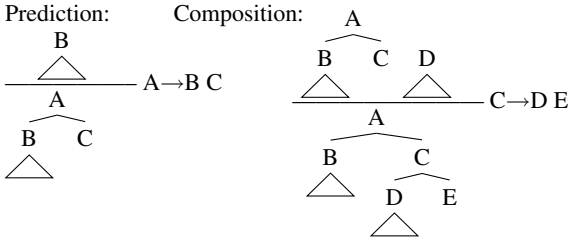
Arc-Eager In the arc-eager system, the stack contains sequences of tokens comprising connected components, so we can define the memory cost as the number of connected components on the stack. With this definition, we can partially resolve the problem with the arc-standard system. The arc-eager system does not incur any cost for processing the structure in Figure1(a) and $a \curvearrowright b \curvearrowright c \curvearrowright \cdots$ since it can connect all tokens on the stack (Nivre, 2004). Because its construction is no longer pure bottom-up, it is difficult to formally characterize the cost based on the type of tree structure. However, this transition system cannot correctly predict difficulties with center-embedding because the cost never increases as long as all dependency arcs are left-to-right, e.g., a sentence $a \curvearrowright b \overset{\frown}{c\ d}$ becomes center-embedding when converted to a CNF, but it does not incur any cost for it. Note that this system still incurs cost for some right-branching structures, such as in Figures 1(b–c), and some center-embedded structures. Therefore, for the arc-eager system, it is complicated to discuss the required order of memory cost. We summarize these results in Table 1. Our goal is to develop an algorithm with the properties of the last column, requiring non-constant memory for only center-embedded structures.

Other systems All systems where stack elements cannot be connected have the same problem as the arc-standard system because of their bottom-up constructions, including the hybrid system of Kuhlmann et al. (2011). Kitagawa and Tanaka-Ishii (2010) and Sartorio et al. (2013) present an interesting variant, which attaches a node to another node that may not be the head of a subtree on the stack. We can use the same reasoning for the arc-eager system for these systems: they sometimes do not incur costs for center-embedded structures, while they incur a non-constant cost for some right-branching structures.

3 Left-corner Dependency Parsing

We now discuss the construction of our transition system with the left-corner *strategy*. Resnik (1992) proposed a push-down recognizer for a CFG. In the following, we instead characterize his algorithm by inference rules, which are more intuitive and helpful to adapt the idea for dependency parsing.

Prediction and Composition There are two characteristic operations in the push-down recognizer of Resnik (1992): **prediction** and **composition**. We show inference rules of these operations on the right side:



Prediction is used to predict the parent node and the sibling of a recognized subtree when the sub-

SHIFT	$(\sigma, j\|\beta, A) \mapsto (\sigma\|\langle j\rangle, \beta, A)$
INSERT	$(\sigma\|\langle\sigma_1'\|i\|x(\lambda)\rangle), j\|\beta, A) \mapsto (\sigma\|\langle\sigma_1'\|i\|j\rangle, \beta, A \cup \{(i,j)\} \cup \{\cup_{k\in\lambda}(j,k)\})$
LEFT-PRED	$(\sigma\|\langle\sigma_{11}, \cdots\rangle, \beta, A) \mapsto (\sigma\|\langle x(\sigma_{11})\rangle, \beta, A)$
RIGHT-PRED	$(\sigma\|\langle\sigma_{11}, \cdots\rangle, \beta, A) \mapsto (\sigma\|\langle\sigma_{11}, x(\emptyset)\rangle, \beta, A)$
LEFT-COMP	$(\sigma\|\langle\sigma_2'\|x(\lambda)\rangle\|\langle\sigma_{11}, \cdots\rangle, \beta, A) \mapsto (\sigma\|\langle\sigma_2'\|x(\lambda \cup \{\sigma_{11}\})\rangle, \beta, A)$
RIGHT-COMP	$(\sigma\|\langle\sigma_2'\|x(\lambda)\rangle\|\langle\sigma_{11}, \cdots\rangle, \beta, A) \mapsto (\sigma\|\langle\sigma_2'\|\sigma_{11}\|x(\emptyset)\rangle, \beta, A \cup \{\cup_{k\in\lambda}(\sigma_{11}, k)\})$

Figure 2: Actions of the left-corner transition system.

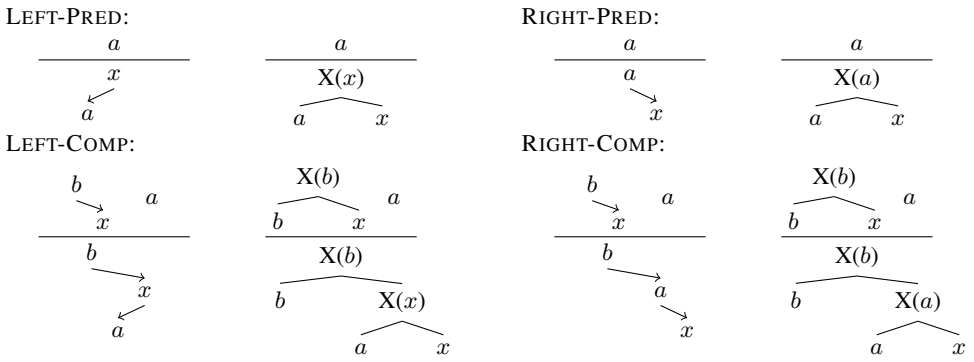


Figure 3: Correspondences of reduce actions between dependency and CFG. Nonterminal X(t) means that its lexical head is t. We only show minimal example subtrees for simplicity. However, a can have an arbitrary number of children, so can b or x, as long as x is on a right spine and has no right children.

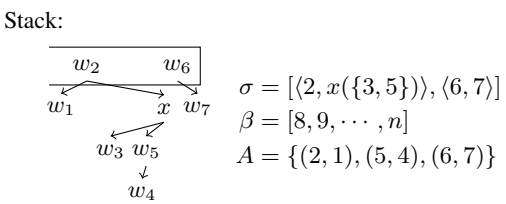
tree is complete and its parent node is not yet recognized. **Composition** composes two subtrees by first predicting the parent and the sibling of a recognized subtree then immediately connecting trees by identifying the same node on two trees (C, in this case). This is used when the parent node of a completed subtree has already been predicted as a part of another tree in a top-down fashion.

Dummy Node We now turn to the discussion of dependency parsing. The key characteristic of our transition system is the introduction of a dummy node on a subtree, which is needed to represent a subtree containing some predicted structures as in constituency subtrees for Resnik's recognizer. To get an intuition of the parser actions, we present a simulation of transitions for the sentence in Figure 1(b), of which current systems fail to predict its difficulty. Our system first shifts a then conducts a kind of **prediction** operation, resulting in a subtree $a \swarrow x$, where x is a dummy node. This means that we predict that a will become a left dependent of an incoming word. Next, it shifts b to the stack then conducts a **composition** operation to obtain a tree $a \swarrow b \swarrow x$. It finally inserts c to the position of x, recovering the tree.

Transition system As in many other transition systems, a configuration for our system is a tuple $c = (\sigma, \beta, A)$, where σ is a stack, and we use a vertical bar to signify an append operation, e.g., $\sigma = \sigma'|\sigma_1$ denoting σ_1 is the top most element of the stack σ, and β is an input buffer consisting of token indexes not processed yet. $\beta = j|\beta'$ means j is a first element of β, and $A \subseteq V_w \times V_w$ is a set of arcs given V_w, a set of token indexes for a sentence w.



Each element of a stack is a list representing a **right spine** of a subtree, as in Kitagawa and Tanaka-Ishii (2010) and Sartorio et al. (2013). A right spine $\sigma_i = \langle\sigma_{i1}, \sigma_{i2}, \cdots, \sigma_{ik}\rangle$ consists of all nodes in a descending path from the head of σ_i, i.e., σ_{i1}, taking the rightmost child at each step. We also write $\sigma_i = \sigma_i'|\sigma_{ik}$ meaning that σ_{ik} is the right most node of spine σ_i. Each element of σ_i is an index of a token in a sentence, or a dummy node $x(\lambda)$, where λ is a set of the left dependents of x. The figure above depicts an example of the configuration, where the i-th word in a sentence is written as w_i on the stack.

In the following, we say a right spine σ_i is *complete* if it does not contain any dummy nodes, while σ_i containing a dummy node is referred to as *incomplete*. Our transition system uses six actions, two of

which are **shift** actions and four are **reduce** actions. All actions are defined in Figure 2.

Shift Actions There are two kinds of shift actions: SHIFT and INSERT[3]. SHIFT moves a token from the top of the buffer to the stack. INSERT replaces a dummy node on the top of the stack with a token from the top of the buffer. This adds arcs from/to tokens connected to the dummy node. Note that this action can be performed for a configuration where $x(\lambda)$ is the top of σ_1 or λ is empty, in which case arcs (i, j) or $\cup_{k\in\lambda}(j, k)$ are not added. Resnik (1992) does not define this action, but instead uses a verification operation (Rule 9). One can view our INSERT action as a composition of two actions: SHIFT and a verification. We note that after these shift actions, the top element of the stack must be complete.

Reduce Actions Reduce actions create new arcs for subtrees on the stack. LEFT-PRED and RIGHT-PRED correspond to the predictions of the CFG counterpart. Figure 3 describes these transitions for minimal subtrees. LEFT-PRED assigns a dummy node x as the head of a (this corresponds to σ_{11}), while RIGHT-PRED creates x as a new right dependent. When we convert the resulting tree into a CNF, we can see that the difference between these two operations lies in the predicted parent node of a: LEFT-PRED predicts a nonterminal X(x), i.e., it predicts that the head of this subtree is the head of the predicting sibling node, while RIGHT-PRED predicts that the head is a. Note that different from CFG rules, we do not have to predict the actual sibling node; rather, we can abstract this predicted node as a dummy node x. A similar correspondence holds between the composition actions: RIGHT-COMP and LEFT-COMP.

We note that to obtain a valid tree, shift and reduce actions must be performed alternatively. We can prove this as follows: Let $c = (\sigma|\sigma_2|\sigma_1, \beta, A)$. Since reduce actions turn an incomplete σ_1 into a complete subtree, we cannot perform two consecutive reduce actions. Shift actions make σ_1 complete. After a shift action, we cannot perform INSERT since it requires σ_i to be incomplete; if we perform SHIFT, the top two elements on the stack become complete, but we cannot connect these two trees since the only way to connect two trees on the stack is composition, but this requires σ_2 to be incomplete.

Defining Oracle The oracle for a transition system is a function that returns a correct action given the current configuration and a set of gold arcs. It is typically used for training a parser (Nivre, 2008), but we define it to analyze the behavior of our system on treebank sentences.

First, we show that our system has the **spurious ambiguity**, and discuss its implications. Consider a sentence $a^\frown b^\frown c$, which can be parsed with two different action sequences as follows:

1. SHIFT → LEFT-PRED → INSERT → RIGHT-PRED → INSERT
2. SHIFT → LEFT-PRED → SHIFT → RIGHT-COMP → INSERT

The former INSERTs b at step 3, then RIGHT-PREDs to wait for a right dependent (c). The latter, on the other hand, SHIFTs b at step 3, then RIGHT-COMPs to combine two subtrees ($a^\frown x$ and b) to obtain a tree $a^\frown b^\frown x$. These ambiguities between action sequences and the resulting tree are referred to as the spurious ambiguity. Next, we analyze the underlying differences between these two operations. We argue that the difference lies in the form of the recognized constituency tree: The former RIGHT-PREDs at step 4, which means that it recognizes a constituency of the form $((a\ b)\ c)$, while the latter recognizes $(a\ (b\ c))$ due to its RIGHT-COMP operation. Therefore, the spurious ambiguity of our system is caused by the ambiguity of converting a dependency tree to a constituency tree. Recently, some transition systems have exploited similar ambiguities using *dynamic oracles* (Goldberg and Nivre, 2013; Sartorio et al., 2013; Honnibal et al., 2013). The same type of analysis might be possible for our system, but we leave it for future work; here we only present a *static oracle* and discuss its properties.

Since our system performs shift and reduce actions interchangeably, we need two functions to define the oracle. Let $c = (\sigma|\sigma_2|\sigma_1, \beta, A)$. The next shift action is determined as follows:

- INSERT: if $\sigma_1 = \langle\sigma_1'|i|x(\lambda)\rangle$ and $(i, j) \in A_g$ and j has no dependents in β (if i exists) or $\exists k \in \lambda; (j, k) \in A_g$ (otherwise).
- SHIFT: otherwise.

The next reduce action is determined as follows:

[3]We use small caps to refer to a specific action, e.g., SHIFT, while "shift" refers to an action type.

- LEFT-COMP: if $\sigma_2 = \langle \sigma_2' | i | x(\lambda) \rangle, \sigma_1 = \langle \sigma_{11}, \cdots \rangle$, σ_{11} has no dependents in β, and σ_{11} can be a left dependent of x: i's next dependent is the head of σ_{11} (if i exists) or $k \in \lambda$ and σ_{11} share the same head (otherwise).
- RIGHT-COMP: if $\sigma_2 = \langle \sigma_2' | i | x(\lambda) \rangle, \sigma_1 = \langle \sigma_{11}, \cdots \rangle$, σ_{11} has one more dependent in β, and σ_{11} can be insertable at the position of x: $(i, \sigma_{11}) \in A_g$ or $\exists k \in \lambda; (\sigma_{11}, k) \in A_g$.
- RIGHT-PRED: if $\sigma_1 = \langle \sigma_{11}, \cdots \rangle$ and σ_{11} has one more dependent in β.
- LEFT-PRED: otherwise.

Each condition checks whether we can obtain the gold dependency arcs after the transition. This oracle follows the strategy of "compose or insert when possible". As we saw in the example, sometimes INSERT and SHIFT both can be valid to recover the gold arcs; however, we always select INSERT. Sometimes the same ambiguity occurs between LEFT-COMP and LEFT-PRED or RIGHT-COMP and RIGHT-PRED, but we always prefer composition.

As we saw above, the spurious ambiguity of our system occurs when the conversion from a dependency tree to a constituency tree is not deterministic. This oracle has the property that its recognized constituency tree corresponds to the one that can be obtained by constructing all left-arcs first given a dependency tree. For example, in the above example for $a \overset{\curvearrowleft}{b} \overset{\curvearrowright}{c}$, we select action sequences 1 to recognize a constituency of $((a\ b)\ c)$. We can prove this property by showing that the algorithm always collects all left-arcs for a head before any right-arcs; Not doing INSERT or composition when possible means that we create a right-arc for a head when the left-arcs are not yet completed. We can also verify that this algorithm can parse all no-center-embedded sentences in a CNF converted in this manner with the stack depth never exceeding three, requiring non-constant memory for only center-embedded structures.

4 Memory Cost Analysis

To characterize our transition system, we compare it to other systems by observing the incurred memory cost during running oracle transitions for sentences on a set of typologically diverse languages. For this analysis, we aim to verify the language universality of the claim: naturally occurring sentences should be parsed with a left-corner parser with less required memory.

Settings We collect 18 treebanks from the CoNLL-X and 2007 shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007). Some languages were covered by both shared tasks; we use only 2007 data. We remove sentences with non-projective arcs (Nivre, 2008) or without any root nodes. We follow the common practice adding a dummy root token to each sentence. This token is placed at the end of each sentence, as in Ballesteros and Nivre (2013), since it does not change the cost on sentences with one root token on all systems.

We compare three transition systems: arc-standard, arc-eager, and left-corner. For each system, we perform oracle transitions for all sentences and languages, measuring the memory cost for each configuration defined as follows. For the arc-standard and left-corner systems, we use the number of elements on the stack. This arc-standard system uses the original formulation of Nivre (2003), connecting two items on the stack at the reduce action. For the arc-eager system, we use the number of connected components. The system can create a subtree at the beginning of a buffer, in which case we add 1 to the cost.

We run a static oracle for each system. For the left-corner system, we implemented the algorithm presented in Section 3. For the arc-standard and arc-eager systems, we implemented an oracle preferring reduce actions over shift, which can minimizes the memory cost.

Memory costs for general sentences For each language, we count the number of configurations for each memory cost during performing oracles on all sentences. In Figure 4, we show the cumulative frequencies of configurations having each memory cost (see solid lines in the figure). These lines can answer the question: What memory cost is required to cover X% of configurations when recovering all gold trees? Note that comparing absolute values are not meaningful since the minimal cost to construct an arc is different for each system, e.g., the arc-standard system requires at least two items on the stack,

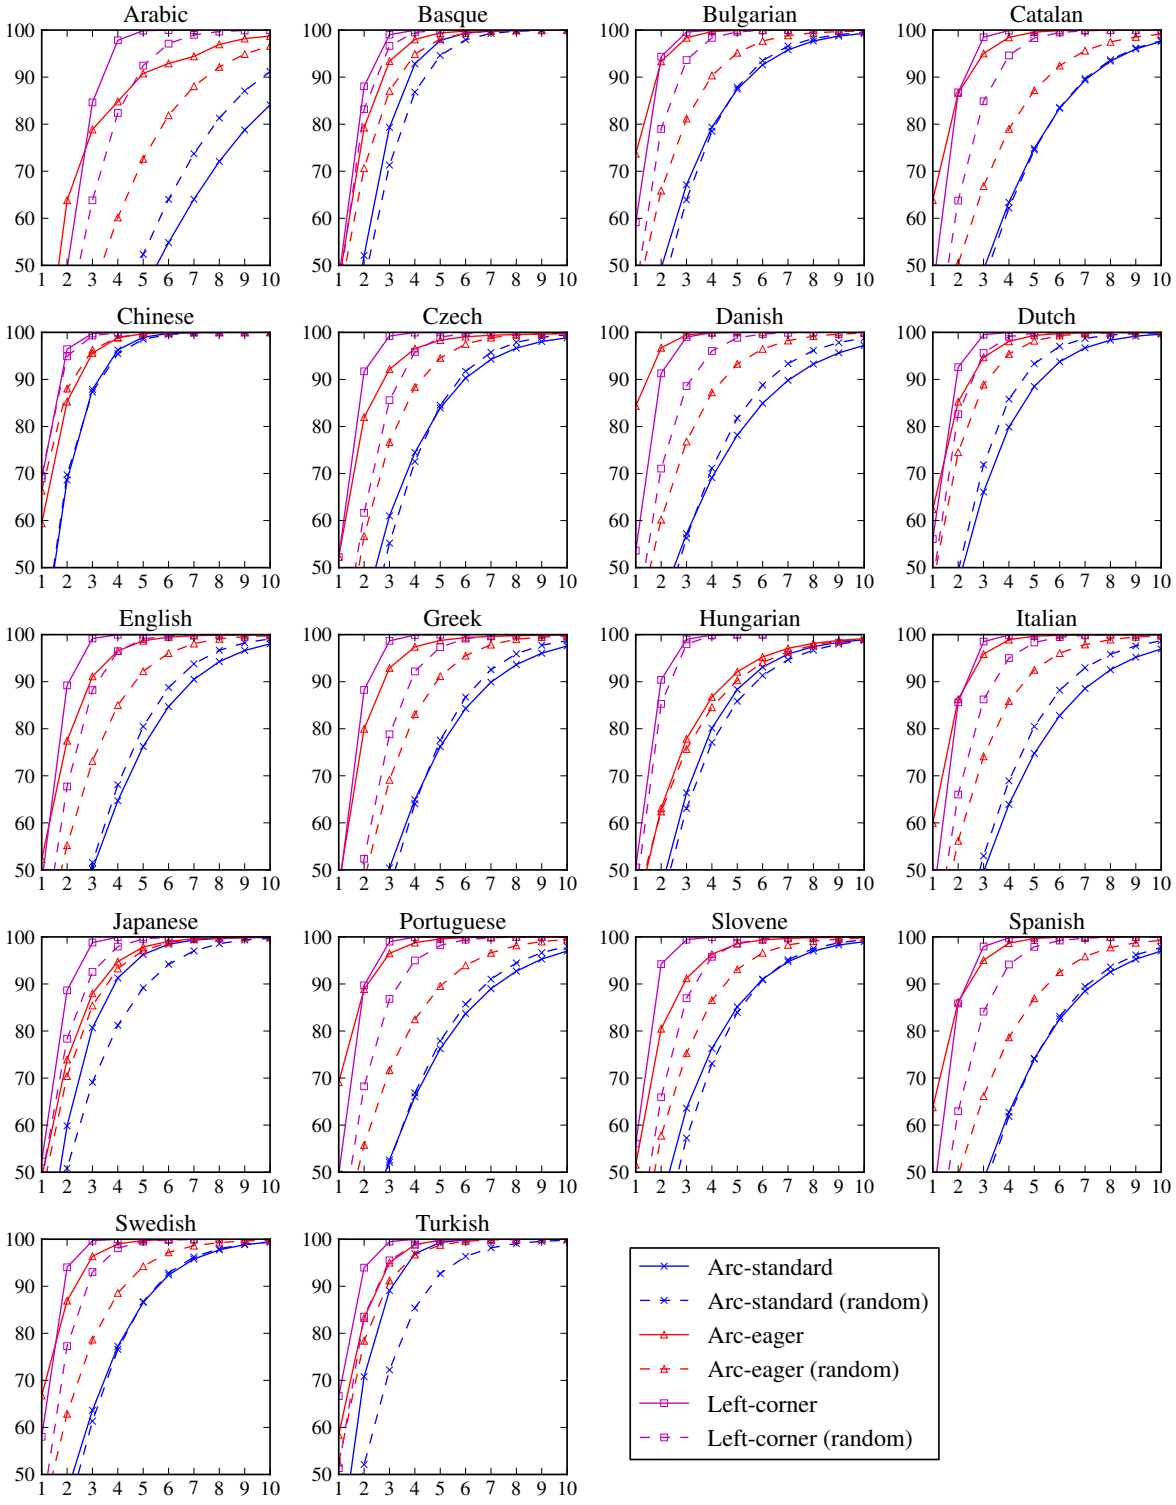


Figure 4: Crosslinguistic comparison of cumulative frequency of memory cost when processing all sentences for each system. For example, in Arabic, for the arc-eager system, around 90% of all configurations incurred memory cost of ≤ 5. Dotted lines (random) are results on the sentences, which are randomly reordered while preserving the graph structure and projectivity.

while the arc-eager system can create a right arc if the stack contains one element. Instead, we focus on the universality of each system's behavior for different languages.

As we discussed in section 2.2, the arc-standard system can process only left-branching structures with a constant memory, which are typical in head-final languages such as Japanese or Turkish, and we can

see this tendency. The system behaves poorly in many other languages.

The arc-eager and left-corner systems behave similarly for many languages, but we can see that there are some languages for which the left-corner system behaves similarly to other languages, while the arc-eager system requires larger cost; Arabic, Hungarian, or Japanese, for example. In fact, except Arabic, the left-corner system reaches 98% of configurations with a memory cost of ≤ 3, which indicates that the property of the left-corner system requiring less memory is more universal than that of other systems.

Comparison to randomized sentences One might wonder that the results above come from the nature of left-corner parsing reducing the stack size, not from the bias in language avoiding center-embedded structures. To partially answer this question, we conduct another experiment comparing oracle transitions on original treebank sentences and on wrong sentences. We create these wrong sentences by using the method from Gildea and Temperley (2007). We reorder words in each sentence by first extracting a directed graph then randomly reordering the children of each node while preserving projectivity. The dotted lines in Figure 4 denotes the results of randomized sentences for each system.

There are notable differences in required memory between original and random sentences for many languages. This result indicates that our system can parse with less memory for only naturally occurring sentences. For Chinese and Hungarian, the differences are subtle. However, the differences are also small for the other systems, which implies that these corpora have some biases on graphs reducing the differences.

5 Related Work and Discussion

To the best of our knowledge, parsing with a left-corner strategy has only been studied for constituency. Roark (2001) proposed a top-down parser for a CFG with a left-corner grammar transform (Johnson, 1998), which is essentially the same as left-corner parsing but enables several extensions in a unified framework. Roark et al. (2009) studied the psychological plausibility of Roark's parser, observing that it fits well to human reading time data. Another model with a left-corner strategy is Schuler et al. (2010): they observed that the transformed grammar of English requires only limited memory, proposing a finite state approximation with a hierarchical hidden Markov model. This parser was later extended by van Schijndel and Schuler (2013), which defined a left-corner parser for constituency with shift and reduce actions. In fact, they used the same kind of actions as our transition system: shift, insert, predict, and composition. Though they did not mentioned explicitly, we showed how to construct a left-corner parsing algorithm with these actions by decomposing the push-down recognizer of Resnik (1992). These are examples of broad-coverage parsing models with cognitively plausibility, which has recently received considerable attention in interdisciplinary research on psycholinguistics and computational linguistics (Schuler et al., 2010; Keller, 2010; Demberg et al., 2013).

Differently from previous models, our target is dependency. A dependency-based cognitively plausible model is attractive, especially from a crosslinguistical viewpoint. Keller (2010) argued that current models only work for English, or German in few exceptions, and the importance of crosslinguistically valid models of human language processing. There has been some attempts to use a transition system for studying human language processing (Boston and Hale, 2007; Boston et al., 2008), so it is interesting to compare automatic parsing behaviors with various transition systems to human processing.

We introduced a dummy node for representing a subtree with an unknown head or dependent. Recently, Menzel and colleagues (Beuck and Menzel, 2013; Kohn and Menzel, 2014) have also studied dependency parsing with a dummy node. While conceptually similar, the aim of introducing a dummy node is different between our approach and theirs: We need a dummy node to represent a subtree corresponding to that in Resnik's algorithm, while they introduced it to confirm that every dependency tree on a sentence prefix is fully connected. This difference leads to a technical difference; a subtree of their parser can contain more than one dummy node, while we restrict each subtree to containing only one dummy node on a right spine.

Our experiments in section 4 can be considered as a study on functional biases existing in language or language evolution (Jaeger and Tily, 2011). In computational linguistics, Gildea and Temperley (2007; 2010) examined the bias on general sentences called *dependency length minimization* (DLM), which

argues that grammar should favor the dependency structures that reduce the sum of dependency arc lengths. They reordered English and German treebank sentences with various criteria: original, random with projectivity, and optimal that minimizes the sum of dependency lengths. They observed that the word order of English fits very well to the optimal ordering, while German does not. We examined the universality of the bias to reduce memory cost for left-corner parsing. Although we cannot compare the incurred cost with the *optimal* reordered sentences, our results on original sentences, in which there are few configurations requiring the stack depth ≥ 4, suggest the bias to avoid center-embedded structures is language universal. It will be interesting to analyze in more detail the relationships between DLM and the bias of our system since the two biases are not independent, e.g., center-embed structures typically appear with longer dependencies. Are there languages that do not hold DLM while requiring less memory, or vice versa? For these analyses, we might have to take care of the grammar construction, e.g., there are several definitions for coordination structures for dependency grammars (Popel et al., 2013). The functional views discussed above might shed some light on the desired construction for these cases.

6 Conclusion

We have pointed out that the memory cost on current transition systems for dependency parsing do not coincide with observations in people, proposing a system with a left-corner strategy. Our crosslinguistical analysis confirms the universality of the claim that people avoid generating center-embedded sentences, which also suggests that it is worthy for crosslinguistical studies of human language processing.

As a next stage, we are seeking to train a parser model as in other transition systems with a discriminative framework such as a structured perceptron (Zhang and Nivre, 2011; Huang and Sagae, 2010). A parser with our transition system might also be attractive for the problem of grammar induction, where recovering dependency trees are a central problem (Klein and Manning, 2004), and where some linguistic biases have been exploited, such as reducibility (Mareček and Žabokrtský, 2012) or acoustic cues (Pate and Goldwater, 2013). Recently, Cohen et al. (2011) showed how to interpret shift-reduce actions as a generative model; combining their idea and our transition system might enable the model to exploit memory biases that exist in natural sentences.

Finally, dependency grammars are suitable for treating non-projective structures. Extensions for transition systems have been proposed to handle non-projective structures with additional actions (Attardi, 2006; Nivre, 2009). Although our system cannot handle non-projective structures, a similar extension might be possible, which would enable a left-corner analysis for non-projective structures.

Abstract

When assessing child language development, researchers have traditionally had to choose between easily computable metrics focused on superficial aspects of language, and more expressive metrics that are carefully designed to cover specific syntactic structures and require substantial and tedious labor. Recent work has shown that existing expressive metrics for child language development can be automated and produce accurate results. We go a step further and propose that measurement of syntactic development can be performed automatically in a completely data-driven way without the need for definition of language-specific inventories of grammatical structures. As a crucial step in that direction, we show that four simple feature templates are as expressive of language development as a carefully crafted standard inventory of grammatical structures that is commonly used and has been validated empirically.

1 Introduction

Although child language has been the focus of much study, our understanding of first language acquisition is still limited. In attempts to measure child language development over time, several metrics have been proposed. The most commonly used metric is Mean Length of Utterance, or MLU (Brown, 1973), which is based on the number of morphemes per utterance. The main appeal of MLU is that it can be easily computed automatically, given machine-readable transcripts. Although MLU values may not be meaningful across languages, the general approach is suitable for analysis within different languages. However, MLU's ability to track language development from age four has been questioned (Klee and Fitzgerald, 1985; Scarborough, 1990), and its usefulness is still the subject of debate (Rice et al., 2010).

Several metrics based on the usage of grammatical structure have been proposed as more sensitive to changes in language over a wider range of ages (Scarborough, 1990; Lee and Canter, 1971; Fletcher and Garman, 1988). These metrics continue to show score increases where MLU plateaus, but their increased expressivity is typically associated with two severe drawbacks. The first is that their use for computation of language development scores involves identification of several specific grammatical structures in child language transcripts, a process that requires linguistic expertise and is both time-consuming and error-prone. This issue has been addressed by recent work that shows that current natural language processing techniques can be applied to automate the computation of these metrics, removing the bottleneck of manual labor (Sagae et al., 2005; Roark et al., 2007; Sahakian and Snyder, 2012). The second drawback is that these measures are language-specific, and development of a measure for a specific language requires deep expertise and careful design of an inventory of grammatical structures that researchers believe to be indicative of language development. Going beyond previous work, which addressed the first drawback of traditional metrics for child language development, we address the second, paving the way for a language-independent methodology for tracking child language development that is as expressive as current language-specific alternatives, but without the need for carefully constructed inventories of grammatical structures.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2151–2160, Dublin, Ireland, August 23-29 2014.

The specific hypothesis we address in this paper is whether a fully-data driven approach that uses only a few simple feature templates applied to syntactic dependency trees can capture the same information as the well-known Index of Productive Syntax, or IPSyn (Scarborough, 1990). In contrast to previous work that showed that the computation of IPSyn scores can be performed automatically by encoding each of the 60 language structures in a language-specific inventory (e.g. wh-questions with auxiliary inversion, propositional complements, conjoined sentences) as complex patterns over parse trees, we propose that child language development can instead be measured automatically in a way that is fully data-driven and can be applied to many languages for which accurate dependency parsers are available, without relying on carefully constructed lists of grammatical structures or complex syntactic patterns in each language. Specifically, we examine two hypotheses: (1) counts of features extracted from syntactic parse trees using only simple templates are at least as expressive of changes in language development as the Index of Productive Syntax (Scarborough, 1990), an empirically validated metric based on an inventory of grammatical structures derived from the child language literature; and (2) these parse tree features can be used to model language development without the use of an inventory of specific structures, assuming only the knowledge that in typically developing children the level of language development is correlated with age. We emphasize that the goal of this work is not to develop yet one more way to compute IPSyn scores automatically, but to show empirically that lists of grammatical structures such as those used to compute IPSyn are not essential to measure syntactic development in children.

In this paper, we start by reviewing IPSyn and previous work on automatic IPSyn scoring based on manually crafted syntactic patterns in section 2. Using a similar approach, we validate the language development curves observed by Scarborough (1990) in the original IPSyn study. In section 3 we show how IPSyn scores can be computed in an entirely different, fully data-driven way, using a support vector regression. In section 4 we examine how this data-driven framework can be used to track language development in the absence of a metric such as IPSyn, which allows for application of this approach to languages other than English. We discuss related work in section 5, and conclude in section 6.

2 Index of Productive Syntax (IPSyn)

The Index of Productive Syntax (Scarborough, 1990) evaluates a child's linguistic development by analyzing a transcript of utterances and awarding points when certain syntactic and morphological structures are encountered. The end result is a number score ranging from 0 to 120, with a higher score corresponding to the presence of more complex grammatical structures, and thus further linguistic development. IPSyn was designed to be more sensitive to language changes after age 3 than the more common Mean Length of Utterance (MLU) (Brown, 1973), which fails to account for the fact that children's speech increases in complexity even after utterances stop increasing in length.

IPSyn scores are calculated by analyzing a transcript of 100 utterances of a child's speech, and awarding points to specific language structures encountered. There are 60 forms in total from four categories of noun phrases, verb phrases, questions and negations, and sentence structures. Each form is awarded 0 points if not encountered, 1 point if found once in a transcript, and 2 points if found at least twice. This sums to a total ranging between 0 and 120 points. Scarborough (1990) motivates the use of this specific inventory of 60 forms by stating that they "have been shown to occur in preschool language production in innumerable studies of language acquisition during the past 25 years," highlighting that the task of generating such an inventory and performing empirical validation for additional languages requires considerable expertise and is far from trivial.

2.1 Automating IPSyn

In support of empirical testing of our first hypothesis–that features extracted from parse trees using only simple feature templates are as expressive of child language development as the carefully constructed inventory of grammatical structures in IPSyn–we first implemented an automated version of IPSyn following Sagae et al. (2005), who showed that this task can be performed nearly at the level of trained human experts. This allows us to generate IPSyn scores for a large set of child language transcripts. Our implementation differs from previous work mainly in that it uses only the tools provided in the CLAN

software suite (MacWhinney, 2000), which were designed specifically for analysis of child language transcripts, instead of the Charniak (2000) parser, which was used by Sagae et al. and later by Hassanali et al. (2014) in a more recent implementation of the same general approach.

We evaluated our implementation using the set of 20 manually scored transcripts described by Sagae et al. as Set A, and subsequently used to evaluate the implementation of Hassanali et al. Three transcripts were used as development data, following Sagae et al. The mean absolute difference between manually generated and automatically generated scores was 3.6, which is very similar to what has been reported by Hassanali et al. and by Sagae et al. (3.05 and 3.7, respectively) for the same set of transcripts. Given the possible score differences in manual scoring reported by Scarborough (1990) and the small number of transcripts used for testing, the differences observed among the automatic systems are not meaningful. In fact, in examining our development data, we found multiple errors in the manual coding, causing point discrepancies when our system produced correct results. This highlights the difficulty of performing this scoring task manually, and raises the question of whether automatic scoring has in fact surpassed the reliability of manual scoring. That three different implementations of IPSyn appear to perform comparably suggests this might be the case. We leave an empirical investigation of this question to future work.

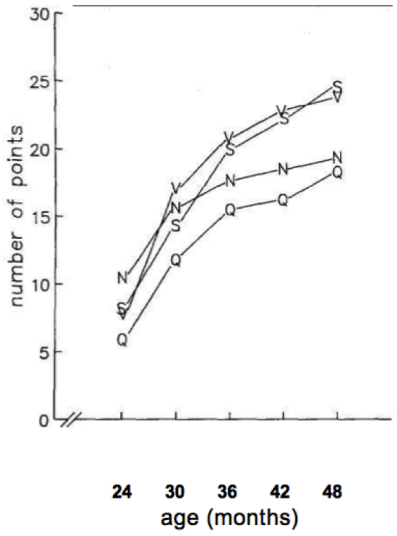
3 From automatic IPSyn to data-driven IPSyn

The fully automatic way of computing IPSyn scores described above in section 2.1, paired with a sufficiently large amount of child language transcript data, gives us a way to test the hypothesis mentioned in the beginning of section 2.1, that simple features of parse trees are as expressive as the hand-crafted IPSyn language structure inventory. We did this by first creating several 100-utterance transcripts from existing child language transcripts, then automatically assigning them IPSyn scores, and using these scores as targets to be learned from features extracted from the corresponding 100-utterance transcripts. Details of the data and learning approach used for this experiment, as well as empirical results, are described in the remainder of this section.

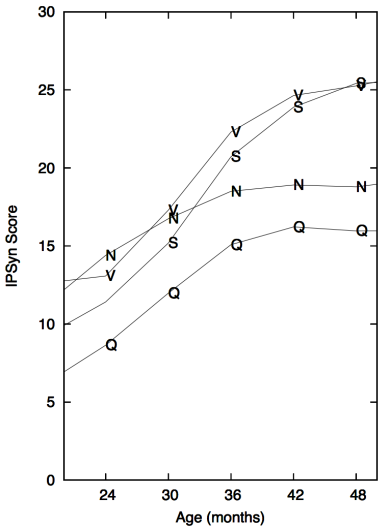
3.1 Generating IPSyn data

To obtain enough child language transcripts in a wide range of ages to test our hypothesis, we turned to the CHILDES database. To generate training and development sets for our experiments, we used transcripts from CHILDES of 14 different children with ages ranging from 1 year 1 month to 8 years. Because each application of IPSyn requires only 100 child utterances, transcripts were split, producing a total of 593 transcripts, each containing 100 utterances. The 14 children in our dataset came from the following CHILDES corpora: Brown, MacWhinney, Sachs and Warren. The reason for choosing these corpora is that they were quickly identified as containing spontaneous natural interactions, as opposed to reading or specific games and activities designed to elicit a certain kind of language production. It is likely that other corpora in CHILDES would also suit our purposes, but the data in these four corpora was sufficient for our experiments. Each of the 593 transcripts was assigned an IPSyn score automatically. From the Brown, MacWhinney and Sachs corpora, we used transcripts from a total of four children (Adam from Brown, Mark and Ross from MacWhinney, and Naomi from Sachs), from whom language data was collected over several years. Transcripts from these three corpora, 572 in total, served as our training set. The Warren corpus includes data from ten children with ages ranging from 1;6 to 6;2 (that is, 1 year and 6 months to 6 years and 2 months, using the commonly accepted age notation for this type of data), from which we created 21 transcripts that served as our development set.

The complete set of 593 transcripts with IPSyn scores gives us the opportunity to verify whether the language development curves observed by Scarborough (1990) averaged over 75 transcripts in the original IPSyn study matches curves produced from averaging results from 593 transcripts from entirely different subjects. Figure 1 shows a side-by-side comparison between the original figure from (Scarborough, 1990) and a corresponding figure generated with our automatically scored transcripts. Although not identical, the two figures are remarkably similar, reflecting that aspects of the emergence of grammar in child language development are shared across children, and that IPSyn captures some of these aspects.



(a) Original IPSyn study.



(b) Automatically generated.

Figure 1: Comparison between the IPSyn development curves for the four subscales in (a) the 75 transcripts in the original IPSyn study (reproduced from (Scarborough, 1990)), and (b) our set of 593 transcripts scored automatically.

Finally, we used the Garvey corpus to generate a test set. This corpus includes data from 48 different children with ages ranging from 2;10 to 5;7, from which we extracted 60 transcripts covering all 48 children and the full range of ages in the corpus. No data from the 48 children in the Garvey corpus, which we used as a test set, were used for training or development of the models used in our experiments.

3.2 A regression model for IPSyn

Given 593 pairs of transcript and IPSyn score, we approached the task of learning a data-driven model for IPSyn scoring as one of regression. For each transcript, a set of features is extracted, and the IPSyn score is associated with that feature vector. The features extracted from the transcripts followed four templates, described in the next subsection. If an accurate function for predicting IPSyn scores from these feature vectors can be learned, our hypothesis that these features are at least expressive enough to track child language development as well as the inventory of IPSyn structures is confirmed. To learn our model, we used the SVM Light[1] implementation of support vector regression (Drucker et al., 1997).

3.3 Features

An important step in learning a regression model for IPSyn is choosing what features to use. To support our goal of language independence, we decided not to consider language specific features that have been shown to be useful in this task but are language dependent[2], and opted instead to see whether the use of only simple parse tree features would be sufficient. The only prerequisite for extraction of our feature set is that each transcript must be parsed to produce a syntactic dependency tree. We used the CLAN tools for morphology analysis (MOR), part-of-speech tagging (POST) and parsing (MEGRASP)[3], since it is straightforward to process CHILDES transcripts using those, and they provide high-accuracy analyses for child language transcripts. The accuracy of the MEGRASP dependency parser for child utterances in English is estimated to be close to 93% (Sagae et al., 2010).

All of the features used in our model are extracted from parse trees according to four simple classes that target the following information:

[1] http://svmlight.joachims.org/

[2] This is in contrast to, for example, the related work of Sahakian and Snyder (2012), which we discuss in section 5.

[3] Models for MOR and POST are available for a wide variety of languages. Models for MEGRASP are available only for English and Japanese, but our data-driven approach is not tied to any specific tagger or parser.

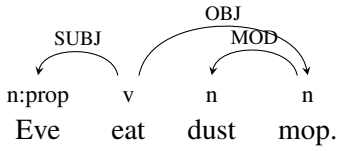


Figure 2: A dependency tree generated with part-of-speech and grammatical relation information.

Part-of-speech tags: The first type of feature we used is simply the part-of-speech tag of each word. This can be thought of as a bag of part-of-speech tags. We intentionally avoided the commonly used bag-of-words, because our goal is to obtain a model that tracks changes in syntax structure, not content. Although it is highly likely that lexical features would be very informative in this learning task, they would be useful for the wrong reason: our model is intended to target the emergence of *syntax*, and not what children talk *about* at different ages. We note, however, that as with the Penn Treebank tagset, the tags used by MOR and POST also reflect morphology, so that information is accounted for. The full tag set is listed in (MacWhinney, 2000).

Grammatical relations: The second feature class in our model is a bag of dependency labels, where each label correspond to a grammatical relation that holds between two words in the dependency tree (the head word and the dependent word). The full set of grammatical relations is listed in (Sagae et al., 2010).

Head-dependent part-of-speech pairs: Our third feature class is based on pairs of part-of-speech tags, where each pair corresponds to a bilexical dependency relation in the parse tree, and one of the tags comes from the head in the dependency, and the other tag comes from the dependent.

Head-relation-dependent triples: The last feature class is similar to the head-dependent pairs described above, but also including the dependency label that indicates the grammatical relation that holds between the head and dependent words. Features in this class are then triples composed of a head part-of-speech tag, a dependent part-of-speech tag, and a dependency label.

As an example, given the parse tree shown in Figure 2, the following features would be extracted:

```
n:prop v n n
SUBJ OBJ MOD
v_n:prop v_n n_n
v_n:prop_SUBJ v_n_OBJ n_n_MOD
```

Features are extracted for every tree in each transcript. Because our goal is to measure grammatical development in child language, these four feature templates were designed to capture the grammatical relations represented in dependency trees, while leaving out the content reflected in specific lexical items. While the content of what is said may be related to language development, our features are intended to focus on syntactic information, covering exactly each of the labeled arcs and the part-of-speech tags in a dependency tree (Figure 2) with the words removed. We also experimented with part-of-speech tag bigrams (pairs of adjacent part-of-speech tags), and dependency chains formed by two dependency arcs. The final choice of the four templates described above was based on results obtained on development data.

3.4 Data-driven IPSyn evaluation

We trained a support vector regression model using our training set of 572 transcripts, using a polynomial kernel and tuning the degree d and the regularization metaparameter C on the development set. While the default C and d values resulted in a mean absolute error of 6.6 points in the score predictions in the development set, setting $C = 1$ and $d = 3$ resulted in a mean absolute error of 4.1 on the development set. We used these values for the rest of our experiments. The mean absolute error obtained on our

test set of 48 children (60 transcripts) not used in training or tuning of the system was 3.9. When applying our regression model to the manually scored set of 20 transcripts used by Sagae et al. (2005), the mean absolute difference was 4.2 from the scores computed automatically using the approach in section 2.1, and 5.4 from the manually computed scores, which we consider our gold standard target. Compared to these manually computed scores, the absolute difference of 5.4 is higher than what we obtained using carefully designed templates based on the IPSyn inventory, but still within the range of variability expected for trained human scorers (Scarborough, 1990). It is important to keep in mind that the goal of this experiment was not to improve on the accuracy of previous automatic scoring programs, which work quite differently by listing manually crafted patterns over parse trees, but to show that a scoring function can be learned in a data-driven way, without manually crafted patterns. The results obtained with our regression model do confirm our hypothesis that simple features extracted from parse trees are enough for tracking child language development in the same way as the much more complex patterns included in IPSyn.

4 Age prediction

Given the ability of our data-driven approach to approximate IPSyn scores, confirming that a regression approach with parse tree features is capable of capturing the progression of language development, we now turn to the question of whether the same type of data-driven framework can be used to track child language development without the need for a metric such as IPSyn.

Assuming only that language acquisition progresses monotonically over time, we can apply the same data-driven regression approach to predict a child's age given a language sample. This task was approached recently by Sahakian and Snyder (2012), who used an ensemble of existing metrics with a few additional features. Unlike in our approach, Sahakian and Snyder do include lexical features and hand-selected patterns in the form of an existing metric (D-level). They make the reasonable argument that the task of age prediction is child-dependent, and that prediction across children would not make sense due to individual variation in the rate of language development. Following Sahakian and Snyder, we first approach age prediction as a child-specific task, but then discuss the application of our regression models for other children than those used for training.

4.1 Child-specific age prediction

To determine whether our data-driven regression approach can model the development of individual children at the level where accurate age predictions can be made, we used the same feature templates described in section 3.3, but trained a regression model to predict age in months, rather than IPSyn scores. Because this is a child-specific prediction task, we train separate regression models for each child. We tested our age predictions using 10-fold cross-validation for three children from three different CHILDES corpora (Adam from Brown, Ross from MacWhinney and Naomi from Sachs) for whom enough data was available over a wide enough range of ages. In each case the regression approach performed well. Table 1 shows the mean absolute error in months for each child, and the Pearson r for the correlation between predicted age and actual age.

Child (corpus)	Mean Abs Err	Pearson (r)
Adam (Brown)	2.5	0.93
Ross (MacWhinney)	3.7	0.84
Naomi (Sachs)	3.1	0.91

Table 1: Regression results for single corpus age prediction ($p < 0.0001$ for all r values.)

Perhaps more interesting than the strong correlations between actual age and predicted age for each of the individual corpora is a comparison of these correlations to correlations between age and MLU, and age and IPSyn score. One main general criticism of MLU is that it fails to correlate well with age for older children (around three to four years old). More detailed metrics such as IPSyn are believed to have better correlation with age after that point. We do observe this situation in our data. Interestingly, our

predicted age scores have much stronger correlations to actual age for older children, which suggests that our regression approach with simple syntactic features is more expressive in tracking syntactic development in older children than either MLU or IPSyn. This is shown in Table 2, which contains Pearson r correlation coefficients for age and MLU, age and IPSyn, and age and predicted age using our regression approach.

Child (corpus)	MLU r	IPSyn r	Regression r
Adam (Brown)	$0.37^{\dagger}$	$0.53^{\dagger}$	$0.85^{\dagger}$
Ross (MacW)	0.19	0.34^{*}	$0.79^{\dagger}$
Naomi (Sachs)	0.27	0.52	$0.82^{\dagger}$

Table 2: Pearson correlation coefficients between actual age and MLU, actual age and IPSyn score, and actual age and predicted age, for children at least three years and four months old. $^{\dagger}p < 0.0001$. $^{*}p < 0.05$.

The results shown in Table 2 confirm that features extracted from parse trees alone can offer substantially better prediction of age for individual children than MLU or even IPSyn scores. This is not surprising, given that weights for these features are optimized to predict age using data from the specific child and discriminative learning, but it does show that these features offer enough resolution to track syntactic development in child language, confirming our second hypothesis.

4.2 Pilot experiment with Japanese language data

A great advantage of using a data-driven framework based on simple feature templates rather than a traditional approach for measuring syntactic development with manually crafted lists of grammatical structures is that the data-driven approach is, in principle, language-independent. The same features described in section 2.1 could be extracted from dependency parse trees in any language, assuming only that these dependency trees can be produced automatically. Syntactic dependency parsers and treebanks are in fact available for a variety of languages (Buchholz and Marsi, 2006; Nivre et al., 2007). Although the availability of treebanks that include child language samples is certainly desirable, it is not clear whether it is strictly required in order to generate the syntactic structures used in our approach. While Sagae et al. (2005) and Hassanali et al. (2014) obtained high levels of accuracy in IPSyn scoring using the Charniak (2000) parser with a model trained on the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1993), we have not verified the effects of parser errors in our data-driven approach. Of course, the language independence claim applies only to the ability to measure syntactic development within different languages, and direct numerical comparisons across languages are not meaningful, since the available syntactic annotations for different languages follow different conventions and syntactic theories.

Although a full empirical validation of our regression approach in other languages is left as future work, we performed a pilot experiment with a single Japanese child that suggests our findings may be robust across languages. We used transcripts from the child Ryo, from the Miyata corpus of the Japanese section of the CHILDES database[4]. We extracted 80 transcripts of 100 utterances each, covering ages 1;10 (22 months) to 3;0 (36 months). These transcripts were analyzed with the Japanese version of the MEGRASP parser for CHILDES transcripts at an estimated accuracy of 93% (Miyata et al., 2013). Using the exact same experimental settings and feature templates as for English, we performed a 10-fold cross-validation for age prediction using the Japanese data. We obtained a strong correlation between predicted age and actual age, with $r = 0.82$ ($p < 0.0001$). Although this value is slightly lower than the values in Table 1 for English, the range of target values (age in months) is more compressed. Although this experiment included only one child, it does suggest that our approach may work well for Japanese.

5 Related work

Within the literature on assessment of child language development, the metric most closely related to our work is the Index of Productive Syntax (Scarborough, 1990), which we discussed in more detail in

[4]http://childes.psy.cmu.edu/data/EastAsian/Japanese/Miyata/

section 2, and used as a target for data-driven learning. Other traditional metrics include Developmental Sentence Scoring (Lee and Canter, 1971), Language Assessment Remediation and Screening Procedure (Fletcher and Garman, 1988), and D-level (Parisse and Le Normand, 1987) all of which share with IPSyn the reliance on a hand-crafted inventory of grammatical structures meant to be identified manually in transcribed child language samples.

Each of these metrics for child language development, along with the Mean Length of Utterance (Brown, 1973), can be computed semi-automatically using the Computerized Profiling system (Long et al., 2004). Although fully automatic computation with Computerized Profiling produces levels of reliability lower than that of manual scoring, the system can be used with human intervention to produce results of higher quality. More closely related is the work of Sagae et al. (2005) on automating IPSyn using patterns extracted from automatic parse trees. The work we describe in section 2.1 is closely based on that of Sagae et al., which we use as a way to validate our data-driven approach.

Roark et al. (2007) examined the ability of several automatically computed syntactic complexity metrics to discriminate between healthy and language impaired subjects. Among other metrics, Roark et al. used Frazier scoring (Frazier, 1985) and Yngve scoring (Yngve, 1960), which are more commonly associated with processing difficulty than with emergence of syntax in child language development, but are related to our approach in that they are based on straightforward generic features of parse trees (depth, node count), like our counts of grammatical relation labels. Finally, Sahakian and Snyder (Sahakian and Snyder, 2012) have also approached the problem of learning automatic metrics for child language development using a regression approach. Their focus, however, was on the combination of the existing metrics MLU, mean depth of tree (similar to Yngve scoring mentioned above) and D-level, along with a few hand-picked features (counts of certain closed-class words, ratio of function words to content words, and average word frequency), to achieve better discrimination than any of these metrics or features alone. A key difference between our approach and that of Sahakian and Snyder is that their approach builds on and assumes the existence of a metric such as D-level, which, like IPSyn, includes a carefully designed language-dependent inventory of language structures, while we use only simple feature templates applied to parse trees. In addition, they include vocabulary-centric features, while we explicitly avoid vocabulary features, focusing on structural features. It is possible that Sahakian and Snyder's approach would benefit from the parse tree features of our approach, either by using the features directly, or by taking a score obtained by our approach as an additional feature in theirs.

6 Conclusion and future work

We presented a framework for assessment of syntactic development in child language that is completely data-driven, and unlike traditional metrics such as IPSyn, LARSP and D-level, does not rely on a language-dependent inventory of language structures chosen specifically for the task. Instead, our approach is based on the application of support vector regression with simple features extracted from syntactic parse trees. In our experiments we used dependency parses produced by the MEGRASP parser for CHILDES transcripts, but it is likely that other modern dependency and constituent parsers would provide similar results. We showed that our framework is capable of learning IPSyn scores, and that for individual children it can model syntactic development well after MLU and IPSyn scores fail to correlate with age.

Having shown that the feature templates described in section 2.1 are as expressive as the inventory of grammatical structures in IPSyn at tracking language development, and that syntactic development of individual children can be modeled using our data-driven framework in complete absence of an existing metric such as IPSyn, it is interesting to consider the applicability of this framework to different languages for which child language development metrics have not been developed or are not widely used. One possible way to do this is to train several age regression models representing different development profiles. In most practical scenarios, the child's age is known and would not need to be predicted by a model. By predicting age with several different models and selecting the one that most closely predicts the child's actual age, a language development profile matching the child can be found. This could be used, for example, in diagnosis of language impairment. In this paper we established only the expressive

power of regression using simple syntactic features, and the application of this approach to practical tasks is left as an interesting direction for future work.

A related direction for future work is the application of this method for assessment of syntactic development in languages other than English. Given the availability of child language data in various languages (MacWhinney, 2000) and recent progress in syntactic analysis for many of these languages (Buchholz and Marsi, 2006; Nivre et al., 2007), we are optimistic about the applicability of our approach to other languages. Preliminary results using data from one Japanese child suggest that the same set of simple feature templates can be used to track language development in Japanese.

Abstract

Although semi-supervised model can extract the event mentions matching frequent event patterns, it suffers much from those event mentions, which match infrequent patterns or have no matching pattern. To solve this issue, this paper introduces various kinds of linguistic knowledge-driven event inference mechanisms to semi-supervised Chinese event extraction. These event inference mechanisms can capture linguistic knowledge from four aspects, i.e. semantics of argument role, compositional semantics of trigger, consistency on coreference events and relevant events, to further recover missing event mentions from unlabeled texts. Evaluation on the ACE 2005 Chinese corpus shows that our event inference mechanisms significantly outperform the refined state-of-the-art semi-supervised Chinese event extraction system in F1-score by 8.5%.

1 Introduction

An event is a specific occurrence involving arguments (participants and attributes) of the specific roles. In an event, trigger is the main word which most clearly expresses its occurrence, so recognizing an event can be recast as identifying a corresponding trigger. An event may have several arguments, which are entity mentions (e.g., person name, time, location, etc.) and must fulfill the corresponding roles. Take the following sentence as an example:

S1: On the 25th Dec. (A1: *Artifact*), peacekeepers (A2: *Artifact*) **returned** (E1: *Transport*) to Amman (A3: *Place*) by flight (A4: *Vehicle*).

For this example, an event extraction system should identify one event mention E1, which is triggered by verb "returned" whose event type is *Transport*, with four arguments, "peacekeepers", "25th Dec.", "flight", and "Amman", fulfilling the roles of *Artifact*, *Time*, *Vehicle*, and *Place*, respectively.

Automatically extracting events from free texts is a higher-level Information Extraction (IE) task, which is still a challenge due to the complexity of natural language and the domain-specific nature, especially in Chinese for its specific characteristics. In particular, most of previous studies have focused on English event extraction, while only a few concern Chinese.

Currently, supervised learning models have dominated event extraction. To reduce the labeled data required, a few semi-supervised models have been applied to English event extraction (e.g., Riloff 1996; Yangarber et al., 2000; Stevenson and Greenwood, 2005; Huang and Riloff, 2012). Since classifier-based model needs dozens of annotated documents to train model, most of previous semi-supervised models focused on pattern-based approach, which only needed a few seed (event) patterns. In those pattern-based approaches, frequent event patterns, which occur in many documents, were chosen as relevant patterns to match event mentions in unlabeled texts. However, the order of words in a Chinese sentence is rather agile for its open and flexible structure, and different orders might express the same meaning due to the semantics-driven nature of the Chinese language. This results in the diversity of Chinese event patterns and numerous infrequent patterns, even some event mentions having no matching patterns. Hence, it is an issue to extract the event mentions with infrequent patterns.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2161–2171, Dublin, Ireland, August 23-29 2014.

In this paper, we first implement a pattern-based semi-supervised model for Chinese event extraction as a baseline, following the state-of-the-art system as described in (Liao and Grishman, 2010a) and then refine this model to suit Chinese event extraction. Moreover, we propose various kinds of novel linguistic knowledge-driven event inference mechanisms to address the above issue and recover missing event mentions. These event inference mechanisms can capture the linguistic knowledge from semantics of argument role, compositional semantics of trigger, consistency on coreference events and relevant events. Evaluation on the ACE 2005 Chinese corpus shows that our event inference mechanisms dramatically outperform the baseline.

The rest of this paper is organized as follows. Section 2 overviews related work. Section 3 presents the refined semi-supervised model for Chinese event extraction. Section 4 proposes several linguistic knowledge-driven event inference mechanisms. Section 5 reports and analyzes the experimental results. Finally, we conclude our work in Section 6.

2 Related Work

Almost all previous semi-supervised models focus on English event extraction, which can be subdivided into pattern-based models (e.g., Riloff, 1996; Yangrber et al., 2000; Liao and Grishman, 2010a; Chambers and Jurafsky, 2011; Balasubramanian et al., 2013) and classifier-based models (e.g., Chieu et al., 2003; Maslennikov and Chua, 2007; Patwardhan and Riloff, 2009; Liu and Strzalkowski, 2012; Wang et al., 2013). Classifier-based models normally require a small set of annotated data (e.g., 100 annotated documents), while pattern-based models need dozens of high quality seed patterns.

Riloff (1996) first divided unlabeled documents into irrelevant and relevant documents, and the latter was much likely to contain further relevant patterns. Then event patterns from relevant documents were generated by using an annotated data and a set of heuristic rules. Yangarber et al. (2000) proposed a document-centric view to boost a semi-supervised event extraction system, which assumes relevant documents always contain some shared patterns. Yangarber (2003) further introduced multiple learners into the bootstrapping procedure to make the final decision on the combination of multiple learners on distinct event types. Huang and Riloff (2012) employed role-identifying nouns, which proposed by Phillips and Riloff (2007), as seed terms to extract patterns from relevant documents and then generated the labeled instances to train three classifiers in their event extraction system.

As an alternative, Stevenson and Greenwood (2005) proposed a pattern similarity-centric view and selected relevant patterns on similarity scores. Normally, bootstrapping on the document-centric view tends to accept the irrelevant patterns with a high occurrence frequency in relevant documents. To address this problem, Liao and Grishman (2010a) introduced a pattern similarity metric into the document-centric view as a filter to eliminate those irrelevant patterns. Liao and Grishman (2011) further applied an information retrieval mechanism to detect relevant documents and proposed a self-training strategy for bootstrapping.

In addition, several studies focused on the event pattern representation, such as pairwise (e.g., Subject-Verb, Verb-Object) (Chambers and Jurafsky, 2008, 2009), SVO (Subject-Verb-Object) (Yangarber, 2000; Balasubramanian et al., 2013), chain (Sudo et al., 2001), subtree (Sudo et al., 2003) and complex pattern (Liu and Strzalkowski, 2012).

In the literature, only one paper concerns semi-supervised Chinese event extraction. Chen and Ji (2009a) applied various kinds of cross-lingual features in the bootstrapping procedure to extract Chinese event. With the help of over 500 annotated seed event mentions in 100 documents, they only achieved 35% in F1-score. This indicates the critical challenge in semi-supervised Chinese event extraction.

Only a few studies concern event inference mechanisms. Ji and Grishman (2008) employed a rule-based approach to propagate consistent triggers and arguments across topic-related documents. Liao and Grishman (2010b) employed cross-event consistent information to improve sentence-level event extraction. Hong et al. (2011) regarded entity type consistency as a key feature to predict event mentions and adopted an information retrieval mechanism to promote event extraction. Li et al. (2013) proposed a global argument inference model on Chinese argument extraction to explore specific relationships among relevant event mentions to recover those inter-sentence arguments in the sentence, discourse and document layers. Li et al. (2014) also introduced Markov Logic Network (MLN) to capture the discourse-level consistency between Chinese trigger mentions to further recover those poor-

context event mentions. In a word, all of above mechanisms focus on supervised event extraction and no literature involves in the event inference of semi-supervised event extraction.

3 Semi-supervised Model for Chinese Event Extraction

In this section, we refine a semi-supervised model for Chinese event extraction as a baseline, which includes two views, the document-centric view and pattern similarity-centric view.

3.1 Semi-supervised Model

Liao and Grishman (2010a) proposed a state-of-the-art semi-supervised event extraction system, which was a pattern-based approach and adopted bootstrapping mechanism to extract relevant patterns. Besides, two distinct views, the document-centric view and the pattern similarity-centric view as described in Subsection 3.2 and 3.3, are incorporated in the bootstrapping procedure to rank event patterns on different metrics. In each iteration, the candidate patterns, which extracted from unlabeled texts as the candidates of relevant patterns, are ranked following the document-centric view, then the candidate patterns with pattern similarity scores below a similarity threshold (0.9 in (Liao and Grishman, 2010a)) will be removed; only top 3 candidate patterns in the ranking scores of the document-centric view will be accepted as relevant patterns. In addition, if no pattern is found in the current iteration, the threshold will be reduced by 0.1 until new relevant patterns are extracted.

As we mentioned earlier, the open and flexible structure of Chinese sentences results in the diversity of Chinese event patterns. Moreover, the syntax or semantic path is often used to represent event patterns, but the performance in Chinese syntactic parsers and Semantic Role Labeling (SRL) tools is lower than that in English. Therefore, we refine this semi-supervised model to suit Chinese event extraction in three aspects as follows, due to the above characteristics of Chinese language.

Firstly, we construct a refined event pattern representation of Chinese events. Liao and Grishman (2010a) used semantic roles to represent the relationship between the trigger and its arguments. Due to the wide spread of ellipsis (especially entities) and the relatively low performance of Chinese SRL, pairwise (trigger-entity) representation and dependency path are introduced to represent Chinese event pattern in our refined model. Hence, the event pattern in this paper is a triple-style template as follows.

<trigger, entity type, their dependency path >

A pattern is formed by a trigger, the entity type of its argument[1] and the dependency path from the trigger to the argument. For example, trigger "returned" and its argument "peacekeepers" (entity type: PER) in sentence S1 can be described as a pattern *<returned, PER, nsubj>*.

Secondly, we introduce a novel mechanism to extract candidate patterns. Since verb and noun dominate in triggering an event in Chinese and they are chosen as candidate triggers to create candidate patterns. Besides, since different event types may have different roles and different roles are fulfilled by entities with different types, the entities whose types can fulfil the core roles of a specific event are chosen as candidate entities. For example, *Attacker* and *Target* are the core roles of event *Attack* and entity types *PER/ORG/GPE*[2] can fulfil above two roles, so we only accept those entities, whose types belong to *PER/ORG/GPE*, to form candidate patterns. For each sentence in the unlabeled data, all candidate trigger-entity pairs and their dependency path are enumerated as candidate patterns.

Finally, we present a new mechanism to generate seed patterns based on seed triggers. Considering the relatively large number of Chinese triggers and the flexibility of Chinese sentences, an instance-based approach is adopted by enumerating a few high-quality seed triggers with explicit meaning and high probability to trigger a specific event. Instead of dozens of predefined patterns required in previous studies, only one seed trigger is given to each event type or subtype without any predefined patterns. Hence, all patterns consisting of a seed trigger in the candidate patterns are accepted as seed patterns for their high probability to trigger a specific event.

3.2 Document-centric View

The document-centric view regards those documents containing the patterns always identified as relevant to a specific event as relevant documents and concludes that they are likely to contain additional

[1] All event arguments must be entity mentions following the ACE 2005 annotation guidelines of events.

[2] PER/ORG/GPE refers to person, organization and geo-political entity respectively, which are annotated in the ACE 2005 corpus. These helpful information can be seen as ontological classes.

relevant patterns. Hence, those candidate patterns occurring in the relevant documents frequently will be extracted as relevant ones. Following Yangarber et al. (2000) and Liao and Grishman (2010a), we also employ the disjunctive voting scheme to calculate the ranking scores $R_{score}(p)$ of pattern p as follows.

$$R_{Score}(p) = \frac{\sum_{d \in L(p)} Rel(d)}{|L(p)|} * log \sum_{d \in L(p)} Rel(d) \quad (1)$$

where $L(p)$ is the set of documents, which contain candidate pattern p, and $Rel(d)$ is the relevance score of document d as follows.

$$Rel(d) = 1 - \prod_{p \in P} (1 - \frac{\sum_{d \in L(p)} Rel'(d)}{|L(p)|}) \quad (2)$$

where $Rel'(d)$ is the relevance score of document d in the previous iteration. Initially the relevance score of document d is set to n if document d has n relevant patterns in the set of extracted patterns P.

3.3 Pattern Similarity-centric View

The similarity-centric view tries to find the candidate patterns who are similar to those seed patterns. The similarity scores derive from two aspects, lexical similarity and syntactic similarity, while the former is based on the trigger and entity type in a pattern and the latter is based on the relation between the trigger and the entity. Especially, we realize the pattern similarity view following the lexical and syntactic similarity, and refine the similarity ranking score $I_{score}(p)$ of candidate pattern p as follows:

$$I_{score}(p) = \max_{s \in P}(WSim(t_p, t_s) \times ESim(e_p, e_s) \times DSim(d_p, d_s)) \quad (3)$$

where t, e and d represent the trigger, entity type and dependency path in candidate pattern $p(t_p, e_p, d_p)$ or seed pattern $s(t_s, e_s, d_s)$ in the set of extracted patterns P, respectively; *ESim* identifies whether two entities have the same type, and assigned 1 if two entities have the same entity type and otherwise a small number 0.1; *DSim* calculates the similarity between two dependency paths in edit distance. Finally, *WSim* is to obtain the trigger similarity in lexical semantics, using Hownet (Dong and Dong, 2006) following Liu and Li (2002):

$$WSim(t_p, t_s) = \frac{\phi}{Dis(t_p, t_s) + \phi} \quad (4)$$

where $Dis(t_p,t_s)$ is the distance between the sememes of triggers t_p and t_s, in HowNet's sememe hierarchical architecture, with parameter ϕ assigned 0.75 following Liu and Li (2002).

4 Event Inference

The pattern-based semi-supervised model cannot extract those event mentions matching infrequent patterns or without matching patterns. The knowledge from linguistic aspect (e.g., definition of events, compositional semantics of Chinese words, coreference events and relevant events, etc.) is helpful to further recover missing event mentions or filter pseudo event mentions. In this section, various kinds of event inference mechanisms based on linguistic knowledge are proposed to improve the performance of semi-supervised Chinese event extraction.

We unify the semi-supervised model and the event inference mechanisms into one model as follows: In each iteration, after the top 3 patterns have been chosen following the document-centric view and event mentions in the unlabeled data have been extracted by pattern matching, all event inference

mechanisms are applied to recover missing event mentions,. Due to our inference mechanisms are trigger-based and each inferred event mention may have more than one pattern while most of them are noisy, we do not add those patterns in the set of relevant patterns for bootstrapping.

4.1 Event Inference on Role Semantics

The core of an event can be expressed as "*Who do What to Whom*" in which "Who" and "Whom" are the core roles[3] to participate in an event, while "What" often refers to event trigger. The relationship between the verbal trigger and its core roles are the key clues to express event semantics. Since the subject or object always play the core roles in an event mention, SVO (Sbject-Verb-Object) is a better representation of event pattern. However, ellipsis is a widespread phenomenon in Chinese language and many sentences do not have an overt subject or object, so lots of event mentions cannot be represented as SVO pattern. In this paper, we only use the trigger-entity pair to represent event pattern and one of the disadvantages of this representation is its loose constraint on events, which will extract lots of pseudo event mentions.

In most cases in Chinese, the object is often the most important core role to identify a specific event and it is more helpful than the subject to distinguish true event mentions from pseudo ones. Take following two sentences as examples:

S2: 老师(PER) **打(hit)**了 这个学生(PER)。(The teacher **hit** this student.)

S3: 老师(PER) **打(call)**了 电话 给 这个学生(PER)。(The teacher made a phone **call** to this student.)

The relation between verb 打 (hit) and object 这个学生 (this student) is clear to indicate sentence S2 is an *Attack* event mention since the object is a person, while object 电话 (phone) in sentence S3 is not a person and it indicates this sentence is not an *Attack* event mention following the sense of verb 打 (call). Therefore, the object is an effective evidence to indicate event mentions and it is incorporated in our model to remove pseudo event mentions as follows.

Role Semantics: If the object of a candidate verbal trigger mention is not an entity or its entity type cannot fulfil the object roles (e.g., *Victim* in events *Injure* and *Die*) in a specific event, this candidate trigger mention[4] will be inferred as pseudo one.

For example, core role *Target* of event *Attack* often acts as the object of a verbal trigger and entity types PER, ORG and GPE can fulfill this role according to be definition of event *Attack* in the ACE 2005 corpus. Hence, a candidate trigger mention of event *Attack* will be regarded as pseudo one when this mention has an object which is not an entity or whose entity type is not PER, ORG or GPE.

4.2 Event Inference on Compositional Semantics

In Chinese language, a word is composed of one or more characters. Almost all Chinese characters have their own meanings and are morpheme (or single-morpheme word), the minimal meaningful unit. If a Chinese word contains more than one character, its meaning can often be derived from its composite morphemes. This more fine-grained semantics is compositional semantics of Chinese words. Actually, it is also a normal way for a native Chinese speaker to understand a new Chinese word.

Two-morpheme words are used widely in Chinese language and almost all Chinese triggers contain one or two morphemes. The compositional semantics of a two-morpheme word comes from both its morphemes and morphological structure. Besides morphological structure *Coordination*, all other morphological structures (e.g., *Modifier-Head, Predicate-Object, Predicate-Complement* (Li and zhou, 2012)) always have one head morpheme, the morpheme as the governing semantic element, to express the meaning of a word. Commonly, there are two head morphemes in a two-morpheme word of *Coordination* structure. In particular, a two-morpheme word triggers an event if its two head morphemes are homogeneous (e.g., 攻(attack)击(attack), 死(die)亡(die)). Otherwise, it may refer to more than one event and this means that two triggers are within a word whose morphological structure is *Coordination*. Take the following sentence as an example:

[3] We select core roles following the ACE Chinese annotation guidelines of events. *Agent/Victim* are the core roles of events *Die/Injure* while *Attacker/Target* are the core roles of event *Attack*.

[4] Recognizing a trigger mention can be recast as identifying a corresponding event mention, since trigger is the main word which most clearly expresses the occurrence of an event.

S4: 一名少年**刺**(E2: *Attack*)**死**(E3: *Die*)一名妇女。(A younger **stabbed** (E2: *Attack*) a woman to **death** (E3: *Die*).)

In S4, two-morpheme word 刺死 (stab a person to death) is a trigger with the *Coordination* structure. There are two event mentions in sentence S4, one *Attack* (E2) and one *Die* (E3), while morpheme 刺 (stab) triggers an *Attack* event and 死 (die) refers to a *Die* one.

Almost all event extraction systems assigned only one event type to a trigger and this will lead to that the other event type does not have any patterns to match and then cannot be identified. To address this issue, we first identify those triggers who refers to two distinct events as follows: for each two-morpheme candidate trigger in the candidate patterns whose morphemes are m_1 and m_2, it will be identified as candidate trigger with two event types and split into two single-morpheme word to generate two candidate trigger mentions when the following three conditions are satisfied:

1) $verb \in POS(m_1) \wedge verb \in POS(m_2)$
2) $\underset{s_1 \in seeds}{Max}(Wsim(m_1, s_1)) = 1 \wedge \underset{s_2 \in seeds}{Max}(Wsim(m_2, s_2)) = 1 \wedge Etype(s_1) \neq Etype(s_2)$
3) $Morph(m_1\ m_2) = Coordination$

where *POS(m)* returns all possible parts of speech of morpheme *m* in Hownet and *Etype(s)* is to obtain the event type of seed trigger *s*; *WSim(m,s)* is defined in Subsection 3.3 and returns 1 when one word *m* is the synonym of the other word *s*; *Morph(w)* is to obtain the morphological structure of word *w* following Li and Zhou (2012).

Since there is a strong trigger consistency in those two-morpheme words of *Coordination* structure which refers to two distinct events, we propose an event inference mechanism as follows.

Compositional semantics: For each two-morpheme word identified by the above three conditions, if one of its morphemes has been extracted as an trigger mention of a specific event type, the other morpheme in the same word will refer to an a relevant event type.

4.3 Event Inference on Coreference Events

To mine more event mentions, we use the simple trigger-entity pair to represent event pattern in this paper. However, lots of event mentions still cannot be extracted due to the ellipsis of arguments. Take following sentences as examples:

S5: 美国与北韩在吉隆坡结束**会谈**(E4: *Meeting*)。(The US and DPRK finished **talking** (E4: *Meeting*) in Kuala Lumpur.)

S6: **会谈**(E5: *Meeting*)的气氛严肃。(The **talks** (E5: *Meeting*) are serious.)

Obviously, more than one pattern of event mention E4 can be generated from sentence S5, since it contains more than one entity. On the contrary, no pattern can be extracted from S6 and this leads to event mention E5 cannot be extracted in our pattern-based semi-supervised model.

Within a document, almost all event mentions are around a topic and there is a strong trigger consistency: if one mention of a word triggers a specific event, its other mentions in the same document will refer to the same event type. Besides, similar words (e.g., 炸 (bomb), 爆炸 (bomb), 轰炸 (bomb)), which contains the same head morpheme, always express the same or similar meaning following the principle of compositional semantics. Similarly, there is a strong trigger consistency on those similar words: If one mention of a word refers to a specific event, the mentions of its similar words in the same document will trigger events of the same type.

Since the mentions of the same word or similar words are often coreference ones and always refer to the same event type, we propose an event inference mechanism on coreference events to recover missing event mentions based on head morpheme as follows. In particular, head morphemes are also identified following Li and Zhou (2012).

Coreference events: 1) if a mention of a candidate trigger refers to a specific event, all its other mentions in the same document will trigger the same type event; 2) if one mention of a candidate trigger refers to a specific event, all the mentions of its similar words in the same document will trigger the same type event too.

4.4 Event Inference on Relevant Events

The bootstrapping procedure of the document-centric view selects frequent patterns in relevant docu-

ments and ignores those infrequent patterns both in relevant or irrelevant documents. However, the number of infrequent patterns in Chinese is larger than that in English, due to its open and flexible sentence structure, as mentioned in Subsection 3.1.

Besides the pattern-based semi-supervised model, we propose a trigger-based mechanism as a supplement to recover those missing event mentions concerning infrequent patterns following this assumption: if a trigger mention refers a specific event in a document, there is a high probability that its relevant events occur in the same document. Take the following sentence as an example:

S7: 在**冲突**(E6: *Attack*)中，有 *1 名阿拉伯人***死亡**(E7: *Die*)。(An Arabian was **dying** (E7: *Die*) in this **conflict** (E6: *Attack*).)

In sentence S7, there is an extracted *Die* event mention E7 triggered by 死亡 (die) and 冲突 (conflict) is a candidate trigger mention. If there is an evidence that 冲突 (conflict) triggers an *Attack* event in the other documents, it is possible to identify 冲突 (conflict) as a trigger mention of *Attack* event in S7 for the high probability that events *Die* and *Attack* occur in the same document. We propose an inference mechanism on relevant events as follows.

Relevant Events: If a trigger mention is identified in a document, each candidate trigger mention in the same document will be recognized as true ones when it satisfies the following condition: this candidate trigger occurs in the other documents as an event trigger and refers to the relevant events of this identified trigger mentions.

Since the seed triggers have a high probability to trigger a specific event, to further explore those missing event mentions, we expand this inference mechanism following compositional semantics in Chinese and expand the condition as follows: This candidate trigger occurs in the other documents as an event trigger or contains one of the seed triggers, which refers to the relevant events of this identified trigger mentions.

5 Experimentation

In this section, we systematically evaluate our event inference mechanisms on the ACE 2005 Chinese corpus and provide the analysis.

5.1 Experimental Setting

The ACE 2005 Chinese corpus is the only available corpus in Chinese event extraction and it is used in all our experiments. This corpus contains 633 documents annotated with 33 predefined types. Due to evaluation on all 33 types is a hard work for the time-consuming bootstrapping procedure and the diversity of distinct event types, most of previous works selected part of event types for evaluation. In this paper, 3 event types (i.e. *Die*, *Injure* and *Attack*) are selected for evaluation, because they reflect the relevance of different event types and occur at different frequencies in the corpus. While events *Die* and *Injure* are easy to define, event *Attack* is rather complicated and can be divided into several subtypes. In the ACE 2005 Chinese corpus, almost one third of the annotated event mentions belong to the above three event types. Moreover, we report the experimental results on all 33 event types to further verify the effectiveness of our inference mechanisms in Subsection 5.2.

Unlike MUC shared task, which only distinguishes whether a sentence contains a specific event mention or not, we follow previous studies on the ACE 2005 corpus and report the performance of trigger-based event extraction: a trigger is correctly identified if its position and event type match a reference trigger. As for evaluation, we use the ground truth entities, time and values annotated in the ACE 2005 Chinese corpus, and report the micro-average Precision (P), Recall (R) and F1-score (F1).

Table 1 shows the seed triggers for the three event types. For example, only one seed trigger is provided for either the *Die* or *Injure* event, while three seed triggers are given for event *Attack.* Since the *Attack* event contains several distinct event subtypes, we assign one seed trigger to each of its major subtypes. Thus, all patterns whose triggers belong to the set of seed triggers are accepted as seed patterns automatically.

Type	Die	Injure	Attack
Seed triggers	死(die)	伤(injure)	攻击(attack), 冲突(conflict), 打(hit)

Table 1. Seed triggers of *Die*, *Injure* and *Attack* event types

Besides, all the sentences in the corpus are divided into words using a Chinese word segmentation tool (*ICTCLAS*) with all entities annotated in the corpus kept. We use *Berkeley Parser* and *Stanford Parser* to create the constituent and dependency parse trees.

5.2 Experimental Results

To verify the performance of our event inference mechanisms, it is compared with the refined baseline, a supervised model for Chinese event extraction. Table 2 shows the results of our event inference mechanisms with peak recall, precision and F1-score, following Liao and Grishman (2010a). Compared with the baseline, Table 2 shows that our event inference mechanisms improve the F1-score of Chinese event extraction by 8.5%, largely due to the improvement of 11.8% in recall. These results confirm the effectiveness of our event inference mechanisms in recovering missing event mentions. The disadvantage of our event inference mechanisms is the fact that it will also introduce some pseudo event mentions into our model and harm the precision. Additionally, there is still a big performance gap between our model and the supervised model and this leaves much room for future research.

Approach	Attack			Injure			Die			All (micro-average)		
	P(%)	R(%)	F1	P(%)	R(%)	F1	P(%)	R(%)	F1	P(%)	R(%)	F1
Baseline	**71.4**	36.6	48.4	**93.2**	41.7	57.6	**90.1**	44.0	59.3	**79.7**	39.4	52.7
+Event inference	70.9	**47.5**	**56.9**	83.2	**54.6**	**65.9**	80.8	**57.2**	**67.0**	75.5	**51.2**	**61.2**
Supervised model	*70.4*	*72.5*	*71.4*	*85.3*	*78.4*	*81.7*	*83.9*	*92.9*	*88.1*	*77.2*	*78.4*	*77.8*

Table 2. Performance of event inference mechanisms in Chinese event extraction *(Attack/Injure/Die*).

Table 2 also indicates the performance difference of our inference mechanisms for distinct event types. Among all event types, event *Attack* achieves the highest improvement (8.5%) in F1-score, with a dramatic improvement of 10.9% in recall and a less loss of 0.5% in precision. Event *Die* and *Injure* also gain a significant improvement of 7.7% and 8.3% in F1-score respectively, largely due to the increase in recall, while their precisions reduce rapidly due to those pseudo event mentions inferred by our inference mechanisms. However, the loss of precision of event *Attack* is much less than these of events *Die* and *Injure*. The reason is that the inference on role semantics mainly impacts on *Attack* events to remove pseudo event mentions.

To well evaluate different approaches, it is better to compare them on different corpora. Since the ACE 2005 Chinese corpus is the only available corpus in Chinese event extraction, we divide it into three sub-corpora according to data sources, i.e. Broadcast News, Newswire and WebLog, which are much different in various aspects, such as quality, length and style. Figure 1 compares the performance of different models on different sub-corpora. It indicates that our event inference mechanisms perfect better than the baseline in all three sub-corpora and that results confirm the huge influence of the event inference mechanisms. It also shows that the WebLog sub-corpus reports the worst F1-score due to the low document quality and the low percentage of relevant documents, and that the Newswire sub-corpus reports significantly better performance than the Broadcast News sub-corpus due to its spoken nature.

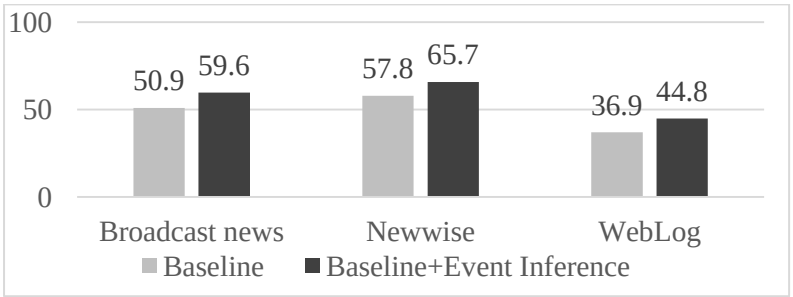

Figure 1. Performance comparison (F1-score) on different data sources.

To further verify the effectiveness of our event inference mechanisms, we evaluate them on all 33 event types. Due to event extraction is a domain-specific task, distinct event types have the different seed triggers and different pro-process procedures. In this paper, we just report the final results for the

sake of brevity. Table 3 shows the experimental results on all 33 event types and it ensures that our mechanisms are effective on extracting all event types. Compared with the baseline, our approach improves the F1-score by 7.6%, which is less than that reported in Table 2. Among all 33 event types, the performances of almost all event types associated with justice are higher than other event types for their unambiguous definitions and high coverage of seed triggers while event *Transport* achieves the lowest performance for its complexity and low coverage of seed triggers. Besides, the performance on all event types is lower than that on 3 event types and this result comes from the low performance of the *Transport* event which occupies almost 20% of all annotated event mentions in the ACE 2005 Chinese corpus.

Approach	P(%)	R(%)	F1
Baseline	**70.7**	34.2	46.1
+Event inference	65.2	**45.7**	**53.7**

Table 3. Performance of event inference mechanisms in Chinese event extraction (All 33 event types).

5.3 Analysis on Event Inference Mechanisms

Table 4 shows the contributions of the different event inference mechanisms. It is worthy to mention that an event mentions may be identified by both the semi-supervised model and the event inference mechanisms. In this paper, we attribute those extracted event mentions to the former and the contribution of our inference mechanisms is greater than those in Table 4.

Inference	P(%)	R(%)	F1
Baseline	79.7	39.4	52.7
+Inference on role semantics (**RS**)	87.5(+7.8)	39.1(-0.3)	54.1(+1.4)
+Inference on compositional semantic (**CS**)	85.7(+6.0)	43.7(+4.3)	57.8(+3.7)
+Inference on coreference events (**CE**)	83.0(+3.3)	45.8(+6.4)	59.0(+1.2)
+Inference on relevant events (**RE**)	75.7(-4.0)	51.3(+11.9)	61.2(+2.2)

Table 4. The contribution of event inference on Chinese event extraction.

Actually, inference mechanism **RS** is a filter to remove those pseudo event mentions and it can improve the precision (+7.8%), with a less lost (-0.3%) in recall. Moreover, it can also help the seed pattern generation to generate high quality seed patterns. Table 5 shows the contribution of **RS** on seed pattern generation and we report the result of Chinese event extraction which only uses the seed patterns[5]. It improves the accuracy from 75.8% to 82.5%, largely due to the decline (-30) in the set of pseudo event mentions. These results indicate that the object is a key clue to identify event mentions.

Method	#True event mentions	#Pseudo event mentions
w/o **RS**	273	87
w/ **RS**	269	57

Table 5. The contribution of **RS** on seed pattern generation.

Chen and Ji (2009b) have reported that almost 13% of Chinese triggers are in-word or cross-words and this figure ensures it is an important issue. Inference mechanism **CS** gains the highest improvement (+3.7%) in F1-score and this result indicates that compositional semantics is an effective way to solve such issue. The accuracy of this inference mechanism is very high (~92%) and most of the exceptions need the help of deep semantics since these instances are also hard to be distinguished by humans without the context.

Inference mechanisms **CE** and **RE** improve the F1-scores by 1.2% and 2.2% respectively. **CE** assumes all mentions of a word in a document only have one sense and it will introduce lots of pseudo event mentions to reduce precision. The experimental results also show that **RE** is an effective supplement of the document-centric view to mine event mentions. Although they derive from the similar

[5] Since sometimes a pattern can infer both true event mentions and pseudo event mentions, it is hard to identify whether a pattern is relevant or irrelevant without the test data. Hence, we compare their extracted event mentions in this paper.

principle of occurrence of relevant events, they focus on different perspectives where **RE** is trigger-based and the document-centric view is pattern-based. **RE** ignores the difference on patterns and identifies event mentions on the occurrence of their relevant event mentions. In addition, sense shifting of Chinese words in different contexts is the main factor to extract lots of pseudo event mentions and then reduce the precision rapidly.

It's obvious that these inference mechanisms interact with others. In particular, almost 20% event mentions can be inferred by both **CE** and **RE** for the transitivity of event inference on coreference and relevant events. Besides, **RS** is not only beneficial to the semi-supervised model, but also helpful to the other inference mechanisms to further remove pseudo event mentions.

6 Conclusion

This paper proposes various kinds of novel linguistic knowledge-driven event inference mechanisms as a supplement of the semi-supervised Chinese event extraction to recover missing event mentions. The experimental results verify their effectiveness to extract the event mentions with infrequent patterns or without matching pattern. Although this paper focuses on Chinese language, most of the event inference mechanisms are language-independent and can be applied to other languages. Our future work will focus on how to apply our event inference mechanisms to other languages and introduce more effective inference mechanisms to further improve the performance of semi-supervised event extraction.

Supervised Ranking of Co-occurrence Profiles for Acquisition of Continuous Lexical Attributes

Abstract

Certain common lexical attributes such as polarity and formality are continuous, creating challenges for accurate lexicon creation. Here we present a general method for automatically placing words on these spectra, using *co-occurrence profiles*, counts of co-occurring words within a large corpus, as a feature vector to a supervised ranking algorithm. With regards to both polarity and formality, we show this method consistently outperforms commonly-used alternatives, both with respect to the intrinsic quality of the lexicon and also when these newly-built lexicons are used in downstream tasks.

1 Introduction

Lexicon acquisition represents one key way that the information in large corpora and other resources can be leveraged in various NLP tasks, particularly when the range of lexical items involved in a particular phenomenon is much more diverse than can typically be captured in manually-built resources. Another property of the lexicon which might limit a manual approach is the fact that certain attributes are not discrete, instead falling on a continuous spectrum; although there are manually-built dictionaries which contain fine-grained judgments of spectra—an example is the MRC psychological database (Coltheart, 1980)—these tend to be very low in coverage, reflecting the difficulty in collecting this information.

Within computational linguistics, the continuous lexical attribute that has received the most attention is undoubtedly the positive-negative spectrum, otherwise known as *semantic orientation* (SO) or *polarity*. Much of the work focused on acquisition of this attribute at the lexical level has involved simplification to a binary (positive-negative) or ternary (positive-neutral-negative) distinction (Hatzivassiloglou and McKeown, 1997; Takamura et al., 2005; Kaji and Kitsuregawa, 2007; Rao and Ravichandra, 2009; Mohammad et al., 2009; Volkova et al., 2013) but other work explicitly offers a continuous quantification (Turney, 2002; Turney and Littman, 2003; Baccianella et al., 2010). Another spectrum with a prominent role in the lexicon is *formality* (Brooke et al., 2010; Lahiri et al., 2011), which includes colloquial words at one end, socially-distancing words at the other, and common vocabulary in the middle. In this paper, we will focus on these two spectra; the method presented, however, is intended to be general, and as such could be easily applied to other spectra such as those in the MRC database, e.g. abstractness (Turney et al., 2011), and other kinds of variation captured in, for instance, Osgood's semantic differential (Osgood et al., 1957).

The typical approach to this problem involves semi-supervised methods using vector space and/or graph representations and a set of seed terms. Our method is novel in that it uses fully supervised SVM ranking of co-occurrence profiles, i.e. normalized counts of instances of binary text co-occurrence between the target word and a large set of profiling words, selected on the basis of their frequency, in a publicly-available blog corpus. The seed terms from earlier methods are now viewed as training examples for building a supervised model that can connect the distributions of co-occurring words in this wider vocabulary to relative locations on a continuous spectrum. This approach depends somewhat upon improved manual lexical resources available for these tasks, such as the SO-CAL dictionary (Taboada

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2172–2183, Dublin, Ireland, August 23-29 2014.

et al., 2011) in the case of polarity, but we limit our (word) training set size in order to show it will work in resource-scarce situations, such as languages other than English. Our method is straightforward, practical, and offers essentially full coverage, including words and lexicogrammtical patterns that are simply not accessible by the many popular methods that are primarily based on WordNet.

To evaluate, we compare our method with popular alternatives in both polarity and formality, with particular emphasis on other methods based on corpus co-occurrence that have also been shown to be generalizable across various spectra, i.e. LSA and PMI. For both spectra of interest here, we evaluate both intrinsically using pairwise comparisons from manually-built lexical resources, and also extrinsically in downstream tasks such as text-level polarity classification and sentence-level formality judgments. We show our method is consistently superior across our various evaluations. We also show that not only are co-occurrence profiles a good source of information for supervised ranking, but that a focus on ranking rather than regression in this space appears to be fundamental to the success of a supervised approach to lexical spectra.

2 Related Work

Viewed primarily as a categorical task, the creation or expansion of lexical resources for sentiment analysis is a commonly-addressed problem. In addition to SentiWordNet (Baccianella et al., 2010), which we will compare to directly to here, there are numerous mostly semi-supervised approaches based on exploiting the glosses and/or the graph structure of WordNet to determine whether a word is positive or negative (Kamps et al., 2004; Hu and Liu, 2004; Kim and Hovy, 2004; Takamura et al., 2005; Andreevskaia and Bergler, 2006; Rao and Ravichandra, 2009; Hassan and Radev, 2010), or taking advantage of some other lexicographic resources (Mohammad et al., 2009; Klebanov et al., 2013). The earliest corpus-based approach was that of Hatzivassiloglou and McKeown (1997) who used local syntactic information, i.e. conjunctions, to make connections between adjectives; other work that makes use of local patterns in a corpus includes that of Kaji and Kitsuregawa (2007) and Kanayama and Nasukawa (2006). Turney (2002) built a continuous polarity lexicon using PMI based on Internet hit counts as a useful measure of relatedness between seeds, and Turney and Littman (2003) compared this approach with LSA, which uses general patterns of co-occurrence based on dimensionality reduction. Velikovich et al. (2010) combined web-scale corpora with a graph-based approach, assigning polarity scores to n-grams on the basis of the maximum weighed path from an n-gram to the seed terms, using a small (6-word) context around the word. Like us, Volkova et al. (2013) use social media, iteratively labeling tweets and words for subjectivity and polarity. Fully-supervised approaches to polarity lexicon acquisition are rare, but one example is the work of Chetviorkin and Loukachevitch (2012), who classify words as being sentiment-relevant in Russian using a small set of statistical features, including ratios across disparate corpora.

Our interest in the continuous aspect of polarity overlaps with work on deriving the semantic intensity of lexical items from corpora (Sheinman and Tokunaga, 2009); in this task, small sets of synonyms are ranked according to their intensity, including (but not limited to) polarity. De Melo and Bansal (2013) use a Mixed Integer Linear Programing algorithm to combine information from multiple pairs into a single coherent ranking. As with some of the work in polarity, the focus is on adjectives and local patterns which explicitly distinguish degrees of intensity e.g. *not only x but also y*, which limits its range of application; it would not, for instance, be useful for formality or other more pragmatic variations.

Beyond the our work in LSA-based formality lexicon creation (Brooke et al., 2010) and the sentence-level formality annotation of Lahiri et al. (2011), which we discuss later in more detail, there is a relatively small amount of computational research that directly addresses formality. At lexical level, Li and Yarowsky (2008) identify formal and informal synonyms in Chinese. Heylighen and Dewaele (2002) and Li et al. (2013) both offer text-level quantifications of formality; the former is based on POS frequency, while the latter is based on the Coh-Metrix textual metrics. Using these kinds of metrics, formality has been evaluated in social media (Mosquera and Moreda, 2012). A supervised text classification approach to formality is offered by Sheika and Inkpen (2012). Lexical formality is obviously related to lexicon-based readability (Kidwell et al., 2009) and lexical simplification (Carroll et al., 1999), and is

also relevant to the recent interest in identifying social relationships (Peterson et al., 2011) and shows of politeness (Danescu-Niculescu-Mizil et al., 2013).

3 Method

Our approach to lexicon acquisition falls into the general category of corpus-based techniques. For both attributes addressed in this paper, we use the same corpus, the 2009 ICWSM Spinn3r dataset (Burton et al., 2009), a publicly-available blog corpus which we also used in our earlier work on lexical formality (Brooke et al., 2010). Blogs are a good resource for broad lexical acquisition because they are very broad in style and content, and are available in essentially unlimited amounts. We use the English Tier 1 (high-quality) blogs that have at least 100 word types, excluding duplicate texts; after this filtering, our dataset contains a total of about 2.4 million blogs.

To build a lexicon for any continuous attribute of interest, we begin by creating *co-occurrence profiles* as follows: First, we select a document frequency range *min-df*, *max-df* that determines a set of profile words P in a corpus S, where for each $p \in P$, the document frequency df_p^S of p in S is limited to be *min-df* $< df_p^S <$ *max-df*; that is, each profile word appears in more than *min-df* documents, but fewer than *max-df* documents in our corpus. Then, given a sample size n and a target word w that we wish to profile, we sample a set of n texts from S which contain the target word (or all the documents where the word appears, if it appears fewer than n times), and count the document frequency of each profile word p in this subcorpus, T_w. We ignore the term frequencies within individual documents because a binary representation is known to be preferred for stylistic dimensions like formality (Brooke et al., 2010), and this seems to be also somewhat true in the domain of polarity, where better results can be obtained when multiple instances of a polar word are discounted (Taboada et al., 2011). To avoid overfitting our statistical model, we do not count a word as appearing with itself. Once we have sub-corpus document frequences $df_p^{T_w}$ for each p, for each profile word p we define the element of our co-occurrence profile vector $\mathbf{v}_p$ as

$$\mathbf{v}_p = \frac{df_p^{T_w}}{\sum_{q \in P} df_q^{T_w}}$$

That is, we normalize each count by the sum across all counts, such that the L1 norm of $\mathbf{v}$ is 1. For our applications here, the dimension of the co-occurrence profile vector is typically in the tens of thousands, but to illustrate the creation of this vector, suppose we choose an extremely narrow document frequency band *min-df*, *max-df*, such there were only three co-occurrence profile words: p_1,p_2,p_3. For some word w, we sample n instances of texts from our corpus which contain w, and find that p_1 appears in 10 of these texts, p_2 in 40 of them, and p_3 in 50 of them. The resulting co-occurrence profile vector is $\mathbf{v} = \langle 0.1, 0.4, 0.5 \rangle$. This profile could be viewed as a distributional vector space representation of the word (Turney and Pantel, 2010), or as an estimate of the probability of each p occurring with w; without any further manipulation, however, we will use it directly as a feature vector for our supervised ranking.

In order to proceed with a supervised approach, we need a ranking of a set of words relevant to the lexical attribute that we wish to acquire; this ranking is specific to the attribute in question, so we discuss this in later sections. Given such a ranking (which, we note, may be partial), we apply SVM^{rank} (Joachims, 2002), which is part of the SVM^{light} set of SVM-based machine learning tools. SVM^{rank} was developed for ranking web page results, and, to our knowledge, has not been applied in this space. SVM^{rank} uses an algorithm which optimizes the Kendall's τ (Kendall, 1955) between a correct ranking r_a and the automatically-generated ranking r_b. The simplest version of τ is based on the number of pairwise rankings which are in concord (C), i.e. both rankings rank the pair relative to each other and the pairwise rankings are the same, or in discord (D), i.e. both rankings rank the pair relative to each other but the rankings offered are contradictory. τ is defined as:

$$\tau(r_a, r_b) = \frac{C - D}{C + D}$$

In practice, this is accomplished in SVM^{rank} by modifying the original SVM algorithm to use as feature vectors the difference between ranked input vectors, rather than the input vectors directly. In the context of this feature space, this means that the model is trained on vectors which represent the differences in the co-occurrence profiles of ranked words; if the word with co-occurrence profile $\mathbf{u}$ is ranked higher than a word with co-occurrence profile $\mathbf{v}$ in our annotation, then SVM^{rank} will try to find a weight vector $\mathbf{w}$ such that $(\mathbf{u}-\mathbf{v})\cdot\mathbf{w}>0$, where $\mathbf{w}$ is constrained to be a sum of co-occurrence profile differences (i.e. the support vectors). Like standard SVM, ranking SVM uses a C parameter which represents the trade-off between margin size and classification errors, though the interpretation of the margin in ranking SVM is less clear. The output of the classification step of SVM^{rank} is a number for each word which can be used directly to rank words, or which can be normalized across words into a scale. If the input rankings also have a continuous numerical representation (which is true in our case for polarity), then this ranking approach can be compared directly to a standard regression which is not directly sensitive to rankings; to maximize comparability, we use the regression function included in SVM^{light} for this purpose. For both, we used a linear kernel.

There is a small number of parameters that need to be set: the sample size n, the frequency range *min-df*, *max-df*, and the SVM C parameter. For each of the two lexical attributes of interest, we carried out independent tuning of these parameters using 5-fold crossvalidation in the training set, carrying out a grid search at powers of 10. We will discuss the values of parameters with respect to specific experiments later, but we mention here that a higher-than-default C, which corresponds to more emphasis on avoiding error rather than maximizing the margin, gave better results for both ranking and correlation, though with diminishing returns. The role of n is primarily to make the method (much) more tractable, but we suspect it might be beneficial to the training of the model for the profiles to be based on a uniform number of examples across word types.

Before we move on to the experimental evaluation, we highlight some intrinsic advantages of this model, independent of performance. As a technique based on large corpus co-occurrence, it has the important property that it can go beyond the limited vocabulary offered by, for instance, WordNet. Since we rely only on co-occurrence, we are not at all limited to individual words (or specific types of words): we could just as easily derive attribute values for n-grams, collocations, or full lexico-grammatical constructions (for instance, distinguishing *high* as related to *price* from *high* as related to *quality*); though our interest here is in general lexical properties, there is no reason this approach could not be used for domain-specific applications, for any lexical units that appear often enough to obtain a reliable co-occurrence profile. Unlike many graph-based techniques, new vocabulary can be classified directly without perturbing the model, potentially in an online fashion if the corpus is properly indexed (which, we note, is by far the most time-consuming step of our method). Though some lemmatization may be required for highly inflectional languages, the method extends easily to any language for which blog data is likely to be available in sufficient quantities. Our approach is more straightforward than most other methods based on co-occurrence, which means fewer arbitrary choices and nuisance variables (such as the dimensionality k or feature weighting typically used in dimensionality-reduction approaches such as LSA); the parameters that we have are fairly well-behaved. Unlike methods which rely only on examples from the extremes of a spectrum to derive a quantification of it, our method naturally integrates examples from the middle of the spectrum (e.g. neutral examples in the case of polarity), but does not inherently require fine-grained quantification of the entire spectrum; in fact, pairwise examples alone could be used for training.

4 Polarity experiments

4.1 Word-level Evaluation

We first consider whether our model can be used to build a lexicon which reflects the polarity spectrum. Our training set of words is taken from the SO-CAL dictionary (Taboada et al., 2011), which has manually assigned SO (polarity) values for words at integer intervals in the range $+5$ to -5. The entire dictionary contains about 5000 words, but we do not use the entire set: first, we restrict our investigation here to adjectives, which allows us to sidestep inflection issues (we do not consider comparative adjec-

tives), and we randomly select only 50 words from each of the 11 possible SO ratings in the dictionary (for a total of 550 words), so as to mimic a (relatively) low-resource situation as we might find working in other languages, and to make it possible to keep the counts equal across SO ratings. Note that the SO-CAL dictionary does not contain neutral words (words not in the dictionary are assumed to be neutral), but we used a set of about 200 hand-marked neutral adjectives that had been excluded from the lexicon during its creation from the words in a set of Epinions product reviews, and which were used for the original dictionary evaluation by Taboada et al. (2011).

After training our model, we evaluate in two test sets. The first test set is the rest of the SO-CAL dictionary, excluding words in the training set as well as those not given a rating by SentiWordNet (see below). Note that this set is not balanced across SO values, since there are many more weakly positive (SO 1 to 3) or weakly negative (SO -1 to -3) words than more-extreme or neutral words; we would argue, though, that this reflects the actual situation in subjective corpora such as product reviews. To test whether we might be overfitting to the product reviews domain, we also test using annotations from the MPQA (Subjectivity) lexicon (Wilson et al., 2005), which was built primarily from news texts.[1] For this, we again include only words that are in SentiWordNet. The MPQA lexicon uses a very different tagging schema than the SO-CAL dictionary, with 3 polarity categories (positive, negative, and neutral) as well as two degrees of subjectivity, weak or strong. Strong or weak subjectivity is defined as how reliable an indicator of subjectivity the word is, which does not directly correspond to the rationale used for the SO-CAL dictionary (which is closer to the notion of force or intensity); the results in Taboada et al. (2011) and our own examination of the lexicon suggest, however, that there is some correlation.[2] Despite this uncertainty, we combined the MPQA tags to form a polarity spectrum: strongly subjective negative, weakly subjective negative, neutral, weakly subjective positive, strongly subjective positive. Given a ranking by our SVM ranker, we evaluate overall pairwise accuracy by considering all possible pairings of words across different ratings within the SO-CAL or MPQA test sets, and count the percentage of those where the ordering of the pair with respect to the polarity spectrum is correctly predicted by the ranking. For a more detailed breakdown, we divide these pairwise comparisons into 3 categories: polarity (pairs which involve one positive and one negative word), neutrality (pairs which have one neutral word), and intensity (pairs which have two words with the same polarity). Note that much work in bootstrapping lexicons for sentiment analysis uses precision and recall, but this is not the most appropriate evaluation metric in this case because our method can assign a rank (and, eventually, an SO value) to any word in the 2 million word vocabulary of our corpus.[3] Here, we are interested only in reliability of these rankings.

During parameter tuning in the development phase, we found that *min-df* $= 10^3$, *max-df* $= 10^5$ was a good choice: in other words, our profile words are words that appear less than once in 24 texts, but more than once in 2400 texts. In the ICWSM, there are 30,852 words that fall into this category, so that is the length of our feature vector. Based on results in the development set, we take $n = 1000$ as our default; larger samples provided no appreciable benefit and were even slightly worse in some cases. For the SVM C parameter, we used 100. We also test using SVM correlation, using the same parameters.

In addition to these variations on our co-occurrence profile technique, we also compare with three independent alternatives. The first is SentiWordNet 3.0 (Baccianella et al., 2010), which uses a random walk method in WordNet to derive positive, negative, and neutral values (which sum to 1) for each synset in WordNet. We follow Taboada et al. (2011) in converting this to a single spectrum for each word by subtracting the negative score from the positive score, and averaging the result across senses for each

[1] There are of course other popular manually-built lexicons, for instance the General Inquirer (Stone et al., 1966), but they tend to have only binary annotations.

[2] One example of where these two dictionaries differ is the word *nervous*, which is tagged as a strongly subjective negative word in the MPQA, but has only a -1 score in the SO-CAL dictionary, since it does not describe a particularly intense negative emotion. An example of a -5 word is *horrendous*, which is also a strongly subjective negative word in the MPQA. Instances of discord where the SO-CAL dictionary is clearly stronger are rarer, but an example is *comprehensive*, which has an SO of 3 in SO-CAL, but is weakly subjective in the MPQA, probably because of its common descriptive uses, such as in the context of insurance and (in the UK) education.

[3] We have not yet build such a lexicon, but, to facilitate comparison, but we are making available raw scores for all the adjectives already contained in at least one of the SO-CAL, MPQA, and SentiWordNet lists (excluding the 550 training words), as well as lists of specific words used for training and testing. These resources can be found at http://www.cs.toronto.edu/~jbrooke/rankingpolarity.zip .

Table 1: Results of polarity experiments. Left side of table shows pairwise accuracy (%) for various sentiment lexicon ranking methods in SO-CAL and MPQA test sets. Pol. = Pairs with different polarity; Neu. = Pairs with at least one neutral word; Int. = Pairs with the same polarity, but different intensities. Right side of table shows text polarity classification accuracy (%) in Epinions Corpus for various adjective lexicons. Bold is best in column.

	SO-CAL words				**MPQA words**				**Epinions texts**
Method	**Pol.**	**Neu.**	**Int.**	**All**	**Pol.**	**Neu.**	**Int.**	**All**	**Acc.**
SentiWordNet	82.3	72.3	57.4	72.1	82.8	72.0	49.9	72.0	65.8
LSA	83.5	70.6	63.0	74.5	82.5	70.2	64.0	75.8	66.3
PMI	86.3	73.6	65.8	77.3	84.5	73.4	61.6	76.9	68.0
Profile regression	80.2	67.6	59.6	71.2	77.6	69.0	**74.7**	75.8	60.3
Profile ranking	**88.6**	**75.7**	**67.5**	**79.4**	**87.5**	**74.0**	56.5	**77.0**	**71.8**

word (in that paper, they also considered using only the most common sense but found the results to be indistinguishable). The second alternative uses the semi-supervised LSA-based method of Turney and Littman (2003). For the first step, singular value decomposition, we use a binary term-document matrix with the same ICWSM texts as our supervised model, with $k = 500$ (a fairly standard choice). In the second step, which involves calculating the cosine similarity with a set of seed terms using the LSA vectors and then taking the difference, the positive and negative seeds are just the training instances for our supervised model (neutral terms are discarded). Our third comparison is the PMI approach of Turney (2002), which is still popular: for instance, PMI was used to built a Twitter sentiment lexicon in the winning entry in a recent shared task (Mohammad et al., 2013). Because they have access to the same corpus and even the same example words as our method, the LSA and PMI alternatives are most directly comparable to ours.

The results for the word-level polarity experiments are shown in the left side of Table 1. In the SO-CAL test set, the results are clear: our SVM ranking method is preferred over alternatives, across all the different categories of pairwise comparison. The relative difficulty of each pair type reflects the average distance between relevant pairs on the spectrum, as expected. Surprisingly, the correlation method, despite using the same feature input as the ranking method, is the worst performing method here, though SentiWordNet is only marginally better, while LSA falls roughly in the middle of the range, and PMI is the strongest competitor. One potential criticism is that a ranking method is likely to have an advantage when evaluating by rank. This is true, but we think that relative rank among words is fundamental to the notion of a spectrum, whereas the bucketing of words into evenly spaced integer ratings is just an annotation convenience. That said, our output ranking is perhaps too fine-grained in comparison to our input (offering a full ranking for all words), and it would be desirable if our ranking algorithm allowed us to encourage some words to be ranked the same.

Although SVM ranking is also the best method on the MPQA test set, the results are marginal as compared to the SO-CAL test. Part of this could be a moderate amount of domain overfitting, or perhaps the ranking method is better at fine-grained scales relative to the other methods. However, the most obvious difference between the test sets appears relative to the intensity comparison, where the profile ranking performance is relatively poor. This is likely attributable to the differences between the two kinds of annotations: the SVM ranking method learns the SO-CAL intensity scale fairly well, but this actually becomes a handicap when degree of subjectivity and not force is the deciding factor; on the other hand, corpus-based models which did relatively poorly in all the other evaluations (profile regression, LSA) actually do somewhat better in MPQA intensity than their most comparable alternatives (profile ranking, PMI) to a degree that is in fact proportional to their relative inferiority elsewhere, suggesting that sensitivity to degree of subjectivity might be interfering with acquisition of the SO-CAL polarity spectrum. Interestingly, the value provided by SentiWordNet does not seem to correspond well to either of these interpretations of intensity, since it does rather poorly with respect to both.

4.2 Text-level Evaluation

The most common use of polarity lexicons is the task of text polarity classification (Turney, 2002), identifying whether an opinionated text is positive or negative. In this section, we convert the initial output of the models to polarity lexicons with an appropriate scale so that we can use the SO-CAL software (Taboada et al., 2011) to carry out text sentiment analysis with our alternative adjective lexicons rather than its original, manually-built one. SO-CAL is an unsupervised lexical sentiment analysis system with a number of built-in features, e.g. handling of negation and intensification, that improve the accuracy of the model, particularly when using a fine-grained, high-precision lexicon. Taboada et al. evaluate across 4 corpora of balanced product reviews. For our evaluation, we use one of those corpora, a set of 400 product reviews from Epinions, with 50 balanced texts from each of 8 product categories (movies, books, cars, computers, cookware, hotels, phones, and music). Taboada et al. call this corpus Epinions 2, to distinguish it from the Epinions corpus that the SO-CAL dictionary was built from. They report an accuracy of 80% using SO-CAL with all word types and features enabled.

Our interest here is to test the influence of lexicon quality on polarity detection. Coverage, though of course important, is actually a potential source of noise: Low coverage can naturally result in low performance, but Taboada et al. point out that high coverage can also cause problems, when many of the rarer words added to the lexicon, even when human-tagged, are not relevant to the primary sentiment of the text, but rather irrelevant aspects like (in the movie or book domain) character descriptions. Steps can be taken to mitigate this by identifying relevant sentiment (Scheible and Schütze, 2013), but here we sidestep this problem by forcing our lexicons to have exactly the same coverage by limiting them to words that appear in the static SentiWordNet lexicon. Again, we also consider only adjectives here.

To build the lexicon for this evaluation we used a different training set: it is not possible to take 50 samples from each SO rating in the SO-CAL adjective lexicon and not have training words that also appear in the corpus, which we explicitly wanted to avoid.[4] Instead, we train using all the adjectives in the SO-CAL dictionary that either don't appear in the Epinions corpus or don't appear in SentiWordNet (since we are limiting our output lexicon to SentiWordNet words). This results in a much larger training set than in the word-level evaluation (about 1500 words), but they are distributed unevenly across SO ratings. Relative to the word-level evaluation, this is closer to the situation if we were using the entire SO-CAL dictionary to expand the lexicon. We use the same set of training words as seeds for LSA.

To convert SentiWordNet to a SO-CAL-compatible dictionary, we simply multiply the raw score, guaranteed to be between -1 and $+1$, by 5, creating a range of -5 to $+5$. For the raw scores for our other three options (LSA, profile regression, and profile ranking), we linearly scale the raw score so that the mean within the lexicon is 0, and a SO $+5$ word is at the third standard deviation away from the mean; we choose a rather severe scaling so that there are only a handful of words in the lexicon whose absolute value is over 5, which SO-CAL is not designed for.

The results of this evaluation are shown on right side of Table 1. Profile ranking is once again dominant, almost 4 percentage points better than the second-best option. The ordering of the lexicons here is exactly the same as we saw for the word-level evaluation in SO-CAL, though SentiWordNet does somewhat better than would be expected from those scores. Again, regression does quite poorly despite having access to the same feature vectors as the ranking method. We note that our results here are also markedly better than all the other automatic lexicons compared by Taboada et al., namely a PMI-derived lexicon based on Google counts (Taboada et al., 2006), and a binary lexicon built by expanding entries in a thesaurus (Mohammad et al., 2009), and are even a bit better than using the human-tagged (binary) annotations from the General Inquirer (Stone et al., 1966), though we are still quite a long way from what is possible with the full manual SO-CAL dictionary. Since the quality of the lexicon is directly reflected in our polarity classification scores here, it is not surprising that our gold-standard lexicon is superior; in this context, it should be viewed as an upper bound. Nevertheless, we have strong evidence here that our co-occurrence profile ranking method is a step in the right direction relative to other methods for automatically building lexicons.

[4] For all of our evaluations in this paper we were careful never to use the score of a word which appeared in our training set; the drawback of this is that our training set size is not constant.

5 Formality Experiments

5.1 Word-level Evaluation

Though the lexicon is perhaps more fundamental to distinctions of polarity than is the case for formality, nevertheless formality is strongly expressed through word choice; for instance, in English using the word *dude* to address a socially-powerful stranger would generally be unacceptable, and it would be very strange to address a good friend as *sir*, except as a joke. These are not isolated examples: a huge portion of the vocabulary is marked to some degree in this fashion, and requires special attention when moving across text genres or social situations. Word length (in English, at least) and word frequency can be used as a simple proxy (longer, rarer words are, on average, more formal), but the example above belies this approach: *sir* is a shorter word than *dude*, and it is not immediately obvious that it would appear less in, for instance, a news corpus, than *dude*.

In previous work (Brooke et al., 2010), we used the LSA co-occurrence method of Turney and Littman (2003) discussed in the previous section to derive a formality lexicon using the ICWSM (which was the best among various corpora tested, including the BNC). For testing, we used a set of 399 synonym pairs that were pulled from a writing manual focused on word choice, *Choose the Right Word* (CTRW) (Hayakawa, 1994), where the author explicitly compared words for their formality, showing that co-occurrence was a better approach to identifying lexical formality than proxies related to word length or word frequency. We note that many of the distinctions in the CTRW set are quite subtle, for example *determine* vs. *ascertain*, both of which seem at least somewhat formal, though *ascertain* was judged by the expert to be the more formal of the two. In this section we will build a formality ranking using our profile ranking method, and show that it is better than the LSA method in the CTRW dataset. Here, we follow our earlier work in using a much smaller k value (20) than is typical for topical uses of LSA, which we found was better for this dataset, since major stylistic differences seem to be mostly captured in the first few dimensions after dimensionality reduction, a result which is consistent with the work of Biber (1988) looking at differences across registers.

Unlike for polarity, there is no resource available that offers a full scale of formality for a large number of words, and the set used in our initial work on formality has only extreme, handpicked words. In more recent work (Brooke and Hirst, 2013), we used a larger set of words (900) that included a variety of different styles that had been tagged by a group of 5 annotators. In that work, we did not use the term "formality," but one of our styles, *colloquial*, corresponds to the informal end of the spectrum, and two other styles, *objective* and *literary*, can both be viewed as social-distancing language.[5] The words tagged by annotators as belonging to neither of these categories will serve as the middle of this spectrum. Compared to our polarity lexicon, our training set therefore is much more coarse-grained (with only 3 rankings, as compared to 11 for polarity), but the pairwise relationships can be used to build a fine-grained scale. As before, we remove all words that overlap with our test set.

With respect to parameters, we use the same n as in the polarity experiments, but in development we saw better performance from a higher C (10,000) and a lower bottom bound on the document frequency range, $df\text{-}min = 10^2$. The latter might reflect the fact that rare vocabulary has a strong tendency to be associated with extreme formality, though there is also a limit to this, since if a word is so rare that it hardly ever co-occurs with anything, it cannot possibly be useful for training no matter how good an example of extreme formality it is. The results using these settings are shown in the left side of Table 2. Again, our profiling method is clearly better than lexicon-based alternatives. LSA outperforms PMI in the word-level task, a result which is consistent with our other work in stylistic lexical induction (Brooke and Hirst, 2013),[6] and all the co-occurrence methods are well above the word-length baseline.

Figure 1 contains a more detailed analysis of the influence of individual document frequency bands: we

[5]The objective dimension corresponds roughly to the style of a technical document, while the literary dimension involves flowery, even archaic language that suggests a literary sophistication. Contrast *so* with synonyms *therefore* (objective) and *thus* (literary), which are both more formal, but in different ways.

[6]We suspect this is due to the fact that LSA vectors encode information about word frequency: even when the vector norm is controlled for, we have found that the LSA vectors of high- and low-frequency words have consistently different distributions, which may help in identifying extremely low frequency, highly formal words appearing in the CTRW dataset; by contrast, PMI and other probability-based approaches seem to behave more erratically when presented with low-frequency items.

Table 2: Results of the formality experiments. The second column shows pairwise accuracy of different models identifying the more formal of two synonyms in CTRW test set. The third column shows average correlation with two human 5-point Likert-scale formality annotations of the 500 sentence test set.

Method	CTRW words	Sentence Evaluation
Word length	63.7	0.36
LSA	78.7	0.49
PMI	72.2	0.52
Profile ranking	**86.5**	**0.55**

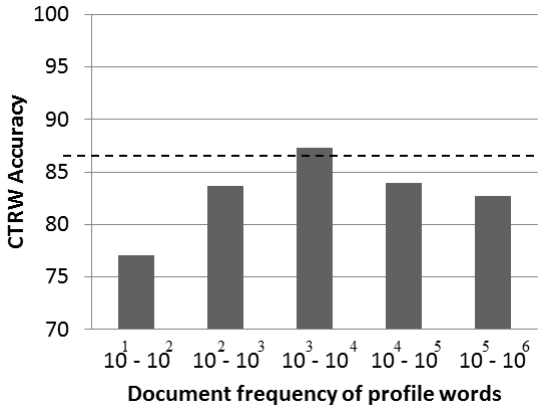

Figure 1: Pairwise accuracy in the CTRW test set for various frequency bands. Dotted line represents performance using best parameters from development phase, i.e. *max-df* $= 10^2$, *max-df* $= 10^5$.

built models for each of our frequency bands (ranges between two consecutive powers of ten), and tested them in the CTRW corpus. The flat dotted line represents the larger band we used based on development performance, 10^2–10^5. We see that accuracy peaks at 10^3 to 10^4 *df* band, at a value (87.3%) which is higher than we saw with the larger band chosen based on the development set. The words in this band are fairly uncommon, appearing less than once in 240 texts, but greater than once in 2400 texts; still, as a group they provide enough evidence to make a strong determination of formalty.

5.2 Sentence-level Evaluation

Lahiri and Lu (2011) report on the creation of 5-point Likert scale annotations of sentence-level formality, with two ratings for each of 500 sentences taken from separate texts in a diverse corpus which includes news, blogs, forums, and academic papers (Lahiri et al., 2011). In this section, we use this annotation to carry out an extrinsic evaluation of our lexical formality ratings. As far as we are aware, this is the first use of this annotation for evaluating metrics of formality. We extract all lexical words (verbs, adjectives, adverbs, and nouns, though we omit proper nouns) from the sentences and use the 3-way formality annotation with these words removed to create LSA, PMI, and profile ranking models, which are then used to create a formality lexicon for these words, using the same method we used to create the SO lexicon. Given a lexicon, we averaged the formality score across each sentence (ignoring duplicate items) to get a formality score for each sentence. We calculate Pearson's correlation coefficient between our score and each of the two annotators, and then average the result. For comparison, the correlation between the two human annotators is 0.60.

The results in Table 2 indicate that the preference for the profile ranking method seen in the CTRW set extends directly to sentence-level formality ranking, and the level of correlation reached by the profile ranking method approaches correlation between humans. This supports our claim that lexical choice is very important to formality: our results here indicate that humans with access to other indicators of formality (for instance, use or avoidance of particular syntactic constructions) agree only slightly more with each other than our lexicon-only model does with them.

6 Conclusion

In this paper we have presented a novel approach to determining where a word lies on a spectrum, using just counts of words that it tends to appear with and an SVM ranking algorithm, both of which are key components to its success. We have shown that it can be applied to at least two continuous attributes of interest in computational linguistics, namely polarity and formality, and that the benefits of this method relative to established alternatives are visible not just in direct lexicon evaluation, but also in the NLP tasks where these lexicons can be used. Even with a relatively small set of words to train with, we see little sign of overfitting, and although we have focused on a small set of words here, our method is efficient enough that it could easily be applied to a much larger set of lexicogrammatical units, though we will also have to derive ways to filter out unreliable assignments to reduce overall noise. Other future work will involve looking at other spectra, other languages, other supervised ranking models, and improving our performance generally by being more selective of profile words or training examples or by refining our rankings by including other sources of information such as WordNet.

Abstract

This paper presents a knowledge base containing triples involving pairs of verbs associated with semantic or discourse relations. The relations in these triples are marked by discourse connectors between two adjacent instances of the verbs in the triple in the large French corpus, frWaC. We detail several measures that evaluate the relevance of the triples and the strength of their association. We use manual annotations to evaluate our method, and also study the coverage of our resource with respect to the discourse annotated corpus Annodis. Our positive results show the potential impact of our resource for discourse analysis tasks as well as other semantically oriented tasks like temporal and causal information extraction.

1 Introduction

Relational lexical resources, which describe semantic relations between lexical items, have traditionally focused on relations like synonymy or similarity in thesauri, perhaps including some hierarchical semantic relations like hyperonymy or hyponomy or part-whole relations as in the resource Wordnet (Felbaum, 1998). Some distributional thesauri contain more varied relations, see e.g. (Grefenstette, 1994), however these relations are not typed. The lexical semantics given by FrameNet (Baker et al., 1998) does include causal and temporal relations, as does Verbocean (Chklovski and Pantel, 2004), but coverage is limited and empirical validation of these resources is partial and still largely remains to be done.

Lexical relations, in particular between verbs, are nevertheless crucial for understanding natural language and for many information processing tasks. They are needed for textual inference, in which one has to infer certain relations between eventualities (Hashimoto et al., 2009; Tremper and Frank, 2013), for information extraction tasks, like finding temporal relations between eventualities mentioned in a text (UzZaman et al., 2013), for automatic summarization (Liu et al., 2007), and for discourse parsing in the absence of explicit discourse markers (Sporleder and Lascarides, 2008).

In this paper we report on our efforts to extract semantic relations essential to the analysis of discourse and its interpretation, in which links are made between units of text or rather their semantic representations as in (1) in virtue of semantic information about the two main verbs of those clauses.

(1) The candidate demonstrated his expertise during the interview. The committee was completely convinced.

We follow similar work on the extraction of causal, temporal, entailment and presuppositional relations from corpora (Do et al., 2011; Chambers and Jurafsky, 2008; Hashimoto et al., 2009; Tremper and Frank, 2013), though our goals and validation methods are different. While one of our goals is to use this information to improve performance in predicting discourse relations between clauses, we believe that such a lexical resource will have other uses in other tasks in which semantic information is needed.

Discourse analysis is a difficult task. Rhetorical relations are frequently implicit and require for their identification inference using diverse sources of lexical and compositional semantic information. In the Penn Discourse Treebank corpus for example, 52% of the discourse relations are unmarked (Prasad et

This work has been supported by the French agency Agence Nationale de la Recherche (ANR-12-CORD-0004).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2184–2194, Dublin, Ireland, August 23-29 2014.

al., 2008). Accordingly, annotation with discourse structure is a slow and error prone task, and relatively little annotated data is currently available ; and so machine learning approaches have had limited success in this area. Our approach addresses this problem, using non annotated data with features that can be automatically detected to find typical contexts (pairs of discourse units) in which various discourse relations occur. We suppose with (Sporleder and Lascarides, 2008; Braud and Denis, 2013) that such contexts display regular lexical associations, in particular with verbs in those discourse units. An explicit, manually compiled list of all possible associations between two verbs and the semantic relations they suggest is infeasible, so we present here an automatic method for compiling such a list, inspired by the Verbocean project (Chklovski and Pantel, 2004).

Our hypothesis, supported by existing corpora, is that adjacent clauses are often arguments of discourse relations. When these clauses contain certain adverbs or other discourse connectors, we can recover automatically one or more discourse relations that we associate with the main verbs of those clauses. We extract triples consisting of the two verbs and a semantic relation from a large corpus with the aim of inferring that such a pair of verbs can suggest the semantic relation even in the absence of an explicit discourse marker. We thus also suppose, with (Sporleder and Lascarides, 2008; Braud and Denis, 2013), that such discourse markers are at least partially redundant ; inferring a discourse relation between two clauses relies not only the marker but on the two verbs in the related clauses as well. All of our work has been done on French data.

Our paper is organized as follows. We describe first the knowledge base of verb semantic relation triples that we have constructed (section 2) ; we then present our methods for isolating verb pairs implicating discourse or temporal information (section 3). A third section describes our methods of evaluation (section 4) and a fourth discusses related work (section 5).

2 Exploring relations between verbs in a corpus

We built a knowledge base (V^2R) [1] using the frWaC corpus(Baroni et al., 2009). frWaC contains about 1.6 billion words and was collected on the Web on the .fr domain. We first parsed the documents in our corpus using BONSAI [2], which first produced a morpho-syntactic labeling using MElt (Denis and Sagot, 2012) and then a syntactic analysis in the form of dependency trees via a French version of the MaltParser (Nivre et al., 2007).

Our goal is to find pairs of verbs linked by a relation explicitly marked by a discourse connector in the corpus, as an indication of a regular semantic relation between the two verbs. The relations we have considered are common to most theories of discourse analysis, and they can be grouped into four classes (Prasad et al., 2008) : causal (*contingency*) relations, temporal relations, comparison relations (mainly contrast type relations), and expansion relations (e.g. elaboration or continuation).

To find explicitly marked relations, we used a lexicon of discourse connectors for French, the manually constructed LEXCONN resource (Roze et al., 2012) [3]. LEXCONN includes 358 connectors and gives their syntactic category as well as associated discourse relations inspired from (Asher and Lascarides, 2003). Some connectors are ambiguous in that they are associated with several relations. We used only the unambiguous connectors (263 in all) in LEXCONN, as a first step. We regrouped the LEXCONN relations into classes [4] : explanation relations (*parce que*/because) and result (*ainsi*/thus) form the causal class ; temporal relations (*puis, après que*/then,after that) form the narration group. We also considered other relations like contrast (*mais*/but), continuation (*et, encore*/and,again), background (*alors que*/while), temporal location (*quand, pendant que*/when), detachment (*de toutes façons*/anyway), elaboration (*en particulier*/in particular), alternation (*ou*/or), commentary (*au fait*/by the way), rephrasing (*du moins*/at least), and evidence (*effectivement*/indeed).

We searched our syntactically parsed corpus for connectors. When a connector is found and its syntactic category verified, if it is close enough to the root of the sentence (at most one dependency link from the root), we look for an inter-sentential link. The first verb of our pair corresponds in this case

1. Available as an SQLite database at `https://dl.dropboxusercontent.com/u/78938139/v2r_db`
2. `http://alpage.inria.fr/statgram/frdep/fr_stat_dep_parsing.html` or (Candito et al., 2010)
3. Freely available at : `https://gforge.inria.fr/frs/download.php/31052/lexconn.tar.gz`.
4. We illustrate each relation with examples of potentially ambiguous markers.

to the last verb of the previous sentence in the case of connectors for narration, or to its main verb for all the other relations. We search for the second verb in the pair within a window of two dependency links after the connector. If the connector is not close enough to the root of the sentence, we look for a intra-sentential link. In this case, we look for the two verbs of the pair in the same sentence within a forward and backward window of two dependency links.

If two verbs are found, we examine their local context to better characterize their usage and to improve our results. If one of the verbs is a modal or support verb, we look for the verb dependent on the modal or support verb and use that as the verb in our pair (if it exists), while keeping the presence of the support verb in memory. Unlike support verbs, we use the presence of a negation or a reflexive particle in the local context to distinguish verbs with different meanings ; e.g., *comprendre*/understand vs. *ne pas comprendre*/not understand, *agir*/act vs. *s'agir*/concern are all distinct entries. To get at different verb senses, we search for idiomatic usage of prepositions using the Dicovalence resource (Van Den Eynde and Mertens, 2010), which contains valency frames for more than 3700 simple French verbs. We also use the Lefff resource (Sagot, 2010) to find idiomatic verbal locutions. We also encode other information that do not lead to distinct lexical entries : tense, and voice.

Relation	Distribution
contrast	50,104%
cause	33,108%
continuation	8,243%
narration	6,362%
background	1,853%
temporal localisation	0.177%
detachement	0.149%
elaboration	0.002%
alternation	0.002%

TABLE 1 – Distribution of relations in V^2R ;commentary, reformulation and evidence occur with negligible frequency.

Once we have obtained a list of verb pairs associated with a connector, we aggregate this data to get a list of triple types (verb1, verb2, relation). Given that we have used only unambiguous connectors (so classified by LEXCONN), the association of a relation with a connector is immediate. We associate to each triple type the number of intra-sentential, inter-sentential and total number of occurrences. The other features mentioned above are stored in a separate table.

Our method has isolated more than 1 million distinct types of triples for V^2R and 2 million occurrences, of which 95% are intra-sentential [5]. Among these triples, 6.2% have 5 or more occurrences.

Table 1 summarizes the distribution of triples by relation in V^2R. Note that triples with contrast and causal relations comprise the majority. This does not mean that these are the most frequent relations in the corpus but only that they are the most frequently marked by the connectors we considered. This makes for a very different distribution than that of the French manually annotated discourse corpus Annodis (Afantenos et al., 2012).

3 Measuring the association of a pair of verbs with a relation

In the last section we presented our extraction method. We now present the measures we have used to rank verb pairs with respect to the strength of their association with a particular discourse relation. We adapted versions of standard lexical association measures like PMI (*pointwise mutual information*) and their variants, as well as some measures specific to the association of a causal relation between items (Do et al., 2011). We also experimented with a new measure specifically designed for our knowledge base.

Measures of lexical association used in research on co-occurrences in distributional semantics pick out significant associations, taking into account the frequency of the related items. We examined over 10 measures ; we discuss the ones with the best results (see section 4). One simple measure, PMI, and its variants, *normalized*, *local* (Evert, 2005), *discounted* (Lin and Pantel, 2002), which are designed to reduce biases in the original measure, work well. The idea behind PMI is to estimate whether the probability of the co-occurrence of two items is greater than the *a priori* probability of the two items appearing independently. In distributional semantics, the measure is also used to estimate the significance of two items co-occurring with a particular grammatical dependency relation like the subject or object relation between an NP and a verb. This use of PMI measures over triples in distributional semantics fits perfectly with our task of measuring the significance of triples consisting of a pair of verbs and

5. The low proportion of inter-sentential occurrences comes from our conservative scheme for finding these occurrences, which uses only those connectors at the beginning of the second sentence. Other schemes are possible but would, we fear, introduce too much noise into the data.

a particular semantic or discourse relation ; our PMI measures estimate whether the co-occurrence of two items with a particular discourse relation is higher than the *a priori* probability of the three items occurring independently. Our measures consider co-occurrences of two lexical items in a certain relation denoted by an explicit discourse marker. PMI and normalized PMI are defined as :

$$PMI = \log(\frac{P(V_1, V_2, R)}{P(V_1) \times P(V_2) \times P(R)}) \qquad PMI\_normalized = \frac{PMI}{-2\log(P(V_1, V_2, R))}$$

Indeed, when we have a complete co-occurrence of the three items, we have : $P(V_1) = P(V_2) = P(R) = P(V_1, V_2, R)$, and $PMI = -2\log(P(V_1, V_2, R))$. The values of normalized PMI lie between -1 and 1, approaching -1 when the items never appear together, taking the value 0 in the case of independence, and the value 1 when they always appear together. We also considered a weighted PMI measure (Lin and Pantel, 2002) that corrects the bias of PMI for rare triples.

A specificity measure (Mirroshandel et al., 2013), originally used to measure the precision of subcategorization frames, also performed well :

$$specificity = \frac{1}{3} \times (\frac{P(V_1, V_2, R)}{\sum_i P(V_1, V_i, R)} + \frac{P(V_1, V_2, R)}{\sum_i P(V_i, V_2, R)} + \frac{P(V_1, V_2, R)}{\sum_i P(V_1, V_2, R_i)})$$

A version of Do et al. (2011)'s measure for triples involving causal relations did not fare so well on other types of relation. The definition of the measure can be found in (Do et al., 2011). [6]

Finally, we investigated a measure that evaluates the contribution of each element in the triple to the significance measure (this measure is similar to specificity).

$$W_{combined}(V_1, V_2, R) = \frac{1}{3}(w_{V_1} + w_{V_2} + w_R)$$

with : $w_{V_1} = \frac{P(V_1,V_2,R)}{\max_i(P(V_i,V_2,R))}$, $w_{V_2} = \frac{P(V_1,V_2,R)}{\max_i(P(V_1,V_i,R))}$, and $w_R = \frac{P(V_1,V_2,R)}{\max_i(P(V_1,V_2,R_i))}$.

4 Evaluating extracted relations

We evaluated V^2R in several ways ; we provided : (i) an intrinsic evaluation of the relations between verbs (section 4.1) and (ii) an extrinsic evaluation where we evaluated the coverage of the resource on a discourse annotated corpus and its potential to help in predicting discourse relations in contexts with no explicit marking (section 4.2).

4.1 Intrinsic evaluation

Our intrinsic evaluation first evaluates the feasibility of assigning an "inherent" semantic link to a verb pair, independently of any linguistic context. For example, is it possible to judge that there is a typical causality link between *push* and *fall*, in scenarios where they share some arguments (subject, object, ...), these scenarios being left to the annotator's imagination (section 4.1.1). In a second stage, we selected several verb pairs linked with different relations in V^2R, and 40 contexts in which these verbs occur together in the original corpus, to judge the semantic link in context (section 4.1.2).

In both cases we restricted the study to three relation groups : causal, contrastive, and narrative. These are the most often marked relations and correspond to different types of links with a meaningful semantic aspect (as opposed to the "continuation" relation for instance, which is often marked too).

4.1.1 Out of context evaluation

For out of context judgments, we adopted the following protocol : one of the authors chose for each relation 100 verbs with equivalent proportions of good and bad normalized PMI scores. Then the other

6. We simplified their measure by ignoring IDF (inverse document frequency) and the distance between the verbs, as neither measure applies to our task.

three authors judged the validity of associating each of the 300 pairs with the corresponding relation, without any knowledge of the source of these pairs.

We measured the inter-annotator agreements with Cohen's Kappa (Carletta, 1996), which resulted in : 0.17 for cause, 0.42 for narration and 0.56 for contrast as mean values. If a 0.6 kappa serves a measure for a feasible semantic judgment task, out of context judgments appear very difficult, with only contrastive pairs as a relative exception. We decided to only consider judgments about contrast, after an adjudication phase, and we evaluated the measures presented in section 3 to see if they could discriminate between the two verb groups, those judged positively or negatively according to human annotations. A Mann-Whitney U statistical test showed all of our measures to be discriminative, with the exception of raw co-occurrence counts for which p>0.05.

4.1.2 In context evaluation

We also judged associations in context. This task was easier and also gave more fine-grained results, because with it we can quantify the degree of association, and the typicality of the link, as a proportion of contexts where the two verbs appear together in a given semantic relation. We can then observe if this proportion is correlated with the association measures we already presented. Nevertheless, this is a costly way of evaluating a verb pair, as we require a number of judgments on each pair. It is also not easy to sample the possible pairs with different values to be able to observe significant correlations, because we cannot predict in advance how they will be judged by the annotators.

We selected 40 contexts for each of the 15 pairs of verbs we chose, 5 for each of the target relation (cause, narration, contrast). Selected pairs range over different values of normalized PMI, again chosen by one of the authors independently of the others, who annotated the 600 contexts. Prior to adjudication, raw agreement was 78% on average, for an average kappa of 0.46 (and a maximum of 0.49). These values seem moderately good, as the task is also rather difficult.

Verb pair	translation	association /human
Cause		
inviter/souhaiter	invite/wish	12.8%
promettre/élire	promise/elect	25.6%
aimer/trouver	like/find	38.5%
bénéficier/créer	benefit/create	51.3%
aider/gagner	help/win	53.8%
Contrast		
proposer/refuser	propose/refuse	59.0%
augmenter/diminuer	increase/decrease	64.1%
tenter/échouer	try/fail	64.1%
gagner/perdre	win/lose	71.8%
autoriser/interdire	authorize/forbid	74.4%
Narration		
parler/réfléchir	speak/think	42.5%
acheter/essayer	buy/try	70.0%
atteindre/traverser	reach/cross	77.5%
commencer/finir	begin/end	80.0%
envoyer/transmettre	send/transmit	82.5%

TABLE 2 – For each relation, the list of verb pairs manually evaluated in context (and an approximate translation), and the association percentage resulting from the adjudicated human annotation.

Table 2 shows the results after adjudication : for each pair, the proportion of contexts in which the considered relation is judged to appear.

We computed two correlation values between the association ratio in contexts manually annotated and each association measure considered : one based on all annotated contexts, and one on the subset of contexts devoid of explicit markers of a semantic relation (implicit contexts). The latter is important to quantify the actual impact of the method, since explicit marking is already used as the basis of verb association in the same corpus. Implicit contexts, however, never appeared in the computation of the verb pair associations.

	normalized PMI	specificity	W_combined	discounted PMI	PMI	local PMI	U_do	raw frequency
Global correlation	0.749	0.747	0.720	0.716	0.709	0.434	0.376	0.170
Correlation for implicit instances	0.806	0.760	0.738	0.761	0.756	0.553	0.499	0.242

TABLE 3 – Pearson correlation for the 15 pairs considered and measures from section 3, in decreasing order.

Table 3 shows that mutual information measures are well correlated with human annotations, and that our W_combined seems useful too. We also observed results on each relation separately, although one should be careful drawing conclusions from these results since the correlations are then computed on 5 points only. These results (not shown here) show a lot of variation between relations. The U_do measure, designed for causal relations, does indeed produce good results for these relations, but does not generalize well to our other chosen relations.

Also, local PMI seems to work very well on narration and causal relations. This needs to be confirmed with more verb pairs.

We conclude that the best three measures are : normalized PMI, specificity, and W_combined. The last two assign their maximal value to several pairs, so we used them in a lexicographical ordering to sort all associated pairs, using normalized PMI to break ties.

Verb pair	Translation	Relation
abandonner / *mener*	abandon / lead	background
ne pas s'arrêter / *rouler*	not stop / drive	narration
donner satisfaction sur / *réélire*	give satisfaction concerning / re-elect	continuation
emporter / *ne pas cesser*	take away / not stop	summary
emprunter / *assurer*	borrow / insure	cause
ne pas manquer / *prolonger*	not miss / prolong	detachment
ratifier / *trembler*	ratify / tremble	background
avoir honte / *faire pitié*	be ashamed / cause pity	cause
avoir droit / *cotiser pour*	be entitled / contribute to	temploc
ne pas représenter / *stéréotyper*	not represent / stereotype	temploc

TABLE 4 – Ten best triples in the database.

Table 4 shows the best triples with our lexicographical ranking.

4.2 Extrinsic evaluation

In order to evaluate the performance of our resource relative to its main intended application—predicting rhetorical relations in text, we intend to use our association measures as additional features to an inductive prediction model. Whether this evaluation produces results depends on the proportion of cases in which this information could help and on the coverage of our resource with respect to these cases. We used the Annodis corpus (Afantenos et al., 2012), a set of French texts annotated with rhetorical relations, for our study.

To improve existing models, a significant number of the predictions to be made must involve a verb pair for which we have information in the resource. A first indication of its usefulness is also that the verb pair appears most frequently with the relation group to which the annotation belongs, for instance the fact that two verbs are related with a causal relation whenever we want to predict an explanation. This is interesting only in the absence of an explicit marking of the target relation, i.e for implicit relations.

Beyond that, it should be interesting to use all the available information about other semantic relations too : for instance a potential causal link between two events could indicate the relevance of a temporal link for the prediction of a relation. We relied again on the Lexconn marker database. As an approximation we considered that a relation between two discourse units is explicit when a Lexconn marker is present in any of the two segments, and one of the potential senses of the marker is the annotated relation. This may overestimate the number of explicit instances but ensures that all implicit instances are indeed implicit (assuming a good enough coverage of the marker resource). The Annodis corpus lists rhetorical relations between elementary discourse units (EDUs), typically clauses, and complex discourse units (sets of EDUs) ; as a simplification we only consider EDUs, since the question of what is a main verb of a complex unit is difficult to answer. This is a relatively small corpus, as it includes about 2000 instances of relations between elementary discourse units.

Table 5 present results for coverage, for the main relations in the annotated corpus. Note that only a small part of the set of relations between EDUs is considered when we restrict instances to both EDUs with verbs (about 20% of the whole). It turns out that a lot of EDUs in Annodis are short segments (incises, detached segments, ...).

	global	narration	cause	contrast	elab.	cont.	BG	other
Annodis pairs	427	73	67	41	96	92	24	16
Annodis pairs $\in V^2R$	68.9	71.2	70.8	78.0	68.3	61.9	74.1	62.5
Annodis triples $\in V^2R$	26.5	34.2	50.0	70.7	0.0	20.6	11.1	0.0
Implicit Annodis pairs	83.4	71.2	79.2	36.6	99.0	94.8	88.9	100.0
Implicit Annodis pairs $\in V^2R$ (any relation)	56.9	52.1	54.2	31.7	67.3	58.8	66.7	62.5
Implicit Annodis triples $\in V^2R$ (with correct relation)	17.7	24.7	40.3	31.7	0.0	19.6	11.1	0.0

TABLE 5 – Coverage of verb pairs in V^2R with respect to EDU pairs in the Annodis corpus containing two verbs. Except for the first line, all numbers are percentages. Pair = verb pairs in the EDUs linked by a rhetorical relation R, Triple=verb pair associated with a relation R in V^2R, BG = Background, cont.=continuation, elab.=elaboration.

Our table includes : the proportion of verb pairs found in Annodis EDUs that appear in V^2R, the proportion of triples from Annodis that appear in V^2R (with the correct relation), and the restriction of these proportions to implicit contexts in Annodis. Except for a few exceptions due to lemmatisation errors, all verbs in Annodis are in V^2R in at least one pair, and we can see that the pairs in V^2R cover most of the pairs appearing in Annodis (almost 70% globally and between 60 and 80% depending on the relation), and a little less of implicit cases (around 55% on average). We note that a high proportion of the implicit cases contains verb pairs that have been collected in a marked context, even for rarely marked relations like elaboration or continuation—contexts with these relations are the majority in Annodis. Furthermore more than half of these contexts are associated with the right relation in V^2R. Thus the hypothesis of the partial redundancy of connectors appears useful when isolating verbal associations relevant for discourse from a large corpus. We also looked at semantic neighbors of the verbs in V^2R but this did not increase coverage significantly.

A good test of the predictive power of the semantic information we gathered is also to include the association measures as additional features to a predictive model, to improve classically low results on implicit discourse relations. The only available discursive corpus in French, Annodis, is small, and as shown above only about 400 instances have a verb in both related EDUs. We trained and tested a maximum entropy model with and without the association measures as features, on top of features presented in Muller et al. (2012), who trained a relation model on the same corpus. We did a 10-fold cross-validation on the 400 instance subset as evaluation, and did not find a significant difference between the two set-ups (F1 score was in the range .40–.42, similar to the cited paper), which is unsurprising

given the size of the subset. We plan to evaluate our method relative to discourse parsing by building an English resource like V^2R ; we will then be able to use the much larger PDTB corpus (10 times as large as Annodis) as a source of implicit discourse relations. This should prove a much more telling evaluation of the usefulness of association measures in predicting implicit discourse relations.

5 Related work

There are two different groups of related work. The first group aims to alleviate the lack of annotated data for discourse parsing by using a weakly supervised approach, exploiting the presence of discourse connectors in a large non-annotated corpus. Each pair of elementary discourse units is automatically annotated with the discourse relation triggered by the presence of the connector (connectors are often filtered for non-discursive uses). Those connectors are afterwards eliminated from the corpus so that the model trained on this dataset will not be informed by the presence of those connectors. The pioneering article in this group is Marcu and Echihabi (2002). Such learning methods with such "artificial data" obtain low scores, barely above chance as shown in Sporleder and Lascarides (2008). Braud and Denis (2013) observe that the performance of a classifier for the prediction of implicit relations is much lower when using "artificial" data than on "natural" data (implicit relations annotated by a human being). They propose a method which exploits these two different kinds of datasets together in various mixtures and on the level of the prediction algorithm, obtaining thus a significant improvement on the Annodis corpus. Our approach is different and complementary ; we isolate the semantic relations between pairs of verbs. We can use that as a feature on discourse units for discourse parsing but it has other uses as well.

A second group aims at identifying discourse relations (implicit or not) by focusing on the use of fine-grained lexical relations as another feature during the training phase. Most of this work focuses mainly on the use of lexical relations between two verbs. Chklovski and Pantel (2004), for example, rely on specific patterns constructed manually for each semantic relation between (*similarity, strength, antonymy, enablement* and *temporal happens-before*). They use the web as a corpus in order to estimate the PMI between a pattern and a pair of verbs (a precise measurement cannot be achieved over the web since the probability of a pattern is not precisely known over all the web). A threshold on the value of the PMI (manually fixed) permits thus to determine the pairs of verbs that are related to the relation denoted by the pattern. In the same spirit, Kozareva (2012) is using a weakly supervised approach for the extraction of pairs of verbs that are potentially implied in a *cause-effect* relation. Her method consists in using patterns applied to the web in order to extract pairs and generate new seeds. Do et al. (2011) focus on causal relations and take into account not only verbs but also event denoting nouns. According to this paper, an event is denoted by a predicate with a specific number of arguments and thus the association of the events is the sum of the association between predicates, between predicates and arguments and between arguments. Their association measures are based on PMI and are quite complex. Our results show that their measures do not generalize well to association with all discourse relations. Using Gigaword as a corpus and a reimplementation of Lin et al. (2014) they have extracted discourse relations. An inductive logic programming approach is finally used exploiting the interaction between causal pairs and discourse relations in order to extract causal links. Those papers focus on specific relations with the exception of Chklovski and Pantel (2004) who do not present a systematic evaluation of their results. An important difference of our approach is also to consider predicates and their negation as separate entries.

Finally, we mention the approaches which while focusing on the learning of discourse structures, nonetheless enrich their systems with lexical information. Feng and Hirst (2012) have used HILDA (Hernault et al., 2010) adding more features. A specific family of features represents lexical similarity based on the hierarchical distance in VERBNET and WORDNET. In a similar fashion, Wellner et al. (2006) focus on intra-sentential discourse relations adding lexical information on the features based on measures proposed by Lin (1998) calculated on the British National Corpus. Those approaches use thus only information on lexical similarity without semantically typing this link. The impact of this information seems limited. As far as evaluation is concerned, our method is similar to that followed in Tremper and Frank (2013) for implication relations combining in and out of context evaluation for verbal associations. Their inter-annotator agreement is similar to ours (0.42-0.44 of Kappa) with very different choices : the anno-

tators were supposed to discriminate verbal links between the different possible sub-cases. The pairs of verbs were identified by the system of Lin and Pantel. These authors also present a classification model among the different types of relationships, assuming that two verbs are semantically related.

6 Conclusions

We have presented a knowledge base of triples involving pairs of verbs associated with semantic or discourse relations. We extracted these triples from the large French corpus, frWaC, using discourse connectors as markers of relations between two adjacent clauses containing verbs. We investigated several measures to give the strength of association of a pair of verbs with a relation. We used manual annotations to evaluate our method and select the best measures, and we also studied the coverage of our resource on the discourse annotated corpus Annodis. Our positive results show our resource has the potential to help discourse analysis as well as other semantically oriented tasks.

Abstract

Collections of relational paraphrases have been automatically constructed from large text corpora, as a WordNet counterpart for the realm of binary predicates and their surface forms. However, these resources fall short in their coverage of hypernymy links (subsumptions) among the synsets of phrases. This paper closes this gap by computing a high-quality alignment between the relational phrases of the Patty taxonomy, one of the largest collections of this kind, and the verb senses of WordNet. To this end, we devise judicious features and develop a graph-based alignment algorithm by adapting and extending the SimRank random-walk method. The resulting taxonomy of relational phrases and verb senses, coined HARPY, contains 20,812 synsets organized into a *Directed Acyclic Graph (DAG)* with 616,792 hypernymy links. Our empirical assessment, indicates that the alignment links between Patty and WordNet have high accuracy, with *Mean Reciprocal Rank (MRR)* score 0.7 and *Normalized Discounted Cumulative Gain (NDCG)* score 0.73. As an additional extrinsic value, HARPY provides fine-grained lexical types for the arguments of verb senses in WordNet.

1 Introduction

Motivation: This paper addresses the task of discovering and organizing paraphrases of relations between entities (Lin and Pantel, 2001; Fader et al., 2011; Nakashole et al., 2012; Moro and Navigli, 2012; Alfonseca et al., 2013). This task involves understanding that the phrases "travels to", "visits" and "on her tour through" (relating a person and a country) are synonymous and that "leader of" and "works with" (relating a person and an organization) are in a hypernymy relation: the former is subsumed by the latter. This kind of lexical knowledge can be harnessed for advanced tasks like question answering (Fader et al., 2013), search over web tables (Gupta et al., 2014), or event mining over news (Alfonseca et al., 2013).

Work along these lines has developed large repositories of relational paraphrases, most notably, the collections ReVerb (Fader et al., 2011), Patty (Nakashole et al., 2012), and WiSeNet (Moro and Navigli, 2012). The largest of these, Patty, contains ca. 350,000 synsets of phrases, each annotated with ontological types of their two arguments (e.g., person $\times$ country, or politician $\times$ political_party). However, the subsumption hierarchy of Patty is very sparse. It contains only 8,000 hypernymy links between phrases, and the entire taxonomy is kind of fragmented into a many-rooted DAG (directed acyclic graph). Moreover, the synsets are rather noisy in the long tail with low confidence. WiSeNet, an alternative resource, has ca. 40,000 synsets and no hypernymy links.

WordNet (Fellbaum, 1998), on the other hand, is a very rich resource on synonymy and hypernymy. However, its coverage of binary relations (as opposed to unary predicates, mostly nouns) is restricted to (mostly) single-word verbs. WordNet has ca. 13,767 verb synsets, organized into a hierarchy with 13,239 hypernymy links. Unlike Patty, though, WordNet does not associate verb senses with a lexical type signature for the subject and object arguments of a verb, and it is sparse in multi-word phrases.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2195–2204, Dublin, Ireland, August 23-29 2014.

Resources like VerbNet (Kipper et al., 2008) or FrameNet (Baker et al., 1998) aim to overcome these deficiencies, but are much smaller.

Goal and Approach: In this paper, our goal is to overcome the limitations of resources like Patty and WordNet. We want to reconcile the wealth of Patty's multi-word paraphrases with lexical typing, on one hand, and the clean hypernymy organization of WordNet verbs, on the other hand. To this end, we compute an alignment between the phrase synsets that Patty provides with the verb senses of WordNet. This has mutual benefits: 1) we enhance many Patty phrases with the clean hypernyms of WordNet, this way augmenting the subsumption hierarchy, and 2) we extend WordNet verb senses with the lexical type signatures derived from Patty. Our approach uses a variety of features from both of the two aligned resources, as well as further auxiliary sources. Algorithmically, we build on an advanced notion of random walks over graphs, known as SimRank (Jeh and Widom, 2002).

Contributions: Our method is able to construct a high-quality taxonomy of relational paraphrases, coined *HARPY*, that combines the richness of Patty with the clean hierarchy of WordNet. The algorithm for computing the alignment is efficient and robust. One can think of the alignment as a way of sense-disambiguating Patty phrases by mapping them to WordNet. HARPY links 20,812 of the Patty phrases to WordNet. Conversely, 4,789 out of 13,767 WordNet verb senses are enriched with information from Patty. We evaluate the quality of HARPY by extensive sampling with human assessment. We also demonstrate its benefit by the extrinsic use-case of annotating WordNet verb senses with lexical type signatures. All experimental data and the HARPY resource will be available on a public web site.

2 Related Work

With the proliferation of knowledge bases, like Freebase (Google Knowledge Graph), DBpedia, YAGO, or ConceptNet, there is a wealth of resources about entities and semantic classes (i.e., unary predicates and their instances). In contrast, the systematic compilation of paraphrases for relations (i.e., binary predicates) has received much less attention. Some of the knowledge-base projects, especially those that center on Open Information Extraction, make intensive use of surface patterns (e.g., verbal phrases) that indicate relations (e.g., (Carlson et al., 2010; Fader et al., 2011; Mausam et al., 2012; Speer and Havasi, 2012; Wu et al., 2012)); however, they do not organize these patterns into a WordNet-style taxonomy.

Prior work towards such taxonomies go back to the projects DIRT (Lin and Pantel, 2001), VerbOcean (Chklovski and Pantel, 2004), and VerbNet (Kipper et al., 2008). However, the resulting resources were mostly restricted to single verbs. ReVerb (Fader et al., 2011) extended these approaches by automatically mining entire phrases from Web contents, but still with focus on verbal structures. Patty (Nakashole et al., 2012) used sequence mining algorithms for gathering a general class of relational phrases, organizing them into synsets, and inferring lexical type signatures. WiseNet (Moro and Navigli, 2012) harnessed phrases from Wikipedia articles and clustered them into synsets of relational phrases. All of these works are fairly limited in their coverage of subsumptions (hypernymy) between relational phrases.

There is ample work on computing alignments among different kinds of lexical thesauri, dictionaries, taxonomies, ontologies, and other forms of linguistic or semantic resources. Prominent cases along these lines include the alignments between FrameNet and WordNet (Ferrández et al., 2010), VerbNet and PropBank (Palmer, 2009), Wikionary and WordNet (Meyer and Gurevych, 2012), and across multilingual WordNets and/or Wikipedia editions (e.g., (de Melo and Weikum, 2009; Navigli and Ponzetto, 2012)). For aligning ontologies based on OWL and RDF logics, there is a series of annual benchmark competitions (Grau et al., 2013). Most approaches are based on relatedness measures and context similarities between words or concepts and their neighborhoods in the respective resources (e.g., (Banerjee and Pedersen, 2003; Budanitsky and Hirst, 2006; Gabrilovich and Markovitch, 2007)). Algorithmically, this translates into a nearest-neighbor (most-similar) assignment between entries of different resources. More sophisticated methods use similarities merely to assign weights to relatedness edges in a graph, and then employ random walks on such a graph (e.g., (Pilehvar et al., 2013)). The prevalent method of this kind uses Personalized Page Rank (Haveliwala, 2002)), computing stationary probabilities for reaching nodes in one resource when starting random walks on a given node of the other resources (with randomized restarts).

Computing alignments between resources can sometimes be viewed as a task of disambiguation words or concepts in one resource by mapping them to the other resource (e.g., mapping Wiktionary entries onto WordNet senses). Thus, the huge body of work on word sense disambiguation (WSD) is relevant, too. Methodologically, this research also relies, to a large extent, on relatedness/similarity measures and random walks on appropriately constructed graphs. See (Navigli, 2009) for an extensive survey.

There is remotely related work on several other tasks in computational linguistics and text mining. These include semantic relatedness between concepts or words (e.g., (Gabrilovich and Markovitch, 2007; Pilehvar et al., 2013)), type inference for the arguments of a phrase (e.g., (Kozareva and Hovy, 2010; Nakashole et al., 2013)), and entailment among verbs (e.g., (Hashimoto et al., 2009)). The SemEval-2010 task on classification of semantic relations (Hendrickx et al., 2010) addressed the problem of predicting the relation for a given sentence and pair of nominals, but was limited to a small prespecified set of relations.

3 Constructing a Candidate Alignment Graph

The general idea of the main algorithm is to align phrase synsets from the Patty taxonomy with verb synsets in WordNet. To this end, we first construct a directed *candidate alignment graph (CAG)*. Section 4 will then discuss the actual alignment algorithm.

Vertices of the CAG represent

- synsets of *relational phrases* in Patty, or phrases for short,
- *verb senses* from WordNet, verbs for short,
- *features* of either phrases or verbs.

Edges of the CAG correspond to relations between phrases, verbs, and features. We consider three types of relations here: similarity, hypernymy, and vertex-features. Edges are weighted (see below).

Vertex Types: There are 6 kinds of vertices in the CAG. Since we aim to connect Patty *phrases* with WordNet *verbs*, these two are the main kinds of vertices. Additionally, the graph contains feature vertices representing *noun senses* from WordNet (nouns for short), *surface verbs* as occurring in sample texts, *sentence frames* from WordNet, and specifically derived *phrase-verb vertices* connecting phrases and verbs. The latter are constructed by combining each phrase with its top-10 most similar verb senses. To this end, we retrieve all verb synsets from WordNet and rank the verb synsets by the cosine similarity between the support sentences that Patty provides for its phrases (i.e., sentences from Wikipedia that contain instances of a phrase) and the usage examples in WordNet glosses. The resulting vertices are labeled by the combination of phrase id and verb-sense id. Having these combinations as vertices, rather than simply connecting phrases and verbs via edges, leads to a CAG structure that is better suited for our random walk algorithms (see Section 4). Table 1 gives examples for the 6 vertex types.

Relational Phrase	Verb Sense	Noun Sense	Surface Verb	Sentence Frame	Phrase-Verb Pair
[person] succeeded [person]	succeed2#verb	king1#noun	succeed	Somebody ----s somebody	(phrase_1, verb_sense_2)
[musician] played jazz with [musician]	play3#verb	music1#noun	play	Somebody ----s something	(phrase_2, verb_sense_3)

Table 1: Examples of vertex types

Edge Types: Edges in the graph represent 3 different types of relationships between vertices:

- For all relational phrases, all verb senses from WordNet and also all noun senses (as feature vertices), we capture their *hypernymy relations* as edges.
- We connect phrase-verb vertices with their constituents, phrase vertices and verb vertices, by *similarity edges*, with weights derived from the similarity computation.
- The remaining edges connect phrases or verbs with their respective feature vertices. There are 6 kinds of such *vertex-feature edges*, explained next.

Verb Features: The following features are associated with verb senses. A *lemma edge* connects a verb sense with one or more surface-verb vertices, as given in WordNet glosses. A *domain edge* edge connects a verb sense with noun senses that describe the usage domain of the verb (e.g. literature, politics). This information is retrieved from WordNet and the WordNet Domains project (Bentivogli et al., 2004). While the latter does not provide sense-disambiguated information, we need to add a mechanism which maps domain information to its WordNet noun sense counterpart. Therefore, we map domain surface nouns to their most frequent senses.

In addition, we harness the WordNet links of type *derivationally related form* to construct further edges between verb senses and noun-sense features in our CAG. The last type of edges for verb-sense features are *sentence frame edges*, between verb vertices and feature vertices of type sentence frame. WordNet for each verb sense provides information about its sentence frames. There are defined 35 possible sentence frames.

Phrase Features: Relational phrases are associated with the following features. A *verb-in-phrase edge* connects a phrase with a surface verb whenever the phrase contains the verb after lemmatization. Analogously to the domain edges for verb senses, we introduce *Wikipedia-category edges* between relational phrases and noun senses. Patty provides us with Wikipedia articles where instances of a phrase occur. We consider all Wikipedia categories of such an article as a source for related noun senses. We use ontological types of the articles and the categories and their mappings to Wordnet provided by the YAGO project (Suchanek et al., 2007). Finally, we also introduce *sentence-frame edges* between relational phrases and sentence-frame feature vertices. To avoid polluting the CAG with overly noisy connections, we apply specific tests. First, we check if the lexical argument types of a phrase and a frame are compatible (e.g., musician is compatible with person, but not with location). Second, we compare characteristic prepositions in the phrase and the frame. We create and edge only if these additional tests are affirmative.

Examples of vertices connected by the different edge types with verb vertices and phrase vertices are shown in Table 2 and 3, respectively.

Hypernymy	Similarity	Lemma	Domain	Derivationally Related Form	Sentence Frame
replace2#verb	(phrase_1, verb_sense_2)	"succeed", "come after"	politics1#noun	successor1#noun	Somebody `----s` somebody

Table 2: Vetices connected by different edges with vertex "succeed2#verb" of type verb.

Hypernymy	Similarity	Verbs in phrase	Wikipedia Category	Sentence Frame
[person] replaced [person]	(phrase_1, verb_sense_2)	"succeed"	politician1#noun	Somebody `----s` somebody

Table 3: Vetices connected by different edges with vertex "[person] succeeded [person]" of type phrase.

Edge Weights: All edges in the graph are weighted. The weights are derived from frequency counts of features and/or similarity scores, or are simply set to 1 for binary cases (e.g., hypernymy edges). Lemma edges between verb senses and surface verbs vertices are weighted in proportion to the frequency count of a verb sense, as given by WordNet. Wikipedia-category edges have weights based on the number of occurrences of a relational phrase in Wikipedia articles and the frequencies of categories. Similarity edges have weights set according to the cosine similarity between examples of a verb sense and examples of a relational phrase.

Finally, we normalize all weights in the graph by requiring that the sum of weights of the incoming edges is equal to 1 for every vertex. For the verb and phrase vertices, we perform an additional normalization so that each kind of edge has the same impact in terms of the total edge weight per edge kind.

The above procedure leads to a CAG with 238,437 vertices and 4,776,116 edges. Figure 1 shows an excerpt for illustration.

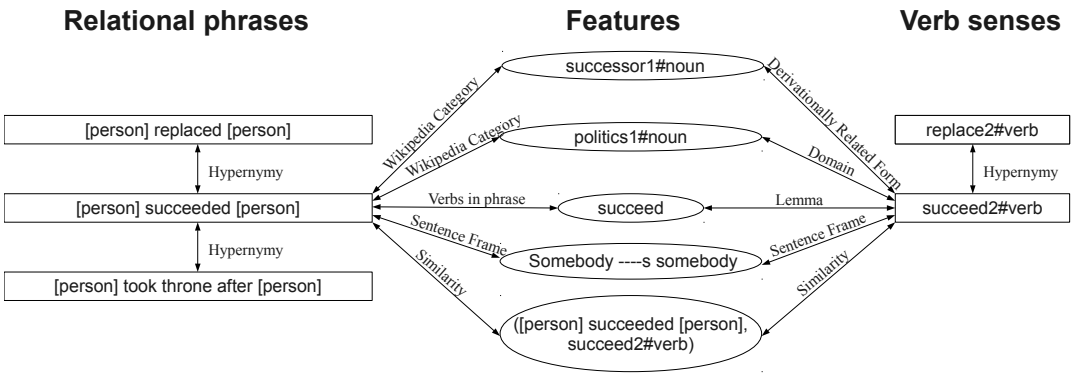

Figure 1: Excerpt from Candidate Alignment Graph

4 Alignment Algorithm

Our algorithm runs on the directed *candidate alignment graph (CAG)*. Intuitively, it aims to find "strong paths" between relational-phrase vertices and verb-sense vertices. We use random-walk methods to this end. For each relational phrase, we compute scores and a ranked list of verb senses to which the phrase likely corresponds. The top-ranked verb would ideally be the desired alignment.

SimRank: We employ the SimRank algorithm (Jeh and Widom, 2002), an advanced form of random walks. SimRank computes similarity scores between a pair of vertices in a weighted graph, based on the neighborhoods of the two vertices. The definition, formally given in Equation 1, is recursive: two vertices are similar if their neighborhoods are similar. In the standard SimRank equation, $I_i(a)$ represents the i^{th} (incoming) neighbor of vertex a, and C is a constant dampening factor.

$$s(a,b) = \frac{C}{|I(a)|\,|I(b)|} \sum_{i=1}^{|I(a)|} \sum_{j=1}^{|I(b)|} s\left(I_i(a), I_j(b)\right) \tag{1}$$

SimRank helps capturing long-distance dependencies between vertices in a graph. This would not be achieved by simpler similarity measures of context vectors. Note that SimRank is quite different from (Personalized) PageRank methods; SimRank can be seen as a random walk over pairs of nodes, not over individual nodes. During the CAG construction, we tried to keep the path lengths between phrase vertices and verb vertices uniform for all kinds of feature vertices, to avoid biasing the influence of specific features. Since the SimRank similarity is based on two random walks meeting, the method works best when all paths between source-target node pairs have even length. With this property SimRank produces better results; we introduced explicit phrase-verb vertices for this reason.

SimRank with Fingerprints: Unfortunately, SimRank has very high computational complexity: the run-time of a straightforward implementation is O(Kn^4), where n is the number of vertices in the graph and K is the number of iterations in an iterative fixpoint computation (in the style of the Jacobi method). However, there are much faster approximations of SimRank. We use a variant known as *SimRank with fingerprints* (Fogaras and Rácz, 2005) To approximate the SimRank score for two vertices, this method computes the *expected first meeting time* for two random walks originating from the two vertices (with randomized restarts). To this end, the method precomputes a fingerprint for each vertex a: a data structure holding the visiting probabilities of vertices for standard random walks originating in a. A fast implementation actually runs random walks a specified number of times, to estimate the visiting probabilities. For two vertices a and b, the expected number of hops until their random walks meet in a common vertex is then efficiently computed from the fingerprints of a and b. Moreover, this method allows computing the SimRank score for a pair of vertices on demand, only for vertex pairs of interest, rather than having to compute all $O(n^2)$ scores.

The original SimRank method works with unweighted graphs. In our setting, we modify transition probabilities according to edge weights. Our extended SimRank variant is equivalent to Equation 2,

where $W(a, b)$ denotes the weight of the edge between a and b. This equation is similar to the weighted variant of (Antonellis et al., 2007).

$$s_w(a, b) = C * \sum_{i=1}^{|I(a)|} \sum_{j=1}^{|I(b)|} W(a, I_i(a)) * W(b, I_j(b)) * s_w(I_i(a), I_j(b)) \quad (2)$$

Unlike the original SimRank method, we also incorporate random jumps in the underlying random-walk model. Each vertex has a different random jump probability, explained next.

Random Jumps: The original SimRank definition favors vertices with smaller neighborhoods. To avoid this bias, we introduce a form of smoothing on the graph. Whenever a phrase vertex or verb vertex lacks some of the feature types that other vertices may have, we introduce an option for random jumps from the given vertex to any other vertex in the graph. For each missing kind of feature (e.g., domain feature or sentence-frame feature), we assign a probability mass of ϵ, a small constant, for a random jump. So if several features are missing, there is an accumulated probability for a jump. The target of a random jump is always chosen with uniform distribution. A final normalization of edge weights (with linear adjustment) ensures that the possible transitions from a vertex form a proper probability distribution. he method works also without smoothing (i.e., setting the constant to 0), but the results tend to be worse. The results are not very sensitive to the exact choice of the random-jump parameter.

Filtering and Candidate Pruning: The target of our alignment is the WordNet verb hierarchy, but not all relational phrases can be mapped into this target space. Therefore, we restrict ourselves to a subset of relational phrases that contain exactly one verb. This eliminates noun phrases (e.g. "father of") and phrases that contain multiple verbs (e.g. "succeed and died", "succeeded in persuading"). Noun phrases should be aligned to the WordNet noun hierarchy and it should be treated as a different task (using e.g. state-of-the-art work (Ponzetto and Navigli, 2010)). Multi-verb phrases often pose semantic difficulties. Note that the verbs in these phrases are always transitive verbs, as Patty is derived from subject-phrase-object structures in large corpora. We also used the cardinalities of the support sentences in Patty for pruning the noisy tail of phrases, by dropping all phrases that have only a single instance.

To avoid computing SimRank scores for every pair of vertices, we prune the search space as follows. We consider only pairs of relational phrases and verb senses which contain the same surface verb (with lemmatization).

Deriving Hypernymy Links: Once we have alignments between phrases and verbs, we derive hypernymy relations *among phrases* as follows. Whenever phrases p_1 and p_2 are aligned with verb senses v_1 and v_2, respectively, and v_1 is a direct or transitive hypernym of v_2, we infer that p_1 is a hypernym of p_2. We consider transitive hypernyms because not every WordNet verb sense has a phrase aligned with it; without transitivity we would obtain a very sparse hierarchy. By the acyclicity of the WordNet hypernymy structure, the process yields a proper DAG. However, the output contains redundant links (direct ones and transitive ones connecting the same pair of phrases); these are subsequently eliminated by a transitive reduction algorithm (Aho et al., 1972).

5 Evaluation

We evaluated the quality of the HARPY alignments by manual assessment of a large sample set, and compared it against several alternative methods.

Baselines: We compared our SimRank-based method against the following baselines, each given the same feature set:

- *Cosine Similarity:* for each relational phrase and verb sense, we create a contextual vector (in the spirit of distributional semantics) consisting of the features described in Section 3, with tf-idf-based weights (Manning et al., 2008). The alignment ranking is computed by the cosine similarity of tf-idf-weighted contextual vectors.
- *Modified Adsorption (MAD):* a label propagation algorithm (Talukdar and Crammer, 2009) run on the candidate alignment graph. In our setting, each relational phrase is a label. Initially, only the respective phrase vertices have this label. The algorithm propagates labels to other vertices, based on

the graph's edge weights. The top-k results for the alignment of a phrase are the verb senses with the highest probability for the phrase label. We use the Junto Label Propagation Toolkit [1].

- *Personalized PageRank (PPR):* a method for random walks with random jumps back to the start vertex (Haveliwala, 2002). For each phrase, a separate PPR is performed. The ranking of verb senses is produced by the visiting probabilities according to the PPR scores.
- *Most Frequent Sense (MSF):* For each phrase, we consider only verb senses that contain the same surface verb (with lemmatization), and rank them by the WordNet frequency information.

Assessment: We retrieved a random subset of 261 relational phrases considered for alignment, and showed the results of the different alignment methods to two human judges. For each relational phrase, we displayed its textual form, list of usage examples, and the top-5 ranked list of verb senses computed by each method under comparison. Each verb sense was enriched with information about its lemmas, its gloss, and examples. The evaluators were asked to identify the verb sense that is semantically equivalent to the given relational phrase (including the option of saying "none").

Quality Measures: As all methods compute a ranked list of verb senses for a given phrase where exactly one list item is correct, we use quality measures geared for such rankings: Mean Reciprocal Rank (MRR) and Normalized Discounted Cumulative Gain ($NDCG$). In addition, we report on the precision for top-k results, for small k (1, 3, or 5). Here, a top-k result is considered good if the correct verb senses appears among the top-k alignments, for a given phrase.

Results: The results are shown in Table 4. Our method outperforms all baselines. Among the competitors, MFS shows the best performance. This is not so surprising; MFS is rarely outperformed in word sense disambiguation (McCarthy et al., 2004; Navigli and Lapata, 2010). Our gains over MFS are remarkable. In total, HARPY aligned 20,812 phrases to 4,789 verb senses, and also obtained 616,792 hypernymy links between phrases.

The evaluation process led to high inter-judge agreement, with Cohen's Kappa around 0.678. The number of samples, 261, was large enough for statistical significance: we performed a paired t-test for MRR, $NDCG$ and $Precision@1$ of the SimRank results against each of the baselines, and obtained p-values below 0.05.

	SimRank	MFS	PPR	MAD	Cosine
MRR	0.698	0.664	0.553	0.463	0.252
NDCG	0.733	0.705	0.584	0.51	0.279
Precision@1	0.571	0.517	0.41	0.318	0.161
Precision@3	0.793	0.778	0.644	0.594	0.307
Precision@5	0.874	0.866	0.736	0.67	0.391

Table 4: Evaluation

Tables 5 and 6 shows example results that HARPY computed. Table 5 has correct outputs. We see that HARPY manages to distinguish between the sport, musical, and theatrical senses of the verb "play". As shown in Table 6, HARPY also produces some spurious results, with various factors contributing to these errors. For example, the phrase "covered on album" was aligned with the first sense of "cover" since there is no musical sense for "cover" in WordNet. Other errors arise from mistakes in the original Patty repository of relational phrases. For example, the travel sense of the verb "head" was aligned with the phrase "head of" because "head of" and "head to" were in the same Patty synset. Yet another cause of problems is the extremely fine granularity of WordNet: even for humans it is often hard to distinguish between love as a state of liking and love as being enamored.

6 Extrinsic Study: Lexical Types for WordNet Verbs

As an extrinsic use-case for the HARPY resource, we studied the task of inferring lexical types for the subject and object arguments of a WordNet verb sense. For a given verb sense, we propagate the type signature of the relational phrase with the highest alignment score.

[1] http://code.google.com/p/junto/

Relational phrase	Verb Sense	WordNet definition
[musician] played with [musician]	play3	play on an instrument
[actor] played [[det]] role in [event]	act3	play a role or part
[person] played hockey for [organization]	play1	participate in games or sport
[person] was shooting [person]	shoot2	kill by firing a missile
[movie] be shot in [city]	film1	make a film or photograph of something
[composition] written by [composer]	compose2	write music
[writer] writing at [organization]	write1	produce a literary work

Table 5: Correct examples

Relational phrase	Verb Sense	WordNet definition
[person] covered on album [artifact]	cover1	provide with a covering or cause to be covered
[person] head of [artifact]	head1	to go or travel towards
[person] becomes convinced that [person]	become1	enter or assume a certain state or condition
[person] is loved by [person]	love1	have a great affection or liking for
[wrestler] wrestled in [organization]	wrestle1	combat to overcome an opposing tendency or force

Table 6: Wrong alignment examples

For comparison, this procedure is performed with the HARPY alignments as well as the alignments by the baseline methods. We showed a uniformly sampled set of 261 results to human judges, who assessed as valid or invalid. Additionally, we had a set of the 100 most-confident results (those derived from the highest alignment scores) assessed in the same manner.

For the uniform samples, the type signature derived from HARPY had a precision of 0.46, whereas the best of the baselines (PPR and Cosine) achieved 0.39. For the top-100 samples, HARPY achieved a precision of 0.81. Table 7 shows some example results, demonstrating the added value beyond WordNet.

Domain	Range	Verb Sense	WordNet definition
country	country	export1	sell or transfer abroad
person	country	head2	be in charge of
organization	organization	own1	have ownership or possession of
person	person	predate1	be earlier in time; go back further
saint	organization	reverence1	regard with feelings of respect and reverence
person	artifact	rush5	run with the ball, in football
organization	person	sustain4	supply with necessities and support
musician	musician	play3	play on an instrument
football_player	athlete	pass20	throw (a ball) to another player
singer	composer	inspire2	supply the inspiration for
ruler	country	suppress1	to put down by force or authority
architect	city	design2	plan something for a specific role or purpose or effect
priest	saint	canonize2	treat as a sacred person
country	country	ally_with1	unite formally; of interest groups or countries
company	organization	deal13	sell
artifact	computer_game	port8	modify (software) for use on a different machine or platform

Table 7: Type inference examples by HARPY

7 Conclusion

HARPY is a new resource that aligns lexically typed multi-word phrases for binary relations with WordNet verb senses. By judiciously devising appropriate features and adapting and extending an advanced random-walk method, SimRank, we achieved high-quality alignments, as shown in our evaluation. This creates added value for both the resource of relational phrases, Patty, and WordNet. Phrases are now organized into a clean hypernymy hierarchy, an important aspect on which the Patty work fell short. WordNet verb senses, on the other hand, are extended by a rich set of paraphrases and also by lexical type signatures inherited from the phrases. We believe that this new resource is a useful asset for computational linguistics. As a future work, we plan to align additional resources like WiseNet (Moro and Navigli, 2012), FrameNet (Baker et al., 1998) or VerbNet (Kipper et al., 2008). The HARPY resource is publicly available at `www.mpi-inf.mpg.de/yago-naga/patty/`.

Abstract

In this paper we address the question of the reliability of the predictions made by MT Quality Estimation (QE) systems. In particular, we show that standard supervised QE systems, usually trained to minimize MAE, make serious mistakes at predicting the quality of the sentences in the tails of the quality range. We describe the problem and propose several experiments to clarify their causes and effects. We use the WMT12 and WMT13 QE Shared Task datasets to prove that our claims hold in general and are not specific to a dataset or a system.

1 Introduction

Machine Translation (MT) Quality Estimation (QE) has become an important subject of study in the past few years (Callison-Burch et al., 2012; Bojar et al., 2013). This follows directly from the erratic quality of MT output in general: although MT is now widely used in professional contexts, it is still prone to many errors; therefore a careful post-editing stage, performed by human experts, is usually needed. In this context, QE can help carrying out this process more efficiently, and more specifically to help in the decision process between the automatic and the manual stages: if a reliable indication of quality is provided for every machine-translated sentence, the human effort can be reduced. For example, a very bad translation is worthless because the translator usually has to spend more time fixing it than she or he would have spent translating the sentence from scratch; thus it makes more sense in such cases to either send the sentence back to an alternative MT system (e.g. trained on a different corpus), or simply leave it untranslated for the translator. Clearly the advantage of using a QE system depends on the reliability of its predictions. If it makes too many errors, then it only confuses the translation workflow; in this case the translators would perform better without it.

The quality of an (automatic) QE system cannot be perfect, but it should be at least controllable. That is, it should be possible to assess the reliability of the predictions made by a system, for instance by estimating the level of confidence of the predictions. Hopefully, QE systems will progress towards this kind of behaviour, but currently the evaluation methods are not entirely satisfactory from this perspective. In particular, after describing our experimental setting in §2, we will observe in §3 that the use of the Mean Absolute Error[1] (MAE) as a global evaluation measure hides huge discrepancies in the distribution of errors among the range of scores. More precisely, supervised systems optimized to minimize the MAE have intrinsic flaws in the way they assess the tails of the quality range, i.e. the "very good" and the "very bad" sentences. In §4 we propose different ways to evaluate the impact of this problem, and also clarify what might be an important misunderstanding in what a QE system actually does (§4.2). Finally we propose in §5 several experiments: in §5.1 we show that the problem is not system-specific, and we test two ways to circumvent it in §5.2 and §5.3, but the price to pay in global performance is high.

[1] The MAE is defined as the mean over all instances of the absolute error, where the absolute error is the absolute value of the difference between the predicted and the actual value of the instance. Thus, the MAE score depends on the range of possible values (i.e., two datasets using different ranges cannot be compared).

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2205–2216, Dublin, Ireland, August 23-29 2014.

2 Experimental Setup

2.1 Data

In this paper we use the three datasets from the WMT12 and WMT13 QE Shared Task (Callison-Burch et al., 2012; Bojar et al., 2013) which are intended to predict the quality of individual machine-translated sentences: the WMT12 task and the WMT13 task 1.1 and 1.3. The last two datasets are renamed *wmt13a* and *wmt13b* in the rest of this paper. These three datasets differ by the way quality is measured:

- *wmt12:* **effort scores**, which have been assigned by three professional post-editors according to predefined guidelines; scores range from 1: "the MT output is incomprehensible [..]" to 5: "the MT output is perfectly clear [..]". The dataset was cleaned to avoid the cases with a high level of disagreement, and the scores were post-processed to harmonize the scale between the judges.
- *wmt13a:* **HTER scores**, which measure the distance between the MT output and the post-edited sentence (Snover et al., 2006).
- *wmt13b:* **post-editing time**, that is, the time that the post-editor has spent correcting the MT output.

As a consequence, the set of scores have different characteristics: in *wmt12*, the distribution is highly discrete due to the integer values assigned by the judges. In *wmt13a* the distribution is more dense, whereas in *wmt13b* some values are spread extremely far from the mean.[2] General statistics for the datasets are given in table 1. In all datasets the input and MT output sentences are available to the system; the post-edited version of the sentences is also available, but it cannot be used by the QE systems (the test set post-edited sentences were provided only after the end of the task). We focus on predicting an absolute indication of quality rather than only ranking the sentences by quality; this is why we use the Mean Absolute Error (MAE) as the main evaluation measure rather than Spearman's correlation or DeltaAvg (Callison-Burch et al., 2012).

2.2 Supervised QE System

In the observations and experiments described in this paper we use a QE system which follows a standard supervised learning approach: it was trained on the full training set for every task considered; when the performance on the training set is observed, it was assessed using 10-fold cross-validation (thus obtaining a prediction for every sentence in the train set based on a 90% subset). We have used Quest[3] (Shah et al., 2013), an open-source tool for QE, to compute the 17 "black box features" which are also used in the WMT QE "baseline" system (see below). We have used Weka (Hall et al., 2009) (version 3.6.10), and after testing several options[4] we found that using the *SMOreg* algorithm (Smola and Schölkopf, 2004; Shevade et al., 2000) with an RBF kernel[5] was optimal with respect to the performance on the three datasets.

We did not perform any feature selection or parameter tuning, because our main goal was to build a generic system. Additionally we favor the ease of reproducibility over optimal performance, which is out of the scope of this paper. We want our system to be as generic as possible (but still performing decently, of course), because we need it to be fairly representative of standard, state-of-the-art, supervised learning QE systems. This is very important, since our observations and experiments are supposed to generalize to the current most common approaches in QE.

Our task of making the system representative of state-of-the-art QE systems has been greatly facilitated by the fact that the organizers of the WMT12 and WMT13 QE Shared Task provide for every task the performance of a so-called "baseline system". We can use exactly the same set of features and compare the results of our system against these obtained by this baseline system, which in turn does not deserve

[2] This is why we exclude the most striking outlier from the training set: 1115.906, line 294. The test set is left unchanged.

[3] `http://staffwww.dcs.shef.ac.uk/people/L.Specia/projects/quest.html` – last verified 05/14.

[4] In particular, M5P regression trees generally achieve nearly as good performance as SVM regression. We have also observed that at least the most important characteristics reported in this paper for an SVM system hold for M5P regression as well.

[5] With the default value C=1 and standardization of the features values.

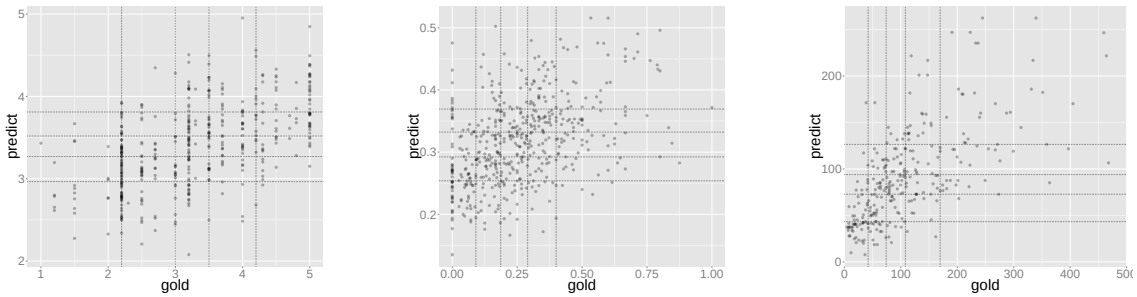
its name since it has actually always performed well in every task: it ranked 8th out of 20 in the WMT12 official ranking, 12th out of 17 in WMT13a, and 6th out of 14 in WMT13b (MAE ranking). Thus, we can simply check that our system performs as well as this baseline system to ensure that it is equivalent, and therefore probably reasonably similar to the other supervised systems submitted to the Shared Tasks which perform similarly.[6] Table 1 shows that our system performs roughly the same as the baseline system on the three datasets.

Dataset	Range of values	Quality direction	Statistics						Performance (test set)			
			Train set			Test set			Our system		Baseline system	
			instances	mean	std. dev.	instances	mean	std. dev.	cor.	MAE	cor.	MAE
wmt12	$[1, 5]$	$\rightarrow$	1832	3.44	0.88	422	3.29	0.98	0.56	0.69	0.58	0.69
wmt13a	$[0, 1]$	$\leftarrow$	2254	0.32	0.17	500	0.26	0.19	0.44	0.15	0.46	0.15
wmt13b	$[0, +\inf[$	$\leftarrow$	802	95.6	84.2	284	116.9	108.3	0.70	50.9	0.70	51.9

Table 1: **Datasets: statistics and performance.** Quality direction: $\rightarrow$ means that the quality is better when the score is higher, $\leftarrow$ means the opposite; "cor." is the Spearman's correlation.

3 The Tails Prediction Problem

In this section we mostly observe the training set (using cross-validation), in order to dismiss the possibility that the observed phenomenon is caused by the differences in the distributions of scores between the training set and the test set. Since it is easier for a supervised learning algorithm to annotate some data from the set it was trained on than from a different dataset, problems which appear with the former are very likely to appear as well (possibly accentuated) with the latter.



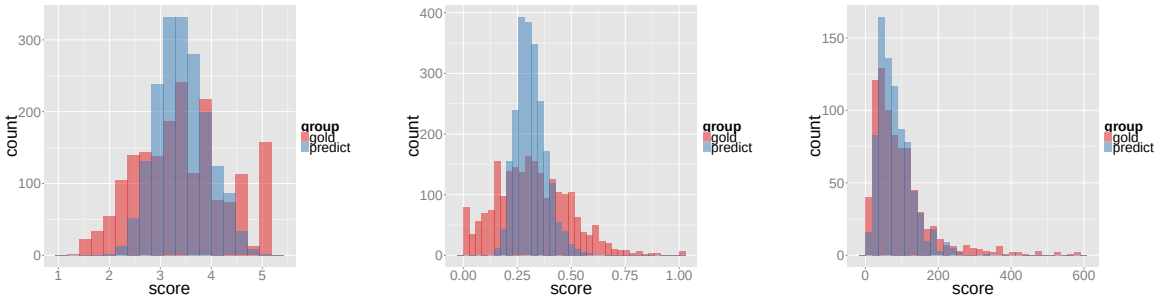
(a) wmt12. Spearman cor.: 0.53 (b) wmt13a. Spearman cor.: 0.37 (c) wmt13b. Spearman cor.: 0.62

Figure 1: **Scatter plots showing how predicted scores differ from gold scores (test set).** Every point (X,Y) corresponds to one sentence for which X is the gold score and Y the predicted score. Darker areas correspond to more dense areas; the vertical and horizontal lines indicate the frontiers of 20%-quantiles for both variables (for instance, the points which are on the right side of the rightmost vertical line account for the 20% highest gold scores). Remark: a few outliers are not visible on the wmt13b plot (their gold scores are higher than 500, and their predicted scores are lower than 250).

Figure 1 shows that the points are very scattered and do not follow the diagonal very closely, but also that the range of predicted scores is significantly different from the range of gold scores: no sentence is predicted below 2 for wmt12, above 0.55 for wmt13a and above 260 for wmt13b, whereas the corresponding range of gold scores is much wider. Figure 2, which shows the distribution of gold vs. predicted scores for the training sets, gives a more precise picture of this difference: in all three datasets, the predicted scores tend to belong to a smaller set of values centered approximately around the mean. There are clearly more predicted values than gold values in this area, and this is confirmed by the much smaller standard deviation for the predicted scores.

It is possible to obtain a clearer picture by "flattening" the distribution, that is, instead of drawing histograms in which points with the same value (or a close value) are accumulated, we represent every

[6] In section 5.1 we also check more specifically that our observations hold for most of the systems submitted to WMT12.

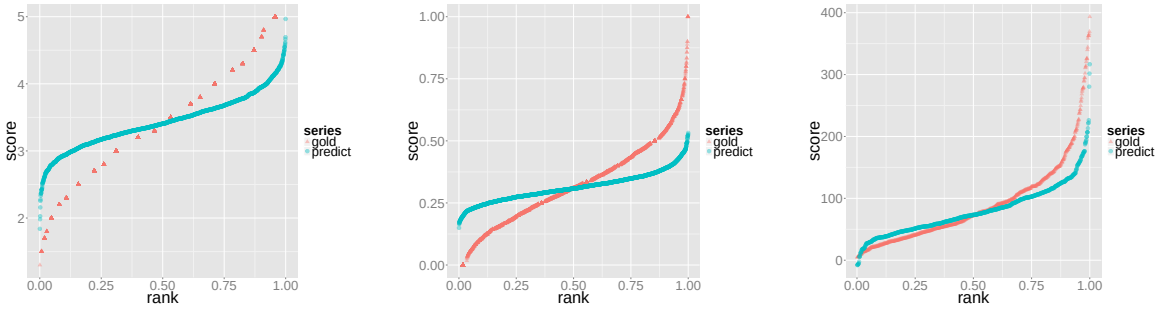


(a) wmt12. $\sigma_G = 0.88,\ \sigma_P = 0.50$ (b) wmt13a. $\sigma_G = 0.17,\ \sigma_P = 0.07$ (c) wmt13b. $\sigma_G = 84.2,\ \sigma_P = 46.5$

Figure 2: **Combined distributions of the gold scores and predicted scores** on the training set for the three datasets. σ_G (resp. σ_P) is the standard deviation for gold (resp. predicted) scores.

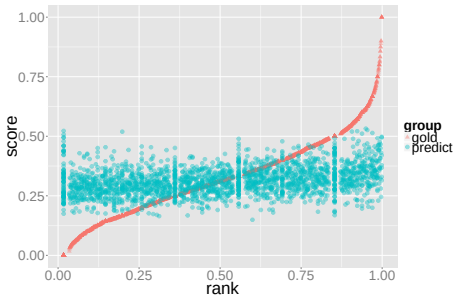
point on the X axis and sort the values on this axis, so that their actual value can be observed on the Y axis, as shown on figure 3. This figure shows that, in all three cases, the predicted scores are tightly clustered around the median, which is the point where the two curves cross each other. If the system predicted scores according to the distribution it observed on the training set, the two curves would be close; instead, they clearly diverge from each other as the distance to the median increases. This means that the model tends globally to overestimate the points below the median and, symmetrically, underestimate the points above the median (though the symmetry is degraded in 3c, since the range is unbound to the right).

In figure 3 the two sets of points are sorted independently: the sentence (x, y) on the curve of gold scores is different from the one with the same x on the curve of predicted scores. Yet this observation of "tightened" predicted scores cannot be fully understood without taking into account the risk of error in the prediction process, as it was visible on the scatter plots in figure 1. Thus it is also useful to look at the sorted scores, but with their corresponding predicted score (for the same sentence) plotted on the same x coordinate; this what is shown on figure 4, for the *wmt13a* dataset only (because the phenomenon is the most accentuated in this dataset, and scores conveniently belong to $[0, 1]$). On figure 4a one can see that the set of predicted scores are mostly contained in a slightly inclined rectangle; clearly they do not follow the curve of gold scores, but here one can see why: the fact that there are many points at the same level on the Y axis along the whole X axis shows that the algorithm cannot make a clear distinction between the different levels of quality. For example, there are approximately as many scores predicted around 0.3 which correspond to actually very good (rank near 0) and very bad sentences (rank near 1). From a different perspective, figure 4b shows very clearly that the farther the gold score of a sentence is from the mean (0.32), the more likely it is to be predicted with a large error.

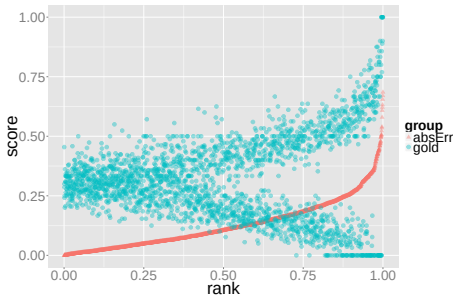


(a) wmt12 (b) wmt13a (c) wmt13b

Figure 3: **Sorted gold and predicted scores** for the three datasets. The two sets of scores are sorted independently. The X axis is the normalized rank (0 to 1 instead of 1 to the total number of sentences), so that it is easier to observe the quantiles. Example: for wmt13a, the lowest fourth of gold scores ranges from 0 to around 0.20, whereas the lowest fourth of predicted scores ranges from 0.125 to around 0.27. Remark: on the wmt13b plot the scores higher than 400 are not visible (all are gold scores).



(a) **Gold scores as reference.** Sentences are sorted by their gold score; the X axis gives their corresponding rank; the *predicted* score of a sentence is plotted on the same abscissa, thus showing both the gold (in red) and predicted score (in blue) of the sentence on the Y axis. The predicted scores which appear on the same vertical line correspond to different sentences which have the same (or very close) gold scores.



(b) **Absolute error as reference.** Sentences are sorted by their absolute error; the X axis gives their corresponding rank; the *gold* score of a given sentence is plotted on the same abscissa, thus showing both the error (in red) and gold score (in blue) of the sentence on the Y axis. The gold scores which appear on the same vertical line correspond to different sentences which have the same (or a very close) absolute error.

Figure 4: **wmt13a, training set: sentences sorted by gold score (left) or absolute error (right).**

The issue is constant among the datasets, but with a variable impact. To some extent, it could be summarized in the following way: it appears that the system does not try to predict the actual quality of the sentences, but instead applies a simple optimization strategy; since a large majority of sentences belong to a relatively small range of values in the middle of the full possible range of scores, predicting any score outside this range is taking a big risk. Consequently it is safer, in order to minimize the error rate, to ignore (or barely take into account) the rare cases which belong to the tails. Hence the system ends doing the opposite of what is usually expected from a quality estimation system: the most common cases are rather accurately recognized, but the most striking anomalies are left undetected or poorly labelled as such. This behaviour can be explained by the following reasons:[7]

- **The supervised learning optimization criterion is very often the minimization of the MAE,**[8] as in our system. This leads the algorithm to favor the interval of scores where there are many instances, since their weight is more important in the average.
- **The datasets are unbalanced**, which is certainly realistic in terms of application, but it also encourages the algorithm to assign scores in the interval which would be the "default class" in a classification problem; that is, without any clear indication in the features, it is strategically wiser to bet on the most probable answer.
- **The risk is lower with respect to MAE** to assign a score in the middle of the range of possible values rather than at the extremes. For instance if the range is $[1, 5]$ the maximum absolute error at 3 is 2, whereas it is 4 at 1 or 5. However, at least for *wmt13a*, the data shows that, if this hypothesis had a real impact, the predicted scores would be closer to 0.5 than to the mean 0.32.

4 Detecting and Evaluating the Tails Quality

4.1 Possible Measures

We propose below different measures intended to evaluate the impact of the tails prediction problem. Since it can be defined as an increased level of error for sentences which are far from the mean, a simple first measure is the correlation between the distance from the gold score to the mean and the absolute error: this value reflects whether the errors are higher in the tails than close to the mean and to what extent (in other words, it measures how strong the divergence observed on the right part of figure 4b is). Table 2 shows how high Pearson's correlation is in our data.

A simple way to measure the performance locally in the tails is to consider the task as a binary classification problem, as if we were only interested in recognizing whether a sentence belongs to a particular

[7] The first two reasons are actually closely related, they only show different aspects of the same problem.

[8] Especially in the WMT QE tasks, since this is the main evaluation measure for the scoring task.

wmt12						wmt13a						wmt13b					
train			test			train			test			train			test		
all	>0	<0	all	>0	<0	all	>0	<0	all	>0	<0	all	>0	<0	all	>0	<0
0.58	0.54	0.64	0.62	0.64	0.65	0.82	0.84	0.78	0.76	0.86	0.76	0.80	0.89	-0.18	0.83	0.91	-0.01

Table 2: **Correlation between the absolute error and the distance to the mean of the gold score.** ">0" (resp. "<0") is the correlation when taking only into account the scores above (resp. below) the mean; this gives a more precise picture for the top/bottom quality scores. For example, in *wmt13b* the top quality (lowest) scores are very well predicted, as opposed to the bottom quality (highest) scores.

subset of scores. For example, the frontier between the classes can be fixed between the 90% lowest scores (negative) and the 10% highest (positive): it is then possible to observe the last 10% using the standard evaluation measures: precision (proportion of true positive among the sentences labeled as positive), recall (proportion of sentences labeled as positive among all positive sentences) and F1-score (harmonic mean of the precision and recall).[9] The values of these measures are given for three thresholds in table 3. As expected, the recall is extremely low in the tails; it is even 0 in most cases for the 5% threshold, which means that the system does not assign any score in the 5% top/bottom of the range observed on the training data.

Data+tail	5%				10%				20%			
	limit	P	R	F1	limit	P	R	F1	limit	P	R	F1
wmt12 B	≤ 2.0	–	0.0	–	≤ 2.3	0.33	0.01	0.02	≤ 2.7	0.73	0.16	0.26
T	≥ 5.0	–	0.0	–	≥ 4.7	0.50	0.02	0.04	≥ 4.2	0.65	0.18	0.28
wmt13a B	≥ 0.62	–	0.0	–	≥ 0.54	–	0.0	–	≥ 0.47	0.62	0.11	0.19
T	≤ 0.06	–	0.0	–	≤ 0.11	–	0.0	–	≤ 0.17	0.50	0.01	0.01
wmt13b B	≥ 272	–	0.0	–	≥ 186	0.76	0.26	0.39	≥ 134	0.71	0.43	0.54
T	≤ 18.2	0.5	0.05	0.09	≤ 24.8	0.18	0.06	0.10	≤ 35.7	0.52	0.30	0.38

Table 3: **Local classification measures (test set).** "T" (resp. "B") refers to the top (resp. bottom) quality tail; P/R/F1 are the standard Precision/Recall/F1-score.[10] Example: 10% of the scores for the *wmt12* training data are higher than 4.7 (top quality tail); among the gold scores in the test set which are higher than this 4.7 threshold, only 2% are predicted as higher than 4.7 (recall); and among the scores predicted as higher than 4.7, exactly 50% are actually higher than 4.7 (precision).

Additionally, we have separately proposed a measure which aims to evaluate the ranking error locally (Moreau and Vogel, 2013). The same idea can be applied to scoring errors: the Local MAE (LMAE) can be computed on a particular range of scores. The difference with global MAE is that, for a given sentence, the gold score or the predicted score can belong to the range while the other does not. This is why there are two versions of this measure: gold-based LMAE and prediction-based LMAE, which, as their names suggest, take into account only the gold scores (resp. predicted scores) which belong to the range in the absolute difference $\mid gold - predicted \mid$, as defined in definition 4.1.

Definition 1 (Local MAE (LMAE))**.** *Let S be a set of sentences, and D the interval of possible scores:*

[9] In the observations which follow we choose to set the limits (5%, etc.) based on the training set even though the test set is observed. In other words, the absolute score corresponding to the percentage is calculated using the training set gold scores, which might differ from the value calculated from the test set. The disadvantage is that the number of values in the test set in the corresponding range does not necessarily correspond to the percentage, but this way the limits do not depend on the test set, so that values obtained on different test sets would be comparable.

[10] We consider the $N\%$ limits computed from the range of gold scores, and not from the range of predicted scores: this makes more sense because otherwise the system is not evaluated against the actual scores in the tails, but since the range of predicted scores is actually smaller than the range of gold scores, sometimes there are no predicted scores at all in this range of values (especially for the lowest values of N, e.g. 5%). For example in the *wmt12* dataset 5% of the gold scores are below 2, but the system does not predict any value below 2. In such a case we consider that this is equivalent to a classifier which decides not to label any instance in a given category. Since there are no instances labelled as positive at all, the precision is undefined, which makes the F1-score undefined as well. The corresponding cells are marked as "–" in tables 3 and 6.

for every sentence $s \in S$, $predicted(s) \in D, gold(s) \in D$. *For any subinterval* $I \subseteq D$:[11]

$$LMAE_{gold} = mean\left(\left\{ \left| \, gold(s) - predicted(s) \, \right| \, \middle| \, s \text{ such that } gold(s) \in I \right\} \right)$$
$$LMAE_{pred} = mean\left(\left\{ \left| \, gold(s) - predicted(s) \, \right| \, \middle| \, s \text{ such that } predicted(s) \in I \right\} \right)$$

To some extent, the gold-based LMAE (resp. prediction-based) is similar to a recall measure (resp. precision) because it takes into account the true positive and the false negative (resp. the true positive and the false positive) with respect to the range. This can be observed in table 4, which gives the values of these two measures for three thresholds on the three datasets: $LMAE_{gold}$ is almost always much higher than the global MAE, whereas there $LMAE_{pred}$ is often close to or lower than the global MAE. This is because, compared to the gold scores, the top or bottom predicted scores are closer to the centre of the range. Therefore the sentences taken into account include some actual "tails sentences" (for which the absolute error is high), but they can also contain many sentences which actually belong to the area (for which the absolute error is low).

		5%		10%		20%	
Data+tail	(Global) MAE	$LMAE_{gold}$	$LMAE_{pred}$	$LMAE_{gold}$	$LMAE_{pred}$	$LMAE_{gold}$	$LMAE_{pred}$
wmt12 B	0.69	1.37	0.47	1.02	0.57	1.02	0.62
T		1.08	0.68	1.08	0.67	0.89	0.68
wmt13a B	0.15	0.35	0.18	0.28	0.18	0.19	0.17
T		0.28	0.12	0.28	0.13	0.24	0.13
wmt13b B	50.9	264	154	192	129	135	90.3
T		26.1	22.9	24.5	27.4	27.4	25.2

Table 4: **Local MAE evaluation (test set).** "T" (resp. "B") refers to the top (resp. bottom) quality tail. Example: for the wmt13b data, among the 10% actual top quality sentences (i.e. the 10% lowest gold scores), the mean absolute error is 26.1. This is lower than the global MAE (50.9), as opposed to all the other cases; this confirms that the top quality tail in *wmt13b* is particularly well predicted (this is certainly a consequence of the strongly skewed distribution in this dataset).

4.2 The Post-edited Sentences Test

A good way to evaluate the discrepancies in the reliability of the quality scores in the tails is to apply the QE system to a set of very good or very bad sentences. Thankfully the post-edited versions of the sentences were provided with the WMT datasets; since by definition their quality is perfect, they make a perfect case for such a test.[12] In theory, all these sentences should be assigned a score close to top quality.[13] For every dataset we run the same QE system, i.e., we compute the features for the post-edited sentences using Quest, then apply the model built with the regular training data to these features. We tried with both the post-edited version of the training set and test set, when provided.[14]

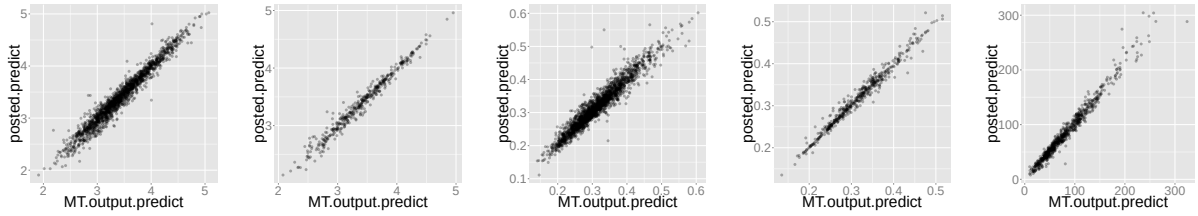
Our original goal was to observe how high the error rate was globally, but it turned out that the predicted scores follow a distribution which is very similar to the one followed by the MT output (the means are very close as well, which implies that the MAE is very high). This led us to observe how the MT output scores and the post-edited version scores are correlated. In most cases the two scores are very close, as shown on figure 5. This is obviously a very serious issue, since it means that, in general, the system is not able to distinguish between a sentence which needs correction and the same sentence after correction.

[11] Remark: if $I = D$, $LMAE_{gold} = LMAE_{pred} = MAE$.

[12] Independent assessment of the post-edited sentences is, of course, not guaranteed to yield the judgement that they would not benefit from further editing, though.

[13] That is, 5 for the *wmt12* dataset and 0 for the *wmt13a* dataset (since HTER scores measure the distance against the post-edited version, and here we compare the post-edited sentence against itself); the *wmt13b* dataset is based on post-edited time, so there is no exact value corresponding to perfect sentences but the scores should very low.

[14] The post-edited version was not available for the wmt13b test set.



(a) wmt12, train set; cor.=0.977; mean diff.=-0.03=-0.03σ

(b) wmt12, test set; cor.=0.986; mean diff.=-0.02=-0.02σ

(c) wmt13a, train set; cor.=0.962; mean diff.=0.004=0.02σ

(d) wmt13a, test set; cor.=0.987; mean diff.=0.002=0.01σ

(e) wmt13b, train set; cor.=0.985; mean diff.=3.14=0.04σ

Figure 5: **MT output predicted scores vs. post-edited predicted scores** "mean diff." is the mean of the difference between the post-edited score and the MT output score; it is also expressed as a multiple of σ, where σ is the standard deviation of the MT output gold scores (specific to each particular dataset).

It is however able to see a slight difference at the document level: we have performed a paired Student's test for each dataset, which shows that the mean of the scores predicted for the post-edited sentences is significantly lower in the *wmt12* case and higher in the *wmt13a* and *wmt13b* cases (as expected by the definition of scores) than the scores predicted for the MT output sentences. Nevertheless, the mean difference is extremely low (see figure 5), never higher than 0.04 standard deviations.

Furthermore, there is no visible impact of the quality of the MT output, although one would expect the correlation to be lower for low quality sentences: by definition, there are more differences between the MT output and the post-edited version for these sentences, so it should be easier for the system to detect the different level of quality between the two. In other words, it is quite understandable that the system does not detect the difference for an MT output of relatively good quality, but the fact the post-edited version of the really bad translations are also rated as really bad is a major issue. It must be remembered that we are not refering to a flaw solely in our own system, but nearly across the board in the state of the art systems.

These observations, which hold for every dataset, show that QE systems do not capture the actual quality of the sentences: instead, it seems that what they measure is probably the *difficulty of machine-translating a sentence*. Indeed, the set of Quest features that we use contains many features which depend only on the source sentences. Moreover, this conclusion is consistent with the fact that Biçici et al. (2013) obtain very good results on the WMT12 dataset using only the source sentences.

Explaining this observation with precision would require a more detailed analysis which is out of the scope of this paper. Nevertheless, it is fairly clear that the features which are used fail to capture the subtlety and/or the diversity of the difference between a faulty sentence and its corrected version; this might be because a single sentence does not offer enough clues for the system to make such a fine-grained distinction, in which case it would be necessary to rethink the definition of the QE problem.

In other work, we examine linguistic quality of items in relation to reference corpora (Moreau and Vogel, 2013; **?**). By comparison to the supervised learning studied here, such work is weakly supervised since there is no use of absolute scores. This yields a version of the QE problem that may be deemed too relativistic, but does represent an alternative approach. Unfortunately, because of the very difference in the use of absolute scores, they cannot be directly compared on this. Thus, we focus here on empirical exploration of the nature of the problem in estimating quality in the case of supervised learning.

5 Experiments

In this section we devise several experiments intended to explore different aspects of the problem in more detail. In particular, we try to evaluate the impact of the possible causes described in §3: first we show in §5.1 that it affects most QE systems, especially those optimized to minimize MAE. Then in §5.2 and §5.3 we confirm that the distribution of the training set is a major cause of the issue by showing that alternative distributions have different effects.

5.1 Tails Prediction for WMT12 Participating Systems

In order to test if the tails prediction problem is general to most supervised QE systems, we apply the local performance measures to the scores predicted on the test set by the participating systems in WMT12.[15] Table 5 shows some detailed results for the four best systems at WMT12. It confirms that the predictions made for the tails are generally significantly worse than they are globally, and especially that the systems tend to predict very few values at the ends of the range of values: recall in the 10% bottom or top scores is never higher than 12%.[16] It is also worth noticing that the first system, which performs significantly better than the others, is the only one which was not optimized to minimize the MAE but to maximize the DeltaAvg score (Soricut et al., 2012). In particular, this system obtains a recall higher than the others in most cases (especially in the 5% and 10% tails), which is certainly due to the fact that it assigns more scores far from the mean (in other words, this system takes more risk). This tends to confirm our hypothesis that the minimization of the MAE as learning criterion is one of the causes of the problem.

System ID	Global MAE	Correlation dist.mean. vs abs.err.	Bottom 5% R	Bottom 5% G-LMAE	Bottom 10% R	Bottom 10% G-LMAE	Bottom 20% R	Bottom 20% G-LMAE	Top 5% R	Top 5% G-LMAE	Top 10% R	Top 10% G-LMAE	Top 20% R	Top 20% G-LMAE
SDLLW_M5PbestDeltaAvg	0.61	0.49	0.05	1.02	0.07	0.76	0.32	0.76	0.02	0.96	0.12	0.99	0.26	0.84
UU_best	0.64	0.53	0.0	1.21	0.07	0.91	0.26	0.91	0.0	1.02	0.04	1.01	0.22	0.81
SDLLW_SVM	0.64	0.55	0.0	1.33	0.0	0.98	0.17	0.98	0.02	0.89	0.06	0.91	0.32	0.75
UU_bltk	0.64	0.58	0.0	1.22	0.06	0.91	0.27	0.91	0.0	1.07	0.02	1.05	0.27	0.83

Table 5: **Tails prediction quality for the 4 best systems at WMT12 (test set).** The second column contains the correlation between the distance to the mean and the absolute error; the columns R and G-LMAE contain respectively the recall and the gold-based local MAE scores (see §4.1).

5.2 Adding the Post-edited Sentences to the Training Set

In this experiment we use the post-edited sentences again (see §4.2), but this time adding them to the training set in order to observe the impact on the test set.[17] These instances are progressively added to the official training set (in random order). We focus on the top quality tail, since it is the one which is expected to benefit from adding sentences with top scores to the training set. Figure 6 shows how the local MAE scores improve as post-edited instances are added. Only the gold-based LMAE scores are represented, because these provide a recall-like information and the observations show that recall (in the tails) is the main weakness of QE systems (see §4.1).

As expected, in all cases adding top quality sentences to the training set makes the system decrease the error rate in the top quality tail. Of course this local improvement comes at the price of degrading the global performance, although for the *wmt13a* dataset (fig. 6b) the global error even improves until almost half of the sentences have been added. In the case of the *wmt13b* dataset (fig. 6c), since the QE system was already very good in predicting the top quality sentences (the LMAE is even better than the global MAE), the improvement is smaller and proportionally more costly for the global performance.

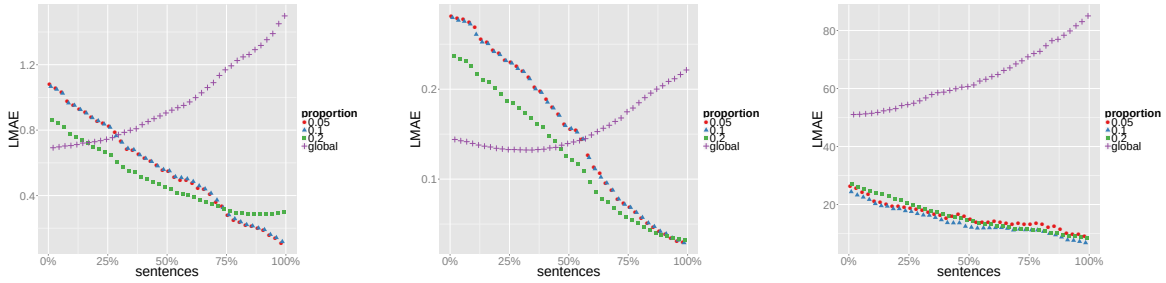
5.3 Balancing the Training Set

In this final experiment, we resample the training set (with replacement), in order to balance the gold scores over the full range of values. Since we can only use the discrete gold scores provided with the original training set, we compute a (random) uniform distribution but select the closest available score (randomly picking an instance among those with this score). The resulting distribution is not uniform, and the training set contains many duplicate instances; therefore, the resulting training set is unlikely to yield very good results in general, but it is no longer subject to the "statistical attraction" towards the mean that we have observed.

[15] These values were kindly provided by the organizers of the WMT12 QE Shared Task.

[16] This is true for all but 3 participating systems, and these exceptions correspond to systems which performed worse globally.

[17] We assign perfect scores to all these sentences: 5 for *wmt12*, 0 for *wmt13a*; for *wmt13b*, we use the mean of the time spent for the sentences in the training set which were left unmodified: there are 23 such sentences, and the mean is 16.19s.



(a) wmt12. (b) wmt13a. (c) wmt13b.

Figure 6: **Improvement of gold-based LMAE as post-edited sentences are added to the train set.** Example: in *wmt12*, the gold-based LMAE for the top 20% sentences is higher than 0.8 when the system is trained only on the official train set (0% of the post-edited sentences added), but reaches 0.4 when about half of the post-edited sentences are added to the training set. However the global MAE (which takes all the sentences into account) increases from 0.7 (0%) to 0.9 (50% of the post-edited sentences added): since the system assigns more scores in the top tail, it makes larger errors globally. Remark: the MAE and LMAE values are measured on the same set of sentences for every percentage on the X axis.

The model obtained from the balanced training set has been applied to the original test set. Table 6 gives the local results observed in the tails: in most cases, the recall increases drastically compared to using the regular training set, or is at least identical,[18] causing a great increase in the F1-scores as well. The LMAE scores do not show such an improvement, in fact the mean error is often higher than with the regular training set. This is due to the fact that the system is forced to assign scores far from the "easy cases" around the mean, therefore makes much bigger mistakes than in the previous case. As expected, the global MAE scores for *wmt13a* and *wmt13b* are much higher than the original MAE values (0.27 and 110.7 respectively, i.e. about twice the original values). Interestingly, the MAE stays almost constant (0.71 instead of 0.69) for *wmt12*. The correlation between the distance to the mean and the mean absolute decreases to 0.42, 0.05 and 0.26 for *wmt12*, *wmt13a* and *wmt13b*, respectively.

Table 6: **Local evaluation of the test set using a balanced training set.** Cells in bold show an improvement over the corresponding value with the original training set, as given in tables 3 and 4. The classification limits were computed on the original training set.

6 Conclusion and Future Work

To conclude, we have shown that there are very serious issues with the way supervised QE systems are built: they tend to be unable to reliably evaluate both the worst and the best quality sentences. Furthermore, they cannot distinguish between a faulty MT output sentence and its post-edited version. We have also shown that it is possible to improve the detection of the best/worst sentences by altering the distribution of the training set; however the question whether this can be achieved while maintaining a decent level of global performance remains open. But even if the cost in global performance is high,

[18]The only exception is the 20% top quality recall of the wmt13b dataset. This is certainly due to the very particular distribution of scores in this dataset, and to the fact that the top quality tail was already predicted reliably in the regular version.

the techniques that we have tested could be useful in some specific applications of QE (for example, if the recall in the tails is more important than the precision).

We think that these observations raise questions about the definition of the QE problem. It might actually be necessary to define different kinds of QE tasks: depending on the targeted application (e.g. estimating post-editing time, retraining the MT model, discarding the worst sentences, etc.), there could be a specific setting which is more appropriate in terms of supervised/unsupervised learning, evaluation measure, precision/recall trade-off, etc. For instance, minimizing the MAE does not seem compatible with detecting anomalies, but might be relevant for estimating the cost of post-editing. Similarly, under the hypothesis that the sentence level is not sufficiently rich in information in order to obtain accurate predictions, an intermediate level of granularity might be considered (e.g. at paragraph level).

Finally, another great challenge with respect to the reliability of QE systems is their consistency when applied to different test sets, or more generally their dependency on the training set: in the perspective of applications, it is very important to know what level of confidence can be expected when applying a QE system or model to a new document.

Acknowledgements

We are grateful to Lucia Specia, Radu Soricut and Christian Buck, the organizers of the WMT 2012 and 2013 Shared Task on Quality Estimation, for releasing all the data related to the competition, including post-edited sentences, features sets, etc.

Abstract

In this paper, we propose an augmented dependency-to-string model to combine the merits of both the head-dependents relations at handling long distance reordering and the fixed and floating structures at handling local reordering. For this purpose, we first compactly represent both the head-dependent relation and the fixed and floating structures into translation rules; second, in decoding we build "on-the-fly" new translation rules from the compact translation rules that can incorporate non-syntactic phrases into translations, thus alleviate the non-syntactic phrase coverage problem of dependency-to-string translation (Xie et al., 2011). Large-scale experiments on Chinese-to-English translation show that our augmented dependency-to-string model gains significant improvement of averaged +0.85 BLEU scores on three test sets over the dependency-to-string model.

1 Introduction

As a representation holding both syntactic and semantic information, dependency grammar has been attracting more and more attention in statistical machine translation. Lin (2004) took paths as the elementary structures and proposed a path-based transfer model. Quirk et al. (2005) extended path to treelets (connected subgraphs of dependency trees) and put forward dependency treelet translation. Ding and Palmer (2005) proposed a model on the basis of dependency insertion grammar. Shen et al. (2008) employed the fixed and floating structures as elementary structures and proposed a string-to-dependency model with state-of-the-art performance. Xie et al. (2011) employs head-dependents relations as elementary structures and proposed a dependency-to-string model with good long distance reordering property. A head-dependents relation (HDR) is composed of a head and all its dependents, which can be viewed as an instance of a sentence pattern or phrase pattern.

However, since dependency trees are much flatter than constituency trees, the dependency-to-string model suffers more severe non-syntactic phrase coverage problem (Meng et al., 2013) than constituency-based models (Galley et al., 2004; Liu et al., 2006; Huang et al., 2006). Non-syntactic phrases are those phrases that can not be covered by whole subtrees. To address this problem, Meng et al. (2013) proposed to translate with both constituency and dependency trees, which can incorporate non-syntactic phrases covered by the constituents of the constituency trees. This model requires both constituency and dependency trees, thus may suffer from both constituency and dependency parse errors. Additionally, there are only few languages that have both constituency and dependency parsers, which limits its practical use.

In this paper, we propose to address non-syntactic phrase coverage problem of the dependency-to-string model without resort to extra resources (Section 3). To this end, we augment the dependency-to-string model at two aspects. First, we combine the merits of both the head-dependent relations and the fixed and floating structures (Shen et al., 2008), and compactly represent these two kinds of knowlege into augmented HDR rules (Section 3.1). We acquire the augmented HDR rules automatically from the

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2217–2226, Dublin, Ireland, August 23-29 2014.

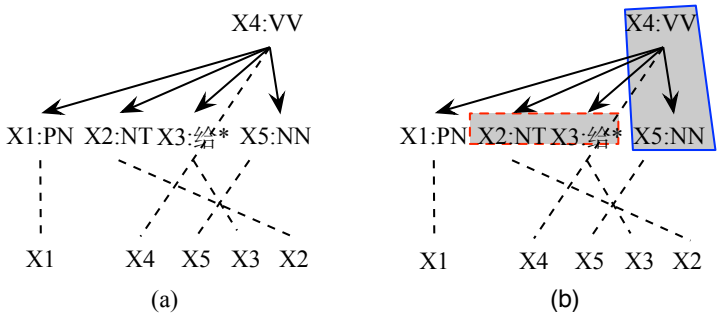

Figure 1: Examples of an HDR rule (a) and an augmented HDR rule (b). Where each "*" denotes a substitute site which is a compact representation of a whole subtree. The shadow with line border indicates a fixed structure and the shadow with dash line border indicates a floating structure.

word-aligned source dependency tree and target string paris (Section 3.2). In decoding we propose an "on-the-fly" rule building strategy, which builds new translation rules from the augmented HDR rules and incorporates non-syntactic phrases into translations (Section 3.4). Large-scale experiments (Section 4) on Chinese-to-English translation show that our augmented model gains significant improvement of averaged +0.85 BLEU points on three test sets over the dependency-to-string model.

2 Background

For convenience of the description of our augmented dependency-to-string model, we first briefly review the dependency-to-string model and the fixed and floating structures of string-to-dependency model (Shen et al., 2008).

2.1 Dependency-to-String Translation

The dependency-to-string model (Xie et al., 2011) takes head-dependents relations as the elementary structures of dependency trees, and represents the translation rules with the source side as HDRs and the target side as string. Since the HDRs in essence relate to phrase patterns and sentence patterns, the HDR rules specify the reordering of these patterns. For example, Figure 1 (a) is an example HDR rule, which represents a reordering manner of a sentence pattern composed of a proper noun (X1:PN), a temporal noun (X2:NT), an prepositional phrase relate to "给 (give)" (X3:给), a verb (X4:VV) and a noun (X5:NN).

With the HDR rules, the dependency-to-string model gets rid of the extra reordering heuristics and reordering models of the previous models (Lin, 2004; Ding and Palmer, 2005; Quirk et al., 2005). More importantly, the model shows state-of-the-art performance and exhibits good long distance reordering property.

2.2 Fixed and Floating Structures

The fixed structures and floating structures are fundamental structures of the string-to-dependency model (Shen et al., 2008), which are introduced to handle the coverage of non-constituent rules. Given the dependency tree $d_1 d_2 ... d_n$ of a sentence $f_1 f_2 ... f_n$, where d_i indicates the parent word index of word f_i.

Definition 1. *A dependency structure $d_{i...j}$ is **fixed** on the head h, where $h \in [i, j]$, if and only if it meets the following conditions:*

- $d_h \notin [i, j]$
- $\forall k \in [i, j]$ *and* $k \neq h$, $d_k \in [i, j]$
- $\forall k \notin [i, j]$, $d_k = h$ *or* $d_k \notin [i, j]$

A fixed structure describes a fragment with a sub-root, where all the children of the sub-root are complete.

Definition 2. *A dependency tree $d_{i...j}$ is **floating** with children C, for a non-empty set $C \subseteq i, ..., j$, if and only if it meets the following conditions:*

- $\exists h \notin [i, j], s.t. \forall k \in C, d_k = h$
- $\forall k \in [i, j]$ *and* $k \notin C$, $d_k \in [i, j]$
- $\forall k \notin [i, j]$, $d_k \notin [i, j]$

A floating structure consists of sibling nodes of a common head, but the head itself is unspecified.

In nature, the fixed and floating structures represent the phrases under the structural constraint of dependency trees, most of them are non-syntactic phrases.

The HDRs are good at handling long distance dependencies, while the fixed and floating structures excels at handling local reordering. This encourages us to address the non-syntactic phrase coverage problem of dependency-to-string model by exploiting these two kinds of structures.

3 Augmented Dependency-to-String Translation

In the following, we will describe our augmented dependency-to-string model in detail, including the augmented HDR rules (Section 3.1), rule acquisition (Section 3.2) and "on-the-fly" rule building in decoding (Section 3.4).

3.1 Augmented HDR rules

Our augmented HDR rules aim at combining the merits of both the HDRs at handling long distance reordering and the fixed and floating structures at handling local reordering. For this purpose, we augment the HDR rules (Xie et al., 2011) by labelling the HDRs with the fixed and floating structures.

Figure 1 (b) shows an example augmented HDR rule. Which is an augmented version of the HDR rule Figure 1 (a) by labelling it with a fixed structure (shadow with line border) and a floating structure (shadow with dash line border). The labeled fixed and floating structures indicate the bilingual phrases that we can incorporate in this sentence pattern.

3.2 Rule Acquisition

Given a word-aligned parallel corpus defined as a set of triples $\langle T, e, A \rangle$, where T is a dependency tree of source sentence f_1^J, e_1^I is the target sentence and A is an alignment relation between f_1^J and e_1^I, we acquire the augmented HDR rules by three steps: tree annotation, acceptable HDR identification and rule induction. The process is similar with that of Xie et al. (2011). However, we make some extensions so that we can take the fixed and floating structures into account.

3.2.1 Tree Annotation

Besides annotating each node of T with *head span* and *dependency span* as Xie et al. (2011), we also label the tree with consistent fixed and floating structures.

Definition 3. *The **head span** hsp(n) of a node n is the closure of the set taking the index of the target words aligned to n as its elements.*

The *closure* of a set contains all the elements between the minimum and the maximum of the set and each element has only one copy. For example, the closure of set $\{1, 3\}$ is $\{1, 2, 3\}$.

We say a head span is *consistent* with alignment if the bilingual phrase it covers is consistent with the alignment (Koehn et al., 2003).

Definition 4. *Given a subtree T' rooted at n, the **dependency span** dsp(n) of n is the closure of the union of the consistent head spans of all the nodes of T'.*

$$dsp(n) = closure(\bigcup_{\substack{n' \in T' \\ hsp(n') \text{ is consistent}}} hsp(n'))$$

If no head spans of all the nodes of T' are consistent, $dsp(n) = \varnothing$.

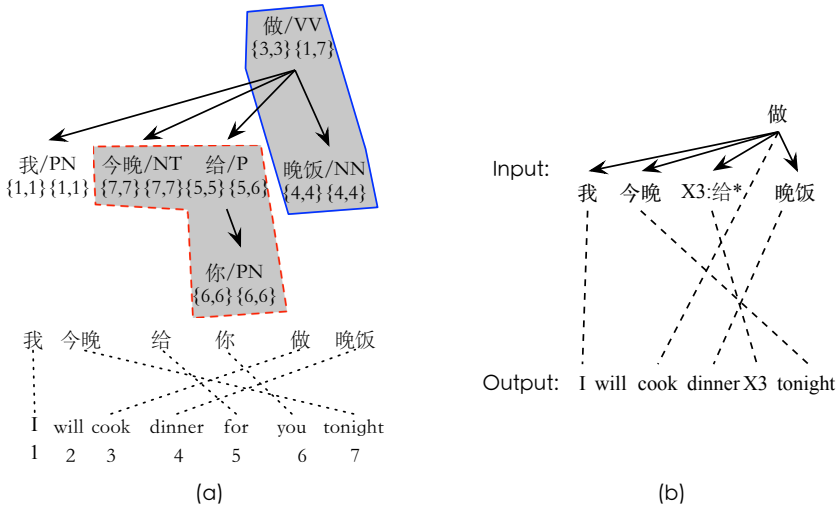

Figure 2: An example annotated dependency tree (a) and an example lexicalized augmented HDR rule (b) induced from the top-level HDR of (a). Each node of the dependency tree is annotated with two spans: head span (the former) and dependency span (the latter). The shadows denote a consistent fixed structure (shadow with line border) and a floating structure (shadow with dash line border). The "*" denotes a substitute site.

Definition 5. *A fixed or floating structure is **consistent** with alignment if the phrase it covers is consistent with alignment.*

Tree annotation can be readily accomplished by a single post-order traversal of dependency tree T. For each accessed node n, annotate it with head span and dependency span according to A. If n is an internal node, enumerate all the fixed and floating structures relate to n, and label those consistent ones on T. Repeat the above process till the root is accessed.

Figure 2 (a) shows an example annotated dependency tree. Where each node is annotated with two spans: head span (the former) and dependency span (the latter). Moreover, the dependency tree is also labeled with two consistent fixed and floating structures that cover phrases "做 饭" and "今晚 给 你" respectively.

3.2.2 Acceptable HDR Identification

From the annotated dependency tree, we identify the HDRs that are suitable for rule induction. These HDRs are called as acceptable HDRs. To this end, we traverse the annotated dependency tree in post-order and identify the HDRs with the following properties:

- for the head, its head span is consistent;
- for the dependents, the dependency span of each dependent should not be $\varnothing$ unless the dependent is a leaf node;
- the intersection of the head span of the head and the dependency spans of the dependents is $\varnothing$ (or do not overlap).

Different from those acceptable HDRs of Xie et al. (2011), the acceptable HDRs here may be labeled with fixed and floating structures. For example, the top level of Figure 2 (a) is an acceptable HDR, which is labeled with a fixed structure and a floating structures. Typically an acceptable HDR has three types of nodes: leaf node (of the dependency tree), internal node (of the dependency tree) and head node (an internal node function as the head of the HDR).

3.2.3 Rule Induction

From each acceptable HDR, we induce a set of lexicalized and unlexicalized augmented HDR rules. This process is similar with that of Xie et al. (2011) except that here we have to consider the consistent fixed

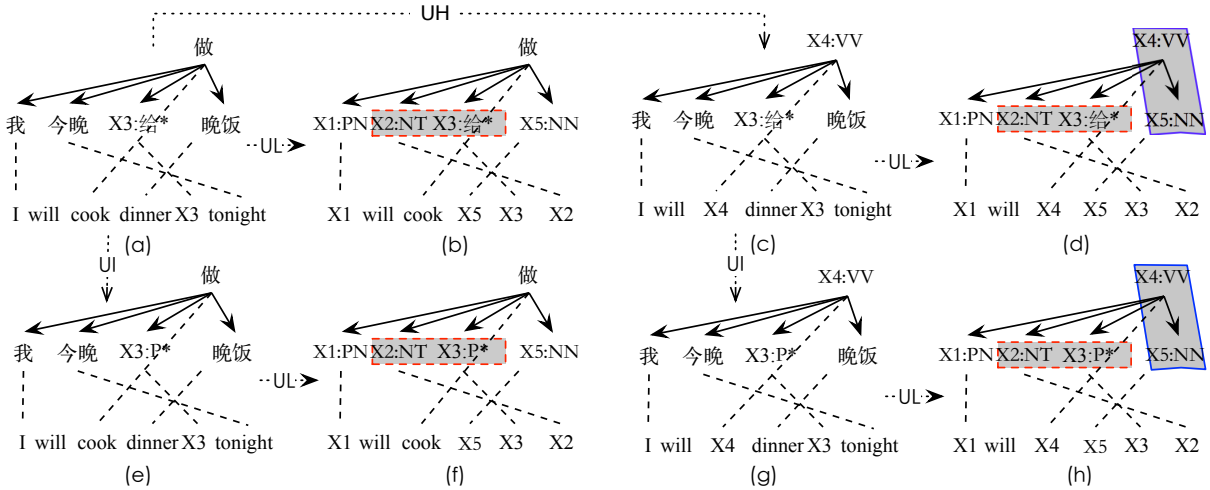

Figure 3: Lexicalized augmented HDR rule (a) and unlexicalized augmented HDR rules (b)∼(h) induced from the top level HDR of the annotated dependency tree in Figure 2. Where "UH", "UI" and "UL" denotes "unlexicalize head", "unlexicalize internal" and "unlexicalize leaf" , respectively. The shadows with line border denote fixed structures and the shadows with dash line border denotes floating structures.

and floating structures.

First, we induce a lexicalized augmented HDR rule with the following principles:

1. extract the HDR, mark each internal node as a variable, and label the HDR with the floating structures that cover only variables. This forms the input of a lexicalized rule.

2. generate the target string according to head span of the head and the dependency spans of the related dependents, and turn the word sequences covered by the dependency spans of the internal nodes into variables. This forms the output of a lexicalized rule.

Figure 2 (b) illustrates a lexicalized augmented HDR rule induced from the top-level HDR of the annotated dependency tree Figure 2 (a).

From each lexicalized augmented HDR rule (along with the acceptable HDR), we then induce a set of unlexicalized augmented HDR rules with the following principles:

1. turn each type (leaf, internal or head) of nodes simultaneously into variables;
2. when turning a head or leaf node into a variable, change the counterpart of the target side into the variable; label the unlexicalized HDR with the fixed and floating structures that cover only variables.
3. when turing an internal node into a variable, keep the counterpart of the target side unchanged.

Totally, we will obtain eight types of augmented HDR rules from an acceptable HDR. In this paper, we call the lexicalized and unlexicalized HDRs generated by the above process as instances of the HDR.

Figure 3 illustrates the rule induction of seven unlexicalized augmented HDR rules (b)-(h) from lexicalized augmented HDR rule (a). Where "UH", "UI" and "UL" on the dash arrows indicate "unlexicalize head", "unlexicalize internal" and "unlexicalized leaf", respectively.

3.2.4 Probability Estimation

We take the augmented HDR rules acquired from word-aligned parallel corpus as the observed data, and employ relative frequency estimation to calculate the translation probabilities of the rules. Note that, here we take the labeled fixed and floating structures of the augmented HDR rules as indicators of bilingual phrases that can be incorporated in the sentence patterns and phrases patterns represented by the HDRs. So we consider only the HDRs when counting the augmented HDR rules.

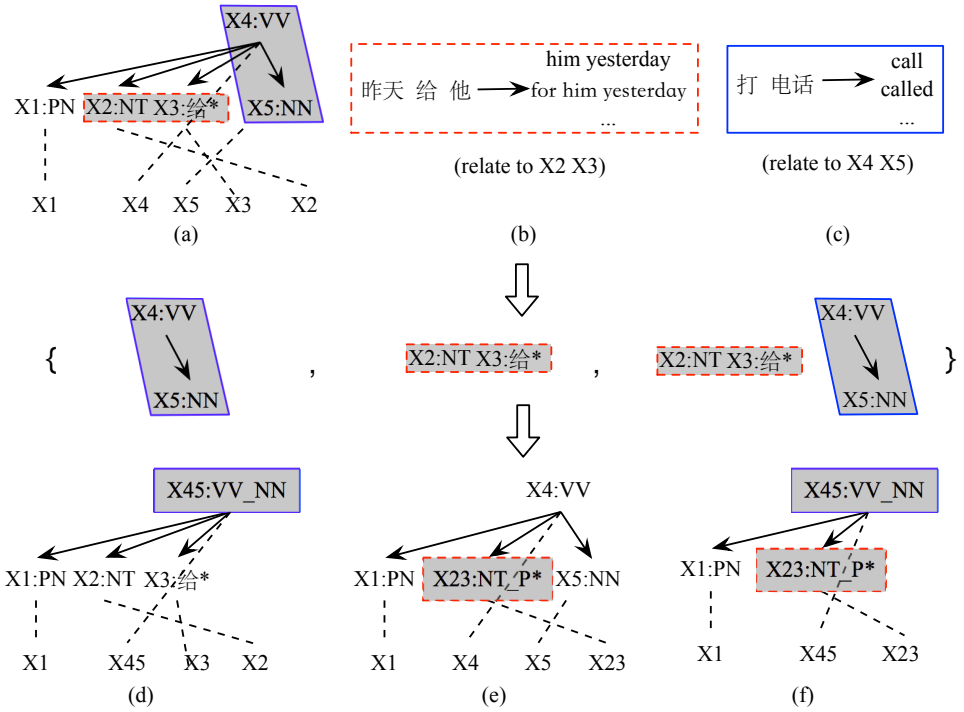

Figure 4: Illustration of "on-the-fly" translation rule building.

3.3 The model

Following Och and Ney (2002), we adopt a general log-linear model for our augmented dependency-to-string model. Let d be a derivation that converts a source dependency tree T into a target string e. The probability of derivation d is defined as:

$$P(d) \propto \prod_i \phi_i(d)^{\lambda_i} \quad (1)$$

where ϕ_i are features defined on derivation and λ_i are feature weights.

In our implementation, we make use of eleven features, including seven features inherited from the dependency-to-string model:

- translation probabilities $P(f|e)$ and $P(e|f)$ and lexical translation probabilities $P_{lex}(f|e)$ and $P_{lex}(e|f)$ of augmented HDR rules
- rule penalty $exp(-1)$
- language model $P_{lm}(e)$
- word penalty $exp(|e|)$, where $|e|$ is the length of the generated target string

and four extra features for bilingual phrases relate to fixed and floating structures:

- translation probabilities $P_{bp}(f|e)$ and $P_{bp}(e|f)$ and lexical translation probabilities $P_{bp\_lex}(f|e)$ and $P_{bp\_lex}(e|f)$ of bilingual phrases

3.4 "On-the-Fly" Decoding

The task of the decoder is to find the best derivation from all possible derivations. Our decoder is based on bottom-up chart parsing, which characterizes at "on-the-fly" translation rule building.

Given an input dependency tree T, the decoder traverses it in post-order. For each accessed node n, the decoder first enumerates all instances of the HDR rooted at n as we do in rule induction, and checks for matched augmented HDR rules. If a matched rule is labeled with fixed and floating structures, the decoder builds new translation rules "on the fly" with the following principles:

1. check the phrases covered by the labeled fixed and floating structures for matched bilingual phrases;
2. if there are no matched bilingual phrases for all labeled fixed and floating structures, take the augmented HDR rule as a HDR rule of dependency-to-string model; otherwise,
   - enumerate all combinations of the fixed and floating structures with matched bilingual phrases;
   - for each combination, build a new translation rule by turning the variable sequences covered by the fixed and floating structures into new variables;
   - the new-built rule inherits the translation probabilities of the deriving augmented HDR rule, and the new variables take the matched bilingual phrases as their translation hypothesis.

Figure 4 illustrates the "on-the-fly" rule building process. Suppose augmented HDR rule (a) is the matched rule, and bilingual phrases (b) and (c) match the phrases covered by the labeled fixed and floating structures of (a). There will be three combinations of the labeled fixed and floating structures as shown in the middle of Figure 4. For each combination, the decoder builds a new translation rule by turning variable sequences "X2:NT X3:给*" and/or "X4:VV X5:NN" into new variables "X23:NT_P*" and/or "X45:VV_NN". And we will obtain three new translation rules (d)-(f) that can incorporate non-syntactic phrases into translations.

If there are no matched rules, the decoder builds a pseudo translation rule with monotonic reordering.

The decoder then employs cube pruning (Chiang, 2007; Huang and Chiang, 2007) to generate k-best hypothesis with integrated language model for node n.

Repeat the above process till the root of T is accessed. The hypothesis with the highest score is output as translation.

4 Experiments

We evaluated our augmented model by comparison with dependency-to-string model and hierarchical phrase-based model on Chinese-to-English translation in terms of BLEU (Papineni et al., 2002).

4.1 Experimental Setup

The parallel training corpus include 1.25M Chinese-English sentence pairs.[1] We parse the Chinese sentences with Stanford Parser (Klein and Manning, 2003) into projective dependency trees, obtain word alignment by running GIZA++ (Och and Ney, 2003) in both directions and applying "grow-diag-final" refinement (Koehn et al., 2003), and train a 4-gram language model by SRI Language Modeling Toolkit (Stolcke, 2002) with Kneser-Ney smoothing on the Xinhua portion of the Gigaword corpus.

We take NIST MT Evaluation test set 2002 as our development set, 2003 (MT03), 2004 (MT04) and 2005 (MT05) as our test sets, evaluate the quality of translations by *case insensitive* NIST BLEU-4 metric[2], tune the feature weights by Max-BLEU strategy with MERT (Och, 2003), and check the statistical difference between the systems with significance test (Collins et al., 2005).

4.2 Systems

We take "Moses-Chart" of Moses[3] (Koehn et al., 2007) as hierarchical phrase-based model baseline. In our experiments, we use the default settings.

Both the dependency-to-string baseline and our augmented model employ the same settings as those of Xie et al. (2011), with the beam threshold, beam size and rule size are set to 10^{-3}, 200 and 100 respectively. And both systems employ bilingual phrases with length ≤ 7 extracted by Moses.

4.3 Experiment results

Table 1 shows the results of the BLEU scores of the three systems. Where "dep2str" and "dep2str-aug" denote dependency-to-string model baseline and our augmented dependency-to-string model, respectively. As we can see, "dep2str" shows better performance (+0.31 BLEU on average) than "Moses-Chart"

[1] From LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

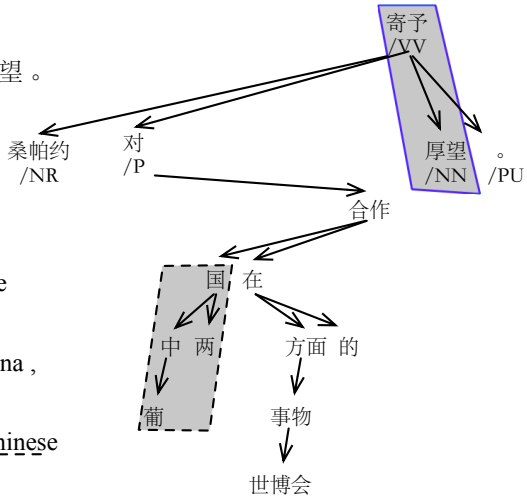

Figure 5: Translation examples of "Moses-Chart", "dep2str" and "dep2str-aug". The line border shadow denotes the phrases successfully captured by "dep2str-aug".

and is a strong baseline."Dep2str-aug" gains significant improvements of +0.74, +0.79 and +1.03 BLEU points over "dep2str" on the test sets, respectively.

Additionally, we compare the actual translations generated by "Moses-Chart", "dep2str" and "dep2str-aug". Figure 5 shows the translations of these three systems on a sentence of MT05. The source sentence holds a common sentence pattern in Chinese, which is composed of a proper noun, a verb, a noun and a prepositional phrases (corresponding to the top level of the dependency tree on the right). However, the preposition phrase related to "对" holds nine words, thus the simple pattern becomes a long distance dependency that challenges SMT systems. Limited by the phrase-based rules, "Moses-Chart" fails to capture the sentence pattern and outputs a messy translation with little sense. "Dep2str", resorting to HDR rules, successfully captures the pattern and outputs a translation with correct reordering, but it is still hard to understand. With the help of augmented HDR rules, "dep2str-aug" captures both the sentence pattern and non-syntactic phrase "寄予 厚望" and gives an translation with good adequacy and fluency.

These results reveal the merits of our augmented dependency-to-string model at handling both long distance reordering (with HDR) and local reordering (with fixed and floating structures), which is promising for translating language pairs that are syntactically divergent.

5 Conclusion and Future Work

In this paper, we propose an augmented dependency-to-string model to address the non-syntactic phrase coverage problem for dependency-to-string model. To this purpose, we make two important augmentations to the dependency-to-string model. First, we propose an compact representation to combine both head-dependent relation and the fixed and floating structures into translation rules. Second, in decoding we build "on the fly" new translation rules from the compact translation rules and incorporate non-syntactic phrases into translations. By this way, we can combine the merits of both head-dependents relation at handling long distance reordering and bilingual phrases at handling local reordering. Large-

scale experiments show that our augmented dependency-to-string model gains significant improvements over the dependency-to-string model.

In the future work, we would like to incorporate semantic knowledge such as typed dependencies and WordNet[4] (Miller, 1995) so as to better direct the process of translation.

Abstract

This paper proposes a soft dependency matching model for hierarchical phrase-based (HPB) machine translation. When a HPB rule is extracted, we enrich it with dependency knowledge automatically learnt from the training data. The dependency knowledge not only encodes the dependency relations between the components inside the rule, but also contains the dependency relations between the rule and its context. When a rule is applied to translate a sentence, the dependency knowledge is used to compute the syntactic structural consistency of the rule against the dependency tree of the sentence. We characterize the structure consistency by three features and integrate them into the standard SMT log-linear model to guide the translation process. Our method is evaluated on multiple Chinese-to-English machine translation test sets. The experimental results show that our soft matching model achieves 0.7-1.4 BLEU points improvements over a strong baseline of an in-house implemented HPB translation system.

1 Introduction

HPB model (Chiang, 2007) is widely used and has consistently delivered state-of-the-art performance. This model extends the phrase-based model (Koehn et al., 2003) by using the formal synchronous grammar to well capture the recursiveness of language during translation. In a formal synchronous grammar, the syntactic unit could be any sequence of contiguous terminals and non-terminals, which may not necessarily satisfy the linguistic constraints. HPB model is powerful to cover any format of translation pairs, but it might introduce ungrammatical rules and produce poor quality translations.

To generate grammatical translations, lots of syntax-based models have been proposed by Galley et al. (2004), Liu et al. (2006), Huang et al. (2006), Mi et al. (2008), Shen et al. (2008), Xie et al. (2011), Zhang et al. (2008), etc. In these models, the syntactic units should be compatible with the syntactic structure of either the source sentence or the target sentence. These approaches can generate more grammatical translations by capturing the structural difference between language pairs. However, these models need special efforts to capture non-syntactic translation knowledge to improve the translation performance.

It is desired to combine the advantages of syntax-based models and the HPB model (Stein et al., 2010). There has been much work trying to improve HPB model by incorporating syntax information. Marton and Resnik (2008) leverage linguistic constituents to constrain the decoding softly. Some work go further to augment the non-terminals in HPB rules with syntactic tags which depend on the syntactic structure covered by the non-terminals (Zollmann and Venugopal, 2006; Chiang, 2010; Li et al., 2012; Huang et al., 2013). For example, given below HPB rules (1-4), the source non-terminal X could be refined into NP or PP as shown in rules (5-8) respectively.

(1) <借 了 X, borrowed X> (2) <借 了 X, lent X>
(3) <X_1 借 了 X_2, borrowed X_2 X_1> (4) <X_1 借 了 X_2, X_1 borrowed X_2>

(5) <借了 NP, borrowed X> (6) <借了 NP, lent X>
(7) <PP 借了 NP, borrow X_2 X_1> (8) <NP 借了 NP, X_1 lent X_2>

Although augmenting the non-terminals with syntactic tags in these methods achieved better results for HPB model, they have limitations that the syntax information on the non-terminals are not discrim-

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2227–2236, Dublin, Ireland, August 23-29 2014.

inative enough due to the limited context covered by the HPB rule. For example, rule (5) and (6) are still not discriminative when translating below two sentences (9) and (10).

(9) 我向他借了一本书(I borrowed a book from him) (10) 我借了一本书给他(I lent a book to him)

where the common phrase "借了一本书" appear in both sentences. Obviously, although rule (5) and (6) share same source sides, rule (5) can only be applied to the translation of sentence (9) and rule (6) to sentence (10). Otherwise, inappropriate application will lead to wrong translations. Rule (5) and (6) are not discriminative due to no consideration of their outside context during the translation.

Motivated by such observation, we proposed an alternative approach, called soft dependency matching model, to incorporate into each HPB rule the source syntactic dependencies connecting the contents inside the rule with the context outside the rule. The dependency knowledge associated with HPB rules is automatically learnt from bilingual training corpus. They make HPB rules discriminative according to global context.

Figure 1. Dependency information associated with two rules. LC and RC mean the source context on the left and right of the rule respectively.

Figure 1 shows two rules associated with different dependencies. The first one is applicable to the case when some word on the left side depends on the word "借" in the rule, and the second one is applicable to the case when the word "借" in the rule depends on some word on the right side.

During SMT decoding, first we parse the source sentence to get the dependency tree. When a HPB rule is applied to translate the sentence, we calculate structural consistency between the dependency knowledge associated with the rule and dependency tree structure of the source sentence. The consistency degree is integrated into the SMT log-linear model as features to encourage syntactic hypotheses and penalize the hypotheses violating syntactic constraints.

Compared with previous work that incorporate syntax knowledge into HPB model, the advantage of our soft dependency matching model is:

- It not only captures the dependency relations between the components inside the rule, but also models the dependency relations between the rule and its context from a global view.
- Without increasing the amount of rules or the searching space, our model can capture the syntactic variation for all of the rules (syntactic or non-syntactic, well-formed or ill-formed).
- Our model can take advantage of the dependency knowledge on both terminals and non-terminals.

We evaluate the performance of our soft dependency matching model on Chinese-to-English translation task. Experimental results show that our method can achieve the improvements of 0.7-1.4 BLEU points over the baseline HPB model on multiple NIST MT evaluation test sets.

2 Related Work

Ever since the invention of phrase-based model, a lot of efforts have been made to incorporate linguistic syntax. Cherry(2008) and Marton and Resnik (2008) leverage linguistic constituent to constrain the decoding softly. In their methods, a translation hypothesis gets an extra credit if it respects the parse tree but may incur a cost if it violates a constituent boundary. The soft constrain based methods achieved promising results on various language pairs. One problem of these methods is that exactly matching syntactic constraints cannot always guarantee a good translation, and violating syntactic structure does not always induce a poor translation. It could be more reasonable if the credit and penalty is learnt from the parallel training data. In this work, we learn this kind of constrain knowledge directly from the syntactic structures over the training corpus.

Xiong et al. (2009) present a method that automatically learns syntactic constraints from training data for the ITG based translation (Wu, 1997; Xiong et al., 2006). They utilize the syntactic constraints to estimates the extent to which a span is bracketable. Though the effect was demonstrated on the ITG based model, the method is also applicable to the HPB model. The main difference between Xiong et al. (2009) and our work is that we try to estimate the structural consistency of each rule

against the source syntax tree. For rules which are same in the source side but different in the target side, our method will distinguish the inconsistency degree for different rules. While, for such rules, Xiong et al. (2009) will give a same score which will be used to compete with rules in other spans.

More recently, Huang et al. (2013) associate each non-terminal with the distribution of tags that is used to measure the consistency of syntactic compatibility of the translation rule on source spans. Our work is similar to Huang et al. (2013) since we also represent the syntactic variation of translation rules in the form of distribution. The main difference is that they annotate non-terminals with head POS tags while we use dependency triples (over both terminals and non-terminals) to explicitly represent both the dependency relations inside the rule, and that between the rule and its context.

Both above related work and our work need parse the source sentence to get syntactic context before decoding. There are also some methods incorporating syntax information without the need of online parsing the source sentences (Zollmann and Venugopal, 2006; Shen et al, 2009; Chiang, 2010). They parse the training data to label the non-terminals with syntactic tags. During the bottom-up decoding, the tags are used to model the substitution of non-terminals in a soft way (Shen et al, 2009; Chiang, 2010) or in a hard way (Zollmann and Venugopal, 2006).

Gao et al. (2011) derive soft constraints from the source dependency parsing for the HPB translation. They focus on the relative order of each dependent word and its head word after translation, while our method models whether the dependency information of a rule matches the context or not.

Our work utilizes contextual information around translation rules. In this sense, it is similar to He et al. (2008) and Liu et al. (2008). The main difference between their work and our work is that they leverage lexical context for rule selection while we focus on the syntactic contextual information.

3 Hierarchical Phrase based Machine Translation

Our model proposed in this paper is an extension of the HPB model (Chiang, 2007). Formally, HPB model is a weighted synchronous context free grammar. It employs a generalization of the standard plain phrase extraction approach in order to acquire the synchronous rules of the grammar directly from word-aligned parallel text. Rules have the form of:

$$X \rightarrow < \gamma, \alpha, \sim >$$

where X is a nonterminal, γ and α are both strings of terminals and non-terminals from source and target side respectively, and $\sim$ is a one-to-one correspondence between nonterminal occurrences in γ and α. Associated with each rule is a set of feature functions with the form $f_i(\gamma, \alpha)$. These feature functions are combined into a log-linear model. When a rule is applied during SMT decoding, its score is calculated as:

$$\sum_i \lambda_i \cdot f_i(\gamma, \alpha)$$

where λ_i is the weight associated with feature function $f_i(\gamma, \alpha)$. The feature weights are typically optimized using minimum error rate training algorithm (Och, 2003).

4 Soft Dependency Matching Model

In order to incorporate syntactic knowledge to refine both the word ordering and word sense disambiguation for HPB model, we propose a soft dependency matching model (SDMM). It extends HPB rule into a form which is named as SDMM rule:

$$X \rightarrow < \gamma, \alpha, \sim, \mathrm{RDT} >$$

where RDT(rule's dependency triples) is a set of dependency triples defined on source string γ. Each element in RDT is a triple representing dependency knowledge in the form:

$$\{m\text{-}h\text{-}l\}$$

where *m* and *h* are the dependent and head respectively, *l* is the label of the dependency relation type. *m* and *h* could be any of terminals, non-terminals, LC and RC, where LC denotes the left context and RC the right context.

In the following two sub-sections, we will explain the details of SDMM rule extensions for both plain phrases (i.e., there are no non-terminals in both γ and α) and hierarchical rules (i.e., there are at

least one non-terminal in both γ and α) respectively. For simplicity, we ignore the correspondence ~ in the representations of both HPB rules and SDMM rules.

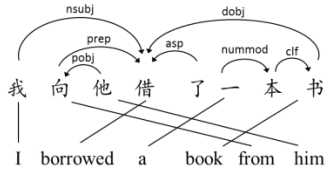

Figure 2: An illustration of a dependency parse tree for the source side of a word-aligned parallel sentences pair.

4.1 SDMM Over Plain Phrase Rules

Figure 2 illustrates a parallel sentence together with word alignments and source dependency parse tree, from which we can extract the phrase pairs of HPB rules like:

(11) < 一 本 书, a book > (12) < 借 了 一 本 书, borrowed a book >

By incorporating syntactic knowledge, we can extend these HPB rules into SDMM rules as shown in Figure 3(a) and Figure 3(b) respectively.

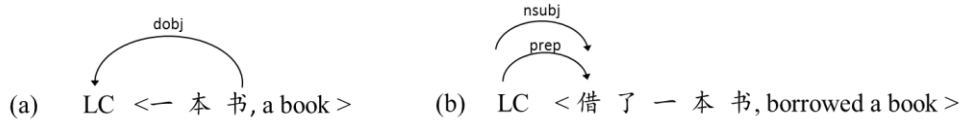

Figure 3: An illustration of two phrase pairs annotated with a set of dependency triples.

Formally, the RDT corresponding to phrase pair (11) is {书-LC-dobj}. The RDT corresponding to phrase pair (12) is {LC-借-nsubj, LC-借-prep}.

Now we describe how to build the RDT when a phrase pair is extracted from a sentence pair during the training step. First, we initialize RDT to be empty. Then, for each dependency triple "*m*-*h*-*l*" in the parse tree of the source sentence, if either *m* or *h* is covered by the source phrase in the rule, we add it to RDT. However, if both *m* and *h* are covered by the source phrase, we will ignore it because it holds less syntactic information beyond HPB rule itself. For example, the dependency triple "一-本-nummod" is excluded from RDT for both phrase pair (11) and phrase pair (12). In addition, we do not add the dependency triple "*m*-*h*-*l*" into RDT if both *m* and *h* are not contained in source phrase, because it is not related to phrase pair at all. The dependency triple "他-向-pobj" is such a case for both phrase pair (11) and phrase pair (12).

Finally, we normalize the word in RDT that is not covered by the source phrase with either LC (stands for the left context) or RC (stands for the right context) according to its relative position to the source phrase. For example, in the RDT for phrase pair (11), we normalize "书-借-dobj" as "书-LC-dobj" since the word "借" is not covered by the source phrase and it is treated as left context.

Note that for each context word outside the source phrase, we only record whether it is on the left or on the right of phrase. We do not further consider its lexical form and its distance to the source phrase. For example, in the two dependency triples in Figure 3(b), both the dependent word "我" and "向" are normalized into LC. In this way, we can generalize the dependency triples in RDT and alleviate the data sparseness problem. In fact, there might be duplicated dependency triples for a phrase pair. In this case, we only keep one of them.

4.2 SDMM over Hierarchical Rules

Hierarchical rules are usually generated by substituting sub-phrases with non-terminals from plain phrase pairs. For example, given the parallel sentence and the two phrase pairs in Section 4.1, we can get a hierarchical rule like:

<借 了 X, borrowed X>

To extend hierarchical rules into SDMM rules, we add dependency information to source terminals or non-terminals in RDT. Figure 4 shows an example representing an SDMM rule:

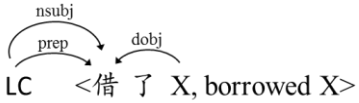

Figure 4: An illustration of a hierarchical rule annotated with a set of dependency triples.

The generation of SDMM rules over hierarchical rules is similar to that of plain phrase rules. The only difference lies in processing the non-terminals, whose dependencies are inferred from the words they covered. For example, the RDT of the above SDMM rule would be:{LC-借-nsubj, LC-借-prep, X-借-dobj}

Similarly, any dependencies over two terminals contained in the source rule are not included in RDT, and dependencies inferred from same non-terminals are excluded as well. In addition, dependencies between two non-terminals are ignored.

4.3 SDMM Rule Composing

A same HPB rule (either plain phrase pair or a hierarchical rule) can be extracted from different bilingual sentences. Therefore, the same HPB rule could be extended into multiple SDMM rules. For example, given a parallel sentence pair shown in Figure 5,

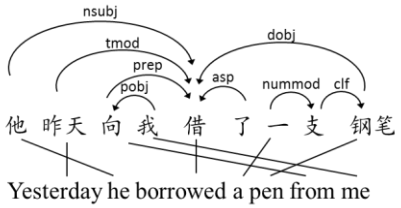

Figure 5: An example of a dependency tree over the source sentence together with the word-aligned target sentence.

we might get a SDMM rule as shown in Figure 6. Compared to the SDMM rule in Figure 4, there is an additional dependency triple "LC-借-tmod" in RDT.

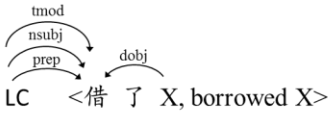

Figure 6: An illustration of dependency triples associated to a hierarchical rule.

Intuitively, we can process SDMM rules independently although they share the same information of HPB rules. However, this will exacerbate the data sparseness problem and make the computation inefficient due to dramatically increased model size. An alternative way is only to keep the most frequent RDT information for the same HPB rules. Though this can get a very concise model, a lot of useful syntactic information might be lost.

We propose a balanced composing method to make a trade-off between knowledge representation and computation efficiency of SDMM rules. Suppose there are more than one SDMM rules with different RDT_i but the same HPB rule, we compose them by the union and get the new form of RDT as:

$$\mathrm{RDT} = \bigcup_i \mathrm{RDT_i}$$

In addition, we record the frequency of HPB rule as well as that of each dependency triple in RDT as:

$$\#(\mathrm{X} \rightarrow < \gamma, \alpha, \sim >) \ , \ \#(t_i, \mathrm{X} \rightarrow < \gamma, \alpha, \sim >)$$

where $\#(\mathrm{X} \rightarrow < \gamma, \alpha, \sim >)$ is the number of times that HPB rule $\mathrm{X} \rightarrow < \gamma, \alpha, \sim >$ is extracted from the training data, and $\#(t_i, \mathrm{X} \rightarrow < \gamma, \alpha, \sim >)$ is the frequency that t_i and $\mathrm{X} \rightarrow < \gamma, \alpha, \sim >$ co-occur. For example, suppose SDMM rules in Figure 4 and Figure 6 occurs 9 and 1 times respectively, we can compose them into the form as shown in Figure 7.

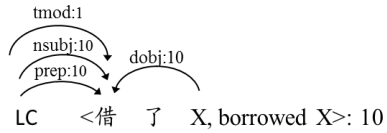

Figure 7: Composed form of the dependency annotation of a rule. The integers following the colons denote occurring times.

Therefore, the composed SDMM rule will be represented by the original HPB rule <借 了 X, borrowed X> together with RDT and its frequency information shown in Table 1.

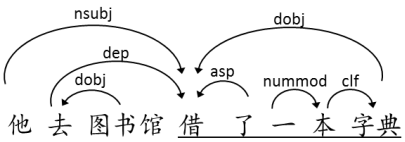
RDT	#
{ LC-借-tmod,	1
LC-借-nsubj,	10
LC-借-prep,	10
X - 借-dobj }	10

Table 1. The RDT and its frequency information of a composed SDMM rule.

4.4 Consistency of SDMM Rules

So far we have described how to enrich a rule with RDT in the training step. Now we introduce how to use the RDT of each rule to guide the translation process.

In the decoding, we parse the source sentence to get the dependency parse tree as shown in Figure 8. When we apply a rule to get a partial translation for a span, we also extract a set of dependency triples based on the parse tree in the exact same way that is used in the training step. We denote this by CDT (context dependency triples). Suppose the rule <借 了 X, borrowed X> is applied to translate the underlined span in Figure 8, then the CDT for the rule is: {LC-借-nsubj, LC-借- dep, X-借-dobj}.



Ref: He went to the library to borrow a dictionary

Figure 8: A sentence to be translated and its dependency parse tree.

In order to evaluate whether a SDMM rule is applicable to translate a sentence or not from the syntactic view, we model the structural consistency of SDMM rule against source dependency tree by calculating the matching degree between RDT and CDT. The example in Figure 9 illustrates how we compute the matching degree between the SDMM rule in Figure 7 and CDT over the source dependency tree in Figure 8. We estimate the matching degree based on three sets including the relative complement set of CDT in RDT, the intersection set of RDT and CDT, and the relative complement set of RDT in CDT.

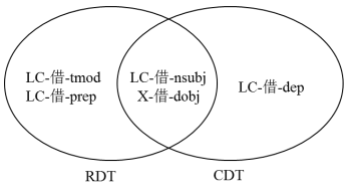


Figure 9: Three different sets of dependency triples to model the structural consistency of syntactic matching.

The statistics over above three sets are leveraged to design three features which are incorporated into SMT log-linear model to encourage and penalize various syntactic motivated hypotheses. The first feature is called as the lost dependency triple feature f_l. It is calculated based on the set RDT\CDT as:

$$f_l = \sum_{t \in RDT \setminus CDT} \delta(\#(t, X \rightarrow < \gamma, \alpha, \sim >) == \#(X \rightarrow < \gamma, \alpha, \sim >))$$

where δ is the indicator function whose value is one if and only if the condition is true, otherwise its value is zero. The motivation of f_l is that: if a dependency triple which always co-occur with the HPB rule is not observed in CDT, it indicates the current SDMM rule may mismatch with the source sentence and therefore we need to penalize its application. In Figure 9, "LC-借-prep" is such a dependency triple. However, for the less frequent dependency triples in RDT such as "LC-借-tmod" in Figure 8, there is no penalty on it although it is not found in CDT.

The second feature is the unexpected dependency triple feature f_u, which is computed as :

$$f_u = |\mathrm{CDT} \backslash \mathrm{RDT}|$$

This feature is the number of dependency triples in CDT that never co-occur with the rule in the training data. In Figure 9, "LC-借-dep" is such a case. Intuitively, the higher the value f_u is, the higher inconsistency degree is, because it means that many dependency triples in CDT are never observed in the training corpus. We should discourage the application of the corresponding SDMM rule.

The third feature is the matched dependency triple feature f_m which is calculated based on RDT∩CDT. It is directly used to model the structural consistency over all the dependency triples in RDT∩CDT for the application of HPB rule $\mathrm{X} \rightarrow < \gamma, \alpha, \sim >$. Formally, f_m is defined as the sum of log probability of each dependency triple in RDT∩CDT conditioned on the HPB rule:

$$f_m = \sum_{t \in \mathrm{RDT} \cap \mathrm{CDT}} \log(P(t|\mathrm{X} \rightarrow < \gamma, \alpha, \sim >))$$

where $\mathrm{P}(t|\mathrm{X} \rightarrow < \gamma, \alpha, \sim >)$ is the probability of a dependency triple t associated to a HPB rule $\mathrm{X} \rightarrow < \gamma, \alpha, \sim >$. We estimate it based on the relative frequency and experimentally use the adding 0.5 smoothing.

5 Experiments

5.1 Experimental Settings

Our baseline is the re-implementation of the Hiero system (Chiang, 2007). When our soft dependency matching model is integrated, the HPB rule is extended into the form of $\mathrm{X} \rightarrow < \gamma, \alpha, \sim, \mathrm{RDT} >$ and the score is calculated by:

$$\sum_i \lambda_i \cdot f_i(\gamma, \alpha) + \lambda_l \cdot f_l(\gamma, \alpha, \mathrm{RDT}) + \lambda_u \cdot f_u(\gamma, \alpha, \mathrm{RDT}) + \lambda_m \cdot f_m(\gamma, \alpha, \mathrm{RDT})$$

where the additional three features are defined in Section 4.3, λ_l, λ_u and λ_m are corresponding feature weights.

We test our soft dependency matching model on a Chinese-English translation task. The NIST06 evaluation data was used as our development set to tune the feature weights, and NIST04, NIST05 and NIST08 evaluation data are our test sets. We first conduct experiments by using the FBIS parallel corpus, and then further test the performance of our method on a large scale training corpus.

Word alignment is performed by GIZA++ (Och and Ney, 2000) in both directions with the default setting. 4-gram language model is trained over the Xinhua portion of LDC English Gigaword Version 3.0 and the English part of the bilingual training data. Feature weights are tuned with the minimum error rate training algorithm (Och, 2003).Translation performance is measured with case-insensitive BLEU4 score (Papineni et al., 2002).

All the Chinese sentences in the training set, development set and test set are parsed by an in-house developed dependency parser based on shift-reduce algorithm (Zhang and Nivre, 2011). There are 45 named grammatical relations plus a default relation representing unknown cases. The detailed descriptions about dependency parsing are explained in Chang et al. (2009).

5.2 Experimental Results on FBIS Corpus

We first conduct experiments by using the FBIS parallel corpus to train the model of both the baseline and the soft dependency matching model. Table 2 shows the statistics of FBIS corpus after the preprocessing.

	#sentences	#words
Chinese	128,832	3,016,570
English	128,832	3,922,816

Table 2. The statistics of FBIS corpus

The evaluation results over FBIS corpus are reported in Table 3. The first row shows the results of baseline, the next three rows show the effect of three features respectively and the last row gives the result when all features are integrated together. Based on Table 3, we can see that each individual feature improves the performance. Among all integrated features, the third feature f_m is the most effective one. The best performance is achieved when using all three features, where we get 1.4, 0.9 and 1.2 BLEU points improvements respectively over the baseline on three test sets.

	NIST04	NIST05	NIST08
Baseline	33.53	32.97	25.08
Baseline+f_l	34.59	33.44	25.69
Baseline+f_u	34.48	33.59	25.51
Baseline+f_m	34.73	33.74	25.76
Baseline+f_l+f_u+f_m	**34.96**	**33.91**	**26.28**

Table 3. Translation performance over BLEU% when models are trained on the FBIS corpus.

5.3 Experimental Results on Large Scale Corpus

To further test the effect of our soft dependency matching model, we use a large scale corpus released by LDC. The catalog number of them is LDC2003E07, LDC2003E14, LDC2005T06, LDC2005T10, LDC2005E83, LDC2006E26, LDC2006E34, LDC2006E85 and LDC2006E92. There are 498K sentence pairs, 12.1M Chinese words and 13.8M English words. Table 4 summarizes the translation performance on the large scale of corpus. Our model is still effective when we train the translation system on large scale data. We get 1.3, 0.7 and 1.0 BLEU point improvements over the baseline on three test sets respectively, which shows that our method can consistently improve HPB system over different sized training corpus.

	NIST04	NIST05	NIST08
Baseline	38.72	37.59	29.03
Baseline+f_l+f_u+f_m	**40.00**	**38.34**	**30.06**

Table 4. Translation performance over BLEU% when models are trained on a large scale parallel corpus.

5.4 Decoding Cost

Incorporating syntax can improve the translation performance, but it might increase the SMT decoding complexity. One advantage of our method is that it does not increase the amount of translation rules, so the searching space is not enlarged. Table 5 shows the decoding time comparison with the baseline when models are trained on the FBIS corpus. The average decoding time per sentence is only increased by about 12% due to the parsing of source sentences and the computation of the features. We believe that this is acceptable given the performance gain.

	NIST04	NIST05	NIST08
Baseline	0.67sec	0.78sec	0.50sec
Baseline+f_l+f_u+f_m	0.88sec	0.87sec	0.56sec

Table 5. The average decoding time per sentence, measured in second/sentence.

6 Conclusion and Future Work

We proposed a soft dependency matching model for HPB machine translation. We enrich the HPB rule with dependency knowledge learnt from the training data. The dependency knowledge allows our model to capture the both the dependency relations inside the rule and the dependency relations between the rule and its context from a global view. During decoding, the syntax structural consistency of rules against source dependency tree is calculated and converted into SMT log-linear model fea-

tures to guide the translation process. The experimental results show that our soft matching model achieves significant improvements over a strong baseline of an in-house implemented HPB system.

In future work, there is much room to improve the performance via our method. First, we can discriminatively learn the contribution of the dependency knowledge of each rule based on the training data. Second, we can go beyond the current "bag of dependency triples" representation by composing them hierarchically to capture deep syntactic information. Third, section 2 has discussed the theoretical difference with related work on adding source syntax into the HPB model, we are interested in empirically comparing our method with them and combining it with them to get further improvement.

Using Spreading Activation to Evaluate and Improve Ontologies

Abstract

In this paper, we explore the relationship between the human-encoded semantics of ontologies and their application to natural language processing (NLP) tasks, such as word-sense disambiguation (WSD), for which such ontologies may not have been originally designed. We present a method for assessing the semantic content of an ontology with respect to a target domain, by spreading activation over a graph that represents instances of ontology concepts and relationships, in domain text. Our proposed method has several advantages beyond existing ontology metrics. By identifying bias or imbalance in the ontology, we can suggest target areas for improvement, and simultaneously facilitate the automated optimisation of the graph for use in the chosen NLP task. On applying this method to the Unified Medical Language System (UMLS) ontology, we significantly outperformed existing graph-based methods for WSD in biomedical NLP (0.82 accuracy). The subsequent introduction of a fall-back mechanism, using word-sense probability, achieved state of the art for unsupervised biomedical WSD (0.89 accuracy).

1 Introduction

Although ontologies do encode human knowledge, the degree to which these artefacts represent the entire scope of semantics in a target domain is difficult to quantify. Since few ontologies offer large enough scope to cater for an entire domain in natural language, merging of multiple ontologies is often necessary (Noy, 2004). This further compounds the problem of assessing the semantic relevance of the merged resource. The collective semantics in multiple source ontologies can often overlap inconsistently, and negotiation of meaning so that the associated set of concepts and relationships in the ontology remains balanced, is critical. The merging process is usually reserved for domain experts, who focus on ontology portions in which they specialise. It's generally a case of painstakingly mapping individual concepts between component data sets, to ensure semantic integrity (Jiménez et al, 2012). Coordinating collaborative ontology editing and merging is a related and well-known problem (Jiménez et al, 2011).

Existing ontology metrics generally focus on structural and logical semantics (Sicilia et al, 2012). Assessing how closely ontologies match the semantics of natural language text, or identifying specific portions of an ontology which require further development, are more difficult tasks. We have identified a robust method for this assessment. This method involves static analysis of a graph representing ontology instances and inter-concept relationships, to address apparent imbalances that hinder spreading activation in the graph. When accuracy and relevance for the task improves, the modified graph or activation strategy identifies portions of interest for further development. Many ontologies used in NLP today are not designed for this (Guarino et al, 2009), and a flexible, automatic evaluation method is useful.

We focused on the Unified Medical Language System (UMLS) as a typical ontology (NLM, 2013), displaying many of the problems associated with use of ontologies in NLP, including merged terminology, strongly overlapping semantic categories, inconsistent levels of structural depth, as well as inconsistent coverage of associated instance data (Pisanelli et al, 1998). We chose to assess this ontology with respect to word sense disambiguation (WSD), which is commonly accepted to be one of the most difficult tasks in NLP (Navigli, 2009). We used the MSH-WSD corpus for testing purposes, which commonly used in assessing methods for biomedical WSD (Jimeno Yepes and Aronson, 2012; McInnes et al, 2011; Gad el Rab et al, 2013). Using node-centric graph metrics, we identified portions of the ontology which were not conducive to WSD via spreading activation. After appropriately modifying the activation strategy, we achieved state of the art performance in graph-based biomedical WSD (0.82).

2 Background

2.1 Ontologies

An ontology, in computer science, is defined as an 'explicit specification of a shared conceptualization' (Gruber, 1993), where a conceptualization may be some subset of real-world semantics, with respect to the requirements for a given task. It can contain concepts or classes of object, object properties, and inter-concept relationships, as well as instances of these in the target domain. Such structured resources facilitate the sharing and re-use of domain knowledge, and are invaluable for NLP applications. A primary example of such a resource is the UMLS, provided by the National Library of Medicine (NLM, 2013). The data set consists of a large lexicon, including millions of instance surface forms, in conjunction with an ontology of concepts and inter-concept relationships in the medical domain. It is composed of 139 different source ontologies or terminologies, each of which have their own labels, descriptions and semantic perspective (e.g. FMA[2] for the body, and RXNORM[3] for drugs, as well as more general ontologies like SNOMED[4]). An example ontology is shown in Figure 1 below.

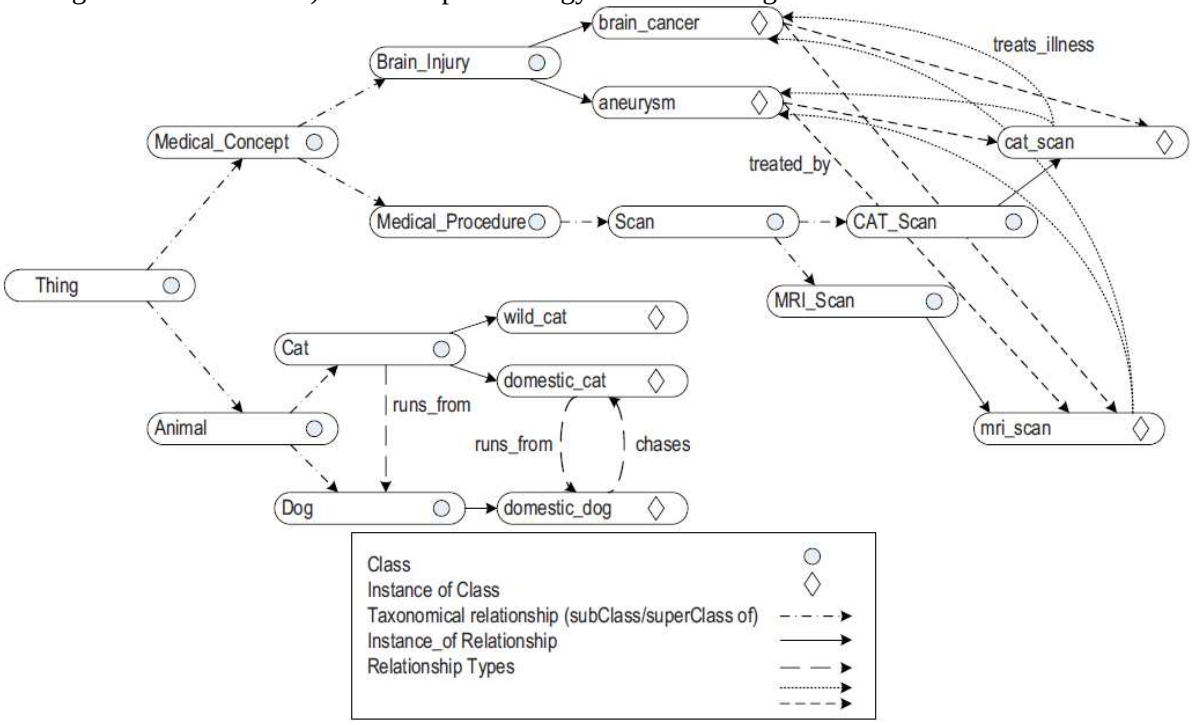

Figure 1. A simple (and incomplete) ontology describing ambiguous senses of the word "cat"

2.2 Ontology Evaluation

Evaluating ontology semantics commonly focuses on the structural and logical nature of the resource. Related efforts may use logical reasoning to ensure that the semantics are internally consistent, or use the structure and labels of another ontology as a baseline, assuming that textual labels for synonymous concepts will be consistent between sources (Vrandecic and Sure, 2007; Ma, 2013). A metric which goes beyond these and evaluates the semantic relevance to a given task is sorely needed (Vrandecic and Sure, 2007). While metrics that examine the completeness of an ontology's content are suggested in the literature (Tartir et al, 2005), these metrics reflect a high-level summary of the content. The evaluation of this content, independent of the ontology itself, and at a sufficiently fine-grained level to suggest areas for improvement, would be of significant additional benefit.

Vrandecic and Sure (2007) recognise the paucity of metrics that take the ontology semantics into account. In terms of semantic quality, they propose leveraging a logical reasoner to evaluate that an ontology is consistent within the context of its own assertions. However, there is no objective analysis of the semantic content with respect to real world human knowledge. Ma et al (2013) point out that prior

[2] FMA: http://sig.biostr.washington.edu/projects/fm/AboutFM.html
[3] RXNORM: http://bioportal.bioontology.org/ontologies/RXNORM
[4] SNOMED: http://bioportal.bioontology.org/ontologies/SNOMEDCT

ontology metrics neglect implicit semantic knowledge. They acknowledge the utility of a graph structure in representing the content of an ontology, and assert that this structure preserves well the semantics of the ontology. However, they do not proceed to examine the ontology in the context of a real-world semantic evaluation. By limiting the scope of comparison to sets of related ontologies, they work on the assumption that similarly labelled concepts and structures are roughly equivalent. Additionally, Sicilia et al (2012) suggest that there is no obvious metric to identify when an ontology needs to be improved.

We propose that graphs composed of instances of ontology concepts and relationships, along with associated unique identifiers, are a less naïve approach to semantic matching than textual labels. We suggest an objective analysis of how annotated instances of ontology concepts and relationships interact, by a process such as spreading activation in an associated graph, would be more reflective of the proximity of the evaluated ontology to the semantics of the target domain text. We also suggest that analysis of particular characteristics of the graph, that amplify or hinder this activation process, are helpful in identifying specific portions of the associated ontology that require further development. Interestingly, the use of spreading activation as a method for ontology assessment has already been carried out previously (Fang and Evermann, 2010). In that case however, the spreading activation was in the context of cognitive psychology, where test subjects manually assessed ontology content. An automated approach, leveraging the same principles, without the requirement for human reviewers, would be of great value.

2.3 Word Sense Disambiguation

WSD is one of the most critical tasks in NLP (Navigli, 2009), and is often described as AI complete. Navigli (2009) identifies several main categories of approach to WSD, namely knowledge based, supervised and unsupervised methods. He proposes knowledge based methods as the most useful in the medium to long term, for several reasons. He points to the availability of knowledge resources such as WordNet, Yago, and DBPedia, resources which are actively developed and enriched, as a starting point of significant value. He also suggests that supervised approaches are better for categorisation tasks like part-of-speech (POS) tagging, rather than tasks that require more fine grained detail such as real-world word-sense disambiguation. As an example of this, consider that the process of disambiguating the correct POS for a word may involve the selection of one from a set of possible POS tags. One such tagset, widely used for English, is the Penn Treebank tagset consisting of 36 separate tags. The UMLS data set, however, contains close to 3 million[5] distinct senses.

Though WSD is still widely regarded as an unsolved problem, supervised approaches to WSD generally perform well. Navigli (2009) suggests that this is due to the lack of real-world considerations in development and testing of WSD methods. We can consider the MSH-WSD corpus as an example demonstrating typical limitations when compared with the requirements for a real-world system. MSH-WSD is a commonly used data set in biomedical WSD, using sense IDs from UMLS, and consisting of approximately 37,000 separate documents or abstracts, where a single ambiguous sense is annotated with the correct UMLS sense ID. A WSD system need only identify this single sense correctly (regardless of the other words in the document), in order to score highly. Additionally, there are a total of 423 distinct word-senses annotated in this test set, greatly reducing the scope of the task involved from approximately 3 million possible senses in the full UMLS. As a result, this data set is not a strong reflection of what is required in real-world biomedical NLP applications, where a high percentage of the words in a given document or context must be assigned their correct senses.

It is generally accepted that unsupervised methods for WSD minimise the cost of developing a suitable application, by relying on features that may be extracted directly from the target domain text, or alternatively using existing knowledge in some form. The latter are often referred to as knowledge-based (KB) methods. For supervised WSD a gold-standard is required input, where manually curated data sets facilitate the training of robust machine learning algorithms. Supervised methods generally outperform unsupervised (Agirre et al, 2010), but are limited by the cost of developing the required training data. However, as mentioned previously, these systems may not perform so well in real world WSD scenarios.

In a biomedical context, there are several examples of both supervised and unsupervised (including knowledge-based) approaches. Most unsupervised approaches leverage the UMLS to some extent, and build on that knowledge using methods like Automated Corpus Extraction (Jimeno Yepes and Aronson, 2012) and Information Content Similarity (McInnes et al, 2011). The commonly cited example of a

[5] UMLS stats: http://www.nlm.nih.gov/research/umls/knowledge_sources/metathesaurus/release/statistics.html

supervised approach that consistently outperforms known unsupervised approaches is Naïve Bayes (Jimeno Yepes and Aronson, 2012; McInnes et al, 2011), achieving 0.94 accuracy on the common data set, although as we've outlined previously, the search space for a correct tag in the chosen data set (with a total number of 423 senses) is much smaller than would be the case in a real-world system.

Several recent approaches to biomedical WSD leverage structured knowledge in the form of a graph. Examples range from the use of co-occurrence data from a domain-specific corpus (Agirre et al, 2006), to variations of PageRank (Agirre and Soroa, 2009; Agirre et al, 2010), to the representation of an ontology, or portion of an ontology, as a graph (Gad El-Rab et al, 2013). Ontologies are often used as a source from which to build the required graph, as they are readily available in many domains, and provide a starting point of high-quality semantic knowledge. As identified previously, the lexical ontology Wordnet is a commonly used resource in open domain WSD. Similarly, in the biomedical domain, the UMLS is equally common. Hybrid approaches leveraging both general lexical semantics like WordNet with domain-specific semantics like UMLS are not as common however, but have been used with promising results in other related NLP tasks such as anaphora resolution (Liang and Lin, 2005).

Graph based methods have not performed as well as other unsupervised approaches, like Machine Readable Dictionaries: 0.8070 (Jimeno Yepes and Aronson, 2012), semi-supervised Automated Corpus Extraction methods: 0.8383 (Jimeno Yepes and Aronson, 2012), and co-occurrence metrics: 0.78 (McInnes and Pedersen, 2013). A recent approach (El-Rab et al, 2013) achieved mixed results with respect to particular terms in the MSH-WSD test corpus, achieving an overall accuracy of 0.603. State of the art accuracy for graph-based methods, in unsupervised biomedical WSD, was 0.72 (McInnes et al, 2011). State of the art in overall unsupervised biomedical WSD was 0.87 (Jimeno-Yepes and Aronson, 2012).

2.4 Spreading Activation

The theory of spreading activation was first proposed by Quillian (1966), in a model of human semantic memory. Quillian proposed an abstract model of human memory, in order to artificially represent the means by which a human's brain might process and understand the semantics of natural language. This model was enhanced by Collins and Quillian (1969) for retrieval tasks, and further modified by Collins and Loftus (1975). The latter provided inspiration for research in many other related fields, from cognitive psychology to neuroscience, to natural language processing, among others (Pace-Sigge, 2013).

The basic premise of spreading activation is related to that of connectionism in artificial intelligence, which uses similar models for neural networks to reflect the fan-out effect of electrical signal in the human brain. In the case of neural networks, a vertex in the graph could represent a single neuron, and edges could represent synapses. In information retrieval (Crestani, 1997) and word-sense disambiguation (Tsatsaronis et al, 2007), generally vertices will represent word-senses and edges will represent some form of relationship, either lexical or semantic linkage, between these senses.

An example implementation is 'Galaxy', developed as part of the Nepomuk Social Semantic Desktop[6], which uses spreading activation to perform clustering on a graph. Instead of traditional methods of hard clustering, which partition a graph into different groups, Galaxy performs soft clustering, which involves identifying a sub-graph located around a set of input nodes, and then finding the focus of this sub-graph. The same implementation provides a configurable weighting model that allows modification of starting weights associated with semantic types, edges and individual nodes in the graph. This has already been used in various scenarios, such as social network analysis and dynamic semantic publication of web content[7], and may also be applied to any set of graph-structured data (Troussov et al, 2008).

By discovering instances of ontology concepts in domain text, using the set of unique identifiers for instances, we can activate corresponding nodes in the graph, from where a signal will traverse outward across adjacent nodes, activating these in turn. As the signal spreads farther from a source node, it gets weaker by an amount specified in an associated weighting model for nodes and edges in the graph. If the signal spreads from multiple nearby source nodes, the signal will combine, and points of overlap will be activated to a greater degree. The nodes which accumulate the most activation are deemed to be the focus nodes for the context. The resulting activated portion of the graph will reflect the inherent meaning of the document, in so far as the ontology's defined semantics will allow.

[6] http://dev.nepomuk.semanticdesktop.org/wiki/TextAnalytics#IBM
[7] http://www.bbc.co.uk/blogs/bbcinternet/2010/07/bbc_world_cup_2010_dynamic_sem.html

To demonstrate this process in action, we will draw examples from the ontology previously defined above. Figure 2 describes the resulting instance graph for the ontology described in Figure 1, on which we can perform spreading activation using instances in text. Firstly, consider the set of surface forms associated with concept instances in table 1. If we annotate the set of contexts below with this lexicon, we can then use the annotations to activate the graph. Nodes that are well connected may benefit from the potential overlap of signal coming from other adjacent nodes. Instances are *italicised* below.

- The *cats* result for the patient's *brain tumour* was assessed by the Doctor.
- *Tigers* and *lions* are *cats* that live in the wild. These *cats* are not afraid of *dogs*.
- The patient survived the *brain tumour*, but died of an allergic reaction to their neighbour's *cats*.

In each example, the ambiguous term is the word “cats”, which can variously refer to: cat_scan, wild_cat and domestic_cat. The surrounding context of each instance contains other concept instances that may help to disambiguate the correct sense of “cats”. In the first example, the nodes representing wild_cat, domestic_cat, cat_scan and brain_cancer will be activated. Since brain_cancer and cat_scan are relatively well connected in the graph, and are also adjacent to one another, the spreading activation will return these nodes as the most likely interpretation of the content.

In the second example, the correct instance is wild_cat. However, this node is isolated in the graph, since there were no associated relationships in the ontology linking this particular instance to other nodes. Since the instance of the class Dog is connected to domestic_cat, these nodes may amplify each other’s signal to a greater degree than is possible at the isolated node wild_cat. It is therefore likely that unless the weighting model is reconfigured, we are unlikely to obtain the correct output. The relevance of isolated nodes may be boosted by increasing the rate of signal decay on other nodes in the graph. However, there is a risk in doing so, since the connectedness of instances in the ontology is likely a better reflection of the semantic content. It would be better to suggest that the ontology would benefit from further development, for example to introduce the ideas of habitat or fear.

The final example demonstrates a more subtle bias in the ontology’s semantics, and the corresponding graph. The overlapping signal from cat_scan and brain_cancer suggests that cat_scan will be returned instead of domestic_cat. Resolving this ambiguity in the graph may require modification of the weighting model, or further development. An advantage in this case however, is the different semantic categories involved: the classes of Cat and Scan. Re-weighting the starting activation signal on the basis of a semantic category is less risky than re-weighting the entire set of nodes in the graph. Even so, further development of the ontology, e.g. to introduce the idea of animal allergies, would be beneficial.

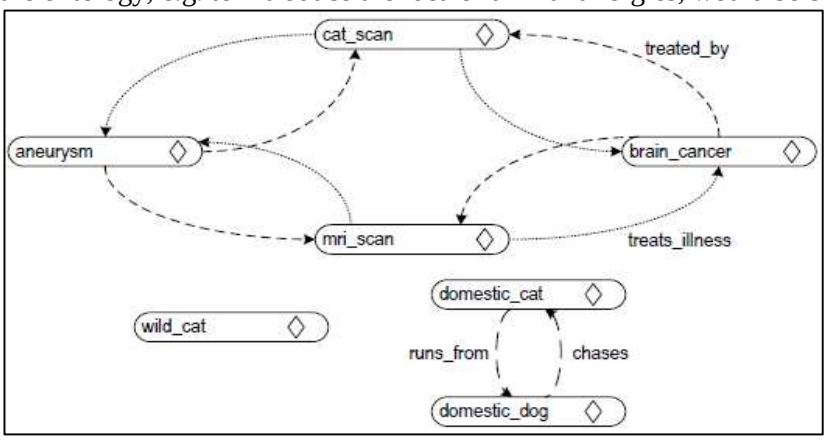

Figure 2. Graph representation of the sample ontology.

Instance ID	Associated Surface Forms
wild_cat	{lions, tigers, cat, cats, cub}
domestic_cat	{cat, cats, kitten }
domestic_dog	{dog, dogs, puppy}
brain_cancer	{brain carcinoma, brain tumour}
cat_scan	{cat, cats, cat scan}

Table 1. Example surface forms for instance data.

3 Method

3.1 Ontology Instance Graph

We extracted data from the UMLS Metathesaurus (MT) and Semantic Network (SN) and built a triple store in RDF/XML[8] format, defining owl:Class and owl:ObjectProperty to reflect concepts and relationships. Using the Galaxy API described in section 2.4, we built a spreading activation network, i.e. a directed graph between instance IDs (vertices) and associated relationships (edges). In order to narrow the proximity between the semantics of domain text and the chosen ontology, we chose to build a graph of instance data. The SN is a high level ontology, and therefore to assume that all relationships between Classes are applicable to all instances would have produced many incorrect assertions, such as "All Drugs have the set of All Drugs as ingredients". Therefore, only instances of relationships that explicitly linked individual concept IDs (Concept Unique Identifiers, CUIs) were used. Across the entire SN, a single CUI may have various types of semantic interactions with other nodes, for example in the context of Drugs and treated Diseases, or separately, in the context of Chemicals and associated Compounds. The UMLS CUIs were used as instance IDs to link surface forms in the text to nodes in the graph.

It is important to point out that the UMLS ontology by no means uses the full expressivity of OWL. However, the general use of spreading activation over a graph derived from ontology content, is not so limited. In other domains, and for ontologies that use the full range of OWL expression, as long as the graph is built from a source that expresses other semantic qualities (e.g. cardinality), the spreading activation strategy will still apply. For example, in the context of our sample ontology, consider activating "cat", the signal spreading to an additional adjacent node for the concept of "four legs", and then other concepts with four legs, such as "dog", becoming activated. The Galaxy API fully supports this.

3.2 Test Corpus and Metric Calculation

We chose to use the MSH-WSD test corpus as our gold-standard. This is a common test set used across the literature in biomedical WSD. The metrics we used were Precision, Recall, FMeasure and Accuracy, whereas prior research mainly focuses on Accuracy. In WSD, a true positive is a disambiguated output that matches a gold-standard, and a false positive is output that does not match. As traditional WSD algorithms are designed to generate output for every word in the text, recall and precision are the same value. However, our algorithm works on the principle of semantic relevance, and there is no guaranteed output; senses with sufficient weight after spreading activation will be displayed. Therefore, we have chosen to take a closer look at precision and recall, which is discussed in more detail in section 4.

Prior literature in biomedical WSD uses older versions of UMLS data, e.g. 2009AB (McInnes et al, 2011). We chose to focus on the 2013AA release of UMLS, in order to assess the most recent version of the ontology's semantic content, and in order to facilitate a useful modification of the current data, which could be leveraged by contemporary NLP systems. This affected the comparison of test results using the MSH-WSD data set.

3.3 Lexical Annotation

In conjunction with the graph described above, we constructed a set of lexical dictionaries that linked UMLS CUIs or instance IDs, to portions of text in a document. These portions of text, otherwise known as surface forms, consisted of potentially many different strings associated with each ID. An example of a data entry for a single UMLS CUI is in table 2 below. Dictionaries were compiled for each semantic category in the UMLS SN, with overlapping associations between ID and textual surface form.

CUI	Semantic Type	Surface Form (Text)
C0018787	BodyPartOrRegion	heart
		cardiac structure
		heart structure
		coronary
		four chambered heart
		the human heart

Table 2. Surface forms associated with the concept "Heart", UMLS CUI: C0018787.

[8] http://www.w3.org/TR/rdf-syntax-grammar/

In order to maximise the potential for spreading activation across the graph, we performed several modifications to the underlying lexical data in UMLS MT, to increase the variations of surface form associated with instances of concepts. Our reasoning for this is as follows: the more instances of concepts that occur in the text, the more nodes that get activated in the graph, and consequently the more opportunities for the activation method to spread out and activate the set of concepts most relevant to the semantics of the document text. For a simple example of this process, please see section 2.4. Examples of transformations carried out in the data are presented in table 3, below.

Pre-existing Term	Transformation Type	New Alternate Surface Form
leg, right	Alternating Comma	right leg
brain cancer	Noun Phrase	cancer of the brain
CANCER	Casing Variants	Cancer
Anaemia	Spelling Variants	Anæmia
Immunoglobulin g	Acronym	Ig
Immunoglobulin g	Term + Acronym	Immunoglobulin g (Ig)

Table 3. Examples of UMLS data transformations applied.

The use of a lexical part-of-speech tagger was particularly effective in filtering out instances of concepts that were obviously introducing unhelpful noise. Some exemplary cases were the Amino Acids "on", "at" and "in" (prepositions), and the GeneOrGenome "was" (verb). UMLS concepts that directly overlapped with words that did not display an appropriate part-of-speech for a true concept (such as adjective or noun), were removed from the document metadata, and thereby not considered as input for spreading activation. For this POS Filter, we chose to use the MaxEntropy model from OpenNLP[9].

3.4 Spreading Activation Strategy

The initial activation strategy was to set starting weights for all semantic categories to a value of 1. Decay factor of the spreading signal at each node in the graph was set to an initial value of 0.5, when the graph was built. The initial threshold of semantic relevance was set to 0.1, and instances retaining a semantic value higher than this would be considered relevant. The lexical annotations from the previous step were used as input to the activation process, and nodes in the graph from instances in the text were assigned their starting weight, according to the number of semantic categories, and their associated weights. As the signal is spread from these starting nodes, the decay factor is applied, reducing the signal strength. For each successive node, the signal is similarly reduced until it falls below the specified threshold, and the activation process is completed. It is important to note that the ambiguity in word-senses may not be entirely removed once the spreading activation has finished. The consequences of this will depend on the particular end-goal. In the case of WSD, we are only interested in obtaining a single most appropriate CUI for a given surface form. We therefore kept only the highest weighted CUI in our system output. In the context of other NLP tasks, such as for named-entity inference or question answering and hypothesis generation (Ferucci et al, 2011), it can be useful to preserve multiple ambiguous outputs for later processing.

It was clear from the outset that simply building a graph of the ontology instance data and semantic relationships was not sufficient to score highly in the WSD task. El-Rab et al (2013), who used the UMLS SN structure for graph-based WSD, reported an overall accuracy of (0.603) on the MSH-WSD test set, which roughly correlates with our baseline system (0.62). Our added advantage is that modification of the weighting strategy allows us to iron out imbalance, or to reduce the influence of those portions of the graph that do not appear to encourage a spreading signal. By focusing on signal amplification and decay, rather than modifying graph semantics, we can change the relevance of particular portions of the ontology without losing any of the original semantic detail. Such modifications are sensitive to performance in the NLP task but, critically, do not require the assistance of domain experts.

We initially pursued a cautious approach to modifying the activation strategy, by only decreasing the starting weight of semantic categories associated with the affected nodes. This weight was decreased by a factor equivalent to the number of overlapping semantic types on the same node. Following this, we measured the accuracy of the approach against the MSH-WSD test corpus for WSD, testing blind, that is by only considering the overall accuracy. Upon close examination of the instance graph, for types of

[9] http://opennlp.apache.org/

structure or characteristics of nodes that may be hindering or over-amplifying the spreading signal (see section 4.1), we further modified the activation strategy to negate the potential influence that certain obviously problematic nodes may have. Modifying our spreading activation strategy in this way, after static graph analysis alone, produced much more accurate output (see table 5, experiment 3).

We then decided to split the test set in the ratio of 4:1, in order to more closely inspect the accuracy of particular cases of WSD, and attempt to correct this specific imbalance in the graph, while still performing some independent validation of the output. The random nature of the split was to choose every fifth example in the data, from the subset for each term. After performing WSD using this 80%, or train set, we discovered that it was possible to distinguish groups of high and low performing nodes in the graph, with respect to the set of static graph metrics, described in the following section.

3.5 Static Graph Analysis (SGA)

As shown in the simple example in 2.4, assessment of ontology semantics can be done up front, before the graph is used. Certain node characteristics may be examined in the graph using a set of graph theoretical metrics, and portions of the graph that are not conducive to spreading activation may be identified. This analysis allows us to make educated modifications to the weighting strategy for spreading activation, as described previously. The set of graph metrics we used is presented in table 4 below.

Metric	**Evaluation**
In Degree	# of inward semantic links
Out Degree	# of outward semantic links
Total Degree	(indegree + outdegree)
Inward Edge Type Variation (ETV)	# of inward edge types
Outward ETV	# of outward edge types
Total ETV	(Inward ETV + Outward ETV)

Table 4. Static Graph Metrics derived from Diestel (2010).

Following the use of these metrics, and the gathering of associated statistics, we categorised particular groups of node in order to apply a common weighting strategy that should maximise performance of the spreading activation algorithm. There were several common patterns that we identified, and chose to target for re-weight. Examples of those nodes that might negatively affect spreading activation are:

- Isolated Nodes, where Total Degree is 0
- Unbalanced Nodes, where inDegree and outDegree are significantly different
- Nodes with few variations in link type, or low Total ETV
- 'Black Hole' nodes, where there is a high Degree to ETV ratio (see section 4.1)

For isolated nodes, we examined the set of associated semantic categories, and boosted their starting weight. For unbalanced nodes, where the indegree was significantly higher or lower than the outdegree, we increased or decreased the decay factor accordingly, to reduce the imbalance of the spreading signal. For nodes with low ETV but high Degree, we increased the decay factor, in order to reduce the potential influence of a single over-used semantic link. For overly promiscuous (Norvig, 1986) or 'Black Hole' nodes, we reduced the starting weight applied by the associated semantic categories, and increased the rate of decay. In certain cases, the intended modifications were incompatible, and resulted in conflicting changes to the graph and weighting strategy. Where certain nodes might require a boost from one category, the starting weight for the same category may need to be reduced, due to an overly-connected node elsewhere. We decided to inhibit the negatively connected nodes only, in light of the increase in system accuracy from reducing noise compared to the gain from improvement of individual nodes.

4 Results and Discussion

The baseline activation strategy was promising. The introduction of a POS filter to ignore invalid instances (see section 3.3) had a strong effect on recall, due to reduced noise in the activation of the graph. Recall significantly improved upon the modification of starting weights after analysis of static graph metrics, although precision fell slightly. This result (0.82) constitutes state of the art in graph-based WSD for biomedical text. The fall in precision was not unexpected, since the graph was no longer so

biased toward specific word senses. We also present a further experiment that incorporates a fall-back mechanism for test cases where the spreading activation did not produce a disambiguated output. This result (0.89) constitutes state of the art in overall unsupervised biomedical WSD. This allows our method to assign a single word-sense for every ambiguous word or surface-form. This fall-back alone achieves accuracy of 59%, comparing favourably with a default-sense approach (54.5%: McInnes et al, 2011).

Finally, by identifying bias in the graph toward specific senses in the test corpus, using an 80% subset of the MSH-WSD data set for training, and then modifying the rate of decay for problematic nodes, we achieved a significant boost to recall, and consequently to overall accuracy. We draw a distinction between this and other results since the testing was not blind, but was using the gold-standard corpus directly, to examine the portions of the graph that did not perform well in testing. We envisage that this may still be of practical use in real-world applications, by firstly developing an appropriate gold-standard, which in conjunction with analysis of the ontology instance graph, will result in optimal output.

The current results reflect the scope of spreading activation being set to the whole document. Only one sense of a word is recognised within that context, and documents containing multiple interpretations of the same word will not be correctly disambiguated. However, by configuring the scope to a sentence or paragraph we may reduce the potential accuracy of the output by decreasing the available instances for activation. Prior research into the "One sense per discourse" hypothesis suggests that the existing approach should be appropriate in up to 98% of cases (Gale et al, 1992).

Experiment Description	Precision	Recall	FMeasure	Accuracy
1. Baseline system	0.935	0.659	0.6639	0.62
2. Baseline + POS Filter	0.901	0.721	0.7872	0.74
3. As in 2, with SGA re-weight	0.841	0.822	0.8317	0.82
4. As in 3, confidence fallback	0.912	0.887	0.8995	0.89
5. SGA+WSD (20% test set)	0.986	0.942	0.9635	0.93

Table 5. Comparison of WSD Results.

4.1 Identifying and Resolving Graph Bias or Imbalance

In experiment 5, having already identified specific cases that remained unbalanced, we attempted to rectify this by examining the graph in parallel with the WSD metric data. If a graph displays characteristics indicating imbalance or bias, for example where a node is unreachable (isolated in the graph), or node degree and node edge-type variation are relatively low (see section 3.5), it is less likely that the spreading activation will reflect the meaning of the text. We made discoveries similar to the following:

- 80% of nodes with Total ETV >15 had WSD precision of over 90%
- 60% of nodes with Total ETV <5 had precision of less than 10%

We also discovered cases in the graph where a node had very high Degree (> 100), and relatively low ETV. In terms of spreading activation, these nodes would be especially problematic. We have coined the term 'Black Hole Node' to describe this phenomenon. In psycholinguistic terms, this may be comparable to the notion of a Freudian slip, where a node in the graph which is not immediately relevant to the context of the document, has become over-stimulated by its connectivity, or as Norvig (1986) would suggest, its "promiscuity". The signal will gravitate towards such an over-connected node during the process of spreading activation, affecting the relevance of other nodes in that context. An example black hole node is the UMLS CUI C0035298, representing a retina in a human eye, with 1636 edges and 19 edge types. The extra noise in activating such a node can skew the signal across the entire graph. Word senses that compete for relevance with this or related nodes will have poorer accuracy. We modified the activation strategy to reflect this by increasing the rate of decay on such nodes from 0.5 to 0.99.

By ensuring that only the graph weighting strategy is modified, we can keep all word-senses present in the graph, resolving the issue identified by Norvig (1986) where such graph content had to be removed. Using the WSD metric output, we also modified the activation strategy to cope with bias toward particular senses in the test corpus. We reduced the starting weight for semantic categories for the high-scoring sense, in order to potentially increase the relative semantic importance of the alternative senses. Table 6 demonstrates some of the improvements achieved with regard to specific ambiguous terms.

Term	F-Measure Before	F-Measure After
Murine Sarcoma Virus	0	0.47
Gamma-Interferon	0.013	0.28
RA	0.021	0.59
CCD	0.033	1
AA	0.899	0.99

Table 6. Examples of term-specific improvement using re-weighting strategy.

4.2 MSH-WSD Data Set

In working with the MSH-WSD data set, we came across many issues that Navigli (2009) previously identified. The number of ambiguous senses (423) in the context of the full UMLS set of almost 3 million, reduces the validity of this corpus for measuring real-world viability and accuracy. Further to this, our results with lexical analysis optimisation demonstrate that the test corpus ignored surrounding context for potentially overlapping terms, such as “bat” and “fruit bat”. In such cases, it would have been more accurate to use the CUI for “fruit bat” as the specific type of “bat”, but the test corpus does not reflect this. Our algorithm is sensitive to contextual semantics, so ensuring that all lexical matches of any length remain present, potentially reduces the accuracy of the algorithm’s output, as well as the real-world utility of the approach. In spite of the various data transformation techniques applied, our recall maximised at 96.4%. Critically, when we normalize our overall accuracy (0.89) to take this into account, we reach accuracy of 0.92, a significant achievement in unsupervised WSD. We are currently examining what may be required to achieve maximum recall of 100%. While such a result is not guaranteed, without full coverage of the test set, we have not yet measured the full potential of this method.

4.3 Identifying Focus Areas for Ontology Improvement

One of the primary outcomes of this research is a method for the identification of specific ontology portions that require further development. As we have seen in section 4.1, there are several candidates which stand out. Other issues pointing to required enhancements in the ontology were around the notion of isolated nodes in the graph. An example of this is "ADA", the American Dental Association. It is surprising to discover that although this term’s associated CUI (C0002456) is listed in 7 source ontologies of the UMLS SN, there are no semantic relationships in the source between this CUI and any others. Of the 203 ambiguous terms in the MSH-WSD data set, 5 of those terms had associated nodes that were similarly isolated in the graph. Without any semantic relationship to other concepts, it is reasonable to suggest that the ontology would benefit from focused development of these nodes’ surrounding context.

In terms of the variation of connectivity, we quickly discovered using our simple graph metrics that the “SIB” or sibling relationship was extremely common. Consider the concept C0325089 representing the *felidae family* or the animal *cat*, which has 8 connections, but for which SIB is the only available link type. Hard-wiring siblings in this fashion, with no other link, is unhelpful since spreading activation can already identify siblings from common parent nodes. We contend that such concepts are not as well connected as they may first appear, and are therefore strong candidates for further development. This will not be apparent from the Degree metric alone, but by combining Degree and Edge Type Variation with node-specific accuracy in an NLP task, it becomes a straightforward process. Following this discovery, we also suggest that an empirical analysis of link quality would be beneficial, although this would not be a trivial task given the size of the data set (~3 million senses and ~700 link types).

5 Summary and Future Research

We have presented a new method for evaluating ontology semantics which has several advantages over existing approaches. We have shown how the application of graph theoretical analysis to semantic structures like ontologies is a valid means by which to assess their semantic quality, while enabling the recommendation of specific focus areas for further development. We have additionally demonstrated that a graph-metric based weighting strategy for spreading activation can overcome an ontology’s inherent semantic inconsistencies, facilitating the optimisation of the ontology for a given NLP task.

In the case of our UMLS prototype, we made significant improvements using this technique, achieving state of the art in unsupervised knowledge based WSD (0.82), as well as achieving state of the art in overall unsupervised WSD, with the use of a fall-back probability score (0.89). An additional semi-

supervised approach, leveraging gold-standard data from a training portion of the MSH-WSD data set, had very promising performance (0.93). The amount of required input data to this method is relatively small when compared with fully supervised approaches, as a single gold-standard annotation in each target context is sufficient to evaluate the graph using our spreading activation algorithm.

In future we would like to apply this technique to other ontologies, and associated test sets, for other domains in NLP. Merging of domain-specific ontologies with more general semantic resources like Yago or Wordnet may help to facilitate the activation of otherwise poorly connected or isolated nodes in the graph. We would like to investigate the automatic learning of an optimal spreading activation weighting strategy. An empirical study comparing data from human ontology reviewers with this spreading activation technique, would also be helpful.

We would like to expand the set of metrics used, by adapting other existing graph theoretical metrics to suit the requirements of NLP. Some promising examples are "Centrality" and "Betweenness" outlined by Brandes and Erlebach (2005), which determine the relative importance of a node within a graph. In the case of UMLS, we can perform a comprehensive static analysis of all ambiguous CUIs within the data set, identifying competing senses which do not have sufficient separation in the graph. These senses could then be targeted in the configuration of the spreading activation strategy.

As interest grows in the use of graph theoretical methods for the analysis of cognitive processes (Van Dijk et al, 2010; Bullmore and Sporns, 2009; Sporns, 2003), exploring the relationship between spreading activation in a graph representing ontology semantics, as performed in this research, and in neural activity during psycholinguistic experimentation (Fang and Evermann, 2010), becomes an exciting prospect that may lead to a better understanding of semantic processing in the human brain.

Abstract

This work is concerned with distinguishing different semantic relations which exist between distributionally similar words. We compare a novel approach based on training a linear Support Vector Machine on pairs of feature vectors with state-of-the-art methods based on distributional similarity. We show that the new supervised approach does better even when there is minimal information about the target words in the training data, giving a 15% reduction in error rate over unsupervised approaches.

1 Introduction

Over recent years there has been much interest in the field of distributional semantics, drawing on the distributional hypothesis: words that occur in similar contexts tend to have similar meanings (Harris, 1954). There is a large body of work on the use of different similarity measures (Lee, 1999; Weeds and Weir, 2003; Curran, 2004) and many researchers have built thesauri (i.e. lists of "nearest neighbours") automatically and applied them in a variety of applications, generally with a good deal of success.

In early research there was much interest in how these automatically generated thesauri compare with human-constructed gold standards such as WordNet and Roget (Lin, 1998; Kilgarriff and Yallop, 2000). More recently, the focus has tended to shift to building thesauri to alleviate the sparse-data problem. Distributional thesauri have been used in a wide variety of areas including sentiment classification (Bollegala et al., 2011), WSD (Miller et al., 2012; Khapra et al., 2010), textual entailment (Berant et al., 2010), predicting semantic compositionality (Bergsma et al., 2010), acquisition of semantic lexicons (McIntosh, 2010), conversation entailment (Zhang and Chai, 2010), lexical substitution (Szarvas et al., 2013), taxonomy induction (Fountain and Lapata, 2012), and parser lexicalisation (Rei and Briscoe, 2013).

A primary focus of distributional semantics has been on identifying words which are similar to each other. However, semantic similarity encompasses a variety of different lexico-semantic and topical relations. Even if we just consider nouns, an automatically generated thesaurus will tend to return a mix of synonyms, antonyms, hyponyms, hypernyms, co-hyponyms, meronyms and other topically related words. A central problem here is that whilst most measures of distributional similarity are symmetric, some of the important semantic relations are not. The hyponymy relation (and converse hypernymy) which forms the ISA backbone of taxonomies and ontologies such as WordNet (Fellbaum, 1989), and determines lexical entailment (Geffet and Dagan, 2005), is asymmetric. On the other hand, the co-hyponymy relation which relates two words unrelated by hyponymy but sharing a (close) hypernym, is symmetric, as are synonymy and antonymy. Table 1 shows the distributionally nearest neighbours of the words `cat`, `animal` and `dog`. In the list for `cat` we can see 2 hypernyms and 13 co-hyponyms[1].

[1]We read `cat` in the sense `domestic cat` rather than `big cat`, hence `tiger` is a co-hyponym rather than hyponym of `cat`.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2249–2259, Dublin, Ireland, August 23-29 2014.

cat	dog 0.32, animal 0.29, rabbit 0.27, bird 0.26, bear 0.26, monkey 0.26, mouse 0.25, pig 0.25, snake 0.24, horse 0.24, rat 0.24, elephant 0.23, tiger 0.23, deer 0.23, creature 0.23
animal	bird 0.36, fish 0.34, creature 0.33, dog 0.31, horse 0.30, insect 0.30, species 0.29, cat 0.29, human 0.28, mammal, 0.28, cattle 0.27, snake 0.27, pig 0.26, rabbit 0.26, elephant 0.25
dog	cat 0.32, animal 0.31, horse 0.29, bird 0.26, rabbit 0.26, pig 0.25, bear 0.26, man 0.25, fish 0.24, boy 0.24, creature 0.24, monkey 0.24, snake 0.24, mouse 0.24, rat 0.23

Table 1: Top 15 neighbours of `cat`, `animal` and `dog` generated using Lin's similarity measure (Lin, 1998) considering all words and dependency features occurring 100 or more times in Wikipedia.

Distributional similarity is being deployed (e.g., Dinu and Thater (2012)) in situations where it can be useful to be able to distinguish between these different relationships. Consider the following two sentences.

The cat ran across the road. (1)

The animal ran across the road. (2)

Sentence 1 textually entails sentence 2, but sentence 2 does not textually entail sentence 1. The ability to determine whether entailment holds between the sentences, and in which direction, depends on the ability to identify hyponymy. Given a similarity score of 0.29 between `cat` and `animal`, how do we know which is the hyponym and which is the hypernym?

In applying distributional semantics to the problem of textual entailment, there is a need to generalise lexical entailment to phrases and sentences. Thus, the ability to distinguish different semantic relations is crucial if approaches to the composition of distributional representations of meaning that are currently receiving considerable interest (Widdows, 2008; Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Grefenstette et al., 2011; Socher et al., 2012; Weeds et al., 2014) are to be applied to the textual entailment problem.

We formulate the challenge as follows: Consider a set of pairs of similar words $\langle A, B \rangle$ where one of three relationships hold between A and B: A lexically entails B, B lexically entails A or A and B are related by co-hyponymy. Given such a set, how can we determine which relationship holds? In Section 2, we discuss existing attempts to address this problem through the use of various *directional* measures of distributional similarity.

This paper considers the effectiveness of various supervised approaches, and makes the following contributions. First, we show that a SVM can distinguish the entailment and co-hyponymy relations, achieving a significant reduction in error rate in comparison to existing state-of-the-art methods based on the notion of distributional generality. Second, by comparing two different data sets, one built from BLESS (Baroni and Lenci, 2011) and the other from WordNet (Fellbaum, 1989), we derive important insights into the requirements of a valid evaluation of supervised approaches, and provide a data set for further research in this area. Third, we show that when learning how to determine an ontological relationship between a pair of similar words by means of the word's distributional vectors, quite different vector operations are useful when identifying different ontological relationships. In particular, using the difference between the vectors for pairs of words is appropriate for the entailment task, whereas adding the vectors works well for the co-hyponym task.

2 Related Work

Lee (1999) noted that the substitutability of one word for another was asymmetric and proposed the alpha-skew divergence measure, an asymmetric version of the Kullback-Leibler divergence measure. She found that this measure improved results in language modelling, when a word's distribution is smoothed using the distributions of its nearest neighbours.

Weeds et al. (2004) proposed a notion of distributional generality, observing that more general words tend to occur in a larger variety of contexts than more specific words. For example, we would expect to be able to replace any occurrence of `cat` with `animal` and so all of the contexts of `cat` must be plausible

contexts for `animal`. However, not all of the contexts of `animal` would be plausible for `cat`, e.g., "the monstrous animal barked at the intruder". Weeds et al. (2004) attempt to capture this asymmetry by framing word similarity in terms of co-occurrence retrieval (Weeds and Weir, 2003), where precision and recall are defined as:

$$P_{ww}(u,v) = \frac{\Sigma_{f \in F(u) \cap F(v)} I(u,f)}{\Sigma_{f \in F(u)} I(u,f)} \text{ and } R_{ww}(u,v) = \frac{\Sigma_{f \in F(u) \cap F(v)} I(v,f)}{\Sigma_{f \in F(v)} I(v,f)}$$

where $I(n,f)$ is the pointwise mutual information (PMI) between noun n and feature f and F(n) is the set of all features f for which $I(n,f) > 0$.

By comparing the precision and recall of one word's retrieval of another word's contexts, they were able to successfully identify the direction of an entailment relation in 71% of pairs drawn from WordNet. However, this was not significantly better than a baseline which proposed that the most frequent word was the most general.

Clarke (2009) formalised the idea of distributional generality using a partially ordered vector space. He also argued for using a variation of co-occurrence retrieval where precision and recall are defined as:

$$P_{cl}(u,v) = \frac{\Sigma_{f \in F(u) \cap F(v)} min(I(u,f), I(v,f))}{\Sigma_{f \in F(u)} I(u,f)} \text{ and } R_{cl}(u,v) = \frac{\Sigma_{f \in F(u) \cap F(v)} min(I(u,f), I(v,f))}{\Sigma_{f \in F(v)} I(v,f)}$$

Lenci and Benotto (2012) took the notion further and hypothesised that more general terms should have high recall and low precision, which would thus make it possible to distinguish them from other related terms such as synonyms and co-hyponyms. They proposed a variant of the Clarke (2009) measure to identify hypernyms:

$$invCL(u,v) = \sqrt[2]{P_{cl}(u,v) * (1 - R_{cl}(u,v))}$$

Evaluation on the BLESS data set (Baroni and Lenci, 2011), showed that this measure is better at distinguishing hypernyms from other relations than the measures of Weeds et al. (2004) and Clarke (2009).

Geffet and Dagan (2005) proposed an approach based on *feature inclusion*, which extends the rationale of Weeds et al. (2004) to lexical entailment. Using data from the web they demonstrated a strong correlation between complete inclusion of prominent features and lexical entailment. However, they were unable to assess this using an off-line corpus due to data sparseness.

Szpektor and Dagan (2008) found that the P_{ww} measure tends to promote relationships between infrequent words with narrow vectors (i.e. those with relatively few distinct context features). They proposed using the geometric average of P_{ww} and the symmetric similarity measure of Lin (1998) in order to penalise low frequency words.

Kotlerman et al. (2010) apply the IR evaluation method of *Average Precision* to the problem of identifying lexical inference and use the balancing approach of Szpektor and Dagan (2008) to demote similarities for narrow feature vectors; their measure is called *balAPinc*. They show that all of the asymmetric similarity measures previously proposed perform much better than symmetric similarity measures on a directionality detection experiment, and that their method and that of Clarke (2009) outperform the others with statistical significance. They also show that their measure is superior when used for term expansion in an event detection task.

Baroni et al. (2012) investigate the relation between phrasal and lexical entailment, and demonstrate that support vector machines can generalise entailment relations between quantifier phrases to entailment involving unseen quantifiers. They compare the performance of their system with the *balAPinc* measure.

The Stanford WordNet project (Snow et al., 2004) expands the WordNet taxonomy by analysing large corpora to find patterns that are indicative of hyponymy. For example, the pattern "NP_X and other NP_Y" is an indication that NP_X is a NP_Y, i.e. that NP_X is a hyponym of NP_Y. They use machine learning to identify other such patterns from known hyponym-hypernym pairs, and then use these patterns to find new relations in the corpus. The transitivity relation of the taxonomy is enforced by searching only over valid taxonomies and evaluating the likelihood of each taxonomy given the available evidence (Snow

et al., 2006). The approach is similar to ours in providing a supervised method of learning semantic relations, but relies on having features for occurrences of pairs of terms rather than just vectors for terms themselves. Our approach is therefore more generally applicable to systems which compose distributional representations of meaning.

Most recently, Rei and Briscoe (2013) note that hyponyms are well suited for lexical substitution. In their experiments with smoothing edge scores for parser lexicalisation, they find that a directional similarity measure, *WeightedCosine*[2], performs best. Also of note, Mikolov et al. (2013) propose a vector offset method to capture syntactic and semantic regularities between word representations learnt by a recurrent neural network language model. Yih et al. (2012) present a method for distinguishing synonyms and antonyms by inducing polarity in a document-term matrix before applying Latent Semantic Analysis. Santus et al. (2014) propose identifying hypernyms using a new measure based on entropy, SLQS, which is based on the hypothesis that the most typical linguistic contexts of a hypernym are less informative than the most typical linguistic contexts of its hyponyms. Evaluated on pairs extracted from the BLESS dataset (Baroni and Lenci, 2011), this measure outperforms P_{ww} at both discriminating hypernym test pairs from other types of relation and at determining the direction of the entailment relation.

3 Methodology

The code used to perform our experiments has been open sourced, and is available online.[3]

3.1 Vector Representations

Distributional information was collected for all of the nouns from Wikipedia provided they had occurred 100 or more times. We used a Wikimedia dump of Wikipedia from June 2011 and extracted text using wp2txt[4]. This was part-of-speech tagged, lemmatised and dependency parsed using the Malt Parser (Nivre, 2004). All major grammatical dependency relations involving open class parts of speech (`nsubj, dobj, iobj, conj, amod, nnmod`) and also occurring 100 or more times were extracted as features of the POS-tagged and lemmatised nouns. The value of each feature is the positive point wise mutual information (PPMI) (Church and Hanks, 1989) between the noun and the feature. The total number of noun vectors which can be harvested from Wikipedia with these parameters is $124,345$.

Our goal is to build classifiers that establish whether or not a given semantic relation, *rel*, holds between two similar words A and B. Support vector machines (SVMs), which are effective across a variety of classification scenarios, learn a boundary between two classes from a set of positive and negative example vectors. The two classes correspond to the relation *rel* holding or not holding. Here, however, we do not start with a single vector, but with two distributional vectors v_A and v_B for the words A and B, respectively. These vectors must be combined in some way to produce the SVM's input, and a number of ways were considered, defined in Table 2. Of these operations, the vector difference (used by *svmDIFF* and *knnDIFF*) and direct sum (used by *svmCAT*) are asymmetric, whereas the sum and pointwise multiplication (used by *svmADD* and *svmMULT*) are symmetric.

We now motivate the use of each of these operations. First, we note that pointwise multiplication (*svmMULT*) is intersective. Similar vectors will have a large intersection and it might be possible to learn the features that nouns occurring in different semantic relations should share. However, it does not retain any information about non-shared features and it is symmetric so it is difficult to see how it would be possible to use it to distinguish hypernyms from hyponyms. Pointwise addition (*svmADD*) effectively performs the union of the features, giving emphasis to the shared features. Whilst it does retain information about the non-shared features, it is also symmetric, making it difficult again to see how it would be useful in determining the direction of an entailment relation

Vector difference (as used in *svmDIFF* and *knnDIFF*), on the other hand, is asymmetric. Further, we might expect a small difference vector (containing many zeroes) to be indicative of similar nouns. Further, considering the majority sign of features in this difference vector might indicate the direction of

[2]The details of this measure are unpublished.

[3]`https://github.com/SussexCompSem/learninghypernyms`

[4]`https://github.com/yohasebe/wp2txt`

entailment. Using an SVM, we might expect to be able to effectively learn which of these features should be ignored and which should be combined, to decide the correct direction of entailment in the majority number of cases in our training data. However, note that if one uses vector difference it is impossible to distinguish between the case where a feature occurred with both nouns (to the same extent) and the case where a feature occurs with neither noun. Accordingly, a small difference vector may indicate that both nouns do not occur in many distinct contexts. A possible solution to this problem is to use the direct sum of the vectors (i.e., the concatenation of the two vectors) which retains all of the information from the original vectors. Finally, we consider the use of the single vector corresponding to the second word (*svmSING*) as a baseline. High performance by this operation would indicate that we can learn features of words which tend to be hypernyms (or co-hyponyms) without any regard to the other word in the putative relationship.

We also note that the behaviour of these methods may differ depending on the weighting used for vectors. For example, PMI is the log of a ratio of probabilities and therefore one might expect vector addition where vectors are weighted using PMI to correspond to multiplication where vectors are weighted using frequency or probability. However, the use of *positive* PMI (where negative PMI scores are regarded equal to zero), which is consistent with other work in this area, means that this correspondence is lost.

Because of the nature of our datasets, we were concerned that systems could learn information about the taxonomy from the relations in the training data, without making use of information in the vectors themselves. To investigate this, we constructed random vectors to be used in place of the vectors derived from Wikipedia. The dimensionality of the random vectors was chosen to be 1000 since this substantially exceeds the average number (398) of non-zero features in the Wikipedia vectors.

3.2 Classifiers

We constructed linear SVMs for each of the vector operations outlined in Section 3.1. We used linear SVMs for speed and simplicity, since the point is to compare the different vector representations of the pairings. For comparison, we also constructed a number of supervised, unsupervised, and weakly supervised classifiers. These are listed in Table 2. For the linear SVMs and kNN classifier, we used the scikit-learn implementations with default settings. For k nearest neighbours, we performed a parameter search, using nested cross-validation, varying k between 1 and 50.

For weakly supervised approaches, we evaluated the measure on the training set, then found the best threshold p on the training set that best divides the two classes using that measure. When classifying, we determine that the relation holds if the value of the measure exceeds p.

svmDIFF	A linear SVM trained on the vector difference $v_B - v_A$
svmMULT	A linear SVM trained on the pointwise product vector $v_B * v_A$
svmADD	A linear SVM trained on the vector sum $v_B + v_A$
svmCAT	A linear SVM trained on the vector concatenation $v_B \oplus v_A$
svmSING	A linear SVM trained on the vector v_B
knnDIFF	k nearest neighbours (knn) trained on the vector difference $v_B - v_A . 1 < k < 50$
widthdiff	$\textit{width}(B) > \textit{width}(A) \rightarrow \textit{rel}(A, B)$ where $\textit{width}(A)$ is number of non-zero features in A
singlewidth	$\textit{width}(B) > p \rightarrow \textit{rel}(A, B)$
cosineP	$\textit{sim}_{cos}(A, B) > p \rightarrow \textit{rel}(A, B)$ where $\textit{sim}_{cos}(A, B)$ is cosine similarity using PPMI
linP	$\textit{sim}_{lin}(A, B) > p \rightarrow \textit{rel}(A, B)$ (Lin, 1998)
CRdiff	$P_{ww}(A, B) > R_{ww}(A, B) \rightarrow \textit{rel}(A, B)$ (Weeds et al., 2004)
clarkediff	$P_{cl}(A, B) > R_{cl}(A, B) \rightarrow \textit{rel}(A, B)$ (Clarke, 2009)
invCLP	$\textit{invCL}(A, B) > p \rightarrow \textit{rel}(A, B)$ (Lenci and Benotto, 2012)
balAPincP	$\textit{balAPinc}(A, B) > p \rightarrow \textit{rel}(A, B)$ (Kotlerman et al., 2010)
most freq	The most frequent label in the training data is assigned to every test point.

Table 2: Implemented classifiers

3.3 Data Sets

One of key the challenges of this work has been to construct a data set which accurately and validly tests our hypotheses. All four of our datasets detailed below are available online [5].

In order to test our hypotheses, a data set needs to be balanced in many respects in order to prevent the supervised classifiers making use of artefacts of the data. This would not only make it unfair to compare the supervised approaches with the unsupervised approaches, but also make it unlikely that our results would be generalisable to other data. Here, we outline the requirements for the data sets, the importance of which is demonstrated by our initial results for a data set which does not satisfy all of them.

There should be an equal number of positive and negative examples of a semantic relation. Thus, random guessing or labelling with the most frequently seen label in the training data will yield 50% accuracy and precision. An advantage of incorporating this requirement means that evaluation can be in terms of simple accuracy (or error rate).

It should not be possible to do well simply by considering the distributional similarity of the terms. Hence, the negative examples need to be pairs of equally similar words, but where the relationship under consideration does not hold.

It should not be possible to do well by pre-supposing an entailment relation and guessing the direction. For example, it has been shown (Weeds et al., 2004) that given a pair of entailing words selected from WordNet, over 70% of the time the more frequent word is also the entailed word.

It should not be possible to do well using ontological information learnt about one or both of the words from the training data that is not generalisable to their distributional representations. For example, it should not be possible for the classifier simply to learn directly from the training pairs $\langle$`cat` ISA `mammal`$\rangle$ and $\langle$`mammal` ISA `animal`$\rangle$ that $\langle$`cat` ISA `animal`$\rangle$. Furthermore, we must ensure that a classifier cannot learn that a particular word is near the top of the ontological hierarchy, and, as a result, do well by guessing that a particular pairing probably has an entailment relation. For example, given many pairs such as $\langle$`cat` ISA `animal`$\rangle$, $\langle$`dog` ISA `animal`$\rangle$, a system which guessed $\langle$`rabbit` ISA `animal`$\rangle$ but not $\langle$`animal` ISA `rabbit`$\rangle$ would do better than random guessing. Whilst both of these types of information could be useful in a hybrid system, they do not require any distributional information and therefore we would not be learning anything about the distributional features of `animal` which make it likely to be a hypernym.

3.3.1 BLESS

We have constructed two data sets from BLESS (Baroni and Lenci, 2011) which is a collection of examples of hypernyms, co-hyponyms, meronyms and random unrelated words for each of 200 concrete, largely monosemous nouns. We will refer to these 200 nouns as the BLESS concepts.

$hyponym_{\text{BLESS}}$ is a set of 1976 labelled pairs of nouns. For each BLESS concept, 80% of the hypernyms were randomly selected to provide positive examples of entailment. The remaining hypernyms for the given concept were reversed and taken with the same number of co-hyponyms, meronyms and random words to form negative examples of entailment. A filter was applied to ensure that duplicate pairs were not included (e.g., if $\langle$`cat`, `animal`$\rangle$ is a positive pair then $\langle$`animal`, `cat`$\rangle$ cannot be a negative pair).

$cohyponym_{\text{BLESS}}$ is a set of 5835 labelled pairs of nouns. For each BLESS concept, the co-hyponyms were taken as positive examples of this relation. The same total number of (and split evenly between) hypernyms, meronyms and random words was taken to form the negative examples. The order of 50% of the pairs was reversed and again duplicate pairs were disallowed.

In both cases the pairs are labelled as positive or negative for the specified semantic relation and in both cases there are equal (± 1) numbers of positive and negative examples. For 99% of the generated BLESS pairs, both nouns had associated vectors harvested from Wikipedia. If a noun does not have an associated vector, the classifiers use a zero vector.

[5] `https://github.com/SussexCompSem/learninghypernyms`

3.3.2 WordNet

We constructed two data sets using WordNet. Whilst these data sets are similar in size to the BLESS data sets they more adequately satisfy the requirements laid out above[6]. We constructed a list of all non-rare, largely monosemous, single word terms in WordNet. To be considered non-rare, a word needed to have occurred in SemCor at least once (i.e. frequency information is provided about it in the WordNet package) and to have occurred in Wikipedia at least 100 times. To be considered largely monosemous, the predominant sense of the word needed to account for over 50% of the occurrences in the SemCor frequency information provided with WordNet. This led to a list of 7613 nouns.

hyponym$_{\text{WN}}$ is a set of 2564 labelled pairs of nouns constructed in the following way. Pairs $\langle A, B \rangle$ were found in the list of nouns where B is an ancestor of A (i.e., A lexically entails B). Each found pair is added either as a positive or a negative in the ratio 2:1 provided that the reverse pairing has not already been added and provided that each word has not previously been used in that position. Co-hyponym pairs (i.e., words which share a direct hypernym) were also found within the list of nouns. Each found pair is added to the data set (as a negative) provided the reverse pairing has not already been added, and provided that neither word has already been seen in that position in a pairing (either in the entailment pairs or the co-hyponym pairs). The same number of co-hyponym pairs as hypernym-hyponym negatives is selected. This provides a balanced data set where half of the pairs are positive examples of entailment and the other half are semantically similar but not entailing.

cohyponym$_{\text{WN}}$ is a set of 3771 labelled pairs of nouns. It was constructed in the same way as *hyponym*$_{\text{WN}}$ except the same number of co-hyponym pairs were selected as the total number of entailment pairs (in either direction). These co-hyponym pairs were labelled as positive and the entailment pairs were labelled as negative. Thus, this provides a balanced data set where half of the pairs are positive examples of co-hyponyms and the other half, the negative examples, are entailment pairs (with direction unspecified)

In both these sets, the average path distance between entailment pairs is 1.64, whereas path distance between co-hyponym pairs is 2.

3.4 Experimental Setup

Most of our experiments were carried out using an implementation of five-fold cross-validation using each combination of data set, vector set and classifier. In this setup, the pairs are randomly partitioned into five subsets, one subset is held out for testing whilst the classifiers are trained on the remaining four, and this process is repeated using each subset as the test set.

In initial experiments with the BLESS datasets, the SVM classifiers were able to achieve classification accuracy of over 95% for *hyponym*$_{\text{BLESS}}$ and over 90% for *cohyponym*$_{\text{BLESS}}$. However, the results using random vectors were not significantly different from using the distributional vectors harvested from Wikipedia. This indicated that the classifiers were learning ontological information implicit in the training data. In order to address this, when using the BLESS datasets, we removed any pair from the training data if either word was present in the test data. In order to preserve a reasonable amount of training data, we implemented this approach with ten-fold cross-validation. In all subsequent experiments, across all datasets and classifiers, we found performance by the random vectors was no higher than 52%. This indicates that the performance seen in Table 3 is due to learning from distributional features rather than any ontological information implicit in the training set.

4 Results

In Table 3, we compare average accuracy for a number of different classifiers on each of two tasks, distinguishing hyponyms and distinguishing co-hyponyms, on each of the two datasets.

Looking at the results for the *hyponym*$_{\text{BLESS}}$ data set, we can see that the SVM methods do generally outperform the unsupervised methods. However, the best performing model is svmSING, suggesting that, for this data set, it is best to try to learn the distributional features of more general terms, rather than comparing the vector representations of the two terms under consideration.

[6]Note that imposing these requirements on the BLESS data sets would lead to very small data sets, since information is only provided for 200 nouns.

dataset	svmDIFF	svmMULT	svmADD	svmCAT	svmSING	knnDIFF		
$hyponym_{\text{BLESS}}$	**0.74**	0.56	0.66	0.68	**0.75**	0.54		
$cohyponym_{\text{BLESS}}$	0.62	0.39	0.41	0.40	0.40	0.58		
$hyponym_{\text{WN}}$	**0.75**	0.45	0.37	**0.74**	0.69	0.50		
$cohyponym_{\text{WN}}$	0.37	0.60	**0.68**	**0.64**	0.58	0.50		
dataset	most freq	cosineP	linP	widthdiff	singlewidth	CRdiff	invCLP	balAPincP
$hyponym_{\text{BLESS}}$	0.54	0.53	0.54	0.56	0.58	0.52	0.54	0.54
$cohyponym_{\text{BLESS}}$	0.61	**0.79**	**0.78**	-	-	-	-	-
$hyponym_{\text{WN}}$	0.50	0.53	0.52	0.70	0.65	0.70	0.66	0.53
$cohyponym_{\text{WN}}$	0.50	0.50	0.55	-	-	-	-	-

Table 3: Accuracy Figures for the data sets generated from BLESS and WordNet (standard errors $<$ 0.02). For cohyponyms, results for measures designed to detect hyponymy have been omitted. We also omit results of clarkediff as these were consistently the same or less than CRdiff.

On the corresponding co-hyponym task, using the $cohyponym_{\text{BLESS}}$ data set, we see the best performing classifier is the cosine measure. The cosine measure is able to perform relatively well here because a substantial proportion of the negative examples (25%) are random unrelated words which will have low cosine scores. It is also consistent with earlier work (e.g., (Lenci and Benotto, 2012)) which suggests that measures such as the cosine measure "prefer" words in symmetric semantic relationships such as co-hyponymy. The poor performance of the SVM methods here can perhaps be explained by the paucity of the training data in this experimental set up with this data set. If, for example, our test concept is `robin`, our approach requires that we will not have any training pairs containing `robin`, or any training pairs containing any of the words to which `robin` is related in the test set. In a dataset as small as BLESS, this requirement effectively removes all knowledge of the distributional features of words in the target domain. Hence, the need for a larger dataset as we have extracted from WordNet.

Looking at the results for the $hyponym_{\text{WN}}$ data set, the directional SVM methods (*svmDIFF* and *svmCAT*) substantially outperform the symmetric SVM methods, and their performance is significantly better (at the 0.01% level) than the unsupervised methods. Also of note is the substantial difference between *svmDIFF* and *knnDIFF*. Both of these methods are trained on the differences of vectors. However, the linear SVM outperforms kNN by 19–25%. This may suggest that the shape of the vector space inhabited by the positive entailment pairs is particularly conducive for learning a linear SVM. Positive and negative pairs are close together (as evidenced by the poor performance of *kNN*), but generally linearly separable.

Looking at the results for the $cohyponym_{\text{WN}}$ data set, it is clear that the unsupervised methods cannot distinguish the co-hyponym pairs from the entailing pairs. The supervised SVM methods do substantially better, with the best performance achieved by *svmADD* and *svmCAT*. Both of these methods essentially retain information about all of the features of both words. *svmMULT* does much better than *svmDIFF*, which suggests that the shared features are more indicative than the non-shared features for this task.

The reasonably high performance of *svmSING* on both data sets suggests that words which have co-hyponyms in the data set tend to inhabit a somewhat different part of the feature space to words which are included as entailed words in the data set. We hypothesise that there are specific features which more general words tend to share (regardless of their topic) which makes it possible to identify more general words from more specific words. This is completely consistent with very recent results using SLQS, a new entropy-based measure (Santus et al., 2014). Here, the authors hypothesise that the most typical contexts of a hypernym are less informative than the most typical linguistic contexts of its hyponyms, with some promising results. It would be plausible to hypothesise that *svmSING* is learning which nouns typically have less informative contexts and are therefore likely to by hypernyms.

Given prior work, the performance of the *balAPincP* measure is lower than expected on the $hyponym_{\text{WN}}$ dataset. Our task is slightly different to that of (Kotlerman et al., 2010), since we are determining the existence (or not) of hyponymy, rather than the direction of entailment for pairs where it is known that a relationship exists. It could be that the measure is particularly suited to the latter task.

5 Conclusions and Further Work

We have shown that it is possible to predict to a large extent whether or not there is a specific semantic relation between two words given their distributional vectors, using a supervised approach based on linear SVMs. The increase in accuracy over unsupervised methods is significant at the 0.01% level and corresponds to a substantial absolute reduction in error rate (over 15%).

We have also shown that the choice of vector operation is significant. Whilst concatenating the vectors, and therefore retaining all of the information from both vectors including direction, generally performs well, we have also shown that different vector operations are useful in establishing different relationships. In particular, the vector difference operation, which loses information about the original vectors, achieved performance indistinguishable from concatenation on the entailment task, where the classifier is required to distinguish hyponyms from other semantically related words including hypernyms. On the other hand, the addition operation, which also loses information, outperformed concatenation by 4% (which is statistically significant at the 0.01% level) on the coordinate task, where the classifier is required to distinguish co-hyponyms from hyponyms and hypernyms. Hence the nature of the relationship one is trying to establish between words determines the nature of the operation one should perform on their associated vectors.

We have also shown that it is possible to outperform state-of-the-art unsupervised methods even when a data set has been constructed without ontological information, and when target words have not previously been seen in that position of a relationship in the training data. Hence, we believe the supervised methods are learning characteristics of the underlying feature space which are generalisable to new words (inhabiting the same feature space).

In future work, we intend to apply this approach to the problem of labelling the distributional neighbours found for a given word with specific semantic relations. We also plan to investigate the use of bag-of-words (windowed) vectors instead of grammatical relations for this task.

Finally, we believe that the data sets constructed from WordNet, which we publish alongside this paper, can be used as a useful benchmark in evaluating future advances in this area, both for supervised and unsupervised methods.

Abstract

The "one sense per discourse" (OSPD) and "one sense per collocation" (OSPC) hypotheses have been very influential in Word Sense Disambiguation. The goal of this paper is twofold: (i) to explore whether these hypotheses hold for entities, that is, whether several mentions in the same discourse (or the same collocation) tend to refer to the same entity or not, and (ii) test their impact in Named-Entity Disambiguation (NED). Our experiments show consistent results on different collections and three state-of-the-art NED system. OSPD hypothesis holds in around 96%-98% of documents whereas OSPC hypothesis holds in 91%-98% of collocations. Furthermore, a simple NED post-processing in which the majority entity is promoted, produces a gain in performance in all cases, reaching up to 8 absolute points of improvement in F-measure. These results show that NED systems would benefit of considering these hypotheses into their implementation.

1 Introduction

The "one sense per discourse" (OSPD) hypothesis was introduced by Gale et al. (1992), and stated that a word tends to preserve its meaning when occurring multiple times in a discourse. They estimated that the probability of two occurrences of the same polysemous noun drawn from one document having the same sense to be around 94% for documents from Grolier encyclopedia, and 96% for documents from Brown, based on word senses from the Oxford Advanced Learner's Dictionary and a handful of examples. A few years later, Krovetz (1998) reported 66% on larger corpora (SemCor and DSO) annotated with WordNet senses by third parties, but, unfortunately, he only reported how many polysemous nouns occurred with a single sense in **all** documents, not in each document. In the context of statistical machine translation, Carpuat (2009) reported that, 80% of the time, words occurring multiple times in a source document are translated into a single word in the target language.

In the case of entities, OSPD is closely related to coreference, where the task is to find whether two different mentions (perhaps using different surface strings like "John" and "he") in a document refer to the same entity or not. For instance, the coreference system presented by (Lee et al., 2013), uses a heuristic which links mentions in a document that share the same surface string: "This sieve [heuristic] accounts for approximately 16 CoNLL F1 points improvement, which proves that a signicant percentage of mentions in text are indeed repetitions of previously seen concepts". Our paper actually quantifies the amount of those repetitions for entities, providing additional evidence for the heuristic.

The "one sense per collocation" (OSPC) hypothesis was introduced by Yarowsky (1993), stating that a word tends to preserve its meaning when occurring with the same collocate. Yarowsky tested his hypothesis for several definitions of collocate, including positional collocates (word to left or right) and syntactic collocations (governing verb of object, governing verb of subject, modifying adjective). He reported entropy on train data, as well as disambiguation performance on unseen data, with the precision ranging between 90% and 99% for a handful of words with two distinct homograph senses, like, e.g. "bass" or "colon". In larger-scale research, Martinez and Agirre (2000) measured the precision

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2260–2269, Dublin, Ireland, August 23-29 2014.

Abbott Beefs Up Litigation Reserves NORTH CHICAGO, Ill. (AP) **Abbott** Laboratories Inc., bracing for a costly settlement in a federal investigation involving the prostate-cancer drug Lupron, said Friday it was increasing litigation reserves by $344 million. As part of the announcement, **Abbott** said it had restated its quarterly results and is now reporting a loss of $319.9 million for the first three months of this year rather than a profit. The move comes amid long-running negotiations between the U.S. Department of Justice and TAP Pharmaceutical Products, the 50-50 joint venture between **Abbott** and Takeda Chemical Industries of Japan that made Lupron. **Abbott** said in January ...

Figure 1: Example of OSPD for entities. All occurrences of "**Abbott**" refer to "Abbott Laboratories".

of similar collocations on corpora (Semcor and DSO) annotated by third parties with finer-grained senses from WordNet, reporting lower figures around 70%.

In this paper, we take a collocation to be a word (or multiword term) that co-occurs with the target named-entity more often than would be expected by chance. In our case we use syntactic dependencies to extract co-occurring terms.

These two hypotheses have been very influential, and have inspired multiple heuristics and methods in Word Sense Disambiguation research (Agirre and Edmonds, 2007, Chapters 5,7,10,11). In this work we are going to show that both hypotheses hold for named-entities as well, and that the hypotheses can be used to post-process the output of any Named-Entity Disambiguation system (NED) to improve its performance. NED, also known as Entity Linking, takes as input a named-entity mention in context and assigns it a specific entity from a given entity repository (Hachey et al., 2012; Daiber et al., 2013).

In the first part of this work we are going to test whether the two hypotheses hold for entity mentions with respect to a repository of entities extracted from Wikipedia. For instance, do all occurrences of mention "Abbott" in a document refer to the same entity? Do all occurrences of mention "CPI" as subject of verb "rise" refer to the same entity? Do all occurrences of "CDU" in relation to "Merkel" refer to the same entity? The examples in Figures 1 and 2 show evidence that this is indeed the case. The experiments aim at quantifying in which degree OSPD and OSPC hypotheses hold for entities[1].

In the second part of the paper, we will explore a simple method to incorporate OSPD and OSPC hypotheses to any existing NED system, showing their potential. After running the NED system, we take its output and observe, for each mention string, which is the entity returned most often for a given document (or collocation), assigning to all occurrences the majority entity. We tested the improvements with a freely available NED system (Daiber et al., 2013), a reimplementation of a strong Bayesian NED system (Han and Sun, 2011) and an in-house graph-based system. We got statistically significant improvements for all systems and "one sense" hypotheses that we tested, with a couple exceptions.

In order to check the OSPD and OSPC hypotheses for entities, we first looked into existing datasets. AIDA (Hoffart et al., 2011)[2] is a publicly available hand-tagged corpus based on the CoNLL named-entity recognition and disambiguation task dataset. AIDA contains links of all entity mentions in full documents, so it is a natural fit for OSPD. We estimated OSPD based on more than 4,000 mentions that occur multiple times in a document. For completeness, we also estimated OSPD at the collection level.

OSPD and OSPC are independent of each other, as one is applied at the document level and the other at the corpus level, focusing on the entities that occur with a specific collocation. Multiple occurrences of a target string in a document usually occur with different collocations, and conversely, multiple occurrences of a target string with a specific collocation typically occur in different documents. Note also that singletons (entities that are only mentioned once in a document) are not affected by OSPD, but could be affected by OSPC.

In order to estimate OSPC, no available corpus existed, so we decided to base our dataset on the TAC KBP 2009 Entity Linking dataset[3] (TAC2009 for short) (Ji et al., 2010). The TAC2009 dataset involves 138 mention strings, which have been annotated in several documents drawn primarily from Gigaword[4].

[1] For the sake of clarity we will also refer to OSPD and OSPC for entities as OSPD and OSPC.

CPI subject-of rise:
China's consumer price index, or **CPI**, rose 2.8 percent last December.
In the 10 months to October, the **CPI** rose 1.35 percent, the core price index grew 1.13 percent ...
Measured on a month-on-month basis, March **CPI** rose 2.3 percent from February, ...
... still lower than in China, Hong Kong and Singapore, whose **CPI**s have rised 8.0 percent, ...
The core **CPI** rose 0.2 percent, in line with Wall Street expectations.
Angela Merkel has **CDU**:
... who share power with Merkel's **CDU** nationally in an uneasy " grand coalition " ...
Economy Minister Michael Glos, also from the CSU, the sister party to Merkel's **CDU** ...
In the past Merkel's **CDU** had been able to rely on the CSU's strength in Bavaria ...
... but while her conservative **CDU** wanted new legal tools to do so, ...
The new development has put a further strain on Merkel's **CDU** ...

Figure 2: Examples of OSPC for entities, showing five examples for a syntactic collocation (top row) and fie examples for a more specific proposition (bottom row). "**CPI**" might refer to "Comunist Party of India" or "Consumer Price Index", among others, but refers to the second in all cases. "**CDU**" can refer to the German "Christian Democratic Union" or "Catholic Distance University", among others, but refers to the first in all cases.

We extracted several syntactic collocations for those 138 mention strings from Gigaword, and hand-annotated them, yielding an estimate for the OSPC. Note that TAC2009 only provides the annotation for a specific mention in a document, so we had to annotate by hand the rest of occurrences in the documents. For instance, we analyzed examples of "CPI" as subject of the verb "rise" (cf. Figure 2). Some of the syntactic collocations like the subjects of verb "has" seemed very uninformative, so we decided to also check the OSPC hypothesis on more specific collocations, involving more complete argument structures. For instance, we checked "ABC" occurring as subject of "has" with object "radio". We call this more specific collocations *propositions* (Peñas and Hovy, 2010).

The paper is structured as follows. We will first present the resources used in this study. Section 3 presents the results of OSPD. Section 3.1 extends OSPD when, instead of documents, we take the complete collection. Section 4 presents the study of OSPC both for syntactic dependencies and propositions. Section 5 presents the experiments where OSPD and OSPC are used to improve the performance of existing systems. Finally, we draw the conclusions and future work.

2 Resources used

AIDA is based on the corpus used in the CONLL named-entity recognition and classification task, where all entities in full documents had been linked to the referred Wikipedia articles (using the 2010 Wikipedia dump). We use the full AIDA dataset, with 1,393 documents, 34,140 disambiguated entity mentions, where 27,240 are linked to a Wikipedia article. All in all there are 6,877 distinct mention strings (types) which are linked at least once to a Wikipedia article. The rest refer to articles not in Wikipedia (NIL instances), and were discarded. This corpus covers news from a sample of a few days spanning from 1996-05-28 to 1996-12-07.

In order to prepare our dataset for OSPC, we chose the dataset of the TAC KBP 2009 Entity Linking competition, as this dataset have been extensively used in Entity Linking evaluation. In addition, the corpus used in the task was very large, allowing us to mine relevant collocations (see below). We manually annotated the occurrences in the extracted collocations, producing two datasets, one for each kind of collocation (cf. Section 4). Note that the TAC KBP organizers only annotated one specific mention in each target document. For completeness, we also tagged the rest of the occurrences of the target mentions in the documents, thus allowing us to provide OSPD estimated based on TAC2009 data as well. This is the third dataset that we annotated by hand. The hand-annotation was performed by a single person, and later reviewed by the rest of the authors. The three annotation datasets are publicly available[5]. Hand-

VNPN	”includes link to website”

Table 1: List of the six patterns used to extract propositions, with some examples.

tagging is costly, so we tagged around 250 examples of syntactic collocations and around 250 examples of propositions.

Note that both AIDA and TAC2009 contain mentions that were not linked to a Wikipedia article because the mention referred to an entity which was not listed in the entity inventory. We ignored all those cases (called NIL cases), as we would need to investigate, for each NIL, which actual entity they refer to.

The collocations were extracted from the TAC KBP collection (Ji et al., 2010), comprising 1.7 million documents, 1.3 millions from newswire and 0.5 millions from the web. We have parsed them with the Stanford CoreNLP software (Klein and Manning, 2003), obtaining around 650 million dependencies (De Marneffe and Manning, 2008). We selected subject, object, prepositional complements and adjectival modifiers as the source for syntactic collocations. In order to provide more specific collocations, we implemented the syntactic patterns proposed in (Peñas and Hovy, 2010), which produce so-called propositions. The result is a database with 16 million distinct propositions. Table 1 shows the six patterns used in this work, together with some examples.

In order to know whether a mention is ambiguous, we built a dictionary based on Wikipedia which lists, for each string mention, which entities it can refer to. We followed the construction method of (Spitkovsky and Chang, 2012), which checked article titles, redirects, disambiguation pages and hyperlinks to find mention strings that can be used to refer to entities. Contrary to them, we could not access hyperlinks in the web, so we could use only those in Wikipedia. According to our dictionary, the ambiguity of the mentions that we are studying is very high, 26.4 entities on average for the mentions in AIDA, and 62.6 entities on average for the mentions in TAC2009.

3 One entity per discourse

In order to estimate OSPD we divided the number of times a mention string referred to different entities in the document with the number of times a mention string occurred multiple times in the document. In the denominator and numerator we count each mention-document pair once.

Regarding AIDA, we found 12,084 occurrences of mentions which occurred more than once in a document, making 4,265 unique mention-document pairs[6] (cf. Table 2). In the vast majority of the cases those mentions refer to a single entity in the document, and only in 170 cases the mentions in the document refer to several entities. The last row in Table 2 shows the ratio between those values, 96.01%, showing that OSPD is strong in this dataset.

We also checked OSPD in the TAC2009 dataset. Out of the 138 distinct mention strings used in the task, we discarded those only linked to NIL (that is, no corresponding Wikipedia article existed) and those which were not ambiguous (that is, they had only one entity in the dictionary, cf. Section 2). That leaves 105 mention strings, occurring 1,776 times in 918 different documents, which we annotated by hand. The 105 strings occurred 1,776 times in 918 documents. Removing the cases where the mention occurred only once, we were left with 1,173 occurrences, which make 334 unique mention-document pairs, of which only 6 occurred with more than one sense (rightmost row in Table 2). This yields an estimate for OSPD of 98.2%.

[6]By unique mention-document pairs we mean that we only count once for a mention occurring multiple times in a document. For instance if mention *Smith* occurs 10 times in the whole corpus, 8 times in document *A* and 2 times in document *B*, we count two unique mention-document pairs.

	AIDA	TAC2009
Mention-document pairs	4,265	334
Ambiguous pairs	170	6
OSPD	**96.0%**	**98.2%**

Table 2: One entity per discourse: per document statistics in AIDA and TAC2009 datasets. Pairs stand for the number of unique mention-document pairs. The 4,265 pairs in AIDA correspond to 12,084 occurrences of mentions, and the 334 pairs in TAC2009 correspond to 1,173 occurrences.

	All mentions		First mention	
	AIDA	TAC2009	AIDA	TAC2009
Mention types	3,363	105	2,731	105
Ambiguous types	475	26	454	25
OSPD (collections)	**85.9%**	**75.2%**	**83.4%**	**76.2%**

Table 3: One entity per collection: statistics in AIDA and TAC2009. In the first two columns ("All mentions") we consider all mention types ($3,363$ types in AIDA correspond to $23,726$ occurrences of mentions, and 105 types in TAC2009 correspond to $1,776$ occurrences). In the second two columns ("First mention") we leave only the first mention of each document (in this case, there are $2,731$ mention types in AIDA which correspond to $15,275$ occurrences, and 105 types in TAC2009 corresponding to 941 occurrences).

Finally, we also thought about measuring OSPD on the Wikipedia articles, where many mentions have been manually linked to their respective article. Unfortunately, we noted that Wikipedia guidelines explicitly prevent authors linking a mention multiple times: *Generally, a link should appear only once in an article, but if helpful for readers, links may be repeated in infoboxes, tables, image captions, footnotes, and at the first occurrence after the lead*[7]. The fact that Wikipedia editors did not explicitly state exceptions to the above rule (e.g. for cases where the word or phrase is used to refer to two different articles, thus breaking the OSPD hypothesis) is remarkable, and might indicate that Wikipedia editors had not felt the need to challenge the OSPD hypothesis.

3.1 One entity per collection

We took the opportunity to also explore "one entity per collection", which gives an idea of what is the spread of entities for whole document collections. In this case, there is no need to count mention-document pairs, as there is one single document, the collection, so we estimate the hypothesis according to mention types. The first two columns in table 3 shows that, overall, mentions which occurred more than once in the collection tend to refer to the same entity 85.9% of the time in AIDA, and 75.2% of the time in TAC2009.

As we know that multiple mentions in a document tend to refer to one entity, the second two columns in table 3 offers the statistics when factoring out multiple occurrences of mention in a document, that is, leaving the first mention in each document. The statistics are very similar, with minor variations.

We think that the lower estimate for TAC2009 is an artifact of how the TAC KBP organizers set up the dataset, as they were explicitly looking for cases where the target string would refer to different entities, making the task more challenging for NED systems. This fact does not affect OSPD for documents, as those strings still tend to refer to a single entity per document, but given the need to find occurrences for different entities, the organizers (Ji et al., 2010) did focus on strings occurring with different entities across the document collection. This is in contrast with AIDA, where they tagged all named-entities occurring in the target documents. Had the organizers of TAC2009 focused on a random choice of strings and documents, the one entity per collection would also hold to the high degree exhibited in AIDA, as the genre of most of the documents is also news (as in AIDA).

[7] http://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Linking#What_generally_should_be_linked

	Syn. coll.	Propositions
Mention-collocation pairs	58	61
Ambiguous pairs	5	1
OSPC	**91.4%**	**98.4%**

Table 4: One entity per collocation: statistics for syntactic collocations and propositions. The 58 mention-collocation pairs correspond to 262 occurrences, and the 61 mention-proposition pairs to 279.

4 One entity per collocation

In order to estimate OSPC for **syntactic collocations**, we manually annotated several occurrences of the 138 mention strings of the TAC2009 dataset. Hand-tagging mention entities is a costly process, so we chose (at random) one syntactic dependency relation for each of the 138 mention strings that occurred more than five times in the corpus. We then hand-tagged at random five occurrences of each collocation (cf. Figure 2). This method would provide a maximum of 5 examples for each of the 138 mentions, but after checking the minimum frequency of the collocations, the quality of the context, repeated sentences, mentions that are not ambiguous in the dictionary, and whether the mention could be attached to an entity in the database, the actual number was lower. All in all we found 58 mention-collocation pairs (262 occurrences) for syntactic collocations (cf. middle column in Table 4). Only 5 mentions referred to more than one entity per collocation, yielding that OSPC for syntactic collocation is around 91.4%.

To gather the dataset for **propositions**, we followed the same method as for the syntactic collocations, that is, we chose (at random) one propositions involving one of the 138 mention strings that occurred more than five times in the corpus, and hand-tagged at random five occurrences of each proposition (cf. Figure 2. As with syntactic collocations, we also found a limited number of mentions filling the desired properties. That left 61 mention-collocation pairs (279 occurrences) for propositions (cf. right column in Table 4). Only 1 mention referred to more than one entity per proposition, yielding OSPC for propositions around 98.4%. This shows that the more specific the context is, the stronger is the link between mention and entity.

5 Improving performance

In order to check whether any of the "one sense" hypothesis above could improve the performance of a NED system, we followed a simple procedure: After running the NED system, we take its output and observe, for each mention string, which is the entity returned most often for a given document (or collocation), assigning to all occurrences the majority entity. In case of ties, we return the entity with the highest support from the NED system. We tested the improvements on three NED systems: the freely available DBpedia Spotlight, a reimplementation of a strong Bayesian NED system and a graph-based system.

DBpedia Spotlight is a freely available NED system (Daiber et al., 2013), based on a generative probabilistic model (Han and Sun, 2011). Nowadays it is one of the most widely used NED systems and attains performances close to state-of-the-art (Daiber et al., 2013)We used the default values of the parameters for all the experiments in this paper.

We also tested an in-house reimplementation of the generative probabilistic model presented in (Han and Sun, 2011). This is a state-of-the-art system which got the same accuracy as the best participant (72.0) when evaluated in the non-NIL subset of TAC2013.

UKB is a freely-available system for performing Word Sense Disambiguation and Similarity based on random walks on graphs (Agirre and Soroa, 2009). Instead of using it on WordNet, we represented Wikipedia as a graph, where vertices are the wikipedia articles and edges represents bidirectional hyperlinks among Wikipedia pages, effectively implementing a NED system. We used a Wikipedia dump from 2013 in our experiments. UKB is a competitive, state-of-the-art system which attained a score of 69.0 when evaluated in the non-NIL subset of the TAC2013 dataset.

The input of the systems is the context of each mention to be disambiguated, in the form of a 100 token window centered in the target mention. In NED, the identification of the correct mention to be

Mention in context	Entity
Abbott Beefs Up Litigation ...	Abbot_Kinney
Abbott Laboratories Inc., bracing ...	Abbott_Laboratories
Abbott said it had restated ...	Abbott_Laboratories
venture between **Abbott** and Takeda ...	Abbott_Laboratories
Abbott said in January ...	Abbott_Laboratories

Figure 3: Applying OSPD: Each of the five occurrences of Abbott in the document in Figure 1 has been tagged independently by a NED systems, which return the correct entity in all but one case (precision 80%). Applying OSPD would return the correct entity (Abbott_Laboratories) in all cases, improving precision to 100%.

	AIDA			TAC 2009		
	Prec.	**Recall**	**F1**	**Prec.**	**Recall**	**F1**
Spotlight	83.24	63.90	72.30	64.48	46.44	53.99

+ OSPD Collection	84.02	**74.64**	**79.05**	56.24	47.98	51.78
UKB	70.09	69.03	69.55	67.70	67.64	67.67
+ OSPD Discourse	71.30	70.23	70.76	**70.21**	**70.21**	**70.21**
+ OSPD Collection	**75.79**	**74.64**	**75.21**	68.84	68.84	68.84
(Han and Sun, 2011)	65.71	65.11	65.41	65.49	65.49	65.49
+ OSPD Discourse	67.77	67.37	67.57	66.27	66.27	66.27
+ OSPD Collection	**74.29**	**73.89**	**74.09**	**68.24**	**68.24**	**68.24**

Table 5: Applying OSPD: NED performance on AIDA and TAC2009 OSPD datasets, including each of the three NED systems, and the results after applying OSPD at the document and collections levels. Bold marks best result for each system.

disambiguated is part of the problem. AIDA does provide gold mentions, but TAC2009 only provides a query string which might be just a substring of the real mention in the document. We treated both corpus in the same way. In the case of DBpedia Spotlight we use the built-in mention spotter. In the case of our in-house implementations, we use the longest string that matches a valid entity mention in the system, as given by the dictionary (cf. Section 3).

Some of the NED systems do not return an entity for all mentions, so we evaluate precision, recall and the harmonic mean (F1 measure). Statistical significance has been estimated using Wilcoxon. We reused the same corpora as in the previous sections for the evaluation, and also removed all NIL mentions (i.e. mentions which refer to an entity not in Wikipedia).

5.1 One entity per discourse

We report the improvements using OSPD for both **document** and **collection** levels. At the document level, we relabel mentions that occur multiple times in a document using the entity returned most times by the NED system in that document. Figure 3 illustrates the idea for a NED system on the same sample document as in Figure 1. At the collection level, we relabel mentions using the entity returned most times by the NED systems in the whole collection.

Table 5 reports the results of the performance as evaluated on mentions occurring multiple times in the AIDA and TAC2009 datasets. The numbers in the left part of the table correspond to the performance as evaluated on mentions occurring multiple times in AIDA documents. Note that the number of occurrences where OSPD at the collection level can be applied is larger (a superset of those for OSPD at the document level), as, for instance, a mention string occurring once in three different documents won't be affected by OSPD at the document level, but it could be relabeled at the collection level. We were especially interested in making the numbers between OSPD at the document and collection levels

CPI subject-of rise	Angela Merkel has CDU:
Consumer_price_index	Christian_Democratic_Union_(Germany)

Table 6: Applying OSPC: NED performance on TAC2009, including each of the three NED systems, and the results after applying OSPC for syntactic collocations and propositions. Bold is used for best results for each system.

directly comparable, and therefore report the results on the same occurrences, that is, the occurrences where OSPD at the document level can be applied.

The results show a small but consistent improvement for OSPD at the document level in precision, recall and F1 for the three NED systems, around 1 or 2 absolute points. The improvements when applying OSPD at the collection level are also consistent, but remarkably larger, between 5 and 9 absolute points. All improvements are statistically significant (p-value below 0.01).

Table 5 also reports the results after applying OSPD to TAC2009 instances which occurred more than once in a document. Results for OSPD at document level and collection level follow the same methodology as for AIDA. The improvement at the collection level is not so consistent, with a loss in performance for Spotlight, a small improvement for UKB, and a larger improvement for (Han and Sun, 2011). All differences across the table are statistically significant (p-value below 0.01).

While the OSPD at the document level is strong in both corpora, Section 3.1 showed that the OSPD at the collection level is only strong in AIDA, with a much lower estimate in TAC2009. This fact would explain why the improvement with OSPD at the collection level is not consistent. Following the rationale in Section 3.1, we think that had the organizers of the task chosen strings and documents at random, the improvement in TAC 2009 at the collection level would be also as high as in AIDA. The high improvement in AIDA at the collection level compared to the more modest improvement at the document level, despite having a lower OSPD estimate (cf. Section 3.1), could be caused by the fact that there are more occurrences and evidence in favor of the majority entity.

5.2 One entity per collocation

Figure 4 shows the application of OSPC to the output of a NED system to two sample collocations in our dataset. In this case, the application of OSPC would increase precision to 100%. The actual result on the datasets produced in Section 4 for syntactic collocations and propositions is reported on table 6.

Regarding syntactic collocations, table 6 shows that the improvement is small but consistent for the three systems on precision, recall and F1, ranging from 0.5 to 2.5 absolute points in F1 score. The results for propositions also show the same trend, with consistent improvements across the table. All differences

in the two tables are statistically significant (p-value < 0.01), except for UKB.

6 Conclusions and future work

Our study shows that OSPD holds for 96%-98% (in the AIDA and TAC2009 datasets, respectively) of the mentions that occur multiple times in documents. We also measured OSPD at the collection level (86% and 75%, respectively). OSPC holds for 91% of the mentions that occur multiple times in the syntactic collocations that we studied, and 98% of the mentions that occur multiple times in more specific collocations. We reused the publicly available AIDA dataset for estimating OSPD. In addition, we created a dataset to study OSPC based on the TAC KBP Entity Linking 2009 task dataset, which is publicly available[8].

We carefully chose to estimate both OPSD and OSPC on TAC2009, in order to make the numbers between OSPD and OSPC comparable. The OSPD numbers for AIDA are very similar to those obtained on TAC2009, providing complementary evidence. Although the high estimate of OSPD for entities was somehow expected, the high estimate of OSPC for the syntactic collocations, especially the propositions, was somehow unexpected, given the high ambiguity rate of the discussed strings, and the fact that the ambiguity included similar entities, like for instance "ABC" which can refer, among other 190 entities, to the American Broadcasting Company or the Australian Broadcasting Corporation.

Our results also show that a simple application of the OSPD and OSPC hypotheses to the output of three different NED systems improves the results in all cases. Remarkably, the highest performance gain, 8 absolute points, was for OSPD at the collection level in the AIDA corpus.

The results presented here could be largely dependent on the domain and genre of the documents, as well as the definition of collocation. Our work is a strong basis for claiming that OSPD and OSPC hold for entities, but the evidence could be further extended exploring alternative operationalization of collocations and a larger breadth of genres and domains.

For the future we would like to check whether these hypotheses can be further used to improve current NED systems. The OSPD hypothesis can be used to jointly disambiguate all occurrences of a mention in a document. The OSPC hypothesis could be used to acquire important disambiguation features, or to perform large-scale joint entity linking. The OSPD for whole collections could be useful for documents on specific domains, and for domain adaptation scenarios.

Abstract

Event extraction is a popular research topic in natural language processing. Several event extraction tasks have been defined for both the newswire and biomedical domains. In general, different systems have been developed for the two domains, despite the fact that the tasks in both domains share a number of characteristics. In this paper, we analyse the commonalities and differences between the tasks in the two domains. Based on this analysis, we demonstrate how an event extraction method originally designed for the biomedical domain can be adapted for application to the newswire domain. The performance is state-of-the-art for both domains, with F-scores of 52.7% for the biomedical domain and 52.1% for the newswire domain in terms of their primary evaluation metrics.

1 Introduction

Research into event extraction was initially focussed on the general language domain, largely driven by the Message Understanding Conferences (MUC) series (e.g., Chinchor (1998)) and the Automated Content Extraction (ACE) evaluations[1]. More recently, the focus of research has been widened to the biomedical domain, motivated by the ongoing series of biomedical natural language processing (BioNLP) shared tasks (STs) (e.g., Kim et al. (2013)).

Although the textual characteristics and the types of relevant events to be extracted can vary considerably between domains, the same general features of events normally hold across domains. An event usually consists of a trigger and arguments (see Figures 1 and 2.) A trigger is typically a verb or a nominalised verb that denotes the presence of the event in the text, while the arguments are usually entities. In general, arguments are assigned semantic roles that characterise their contribution towards the event description.

Until now, however, there has been little, if any, effort by researchers working on event extraction in different domains to share ideas and techniques, unlike syntactic tasks (e.g., (Miyao and Tsujii, 2008)) and other information extraction tasks, such as named entity recognition (e.g., (Giuliano et al., 2006)) and relation extraction (e.g., (Qian and Zhou, 2012)). This means that the potential to exploit cross-domain features of events to develop more adaptable event extraction systems is an under-studied area. Consequently, although there is a large number of published studies on event extraction, proposing many different methods, no work has previously been reported that aims to adapt an event extraction method developed for one domain to a new domain.

In response to the above, we have investigated the feasibility of adapting an event extraction method developed for the biomedical domain to the newswire domain. To facilitate this, we firstly carry out a detailed static analysis of the differences that hold between event extraction tasks in the newswire and biomedical domains. Specifically, we consider the ACE 2005 event extraction task (Walker et al., 2006) for the newswire domain and the Genia Event Extraction task (GENIA) in BioNLP ST 2013 (Kim et al., 2013) for the biomedical domain. Based on the results of this analysis, we adapt the biomedical event

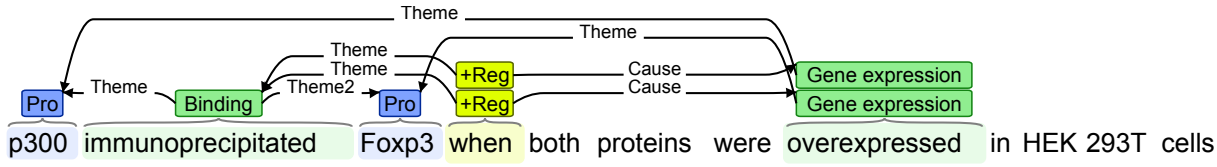

Figure 2: GENIA event example (ID: PMC-1447668-08-Results)

extraction method to the task of extracting events in the newswire domain, according to the specification of the ACE 2005 event extraction task. The original method consists of a classification pipeline that has previously been applied to extract events according to task descriptions that are similar to GENIA. In order to address the differences between this task and the ACE task, we have made a number of changes to the original method, including modifications to the classification labels assigned, the pipeline itself and the features used. We retrained the model of the adapted system on the ACE task, compared the performance, and empirically analysed the differences between the two tasks in terms of entity-related information. We demonstrate that the resulting system achieves state-of-the-art performance for tasks in both domains.

2 Related Work

In this section, we introduce the two domain specific event extraction tasks on which we will focus, i.e., the ACE 2005 event extraction task, which concerns events in the newswire domain, and the GENIA event task from the BioNLP ST 2013, which deals with biomedical event extraction. We also examine state-of-the-art systems that have been developed to address each task.

2.1 Newswire Event Extraction

The extraction of events from news-related texts has been widely researched, largely due to motivation from the various MUC and ACE shared tasks. Whilst MUC focussed on filling a single event template on a single topic by gathering information from different parts of a document, ACE defined a more comprehensive task, involving the recognition of multiple fine-grained and diverse types of entities and associated intra-sentential events within each document.

A common approach to tackling the MUC template filling task has involved the employment of pattern-based methods, e.g., Riloff (1996). In contrast, supervised learning approaches have constituted a more popular means of approaching the ACE tasks[2]. In this paper, we choose to focus on adapting our biomedical-focussed event extraction method to the ACE 2005 task. Our choice is based on the task definition for ACE 2005 having more in common with the BioNLP 2013 GENIA ST definition than the MUC event template task definition.

In terms of the characteristics of state-of-the-art event extraction systems designed according to the ACE 2005 model, pipeline-based approaches have been popular (Grishman et al., 2005; Ahn, 2006). Grishman et al. (2005) proposed a method that sequentially identifies textual spans of arguments, role types, and event triggers. This pipeline approach has been further extended in several subsequent studies. For example, Liao et al. (2010) investigated document-level cross-event consistency using co-occurrence of events and event arguments, while Hong et al. (2011) exploited information gathered from the web to ensure cross-entity consistency.

[2]Note that there are also approaches using few or no training data (e.g., (Ji and Grishman, 2008; Lu and Roth, 2012)) for the ACE 2005 task, but they are not so many and we will focus on the supervised learning approaches in this paper.

Li et al. (2013) recently proposed a joint detection method to detect both triggers and arguments (together with their role types) using a structured perceptron model. The system outperformed the best results reported for the ACE 2005 task in the literature, without the use of any external resources.

2.2 Biomedical Event Extraction

The task of event extraction has received a large amount of attention from BioNLP researchers in recent years. Interest in this task was largely initiated by the BioNLP 2009 ST, and has been sustained through the organisation of further STs in 2011 and 2013. The STs consist of a number of different sub-tasks, the majority of which concern the extraction of events from biomedical papers from the PubMed database. Events generally concern interactions between biomedical entities, such as proteins, cells and chemicals.

Similarly to newswire event extraction systems, pipeline-based methods have constituted a popular approach to extracting events in the biomedical domain (Björne and Salakoski, 2013; Miwa et al., 2012). The pipeline developed by Miwa et al. (2012) consists of a number of modules, which sequentially detect event triggers, event arguments, event structures and hedges (i.e., speculations and negations). The system has been applied to several event extraction tasks, and has achieved the best performance on most of these, in comparison to other systems. It should be noted that the ordering of the components in biomedical event extraction pipelines often differs from pipelines designed for news event extraction, e.g., Grishman et al. (2005), which was described above.

As in newswire event detection, some joint (non pipeline-based) approaches have also been proposed for biomedical event extraction. For example, McClosky et al. (2012) used a stacking model to combine the results of applying two different methods to event extraction. The first method is a joint method, similar to Li et al. (2013), that detects triggers, arguments and their roles. However, in contrast to the structured perceptron employed in Li et al. (2013), McClosky et al. (2012) use a dual-decomposition approach for the detection. The second method is based on dependency parsing and treats event structures as dependency trees.

3 Adaptation of Biomedical Event Extraction to Newswire Event Extraction

In this section, we firstly analyse the differences between the domain-specific ACE 2005 and GENIA event extraction tasks. Based on our findings, we propose an approach to adapting an existing event extraction method, originally developed for biomedical event extraction, to the ACE 2005 task, by resolving the observed differences between the two task definitions.

3.1 Differences in event extraction tasks

Both the ACE 2005 and GENIA tasks concern the task of event extraction, i.e., the identification of relationships between entities. For both tasks, the requirement is to extract events from text that conform to the general event description introduced earlier, i.e., a trigger and its arguments, each of which is assigned a semantic role. Despite this high-level similarity between the tasks, their finer-grained details diverge in a number of ways. Apart from the different textual domain, the tasks adopt varying annotation schemes. The exact kinds of annotations provided at training time are also different, as are the evaluation settings.

Several variants of the official task setting for the ACE 2005 corpus have been defined. This is partly due to the demanding nature of the official task definition, which requires the detection of events from scratch, including the recognition of named entities participating in events, together with the resolution of coreferences. Alternative task settings (such as Ji and Grishman (2008); Liao and Grishman (2010))) generally simplify the official task definition, e.g., by omitting the requirement to perform coreference resolution. A further issue is that the test data sets for the official task setting have not been made publicly available. As a result of the multiple existing variations of the ACE 2005 task definition that have been employed by different research efforts, direct comparison of our results with those obtained by other state-of-the art systems is problematic. The solution we have chosen is to adopt the same ACE 2005 event extraction task specification that has been adopted in recent research, by Hong et al. (2011) and Li et al. (2013). For GENIA, we follow the specification of the original GENIA event extraction task.

	ACE 2005	GENIA
# of entity types	13 (type) / 53 (subtype)	2
Argument	Entity/Nominal/Value/Time	Entity
# of event types	8 (type) / 33 (subtype)	13
# of argument role types	35	7
Max # of arguments for an event	11	4
Nested events	None	Possible
Overlaps of events	None	Possible
Correspondences of arguments	None	Possible
Entity	Available (Given)	Available (Partially given)
Entity attributes	Available (Given)	Not available
Event attributes	Available (Not given)	Available (Not given)
Entity coreference	Available (Given)	Available (Not given)
Event coreference	Available (Not given)	Not available
Evaluation	Trigger/Role	Event

Table 1: Comparison of event definitions and event extraction tasks. *"Available annotations"* are annotations available in the corresponding corpus, while *"Given annotations"* are annotations provided during (training and) prediction. *"Given annotations"* do not need to be predicted during event extraction.

Event annotation examples for ACE 2005 and GENIA are shown in Figures 1 and 2, respectively. Table 1 summarises the following comparison between the two event extraction tasks.

Semantic types There are more event, role and entity types and a greater potential number of arguments in ACE 2005 events than in GENIA events. There is also a hierarchy of event types and entity types in ACE 2005. For example, the *Life* event type has *Be-Born*, *Marry*, *Divorce*, *Injure*, *Die* event subtypes. Some GENIA event types can also be arranged to have a hierarchy but they are limited. Events in ACE 2005 can take non-entity arguments, e.g., *Time*.

Nested events/Overlapping events Event structures are flat in ACE 2005, but they can be nested in GENIA, i.e., an event can take other events as its arguments. Events in GENIA can also be overlapping, in the sense that a particular word or phrase can be a trigger for multiple events. Figure 2 illustrates both nesting and overlapping in GENIA events. These properties of GENIA events are not addressed by methods developed for event extraction according to the ACE 2005 specification, making direct application of these methods to the GENIA task impossible.

Links amongst arguments A specific feature of the GENIA event extraction task, which is completely absent from the ACE 2005 task, is that links amongst arguments sometimes have to be identified. For example, the *Binding* event type in the GENIA task can take the following argument role types: *Theme*, *Theme2*, *Site* and *Site2*. The number *2* is attached to differentiate specific linkages between arguments: *Site* is the location of *Theme*, while *Site2* is the location of *Theme2*.

Entities, events and their attributes Entities in ACE 2005 have rich attributes associated with them. For example, the *Time* entity type has an attribute to store a normalised temporal format (e.g., *2003-03-04* for entities "20030304", "March 4" and "Tuesday") while the *GPE (Geo-Political Entity)* type has attributes such as subtypes (e.g., *Nation*), mention type (proper name, common noun or pronoun), roles (location of a group or person) and style (*literal* or *metonymic*). In contrast, GENIA entities have no attributes[3]. In ACE 2005, all entities are provided (gold) in the training and test data and they do not need to be predicted. In GENIA, some named entities (i.e., *Protein*s) are also provided, but other types of named or non-named entities that can constitute event arguments, such as locations and sites of proteins, are not provided in the test data and thus need to be predicted as part of the extraction process. Events in both corpora also have associated attributes: modality,

[3]Types are not counted as attributes in this paper.

polarity, genericity and tense in ACE 2005 and negation and speculation in GENIA. The GENIA task definition requires event attributes to be predicted, but the ACE 2005 task definition does not.

Coreference Both entity and event coreference are annotated in ACE 2005, but only entity coreference is annotated in GENIA. Events in ACE 2005 can take non-entity mentions, such as pronouns, as their arguments. However, events in GENIA can take only entity mentions as arguments. Thus, instead of non-entity mentions, coreferent entity mentions that are the closest to triggers are annotated as arguments in GENIA. For example, in Figure 2, "*p300*" and "*Foxp3*" are annotated as *Theme*s of *Gene_expression* events instead of "*both proteins*".

Evaluation In ACE 2005, the accuracy of extracted events is evaluated at the level of individual arguments and their roles. Completeness of events is not taken into consideration (Li et al., 2013), presumably because each event can take many arguments. Evaluation is performed by taking into account the 33 event subtypes, rather than the 8 coarser-grained event types. In contrast, evaluation of events according to the GENIA specification considers only the correctness of *complete* events, after nested events have been broken down.

In summary, the ACE 2005 task is in some respects more complex than the GENIA task, because it concerns a greater number event types, whose arguments may constitute a greater range of entity types, and whose semantic roles are drawn from a larger set, some of which are specific to particular event types and entities. In other respects, the task is more straightforward than the GENIA task, because of the simpler nature of the event structures in ACE 2005, i.e., there are no nested or overlapping event structures.

3.2 Adaptation of event extraction method

Since event structures are simpler in ACE 2005 than GENIA, we choose to adapt a biomedical event extraction method to the ACE 2005 task rather than the other way around. The inverse adaptation, starting from a newswire event extraction method, is considered more complex, since we would need to extend the method to capture the more complex event structures required in the GENIA task. It would additionally be inappropriate to employ domain adaptation methods (Daumé III and Marcu, 2006; Pan and Yang, 2010) to allow GENIA-trained models to be applied to the ACE 2005 tasks. This is because such methods require that there is at least a certain degree of overlap between the target information types, which is not the case in this scenario.

We employ the biomedical event extraction pipeline method described in Miwa et al. (2012) as our starting point. Our motivation is that, due to their modular nature, pipeline approaches are often easier to adapt to other task settings than joint approaches, e.g., (McClosky et al., 2012; Li et al., 2013). In addition, the method has previously been shown to achieve state-of-the-art performance in several biomedical event extraction tasks (Miwa et al., 2012).

The pipeline consists of four detectors, i.e., trigger/entity, event role, event structure, and hedge detectors. The trigger/entity detector finds triggers and entities in text. The event role detector determines which triggers/entities constitute arguments of events, links them to the appropriate event trigger and assigns semantic roles to the arguments. The event structure detector merges trigger-argument pairs into all possible complete event structures, and determines which of these structures constitute actual events. The same detector determines links between arguments, such as *Theme2* and *Site2*. The hedge detector finds negation and speculation information associated with events. Each detector solves multi-label multi-class classification problems using lexical and syntactic features obtained from multiple parsers. These features include character n-grams, word n-grams, and shortest paths between triggers and participants within parse structures. More detailed information can be found in Miwa et al. (2012).

We have updated the original method by simplifying the format of the classification labels used by both the event role detector and event structure detector modules. We refer to this method as *BioEE*, which we have applied to the GENIA task. We use only the role types (e.g., *Theme*) as classification labels for instances in the event role detector, instead of the more complex labels used in the original version of the module, which combined event types, roles and semantic entity types of arguments (e.g.,

Binding:Theme-Protein). Similarly, in the event structure detector, we use only two labels ("EVENT" or "NOT-EVENT"), instead of the previously used composite labels, which consisted of the event type, together with the roles and semantic entity types of all arguments of the event (e.g., *Regulation:Cause-Protein:Theme-Protein*.) We employed the simplified labels, since they increase the number of training instances for each label. The use of such labels, compared to the more complex ones, could reduce the potential of carrying out detailed modelling of specific aspects of the task. However, this was found not to be an issue, since the use of the simplified labels improved the performance of the pipeline in detecting events within the GENIA development data set (about 1% improvement in F-score). The simplification of the set of classification labels was also vital to ensure the tractability of the classification problems within the context of the ACE 2005 task. For example, using the same conventions to formulate classification labels as in the original system would result in 345 possible labels (compared to 91 in GENIA) to be predicted by the event role detector (and an even greater number of labels for the event structure detector), based on event-role-semantic type combinations found in the ACE training/development sets.

In order to adapt the system to extract events according to the ACE 2005 specification, we modified BioEE in several ways, making changes to both the pipeline itself and the features employed by the different modules. We refer to this method as *Adapted BioEE*, and we applied this method to the ACE 2005 task. These changes were made in an attempt to address the two major differences between the GENIA and ACE 2005 tasks, i.e., the simpler event structures and the availability of entity attribute and coreference information in ACE.

The pipeline-based modifications consisted of removing certain modules from the original pipeline, such that only two modules remained, i.e., the trigger/entity and event role detectors. The other two modules of the original pipeline, i.e., the event structure and hedge detectors, were designed to deal with problems that do not exist in the ACE 2005 extraction task, and thus their usage would be redundant. Instead of using the event structure detector to piece the different elements of an event, we simply aggregate all the arguments of the same trigger into a single event structure, after the event role detector has been applied.

As mentioned above, the ACE 2005 task definition includes rich information about entities, including attributes and coreference information. Existing systems developed to address this task have exploited this information to generate rich feature sets for classification (Liao and Grishman, 2010; Li et al., 2013). Based on the demonstrated utility of this information within the context of event extraction, we also choose to use it, by adding binary feature that indicate the presence of base forms, entity subtypes, and attributes of the entities and their coreferent entities to features in both detectors above. We choose to use base forms, since surface forms of entities are not used by most biomedical event extraction systems, including BioEE. We also add the features for Brown clusters (Brown et al., 1992) following Li et al. (2013). Further details can be found in Li et al. (2013).

4 Evaluation

4.1 Evaluation settings

To assess the performance of Adapted BioEE on the ACE 2005 task, we followed the evaluation process and settings used in previously reported studies (Hong et al., 2011; Li et al., 2013). ACE 2005 consists of 599 documents. In order to facilitate direct comparison with other systems trained on the same data, we conducted a blind test on the same 40 newswire documents that were used for evaluation in (Ji and Grishman, 2008; Li et al., 2013), and used the remaining documents as training/development sets. We use precision (P), recall (R) and F-score (F) to report the performance of the adapted system in classifying triggers and argument roles. We use the latter F-score as our primary metric for comparing our system with other systems, since this score better reflects the performance of the extraction of event structures.

GENIA consists of 34 full paper articles (Kim et al., 2013). To evaluate the performance of BioEE on the GENIA task, we followed the task setting in BioNLP ST 2013 and used the official evaluation systems provided by the organisers. We also used the same partitioning of data that was employed in the official BioNLP ST 2013 evaluation, with 20 articles being used as the training/development set, and the remaining 14 articles being held back as the test set. For brevity, we show the only the primary P,

	Arg. Role Decomposition			Event Detection		
	P	R	F	P	R	F (%)
BioEE	71.76	47.44	57.12	64.36	44.62	52.71
BioEE (+Entity)	69.47	46.94	56.02	61.81	44.11	51.48

Table 3: Overall performance of Adapted BioEE on the ACE 2005 data set

R and F scores in the shared task, i.e., the EVENT TOTAL results obtained using the approximate span & recursive evaluation method, as recommended by the organisers. The method individually evaluates each complete *core* event, i.e., event triggers with their *Theme* and/or *Cause* role arguments, with relaxed span matching, after nested events have been broken down as explained in Section 3.1. Note that the scores do not count the non-named entities, hedges, and links between arguments, since only core events are considered in the official evaluation.

We applied both a deep parser, Enju (Miyao and Tsujii, 2008) and a dependency parser, ksdep (Sagae and Tsujii, 2007) to generate features for the ACE 2005 task, and their bio-adapted versions for the GENIA task. We also employed the GENIA sentence splitter (Sætre et al., 2007) for sentence splitting, and the snowball (Porter2) stemmer[4] for stemming. We did not make use of any other external resources, such as dictionaries, since this would hinder direct comparison of the two versions of the system.

4.2 Evaluation on GENIA

The "Event Detection" column in Table 2 shows evaluation results of BioEE on GENIA. The effects on performance by including entity-related features, i.e., entity base forms and Brown clustering, as introduced in Section 3.2, are shown as "BioEE (+Entity)". The inclusion of these features slightly degrades the performance.

For completeness, we also show in Table 2 the best and second best performing systems that took part in the official BioNLP 2013 ST evaluation: EVEX (Hakala et al., 2013) and TEES-2.1 (Björne and Salakoski, 2013). TEES-2.1 consists of a modular pipeline similar to BioEE, but it uses a different set of features. EVEX enhances the output of TEES-2.1, by using information obtained from the results of large-scale event extraction. The comparison shows that BioEE achieves state-of-the-art event extraction performance on the GENIA task.

4.3 Evaluation on ACE 2005

The "Trigger Classification" and "Arg. Role Classification" columns of Table 3 summarise the evaluation results of the Adapted BioEE system (as described in Section 3.2) on the ACE 2005 task.

We analysed the effects of incorporating features based on entity-related information into the extraction process, by repeating the experiments with such features omitted (-Entity). As can be observed in Table 3, the removal of entity-related features led to 3% performance decrease in F-score.

For completeness, Table 3 also illustrates the results of state-of-the-art systems that were specifically developed for ACE 2005: the system based on a joint approach (Li et al., 2013) and the pipeline-based system enhanced with web-gathered information (Hong et al., 2011). The difference between the

[4] snowball.tartarus.org

Adapted BioEE and the best system is small and insignificant and the Adapted BioEE achieved performance that is comparable to or better than these other systems, in terms of the F-scores in argument role classification.

5 Discussion

To further investigate the differences in performance of the BioEE and Adapted BioEE systems on the two tasks, we evaluate the scores achieved for each task using the evaluation criteria originally designed for the other task. Specifically, we apply the ACE 2005 argument role classification criteria to the output of GENIA task, and we apply the complete event-based evaluation, originally used to evaluate the GENIA task, to the events extracted for the ACE 2005 task. The "Arg. Role Decomposition" column of Table 2 depicts the former evaluation, while the "Event Detection" column of Table 3 shows the latter.

Table 2 also shows the performance of the other biomedical event extraction systems introduced above in carrying out argument role classification, since such information was provided as "Decomposition" within the results of the original task evaluation[5]. Although the results shown for "Arg. Role Decomposition" in Table 2 are not directly comparable to those shown for "Arg. Role Classification" in Table 3 (given the different characteristics of GENIA and ACE 2005 tasks), the scores are broadly comparable. This demonstrates that the task of argument role classifications is equally challenging for both tasks.

The "Event Detection" column of Table 3 illustrates event-based evaluation scores on ACE 2005. The event structure detector was added to the pipeline to facilitate comparison of the results of the two different tasks in a similar setting, and performance was evaluated according to the GENIA evaluation criteria. Evaluation scores on ACE 2005 are unexpectedly low compared to those in Table 2. Considering that the performance of argument role classification is similar in both tasks, this low performance is likely to be due to the large number of potential event arguments in ACE 2005. This means that, in comparison to GENIA events, which have a small number of possible argument types, there is a greater chance that some arguments of more complex ACE 2005 events will fail to be detected. According to the GENIA evaluation criteria, even if the majority of arguments has been correctly identified, the complete event structure will still be evaluated as incorrect. This helps to explain why such evaluation criteria may have been deemed inappropriate in the original ACE 2005 evaluations.

Subsequently, we analysed the effects of utilising entity-related features. We show the results obtained by adding entity information (+Entity) in Table 2 and the results obtained by removing entity information (-Entity) in Table 3. The positive or negative effect on performance of adding or removing these features is consistent across all subtask evaluations shown in the two tables, although the exact level of performance improvement or degradation depends on the subtask under evaluation. Overall, the inclusion of the features degraded the performance of BioEE on the GENIA task, but improved the performance of Adapted BioEE on the ACE 2005 task. These differences may be due to the increased richness of entity information in the ACE 2005 corpus, suggesting that enriching entities in the GENIA corpus with attribute information could be a possible way to further improve the performance of the system on this task.

6 Conclusions and Future Work

In this paper, we have described our adaptation of a biomedical event extraction method to the newswire domain. We firstly evaluated the method on a biomedical event extraction task (GENIA), and showed that its performance was superior to other state-of-the-art systems designed for the task. We then adapted the method to a newswire event extraction task (ACE 2005), by addressing the major differences between the tasks. With only a small number of adaptations, the resulting system was also able to achieve state-of-the-art performance on the newswire extraction task. These results show that there is no need to develop separate systems for event extraction tasks in different domains, as long as the types of tasks being addressed exhibit domain-independent features. However, further discussion and evaluation is needed to better understand how different potential methods for adapting such tools from one domain to another can be used and/or combined effectively.

[5] bionlp-st.dbcls.jp/GE/2013/results

As future work, we intend to further investigate the adaptation of alternative methods proposed for use in one domain to another domain. Several interesting approaches have been described, such as the utilisation of contextual information beyond the boundaries of individual sentences in the newswire domain (Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011) and joint approaches in the biomedical domain (McClosky et al., 2012), but their adaptability to other domains has not yet been investigated. We also intend to investigate the possibility of discovering and utilising shared information between the two domains (Goldwasser and Roth, 2013). Encouraging greater levels of communication between researchers working on NLP tasks in different domains will help to stimulate such new directions of research, both for event extraction and for other related information extraction tasks, such as relation extraction and coreference resolution.

Abstract

Entity Set Expansion (ESE) aims at automatically acquiring instances of a specific target category. Unfortunately, traditional ESE methods usually have the expansion boundary problem and the semantic drift problem. To resolve the above two problems, this paper proposes a probabilistic Co-Bootstrapping method, which can accurately determine the expansion boundary using both the positive and the discriminant negative instances, and resolve the semantic drift problem by effectively maintaining and refining the expansion boundary during bootstrapping iterations. Experimental results show that our method can achieve a competitive performance.

1 Introduction

Entity Set Expansion (ESE) aims at automatically acquiring instances of a specific target category from text corpus or Web. For example, given the capital seeds {*Rome*, *Beijing*, *Paris*}, an ESE system should extract all other capitals from Web, such as *Ottawa*, *Moscow* and *London*. ESE system has been used in many applications, e.g., dictionary construction (Cohen and Sarawagi, 2004), word sense disambiguation (Pantel and Lin, 2002), query refinement (Hu et al., 2009), and query suggestion (Cao et al., 2008).

Due to the limited supervision provided by ESE (in most cases only 3-5 seeds are given), traditional ESE systems usually employ bootstrapping methods (Cucchiarelli and Velardi, 2001; Etzioni et al., 2005; Pasca, 2007; Riloff and Jones, 1999; Wang and Cohen, 2008). That is, the entity set is iteratively expanded through a pattern generation step and an instance extraction step. Figure 1(a) demonstrates a simple bootstrapping process.

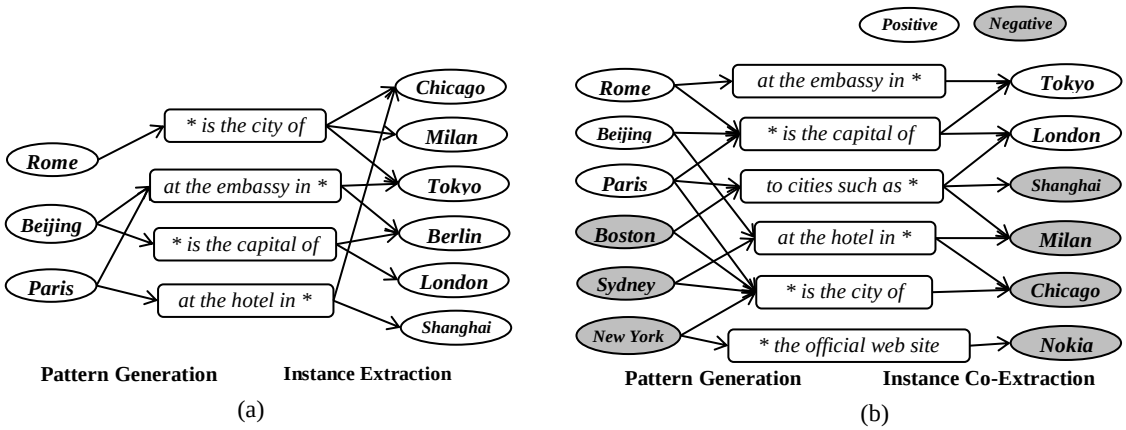

Figure 1: A demo of Bootstrapping (a) and Co-Bootstrapping (b)

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2280–2290, Dublin, Ireland, August 23-29 2014.

However, the traditional bootstrapping methods have two main drawbacks:

1) **The expansion boundary problem**. That is, using only positive seeds (i.e., some example entities from the category we want to expand), it is difficult to represent which entities we want to expand and which we don't want. For example, starting from positive seeds {*Rome, Beijing, Paris*}, we can expand entities at many different levels, e.g., all capitals, all cities, or even all locations. And all these explanations are reasonable.

2) **The semantic drift problem**. That is, the expansion category may change gradually when noisy instances/patterns are introduced during the bootstrapping iterations. For example, in Figure 1 (a), the instance *Rome* will introduce a pattern "* *is the city of*", which will introduce many noisy city instances such as *Milan* and *Chicago* for the expansion of *Capital*. And these noisy cities in turn will introduce more city patterns and instances, and finally will lead to a semantic drift from *Capital* to *City*.

In recent years, some methods (Curran et al, 2007; Pennacchiotti and Pantel, 2011) have exploited mutual exclusion constraint to resolve the semantic drift problem. These methods expand multiple categories simultaneously, and will determine the expansion boundary based on the mutually exclusive property of the pre-given categories. For instance, the exclusive categories *Fruit* and *Company* will be jointly expanded and the expansion boundary of {*Apple, Banana, Cherry*} will be limited by the expansion boundary of {*Google, Microsoft, Apple Inc.*}. These methods, however, still have the following two drawbacks:

1) These methods require that the expanded categories should be mutually exclusive. However, in many cases the mutually exclusive assumption does not hold. For example, many categories hold a hyponymy relation (e.g., the categories *City* and *Capital*, because the patterns for *Capital* are also the patterns for *City*) or a high semantic overlap (e.g., the categories *Movies* and *Novels*, because some movies are directly based on the novels of the same title.).

2) These methods require the manually determination of the mutually exclusive categories. Unfortunately, it is often very hard for even the experts to determine the categories which can define the expansion boundaries for each other. For example, in order to expand the category *Chemical Element*, it is difficult to predict its semantic drift towards *Color* caused by the ambiguous instances {*Silver, Gold*}.

In this paper, to resolve the above problems, we propose a probabilistic Co-Bootstrapping method. The first advantage of our method is that we propose a method to better define the expansion boundary using both the positive and the discriminant negative seeds, which can both be automatically populated during the bootstrapping process. For instance, in Figure 1(b), in order to expand *Capital*, the Co-Bootstrapping algorithm will populate both positive instances from the positive seeds {*Rome, Beijing, Paris*}, and negative instances from the negative seeds {*Boston, Sydney, New York*}. In this way the expansion boundary of *Capital* can be accurately determined.

The second advantage of our method is that we can maintain and refine the expansion boundary during bootstrapping iterations, so that the semantic drift problem can be effectively resolved. Specifically, we propose an effective scoring algorithm to estimate the probability that an extracted instance belongs to the target category. Based on this scoring algorithm, this paper can effectively select positive instances and discriminant negative instances. Therefore the expansion boundary can be maintained and refined through the above jointly expansion process.

We have evaluated our method on the expansion of thirteen categories of entities. The experimental results show that our method can achieve 6%~15% P@200 performance improvement over the baseline methods.

This paper is organized as follows. Section 2 briefly reviews related work. Section 3 defines the problem and proposes a probabilistic Co-Bootstrapping approach. Experiments are presented in Section 4. Finally, we conclude this paper and discuss some future work in Section 5.

2 Related Work

In recent years, ESE has received considerable attentions from both research (An et al., 2003; Cafarella et al., 2005; Pantel and Ravichandran, 2004; Pantel et al., 2009; Pasca, 2007; Wang and Cohen, 2008) and industry communities (e.g., *Google Sets*). Till now, most ESE systems employ bootstrapping methods, such as *DIPRE* (Brin, 1998), *Snowball* (Agichtein and Gravano, 2000), etc.

The main drawbacks of the traditional bootstrapping methods are the expansion boundary problem and the semantic drift problem. Currently, two strategies have been exploited to resolve the semantic drift problem. The first is the ranking based approaches (Pantel and Pennacchiotti, 2006; Talukdar et al., 2008), which select highly confident patterns and instances through a ranking algorithm, with the assumption that high-ranked instances will be more likely to be the instances of the target category. The second is the mutual exclusion constraint based methods (Curran et al., 2007; McIntosh and Curran, 2008; Pennacchiotti and Pantel, 2011; Thelen and Riloff, 2002; Yangarber et al., 2002), which expand multiple categories simultaneously and determine the expansion boundary based on the mutually exclusive property of the pre-given categories.

3 The Co-Bootstrapping Method

3.1 The Framework of Probabilistic Co-Bootstrapping

Given the initial positive seeds and negative seeds, the goal of our method is to extract instances of a specific target semantic category. For demonstration, we will describe our method through the running example shown in Figure 1(b).

Specifically, Figure 2 shows the framework of our method. The central tasks of our Co-Bootstrapping method are as follows:

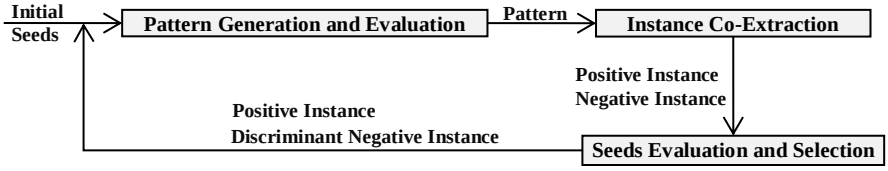

Figure 2: The framework of probabilistic Co-Bootstrapping

1)**Pattern Generation and Evaluation.** This step generates and evaluates patterns using the statistics of the positive and the negative instances. Specifically, we propose three measures of pattern quality: the Generality (*GE*), the Precision of Extracted Instances (*PE*) and the Precision of Not Extracted Instances (*PNE*).

2)**Instance Co-Extraction.** This step co-extracts the positive and the negative instances using highly confident patterns. Specifically, we propose an effective scoring algorithm to estimate the probability that an extracted instance belongs to the target category based on the statistics and the quality of the patterns which extract it.

3)**Seed Selection.** This step selects the high ranked positive instances and discriminant negative instances to refine the expansion boundary by measuring how well a new instance can be used to define the expansion boundary.

The above three steps will iterate until the number of extracted entities reaches a predefined threshold. We describe these steps as follows.

3.2 Pattern Generation and Evaluation

In this section, we describe the pattern generation and evaluation step. In this paper, each pattern is a 4-grams lexical context of an entity. We use the Google Web 1T corpus's (Brants and Franz, 2006) 5-grams for both the pattern generation and the instance co-extraction in ESE. Our method generates patterns through two steps: 1) Generate candidate patterns by matching seeds with the 5-grams. 2) Evaluate the quality of the patterns.

For the first step, we simply match each seed instance with all 5-grams, then we replace the matching instance with wildcard "*" to generate the pattern.

Count	**Positive**	**Negative**
Extracted	Extracted Positive (***ep***)	Extracted Negative (***en***)
Not Extracted	Not Extracted and Positive (***nep***)	Not Extracted and Negative (***nen***)

(a)

Extracted Positive (***ep***)	*London*
Extracted Negative (***en***)	*Shanghai, Milan*
Not Extracted Positive (***nep***)	*Tokyo*
Not Extracted Negative (***nen***)	*Chicago, Nokia*

(b)

Table 1: (a) shows the four classes of instances according to polarity and extraction. (b) shows the four classes of the instances given *"to cities such as *"*

For the second step, we propose three measures to evaluate the quality of a pattern, correspondingly the *Generality (GE)*, the *Precision of Extracted Instances (PE)*, and the *Precision of Not Extracted Instances (PNE)*. Specifically, given a pattern, we observed that all instances can be categorized into four classes, according to whether they belong to the target category and whether they can be extracted by the pattern (shown in Table 1(a)). For example, given the pattern *"to cities such as *"* in Figure 1(b), the instances under its four classes are shown in Table 1 (b).

The proposed three measures of the quality of a pattern can be computed as follows (In most cases, we cannot get the accurate number of *ep*, *en*, *nep* and *nen*. So this paper uses the corresponding known instances in the previous iteration to approximately compute *ep*, *en*, *nep* and *nen*):

1)**Generality** (*GE*). The Generality of a pattern measures how many entities can be extracted by it. A more general pattern will cover more entities than a more specific pattern. Specifically, the *GE* of a pattern is computed as:

$$GE = \frac{ep + en}{ep + en + nep + nen}$$

That is, the proportion of the instances which can be extracted by the pattern in the previous iteration.

2)**Precision of Extracted Instances** (*PE*). The *PE* measures how likely an instance extracted by a pattern will be positive. That is, a pattern with higher *PE* will be more likely to extract positive instances than a lower *PE* pattern. The *PE* is computed as:

$$PE = \frac{ep}{ep + en}$$

That is, the proportion of positive instances within all instances which can be extracted by the pattern in the previous iteration.

3)**Precision of Not Extracted Instances** (*PNE*). The *PNE* measures how likely a not extracted instance is positive. Instances not extracted by a high *PNE* pattern will be more likely to be positive. *PNE* is computed as:

$$PNE = \frac{nep/(ep + nep)}{nep/(ep + nep) + nen/(en + nen)}$$

Because the number of negative instances is usually much larger than the number of positive instances, we normalize the number of positive and negative instances in the formula.

Table 2 shows these measures of some selected patterns evaluated using the Google Web 1T corpus. We can see that the above measures can effectively evaluate the quality of patterns. For instance, *GE("* is the city of")=0.566* is larger than *GE*("at the embassy in **")=0.340*, which is consistent with our intuition that the pattern *"* is the city of"* is more general than *"at the embassy in *"*. *PE*(*"* is the capital of"*)*=0.928* is larger than *PE*(*"* is the city of"*)*=0.269*, which is consistent with our intuition that the instances extracted by *"* is the capital of"* are more likely *Capital* than by*"* is the city of"*.

	GE	***PE***	***PNE***
*at the embassy in **	*0.340*	*0.833*	*0.312*
** is the capital of*	*0.321*	*0.928*	*0.224*
*to cities such as **	*0.426*	*0.875*	*0.566*
*at the hotel in **	*0.333*	*0.192*	*0.571*
** is the city of*	*0.566*	*0.269*	*0.592*
** the official web site*	*0.218*	*0.230*	*0.607*

Table 2: The *GE*, *PE* and *PNE* of some selected patterns

3.3 Instance Co-Extraction

In this section, we describe how to co-extract positive instances and discriminant negative instances. Given the generated patterns, the central task of this step is to measure the likelihood of an instance to be positive. The higher the likelihood, the more likely the instance belongs to the target category. To resolve the task, we propose a probabilistic method which predicts the probability of an instance to be positive, i.e., the *Instance Positive Probability* and we denote it as *P+*. Generally, the ***P+*** is determined by both the statistics and the quality of patterns. We start with the observation that:

1) If an instance is extracted by a pattern with a high *PE*, the instance will have a high ***P+***.
2) If an instance is not extracted by a high *PNE* pattern, the instance will have a high ***P+***.
3) If an instance is extracted by many patterns with high *PE* and not extracted by many patterns with high *PNE*, the instance will have a high ***P+***, and vice versa.

Based on the above observations, the computation of ***P+*** is as follows:

The Situation of One Pattern

For the situation that only one pattern exists, the ***P+*** of an instance can be simply computed as:

$$P+(e) = \begin{cases} PE(p) & \text{when } p \text{ extracts } e \\ PNE(p) & \text{otherwise} \end{cases}$$

where *e* denotes an extracted instance and *p* denotes a pattern which extracts *e*. This formula means that if the instance is extracted by a pattern, the ***P+*** is determined by the *PE* of the pattern. For example, in Figure 3 (a), the instance *Tokyo* is only extracted by the pattern *"at the embassy in *"* and the ***P+*** is determined by the *PE* of *"at the embassy in *"*, i.e., ***P+***(*Tokyo*)=*PE*(*"at the embassy in *"*).

The above formula also means when the instance cannot be extracted by the only pattern, the ***P+*** will be determined by the *PNE* of the pattern. For example, in Figure 3 (b), the instance *Tokyo* is not extracted by the only pattern *"at the hotel in *"* and the ***P+*** is only determined by the *PNE* of *"at the hotel in *"*, that is, ***P+****(Tokyo)=PNE*(*"at the hotel in *"*).

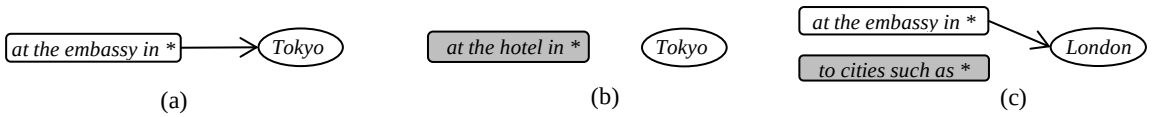

Figure 3: (a) *Tokyo* is extracted by *"at the embassy in *"*. (b) *Tokyo* is not extracted by *"at the hotel in *"*. (c) *London* is extracted by *"at the embassy in *"* and not extracted by *"to cities such as *"*.

The Situation of Multiple Patterns

In this section, we describe how to compute ***P+*** in the situation of multiple patterns. Specifically, we assume that an instance is extracted by different patterns independently. Therefore, given all the pattern-instance relations (i.e., whether a specific pattern extracts a specific instance), the likelihood for an instance *e* being positive is computed as:

$$PosLikelihood(e) \propto \prod_{p \in R^+} P(p \to e, e \in I^+) \prod_{p \in R^-} P(p \nrightarrow e, e \in I^+)$$

where R^+ is all the patterns which extract *e*, and R^- is all the patterns which do not extract *e*. I^+ is the set of all positive instances. $P(p \to e, e \in I^+)$ is the probability of the event *"pattern p extracts instance e and e is positive"*. Using Bayes rule, this probability can be computed as:

$$P(p \to e, e \in I^+) = P(p \to e)P(e \in I^+ | p \to e)$$

where $P(p \to e)$ is the probability of the event *"p extracts an instance e"*, its value is *GE(p)*; $P(e \in I^+ | p \to e)$ is the conditional probability that *e* is positive under the condition *"p extracts e"*, and its value is *PE(p)*. Finally $P(p \to e, e \in I^+)$ is computed as:

$$P(p \to e, e \in I^+) = GE(p)PE(p)$$

$P(p \nrightarrow e, e \in I^+)$ is the probability of the event "*p does not extract e and e is positive*", which can be computed as:

$$P(p \nrightarrow e, e \in I^+) = P(p \nrightarrow e)P(e \in I^+ | p \nrightarrow e)$$

$P(p \nrightarrow e)$ is the probability of *p* not extracting an instance *e*, and its value is 1-*GE(p)*. $P(e \in I^+ | p \nrightarrow e)$ is the conditional probability that *e* is positive under the condition *"p does not extract e"*, and its value is *PNE(p)*. Then $P(p \nrightarrow e, e \in I^+)$ is finally computed as:

$$P(p \nrightarrow e, e \in I^+) = (1 - GE(p))PNE(p)$$

For example, in Figure 3 (c), the instance *London* is extracted by the pattern *"at the embassy in *"* and not extracted by the pattern *"to cities such as *"*. In this situation, *PosLikelihood*(*London*)= [*GE*(*"at the embassy in *"*) × *PE*(*"at the embassy in"*)] × [(1-*GE*(*"to cities such as *"*)) × *PNE*(*"to cities such as *"*)].

Using the same intuition and the same method, the likelihood of an instance being negative is computed as:

$$NegLikelihood(e) \propto \prod_{p \in R^+} P(p \rightarrow e, e \notin I^+) \prod_{p \in R^-} P(p \nrightarrow e, e \notin I^+)$$

where $P(p \rightarrow e, e \notin I^+)$ is the probability of the event *"p extracts e and e is negative"*, which is computed as:

$$P(p \rightarrow e, e \notin I^+) = GE(p)(1 - PE(p))$$

$P(p \nrightarrow e, e \notin I^+)$ is the probability of the event *"p does not extract e and e is negative"*, which is computed as:

$$P(p \nrightarrow e, e \notin I^+) = (1 - GE(p))(1 - PNE(p))$$

For instance, in Figure 3 (c), *NegLikelihood*(*London*) = [*GE*("*at the embassy in **") × (1-*PE*("*at the embassy in*"))] × [(1-*GE*("*to cities such as **")) × (1-*PNE*("*to cities such as **"))].

Finally, the *Instance Positive Probability*, ***P+***, is computed as:

$$P+(e) = \frac{PosLikelihood(e)}{PosLikelihood(e) + NegLikelihood(e)}$$

3.4 Seed Selection

In this section, we describe how to select positive and discriminant negative instances at each iteration.

To determine whether an instance is positive, we use a threshold of ***P+*** to determine the polarity of instances, which can be empirically estimated from data. The instances which have much higher ***P+*** than the threshold will be added to the set of positive instances. For example, *London* and *Tokyo* in Figure 1 (b) are selected as positive instances.

To select discriminant negative instances, we observed that not all negative instances are the same useful for the expansion boundary determination. Intuitively, the discriminant negative instances are those negative instances which are highly overlapped with the positive instances. For instance, due to the lower overlap between categories *Fruit* and *Capital*, *Apple* is not a discriminant negative instance since it provides little information for the expansion boundary determination. Therefore, the instances near the threshold are used as the discriminant negative instances in the next iteration. (Notice that, the computation of *GE*, *PE* and *PNE* still uses all positive and negative instances, rather than only discriminant negative instances). For example, in Figure 1(b), *Shanghai*, *Milan* and *Chicago* are selected as discriminate negative instances, and *Nokia* will be neglected. Finally the boundary between *Capital* and *City* can be determined by the positive instances and the discriminant negative instances.

4 Experiments

4.1 Experimental Settings

Category	Description	Category	Description
CAP	Place: capital name	**FAC**	Facilities: names of man-made structures
ELE	chemical element	**ORG**	Organization: e.g. companies, governmental
FEM	Person: female first name	**GPE**	Place: Geo-political entities
MALE	Person: male first name	**LOC**	Locations other than GPEs
LAST	Person: last name	**DAT**	Reference to a date or period
TTL	Honorific title	**LANG**	Any named language
NORP	Nationality, Religion, Political(adjectival)		

Table 3: Target categories

Corpus: In our experiments, we used the Google Web 1T corpus (Brants and Franz, 2006) as our expansion corpus. Specifically, we use the open source package *LIT-Indexer* (Ceylan and Mihalcea, 2011) to support efficient wildcard querying for pattern generation and instance extraction.

Target Expansion Categories: We conduct our experiments on thirteen categories, which are shown in Table 3. Eleven of them are from Curran et al. (2007). Besides the eleven categories, to evaluate how well ESE systems can resolve the semantic drift problem, we use two additional categories (*Capital* and *Chemical Element*) which are high likely to drift into other categories.

Evaluation Criteria: Following Curran et al (2007), we use *precision at top n (P@N)* as the performance metrics, i.e., the percentage of correct entities in the top n ranked entities for a given category. In our experiments, we use *P@10, P@20, P@50, P@100* and *P@200*. Since the output is a ranked list of extracted entities, we also choose the average precision (AP) as the evaluation metric. In our experiments, the correctness of all extracted entities is manually judged. In our experiments, we present results to 3 annotators, and an instance will be considered as positive if 2 annotators label it as positive. We also provide annotators some supporting resources for better evaluation, e.g., the entity list of target type collected from Wikipedia.

4.2 Experimental Results

In this section, we analyze the effect of negative instances, categories boundaries, and seed selection strategies. We compare our method with the following two baseline methods: i) ***Only_Pos (POS)***: This is an entity set expansion system which uses only positive seeds. ii) ***Mutual_Exclusion (ME)***: This is a mutual exclusion bootstrapping based ESE method, whose expansion boundary is determined by the exclusion of the categories.

We implement our method using two different settings: i) ***Hum_Co-Bootstrapping (Hum_CB)***: This is the proposed Co-Bootstrapping method in which the initial negative seeds are manually given. Specifically, we randomly select five positive seeds from the list of the category's instances while the initial negative seeds are manually provided. ii) ***Feedback_Co-Bootstrapping (FB_CB)***: This is our proposed probabilistic Co-Bootstrapping method with two steps of selecting initial negative seeds: 1) Expand the entity set using only the positive seeds for only first iteration. Return the top ten instances. 2) Select the negative instances in the top ten results of the first iteration as negative seeds.

4.2.1. Overall Performance

Several papers have shown that the experimental performance may vary with different seed choices (Kozareva and Hovy, 2010; McIntosh and Curran, 2009; Vvas et al., 2009). Therefore, we input the ESE system with five different positive seed settings for each category. Finally we average the performance on the five settings so that the impact of seed selection can be reduced.

	P@10	**P@20**	**P@50**	**P@100**	**P@200**	**MAP**
POS	0.84	0.74	0.55	0.41	0.34	0.42
ME	0.83(0.90)	0.79(0.87)	0.68(0.78)	0.58(0.67)	0.51(0.59)	-
Hum_CB	0.97	0.95	0.83	0.71	0.57	0.78
FB_CB	**0.97**	**0.96**	**0.90**	**0.79**	**0.66**	**0.85**

Table 4: The overall experimental results

Table 4 shows the overall experimental results. The results in parentheses are the known results of eleven categories (without *CAP* and *ELE*) shown in (Curran et al., 2007). MAP of ME is missed because there are no available results in (Curran et al., 2007). From Table 4, we can see that:

1) Our method can achieve a significant performance improvement: Compared with the baseline POS, our method Hum_CB and FB_CB can respectively achieve a 23% and 32% improvement on P@200; Compared with the baseline ME, our method Hum_CB and FB_CB can respectively improve P@200 by 6% and 15%.

2) By explicitly representing the expansion boundary, the expansion performance can be increased: Compared with the baseline POS, ME can achieve a 17% improvement on P@200, and our method Hum_CB can achieve a 23% improvement on P@200.

3) The negative seeds can better determine the expansion boundary than mutually exclusive categories. Compared with ME, Hum_CB and FB_CB can respectively achieve a 6% and 15% improvement on P@200. We believe this is because using negative instances is a more accurate and more robust way for defining and maintaining the expansion boundary than mutually exclusive categories.

4) The system's feedback is useful for selecting negative instances: Compared with Hum_CB, FB_CB method can significantly improve the P@200 by 9.0%. We believe this is because that the system's feedback is a good indicator of the semantic drift direction. In contrast, it is usually difficult for human to determine which directions the bootstrapping will drift towards.

4.2.2. Detailed Analysis: Expansion Boundary

In Table 5, we show the top 20 positive and negative *Capital* instances (FB_CB setting). From Table 5, we can make the following observations: 1) Our method can effectively generate negative instances. In Table 5, the negative instances contain cities, states, countries and general terms, all of which have a high semantic overlap with *Capital* category. 2) The positive instances and negative instances generated by our Co-Bootstrapping method can discriminately determine the expansion boundary. For instance, the negative instances *Kyoto* can distinguish *Capital* from *City*; *Australia* and *China* can distinguish *Capital* from *Country*;

Positive Instances		***London***, ***Paris***, ***Moscow***, ***Beijing***, ***Madrid***, ***Amsterdam***, ***Washington***, ***Tokyo***, ***Berlin***, ***Rome***, ***Vienna***, ***Baghdad***, ***Athens***, ***Bangkok***, ***Cairo***, ***Dublin***, ***Brussels***, ***Prague***, *San*, ***Budapest***
Negative Instances (with categories)	City	*Kyoto*, *Kong*, *Newcastle*, *Zurich*, *Lincoln*, *Albany*, *Lyon*, *LA*, *Shanghai*
	Country	*China*, *Australia*
	General	*downtown*, *April*
	State	*Hawaii*, *Oklahoma*, *Manhattan*
	Other	*Hollywood*, *DC*, ***Tehran***, ***Charlotte***

Table 5: Top 20 positive instances and negative instances (True positive instances are in bold)

4.2.3. Detailed Analysis: Semantic Drift Problem

POS	***Stockholm***, *Tampa*, *East*, *West*, *Springfield*, *Newport*, *Cincinnati*, ***Dublin***, *Chattanooga*, *Savannah*, *Omaha*, *Cambridge*, *Memphis*, *Providence*, ***Panama***, *Miami*, ***Cape***, *Victoria*, *Milan*, ***Berlin***
ME	***London***, ***Prague***, *Newport*, ***Cape***, ***Dublin***, *Savannah*, *Chattanooga*, ***Beijing***, *Memphis*, ***Athens***, ***Berlin***, *Miami*, ***Plymouth***, *Victoria*, *Omaha*, ***Tokyo***, *Portland*, *Troy*, *Anchorage*, ***Bangkok***
Hum_CB	***London***, ***Rome***, ***Berlin***, ***Paris***, ***Athens***, ***Moscow***, ***Tokyo***, ***Beijing***, ***Prague***, ***Madrid***, ***Vienna***, ***Dublin***, ***Budapest***, ***Amsterdam***, ***Bangkok***, ***Brussels***, *Sydney*, ***Cairo***, ***Washington***, *Barcelona*
FB_CB	***London***, ***Paris***, ***Moscow***, ***Beijing***, ***Washington***, ***Tokyo***, ***Berlin***, ***Rome***, ***Vienna***, ***Baghdad***, ***Athens***, ***Bangkok***, ***Cairo***, ***Brussels***, ***Prague***, *San*, ***Budapest***, ***Amsterdam***, ***Dublin***, ***Madrid***

Table 6: Top 20 instances of all methods (True positive instances are in bold)

To analyze how our method can resolve the semantic drift problem, Table 6 shows the top 20 positive *Capital* instances of different methods. From Table 6, we can make the following observations: i) Different methods can resolve the semantic drift problem to different extent: ME is better than POS, with 50% instances being positive, and our method is better than ME, with 95% instances being positive. ii) The Co-Bootstrapping method can effectively resolve the semantic drift problem: 25% of POS's top 20 instances and 50% of ME's top 20 instances are positive. In contrast, 90% of Hum_CB's top 20 instances and 95% of FB_CB's top 20 instances are positive respectively. It proves that Co-Bootstrapping method can better resolve the semantic drift problem than POS and ME.

4.3 Parameter Optimization

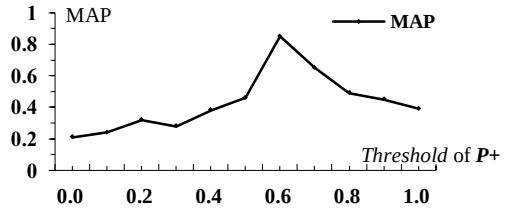

Figure 4: The MAP vs. *threshold* of ***P+***

Our method has only one parameter: *threshold* of ***P+***, which determines the instance's polarity. Intuitively, a larger *threshold* of ***P+*** will improve the precision of the positive instances but will regard some positive instances as negative instances mistakenly. As shown in Figure 4, our method can achieve the best *MAP* performance when the value of the *threshold* is 0.6.

4.4 Comparison with State-of-the-Art Systems

We also compare our method with three state-of-the-art systems: *Google Sets*[1]-- an ESE application provided by Google, *SEAL*[2] -- a state-of-the-art ESE method proposed by Wang and Cohen (2008), and *WMEB* -- a state-of-the-art mutual exclusion based system proposed in McIntosh and Curran (2008). To make a fair comparison, we directly use the results before the adjustment which miss P@10 and P@50 in their original paper (McIntosh and Curran, 2008) and compared the performance of these systems on nine categories in (McIntosh and Curran, 2008). For each system, we conduct the experiment five times to reduce the impact of seeds selection. The average P@10, P@50, P@100 and P@200 are shown in Figure 5.

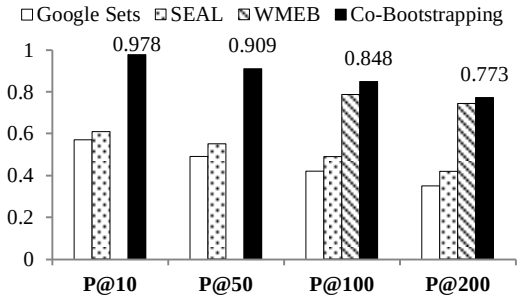

Figure 5: The results compared with three state-of-the-art systems

From the results shown in Figure 5, we can see that our probabilistic Co-Bootstrapping method can achieve state-of-the-art performance on all metrics: Compared with the well-known baseline *Google Sets*, our method can get a 42.0% improvement on P@200; Compared with the *SEAL* baseline, our method can get a 35.0% improvement on P@200; Compared with the WMEB method, our method can achieve a 6.2% improvement on P@100 and a 3.1% improvement on P@200.

5 Conclusion and Future Work

In this paper, we proposed a probabilistic Co-Bootstrapping method for entity set expansion. By introducing negative instances to define and refine the expansion boundary, our method can effectively resolve the expansion boundary problem and the semantic drift problem. Experimental results show that our method achieves significant performance improvement over the baselines, and outperforms three state-of-the-art ESE systems. Currently, our method did not take into account the long tail entity expansion, i.e., the instances which appear only a few times in the corpus, such as *Saipan, Roseau* and *Suva* for the *Capital* category. For future work, we will resolve the long tail entities in our Co-Bootstrapping method by taking the sparsity of instances/patterns into consideration.

Separating Brands from Types: an Investigation of Different Features for the Food Domain

Michael Wiegand and **Dietrich Klakow**
Spoken Language Systems
Saarland University
D-66123 Saarbrücken, Germany
{Michael.Wiegand|Dietrich.Klakow}@lsv.uni-saarland.de

Abstract

We examine the task of separating types from brands in the food domain. Framing the problem as a ranking task, we convert simple textual features extracted from a domain-specific corpus into a ranker without the need of labeled training data. Such method should rank brands (e.g. *sprite*) higher than types (*e.g. lemonade*). Apart from that, we also exploit knowledge induced by semi-supervised graph-based clustering for two different purposes. On the one hand, we produce an auxiliary categorization of food items according to the Food Guide Pyramid, and assume that a food item is a type when it belongs to a category unlikely to contain brands. On the other hand, we directly model the task of brand detection using seeds provided by the output of the textual ranking features. We also harness Wikipedia articles as an additional knowledge source.

1 Introduction

Brands play a significant role in social life. They are the subject matter of many discussions in social media. Their automatic detection for information extraction tasks is a pressing problem since, despite their unique property to refer to commercial products of specific companies, in everyday language they often occur in similar contexts as common nouns. A typical domain where such behaviour can be observed is the food domain, where **food brands** (e.g. *nutella* or *sprite*) are often used synonymously with the **food type**[1] of which the brand is a prototypical instance (e.g. *chocolate spread* or *lemonade*). Such usage is illustrated in (1) and (2).

(1) In the evening, I eat a slice of bread with either **nutella** or marmalade.

(2) I prepare my pancakes with baking soda, water and a lacing of **sprite** instead of sugar.

This particular phenomenon of metonymy (Lakoff and Johnson, 1980), commonly referred to as *generic-ized trademarks*, of course, has consequences on automatic lexicon induction methods. If one automatically extracts food types, one also obtains food brands.

In this paper, we examine features to detect brands automatically. Solving the issue with the help of a manually-compiled list of brands neglects parts of the nature of brands. Brands come and go. Some products may be discontinued after a certain amount of time (e.g. due to limited popularity) while, on the other hand, new products constantly enter the market. For instance, popular food brands, such as *sierra mist* or *kazoozles*, did not exist a decade ago. Therefore, a list of brands that is manually created today may not reflect the predominant food brands that will be available in a decade.

The features we introduce to detect brands consider both the intrinsic properties of brands and their contextual environment. Even though in many contexts, brands are used as ordinary type expressions (1), there might be specific contexts that are only observed with brands. We also consider distributional properties: brands may co-occur with other brands. Moreover, they may be biased towards certain categories, e.g. sweets, beverages etc. For the latter, we actually exploit the usage of food brands to be

[1] We define *food type* as common nouns that denote a particular type of food, e.g. *apple*, *chocolate*, *cheese* etc.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2291–2302, Dublin, Ireland, August 23-29 2014.

Method	Corpus	Corpus Type	P@10	P@100	P@500
ranking by frequency	chefkoch.de	domain specific	0.00	22.00	25.60
induction based on coordination	Wikipedia	open domain	90.00	60.00	47.80
induction based on coordination	chefkoch.de	domain specific	100.00	98.00	92.00

Table 1: Precision at rank n (P@n) of different food induction methods.

Label	Items	Examples
Food Types	1745	apple, baguette, beer, corn flakes, crisps, basmati rice, broccoli, chocolate spread, gouda, orange juice, pork, potato, steak, sugar
Food Brands	221	activia, babybel, becel, butterfinger, kit kat, nutella, pepsi, philadelphia, smacks, smarties, sprite, ramazzotti, tuborg, volvic

Table 2: Gold standard of the food vocabulary.

used as genericized trademarks, allowing food categorization methods for types to be easily extended to brands. Moreover, we examine how external knowledge resources, such as Wikipedia, can be harnessed as a means to separate brands from types. Our task is lexicon construction rather than contextual entity classification, that is, we are interested in what a food item generally conveys and not what it conveys in a specific context.

We consider the food domain as a target domain since there are large, unlabeled domain-specific corpora available gathered from social media which are vital for the methods we explore. It is also a domain for which there has already been done research in the area of natural language processing (NLP), and there are common applications, such as virtual customer advice or product recommendation, that may exploit such NLP technology.

The methods we consider require no, or hardly any human supervision. Thus, we imagine that they can also be applied to other domains at a low cost. In particular, other life-style domains, such as fashion, cosmetics or electronics show parallels, since comparable textual web data from which to extract domain-specific knowledge are available.

Our experiments are carried out on German data, but our findings should carry over to other languages since the issues we address are (mostly) language universal. All examples are given as English translations. We use the term **food item** to refer to the union of food brands and food types. All food items will be written in lowercase reflecting the identical case spelling in German, i.e. types and brands are *both* written uppercase. In English, both types and brands can be written uppercase or lowercase[2], however, there is a tendency in user-generated content/social media to write mostly lowercase.

2 Motivation & Data

Previous research on lexicon induction proposed a widely applicable method based on *coordination* (Hatzivassiloglou and McKeown, 1997; Riloff and Shepherd, 1997; Roark and Charniak, 1998): First, a set of seed expressions that are typical of the categories one wants to induce are defined. Then, additional instances of those categories are obtained by extracting *conjuncts* of the seed expressions (i.e. all expressions that match *<seed> and/or <expression>* are extracted as new instances). A detailed study of such lexicon induction has recently been published by Ziering et al. (2013), who also point out the great semantic coherence of conjuncts.

This method can also be applied to the food domain. As a domain-specific dataset for all our experiments, we use a crawl of *chefkoch.de*[3] (Wiegand et al., 2012) consisting of $418,558$ webpages of forum entries. *chefkoch.de* is the largest German web portal for food-related issues. Table 1 shows the effectiveness of coordination as a means of extracting food items from our domain-specific corpus. Given a seed set of 10 frequent food items (we use: *water*, *salt*, *sugar*, *salad*, *bread*, *meat*, *cake*, *flour*, *butter* and

[2]There are plenty of food types that are written uppercase, e.g. *Jaffa Cakes*, *Beef Wellington*, *BLT*, *Hoppin' John* etc.

Table 3: Comparison of intrinsic properties between brands and types; brands are always underlined; all numbers (except for *length*) are the proportion with the respective property.

potato), we compute all conjuncts and rank them according to frequency. We do this on our domain-specific corpus and on *Wikipedia*. As a baseline, we simply sort all nouns according to frequency in our domain-specific corpus. The table shows that ranking by frequency is no effective method. Conjuncts produce good results provided that they are extracted from a domain-specific corpus.

Even though coordination is a very reliable method to induce food items, it fails to distinguish between food types and food brands. We produced a labeled food vocabulary to be used for all our subsequent experiments consisting of food types and food brands (see Table 2). The food types exclusively comprise the food vocabulary from Wiegand et al. (2014). The food brands were manually selected with the help of the web. We only include food items that occur at least 5 times in our corpus. In our food vocabulary, 87% of our food brands occur as a conjunct of a food type. Therefore, the problem of confusing brands with types is inherent to induction based on coordination.

3 Intrinsic Properties

Table 3 provides some statistics on intrinsic properties of our food items giving some indication which feature types might be used for this task. We also include some stylistic properties of brands that have been addressed in previous marketing research and applied psychology. We focus on fairly straightforward features from *desirable brand name characteristics* (Robertson, 1989), since we assume that there is more general agreement on the underlying concepts than there is on the concepts underlying complex sound symbolism (Klink, 2000; Yorkston and Menon, 2004). For the statistics in Table 3, most properties (i.e. all except *length* and *word-initial plosives*) have been detected manually. The reason for this is that their automatic detection is not trivial (e.g. there is no established algorithm to detect onomatopoeia; even the detection of rhyme or assonance is not straightforward given the low grapheme-phoneme correspondence of English). We did not want the statistics for this exploratory experiment to be distorted by error-proneness of the detection methods.

Table 3 shows that a large part of brands are nonwords indicating that this task is hard to be solved with intrinsic features only. Since there is a high number of brands that are derived from some *existing* proper noun being either a person or a location, named-entity recognition might be applied to this task. Many brands are also foreign words. Unfortunately, applying language checking software on our food items turned out to perform poorly. (These tools are only effective on longer texts, e.g. sentences or entire documents, and do not work on isolated words, as in our problem setting.) We also noticed a difference in average word length between brands and types which is consistent with Robertson (1989) who claims that brand names should be *simple*. Most stylistic features seem to be less relevant to our task as they are either too infrequent or not discriminative. Therefore, we do *not* consider them as features for the detection of brands in our forthcoming experiments.

4 Method

Our aim is to determine predictive features for the detection of brands. Rather than employing some supervised learner that requires manually labeled training data, we want to convert these features directly into a classifier without costly labeled data. We conceive this task as a ranking task. The reason for using a ranking is that our features can be translated into a ranking score in a very straightforward manner. For the evaluation, we do not have to determine some empirical threshold separating the category *brand* from the category *type*. Instead, the evaluation measures we employ for ranking implicitly assume highly ranked instances as brands and instances ranked at the bottom as types.

For the ranking task, we employ the processing pipeline as illustrated in Figure 1. Most of our features are designed in such a way that they assign a ranking score to each of our food items by counting how often a feature is observed with a food item; that is why we call these features **ranking features**. The resulting ranking should assign high scores to food brands and low scores to food types. If we want to combine several features into one ranking, we simply average for each food item the different ranking scores of the individual ranking features. This is possible since they have the same range $[0; 1]$. We obtain such range by normalizing the number of occurrences of a feature with a particular food item by the total number of occurrences of that food item. The combination by averaging is unbiased as it treats all features equally.

We also introduce a **reset feature** which is applied on top of an existing ranking provided by ranking features. A reset feature is a negative feature in the sense that it is usually a reliable cue that a food item is *not* a brand. If it fires for a particular food item, then its ranking score is reset to 0.

Finally, we add **bootstrapping features**. These features produce an output similar to the ranking features (i.e. another ranking). However, unlike the ranking features, the bootstrapping features produce their output based on a weakly-supervised method which requires some labeled input. Rather than manually providing that input, we derive it from the combined output that is provided by the ranking and reset features. We restrict ourselves to instances with a high-confidence prediction, which translates to the top and bottom end of a ranking. (Since the instances are not manually labeled, of course, not every label assignment will be correct. We hope, however, that by restricting to instances with a high-confidence prediction, we can reduce the amount of errors to a minimum.) The output of a bootstrapping feature is combined with the set of ranking features to a new ranking onto which again a reset feature is applied.

Table 4 shows which feature (each will be discussed below) belongs to which of the above feature types (i.e. ranking, reset or bootstrapping features). Most features (i.e. all except WIKI) are extracted from our domain-specific corpus introduced in §2.

4.1 Length

Since we established that brands tend to be shorter than types (§3), we add one feature that ranks each food item according to its number of characters.

4.2 Target Named-Entity Recognition (NER$_{target}$)

Brands can be considered a special kind of named entities. We apply a part-of-speech tagger to count how often a food item has been tagged as a proper noun. We decided against a named-entity recognizer as it usually only recognizes persons, locations and organizations, while part-of-speech taggers employ a general tag for all proper nouns (that may go well beyond the three afore-mentioned common types). We use a statistical tagger, i.e. *TreeTagger* (Schmid, 1994), that also employs features below the word level. As many of our food items will be unknown words, a character-level analysis may still be able to make useful predictions.

4.3 Contextual Named-Entity Recognition (NER$_{context}$)

We also count the number of other named entities that co-occur with the target food brand within the same sentence. We are only interested in organizations; an organization co-occurring with a brand is likely to be the company producing that brand (e.g. *He loves Kellogg's*$_{company}$ *frosties*$_{brand}$.) For this feature, we rely on the output of a named-entity recognizer for German (Chrupała and Klakow, 2010).

4.4 Diversification (DIVERS)

Once a product has established itself on the market for a substantial amount of time, many companies introduce variants of their brand to further consolidate their market position. The purpose of this diversification is to appeal to customers with special needs. A typical variant of food brands are *light* products. In many cases, the names of variants consist of the name of the original brand with some prefix or suffix indicating the particular type of variant (e.g. *mini babybel* or *philadelphia light*). We manually compiled 11 affixes and check for each food item how often it is accompanied by one of them.

4.5 Commerce Cues (COMMERCE)

Presumably, brands are more likely to be mentioned in the context of commercial transaction events than types. Therefore, we created a list of words that indicate these types of events. The list was created ad hoc. We used external resources, such as FrameNet (Baker et al., 1998) or GermaNet (Hamp and Feldweg, 1997) (the German version of WordNet (Miller et al., 1990)), and made no attempt to tune that list to our domain-specific food corpus. The final list (85 cues in total) comprises: verbs (and deverbal nouns) that convey the event of a commercial transaction (e.g. *buy*, *purchase* or *sell*), persons involved in a commercial transaction (e.g. *customer* or *shop assistant*), means of purchase (e.g. *money*, *credit card* or *bill*), places of purchase (e.g. *supermarket* or *shop*) and judgment of price (e.g. *cheap* or *expensive*).

4.6 Food Modifier (PAT$_{mod}$)

Even though many mentions of brands are similar to those of types, there exist some particular contexts that are mostly observed with brands. If the food item to be classified often occurs as a modifier of another food item, then the target item is likely to be some brand. This is due to the fact that many brands are often mentioned in combination with the food type that they represent, e.g. ***volvic*** *mineral water*, ***nutella*** *chocolate spread.*

4.7 Prepositional Phrase Embedding (PAT$_{pp}$)

Instead of appearing as a modifier (§4.6), a brand may also be embedded in some prepositional phrase that has a similar meaning, e.g. *We only buy the chocolate spread* $[$*by* ***nutella***$]_{PP}$.

4.8 Graph-based Methods (GRAPH)

We also employ some semi-supervised graph clustering method in order to assign semantic types to food items as introduced in Wiegand et al. (2014). The underlying data structure is a food graph that is generated automatically from our domain-specific corpus where nodes represent food items and edge weights

Category	Description	General	Brands
MEAT	meat and fish (products)	19.48	1.31
BEVERAGE	beverages (incl. alcoholic drinks)	17.19	**23.96**
SWEET	sweets, pastries and snack mixes	14.90	**25.60**
SPICE	spices and sauces	10.53	2.42
VEGE	vegetables (incl. salads)	10.38	0.00
STARCH	starch-based side dishes	9.21	4.42
MILK	milk products	6.71	**23.48**
FRUIT	fruits	4.48	1.14
GRAIN	grains, nuts and seeds	3.41	0.00
FAT	fat	2.54	**20.00**
EGG	eggs	0.92	0.00

Table 5: Proportion of categories in the entire food vocabulary (*General*) and among brands (*Brands*).

represent the similarity between different items. The weights are computed based on the frequency of co-occurrence within a similarity pattern (e.g. *X instead of Y*). Food items that cluster with each other in such a graph (i.e. food items that often co-occur in a similarity pattern) are most likely to belong to the same class. For the detection of brands, we examine two different types of food categorization. We always use the same clustering method (Wiegand et al., 2014) and the same graph. Depending on the specific type of categorization, we only change the seeds to fit the categories to be induced.

4.8.1 Categories of the Food Guide Pyramid (GRAPH$_{pyramid}$)

The first categorization we consider is the categorization of food items according to the *Food Guide Pyramid* (U.S. Department of Agriculture, 1992) as examined in Wiegand et al. (2014). We observed that food brands are not equally distributed throughout the entire range of food items. There is a notable bias of food brands towards beverages (mostly soft drinks and alcoholic drinks), sweets, snack mixes, dairy products and fat. Other categories, e.g. nuts, vegetables or meat, hardly contain brands.[4] The category inventory and the proportion among types and brands are displayed in Table 5.

We use the category information as a negative feature, that is, we re-set the ranking score to 0 if the category of the food item is either MEAT, SPICE, VEGE, STARCH, FRUIT, GRAIN or EGG. In order to obtain a category assignment to our food vocabulary, we re-run the best configuration from Wiegand et al. (2014) including the choice of category seeds. We just extend the graph that formerly only contained food types by nodes representing brands. We use no manually-compiled knowledge regarding food brands. Even though the seed food items are exclusively food types, we hope to be also able to make inferences regarding food brands. This is illustrated in Figure 2(a): The brand *mars* can be grouped with food types that are sweets, therefore, we conclude that *mars* is also some sweet. (Brands can be grouped with food types of their food category, since food brands are often used as if they were types (§1)). Since sweets are plausible candidates for brands (Table 5), *mars* is likely to be some brand.

We think that such bias of brands towards certain subcategories is also present in other domains. For example, in the electronic domain laptops will have a much larger variety of brands than network cables. Similarly, in the fashion domain there exist much more shoe brands than sock brands.

4.8.2 Direct Graph Clustering Separating Brands from Types (GRAPH$_{brand}$)

We also apply graph clustering directly for the separation of brands from types, i.e. we assign some brand and type seeds and then run graph-based clustering (Figure 2(b)). In order to combine the output of this clustering with that of the previous methods, we interpret the confidence of the output as a ranking score. As we pursue an unsupervised approach, we do not manually label the seeds but rely on the output of a ranker using a combination of above features (Figure 1). Instances at the top of the ranking are considered brand seeds, while instances at the bottom are considered type seeds.

[4]There may be companies which, among other things, also sell these food types, but we do not want to extract the names of *organizations* (as in traditional named-entity recognition), e.g. *Kraft Foods*, but specific product names, e.g. *philadelphia*.

(a) food type categorization (b) brand detection

Figure 2: Similarity graphs; **bold** items are seeds; line width of edges represents strength of similarity.

4.9 Wikipedia Bootstrapping (WIKI)

For many information extraction tasks, the usage of collaboratively-edited resources is increasingly becoming popular. One of the largest resources of that type is *Wikipedia*. For our vocabulary of food items, we could match 57% of the food brands and 53% of the food types with a Wikipedia article.

Even though Wikipedia may hold some useful information for the detection of brands, this information is not readily available in a structured format, such as *infoboxes*. This is illustrated by (3)-(5) which display the first sentence of three Wikipedia articles, where (3) and (4) are food brands and (5) is a food type. There is some thematic overlap across the two categories (e.g. (4) and (5) describe the ingredients of the food item). However, if one also considers the entire articles, some notable topical differences between brands and types become obvious. The articles of food brands typically focus on commercial aspects (i.e. market situation and product history) while articles of food types describe the actual food item (e.g. by distinguishing it from other food items or naming its origin). Therefore, a binary topic classification based on the *entire* document should be a suitable approach. In the light of the diversified language employed for articles on brands (cp. (3)-(4)), we consider a bag-of-words classifier more effective than applying some textual patterns on those texts.

(3) *BRAND:* **Twix** is a chocolate bar made by Mars, Inc.

(4) *BRAND:* **Smarties** is a brand under which Nestlé produces colour-varied sugar-coated chocolate lentils.

(5) *TYPE:* **Milk chocolate** is a type of chocolate made from cocoa produce (cocoa bean, cocoa butter), sugar, milk or dairy products.

Similar to GRAPH$_{brand}$ (§4.8.2), we harness Wikipedia via a bootstrapping method. We generate a labeled training set of Wikipedia articles representing brands and types using the combined output of the ranking features (+ reset feature). We then train a supervised classifier on these data and classify all articles representing food items of our food vocabulary. We use the output score of the classifier for the article of each food item (which amounts to some confidence score) and thus obtain a ranking score. For those food items for which no Wikipedia entry exists, we produce a score of 0.

4.10 Vector Space Model (VSM)

While GRAPH$_{brand}$ (§4.8.2) determines similar food items by means of highly weighted edges in a similarity graph (that represent the frequency of co-occurrences with a similarity pattern), we also examine whether distributional similarity can be harnessed for the same purpose. We represent each food item as a vector, where the vector components encode the frequency of words that co-occur with mentions of the food item in a fixed window of 5 words (in our domain-specific corpus). Similar to GRAPH$_{brand}$ (§4.8.2) and WIKI (§4.9), we consider the n highest and m lowest ranked food items provided by ranking features (+ reset feature) as labeled brand and type instances for a supervised classifier. For testing, we apply this classifier on each food item in our vocabulary, or more precisely, its vector representation. Thus we obtain another ranking score (again, the output amounts to some confidence score).

	Plain					+Graph$_{pyramid}$ *(reset feature)*

5 Experiments

In the following experiments, we mostly evaluate rankings. For that we employ *precision at rank n* and *average precision*. The former computes precision at a predefined rank n, whereas the latter provides an average of the precisions measured at every possible rank. While average precision provides a score that evaluates the ranking as a whole, precision at rank n typically focuses on the correctness of higher ranks.[5]

5.1 Evaluation of Ranking Features

Table 6 (left half) displays the results of the individual and combined ranking features. As a trivial baseline, we also include RANDOM which is randomized ranking of the food items. The table shows that all features except LENGTH produce a notably better ranking than RANDOM. Following the inspection of intrinsic properties of brands in §3, it does not come as a surprise that NER$_{target}$ is the strongest feature. However, also the contextual features NER$_{context}$, PAT$_{pp}$ and PAT$_{mod}$ produce reasonable results. If we combine all features (except the poorly performing LENGTH), we obtain a notable improvement over NER$_{target}$ which proves that those different features are complementary to a certain extent.

5.2 Evaluation of the Reset Feature

In Table 7, we examine the food categorization according to the Food Guide Pyramid as such. For this evaluation, we partition the output of automatic categorization into (actual) types and brands. Thus we can compare the performance between those two different types of food items, and can quantify the loss on the categorization on brands against the categorization on types. (Due to the fact that the seeds exclusively comprise types, we must assume that performance on brands will be lower.)[6] Even though there is a slight loss on brands (mostly recall), we still consider this categorization useful for our purposes.

[5]The manually labeled food vocabulary is available at:
`www.lsv.uni-saarland.de/personalPages/michael/relFood.html`

[6]Since the categories to indicate unlikely brands (§4.8.1) are extremely sparse (Table 5), we conflate them for this evaluation as one large category NEGATIVE. Because of this and due to the fact that the food type vocabulary is slightly smaller than the one used in Wiegand et al. (2014) (since we only consider food items mentioned at least 5 times in our corpus (§2)), the performance scores of food categorization in Table 7 and the one reported in Wiegand et al. (2014) differ accordingly.

Classifier		Acc	Prec	Rec	F
Baselines	Majority-Class Classifier	88.76	44.38	50.00	47.02
	seeds only: 50 top+150 bottom	9.51	91.00	13.85	23.47
	seeds only: 100 top+300 bottom	18.57	86.17	25.48	37.81
Bootstrap. Features	WIKI (*seeds: 50 top+150 bottom*)	43.95	**87.68**	43.33	57.91
	VSM (*seeds: 100 top+300 bottom*)	77.87	64.93	**81.61**	66.39
	GRAPH$_{brand}$ (*seeds: 100 top+300 bottom*)	82.91	81.36	67.27	**73.53**

Table 8: Bootstrapping features in isolation compared with baselines (i.e. reference classifiers).

Table 6 (right half) shows the performance of the corresponding reset feature on the brand detection task. We observe a systematic increase in performance when added on top of the ranking features.

5.3 Evaluation of Bootstrapping Features

Table 9 displays the performance of the bootstrapping features. For the labeled training data, we empirically determined the optimal class ratio (1:3) and the optimal number of seeds (the top 100 and bottom 300 items for VSM and GRAPH$_{brand}$, and top 50 and bottom 150 items for WIKI). As a supervised classifier for VSM and WIKI, we chose Support Vector Machines using *SVM^{light}* (Joachims, 1999).

The table shows that only GRAPH$_{brand}$ and WIKI improve the ranking, whereas WIKI is notably stronger. These results suggest that Wikipedia is a good resource from which to learn whether a food item is a brand or not. However, this task could not be completely solved by WIKI since not all food items are covered by Wikipedia (§4.9). To further prove this, we also evaluate an upper bound of Wikipedia, WIKI$_{oracle}$ (exclusively using that resource), in which we pretend to correctly interpret every Wikipedia page as an article for either a food brand or a food type. We rank all brands having a Wikipedia article highest. They are followed by those food items having no article (ordered randomly) and, finally, by the food types having a Wikipedia article. Table 9 shows that we are able to outperform WIKI$_{oracle}$.

Our pipeline (Figure 1) applies the reset feature at two stages. We also examine whether it is necessary to apply that feature for a second time. Presumably, the bootstrapping feature is so effective that we do not have to apply further type filtering. After all, the reset feature will also downweight some correct food items (Table 5). Table 9 confirms that when the reset feature is applied only once, we obtain a better performance (according to average precision) for all bootstrapping features (even for VSM).

Finally, Table 8 evaluates the bootstrapping features in isolation. Since, unlike the ranking features, the bootstrapping features provide a definite classification for each food item (in addition to a prediction score evaluated as a ranking score), we consider the output for a binary classification task. In this setting, we make use of the four evaluation measures *accuracy*, *precision*, *recall* and *F-score*. For the last three measures, we always compute the macro average score.

As a baseline, we also include a majority-class classifier that always predicts the class *food type*. Interestingly, in terms of F-score, GRAPH$_{brand}$ is the best method rather than WIKI, i.e. the best method from the previous evaluation in Table 9. The reason for this is that we evaluate in isolation rather than in combination with other features (i.e. parts of the additional benefit included in GRAPH$_{brand}$ may already be contained in ranking and reset features). Secondly, in a ranking task (Table 9), good performance is usually achieved by classifiers biased towards a high precision. Indeed, the best ranker in Table 9, i.e. WIKI, achieves the highest precision in Table 8.

6 Related Work

Ling and Weld (2012) examine named-entity recognition on data that also include brands, however, the class of brands is not explicitly discussed. Putthividhya and Hu (2011) explore brands in the context of product attribute extraction. Entities are extracted from eBay's clothing and shoe category. Nadeau et al. (2006) explicitly generate gazetteers of car brands obtained from corresponding websites. Those textual data are very restrictive in that they do not represent sentences but category listings or tables. In this paper, we consider as textual source a more general text type, i.e. forum entries, that comprise full

sentences. Previous work also focuses on traditional (semi-)supervised algorithms. Hence, there are only few additional insights as to the specific properties of brand names. Min and Park (2012) examine the aspect of product instance distinction on the use case of product reviews on jeans from Amazon. Their work focuses on temporal features to identify distinct product instances (these may also include brand names).

The food domain has also recently received some attention. Different types of classification have been explored including ontology mapping (van Hage et al., 2005), part-whole relations (van Hage et al., 2006), recipe attributes (Druck, 2013), dish detection and the categorization of food types according to the Food Guide Pyramid (Wiegand et al., 2014). Relation extraction tasks have also been examined. While a strong focus is on food-health relations (Yang et al., 2011; Miao et al., 2012; Kang et al., 2013; Wiegand and Klakow, 2013), relations relevant to customer advice have also been addressed (Wiegand et al., 2012; Wiegand et al., 2014). Beyond that, Chahuneau et al. (2012) relate sentiment information to food prices with the help of a large corpus consisting of restaurant menus and reviews. Druck and Pang (2012) extract actionable recipe refinements. To the best of our knowledge, we present the first work that explicitly addresses the detection of brands in the food domain. While brands as such present an additional dimension to previously examined types of categorization, we also show that the categorization according to the Food Guide Pyramid helps to decide whether a food item is a brand or not.

7 Conclusion

We examined the task of separating types from brands in the food domain. Framing the problem as a ranking task, we directly converted predictive features extracted from a domain-specific corpus into a ranker without the need of labeled training data. Apart from those ranking features, we also exploited knowledge induced by semi-supervised graph-based clustering for two different purposes. On the one hand, we produced an auxiliary categorization of food items according to the Food Guide Pyramid, and assumed that a food item is a type when it belongs to a category that is unlikely to contain brands. On the other hand, we directly modelled the task of brand detection by using seeds provided by the output of the textual ranking features. We also learned additional high-precision knowledge from Wikipedia webpages using a similar bootstrapping scheme.

Unsupervised Instance-Based Part of Speech Induction Using Probable Substitutes

Mehmet Ali Yatbaz **Enis Rıfat Sert** **Deniz Yuret**
Koç University Artificial Intelligence Laboratory, İstanbul
{myatbaz,esert,dyuret}@ku.edu.tr

Abstract

We develop an instance (token) based extension of the state of the art word (type) based part-of-speech induction system introduced in (Yatbaz et al., 2012). Each word instance is represented by a feature vector that combines information from the target word and probable substitutes sampled from an n-gram model representing its context. Modeling ambiguity using an instance based model does not lead to significant gains in overall accuracy in part-of-speech tagging because most words in running text are used in their most frequent class (e.g. 93.69% in the Penn Treebank). However it is important to model ambiguity because most frequent words are ambiguous and not modeling them correctly may negatively affect upstream tasks. Our main contribution is to show that an instance based model can achieve significantly higher accuracy on ambiguous words at the cost of a slight degradation on unambiguous ones, maintaining a comparable overall accuracy. On the Penn Treebank, the overall many-to-one accuracy of the system is within 1% of the state-of-the-art (80%), while on highly ambiguous words it is up to 70% better. On multilingual experiments our results are significantly better than or comparable to the best published word or instance based systems on 15 out of 19 corpora in 15 languages. The vector representations for words used in our system are available for download for further experiments.

1 Introduction

Unsupervised part-of-speech (POS) induction aims to classify words into syntactic categories using unlabeled, plain text input. The problem of induction is important for studying under-resourced languages that lack labeled corpora and high quality dictionaries. It is also essential in modeling child language acquisition because every child manages to induce syntactic categories without access to labeled sentences, labeled prototypes, or dictionary constraints (Ambridge and Lieven, 2011). Categories induced from data may point to shortcomings or inconsistencies of hand-labeled categories as discussed in Section 4. Finally, the induced categories or the vector representations generated by the induction algorithms may improve natural language processing systems when used as additional features.

Word-based POS induction systems classify different instances of a word in a single category (which we will refer to as the *one-tag-per-word assumption*). Instance-based systems classify each occurence of a word separately and can handle ambiguous words.

Examples of word-based systems include ones that represent each word with the vector of neighboring words (context vectors) and cluster them (Schütze, 1995; Lamar et al., 2010b; Lamar et al., 2010a), use a prototypical bi-tag HMM that assigns each word to a latent class (Brown et al., 1992; Clark, 2003), restrict a HMM based Pitman-Yor process to perform one-tag-per-word inference (Blunsom and Cohn, 2011), define a word-based Bayesian multinomial mixture model (Christodoulopoulos et al., 2011), or

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2303–2313, Dublin, Ireland, August 23-29 2014.

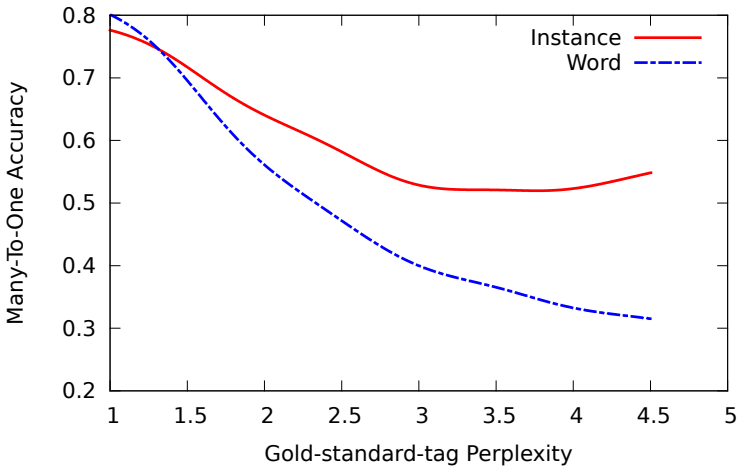

Figure 1: The accuracy comparison of word and instance based part-of-speech induction models as a function of target word ambiguity (as measured by gold-standard-tag perplexity described in Section 3.3) on the Penn Treebank.

construct word vector representations based on co-occurrences with contextual features (Yatbaz et al., 2012).

The obvious limitation of the one-tag-per-word assumption is that instances of ambiguous words that have more than one POS role are grouped into the same class. For example, the word *offer* is tagged as NN(399), VB(105) and VBP(34)[1] in its 538 occurrences in the human labeled Wall Street Journal (WSJ) Section of the Penn Treebank (PTB) corpus (Marcus et al., 1999). If all instances of *offer* are assigned to the most frequent tag NN, 36% (139/538) will be erroneously labeled. In spite of this shortcoming, word-based POS induction systems generally do well because the one-tag-per-word assumption is mostly accurate: 93.69% of the word occurrences are tagged with their most frequent POS tag in the PTB (Toutanova et al., 2003).

In order to handle ambiguous words, models without a strict one-tag-per-word assumption need to group word *instances* into clusters according to their contexts. Some of these instance-based models bias words to have few tags using sparse priors in a Bayesian setting (Goldwater and Griffiths, 2007; Johnson, 2007; Gao and Johnson, 2008), or posterior regularization (Ganchev et al., 2010). Schütze (1993) represents the context of a word instance by concatenating context vectors of its left and right neighboring words, and clusters word instances. Berg-Kirkpatrick et al. (2010) use an EM algorithm where they replace the multinomial components with miniature logistic regressions and achieve the highest instance-based accuracy on PTB. Christodoulopoulos et al. (2010) select prototypes of each cluster from the output of Brown (1992) and feed them to a HMM model that can handle prototypes as features (Haghighi and Klein, 2006). However none of these models achieve results comparable to the best word-based systems.

In this work, we show that one can build an instance-based system that can perform significantly better on highly ambiguous words (see Figure 1) and yet is competitive with word-based systems in overall accuracy.

We follow the state of the art word-based system (Yatbaz et al., 2012) and use probable substitutes of a word instance as its contextual features. The following examples illustrate how such paradigmatic (substitute based) contextual features can capture the similarity between two contexts where a syntagmatic (neighbor based) representation would fail:

[1]NN, VB and VBP are three POS tags from the Penn Treebank corpus and they correspond to singular noun, verb in base form and non-3^{rd}person singular verb in present tense, respectively. The numbers in parentheses are the frequencies.

(1) *"Pierre Vinken, 61 years old, will join the board as a nonexecutive* **director** *Nov. 29."*
director → chairman (.8242), director (.0127), directors (.0127) . . .

(2) *". . . Joseph Corr was succeeded by Frank Lorenzo,* **chief** *of parent Texas Air."*
chief → chairman (.9945), president (.0031), directors (.0012) . . .

Each sentence has the target words marked in bold (**director** and **chief**) and their likely substitutes listed with probabilities[2] in parentheses. Note that the two contexts have no words in common, therefore syntagmatic (neighbor based) contextual features will fail to capture their similarity. However, paradigmatic features such as the top substitutes "chairman", "directors", etc. clearly indicate the similarity and help place these two instances into the same category.

Following (Globerson et al., 2007), we embed words and their contextual, orthographic, and morphological features in a high dimensional Euclidean space that relates their joint probability to distance. In contrast to (Yatbaz et al., 2012) we build an *instance-based* POS induction system where each instance has a vector representation that concatenates the word vector with the average of the contextual feature vectors. We show that clustering of these instance vectors separate different roles of ambiguous words well, and achieve comparable or better performance than the best word-based systems in matching the gold tags on 19 corpora in 15 languages. All the code that can be used to replicate our findings is available at `https://github.com/ai-ku/upos_2014`.

Section 2 describes the instance-based POS induction algorithm, Section 3 gives the results of our experiments, Section 4 compares the output of the induction system with the gold tags, and Section 5 summarizes our contributions.

2 Algorithm

In this section, we describe the steps of our instance-based POS-induction algorithm:

1. Sample r substitutes for each word instance in the target corpus using an n-gram language model.
2. Construct r tuples for each instance where each tuple consists of a sampled substitute, the target word, and the morphological and orthographical features of the target word (see Table 1).
3. Construct Euclidean embeddings of each word and each feature based on all tuples following Gleberson et al.(2007) and Maron et al.(2010).
4. Construct a vector representation for each instance by concatenating the embedding of the target word with the average of its substitute embeddings.
5. Use k-means clustering to cluster the instance vectors where k is equal to the number of gold tags.

Steps 1 and 2 construct a tuple representation for each instance. Table 1 gives some example tuples for Sentence (1) from the previous section. In this example $r = 3$, so three substitutes are sampled for each instance as contextual features. The sampling is with replacement from the substitute word distribution of a context given by the n-gram language model, so some substitute words may be repeated. The target word and its other features are identical for each of the r tuples representing a single instance.

In step 3, we construct Euclidean embeddings for each unique word and feature value using the multivariable version of the CODE algorithm described in (Globerson et al., 2007). Given two categorical variables W and F, the CODE algorithm constructs Euclidean embeddings (vectors) for each of their distinct values in the same space. The distance between the embedding of a w value, $\phi(w)$, and the embedding of an f value, $\psi(f)$, is related to their joint distribution $p(w, f)$ as follows[3]

$$p(w, f) = \frac{1}{Z}\bar{p}(w)\bar{p}(f)e^{-d^2_{w,f}}$$

[2]Substitute probabilities are computed using a 4-gram language model.

[3](Globerson et al., 2007) describes several ways to relate distances to probabilities, the model used here is the marginal-marginal (MM) model.

Word	Subst	Suf	Cap	Num
Vinken	Makhlouf	–	T	F
Vinken	Makhlouf	–	T	F
Vinken	<unk>	–	T	F
61	20	–	F	T
61	2000	–	F	T
61	eleven	–	F	T
years	years	-s	F	F
years	years	-s	F	F
years	years	-s	F	F

Table 1: The tuples constructed for the instances of "Vinken", "61" and "years" from Sentence (1). The elements of each tuple are the target word, sampled substitute, suffix, capitalization, and number features.

where $\bar{p}$ represents empirical probabilities (frequencies from the training data), $d_{w,f}$ is the distance between the embeddings $\phi(w)$ and $\psi(f)$ and $Z = \sum_{w,f} \bar{p}(w)\bar{p}(f)e^{-d^2_{w,f}}$ is a normalization constant. Starting with random vectors for each distinct value of w and f, we use stochastic gradient ascent to move the embedding vectors around to maximize the likelihood given by this model. Calculating the normalization constant Z is the most expensive part of this procedure. We solve this problem following (Maron et al., 2010) who suggest that a constant Z approximation can be used if the embedding vectors are kept on the unit sphere.

As Table 1 shows, considering the target word and its contextual, morphological and orthographic features gives us more than two variables. Yatbaz et al. (2012) adopt the two variable CODE algorithm to this multi-variable case in an ad-hoc manner by considering the target word as w and all other features as distinct f values. We implement the multi-variable extension of CODE suggested by (Globerson et al., 2007) (Section 6.2) which optimizes the following likelihood function:

$$\ell(\phi, \psi^{(1)}, \ldots, \psi^{(K)}) = \sum_{i=1}^{K} \sum_{w, f^{(i)}} \bar{p}(w, f^{(i)}) \log p(w, f^{(i)})$$

where w are the target words, ϕ are the embeddings of target words, K is the number of different types of features[4], $f^{(i)}$ are the values of the i'th feature, and $\psi^{(i)}$ are the embeddings for the values of the i'th feature. This extension can be seen as a set of K bivariate CODE models $p(w, f^{(i)})$ that share the same target word embeddings $\phi(w)$ but build their own feature embeddings $\psi^{(i)}(f^{(i)})$.

Step 4 constructs a vector representation for each word instance with the concatenation of its word type embedding and the average of its r substitute embeddings. If the original embeddings are in d dimensional space, this results in a $2d$ dimensional vector representing an instance.

Step 5 clusters these $2d$ dimensional instance vectors using a modified k-means algorithm with smart initialization (Arthur and Vassilvitskii, 2007) and assigns each instance to one of k clusters.

3 Experiments

In this section we present our instance-based POS induction experiments. Section 3.1 describes the accuracy metrics that we use to evaluate our results. Section 3.2 details the test corpus and the experimental parameters used in the English experiments and compares our results with previous work. Section 3.3 compares the performance of type and instance based systems on ambiguous words. Finally, Section 3.4 extends the language and corpus coverage by applying the best performing instance based models to 19 corpora in 15 languages.

[4]For example the number of features $K = 4$ in Table 1: Subst, Suf, Cap, and Num.

Model	MTO	VM
Clark (2003)	.712	.655
Christodoulopoulos et al. (2011)	.728	.661
Berg-Kirkpatrick et al. (2010)	.755	-
Christodoulopoulos et al. (2010)	.761	.688
Blunsom and Cohn (2011)	.775	.697
Yatbaz et al. (2012)	.8023 (.0070)	.7207 (.0041)
Instance based (Sec. 2)	.7952 (.0030)	.6908 (.0027)

Table 2: Summary of results with MTO and VM scores for POS induction on the Penn Treebank. Standard errors are given in parentheses when available. All the models incorporate orthographic and morphological features. Berg-Kirkpatrick et al. (2010) and Christodoulopoulos et al. (2010) use instance based models.

3.1 Evaluation

We report many-to-one and V-measure scores for our experiments as suggested in (Christodoulopoulos et al., 2010). The many-to-one (MTO) evaluation maps each cluster to its most frequent gold tag and reports the percentage of correctly tagged instances. The MTO score can be increased by simply increasing number of clusters, thus the number of clusters is fixed to match the number of gold tags in each experiment. The V-measure (VM) (Rosenberg and Hirschberg, 2007) is an information theory motivated metric that calculates the harmonic mean of completeness and homogeneity of the clusters. Completeness of a cluster is maximized when all instances of a gold-tag are grouped into the same cluster and the homogeneity is maximized when the members of a cluster belong to the same gold-tag.

3.2 Experimental Settings and Results

To make a direct comparison with previously published results, the Wall Street Journal Section of the Penn Treebank was used as the test corpus (1,173,766 instances, 49,206 unique tokens) for English experiments. PTB uses 45 part-of-speech tags which we used as the gold standard for evaluation in our experiments.

To compute substitutes in a given context we trained a language model using the ukWaC corpus ($\approx$ 2 billion tokens) constructed by crawling the ".uk" Internet domain (Ferraresi et al., 2008)[5]. We used SRILM (Stolcke, 2002) to build a 4-gram language model with interpolated Kneser-Ney discounting. Words that were observed less than 2 times in the language model training data were replaced by <unk> tags, which gave us a vocabulary size of 4,254,946. The perplexity of the 4-gram language model on the PTB is 303 and the unknown word rate is 0.008. For computational efficiency only the top 100 substitutes and their probabilities were computed for each position in the PTB using the FASTSUBS algorithm (Yuret, 2012). We use the same orthographic features defined in (Yatbaz et al., 2012) and generated morphological features using the unsupervised algorithm Morfessor (Creutz and Lagus, 2005).

The experiments were run using the following default settings (unless otherwise stated): (1) each word was kept with its original capitalization; (2) 90 substitutes sampled per instance; (3) the learning rate parameters for S-CODE were set to $\varphi_0 = 50$, $\eta_0 = 0.2$; (4) S-CODE convergence threshold, the log-likelihood difference between two consecutive iterations, was set to 0.001; (5) the S-CODE dimensions and $\tilde{Z}$ were set to 25 and 0.166, respectively; (6) a modified k-means algorithm with smart initialization was used (Arthur and Vassilvitskii, 2007); (7) the number of k-means restarts was set to 128 to improve clustering and reduce variance.

Each experiment was repeated 10 times with different random seeds and the results are reported with standard errors in parentheses or error bars in graphs. Table 2 summarizes all the results reported in this section and the ones we cite from the literature.

[5]We use the Penn Treebank Tokenizer to make the training data compatible with PTB.

3.3 Word vs. Instance-Based Induction

Table 2 shows that the overall many-to-one accuracy of our instance based induction system is comparable to (Yatbaz et al., 2012)[6] and significantly higher than the other published results on the Penn Treebank. However Figure 1 in the introduction suggests that this summary hides the large difference in the answers given by the different systems. In this section we compare the performance of our instance-based model to the word-based model of (Yatbaz et al., 2012) on word types at different levels of ambiguity using the English Penn Treebank results.

We propose the gold-tag perplexity of a word as a measure of its degree of ambiguity defined as:

$$GP(w) = 2^{H(p_w)} = 2^{-\sum_t p_w(t) log_2 p_w(t)}$$

where w is a word, t is a tag, p_w is the gold POS tag distribution of the word w and $H(p_w)$ is the entropy of the p_w distribution. A GP of 1 for a word w indicates that w is always associated with the same POS tag. A word with N equally probable tags would have a GP of N.

Figure 1 plots the gold-tag perplexity versus the smoothed MTO accuracy for the word-based and the instance-based POS induction systems on the Penn Treebank. To compose the plot, we found the best mapping from the induced clusters to the gold-standard tags, then we computed the MTO accuracy for each word using this mapping and plotted the MTO as a function of the word's GP. We used the Nadaraya-Watson kernel regression estimate (Nadaraya, 1964; Watson, 1964) with normal kernel of bandwidth 1.0 to obtain smooth regression lines. The figure shows that the performance of the instance-based induction model does not degrade as much as the word-based model as the ambiguity of the words increase. However, only 14.94% of the instances in the PTB consists of words with GP greater than 1.5 and 45.71% consists of words with GP exactly 1. Thus, the overall accuracy numbers do not adequately reflect the improvement on highly ambiguous words.

3.4 Multilingual Experiments

Following Christodoulopoulos et al. (2011), we extend our experiments to 8 languages from MULTEXT-East (Bulgarian, Czech, English, Estonian, Hungarian, Romanian, Slovene and Serbian) (Erjavec, 2004) and 10 languages from the CoNLL-X shared task (Bulgarian, Czech, Danish, Dutch, German, Portuguese, Slovene, Spanish, Swedish and Turkish) (Buchholz and Marsi, 2006).

To sample substitutes, we trained language models of Bulgarian, Czech, Estonian, Romanian, Danish, German, Dutch, Portuguese, Spanish, Swedish and Turkish with their corresponding TenTen corpora (Jakubíček et al., 2013), and Hungarian, Slovene and Serbian with their corresponding Wikipedia dump files[7]. Serbian shares a common basis with Crotian and Bosnian therefore we trained 3 different language models using Wikipedia dump files of Serbian together with these two languages and measured the perplexities on the MULTEXT-East Serbian corpus. We chose the Croatian language model since it achieved the lowest perplexity score and unknown word ratio on MULTEXT-East Serbian corpus. We use ukWaC corpora to train English language models.

We used the default settings in Section 3.2 and incorporated only the orthographic features[8]. Extracting unsupervised morphological features for languages with different characteristics would be of great value, but it is beyond the scope of this paper. For each language the number of induced clusters is set to the number of tags in the gold-set. To perform meaningful comparisons with the previous work we train and evaluate our models on the training section of MULTEXT-East[9] and CONLL-X languages (Lee et al., 2010).

Table 3 presents the performance of our instance based model on 19 corpora in 15 languages together with the corresponding best published results from $^{\diamond}$(Yatbaz et al., 2012), ‡(Blunsom and Cohn, 2011),

[6]The difference is not statistically significant at $p = 0.05$.

[7]Latest Wikipedia dump files are freely available at `http://dumps.wikimedia.org/` and the text in the dump files can be extracted using WP2TXT (`http://wp2txt.rubyforge.org/`)

[8]All corpora (except German, Spanish and Swedish) label the punctuation marks with the same gold-tag therefore we add an extra *punctuation* feature for those languages.

[9]Languages of MULTEXT-East corpora do not tag the punctuations, thus we add an extra tag for punctuations to the tag-set of these languages.

	Language	Tags	Best Published MTO VM	Instance Based MTO / VM
WSJ	English	45	.802 / **.721** $^{\diamond}$	.795 / .691
MULTEXT-East	Bulgarian	12+1	.665 / **.556***	.664 / .513
	Czech	12+1	.642 / **.539***	**.705** / .511

	Portuguese	22	.785‡ / **.639***	.782 / .607
	Slovene	29	.642* / **.539**†	.638 / .469
	Spanish	47	**.788**‡ / **.632***	.753/ .602
	Swedish	41	.682 / **.589**†	.681 / .546
	Turkish	30	.628 / .408*	.637 / .401

Table 3: The MTO and VM scores on 19 corpora in 15 languages together with number of induced clusters. Statistically significant results shown in bold ($p < 0.05$).

*(Christodoulopoulos et al., 2011) and †(Clark, 2003). All of the state-of-the-art systems in Table 3 are word-based and incorporate morphological features.

Our MTO results are lower than the best systems on all of data-sets that use language models trained on the Wikipedia corpora. ukWaC and TenTen corpora are cleaner and tokenized better compared to the Wikipedia corpora. These corpora also have larger vocabulary sizes and lower out-of-vocabulary rates. Thus language models trained on these corpora have much lower perplexities and generate better substitutes than the Wikipedia based models. Our model has lower VM scores in spite of good MTO scores on 14 corpora which is discussed in Section 4.

Among the languages for which clean language model corpora were available, our model performs comparable to or significantly better than the best systems on most languages. We show significant improvements on MULTEXT-East Czech, Romanian, and CoNLL-X Bulgarian. Our model achieves the state-of-the-art MTO on MULTEXT-East English and scores comparable MTO with the best model on WSJ. Our model shows comparable results on MULTEXT-East Bulgarian and Estonian, and CoNLL-X Czech, Danish, Dutch, German, Portuguese, Swedish and Turkish in terms of the MTO score. One reason for comparably low MTO on Spanish might be the absence of morphological features.

4 Discussion

In this section we perform further analysis on the clustering output of our model. The example below illustrates the advantage of the instance-based approach:

(1) ... it will also **offer** buyers the option ...
Substitutes: give, help, attract

(2) The **offer** is being launched ...
Substitutes: campaign, project, scheme

The word **offer** is a *verb* in the first sentence and a *noun* in the second one. Clustering the word embeddings can not distinguish the different occurrences of the words (Yatbaz et al., 2012). On the other hand, the substitutes of *offer* in the two sentences can disambiguate the correct category of the corresponding occurrences. In our actual experiments our instance based representation distinguishes the instances of **offer** as *noun* (cluster 26 and 12) and *verb* (cluster 35).

To illustrate how words are distributed in the induced clusters, we compare the most frequent clusters of our model in Section 3 with the most frequent gold-tags of PTB in Figure 2.

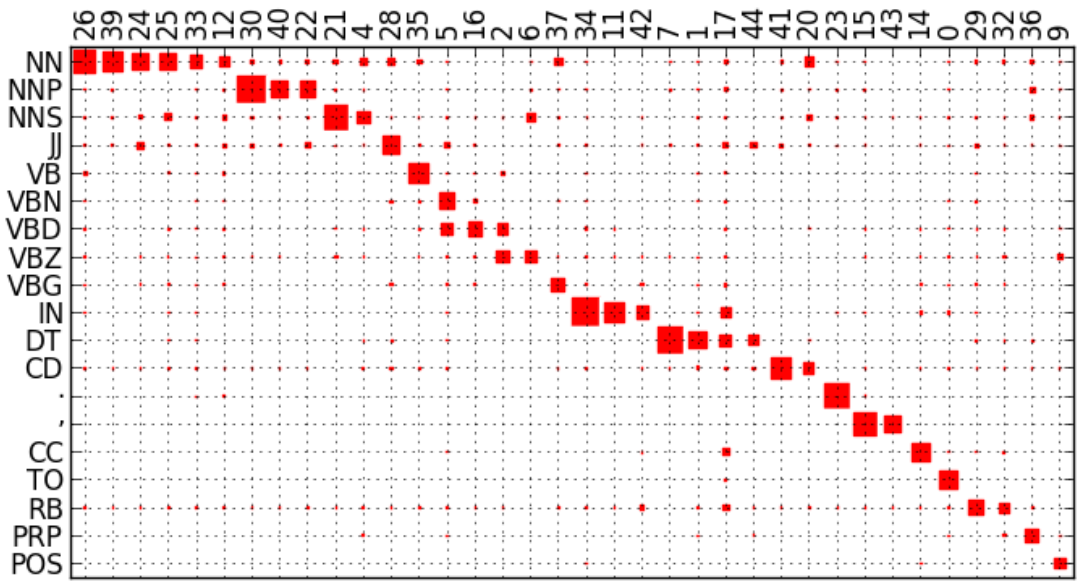

Figure 2: Each row corresponds to a gold tag and each column is an induced tag in the Hinton diagram above. The area of each square is proportional to the joint probability of the given tag and cluster.

The low VM performance of our instance-based model compared to the state-of-the-art word-based systems on some languages is due to the completeness part of the VM score. The Hinton diagram in Figure 2 shows that large gold-tag groups are split into several clusters based on the substitutability of words in that particular cluster (rows of the Hinton diagram). For example, proper nouns (*NNP*) are split into three major clusters such that titles like *Mr.* or person names are in (40), nationality or country related words like *Japanese* or U.S are in (22), and the rest of the proper nouns in cluster (30).

The gold-tags of PTB, on the other hand, do not always respect whether words with the same tag are substitutable for one another. Freudenthal et al. (2005) argues, from the child language acquisition perspective, that the standard linguistic definition of syntactic groups requires the substitutability of words in a syntactic category. Word pairs that are placed in the same category in the PTB, such as "Mr." and "Friday", "be" and "run", "not" and "gladly", "of" and "into" are clearly not generally substitutable.

Another noteworty example of completeness error is that our model splits the punctuation mark (,) class of PTB into the clusters 15 and 43 based on the different usage patterns. The majority of the (,) instances in cluster 15 are used in relative clauses, reported speech clauses or conjunctions while cluster 43 generally consists of (,) instances that are used in non-essential clauses (ex: Time, the largest newsweekly, . . .).

5 Contributions

Our main contributions can be summarized as follows:

- We introduced an instance based POS induction system that can handle ambiguous words and is competitive with the word-based systems in overall accuracy.
- We extended the S-CODE framework to handle more than two categorical variables.
- Our instance based system scores 79.5% many-to-one accuracy on the Penn Treebank and achieves results that are significantly better than or comparable with the best published systems on 15 out of 19 corpora in 15 languages.
- All our code and data, including the substitute distributions and word vectors for the PTB,

Abstract

We propose a novel approach to deciphering short monoalphabetic ciphers that combines both character-level and word-level language models. We formulate decipherment as tree search, and use Monte Carlo Tree Search (MCTS) as a fast alternative to beam search. Our experiments show a significant improvement over the state of the art on a benchmark suite of short ciphers. Our approach can also handle ciphers without spaces and ciphers with noise, which allows us to explore its applications to unsupervised transliteration and deniable encryption.

1 Introduction

Monoalphabetic substitution is a well-known method of enciphering a *plaintext* by converting it into a *ciphertext* of the same length using a *key*, which is equivalent to a permutation of the alphabet (Figure 1). The method is elegant and easy to use, requiring only the knowledge of a key whose length is no longer than the size of the alphabet. There are over 10^{26} possible 26-letter keys, so brute-force decryption is infeasible. Manual decipherment of substitution ciphers typically starts with frequency analysis, provided that the ciphertext is sufficiently long, followed by various heuristics (Singh, 1999).

In this paper, we investigate the task of automatically solving substitution ciphers. Complete automation of the key discovery process remains an active area of research (Ravi and Knight, 2008; Corlett and Penn, 2010; Nuhn et al., 2013). The task is to recover the plaintext from the ciphertext without the key, given only a corpus representing the language of the plaintext. The key is a 1-1 mapping between plaintext and ciphertext alphabets, which are assumed to be of equal length. Without loss of generality, we assume that both alphabets are composed of the same set of symbols, so that the key is equivalent to a permutation of the alphabet. Accurate and efficient automated decipherment can be applied to other problems, such as optical character recognition (Nagy et al., 1987), decoding web pages that utilize an unknown encoding scheme (Corlett and Penn, 2010), cognate identification (Berg-Kirkpatrick and Klein, 2011), bilingual lexicon induction (Nuhn et al., 2012), machine translation without parallel training data (Ravi and Knight, 2011), and archaeological decipherment of lost languages (Snyder et al., 2010).

Our contribution is a novel approach to the problem that combines both character-level and word-level language models. We formulate decipherment as a tree search problem, and find solutions with beam search, which has previously been applied to decipherment by Nuhn et al. (2013), or Monte Carlo Tree Search (MCTS), an algorithm originally designed for games, which can provide accurate solutions in less time. We compare the speed and accuracy of both approaches. On a benchmark set of variable-length ciphers, we achieve significant improvement in terms of accuracy over the state of the art. Additional experiments demonstrate that our approach is robust with respect to the lack of word boundaries and the presence of noise. In particular, we use it to recover transliteration mappings between different scripts without parallel data, and to solve the *Gold Bug* riddle, a classic example of a substitution cipher. Finally, we investigate the feasibility of deniable encryption with monoalphabetic substitution ciphers.

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2314–2325, Dublin, Ireland, August 23-29 2014.

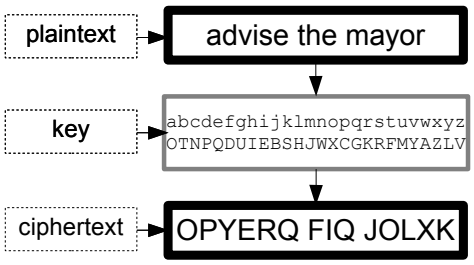

Figure 1: An example of encryption with a substitution cipher.

The paper is organized as follows. After reviewing previous work on automated decipherment in Section 2, we describe our approach to combining character-level and word-level language models with respect to key scoring (Section 3), and key generation (Section 4). In Section 5, we introduce Monte Carlo Tree Search and its adaptation to decipherment. In Section 6, we discuss several evaluation experiments and their results. Section 7 is devoted to experiments in deniable encryption.

2 Related Work

Kevin Knight has been the leading proponent of attacking decipherment problems with NLP techniques, as well as framing NLP problems as decipherment. Knight and Yamada (1999) introduce the topic to the NLP community by demonstrating how to decode unfamiliar writing scripts using phonetic models of known languages. Knight et al. (2006) explore unsupervised learning methods, including the expectation-maximization (EM) algorithm, for a variety of decipherment problems. Ravi and Knight (2009) formulate the problem of unsupervised transliteration as decipherment in order to reconstruct cross-lingual phoneme mapping tables, achieving approximately 50% character accuracy on U.S. names written in the Japanese Katakana script. Reddy and Knight (2011) apply various computational techniques to analyze an undeciphered medieval document. Knight et al. (2011) relate a successful decipherment of a nineteenth-century cipher, which was achieved by combining both manual and computational techniques.

In the remainder of this section, we focus on the work specifically aimed at solving monoalphabetic substitution ciphers. Olson (2007) presents a method that improves on previous dictionary-based approaches by employing an array of selection heuristics. The solver attempts to match ciphertext words against a word list, producing candidate solutions which are then ranked by "trigram probabilities". It is unclear how these probabilities are computed, but the resulting language model seems deficient. For example, given a ciphertext for plaintext *"it was a bright cold day in april*" (the opening of George Orwell's novel *Nineteen Eighty-Four*), the solver[1] produces *"us far a youngs with had up about*". Our new approach, which employs word-level language models, correctly solves this cipher.

Ravi and Knight (2008) formulate decipherment as an integer programming problem in which the objective function is defined by a low-order character language model; an integer program solver then finds the solution that is optimal with respect to the objective function. This method is slow, precluding the use of higher order language models. Our reimplementation of their 2-gram solver deciphers *"it was a bright cold day in april*" as *"ae cor o blathe wind dof as oulan*". By contrast, our approach incorporates word-level information and so tends to avoid out-of-vocabulary words.

Norvig (2009) describes a hill-climbing method that involves both word and character language models, but the models are only loosely combined; specifically, the word model is used to select the best solution from a small number of candidates identified by the character model. When applied to the cipher that corresponds to our example sentence from Orwell, the solver[2] returns *"ache red tab scoville magenta i*".

[2] `http://norvig.com/ngrams` (accessed June 2, 2014)

Corlett and Penn (2010) use fast heuristic A* search, which can handle much longer ciphers than the method of Ravi and Knight (2008), while still finding the optimal solution. The authors report results only on ciphers of at least 6000 characters, which are much easier to break than short ciphers. The ability to break shorter ciphers implies the ability to break longer ones, but the converse is not true. Our approach achieves a near-zero error rate for ciphers as short as 128 characters.

Nuhn et al. (2013) set the state of the art by employing beam search to solve substitution ciphers. Their method is inexact but fast, allowing them to incorporate higher-order (up to 6-gram) character language models. Our work differs in incorporating word-level information for the generation and scoring of candidate keys, which improves decipherment accuracy.

3 Key Scoring

Previous work tend to employ either character-level language models or dictionary-type word lists. However, word-level language models have a potential of improving the accuracy and speed of decipherment. The information gained from word n-gram frequency is often implicitly used in manual decipherment. For example, a 150-year old cipher of Edgar Allan Poe was solved only after three-letter ciphertext words were replaced with high-frequency unigrams *the*, *and*, and *not*.[3] Similarly, a skilled cryptographer might guess that a repeated 'XQ YWZ' sequence deciphers as the high-frequency bigram *"of the*". We incorporate this insight into our candidate key scoring function.

On the other hand, our character-level language model helps guide the initial stages of the search process, when few or no words are discernible, towards English-like letter sequences. In addition, if the plaintext contains out-of-vocabulary (OOV) words, which do not occur in the training corpus, the character model will favor pronounceable letter sequences. For example, having identified most of the words in plaintext *"village of XeYoviY and burned it*", our solver selects *pecovic* as the highest scoring word that fits the pattern, which in fact is the correct solution.

In order to assign a score to a candidate key, we apply the key to the ciphertext, and compute the probability of the resulting letter sequence using a combined language model that incorporates both character-level and word-level information. With unigram, bigram, and trigram language models over both words and characters trained on a large corpus, n-gram models of different orders are combined by deleted interpolation (Jelinek and Mercer, 1980). The smoothed word trigram probability $\hat{P}$ is:

$$\hat{P}(w_k|w_{k-2}w_{k-1}) = \lambda_1 P(w_k) + \lambda_2 P(w_k|w_{k-1}) + \lambda_3 P(w_k|w_{k-2}w_{k-1}),$$

such that the λs sum to 1. The linear coefficients are determined by successively deleting each trigram from the training corpus and maximizing the likelihood of the rest of the corpus (Brants, 2000). The probability of text $s = w_1, w_2, \ldots, w_n$ according to the smoothed word language model is:

$$P_W(s) = P(w_1^n) = \prod_{k=1}^{n} \hat{P}(w_k|w_{k-2}w_{k-1}).$$

The unigram, bigram, and trigram character language models are combined in a similar manner to yield $P_C(s)$. The final score is then computed as a linear combination of the log probabilities returned by both character and word components:

$$\text{score}(s) = \chi \log P_C(s) + (1 - \chi) \log P_W(s),$$

with the value of χ optimized on a development set. The score of a key is taken to be the score of the decipherment that it produces.

The handling of the OOV words is an important feature of the key scoring algorithm. An incomplete decipherment typically contains many OOV words, which according to the above equations would result in probability $P_W(s)$ being zero. In order to avoid this problem, we replace all OOV words in a decipherment with a special UNKNOWN token for the computation of $P_W(s)$. Prior to deriving the word language models, a sentence consisting of a single UNKNOWN token is appended to the training corpus. As a result, word n-grams that include an UNKNOWN token are assigned very low probability, encouraging the solver to favor decipherments containing fewer OOV words.

4 Key Mutation

The process of generating candidate keys can be viewed as constructing a search tree, where a modified key is represented as a child of an earlier key. The root of the tree contains the initial key, which is generated according to simple frequency analysis (i.e., by mapping the nth most common ciphertext character to the nth most common character in the training corpus). We repeatedly spawn new tree leaves by modifying the keys of current leaves, while ensuring that each node in the tree has a unique key. The fitness of each new key is evaluated by scoring the resulting decipherment, as described in Section 3. At the end of computation, we return the key with the highest score as the solution.

There are an exponential number of possible keys, so it is important to generate new keys that are likely to achieve a higher score than the current key. We exploit this observation: any word n-gram can be represented as a pattern, or sequence, of repeated letters (Table 1). We identify the pattern represented by each word n-gram in the ciphertext, and find a set of *pattern-equivalent* n-grams from the training corpus. For each such n-gram, we generate a corresponding new key from the current key by performing a sequence of transpositions.

Pattern	p-equivalent n-grams
ABCD	said, from, have
ABCC	will, jazz, tree
ABCA	that, says, high
ABCD EFG	from you, said the
ABCA ABD	that the, says sam
ABC DEEFGBCHICG	the bookshelves

Table 1: Examples of pattern-equivalent n-grams.

Pattern-equivalence (abbreviated as p-equivalence) induces an equivalence relation between n-grams (Moore et al., 1999). Formally, two n-grams u and v are p-equivalent ($u \stackrel{p}{=} v$) if and only if they satisfy the following three conditions, where ␣ stands for the space character:

1. $|u| = |v|$
2. $\forall i$: $u_i = \text{␣} \Leftrightarrow v_i = \text{␣}$
3. $\forall i, j$: $u_i = u_j \Leftrightarrow v_i = v_j$

For example, consider ciphertext ‘ZXCZ ZXV’. Adopting *“that”*, which is p-equivalent to ‘ZXCZ’, as a temporary decipherment of the first word, we generate a new key in which Z maps to *t*, X to *h*, and C to *a*. This is accomplished by three letter-pair transpositions in the parent key, producing a child key where ‘ZXCZ’ deciphers to *“that”*. Further keys are generated by matching ‘ZXCZ’ to other p-equivalent words, such as *“says”* and *“high”*. The process is repeated for the second word ‘ZXV’, and then for the entire bigram ‘ZXCZ ZXV’. Each such match induces a series of transpositions resulting in a new key. Leaf expansion is summarized in Figure 3.

In order to avoid spending too much time expanding a single node, we limit the number of replacements for each n-gram in the current decipherment to the k most promising candidates, where k is a parameter optimized on a development set. Note that n-grams excluded in this way may still be included as part of a higher-order n-gram. For example, if the word *birddog* is omitted in favor of more promising candidates, it might be considered as a part of the bigram *struggling birddog*.

Two distinct modes of ranking the candidate n-grams are used throughout the solving process. In the initial stage, n-grams are ranked according to the score computed using the method described in Section 3. Thus, the potential replacements for a given ciphertext n-gram are the highest scoring p-equivalent n-grams from the training corpus regardless of the form of the decipherment implied by the current key. Afterwards, candidates are ranked according to their Hamming distance to the current decipherment, with score used only to break ties. This two-stage approach is designed to exploit the fact that the solver typically gets closer to the correct decipherment as the search progresses.

```
1: Root contains InitialKey
2: for m iterations do
3:     recursively select optimal Path from Root
4:     Leaf = last node of Path
5:     BestLeaf = EXPAND(Leaf, CipherText)
6:     append BestLeaf to Path
7:     Max = Path node with the highest score
8:     assign score of Max to all nodes in Path
```

Figure 2: MCTS for decipherment.

5 Tree Search

Nuhn and Ney (2013) show that finding the optimal decipherment with respect to a character bigram model is NP-hard. Since our scoring function incorporates a language model score, choosing an appropriate tree search technique is crucial in order to minimize the number of search errors, where the score of the returned solution is lower than the score of the actual plaintext. In this section we describe two search algorithms: an adaptation of Monte Carlo Tree Search (MCTS), and a version of beam search.

5.1 Monte Carlo Tree Search

MCTS is a search algorithm for heuristic decision making. Starting from an initial state that acts as the root node, MCTS repeats these four steps: (1) **selection** – starting from the root, recursively pick a child until a leaf is reached; (2) **expansion** – add a set of child nodes to the leaf; (3) **simulation** – simulate the evaluation of the leaf node state; (4) **backpropagation** – recursively ascend to the root, updating the simulation result at all nodes on this path. This process continues until a state is found which passes a success threshold, or time runs out.

Previous work with MCTS has focused on board games, including Hex (Arneson et al., 2010) and Go (Enzenberger et al., 2010), but it has also been employed for problems unrelated to game playing (Previti et al., 2011). Although originally designed for two-player games, MCTS has also been applied to single-agent search (Browne et al., 2012). Inspired by such single-agent MCTS methods (Schadd et al., 2008; Matsumoto et al., 2010; Méhat and Cazenave, 2010), we frame decipherment as a single-player game with a large branching factor, in which the simulation step is replaced with a heuristic scoring function. Since we have no way of verifying that the current decipherment is correct, we stop after performing m iterations. The value of m is determined on a development set.

The function commonly used for comparing nodes in the tree is the upper-confidence bound (UCB) formula for single-player MCTS (Kocsis and Szepesvári, 2006). The formula augments our scoring function from Section 3 with an additional term:

$$UCB(n) = \text{score}(n) + C\sqrt{\frac{ln(v(p(n)))}{v(n)}}$$

where $p(n)$ is the parent of node n, and $v(n)$ is the number of times that n has been visited. The second term favors nodes that have been visited relatively infrequently in comparison with their parents. The value of C is set on a development set.

Figure 2 summarizes our implementation. Each iteration begins by finding a path through the tree that is currently optimal according to the UCB. The path begins at the root, includes a locally optimal child at each level, and ends with a leaf. The leaf is expanded using the function EXPAND shown in Figure 3. The highest-scoring of the generated children is then appended to the optimal path. If the score of the new leaf (*not* the UCB) is higher than the score of its parent, we backpropagate that score to all nodes along the path leading from the root. This encourages further exploration along all or part of this path.

5.2 Beam Search

Beam search is a tree search algorithm that uses a size-limited list of nodes currently under consideration, which is referred to as the beam. If the beam is full, a new node can be added to it only if it has a higher

```
1: function EXPAND(Leaf, CipherText)
2:     for all word n-grams w in CipherText do
3:         for k best w' s.t. w' ≡^p w do
4:             NewLeaf = Modify(Leaf, w ↦ w')
5:             if NewLeaf not in the tree then
6:                 add NewLeaf as a child of Leaf
7:             if score(NewLeaf) > score(BestLeaf) then
8:                 BestLeaf = NewLeaf
9:     return BestLeaf
```

Figure 3: Leaf expansion.

score than at least one node currently in the beam. In such a case, the lowest-scoring node is removed from the beam and any further consideration.

Nuhn et al. (2013) use beam search for decipherment in their character-based approach. Starting from an empty root node, a partial key is extended by one character in each iteration, so that each level of the search tree corresponds to a unique ciphertext symbol. The search ends when the key covers the entire ciphertext.

By contrast, we apply beam search at the word n-gram level. The EXPAND subroutine defined in Figure 3 is repeatedly invoked for a specified number of iterations (a tunable parameter). In each iteration, the algorithm analyzes a set of word n-gram substitutions, which may involve multiple characters, as described in Section 4. The search stops early if the beam becomes empty. On short ciphers (32 characters or less), the best solution is typically found within the first five iterations, but this can only be confirmed after the search process is completed.

6 Experiments

In order to evaluate our approach and compare it to previous work, we conducted several experiments. We created three test sets of variable-length ciphers: (1) with spaces, (2) without spaces, and (3) with spaces and added encipherment noise. In addition, we tested our system on Serbian Cyrillic, and the Gold Bug cipher.

We derive our English language models from a subset of the New York Times corpus (LDC2003T05) containing 17M words. From the same subset, we obtain letter-frequency statistics, as well as the lists of p-equivalent n-grams. For comparison, Ravi and Knight (2008) use 50M words, while Nuhn et al. (2013) state that they train on a subset of the Gigaword corpus without specifying its size.

6.1 Substitution Ciphers

Following Ravi and Knight (2008) and Nuhn et al. (2013), we test our approach on a benchmark set of ciphers of lengths, 2, 4, 8, ..., 256, where each length is represented by 50 ciphers. The plaintexts are randomly extracted from the Wikipedia article on *History*, which is quite different from our NYT training corpus. Spaces are preserved, and the boundaries of the ciphers match word boundaries.

Figure 4 shows the decipherment error rate of the beam-search version of our algorithm vs. the published results of the best-performing variants of Ravi and Knight (2008) and Nuhn et al. (2013): letter 3-gram and 6-gram, respectively. The decipherment error rate is defined as the ratio of the number of incorrectly deciphered characters to the length of the plaintext. Our approach achieves a statistically significant improvement on ciphers of length 8 and 16. Shorter ciphers are inherently hard to solve, while the error rates on longer ciphers are close to zero. Unfortunately, Nuhn et al. (2013) only provide a graph of their error rates, which in some cases prevents us from confirming the statistical significance of the improvements (c.f. Table 2).

Examples of decipherment errors are shown in Table 3. As can be seen, the proposed plaintexts are often perfectly reasonable given the cipher letter pattern. The solutions proposed for very short ciphers are usually high-frequency words; for example, the 2-letter ciphers matching the pattern 'AB'

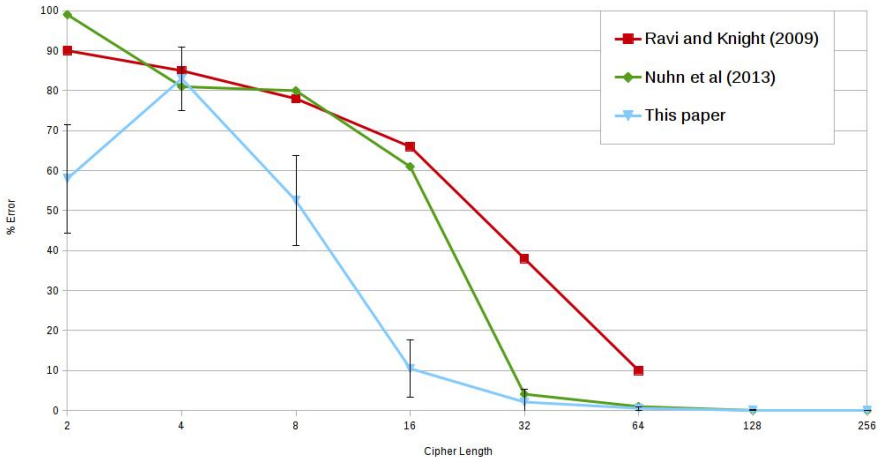

Figure 4: Average decipherment error rate as a function of cipher length on the Wikipedia test set.

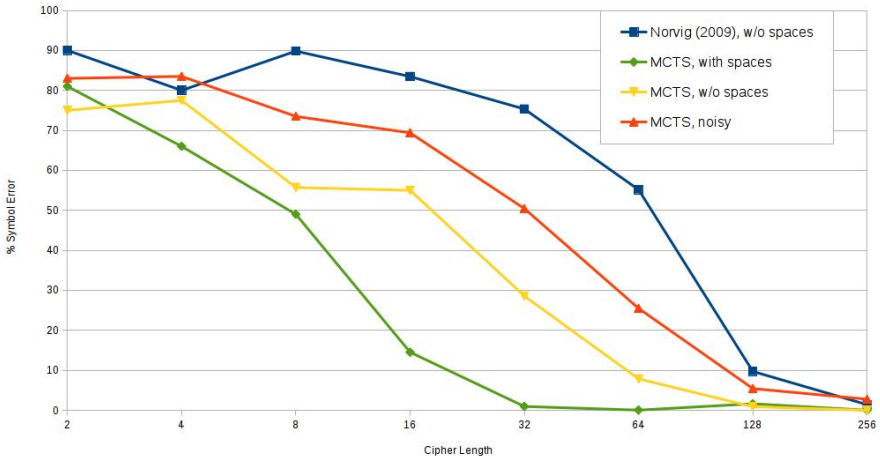

Figure 5: Average decipherment error rate as a function of cipher length on the NYT test set.

	Wikipedia			NYT				
	with spaces			with spaces		no spaces	noisy

4	83.00	83.00	83.00	66.00	66.00	77.50	83.50	83.50
8	52.50	52.50	52.50	49.00	49.00	55.71	73.50	73.50
16	10.50	12.62	18.50	13.50	14.50	55.00	69.75	69.38
32	2.12	6.12	10.88	0.88	0.94	28.57	46.81	50.44
64	0.56	0.72	2.50	0.03	0.03	7.85	16.66	25.47
128	0.14	0.16	0.16	0.00	1.61	0.87	5.20	5.41
256	0.00	0.00	0.10	0.02	0.02	0.00	2.73	2.75

Table 2: Average decipherment error rate of our solver as a function of cipher length on the Wikipedia and the NYT test sets.

Cipher length	Cipher pattern	Actual plaintext	Decipherment
2	AB	to	of
4	ABCD	from	said
4	ABBC	look	been
8	ABCDCEFG	slobodan	original
8	ABCDE FG	filed by	would be
16	ABCCDEE BFG HBCI	jarrett and mark	carroll and part
16	ABCDE FGCHA IJKL	group along with	drugs would make

Table 3: Examples of decipherment errors.

are invariably deciphered as *"of"*. The errors in ciphers of length 32 or more tend to be confined to individual words, which are often OOV names.

6.2 Beam Search vs. MCTS

The error rates of the two versions of our algorithm are very close, with a few exceptions (Table 2). Out of 400 ciphers with spaces in the Wikipedia test set, the MCTS variant correctly solves 260 out of 400 ciphers, compared to 262 when beam search is used. In 9 MCTS solutions and 3 beam search solutions, the score of the proposed decipherment is lower than the score of the actual plaintext, which indicates a search error.

By setting the beam size to one, or the value of C in MCTS to zero, the two search techniques are reduced to *greedy* search. As shown in Table 2, in terms of accuracy, greedy search is worse than MCTS on the lengths of 16, 32, and 64, and roughly equal on other lengths. This suggests that an intelligent search strategy is important for obtaining the best results.

In terms of speed, the MCTS version outperforms beam search, thanks to a smaller number of expanded nodes in the search tree. For example, it takes on average 9 minutes to solve a cipher of length 256, compared to 41 minutes for the beam search version. Direct comparison of the execution times with the previous work is difficult because of variable computing configurations, as well as the unavailability of the implementations. However, on ciphers of the length of 128, our MCTS version takes on average 197 seconds, which is comparable to 152 seconds reported by Nuhn et al. (2013), and faster than our reimplementation of the bigram solver of Ravi and Knight (2008) which takes on average 563 seconds. The trigram solver of Ravi and Knight (2008) is even slower, as evidenced by the fact that they report no corresponding results on ciphers longer than 64 letters.

6.3 Noisy Ciphers

Previous work has generally focused on noise-free ciphers. However, in real-life applications, we may encounter cases of imperfect encipherment, in which some characters are incorrectly mapped. Corlett and Penn (2010) identify the issue of noisy ciphers as a worthwhile future direction. Adding noise also increases a cipher's security, as it alters the pattern of letter repetitions in words. In this section, we evaluate the robustness of our approach in the presence of noise.

In order to quantify the effect of adding noise to ciphers, we randomly corrupt $log_2(n)$ of the ciphertext letters, where n is the length of the cipher. Our results on such ciphers are shown in Table 2. As expected, adding noise to the ciphertexts increases the error rate in comparison with ciphers without noise. However, our algorithm is still able to break most of the ciphers of length 64 and longer, and makes only occasional mistakes on ciphers of length 256. Beam search is substantially better than MCTS only on lengths of 32 and 64. These results indicate that our word-oriented approach is reasonably robust with respect to the presence of noise.

6.4 Croatian and Serbian

We further test the robustness of our approach by performing an experiment on decipherment of an unknown script. For this experiment, we selected Croatian and Serbian, two closely related languages

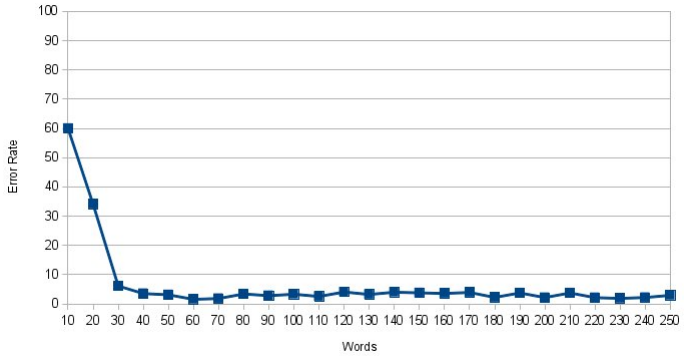

Figure 6: The decipherment error rate on a Serbian sample text as a function of the ciphertext length.

that are written in different scripts (Latin and Cyrillic). The correspondence between the two script alphabets is not exactly one-to-one: Serbian Cyrillic uses 30 symbols, while Croatian Latin uses 27. In particular, the Cyrillic characters љ, њ, and џ are represented in the Latin script as digraphs *lj*, *nj*, and *dž*. In addition, there are differences in lexicon and grammar between the two languages, which make this task a challenging case of noisy encipherment.

In the experiment, we treat a short text in Serbian as enciphered Croatian and attempt to recover the key, which in this case is the mapping between the characters in the two writing scripts. Each letter with a diacritic is considered as different from the same letter with no diacritic. We derive the word and character language models from the Croatian part of the ECI Multilingual Corpus, which contains approximately 720K word tokens. For testing, we use a 250-word, 1583-character sample from the Serbian version of the Universal Declaration of Human Rights.

сва људска бића рађају се слободна и једнака у достојанству и правима она су обдарена разумом и свешћу и треба једни према другима
sva šudska bi**h**a ra**l**aju se sžobodna i jednaka u dostojanstvu i pravima ona su obdarena ra**č**umom i sve**ch**u i treba jedni prema dru**z**ima

Table 4: Serbian Cyrillic deciphered as Croatian. The decipherment errors are shown in boldface.

The decipherment error rate on the Serbian ciphertext drops quickly, leveling at about 3% at the length of 50 words (Figure 6). The residual error rate reflects the lack of correct mapping for the three Serbian letters mentioned above. As can be seen in Table 4, the actual decipherment of a 30-word ciphertext contains only a handful of isolated errors. On the other hand, a pure frequency-based approach fails on this task with a mapping error rate close to 90%.

6.5 Ciphers Without Spaces

Removing spaces that separate words is another way of increasing the security of a cipher. The assumption is that the intended recipient, after applying the key, will still be able to guess the location of word boundaries, and recover the meaning of the message. We are interested in testing our approach on such ciphers, but since it is dependent on word language models, we need to first modify it to identify word boundaries. In particular, the two components that require word boundaries are the scoring function (Section 3), and the search tree node expansion (Section 5).

In order to compute the scoring function, we try to infer word boundaries in the current decipherment using the following simple greedy algorithm. The current decipherment is scanned repeatedly from left to right in search for words of length L, where L gradually decreases from the length of the longest word in the training corpus, down to the minimal value of 2. If a word is found, the process is applied recursively to both remaining parts of the ciphertext. We use a fast greedy search instead of a slower but more accurate dynamic programming approach as this search must be executed each time a key is evaluated.

In the search tree node expansion step, for each substring of length at least 2 in the current decipherment, we attempt to replace it with all pattern-equivalent n-grams (with spaces removed). As a result,

53‡‡†305))6*;4826)4‡.)4‡);806*;48†8¶60))85;1‡(;:‡*8†83(88)5*†;46(;88*96*?;8)*‡(;485);5*†2:*‡(;4956*2(5*-4)8¶8*;4069285);)6†8)4

Table 5: The beginning of the Gold Bug cipher and its decipherment.

each key spawns a large number of children, increasing both time and memory usage. Overall, the modified algorithm is as much as a hundred times slower than the original algorithm. However, when MCTS is used as search method, we are still able to perform the decipherment in reasonable time.

For testing, we remove spaces from both the plaintexts and ciphertexts, and reduce the number of ciphers to 10 for each cipher length. Our results, shown in Figure 5, compare favorably to the solver of (Norvig, 2009), which is designed to work on ciphers without spaces.

The final test of our decipherment algorithm is the cipher from *The Gold Bug* by Edgar Alan Poe. In that story, the 204-character cipher gives the location of hidden treasure. Our implementation finds a completely correct solution, the beginning of which is shown in Table 5. Both experiments reported in this section confirm that our word-based approach works well even when spaces are removed from ciphers.

7 Deniable Encryption

In one of Stanisław Lem's novels, military cryptographers encipher messages in such a way that the ciphertext appears to be plain text (Lem, 1973). Canetti et al. (1997) investigate a related idea, in which the ciphertext "looks like" an encryption of a plaintext that is different from the real message. In the context of monoalphabetic substitution ciphers, we define the task as follows: given a message, find an encipherment key yielding a ciphertext that resembles natural language text. For example, *"game with planes*" is a deniable encryption of the message *"take your places*" (the two texts are p-equivalent).

We applied our solver to a set of sentences from the text of *Nineteen Eighty-Four*, treating each sentence as a ciphertext. In order to ensure that the alternative plaintexts are distinct from the original sentences, we modified our solver to disregard candidate keys that yield a solution containing a content word from the input. For example, *"fine hours*" was not deemed an acceptable deniable encryption of *"five hours*". With this condition added, alternative plaintexts were produced for all 6531 sentences. Of these, 1464 (22.4%) were determined to be composed entirely of words seen in training. However, most of these deniable encryptions were either non-grammatical or differed only slightly from the actual plaintexts. It appears that substitution ciphers that preserve spaces fail to offer sufficient flexibility for finding deniable encryptions.

In the second experiment, we applied our solver to a subset of 757 original sentences of length 32 or less, with spaces removed. The lack of spaces allows for more flexibility in finding deniable encryptions. For example, the program finds *"draft a compromise*" as a deniable encryption of *"zeal was not enough*". None of the produced texts contained out-of-vocabulary words, but most were still ungrammatical or nonsensical. Allowing for some noise to be introduced into the one-to-one letter mapping would likely result in more acceptable deniable encryptions, but our current implementation can handle noise only on the input side.

8 Conclusion

We have presented a novel approach to the decipherment of monoalphabetic substitution ciphers that combines character and word-level language models. We have proposed Monte Carlo Tree Search as a fast alternative to beam search on the decipherment task. Our experiments demonstrate significant improvement over the current state of the art. Additional experiments show that our approach is robust in handling ciphers without spaces, and ciphers with noise, including the practical application of recovering transliteration mappings between Serbian and Croatian.

In the future, we would like to extend our approach to handle homophonic ciphers, in which the one-to-one mapping restriction is relaxed. Another interesting direction is developing algorithms to generate syntactically correct and meaningful deniable encryptions.

Abstract

This paper extends existing word segmentation models to take non-linguistic context into account. It improves the token F-score of a top performing segmentation models by 2.5% on a 27k utterances dataset. We posit that word segmentation is easier in-context because the learner is not trying to access irrelevant lexical items. We use topics from a Latent Dirichlet Allocation model as a proxy for "activities" contexts, to label the *Providence* corpus. We present Adaptor Grammar models that use these context labels, and we study their performance with and without context annotations at test time.

1 Introduction and Previous Works

Segmentation of the speech stream into lexical units plays a central role in early language acquisition. Because words are generally not uttered in isolation, one of the first task for infants learning a language is to extract the words that make up the utterances they hear. Experimental research has shown that infants are able to segment fluent speech into word-like units within the first year of life (Jusczyk and Aslin, 1995). How does this ability emerge? There is evidence that infants use a broad array of linguistic cues to perform word segmentation (e.g., phonotactics (Jusczyk et al., 1993a), prosodic information (Jusczyk et al., 1993b), statistical regularities (Saffran et al., 1996)). Past experimental and modeling research on speech segmentation has mainly focused on linguistic cues, treating them as independent from other non-linguistic cues naturally occurring in the child learning environment. Yet, language appears in context and is constrained by the events occurring in the daily life of the child. For example, during an eating event one is most likely to speak about food, while during a zoo-visit event, people are more likely to talk about the animals they see. Activity contexts may provide a natural structure to speech that would be readily be accessible to children. A recent study using dense recordings of a single child's language development (Roy et al., 2006) showed that words appearing in specific activity contexts are learned faster (Roy et al., 2012). Relatedly, Johnson et al. (2010) showed that Adaptor Grammars (AGs) performed better on a segmentation task when the model has access to a hand-annotated set of objects present in the environment, that it can use to learn simultaneously word-object associations (see also (Frank et al., 2009)). This supports the view that integrating multiple sources of information, linguistic and non-linguistic, can improve learning.

Following this idea, we posit that information from the broader context in which a word has been uttered may simplify the learning problem faced by the child. In particular, our hypothesis postulates that speech segmentation is easier when using vocabularies that are related to a specific activity (eating,

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2326–2334, Dublin, Ireland, August 23-29 2014.

Table 1: Most probable words in the 7 final topics

milk	circle	tree	piece	today	hair	phone
butter	triangle	fish	train	day	head	puzzle
≈food	≈shapes	≈playing	≈toys	≈time	≈drawing	"garbage"

playing...), or place (kitchen, bedroom...). To evaluate this hypothesis, we applied topic modeling (Blei et al., 2003) to automatically derive activity contexts on a corpus of child directed speech, the *Providence* corpus (Demuth et al., 2006), and tested the influence of such topics on a word segmentation task extending the AG models used in (Börschinger et al., 2012). We found that a model augmented with the assumption that words are dependent upon the topic of the discourse (as a proxy for activity context) performs better than the same model without access to the discourse topic. This suggests that the broader context in which sentences are uttered may help in the word segmentation process, and could presumably be used at various stages of language development.

The paper is structured as follows. Section 2 presents a novel approach to augment a corpus with contextual annotations derived from topic models. Section 3 quickly explains Adaptor Grammars, the framework that we used to express all our models. Section 4 presents all the models that were used in the results. Section 5 describes the Providence corpus and the experimental setup. Section 6 shows our quantitative and qualitative results. Finally, we discuss the implications for models of language learning.

2 Topics as Proxies for Contexts

Roy et al. (2012) found high correlations between human-annotated activity contexts and topics from a latent Dirichlet allocation model (LDA) (Blei et al., 2003), thus showing that using topics as proxies for contexts is a sound approach. Topic modeling infers a topic distribution for each "document" (a bag of words) in the corpus. Since "documents" were not annotated in our corpus, we developed the following 3-step approach to automatically segment it into documents.

Firstly, for *all* the children of the Providence corpus, we used recording sessions as hard document boundaries. We considered as a "possible document" every contiguous sequence of sentences separated by at least 10 seconds of silence, according to the orthographic transcript. We also identified "possible documents" using cues such as "bye/hi", indicating a change of participants. This segmentation resulted in an over-segmented corpus (compared to context switches), yielding a total of $16,742$ documents.

Secondly, we used the *gensim* software (Řehůřek and Sojka, 2010) to train a topic model (LDA)[1], and get the topic distributions for each of these documents. We used the symmetric KL-divergence to measure the distance between two topic distributions before and after a "possible document" boundary. If the distance was above a threshold, we considered this boundary as a document boundary. Otherwise we merged both "possible documents" through this silence. The threshold was set empirically to discriminate between two topic distributions that correspond to different activity contexts. After this step, we assume that each of the resulting $8,634$ documents maps to an activity context.

Thirdly, we applied LDA again on this new segmentation to get the topic distribution, hence the activity context, of each document. The number of topics is qualitatively chosen to correspond to the number of main activity contexts (eating / playing / drawing / etc.) that occur in the Providence dataset (we used 7 topics), the resulting most topic specific words are shown in Table 1. Finally, for each document, we got a distribution on topics, and we annotated the document with the most probable topic. By doing that, we throw away graded information about the distribution on topics for each document. We could make use of the full distribution, but here we are only interested in the most probable topic as a proxy for activity context. We do not posit that the infants learn the topic models on linguistic cues while bootstrapping speech and segmentation, but rather that they get activity context from non-linguistic cues.

[1]We did LDA only on nouns (as they contain most of the semantics), weighted by TF-IDF.

3 Adaptor Grammars

Adaptor Grammars (Johnson et al., 2007) are an extension of probabilistic context-free grammars (PCFGs) that learn probability of entire subtrees as well as probabilities of rules. A PCFG (N, W, R, S, θ) consists of a start symbol S, N and W disjoints sets of nonterminals and terminal symbols respectively. R is a set of rules producing elements of N or W. Finally, θ is a set of distributions over the rules $R_X, \forall X \in N$ (R_X are the rules that expand X). An AG $(N, W, R, S, \theta, A, C)$ extends the above PCFG with a subset ($A \subseteq N$) of adapted nonterminals, each of them ($X \in A$) having an associated adaptor ($C_X \in C$). An AG defines a distribution over trees $G_X, \forall X \in N \cup W$. If $X \notin A$, then G_X is defined exactly as for a PCFG:

$$G_X = \sum_{\substack{X \to Y_1 \dots Y_n \\ \in R_X}} \theta_{X \to Y_1 \dots Y_n} \mathrm{TD}_X(G_{Y_1} \dots G_{Y_n})$$

With $\mathrm{TD}_X(G_1 \dots G_n)$ the distribution over trees with root node X and each subtree $t_i \sim G_i$ i.i.d. If $X \in A$, then there is an additional indirection (composition) with the distribution H_X:

$$G_X = \sum_{\substack{X \to Y_1 \dots Y_n \\ \in R_X}} \theta_{X \to Y_1 \dots Y_n} \mathrm{TD}_X(H_{Y_1} \dots H_{Y_n})$$

$$H_X \sim C_X(G_X)$$

We used C_X adaptors following the Pitman-Yor process (PYP) (Perman et al., 1992; Teh, 2006) with parameters a and b. The PYP generates (Zipfian) type frequencies that are similar to those that occur in natural language (Goldwater et al., 2011). Metaphorically, if there are n customers and m tables, the $n+1$th customer is assigned to table z_{n+1} according to (δ_k is the Kronecker delta function):

$$z_{n+1} | z_1 \dots z_n \sim \frac{ma + b}{n + b} \delta_{m+1} + \sum_{k=1}^{m} \frac{n_k - a}{n + b} \delta_k$$

For an AG, this means that adapted non-terminals ($X \in A$) either expand to a previously generated subtree ($T(X)_k$) with probability proportional to how often it was visited (n_k), or to a new subtree ($T(X)_{m+1}$) generated through the PCFG with probability proportional to $ma + b$.

4 Word segmentation models

4.1 Unigram model

This most basic model just generates words as sequences of phonemes. As $\underline{Word}$ is underlined, it means it is adapted, and thus we learn a "word unit -like" vocabulary. $Phon$ is a nonterminal that expands to all the phonemes of the language under consideration.

$$Sentence \to Word^+$$
$$\underline{Word} \to Phon^+$$

where :

$$Word^+ \quad \Leftrightarrow \begin{cases} Words \to Word \\ Words \to Word\, Words \end{cases}$$

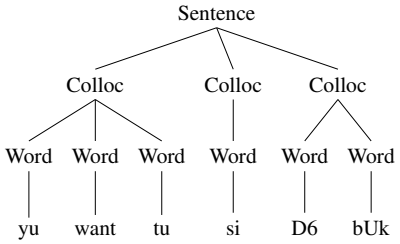
4.2 Collocations and Syllabification

The *baseline* that we are using is commonly called the "colloc-syll" model (Johnson, 2008; Börschinger et al., 2012) and is reported at 78% token F-score on the standard Brent version of the Bernstein-Ratner corpus corpus (Johnson, 2008). It posits that sentences are collocations of words, and words are composed of syllables. (Goldwater et al., 2009) showed how an assumption of independence between words (a unigram model) led to under-segmentation. So, above the $Word$ level, we take the collocations (co-occurring sequences) of words into account.

Furthermore, there is evidence that 8-month-old infants track syllable frequencies (Saffran et al., 1996), and the "colloc-syll" model can take that into account. $Word$ splits into general syllables and initial- or final- specific syllables. Syllables consist of onsets or codas (producing consonants), and nuclei (vowels). Onsets, nuclei and codas are adapted, thus allowing this model to memorize sequences or consonants or sequences of vowels, dependent on their position in the word. Consonants and vowels are the pre-terminals, their derivation is specified in the grammar into phonemes of the language.

$$Sentence \rightarrow Colloc^{+}$$
$$\underline{Colloc} \rightarrow Word^{+}$$
$$\underline{Word} \rightarrow StructSyll$$

For notations purposes, all this syllabification is appended after $Word$ by $\underline{Word} \rightarrow StructSyll$. All details about the collocations and syllabification grammars can be found in (Johnson, 2008). Here is an example of a (good) parse of "`yuwanttusiD6bUk`" with this model, skipping the $StructSyll$ derivations:



4.3 Including topics (contexts)

To allow for the model to make use of the topics (used as proxies for contexts), we modify the grammar by prefixing utterances with topic number (similarly to (Johnson et al., 2010)), $\forall K \in \#topics$:

$$Sentence \rightarrow \_tK\ Colloc^{+}_{tK}$$
$$\underline{Colloc_{tK}} \rightarrow Word^{+}_{tK}$$

For each $\underline{Word_{tK}}$, we can derive it into a common adapted $\underline{Word}$ by $\underline{Word_{tK}} \rightarrow Word$. Consider this lower level adaptor ($\underline{Word}$): it learns a shared vocabulary independently of the topic (all contexts that will derive `b U k` will increment the `Word(b U k)` pseudo-count). This $Word$-hierarchical model is called *share vocab*.

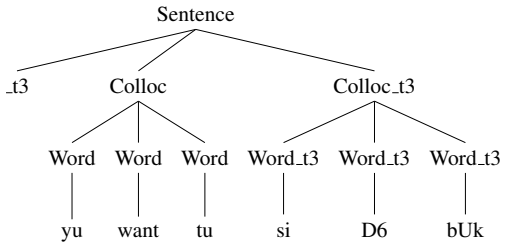
Alternatively, we can learn a separate vocabulary for each topic, by having directly: $\underline{Word_{tK}} \rightarrow StructSyll$ (note that all words then share the same syllabic structure). Words are split across different topics and need to be adapted for each topic in which they appear. This flat structure vocabulary model is called *split vocab*.

4.4 Allowing for non context-specific words

Sentences are not composed only of context-specific words, thus we need a third type of extension that allows for topic-independent and topic-specific words to mix. For this, we add topic-independent types of $Colloc$ and $Word$ that can be used across all topics, but we force each sentence to have at least one topical collocation:

$$\begin{aligned}
Sentence &\rightarrow _tK\ (Colloc^{+}|Colloc^{+}_{tK})\ Colloc^{+}_{tK} \\
&\quad\ (Colloc^{+}|Colloc^{+}_{tK}) \\
\underline{Colloc_{tK}} &\rightarrow Word^{+}_{tK} \\
\underline{Colloc} &\rightarrow Word^{+} \\
\underline{Word_{tK}} &\rightarrow StructSyll \\
\underline{Word} &\rightarrow StructSyll
\end{aligned}$$

Parentheses denote that these terms are optionals, and "|" denotes "or". Both $\underline{Word_{tK}}$ and $\underline{Word}$ are adapted, but this time on the same level of hierarchy. This model allows the use of both topic-specific and common words in sentences, and it learns $\#topics + 1$ vocabularies. We call this model *with common*. An example of a correct parse with this model is given by:



5 Experimental setup

The *Providence* corpus (Demuth et al., 2006) consists of audio and video, weekly or bi-weekly, recordings of 6 monolingual English-speaking children home interactions. Each recording is approximatively 1 hour long. This corpus spans approximatively from their first to third year. We used the whole corpus to extract the topics to get more stable and general activity contexts. For all the following results, we used only the Naima portion between 11 months and 24 months, consisting in 26,425 utterances (sentences) and 135,389 tokens (words). The input consist in DARPABET-encoded sequences of phonemes with about 4200 word-types in the Naima subset. We followed the same preparation procedure as in (Börschinger et al., 2012), where more details about the corpus can be found.

We used the last version of Mark Johnson's Adaptor Grammars software[2]. All the additional code (preparation, topics, grammars, learning) to reproduce these experiments and results is freely available online[3], along with the datasets annotations derived from topic modeling[4]. For the adaptors, we used a $Beta(1, 1)$ (uniform) prior on the PYP a parameter, and a sparse $Gamma(100, 0.01)$ prior on the PYP b parameter. We ran 500 iterations (finishing at $\approx 0.05\%$ of log posterior variation between the lasts iterations) with several runs for each subset of the Naima dataset.

6 Results

6.1 Unsupervised words segmentation

Table 2: Mean (token and boundary) F-scores (f), precisions (p), and recalls (r) for different models depending on the size of dataset (age range).

months	baseline			share vocab			split vocab			with common		
token	f	p	r	f	p	r	f	p	r	f	p	r
11-12	**.80**	.79	.81	.77	.76	.78	.77	.75	.78	.77	.75	.78
11-15	.81	.81	.82	.76	.78	.75	.81	.79	.82	**.82**	.81	.83
11-19	.82	.82	.83	.77	.78	.76	.81	.81	.82	**.83**	.82	.84
11-22	.81	.82	.81	.77	.79	.75	.82	.81	.83	**.83**	.82	.84
boundary	f	p	r	f	p	r	f	p	r	f	p	r
11-12	**.90**	.88	.91	.88	.87	.89	.87	.85	.90	.88	.85	.90
11-15	**.91**	.91	.92	.89	.91	.86	**.91**	.89	.92	**.91**	.90	.93
11-19	**.92**	.92	.93	.90	.92	.88	**.92**	.91	.93	**.92**	.91	.94
11-22	.92	.93	.91	.90	.93	.87	.92	.91	.93	**.93**	.91	.94

The key metric of interest is the token F-score (harmonic mean of precision and recall of words). Table 2 gives all the scores for an increasingly large dataset (as in (Börschinger et al., 2012)). Figure 1 shows the month-by-month evolution of the token F-score of the different models. We can see that

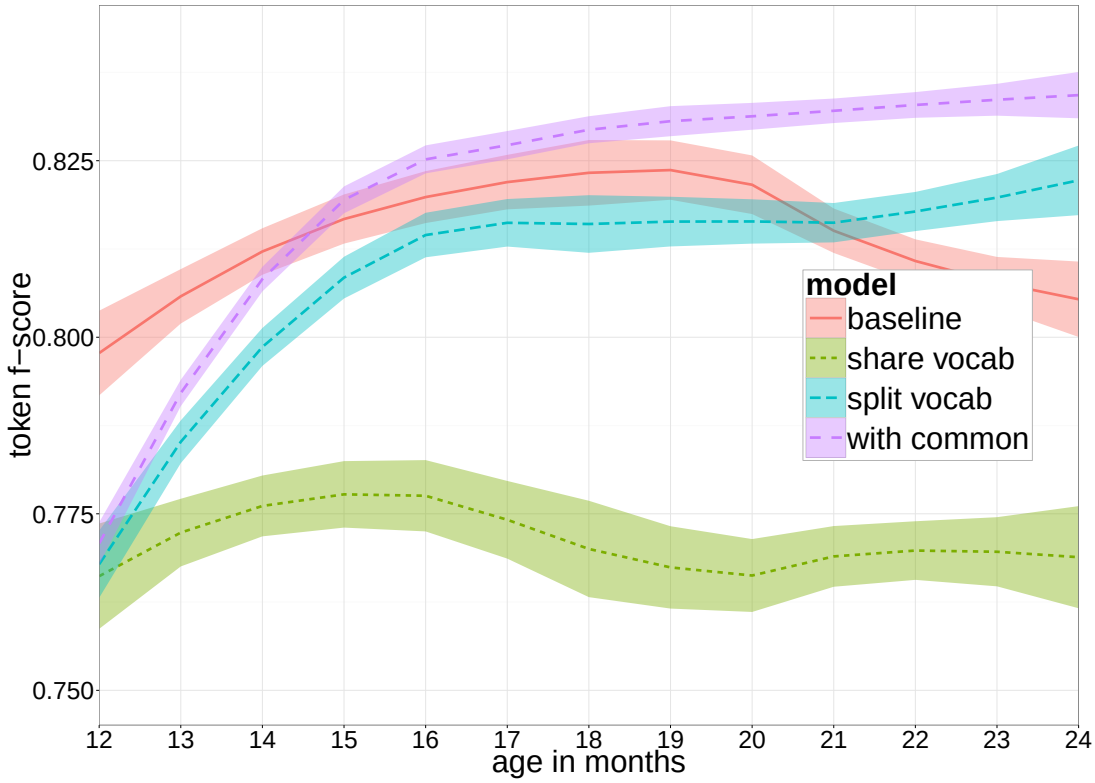
Figure 1: Token F-scores (and standard deviations) evolution with an increasingly bigger and richer dataset (11 months to "X-axis value" months), computed on 8 runs of 500 iterations per data point.



context-based models need more data to get good performances (several vocabularies to learn), but they seem more resilient to over-segmentation.

Preliminary results confirm the trend of *baseline* scores getting slowly worse at **25** and **26** months while *with common* and *split vocab* stabilize (not plotted here). We also tried models for which we can have the "common vocabulary" derived only at the level of the collocations (making topic-specific collocations topic-pure as in *split vocab* for instance), or only at the level of the words (allowing for topic-specific collocations deriving in only common words if needed). Both models are worse than *split vocab* and *with common*.

Using a shared global vocabulary while being able to learn (through adaptation) different topic-specific vocabularies does not seem to be a solution: *share vocab* performs worse than the *baseline*. Token recall and boundary recall are worse off (see Table 2), suggesting that fewer words are correctly adapted. Maybe that is because this is the only model with two levels of adapted word hierarchies ($\underline{Word_{tK}}$ and $\underline{Word}$). Sharing a lower-level vocabulary ($\underline{Word}$) still does not allow for context vocabularies ($\underline{Word_{tK}}$) to mix, thus is simply harder to train. Having only one vocabulary per context (*split vocab*) is a slight improvement over the *baseline*, even though it is not significant (95% confidence interval) before 22 months. Models allowing for both topic-specific vocabularies and a common vocabulary to be learned are the best: *with common* is significantly (95% confidence interval) better than the *baseline*, starting from 20 months (Figure 1). The improvement seems to be due to better token (and boundary) recall (Table 2), suggesting that more words are learned. By looking at their lexicons at 24 months, topic-dependent models have slightly larger lexicon recalls and worse lexicon precisions than the *baseline*. This means that the additional true word-types that they learn are more frequently correctly used than the false word-types (otherwise the token F-scores would be reversed, e.g. between *split vocab* and baseline).

Figure 2: Mean token F-scores (and standard deviations) on 20% held-out test data for 6 different random splits of Naima from 11 to 22 months, 500 iterations each. Grey for *baseline* on *test*, green and blue for context-dependent models on *test* and *no prefix* conditions respectively.

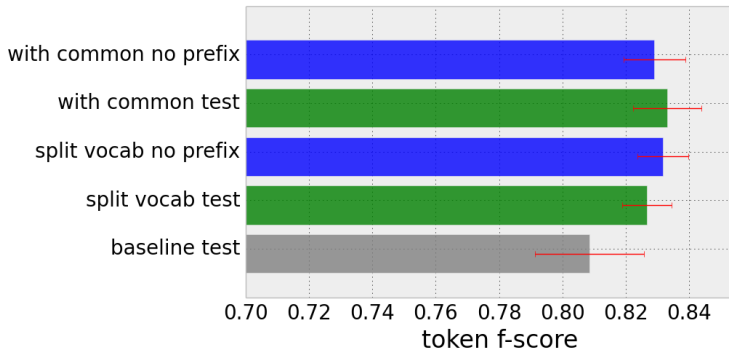


Table 3: Most probable words ($\propto P(word|topic = k)$) in the 7 recovered topics at test time without topic annotations (*no prefix* condition) for the *with common* model (we omitted phonemes clusters yielding non-words).

bread	elephant	lego	Michael	skinny	stick	bubble
delicious	owl	doctor	shorts	massage	remember	pasta
avocado	wearing	brush	towel	ostrich	track	spirals
porridge	turkey	change	shirts	nurse	forget	squirrels
raisin	haircut	squeeze	pirates	hammer	oink	thumb
biscuit	turtle	music	tangled	ruby	towed	pentagon
food	animals	play	clothes	(messy)	verbs	≈shapes

6.2 Recovery of the topics on held-out data

To check whether these models generalize to unseen utterances, and possibly unseen vocabulary, we looked at the scores of held-out data (80/20% train/test split of the Naima 11 to 22 months dataset). Token F-scores for this *test* condition are shown in green and grey in Figure 2. This separates low-frequency collocations to be used at test time and those seen at training time, both for context aware models and the basic *baseline* model. The F-scores show the same pattern as in the previous experiment, with context-aware models (*with common* and *split vocab* here) performing better than the *baseline*.

The topics are learned on the orthographic transcription of the whole *Providence* corpus (6 children), while we test only on the Naima dataset. Still, to check that these results are not simply due to additional information (leaked somehow in the form of the $\_tK$ prefix), we produced another held-out condition, without topic ($\_tK$) prefixes. Models can use topic-specific vocabularies learned during training, but they are given no context information at test time. Token F-scores for this *no prefix* condition are shown in blue (and grey for the baseline) in Figure 2. The fact that *no prefix* performance is on par with the *test* condition means that contextual cues are not only important at test time, but particularly so while learning the vocabulary. In other words, the model acquires its vocabularies making use of the additional context. In the *test* setting, it is evaluated on novel utterances for which additional context information is available. In the *no prefix* condition it is evaluated on novel utterances for which no additional context information is available. This means that topic-specific vocabulary learned during training is successfully used in a consistent way at test time. To confirm this qualitatively, we looked at the most probable words (after unsupervised segmentation from the phonemic input) in recovered topics at test time in the *no prefix* condition. They are shown in Table 3, and they exhibit some of the topics that were found on the orthographic transcript (as they are not limited to nouns, a topic for "verbs" appears).

7 Conclusion

We have shown that contextual information helps segmenting speech into word-like units. We used topic modeling as a proxy for richer contextual annotations, as (Roy et al., 2012) have shown high correlation between contexts and automatically derived topics. We modified existing Adaptor Grammar segmentation models (Johnson, 2008; Johnson and Goldwater, 2009), to be able to learn topic-specific vocabularies. We applied this approach to a large child directed speech corpus that was previously used for segmentation (Börschinger et al., 2012). Our model with the capacity to use both a topic-specific vocabulary and a common vocabulary (*with common*) produces better segmentation scores, ending up with at least 2.5% better absolute F-scores than its context-oblivious counterpart (*baseline*). More generally, both models that learn specialized vocabularies do not get worse F-scores with increasing data (Figure 1). Particularly, they seem to fix a well-known problem of previous models like "colloc-syll" (our *baseline*), that "overlearn" by over-segmenting frequent morphemes as single words (Börschinger et al., 2012). We have controlled for the additional information of giving the topic ($\_tK$), and we have found out that contextual information helps at training time.

It would be interesting to look into the link between semantics and syntax in recovered topics. Further work should integrate syntax (e.g. function words), stress cues and prosody from the audio signal (Börschinger and Johnson, 2014), use even less supervision for contexts, and be applied to other languages. We believe that language acquisition is not a simple sequential process and that segmentation, syntax, and word meaning bootstrap each others. This is only a first step towards integrating multiple sources of information and different modalities at all steps of language acquisition.

Abstract

The state-of-the-art methods used for relation classification are primarily based on statistical machine learning, and their performance strongly depends on the quality of the extracted features. The extracted features are often derived from the output of pre-existing natural language processing (NLP) systems, which leads to the propagation of the errors in the existing tools and hinders the performance of these systems. In this paper, we exploit a convolutional deep neural network (DNN) to extract lexical and sentence level features. Our method takes all of the word tokens as input without complicated pre-processing. First, the word tokens are transformed to vectors by looking up word embeddings[1]. Then, lexical level features are extracted according to the given nouns. Meanwhile, sentence level features are learned using a convolutional approach. These two level features are concatenated to form the final extracted feature vector. Finally, the features are fed into a softmax classifier to predict the relationship between two marked nouns. The experimental results demonstrate that our approach significantly outperforms the state-of-the-art methods.

1 Introduction

The task of relation classification is to predict semantic relations between pairs of nominals and can be defined as follows: given a sentence S with the annotated pairs of nominals e_1 and e_2, we aim to identify the relations between e_1 and e_2 (Hendrickx et al., 2010). There is considerable interest in automatic relation classification, both as an end in itself and as an intermediate step in a variety of NLP applications.

The most representative methods for relation classification use supervised paradigm; such methods have been shown to be effective and yield relatively high performance (Zelenko et al., 2003; Bunescu and Mooney, 2005; Zhou et al., 2005; Mintz et al., 2009). Supervised approaches are further divided into feature-based methods and kernel-based methods. Feature-based methods use a set of features that are selected after performing textual analysis. They convert these features into symbolic IDs, which are then transformed into a vector using a paradigm that is similar to the bag-of-words model[2]. Conversely, kernel-based methods require pre-processed input data in the form of parse trees (such as dependency parse trees). These approaches are effective because they leverage a large body of linguistic knowledge. However, the extracted features or elaborately designed kernels are often derived from the output of pre-existing NLP systems, which leads to the propagation of the errors in the existing tools and hinders the performance of such systems (Bach and Badaskar, 2007). It is attractive to consider extracting features that are as independent from existing NLP tools as possible.

To identify the relations between pairs of nominals, it is necessary to a skillfully combine lexical and sentence level clues from diverse syntactic and semantic structures in a sentence. For example, in the sentence "The $[\text{fire}]_{e_1}$ inside WTC was caused by exploding $[\text{fuel}]_{e_2}$", to identify that *fire* and *fuel* are in a

[1]A word embedding is a distributed representation for a word. For example, Collobert et al. (2011) use a 50-dimensional vector to represent a word.

[2]http://en.wikipedia.org/wiki/Bag-of-words_model

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2335–2344, Dublin, Ireland, August 23-29 2014.

Cause-Effect relationship, we usually leverage the marked nouns and the meanings of the entire sentence. In this paper, we exploit a convolutional DNN to extract lexical and sentence level features for relation classification. Our method takes all of the word tokens as input without complicated pre-processing, such as Part-of-Speech (POS) tagging and syntactic parsing. First, all the word tokens are transformed into vectors by looking up word embeddings. Then, lexical level features are extracted according to the given nouns. Meanwhile, sentence level features are learned using a convolutional approach. These two level features are concatenated to form the final extracted feature vector. Finally, the features are feed into a softmax classifier to predict the relationship between two marked nouns.

The idea of extracting features for NLP using convolutional DNN was previously explored by Collobert et al. (2011), in the context of POS tagging, chunking (CHUNK), Named Entity Recognition (NER) and Semantic Role Labeling (SRL). Our work shares similar intuition with that of Collobert et al. (2011). In (Collobert et al., 2011), all of the tasks are considered as the sequential labeling problems in which each word in the input sentence is given a tag. However, our task, "relation classification", can be considered a multi-class classification problem, which results in a different objective function. Moreover, relation classification is defined as assigning relation labels to pairs of words. It is thus necessary to specify which pairs of words to which we expect to assign relation labels. For that purpose, the position features (PF) are exploited to encode the relative distances to the target noun pairs. To the best of our knowledge, this work is the first example of using a convolutional DNN for relation classification.

The contributions of this paper can be summarized as follows.

- We explore the feasibility of performing relation classification without complicated NLP pre-processing. A convolutional DNN is employed to extract lexical and sentence level features.
- To specify pairs of words to which relation labels should be assigned, position features are proposed to encode the relative distances to the target noun pairs in the convolutional DNN.
- We conduct experiments using the SemEval-2010 Task 8 dataset. The experimental results demonstrate that the proposed position features are critical for relation classification. The extracted lexical and sentence level features are effective for relation classification. Our approach outperforms the state-of-the-art methods.

2 Related Work

Relation classification is one of the most important topics in NLP. Many approaches have been explored for relation classification, including unsupervised relation discovery and supervised classification. Researchers have proposed various features to identify the relations between nominals using different methods.

In the unsupervised paradigms, contextual features are used. Distributional hypothesis theory (Harris, 1954) indicates that words that occur in the same context tend to have similar meanings. Accordingly, it is assumed that the pairs of nominals that occur in similar contexts tend to have similar relations. Hasegawa et al. (2004) adopted a hierarchical clustering method to cluster the contexts of nominals and simply selected the most frequent words in the contexts to represent the relation between the nominals. Chen et al. (2005) proposed a novel unsupervised method based on model order selection and discriminative label identification to address this problem.

In the supervised paradigm, relation classification is considered a multi-classification problem, and researchers concentrate on extracting more complex features. Generally, these methods can be categorized into two types: feature-based and kernel-based. In feature-based methods, a diverse set of strategies have been exploited to convert the classification clues (such as sequences and parse trees) into feature vectors (Kambhatla, 2004; Suchanek et al., 2006). Feature-based methods suffer from the problem of selecting a suitable feature set when converting the structured representation into feature vectors. Kernel-based methods provide a natural alternative to exploit rich representations of the input classification clues, such as syntactic parse trees. Kernel-based methods allow the use of a large set of features without explicitly extracting the features. Various kernels, such as the convolution tree kernel (Qian et

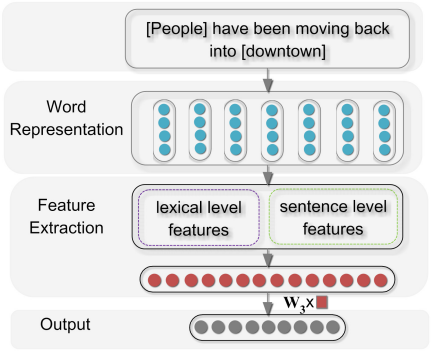

Figure 1: Architecture of the neural network used for relation classification.

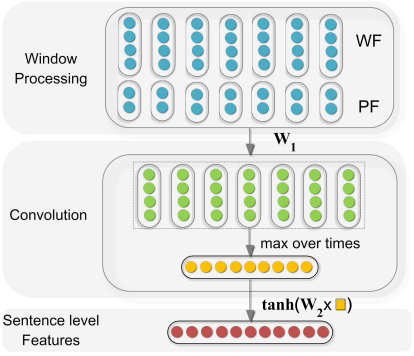

Figure 2: The framework used for extracting sentence level features.

al., 2008), subsequence kernel (Mooney and Bunescu, 2005) and dependency tree kernel (Bunescu and Mooney, 2005), have been proposed to solve the relation classification problem. However, the methods mentioned above suffer from a lack of sufficient labeled data for training. Mintz et al. (2009) proposed distant supervision (DS) to address this problem. The DS method selects sentences that match the facts in a knowledge base as positive examples. The DS algorithm sometimes faces the problem of wrong labels, which results in noisy labeled data. To address the shortcoming of DS, Riedel et al. (2010) and Hoffmann et al. (2011) cast the relaxed DS assumption as multi-instance learning. Furthermore, Takamatsu et al. (2012) noted that the relaxed DS assumption would fail and proposed a novel generative model to model the heuristic labeling process in order to reduce the wrong labels.

The supervised method has been demonstrated to be effective for relation detection and yields relatively high performance. However, the performance of this method strongly depends on the quality of the designed features. With the recent revival of interest in DNN, many researchers have concentrated on using *Deep Learning* to learn features. In NLP, such methods are primarily based on learning a distributed representation for each word, which is also called a word embeddings (Turian et al., 2010). Socher et al. (2012) present a novel recursive neural network (RNN) for relation classification that learns vectors in the syntactic tree path that connects two nominals to determine their semantic relationship. Hashimoto et al. (2013) also use an RNN for relation classification; their method allows for the explicit weighting of important phrases for the target task. As mentioned in Section 1, it is difficult to design high quality features using the existing NLP tools. In this paper, we propose a convolutional DNN to extract lexical and sentence level features for relation classification; our method effectively alleviates the shortcomings of traditional features.

3 Methodology

3.1 The Neural Network Architecture

Figure 1 describes the architecture of the neural network that we use for relation classification. The network takes an input sentence and discovers multiple levels of feature extraction, where higher levels represent more abstract aspects of the inputs. It primarily includes the following three components: *Word Representation*, *Feature Extraction* and *Output*. The system does not need any complicated syntactic or semantic preprocessing, and the input of the system is a sentence with two marked nouns. Then, the word tokens are transformed into vectors by looking up word embeddings. In succession, the lexical and sentence level features are respectively extracted and then directly concatenated to form the final feature vector. Finally, to compute the confidence of each relation, the feature vector is fed into a softmax classifier. The output of the classifier is a vector, the dimension of which is equal to the number of predefined relation types. The value of each dimension is the confidence score of the corresponding relation.

Features	Remark
L1	Noun 1
L2	Noun 2
L3	Left and right tokens of noun 1
L4	Left and right tokens of noun 2
L5	WordNet hypernyms of nouns

Table 1: Lexical level features.

3.2 Word Representation

In the *word representation* component, each input word token is transformed into a vector by looking up word embeddings. Collobert et al. (2011) reported that word embeddings learned from significant amounts of unlabeled data are far more satisfactory than the randomly initialized embeddings. In relation classification, we should first concentrate on learning discriminative word embeddings, which carry more syntactic and semantic information, using significant amounts of unlabeled data. Unfortunately, it usually takes a long time to train the word embeddings[3]. However, there are many trained word embeddings that are freely available (Turian et al., 2010). A comparison of the available word embeddings is beyond the scope of this paper. Our experiments directly utilize the trained embeddings provided by Turian et al.(2010).

3.3 Lexical Level Features

Lexical level features serve as important cues for deciding relations. The traditional lexical level features primarily include the nouns themselves, the types of the pairs of nominals and word sequences between the entities, the quality of which strongly depends on the results of existing NLP tools. Alternatively, this paper uses generic word embeddings as the source of base features. We select the word embeddings of marked nouns and the context tokens. Moreover, the WordNet hypernyms[4] are adopted as MVRNN (Socher et al., 2012). All of these features are concatenated into our lexical level features vector $\mathbf{l}$. Table 1 presents the selected word embeddings that are related to the marked nouns in the sentence.

3.4 Sentence Level Features

As mentioned in section 3.2, all of the tokens are represented as word vectors, which have been demonstrated to correlate well with human judgments of word similarity. Despite their success, single word vector models are severely limited because they do not capture long distance features and semantic compositionality, the important quality of natural language that allows humans to understand the meanings of a longer expression. In this section, we propose a max-pooled convolutional neural network to offer sentence level representation and automatically extract sentence level features. Figure 2 shows the framework for sentence level feature extraction. In the *Window Processing* component, each token is further represented as Word Features (WF) and Position Features (PF) (see section 3.4.1 and 3.4.2). Then, the vector goes through a convolutional component. Finally, we obtain the sentence level features through a non-linear transformation.

3.4.1 Word Features

Distributional hypothesis theory (Harris, 1954) indicates that words that occur in the same context tend to have similar meanings. To capture this characteristic, the WF combines a word's vector representation and the vector representations of the words in its context. Assume that we have the following sequence of words.

$$S : [\text{People}]_0 \quad \text{have}_1 \quad \text{been}_2 \quad \text{moving}_3 \quad \text{back}_4 \quad \text{into}_5 \quad [\text{downtown}]_6$$

The marked nouns are associated with a label y that defines the relation type that the marked pair contains. Each word is also associated with an index into the word embeddings. All of the word tokens of the sentence S are then represented as a list of vectors $(\mathbf{x}_0, \mathbf{x}_1, \cdots, \mathbf{x}_6)$, where $\mathbf{x}_i$ corresponds to the word

[3]Collobert et al. (2011) proposed a *pairwise ranking* approach to train the word embeddings, and the total training time for an English corpus (Wikipedia) was approximately four weeks.

[4]http://sourceforge.net/projects/supersensetag/

embedding of the i-th word in the sentence. To use a context size of w, we combine the size w windows of vectors into a richer feature. For example, when we take $w = 3$, the WF of the third word "moving" in the sentence *S* is expressed as $[\mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_4]$. Similarly, considering the whole sentence, the WF can be represented as follows:

$$\{[\mathbf{x}_s, \mathbf{x}_0, \mathbf{x}_1],\ [\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2],\ \cdots,\ [\mathbf{x}_5, \mathbf{x}_6, \mathbf{x}_e]\}^5$$

3.4.2 Position Features

Relation classification is a very complex task. Traditionally, structure features (e.g., the shortest dependency path between nominals) are used to solve this problem (Bunescu and Mooney, 2005). Apparently, it is not possible to capture such structure information only through WF. It is necessary to specify which input tokens are the target nouns in the sentence. For this purpose, PF are proposed for relation classification. In this paper, the PF is the combination of the relative distances of the current word to w_1 and w_2. For example, the relative distances of "moving" in sentence S to "people" and "downtown" are 3 and -3, respectively. In our method, the relative distances also are mapped to a vector of dimension d_e (a hyperparameter); this vector is randomly initialized. Then, we obtain the distance vectors $\mathbf{d}_1$ and $\mathbf{d}_2$ with respect to the relative distances of the current word to w_1 and w_2, and PF = $[\mathbf{d}_1, \mathbf{d}_2]$. Combining the WF and PF, the word is represented as $[\text{WF}, \text{PF}]^T$, which is subsequently fed into the convolution component of the algorithm.

3.4.3 Convolution

We will see that the word representation approach can capture contextual information through combinations of vectors in a window. However, it only produces local features around each word of the sentence. In relation classification, an input sentence that is marked with target nouns only corresponds to a relation type rather than predicting label for each word. Thus, it might be necessary to utilize all of the local features and predict a relation globally. When using neural network, the convolution approach is a natural method to merge all of the features. Similar to Collobert et al. (2011), we first process the output of *Window Processing* using a linear transformation.

$$\mathbf{Z} = \mathbf{W}_1\mathbf{X} \tag{1}$$

$\mathbf{X} \in \mathbb{R}^{n_0 \times t}$ is the output of the *Window Processing* task, where $n_0 = w \times n$, n (a hyperparameter) is the dimension of feature vector, and t is the token number of the input sentence. $\mathbf{W}_1 \in \mathbb{R}^{n_1 \times n_0}$, where n_1 (a hyperparameter) is the size of hidden layer 1, is the linear transformation matrix. We can see that the features share the same weights across all times, which greatly reduces the number of free parameters to learn. After the linear transformation is applied, the output $\mathbf{Z} \in \mathbb{R}^{n_1 \times t}$ is dependent on t. To determine the most useful feature in the each dimension of the feature vectors, we perform a max operation over time on $\mathbf{Z}$.

$$m_i = \max \mathbf{Z}(i, \cdot) \quad 0 \le i \le n_1 \tag{2}$$

where $\mathbf{Z}(i, \cdot)$ denote the i-th row of matrix $\mathbf{Z}$. Finally, we obtain the feature vector $\mathbf{m} = \{m_1, m_2, \cdots, m_{n_1}\}$, the dimension of which is no longer related to the sentence length.

3.4.4 Sentence Level Feature Vector

To learn more complex features, we designed a non-linear layer and selected hyperbolic tanh as the activation function. One useful property of tanh is that its derivative can be expressed in terms of the function value itself:

$$\frac{d}{dx}\tanh x = 1 - \tanh^2 x \tag{3}$$

It has the advantage of making it easy to compute the gradient in the backpropagation training procedure. Formally, the non-linear transformation can be written as

$$\mathbf{g} = \tanh(\mathbf{W}_2\mathbf{m}) \tag{4}$$

[5] $\mathbf{x}_s$ and $\mathbf{x}_e$ are special word embeddings that correspond to the beginning and end of the sentence, respectively.

$\mathbf{W_2} \in \mathbb{R}^{n_2 \times n_1}$ is the linear transformation matrix, where n_2 (a hyperparameter) is the size of hidden layer 2. Compared with $\mathbf{m} \in \mathbb{R}^{n_1 \times 1}$, $\mathbf{g} \in \mathbb{R}^{n_2 \times 1}$ can be considered higher level features (sentence level features).

3.5 Output

The automatically learned lexical and sentence level features mentioned above are concatenated into a single vector $\mathbf{f} = [\mathbf{l}, \mathbf{g}]$. To compute the confidence of each relation, the feature vector $\mathbf{f} \in \mathbb{R}^{n_3 \times 1}$ (n_3 equals n_2 plus the dimension of the lexical level features) is fed into a softmax classifier.

$$\mathbf{o} = \mathbf{W}_3 \mathbf{f} \tag{5}$$

$\mathbf{W_3} \in \mathbb{R}^{n_4 \times n_3}$ is the transformation matrix and $\mathbf{o} \in \mathbb{R}^{n_4 \times 1}$ is the final output of the network, where n_4 is equal to the number of possible relation types for the relation classification system. Each output can be then interpreted as the confidence score of the corresponding relation. This score can be interpreted as a conditional probability by applying a softmax operation (see Section 3.6).

3.6 Backpropagation Training

The DNN based relation classification method proposed here could be stated as a quintuple $\theta = (\mathbf{X}, \mathbf{N}, \mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3)$[6]. In this paper, each input sentence is considered independently. Given an input example s, the network with parameter θ outputs the vector $\mathbf{o}$, where the i-th component o_i contains the score for relation i. To obtain the conditional probability $p(i|x, \theta)$, we apply a softmax operation over all relation types:

$$p(i|x, \theta) = \frac{e^{o_i}}{\sum_{k=1}^{n_4} e^{o_k}} \tag{6}$$

Given all our (suppose T) training examples $(x^{(i)}; y^{(i)})$, we can then write down the log likelihood of the parameters as follows:

$$J(\theta) = \sum_{i=1}^{T} \log p(y^{(i)}|x^{(i)}, \theta) \tag{7}$$

To compute the network parameter θ, we maximize the log likelihood $J(\theta)$ using a simple optimization technique called stochastic gradient descent (SGD). $\mathbf{N}, \mathbf{W}_1, \mathbf{W}_2$ and $\mathbf{W}_3$ are randomly initialized and $\mathbf{X}$ is initialized using the word embeddings. Because the parameters are in different layers of the neural network, we implement the backpropagation algorithm: the differentiation chain rule is applied through the network until the word embedding layer is reached by iteratively selecting an example (x, y) and applying the following update rule.

$$\theta \leftarrow \theta + \lambda \frac{\partial \log p(y|x, \theta)}{\partial \theta} \tag{8}$$

4 Dataset and Evaluation Metrics

To evaluate the performance of our proposed method, we use the SemEval-2010 Task 8 dataset (Hendrickx et al., 2010). The dataset is freely available[7] and contains 10,717 annotated examples, including 8,000 training instances and 2,717 test instances. There are 9 relationships (with two directions) and an undirected *Other* class. The following are examples of the included relationships: *Cause-Effect*, *Component-Whole* and *Entity-Origin*. In the official evaluation framework, directionality is taken into account. A pair is counted as correct if the order of the words in the relationship is correct. For example, both of the following instances S_1 and S_2 have the relationship *Component-Whole*.

S_1 : The [haft]$_{e_1}$ of the [axe]$_{e_2}$ is make $\cdots \Rightarrow$ Component-Whole(e_1,e_2)
S_2 : This [machine]$_{e_1}$ has two [units]$_{e_2}$ $\cdots \Rightarrow$ Component-Whole(e_2,e_1)

[6] $\mathbf{N}$ represents the word embeddings of WordNet hypernyms.
[7] http://docs.google.com/View?id=dfvxd49s_36c28v9pmw

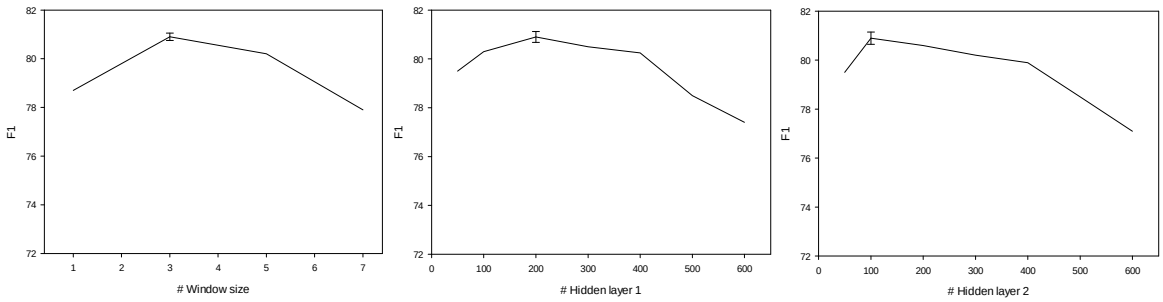

Figure 3: Effect of hyperparameters.

However, these two instances cannot be classified into the same category because *Component-Whole(e_1,e_2)* and *Component-Whole(e_2,e_1)* are different relationships. Furthermore, the official ranking of the participating systems is based on the macro-averaged F1-scores for the nine proper relations (excluding *Other*). To compare our results with those obtained in previous studies, we adopt the macro-averaged F1-score and also account for directionality into account in our following experiments[8].

5 Experiments

In this section, we conduct three sets of experiments. The first is to test several variants via cross-validation to gain some understanding of how the choice of hyperparameters impacts upon the performance. In the second set of experiments, we make comparison of the performance among the convolutional DNN learned features and various traditional features. The goal of the third set of experiments is to evaluate the effectiveness of each extracted feature.

5.1 Parameter Settings

In this section, we experimentally study the effects of the three parameters in our proposed method: the window size in the convolutional component w, the number of hidden layer 1, and the number of hidden layer 2. Because there is no official development dataset, we tuned the hyperparameters by trying different architectures via 5-fold cross-validation.

In Figure 3, we respectively vary the number of hyper parameters w, n_1 and n_2 and compute the F1. We can see that it does not improve the performance when the window size is greater than 3. Moreover, because the size of our training dataset is limited, the network is prone to overfitting, especially when using large hidden layers. From Figure 3, we can see that the parameters have a limited impact on the results when increasing the numbers of both hidden layers 1 and 2. Because the distance dimension has little effect on the result (this is not illustrated in Figure 3), we heuristically choose $d_e = 5$. Finally, the word dimension and learning rate are the same as in Collobert et al. (2011). Table 2 reports all the hyperparameters used in the following experiments.

Hyperparameter	*Window size*	*Word dim.*	*Distance dim.*	*Hidden layer 1*	*Hidden layer 2*	*Learning rate*
Value	$w = 3$	$n = 50$	$d_e = 5$	$n_1 = 200$	$n_2 = 100$	$\lambda = 0.01$

Table 2: Hyperparameters used in our experiments.

5.2 Results of Comparison Experiments

To obtain the final performance of our automatically learned features, we select seven approaches as competitors to be compared with our method in Table 3. The first five competitors are described in Hendrickx et al. (2010), all of which use traditional features and employ SVM or MaxEnt as the classifier. These systems design a series of features and take advantage of a variety of resources (WordNet, ProBank, and FrameNet, for example). *RNN* represents recursive neural networks for relation classification, as

[8]The corpus contains a Perl-based automatic evaluation tool.

Classifier	Feature Sets	F1
SVM	POS, stemming, syntactic patterns	60.1
SVM	word pair, words in between	72.5
SVM	POS, stemming, syntactic patterns, WordNet	74.8
MaxEnt	POS, morphological, noun compound, thesauri, Google n-grams, WordNet	77.6
SVM	POS, prefixes, morphological, WordNet, dependency parse, Levin classed, ProBank, FrameNet, NomLex-Plus, Google n-gram, paraphrases, TextRunner	82.2
RNN	-	74.8
	POS, NER, WordNet	77.6
MVRNN	-	79.1
	POS, NER, WordNet	82.4
Proposed	word pair, words around word pair, WordNet	**82.7**

Table 3: Classifier, their feature sets and the F1-score for relation classification.

proposed by Socher et al. (2012). This method learns vectors in the syntactic tree path that connect two nominals to determine their semantic relationship. The *MVRNN* model builds a single compositional semantics for the minimal constituent, including both nominals as *RNN* (Socher et al., 2012). It is almost certainly too much to expect a single fixed transformation to be able to capture the meaning combination effects of all natural language operators. Thus, *MVRNN* assigns a matrix to every word and modifies the meanings of other words instead of only considering word embeddings in the recursive procedure.

Table 3 illustrates the macro-averaged F1 measure results for these competing methods along with the resources, features and classifier used by each method. Based on these results, we make the following observations:

(1) Richer feature sets lead to better performance when using traditional features. This improvement can be explained by the need for semantic generalization from training to test data. The quality of traditional features relies on human ingenuity and prior NLP knowledge. It is almost impossible to manually choose the best feature sets.

(2) *RNN* and *MVRNN* contain feature learning procedures; thus, they depend on the syntactic tree used in the recursive procedures. Errors in syntactic parsing inhibit the ability of these methods to learn high quality features. *RNN* cannot achieve a higher performance than the best method that uses traditional features, even when POS, NER and WordNet are added to the training dataset. Compared with *RNN*, the *MVRNN* model can capture the meaning combination effectively and achieve a higher performance.

(3) Our method achieves the best performance among all of the compared methods. We also perform a t-test ($p \leqslant 0.05$), which indicates that our method significantly outperforms all of the compared methods.

5.3 The Effect of Learned Features

	Feature Sets	F1
Lexical	L1	34.7
	+L2	53.1
	+L3	59.4
	+L4	65.9
	+L5	73.3
Sentence	WF	69.7
	+PF	78.9
Combination	all	82.7

Table 4: Score obtained for various sets of features on for the test set. The bottom portion of the table shows the best combination of lexical and sentence level features.

In our method, the network extract lexical and sentence level features. The lexical level features primarily contain five sets of features (L1 to L5). We performed ablation tests on the five sets of features from the lexical part of Table 4 to determine which type of features contributed the most. The results are

presented in Table 4, from which we can observe that our learned lexical level features are effective for relation classification. The F1-score is improved remarkably when new features are added. Similarly, we perform experiment on the sentence level features. The system achieves approximately 9.2% improvements when adding PF. When all of the lexical and sentence level features are combined, we achieve the best result.

6 Conclusion

In this paper, we exploit a convolutional deep neural network (DNN) to extract lexical and sentence level features for relation classification. In the network, position features (PF) are successfully proposed to specify the pairs of nominals to which we expect to assign relation labels. The system obtains a significant improvement when PF are added. The automatically learned features yield excellent results and can replace the elaborately designed features that are based on the outputs of existing NLP tools.

A context-based model for Sentiment Analysis in Twitter

Andrea Vanzo and **Danilo Croce** and **Roberto Basili**

Abstract

Most of the recent literature on Sentiment Analysis over Twitter is tied to the idea that the sentiment is a function of an incoming tweet. However, tweets are filtered through streams of posts, so that a wider context, e.g. a topic, is always available. In this work, the contribution of this contextual information is investigated. We modeled the polarity detection problem as a sequential classification task over streams of tweets. A Markovian formulation of the Support Vector Machine discriminative model as embodied by the SVM^{hmm} algorithm has been here employed to assign the sentiment polarity to entire sequences. The experimental evaluation proves that sequential tagging effectively embodies evidence about the contexts and is able to reach a relative increment in detection accuracy of around 20% in F1 measure. These results are particularly interesting as the approach is flexible and does not require manually coded resources.

1 Introduction

Since in the Web 2.0 users can write about their life, personal experiences, share contents about facts and ideas, Social Networks became valuable sources of opinions and sentiments. This huge amount of data is crucial in the study of the interactions and dynamics of subjectivity on the Web, largely relevant for marketing tasks. Twitter is one among these microblogging services that counts about a billion of active users and 500 million of daily messages[1]. However, the analysis of this huge amount of information is still challenging, as language is very informal, affected by misspelling and characterized by slang and *#hashtags*, i.e. special user-generated tags used to contextualize different tweets around a specific topic.

Researches focused on the computational study and automatic recognition of opinions and sentiments as they are expressed in free texts. It gave rise to what is currently known as Sentiment Analysis, a set of tasks aiming to detect the subjective attitude of a writer with respect to some topic. Many Sentiment Analysis studies map sentiment detection in a *Machine Learning* (ML) setting (Pang and Lee, 2008), where labeled data, i.e. known examples, allow to induce the detection function from real world examples. In general, sentiment detection in tweets has been generally treated as any other text classification task, as proved by most papers participating to the *Sentiment Analysis in Twitter* task in SemEval-2013 challenge (Nakov et al., 2013): a computational representation for an incoming instance is generated by just considering one tweet at a time. The short length of the message and the resulting semantic ambiguity are critical limitations and make the task very complex. Let us consider the following example, in which a tweet from `ColMustard` cites `SergGray`:

`ColMustard` : *@SergGray Yes, I totally agree with you about the substitutions! #Bayern #Freiburg*

The tweet sounds like to be a reply to the previous one. Notice how no lexical nor syntactic property allows to determine the sentiment polarity. However, if we look at the entire conversation that follows:

`ColMustard` : *Amazing match yesterday!!#Bayern vs. #Freiburg 4-0 #easyvictory*
`SergGray` : *@ColMustard Surely, but #Freiburg wasted lot of chances to score.. wrong substitutions by #Guardiola during the 2nd half!!*
`ColMustard` : *@SergGray Yes, I totally agree with you about the substitutions! #Bayern #Freiburg*

[1] http://expandedramblings.com/

Proceedings of COLING 2014, the 25th International Conference on Computational Linguistics: Technical Papers, pages 2345–2354, Dublin, Ireland, August 23-29 2014.

it is easy to establish that a first positive tweet has been produced, followed by a second negative one so that the third tweet is negative as well. It is the conversation that allows us here to disambiguate even a very short message and properly characterize it according to its author and posting time.

We want here to capitalize such a richer set of observations (i.e. entire conversations) and to define a context-sensitive SA model along two lines: first, by enriching a tweet representation to include the conversation information, and then introducing a more complex classification model that works over an entire tweet sequence and not on one tweet (i.e. the target) at a time. Accordingly, in the paper we will first focus on different representations of tweets that can be made available to the sentiment detection process. They will also account for contexts, that are *conversations*, as chains of tweets that are reply to the previous ones, and *topics*, built around hashtags. These are in fact topics made explicit by users, such as events (*#easyvictory*) or people (*#Guardiola*). It represents a wider notion of conversation that enforces the sense of belonging to a community. From a computational perspective, the polarity detection of a tweet in a context is here modeled as a sequential classification task. In fact, both conversation and topic-based context are arbitrarily long sequences of messages, ordered according to *time* with the target tweet being the last. The SVM^{hmm} learning algorithm (Altun et al., 2003) has been employed, as it allows to classify an instance (here, a tweet) within an entire sequence. While SVM based classifiers allow to recognize the sentiments from one specific tweet at a time, the SVM^{hmm} learning algorithm collectively labels all tweets in a sequence. It is thus expected to capture patterns within a conversation and apply them in novel sequences, through a standard decoding task.

While all the above contexts extend a tweet representation, they are still *local* to a specific notion of conversation. In this work, we also explore the somehow more abstract notion of contexts given by the emotional attitude shown by each user in his overall usage of Twitter. In the above example, `ColMustard` shows a specific attitude while discussing about the Bayern Munchen. We can imagine that this feature characterizes most of its future messages at least about football. We suggest to enrich the tweet representation with features that *synthesize* a user's profile, in order to catch possible biases towards a particular sentiment polarity. This is quite interesting as it has been shown that communities behave in a coherent way and users tend to take stable standing points. Experimental evaluation (Chapter 4) proves the effectiveness of this proposed sequential tagging approach combined with the adopted contextual information, improving the percentage of correctly recognized tweets up to 12%.

A survey of the existing approaches is presented into Section 2. Then, Section 3 provides an account of the context-based models: conversation, topic-based and user sentiment profiling. The experimental evaluation into Section 4 prove the positive impact of social dynamics on the SA task.

2 Related Work

Sentiment Analysis has been described as a *Natural Language Processing* task at many levels of granularity. Starting from being mapped into a *document level* classification task (Turney, 2002; Pang and Lee, 2004), it has been also applied at *sentence level* (Hu and Liu, 2004; Kim and Hovy, 2004) and more recently at the *phrase level* (Wilson et al., 2005; Agarwal et al., 2009).

The spreading of microblog services where users post real-time opinions about "everything", poses newer and different challenges. Indeed, classical approaches to Sentiment Analysis (Pang et al., 2002; Pang and Lee, 2008) are not directly applicable to tweets: while most of them focus on relatively large texts, e.g. movie or product reviews, tweets are very short and fine-grained lexical analysis is required. Nevertheless, the great prominence of Social Media during the last few years encouraged a focus on the sentiment detection over a microblogging domain. Recent works tried to model the sentiment in tweets (Go et al., 2009; Pak and Paroubek, 2010; Kouloumpis et al., 2011; Davidov et al., 2010; Bifet and Frank, 2010; Croce and Basili, 2012; Barbosa and Feng, 2010; Zanzotto et al., 2011; Si et al., 2013; Agarwal et al., 2011). Specific approaches and feature modeling are used to improve accuracy levels in tweet polarity recognition. For example, the use of *n*-grams, POS tags, polarity lexicons and tweet specific features (e.g. hashtags, re-tweets) are some of the component exploited by these works, in combination with different machine learning algorithms: among these latter, probabilistic paradigms, e.g. Naive Bayes (Pak and Paroubek, 2010), or Kernel-based machines, as discussed in (Barbosa and Feng,

2010; Agarwal et al., 2011; Castellucci et al., 2013), are mostly employed. An interesting perspective, where a kind of contextual information is studied, is presented in (Mukherjee and Bhattacharyya, 2012): the sentiment detection of tweets is here modeled according to lexical features as well as discourse relations like the presence of connectives, conditionals and semantic operators like *modals* and *negations*. Nevertheless, in all the above approaches, features are derived only from lexical resources or from the tweet itself and no contextual information is exploited. However, given one tweet targeted for sentiment detection, more awareness about its content is available to writers and readers by the entire stream of related posts immediately preceding it. In order to exploit this wider information, a Markovian extension of a Kernel-based categorization approach is proposed in the next section.

3 A context based model for Sentiment Analysis in Twitter

As discussed in the introduction, contextual information about one tweet stems from various aspects: an explicit conversation, the user attitude or the overall set of recent tweets about a topic (for example an hastag like `#Bayern`). As individual perspectives on the context are independent (a conversation may or may not depend on user preference or cheer) and they also obey to different notion of analogies or similarity, we should avoid a unified feature vector, but employ independent representations. A structured view on a tweet can thus be provided by considering it as multifaceted entity where a set of vectors, each one contributing to one aspect of the overall representation, exhibits a specific similarity metrics. Notice how this is exactly what Kernel-based learning supports, whereas the combination of the different Kernel functions can be easily made a Kernel function itself (Shawe-Taylor and Cristianini, 2004). Kernel functions are used to capture specific aspects of the semantic relatedness between two tweets and are easily integrated in various Machine Learning algorithms, such as SVM.

3.1 Representing tweets through different Kernel functions

Many Machine Learning approaches for Sentiment Analysis in Twitter benefited by complex ways of modeling of individual tweets, as discussed in many works (Nakov et al., 2013). The representation we propose makes use of individual Kernels as models of different aspects usable within a SVM paradigm.

Bag of Word Kernel (BoWK). The simplest Kernel function describes the lexical overlap between tweets, thus represented as vectors, whose dimensions correspond to the different words. Components denote the presence or not of the corresponding word in the text and Kernel function corresponds to the *cosine similarity* between vector pairs. Even if very simple, the BoW model is one of the most informative representation in Sentiment Analysis, as emphasized since (Pang et al., 2002).

Lexical Semantic Kernel (LSK). Lexical information in tweets can be very sparse, as we will also show in the next Section 4. In order to extend the BoW model, we provide a further vector representation aiming to generalize the lexical information. It can be obtained for every term of a dictionary by a co-occurrence Word Space built according to the Distributional Analysis described in (Sahlgren, 2006). A word-by-context matrix, M, is built through large scale corpus analysis and then processed through *Latent Semantic Analysis* (Landauer and Dumais, 1997). The dimensionality of the space represented by M can be reduced through Singular Value Decomposition (SVD) (Golub and Kahan, 1965). The original statistical information about M is captured by the new k-dimensional space, which preserves the global structure while removing low-variance dimensions, i.e. distribution noise. The result is that every word is projected in the reduced Word Space and a vector for each tweet is represented through the linear combination of the co-occurring word vectors (also called *additive linear combination* in (Mitchell and Lapata, 2010)). The resulting Kernel function is the *cosine similarity* between tweet vector pairs, in line with (Cristianini et al., 2002). Notice that the adoption of a distributional approach does not limit the overall application, as it can be automatically applied without relying on any manually coded resource.

User Sentiment Profile Context (**USPK**). A source of evidence about a tweet is its author, with his attitude towards some polarities. Specific features based on the users' previous tweets can be derived as follows. Let $t_i \in \mathcal{T}$ be a tweet and $i \in \mathbb{N}^+$ its identifier. The *User Profile Context* (U_i) can be defined as the set of the last H tweets posted by the author of t_i, hereafter denoted by u_i. This information is a body of evidence about the opinion holder's profile on which a further tweet representation can be defined. A tweet t_i is here mapped into a three dimensional vector $\vec{\mu}_i = \left(\mu_i^1, \mu_i^2, \mu_i^3\right)$, where each component μ_i^j is

the indicator of polarity inclination, i.e. *positive*, *negative* and *neutral*, expressed through the conditional probability $P(j \mid u_i)$ for the polarity labels $j \in \mathcal{Y}$ given the user u_i. We can suppose that, for each $t_k \in U_i$, its corresponding label y_k is available either as a gold standard annotation or predicted in a semi-supervised fashion by trained classifiers. The estimation of $\mu_i^j \approx P(j \mid u_i)$, is a σ-parameterized *Laplace smoothed version* of the observations in U_i: $\mu_i^j = \sum_{k=1}^{|U_i|}(\mathbb{1}_{\{y_k=j\}}(t_k) + \sigma)/(|U_i| + \sigma|\mathcal{Y}|)$ where $\sigma \in \mathbb{R}$ is the smoothing parameter, $j \in \mathcal{Y}$, i.e. the set of polarity labels. The Kernel function, called User Sentiment Profile Kernel (USPK), is the *cosine similarity* between two vectors $(\vec{\mu}_i, \vec{\mu}_m)$.

The multiple Kernel approach. Whenever the different Kernels are available, we can apply a linear combination αBoWK+βLSK or αBoWK+βLSK+γUSPK in order to exploit lexical and semantic properties captured by BoWK and LSK, or user properties as captured by USPK.

3.2 Modeling tweet conversation as a sequential tagging problem

The User Sentiment Profile Kernel (UPSK) can be seen as an implicit representation of a context describing the writer. However, contextual information is usually embodied by the stream of tweets in which the target one t_i is immersed. Usually, the stream is something available to a reader and includes an entire *conversation* (where links to the previous tweets are made explicit and are supposed to be all available) or a *topic*, i.e. a hashtag, the reader has searched for. In all cases, the stream give rise to an entire sequence on which sequence labeling can be applied: the target tweet is here always labeled within the entire sequence, where contextual constraints are provided by the preceding tweets. More formally, two types of context are defined:

Conversational context. For every tweet $t_i \in \mathcal{T}$, let $r(t_i) : \mathcal{T} \rightarrow \mathcal{T}$ be a function that returns either the tweet to which t_i is a reply to, or $null$ if t_i is not a reply. Then, the *conversation-based context* $\Lambda_i^{C,l}$ of tweet t_i (i.e., the *target tweet*) is the sequence of tweet iteratively built by applying $r(\cdot)$, until l tweets have been selected or $r(\cdot) = null$. In other words, l allows to limit the size of the input context. An example of conversation-based context is given in Section 1.

Topical context. Hashtags allow to aggregate different tweets around a specific topic. An entire tweet sequence can be derived including the n tweets preceding the target t_i that contain the same hashtag set. This is usually the output of a search in Twitter and it is likely the source information that influenced the writer's opinion. Let $t_i \in \mathcal{T}$ be a tweet and $h(i) : \mathcal{T} \rightarrow \mathcal{P}(\mathcal{H})$ be a function that returns the entire hashtag set $H_i \subseteq \mathcal{H}$ observed into t_i. Then, the *hashtag-based context* $\Lambda_i^{H,l}$ for a tweet t_i (i.e., *target tweet*) is a sequence of the most recent l tweets t_j such that $H_j \cap H_i \neq \emptyset$, i.e. t_j and t_i share at least one hashtag, and t_j has been posted before t_i. As an example, the following hashtag-based context of size 4 has been obtained about `#Bayern`:

`MrGreen` : *Fun fact: #Freiburg is the only #Bundesliga team #Pep has never beaten in his coaching career. #Bayern*
`MrsPeacock` : *Young starlet Xherdan #Shaqiri fires #Bayern into a 2-0 lead. Is there any hope for #Freiburg? pic.twitter.com/krzbFJFJyN*
`ProfPlum` : *It is clear that #Bayern is on a rampage leading by 4-0, the latest by Mandzukic... hoping for another 2 goals from #bayernmunich*
`MissScarlet` : *Noooo! I cant believe what #Bayern did!*

It is clear that `MissScarlet` expressed an opinion, but the corresponding polarity is easily evident when the entire stream is available about the *#Bayern* hashtag. As well as in a conversational context, a specific context size n can be imposed by focusing only on the last n tweets of the sequence. Once different representations and contexts are available a structured learning-based approach can be applied to Sentiment Analysis. Firstly, we will discuss a discriminative learning approach that follows the multi-classification schema proposed in (Joachims et al., 2009), namely *SVM*^{multiclass} . Then a sequence labeling approach, based on the *SVM*^{hmm} learning algorithm (Altun et al., 2003), will be introduced, as an explicit account of both *conversational* and *topical* contexts.

The multi-class approach. The *SVM*^{multiclass} schema described in (Joachims et al., 2009) is applied[2] to implicitly compare all polarity labels and select the most likely one, using the multi-class formulation described in (Crammer and Singer, 2001). The algorithm thus acquires a specific function $f_y(x)$ for

[2] `http://svmlight.joachims.org/svm_multiclass.html`

each sentiment polarity label $y \in \mathcal{Y}$, where $\mathcal{Y} = \{positive, negative, neutral\}$. Given a feature vector $x \in \mathcal{X}$ representing a tweet t_i, *SVM*^{multiclass} allows to predict a specific polarity $y^* \in \mathcal{Y}$ by applying the discriminant function $y^* = \arg\max_{y \in \mathcal{Y}} f_y(x_i)$, where $f_y(x) = w_y \cdot x$ is a linear classifier associated to each label y. Given a training set $(x_1, y_1) \ldots (x_n, y_n)$, the learning algorithm determines each classifier parameters w_y by solving the following optimization problem:

$$min\ \frac{1}{2} \sum_{i=1\ldots k} \|w_i\|^2 + \frac{C}{n} \sum_{i=1\ldots n} \xi_i \qquad s.t.\ \forall i, \forall y \in \mathcal{Y} : x_i \cdot w_{y_i} \geq x_i \cdot w_y + 100\Delta(y_i, y) - \xi_i$$

where C is a regularization parameter that trades off margin size and training error, while $\Delta(y_i, y)$ is the loss function that returns 0 if y_i equals y, and 1 otherwise.

The markovian approach. The sentiment prediction of a target tweet can be seen as a sequential classification task over a context, and the *SVM*^{hmm} algorithm can be thus applied. Given an input sequence $\mathbf{x} = (x_1 \ldots x_l) \subseteq \mathcal{X}$, where $\mathbf{x}$ is a tweet context, e.g. the *conversational* and the *hashtag-based* one (i.e. $\Lambda_i^{C,l}$ and $\Lambda_i^{H,l}$, respectively) and x_i is a feature vector representing a tweet, the model predicts a tag sequence $\mathbf{y} = (y_1 \ldots y_l) \in \mathcal{Y}^+$ after learning a linear discriminant function $F : \mathcal{P}(\mathcal{X}) \times \mathcal{Y}^+ \rightarrow \mathbb{R}$ over input/output pairs. The labeling $f(\mathbf{x})$ is thus defined as: $f(\mathbf{x}) = \arg\max_{\mathbf{y} \in \mathcal{Y}^+} F(\mathbf{x}, \mathbf{y}; \mathbf{w})$. It is obtained by maximizing F over the response variable, $\mathbf{y}$, for a specific given input, $\mathbf{x}$. In these models, F is linear in some combined feature representation of inputs and outputs $\Phi(\mathbf{x}, \mathbf{y})$, i.e. $F(\mathbf{x}, \mathbf{y}; \mathbf{w}) = \langle \mathbf{w}, \Phi(\mathbf{x}, \mathbf{y}) \rangle$. As Φ extracts meaningful properties from an observation/label sequence pair $(\mathbf{x}, \mathbf{y})$, in *SVM*^{hmm} it is modeled through two types of features: interactions between attributes of the observation vectors x_i and a specific label y_i (i.e. **emissions** of x_i by y_i) as well as interactions between neighboring labels y_i along the chain (**transitions**). In other words, Φ is defined so that the complete labeling $\mathbf{y} = f(\mathbf{x})$ can be computed efficiently from F, using a *Viterbi-like decoding algorithm*, according to the linear discriminant function

$$\mathbf{y}^* = \arg\max_{\mathbf{y} \in \mathcal{Y}^+} \{ \sum_{i=1\ldots l} [\sum_{j=1\ldots k} (x_i \cdot w_{y_{i-j}\ \ldots\ y_i}) + \Phi_{tr}(y_{i-j}, \ldots, y_i) \cdot w_{tr}] \}$$

In the training phase, *SVM*^{hmm} solves the following optimization problem given training examples $(\mathbf{x}^1, \mathbf{y}^1) \ldots (\mathbf{x}^n, \mathbf{y}^n)$ of sequences of feature vectors $\mathbf{x}^j$ with their correct tag sequences $\mathbf{y}^j$

$$min\ \frac{1}{2}\|w\|^2 + \frac{C}{n} \sum_{i=1\ldots n} \xi_i$$

$$s.t. \quad \forall \mathbf{y}, n : \{ \sum_{i=1\ldots l} (x_i^n \cdot w_{y_i^n}) + \Phi_{tr}(y_{i-1}^n, y_i^n) \cdot w_{tr} \} \geq \{ \sum_{i=1\ldots l} (x_i^n \cdot w_{y_i}) + \Phi_{tr}(y_{i-1}, y_i) \cdot w_{tr} \} + \Delta(y^n, y)$$

where $\Delta(y^n, y)$ is the loss function, computed as the number of misclassified tags in the sequence, $(x_i \cdot w_{y_i})$ represents the emissions and $\Phi_{tr}(y_{i-1}, y_i)$ the transitions. Indeed, through *SVM*^{hmm} learning the label for the target tweet is made dependent on its context history. The markovian setting thus acquires patterns across tweet sequences to recognize sentiment even for truly ambiguous tweets.

4 Experimental Evaluation

The aim of the experiments is to estimate the contribution of the proposed contextual models to the accuracy reachable in different scenarios, whereas rich contexts (e.g. popular hashtags) are possibly made available or just singleton tweets, with no context, are targeted.

We adopted the *"Sentiment Analysis in Twitter"* dataset[3] as it has been made available in the *ACL SemEval-2013* (Nakov et al., 2013). However, in order to rely on tweet identifiers (needed to retrieve contexts from Twitter servers), only the Training and Development portions of the data (11,338 examples), for which id's were made available, have been employed. As about 10,045 tweets were available from the servers,[4] a static split 80/10/10 in *Training/Held-out/Test* respectively, has been carried out as reported in Table 1. As the performance evaluation is always carried out against one target tweet (in analogy with the benchmark of SemEval-2013), the multi-classification may happen when no context is available (i.e. there is no conversation nor hashtag to built the context from) or when a rich conversational or topical context is available. In Table 1 different datasets are shown in columns 2-4, 5-7 and 8-10

[3] http://www.cs.york.ac.uk/semeval-2013/task2/index.php?id=data

[4] Several original messages were no longer reachable during the experiment time of March-June 2013

respectively: the entire corpus of 10,045 is represented in columns 2-4, while 5-7 and 8-10 represents the subsets of target tweets for which a conversational or topical context, respectively, was available. Conversational contexts are available only for 1,391 tweets (columns 5-7), while hashtag-based contexts include 1,912 instances (columns 8-10).

	whole dataset			conversation-filtered			hashtag-filtered		
	train	**dev**	**test**	**train**	**dev**	**test**	**train**	**dev**	**test**
Positive	2984	359	387	454	51	56	621	83	66
Negative	1271	147	142	197	31	24	245	28	22
Neutral	3790	495	470	455	68	55	688	79	80
	8045	1001	999	1106	150	135	1554	190	168

Table 1: Whole dataset composition

As tweets are noisy texts, a pre-processing phase has been applied to improve the quality of linguistic features observable and reduce data sparseness. In particular, a normalization step is applied to each post: fully capitalized words are converted in lowercase; reply marks are replaced with the pseudo-token `USER`, hyperlinks by `LINK`, *hashtags* by `HASHTAG` and emoticons by special tokens[5]. Afterwards, an almost standard NLP chain is applied through the *Chaos* parser (Basili et al., 1998; Basili and Zanzotto, 2002). In particular, each tweet, with its pseudo-tokens produced by the normalization step, is mapped into a sequence of POS tagged lemmas. Emoticons are treated as nouns. In order to feed the LSK, lexical vectors correspond to a Word Space derived from a corpus of about 1.5 million tweets, downloaded during the experimental period and using the topic names from the trial material as query terms. Every word w in such corpus is represented as one co-occurrence vector as in (Sahlgren, 2006) with the setting discussed in (Croce and Previtali, 2010): left and right co-occurrence scores are obtained in a window of size $n = \pm 5$ around each w. Vector components w_f correspond to Pointwise Mutual Information values $pmi(w, f)$ between the word w (the row) and the feature f. Dimensionality reduction is applied to the co-occurrence matrix, through SVD, with a dimensionality cut of $k = 250$.

Existing state-of-the-art approaches neglect the tweet context, so that datasets with labeled contexts are not available: USPK or the markovian approach would not be applicable. The solution consisted in creating a *semi-supervised Gold-Standard* by training the multi-class classifier (not employing any context) fed through a combination of BoWK and LSK Kernel functions and get the classification of all tweets within the context of at least one target tweet. Unfortunately, this can introduce noise, but it is a realistic solution to a cold-start approach, easily portable to other datasets.

Performance scores report the classification accuracy in terms of Precision, Recall and standard F-measure. However, in line with SemEval-2013, we also report the F_1^{pmn} score as the arithmetic mean between the F_1s of *positive*, *negative* and *neutral* classes.

4.1 Experiment 1: Using contexts in a general tweet classification setting

A first experiment has been run to validate the impact of contextual information over generic tweets, independently from the availability of the context. In this case, the entire data set is used. The different settings adopted are reported in independent rows, corresponding to different classification approaches:

- *multi-class* refers to the application of the multi-classification of $SVM^{multiclass}$, that does not require any context and can be considered as a baseline for the employed Kernel combinations;
- *conversation* refers to the SVM^{hmm} classifier observing the conversation-based contexts. The training and testing of the classifier is here run with different *context size*s, by parameterizing l in $\Lambda_i^{C,l}$;
- likewise, *hashtag* refers to the SVM^{hmm} classifier observing the topic-based contexts, when hashtags are considered. Different *context size*s have been considered, by parameterizing l in $\Lambda_i^{H,l}$.

In both *conversation* and *hashtag* models, when no context is available, the SVM^{hmm} classifier acts on a sequence of length one, and no transition is used. Table 2 shows the empirical results over the whole test dataset. The first general outcome is that algorithmic baselines, i.e. context-free models that use no contextual information, in the multi-class rows are better performing whenever richer representations are provided. The LSA information (+8.29%) as well as the user profiling (+10.73%) seem beneficial in

Table 2: Evaluation results on whole dataset.

their relative improvements with respect to the simple BoW Kernel accuracy. Second, almost all context-driven models (i.e. SVM^{hmm} operating on different context sizes) improve *wrt* their $SVM^{multiclass}$ counterpart. Every polarity category benefits from the introduction of contexts, although this is particularly true for the negative (*neg*) case, where a 15.5% of the entire dataset examples are available: it seems clear that contexts allow to compensate against poor training conditions.

4.2 Experiment 2: Measuring the full impact of context-based models over rich contexts

Given the above outcomes, a second set of experiments has been run against the subset of the test data restricted to tweets for which rich contexts are available, as introduced in Table 1. In Figure 1, the performances of different learning paradigms and Kernels trained and tested over these corpora are shown. On the Left of the figure, the performance over the conversation-filtered corpus (Table 1) are reported: these tweets are characterized by rich conversational contexts of different increasing sizes on the X-axis. On the Right of Figure 1, the corresponding performances obtained over the hashtag-filtered corpus are reported. As the number of available examples in both test corpora is much smaller, the baselines corresponding to the $SVM^{multiclass}$ approach are lower.

On the contrary, such poorer training evidence does not seem to afflict the contextual models in both corpora, as the markovian modeling seems to bring a straight benefit. In particular, increasing amount of contextual information is usually beneficial to accuracy scores. In general, the SVM^{hmm} accuracy plots seem to increase up to a given context size, that is around 6 for conversational contexts vs. 16 previous tweets for topical contexts. It seems that a wider context (i.e. a window of 8 or 10 tweets) is not so beneficial, as the generalization emphasized by LSK and USPK tends to diverge. Different genres of discussions seem to provide different useful contexts for sentiment detection. The overall benefit reachable by SVM^{hmm} relatively to the $SVM^{multiclass}$ baseline is striking as only rich contexts are used for training and testing. The BoW Kernel over the conversation corpus has an overall relative improvement of 18.26% in F_1^{pnn}, where the richer BoWK+LSK Kernel improves of about 5.94%. Boosts in F_1^{pnn} over topical contexts are more significant: 23.73% for the BoW Kernel vs. 17.93% for BoWK+LSK. This latter Kernel is optimal, suggesting that user profiling requires possibly a richer description that is not entirely captured by the vectors of the user sentiment profile. In fact USPK, when combined with

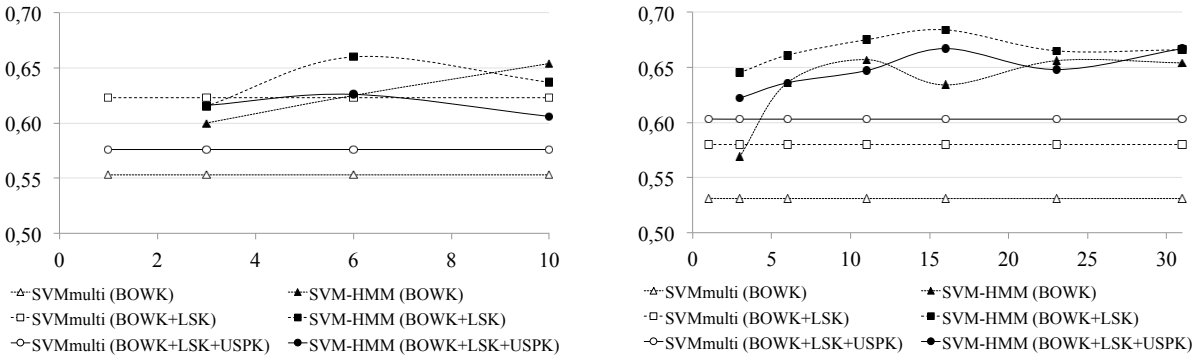

Figure 1: The F_1^{pnn} measure of the different classifiers vs. different context sizes. On the Left: performances when conversational contexts are employed. On the Right: topical contexts are adopted.

BOWK+LSK into the markovian approach, seems to not provide any useful contribution. A clash between the global information (as modeled by the USPK) and the local information (embedded in the recent tweets about a topic) is here observed: when these enter in an opposition, the contrast penalizes the accuracy of the linear combination of Kernels. In general, the improvements implied by contextual information are related to the treatment of particularly ambiguous tweets. In a conversation, such as

`MrGreen` :	*Cannot wait to meet @therealjuicyj and @RealWizKhalifa with @Hill_Gonzz November 29th #trippyniqqas*	$(positive)$
`ColMustard` :	*@MrGreen where they gone be??*	$(neutral)$
`MrGreen` :	*@ColMustard New Orleans!!!*	$(positive)$
`ColMustard` :	*@MrGreen house of blues?*	$(neutral)$
`MrGreen` :	*@ColMustard no it's at the UNO lakefront arena*	$(neutral)$
`ColMustard` :	*@MrGreen I'm going Tuesday to the house of blues to see ASAP Rocky*	$(neutral)$

the switch to a *neutral* mode characterizing the target tweet is a consequence of the entire sequence and captured as a pattern. The contribution of the topical contexts is finally evident in the following example:

	... ...	
`ProfPlum` :	*Can't wait to get out there with my boys Go Team! #goeagles*	$(positive)$
`MrsPeacock` :	*GO my awesome team @WestCoastEagles!!!!! #goeagles #weflyhigh :D*	$(positive)$
`MissScarlet` :	*Let's go eagles :) #goeagles*	$(positive)$
`SergGray` :	*keen for the eagles game today. #goeagles*	$(positive)$

5 Conclusions

In this work the role of contextual information in supervised Sentiment Analysis over Twitter is investigated. While the task is eminently linguistic, as resources and phenomena lie in the textual domain, other semantic dimensions are worth to be explored. In this work, three types of context for a target tweet have been studied. Structured Learning through a markovian approach has been adopted to inject contextual evidence (e.g. the history of preceding posts) in the classification of the most recent, i.e. a target, tweet. The improvement of accuracy in the investigated task are striking as for the large applicability of the approach that does not require additional manually coded resources. The different employed contexts show specific but systematic benefits. On the one side, this proofs the correctness of the initial intuitions. Moreover, the observed relative improvements around 20% over tweets characterized by rich topical or conversational contexts (see Fig. 1) suggest that larger training datasets can even provide better results. In these first experiments, user modeling has only been partially explored, whereas the USPK model does not seem very effective. In fact, USPK seems to express a more static notion of context (i.e. the attitude of the user as observed across a longer period than individual conversations) and two different notions (i.e. information embedded into recent tweets) risk to be incompatible. However, the learning of the optimal Kernel combination as well as a proper history size for the USPK are still worth of deeper investigation. Finally, user interaction dynamics are particularly complex in social networks and deserve better representations about reputation, authority and influence in future explorations.
